Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Track B: Logic, Semantics, Automata and Theory of Programming

Track C: Foundations of Networked Computation: Models, Algorithms, and Information Management

Preface

This volume contains the papers presented at ICALP 2018, the 45th edition of the International Colloquium on Automata, Languages and Programming, held in Prague, Czech Republic during July 9–13, 2018. ICALP is a series of annual conferences of the European Association for Theoretical Computer Science (EATCS), which first took place in 1972. This year, the ICALP program consisted of three tracks:

- Track A: Algorithms, Complexity, and Games,
- Track B: Logic, Semantics, Automata and Theory of Programming,
- Track C: Foundations of Networked Computation: Models, Algorithms, and Information Management.

In response to the call for papers, a total 502 submissions were received: 346 for track A, 96 for track B, and 60 for track C. Each submission was assigned to at least three Program Committee members, aided by many subreviewers. Out of these, the committee decided to accept 147 papers for inclusion in the scientific program: 98 papers for Track A, 30 for Track B, and 19 for Track C. The selection was made by the Program Committees based on originality, quality, and relevance to theoretical computer science. The quality of the manuscripts was very high, and many deserving papers could not be selected.

This year ICALP also solicitated brief announcements of work in progress with substantial interest for the community. In total 14 brief announcements were accepted for publication: 10 for Track A and 4 for Track C. The selection of the brief announcements was made by the Program Committees.

The EATCS sponsored awards for both a best paper and a best student paper for each of the three tracks, selected by the Program Committees.

The best paper awards were given to the following papers:

- Track A: Heng Guo and Mark Jerrum. "A polynomial-time approximation algorithm for all-terminal network reliability".
- Track B: Dirk Nowotka and Aleksi Saarela. "An optimal bound on the solution sets of one-variable word equations and its consequences".
- Track C: Dariusz Kowalski and Miguel A. Mosteiro. "Polynomial Counting in Anonymous Dynamic Networks with Applications to Anonymous Dynamic Algebraic Computations".

The best student paper awards, for papers that are solely authored by students, were given to the following papers:

- Track A: Shashwat Garg. "Quasi-PTAS for Scheduling with Precedences using LP Hierarchies".
- Track B: Sarah Winter. "Uniformization problems for synchronizations of automatic relations on words".

Apart from the contributed talks and the brief announcements, ICALP 2018 included invited presentations by Jaroslav Nešetřil, Alexander Schwarzmann, Sam Staton and Ryan Williams. This volume of the proceedings contains all contributed papers and brief announcements presented at the conference together with the papers and abstracts of the invited speakers.

The program of ICALP 2018 also included presentation of the EATCS Award 2018 to Noam Nisan, the Gödel Prize 2018 to Oded Regev, the Presburger Award 2018 to Aleksander

45th International Colloquium on Automata, Languages, and Programming (ICALP 2018).
Editors: Ioannis Chatzigiannakis, Christos Kaklamanis, Dániel Marx, and Donald Sannella
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Mądry, and the EATCS Distinguished Dissertation Award to Bas Ketsman, Ilya Razenshteyn and Aviad Rubinstein.

The program also included a memorial session for Maurice Nivat, the founder of ICALP and EATCS, who passed away in September 2017.

Six satellite events of ICALP were held on 9 July, 2018:

- Modern Online Algorithms (MOLI)
- Game Solving: Theory and Practice
- Parameterized Approximation Algorithms Workshop (PAAW)
- Infinity
- Algorithmic Aspects of Temporal Graphs
- Constrained Recognition Problems

The Summer School on Algorithms and Lower Bounds was organized immediately before ICALP during 6-9 July, 2018, with a follow-up workshop on Monday afternoon. The workshop was a satellite ICALP workshop devoted to presentations by selected participants of the school.

The Summer School on Discrete Mathematics was organized after the conference during 16-20 July, 2018. The event was organized by the Institute of Mathematics of the Czech Academy of Sciences and the Computer Science Institute of Charles University.

We wish to thank all authors who submitted extended abstracts for consideration, the Program Committees for their scholarly effort, and all referees who assisted the Program Committees in the evaluation process. We are also grateful to Anna Kotěšovcová from CONFORG and to Jiří Sgall, Andreas Emil Feldmann, Tomáš Masařík, Michal Opler, Jiří Fiala and Jan Musílek and all the support staff of the Organizing Committee from Charles University for organizing ICALP 2018.

We are grateful for generous support from AVAST and RSJ companies which included both travel grants for young women researchers and students and a direct support of the conference. We thank the School of Computer Science (Charles University, Faculty of Mathematics and Physics) and Center of Excellence - Institute for Theoretical Computer Science (project P202/12/G061 of Czech Science Foundation) for their support.

We would like to thank Jiří Sgall for his continuous support and Paul Spirakis, the president of EATCS, for his generous advice on the organization of the conference.

Consistent Distributed Memory Services: Resilience and Efficiency

Theophanis Hadjistasi
University of Connecticut, Storrs CT, USA

University of Connecticut, Storrs CT, USA
ass@uconn.edu

Abstract

Reading, *'Riting*, and *'Rithmetic*, the three *R*'s underlying much of human intellectual activity, not surprisingly, also stand as a venerable foundation of modern computing technology. Indeed, both the Turing machine and von Neumann machine models operate by reading, writing, and computing, and all practical uniprocessor implementations are based on performing activities structured in terms of the three *R*'s. With the advance of networking technology, communication became an additional major systemic activity. However, at a high level of abstraction, it is apparently still more natural to think in terms of reading, writing, and computing. While it is hard to imagine distributed systems—such as those implementing the World-Wide Web—without communication, we often imagine browser-based applications that operate by retrieving (i.e., reading) data, performing computation, and storing (i.e., writing) the results. In this article, we deal with the storage of shared readable and writable data in distributed systems that are subject to perturbations in the underlying distributed platforms composed of computers and networks that interconnect them. The perturbations may include permanent failures (or crashes) of individual computers, transient failures, and delays in the communication medium. The focus of this paper is on the implementations of distributed atomic memory services. Atomicity is a venerable notion of consistency, introduced in 1979 by Lamport [35]. To this day atomicity remains the most natural type of consistency because it provides an illusion of equivalence with the serial object type that software designers expect. We define the overall setting, models of computation, definition of atomic consistency, and measures of efficiency. We then present algorithms for single-writer settings in the static models. Then we move to presenting algorithms for multi-writer settings. For both static settings we discuss design issues, correctness, efficiency, and trade-offs. Lastly we survey the implementation issues in dynamic settings, where the universe of participants may completely change over time. Here the expectation is that solutions are found by integrating static algorithms with a reconfiguration framework so that during periods of relative stability one benefits from the efficiency of static algorithms, and where during the more turbulent times performance degrades gracefully when reconfigurations are needed. We describe the most important approaches and provide examples.

2012 ACM Subject Classification Networks → Cloud computing,General and reference → Surveys and overviews

Keywords and phrases Atomicity, shared-memory, read/write objects, fault-tolerance, latency

1 Introduction

Shared storage services are located at the core of most information-age systems. Shared memory systems surveyed in this work provide objects that support two different access operations. That is, a *read*, that obtains the current value of the object, and a *write* that replaces the old value of the object with a new one. To be useful, such objects need to be *resilient* to failures and perturbations in the underlying computing medium, and must be *consistent* in that there are guarantees regarding relationships between previously written values and the values read by subsequent read operations. Such resilient and consistent object are also called registers. Here we focus on read/write objects, however for objects with more complicated semantics, such as transactions or read-modify-write operations, there exist common implementation challenges that any distributed storage system faces and needs to resolve. Imagine a storage system that is implemented as a central server. The server accepts client requests to perform operations on its data objects and returns responses. Conceptually, this approach is simple, however, two major problems can already be observed. The first is that the central server is a performance bottleneck. The second is that the server is a single point of failure. The quality of service in such an implementation degrades rapidly as the number of clients grows, and the service becomes unavailable if the server crashes (imagine how inadequate a web news service would be were it implemented as a central server). Thus the system must be *available*. This means it must provide its services despite failures within the scope of its specification, for example, the system must be able to mask certain server and communication failures. The system must also support multiple concurrent accesses without imposing unreasonable degradation in performance. The only way to guarantee availability is through *redundancy*, that is, by using multiple servers and by replicating the contents of objects among these servers.

Replication introduces the challenge of ensuring *consistency*. How does the system record new values so that consequently the it can find and return the latest value of a replicated object? This problem was not present with a central server implementation: the server always contains the latest value. In a replicated implementation, one may attempt to consult all replicas in search of the latest value, but this approach is expensive and not fault-tolerant as it assumes that all replicas are accessible. A trivial solution would be in each operation to consult all replicas servers in search of the latest value, however, this is not fault-tolerant (as it assumes all replicas are accessible) and expensive. In any case, none of the implementation issues should be a concern for the clients of the distributed memory service. What the clients should expect to see is the illusion of a single-copy object that serializes all accesses so that each read operation returns the value of the preceding write operation, and that this value is at least as recent as that returned by any preceding read. More generally, the behavior of the object, as observed externally, must be consistent with the abstract sequential data type of the object, and in developing applications that use such objects the clients must be able to rely on the abstract data type of the object. This notion of consistency is formalized as *atomicity* [35] for read/write objects, and equivalently, as *linearizability* [32] that extends atomicity to arbitrary data types. While there is no argument that atomicity is the most convenient notion of consistency, we note that weaker notions have also been proposed and implemented, motivated primarily by efficiency considerations. Atomicity provides strong guarantees, making it more expensive to provide than weaker consistency guarantees [7]. We take the view that it is nevertheless important to provide simple and intuitive, be it more expensive, atomic consistency. Barbara Liskov, a Turing Prize laureate, in a keynote address (at [37]) remarked that atomicity is not cheap, however, if we do not guarantee it, this creates headaches for developers.

Contemporary storage systems may also provide more complex data access primitives implementing atomic *read-modify-write* operations. Such access primitives are much stronger than separate *read* and *write* primitives we consider in this work. Implementing such operations is expensive, and at its core requires atomic updates that in practice are implemented by reducing parts of the system to a *single-writer* model (ex., Microsoft's Azure [10]), by depending on clock synchronization hardware (ex., Google's Spanner [13]), or by relying on complex mechanisms for resolving event ordering such as *vector clocks* (ex., Amazon's Dynamo [15]). Our exposition of atomic read/write storage illustrates challenges that are common to all distributed storage systems.

Document structure. Section 2 describes the general distributed setting for implementing consistent shared memory services, defines atomic conistency, and describes the measures of efficiency. In Sections 3 and 4 we present several approaches that implement consistent shared memory in static services for the SWMR and the MWMR setting respectively. Lastly, we survey several approaches for providing consistent shared memory in dynamic systems in Section 5. We conclude with a discussion in Section 6.

2 Distribution and Consistency

We now describe a general distributed setting for implementing consistent shared memory services.

Modeling distributed platforms. We model the system as a collection of interconnected computers, or nodes, that communicate by sending point-to-point messages. Each node has a unique identifier from some well-ordered set $\mathcal{I}$, local storage, and it can perform local computation. A node may fail by *crashing* at any point of the computation. The time of failure is chosen by and adversary that has knowledge of the past computation and the algorithms implementing a particular distributed service. Any node that crashes stops operating: it does not perform any local computation, it does not send any messages, and any messages sent to it are not delivered. Common approaches to implementing resilient in the face of failures algorithm specify failure models that provide qualitative or quantitative restrictions on the power of adversaries, e.g., by limiting the adversary to causing at most f crashes for some algorithm-specific parameter f.

The system is *asynchronous*, and the nodes have no access to a global clock or synchronization mechanisms. This means that relative processing speeds at the nodes can be arbitrary, and that the nodes do not know the upper bound on time that it takes to perform a local computation. The message delays can also be arbitrary, and the nodes do not know bounds on message latency (although such bounds may exist). Thus algorithms may not rely on assumptions about global time or delays.

We assume that messages can be reordered in transit, however, the messages cannot be corrupted, duplicated, or generated spontaneously. If a message is received then it must have been previously sent. The messages are not lost, but message loss can be modeled as long delays (we do not address techniques for constructing more dependable communication services, e.g., by using retransmission or gossip).

The nodes with ids in the set $\mathcal{I}$ include a set of writers $\mathcal{W}$, a set of readers $\mathcal{R}$, and a set of replica servers $\mathcal{S}$. These sets need not be disjoint, but it is helpful to view separately the roles a participant in the service can play. We categorize a distributed networked system as either *static* or *dynamic* as follows. In the *static* system the set of participating nodes is fixed,

and each node may know the identity of all participants; crashes (or voluntary departures) may remove nodes from the system. Static algorithms are commonly designed to tolerate up to $f < |\mathcal{S}|/2$ server crashes and arbitrary number of crashes among readers and writers. In the *dynamic* system the set of nodes may be unbounded, and the set of participating nodes may completely change over time as the result of crashes, departures, and new nodes joining. The failure models considered in dynamic settings are much more complicated, given the systems may dramatically evolve over time.

Distributed shared memory and consistency. A distributed shared memory service emulates a shared memory space comprised of readable and writable objects, often called registers, over a networked platform that where distributed nodes communicate by message passing. Service implementations use replication to ensure survivability and availability of the objects, but the service makes this invisible to the clients. The contents of each object is replicated across several *servers* or *replica hosts*. Clients invoke read and write operations on the objects, where the clients that perform read operations are called *readers*, and those that perform write operations are called *writers* (a client may be both a reader and a writer).

In response to client requests the service invokes a *protocol* that involves communication with the replica hosts. This protocol implements and determines the consistency guarantees of the memory system. Atomic consistency definition involves "shrinking" the duration of each operation in any execution to a chosen *serialization point* between the operation's invocation and response, and requiring that the ordering of the operations according to the serialization points preserves their real-time ordering, and the resulting behavior of the object is consistent with its sequential specification. In particular, if a read is invoked after a write completes, then the read is guaranteed to return either the value of that write, or a value written by subsequent write that precedes the read. Additionally, if a read is invoked after another read completes, it returns the same or a "newer" value than the preceding read.

Whereas atomicity is often defined in terms of an equivalence with a serial memory, the definition given below implies this equivalence (as shown in in Lemma 13.16 in [39]), and is more convenient to use because it provides a usable recipe for proving atomic consistency.

▶ **Definition 1** (Atomicity, [39])**.** An implementation of an object is atomic, if for any execution if all the read and write operations that are invoked on an object complete, then the read and write operations for the object can be partially ordered by an ordering $\prec$, so that the following conditions are satisfied:

A1. The partial order is consistent with the external order of invocations and responses, that is, there do not exist read or write operations π_1 and π_2 such that π_1 completes before π_2 starts, yet $\pi_2 \prec \pi_1$.

A2. All write operations are totally ordered and every read operation is ordered with respect to all the writes.

A3. Every read operation ordered after any writes returns the value of the last write preceding it in the partial order; any read operation ordered before all writes returns the initial value.

Efficiency, Rounds and Message Exchanges. In assessing the efficiency of read and write operations of an implementation, we measure *communication latency*, *local computation time*, and *message complexity* of operations.

Communication latency of an operation is measured in terms of *communication rounds* or *communication exchanges*. The protocol implementing each operation involves a collection of sends of typed messages and the corresponding receives. A communication round is defined following [17].

▶ **Definition 2** (Communication Round, [17]). A process p performs a communication round during an operation π in an execution of an implementation A if all the following hold:

1. process p sends message(s) for operation π to a set of processes $Z \subseteq \mathcal{I}$,
2. upon the delivery of the message for π to process q, $q \in Z$, q sends a reply for π to p without waiting for any other messages, and
3. when p receives the collection of replies that is deemed sufficient by the implementation, it terminates the round. After this either p starts a new round or π completes.

A communication exchange is defined in [30].

▶ **Definition 3** (Communication Exchange, [30]). Within an execution of an implementation A, a communication exchange is the set of sends and corresponding matching receives for a specific type of message within the protocol.

We can observe that a round in Definition 2 is composed of two exchanges: the first is comprised of sends in item (1) and the corresponding receives in item (2), and the second is comprised of the reply sends in item (2) and the corresponding receives in item (3). Thus, in essence each exchange constitutes "one half" of a round. Traditional implementations in the style of ABD are structured in terms of communication rounds, cf. [5, 26], each consisting of two exchanges. The first is a broadcast from a reader or writer process to the servers, and the second is a convergecast in which the servers send corresponding responses to the initiating process.

Computation time accounts for all local computation within an operation; here time complexity of local computation may be significant. When local computation is not more than a constant time per each message send and receive, we consider this to be insignificant relative to the communication latency of an operation. Otherwise, computation time needs to be assessed in addition to communication latency.

Message complexity of an operation is determined by the worst case number of messages sent during the operation.

3 SWMR Implementations

Algorithms designed for single-writer static settings assume a fixed set known participants and accommodate some dynamic behaviors, such as asynchrony, transient failures, and permanent crashes within certain limits. A summary of the most relevant results for this setting is given in the first part of Table 1.

We commence by presenting the the seminal work of Attiya, Bar-Noy, and Dolev [5] that provides an algorithm, colloquially referred to as ABD, that implements SWMR atomic objects in message-passing crash-prone asynchronous environments. This work won the Dijkstra Prize in 2011. In ABD replication helps achieve fault-tolerance and availability, and the implementation replicates objects at nodes in the set $\mathcal{S}$, called servers, and it tolerates f replica servers crashes, provided a majority of replicas do not fail, i.e., $|\mathcal{S}| > 2f$. Read and write operations are ordered using logical *timestamps* associated with each written value. These timestamps totally order write operations, and therefore determine the values that read operations return. All operations terminate provided a majority of replicas do not crash.

A pseudocode for ABD is given in Algorithm 1; in referring to the numbered lines of code we use the prefix "L" to stand for "line". Write operations involve a single communication round-trip consisting of *two* communication exchanges. The writer broadcasts its request to all replica servers during the first exchange and terminates once it collects acknowledgments from some majority of servers in the second exchange (L19-23). Each read operation takes two rounds involving in *four* communication exchanges. The reader broadcasts a read request

Table 1 Model, Communication Exchanges, Message Complexities, Participation Bounds, and Predicate Computational Class.

Algorithm	Model	Write Exch.	Read Exch.	Wrt Msg Comp	Rd Msg Comp	Client Participation	Local Complexity
ABD [5]	SWMR	2	4	$2\|\mathcal{S}\|$	$4\|\mathcal{S}\|$	Unbounded	Constant
Fast [17]	SWMR	2	2	$2\|\mathcal{S}\|$	$2\|\mathcal{S}\|$	$\|\mathcal{R}\| < \frac{\|\mathcal{S}\|}{f} - 2$	NP-Hard
Sf [26]	SWMR	2	2 or 4	$2\|\mathcal{S}\|$	$4\|\mathcal{S}\|$	$\|\mathcal{V}\| < \frac{\|\mathcal{S}\|}{f} - 1$	NP-Hard
Sliq [25]	SWMR	2	2 or 4	$2\|\mathcal{S}\|$	$4\|\mathcal{S}\|$	Unbounded	Constant
ccFast [4]	SWMR	2	2	$2\|\mathcal{S}\|$	$2\|\mathcal{S}\|$	$\|\mathcal{R}\| < \frac{\|\mathcal{S}\|}{f} - 2$	Polynomial
OhSam [30]	SWMR	2	3	$2\|\mathcal{S}\|$	$2\|\mathcal{S}\| + \|\mathcal{S}\|^2$	Unbounded	Constant
OhSam′ [30]	SWMR	2	2 or 3	$2\|\mathcal{S}\|$	$3\|\mathcal{S}\| + \|\mathcal{S}\|^2$	Unbounded	Constant
ccHybrid [3]	SWMR	2	2 or 4	$2\|\mathcal{S}\|$	$4\|\mathcal{S}\|$	Unbounded	Polynomial
OhFast [3]	SWMR	2	2 or 3	$2\|\mathcal{S}\|$	$\|\mathcal{S}\|^2$	Unbounded	Polynomial
MR [41]	SWMR	2	2 or 3 or 4	$\|\mathcal{S}\|^2$	$4\|\mathcal{S}\|$	Unbounded	Constant
Erato [21]	SWMR	2	2 or 3	$2\|\mathcal{S}\|$	$3\|\mathcal{S}\| + \|\mathcal{S}\|^2$	Unbounded	Constant
ABD-mw [5, 40]	MWMR	4	4	$4\|\mathcal{S}\|$	$4\|\mathcal{S}\|$	Unbounded	Constant
Sfw [18]	MWMR	2 or 4	2 or 4	$4\|\mathcal{S}\|$	$4\|\mathcal{S}\|$	Unbounded	NP-Hard
CwFr [24]	MWMR	4	2 or 4	$4\|\mathcal{S}\|$	$4\|\mathcal{S}\|$	Unbounded	Constant
OhMam [30]	MWMR	4	3	$4\|\mathcal{S}\|$	$2\|\mathcal{S}\| + \|\mathcal{S}\|^2$	Unbounded	Constant
OhMam′ [30]	MWMR	4	2 or 3	$4\|\mathcal{S}\|$	$3\|\mathcal{S}\| + \|\mathcal{S}\|^2$	Unbounded	Constant
Erato-mw [21]	MWMR	4	2 or 3	$4\|\mathcal{S}\|$	$3\|\mathcal{S}\| + \|\mathcal{S}\|^2$	Unbounded	Constant

to all replica servers in the first exchange, collects acknowledgments from some majority of servers in the second exchange, and it discovers the maximum timestamp (L3-7). In order to ensure that any subsequent read will return a value associated with a timestamp at least as high as the discovered maximum, the reader propagates the value associated with the maximum timestamp to at least a majority of servers before completion (L8-11). The correctness of this implementation, that is, atomicity, relies on the fact that any two majorities have a non-empty intersection. The local computation at readers, writers and servers in ABD incurs insignificant computational overhead.

Following ABD, a folklore belief developed that in atomic memory implementations, "reads must write." The work by Dutta et al. [17] refuted this belief by presenting an algorithm, called Fast, in which all read and write operations involve only *two* communication exchanges. Such operations are called *fast*. To avoid the second round in read operations, Fast uses two mechanisms: (i) a recording mechanism at the servers, and (ii) a predicate that uses the server records at the readers. Here, each server records in a set all processes that witness its local timestamp and resets it whenever it learns a new timestamp. Each reader explores the sets from the different server replies to determine whether "enough" processes witnessed the maximum observed timestamp. If the predicate holds, the reader returns the value associated with the maximum timestamp. Otherwise it returns the value associated with the previous timestamp. The predicate takes in account *which* processes witnessed the latest timestamp as it examines the intersection of the received sets.

It was also shown in [17] that atomic memory implementations are only possible when the number of readers is constrained in with respect to the number of replicas servers and in inverse proportion to the number of crashes as stated in the following theorem.

▶ **Theorem 4** ([17]). *Let $f \geq 1$, $|\mathcal{W}| = 1$ and $|\mathcal{R}| \geq 2$. If $|\mathcal{R}| \geq \frac{|\mathcal{S}|}{f} - 2$, then there is no fast atomic register implementation.*

Algorithm 1 Reader, Writer, and Server Protocols for SWMR algorithm ABD

```
1: At each reader r
2: function READ(v: output)
3: Get: broadcast ⟨get, i⟩ to all replica servers
4:       await responses ⟨get-ack, v′, ts′⟩
5:             from some majority of servers
6:       Let v be the value associated with the
7:       maximum timestamp maxts received
8: Put: broadcast ⟨put, v, maxts, i⟩ to all servers
9:       await responses ⟨put-ack⟩
10:            from some majority of servers
11:      return(v)

12: At each server s
13: State v init ⊥, ts init 0
14: Upon receive ⟨get, j⟩
15:      send ⟨get-ack, v, ts⟩ to j

16: At each writer w
17: State ts init 0
18: function WRITE(v: input)
19: Put: ts ← ts + 1
20:      broadcast ⟨put, v, ts, i⟩ to all servers
21:      await responses ⟨put-ack⟩
22:            from some majority of servers
23:      return()

24: At each server s
25: Upon receive ⟨put, v′, ts′, j⟩
26:   if ts′ > ts then
27:         (ts, v) ← (ts′, v′)
28:   send ⟨put-ack⟩ to j
```

A recent work by Fernández Anta, Nicolaou, and Popa [4], has shown that, although the result in [17] is efficient in terms of communication, it requires reader processes to evaluate a computationally hard predicate. The authors abstracted the predicate used in FAST as a computational problem that they show to be NP-hard via a reduction from the decision version of the Maximum Edge Biclique Problem [43], which is NP-Complete. This suggest the existence of a trade-off between communication efficiency and computational overhead in atomic memory implementations.

Given the inherent limitation on the number of readers in fast single-writer implementations, Georgiou et al. [26] sought a solution that would remove the limit on the number of readers, in exchange for slowing down some operations, i.e., the goal is to enable fast operations, but allow slower operations, taking more than two communication exchanges, when this is unavoidable. They provided a SWMR algorithm, named SF, that adopts an approach to implementing readers similar to the one in [17], but uses a polynomial time predicate to determine whether it is safe for a read operation to terminate after two exchanges. In order not to place bounds on the number of readers, the authors group readers into abstract entities, called virtual nodes, serving as enclosures for multiple readers. This refinement has a non-trivial challenge of maintaining consistency among readers within the same virtual node. This solution trades communication for the scalability in the number of participating readers. In SF significant computational overheads incur in order to determine the speed of an operation (to evaluate the mentioned predicate). At most a single complete read operation performs *four* exchanges for each write operation. Writes and any read operation that precedes or succeeds a *four* exchange read, is *fast*. This development motivated creating a new class of implementations, called *semifast* implementations. Informally, an implementation is *semifast* if either all reads are *fast* or all write operations *fast*. Algorithm SF becomes fast (same as [17]) when each virtual node contains one reader.

Georgiou et al. [25] showed that fast and semifast quorum-based SWMR implementations are possible iff a common intersection exists among all quorums. Because a single point of failure exists in such solutions (i.e., any server in the common intersection), this renders such implementations not fault-tolerant. The same work introduced Quorum Views, client-side tools that examine the distribution of the latest value among the replicas in order to enable fast read operations (two exchanges) under read and write operation concurrency. The authors derived a a SWMR algorithm, called SLIQ, that requires at least one single *slow* read per any write operation, and where all writes are *fast*. No bound is placed on the number of readers. SLIQ trades communication for the scalability in the number of participating

readers. Here only insignificant computation effort is needed to examine the distribution of object values among the replicas that the reader receives during the read operation.

Another algorithm, called ccFast, with a new predicate, is given by Fernández Anta et al. [4], that allows the operations to be *fast* with only polynomial computation overhead. The idea of the new predicate is to examine the replies received in the first communication round of a read operation and determine *how many* (instead of *which* [17]) processes witnessed the maximum timestamp among those replies. With this modification, the predicate takes polynomial time to decide the value to be returned and it reduces the size of each message sent by the replica nodes. Algorithm ccFast is more practical than [17], but it has the same constraint on the number of readers.

Previous works dealt with algorithms that used only communication between clients (readers and writers) and the replica servers. Hadjistasi, Nicolaou and Schwarzmann [30] explored another approach that exploits server-to-server communication. In particular, they showed that atomic operations do not need to involve complete communication round trips between clients and servers. The authors focused on the gap between one-round and two-round algorithms, seeking implementations where operations can take "one and a half rounds," i.e., be able to complete in *three* exchanges. They presented a SWMR algorithm, called OhSam, which stands for *One and a Half Rounds Single-writer Atomic Memory*. Here reads take *three* exchanges: the first from the client to the servers, the second is server-to-server, and the third is from the servers to the client. Such implementations trade latency for message complexity: the latency is reduced to three exchanges, while server-to-server exchange has quadratic message complexity in the number of servers. A key idea of the algorithm is that the reader returns the value that is associated with the *minimum* timestamp that corresponds to the last complete write operation (cf. the observation in [17]).

In the same work [30], authors revised the protocol implementing read operations of algorithm OhSam to yield a protocol that implements read operations that terminate in either *two* or *three* communication exchanges, OhSam′. The idea here is to let the reader determine "quickly" that a majority of servers hold the same timestamp (or tag) and its associated value. This is done by having the servers send relay messages to each other as well as to the readers. While a reader collects the relays and the read acknowledgments, if it observes in the set of the received relay messages that a majority of servers holds the same timestamp, then it safely returns the associated value and the read operation terminates in *two* exchanges. If that is not the case, then the reader proceeds similarly to algorithm OhSam and terminates in *three* communication exchanges. Algorithms OhSam and OhSam′ do not impose constraints on reader participation and perform a modest amount of local computation, resulting in negligible computation overhead.

Fernández Anta et al. [3] introduced a "multi-speed" algorithm, named ccHybrid that allows operations to terminate in either *two* or *four* communication exchanges. Algorithm ccHybrid does not impose any bounds on the number of the participating readers. ccHybrid uses the polynomial predicate introduced in [4] to determine the speed of a read operation, and it requires at most one *complete* slow operation per written value. This is similar to the semifast algorithm Sf [26]. However, in contrast with Sf, in which processes have to decide NP-hard predicates, ccHybrid performs only linear computation.

The same work [3] explores the idea of combining the polynomial predicate with the *three* communication exchanges read protocol of algorithm OhSam [30]. The resulting "multi-speed" algorithm, called OhFast, allows *one* and *one-and-a-half* round-trip operations, equivalent *two* or *three* communication exchanges. In algorithm OhFast, the decision of whether the read operation must be slow is moved to the replica servers. When replica servers determine

that a slow read is necessary, they perform a *relay* phase to inform other servers before replying to the requesting reader. It is interesting that in OhFast not all servers uniformly perform a relay for a particular read operation. Some servers may be replying directly to the requesting reader, whereas others may perform a relay phase. Thus, it is possible for a read operation to terminate before receiving a reply from the server that initiates the relay.

A recent work by Mostefaoui and Raynal [41] defines what a *time-efficient* implementation of atomic registers is based on two different synchrony assumptions. The first assumes bounded message delays and is expressed in terms of delays, and the second assumes *round-based synchrony*. Authors then present a *time-efficient* implementation of atomic registers while trying to keep its design spirit as close as possible to ABD. We refer to this solution as algorithm MR. In the algorithm a write operation takes *two* communication exchanges and a read operation takes *two*, or *three*, or *four* exchanges. The heart of the given algorithm is the *wait predicate* that takes place on the servers side and it is associated with write operations. The wait predicate ensures both atomicity and the fact that the implementation is time-efficient. The trade-off between ABD and this implementation lies in the message complexity of write operations, which for ABD is linear and for MR is quadratic in to the number of replica servers. Algorithm MR is particularly interesting for registers used in read-dominated applications.

Lastly, Georgiou et al. [21] presented algorithm Erato, which stands for *Efficient Reads for ATomic Objects*. The algorithm improves the *three*-exchange read protocol of OhSam [30] to allow reads to terminate in either *two* or *three* exchanges using client-side tools, *Quorum Views*, introduced in algorithm Sliq [25]. The three exchanges of the new read protocol are as follows: (1) reader broadcasts a request to servers; (2) the servers share this information among themselves, including the reader, and (3) once this is "sufficiently" done, servers reply to the reader. During the second exchange, the reader uses Quorum Views [25] to categorize the distribution of timestamps, and determines whether it is able to complete the read. If not, it awaits "enough" messages from the third exchange before completion. Here, the idea of the algorithm is that when the reader is "slow" it returns the value associated with the *minimum* timestamp, i.e., the value of the previous write that is guaranteed to be complete (cf. [30] and [17]). Similarly to ABD, write operations take *two* exchanges.

4 MWMR Implementations

We now turn out attention to the multi-writer/multi-reader (MWMR) implementations of atomic memory. Whereas logical timestamps alone are sufficient to order write operations in the single-writer algorithms, the existence of multiple writers requires a somewhat different approach. The simplest approach is instead of a timestamp to use pairs consisting of a timestamp and processor id to order the written values. Such a pair is termed a *tag*. When a writer performs a write operation it associates the value with a tag $\langle ts, id \rangle$, where ts is a logical timestamp, and id is the writer's unique id that distinguishes the current write operation from all others. Tags are ordered lexicographically in establishing an order on the operations. A summary of the most relevant results for this setting is given in the second part of Table 1.

The work of Lynch and Schwarzmann [40] presented a multi-writer extension of algorithm ABD (and also introduced the notion of reconfigurable memory, where the set of replica servers can be dynamically reconfigured). The static version of their MWMR implementation, that we call ABD-MW, is given in Algorithm 2. In contrast with ABD, where the sole writer generates new timestamps without any communication, the writers in ABD-MW start a

Algorithm 2 Reader, Writer, and Server Protocols for MWMR algorithm ABD-mw

```
1: At each reader r
2: function READ(v: output)
3: Get: broadcast ⟨get, i⟩ to all replica servers
4:       await responses ⟨get-ack, v′, tag′⟩
5:             from some majority of servers
6:       Let v be the value associated with the
7:       maximum tag maxtag received
8: Put: broadcast ⟨put, v, maxtag, r⟩ to all servers
9:       await responses ⟨put-ack⟩
10:            from some majority of servers
11:      return(v)

12: At each server s
13: State v init ⊥, tag init ⟨0, ⊥⟩
14: Upon receive ⟨get, j⟩
15:      send ⟨get-ack, v, tag⟩ to j

16: At each writer w
17: function WRITE(v: input)
18: Get: broadcast ⟨get, i⟩ to all replica servers
19:      await responses ⟨get-ack, v′, tag′⟩
20:            from some majority of servers
21:      Let maxtag = ⟨ts, pid⟩ be the max tag
22:      Let newtag = ⟨ts + 1, w⟩
23: Put: broadcast ⟨put, v, newtag, w⟩ to all servers
24:      await responses ⟨put-ack⟩
25:            from some majority of servers
26:      return()

27: At each server s
28: Upon receive ⟨put, v′, tag′, j⟩
29:   if tag′ > tag then
30:         (tag, v) ← (tag′, v′)
31:   send ⟨put-ack⟩ to j
```

write operation by performing an additional round in which the replica servers are queried for their latest tags. Once tags are received from a majority of servers, the writer increments the timestamp of the highest detected timestamp to produce its new tag. The the second round is performed as in ABD.

In more detail, the writer performs the "Get" round, broadcasting its request to the servers in the first exchange (L18). Servers reply with their latest timestamps in the second exchange (L18-22 and L12-15). The writer determines the highest timestamp among the replies, increments it, produces a new tag that includes its id, and then performs the "Put" round in which it in the third exchange broadcasts the new tag and the new value to all servers (L23-26). On the server side, if the incoming message contains a higher tag, then the server update its local information and send an acknowledgment in the fourth communication exchange (L27-31). The write protocol completes once the writer collects acknowledgments from a majority of servers. The first two exchanges ensure that the writer produces a tag that is higher than that of any preceding write. Thus a write operation for ABD-MW takes *four* exchanges in comparison with the *two* exchanges in ABD. The read protocol is identical to the four-exchange protocol in ABD, the only difference being that tags are used instead of timestamps. The correctness (atomicity) of this implementation, relies on the fact that any two majorities have a non-empty intersection and that in each round, the read and write protocols await responses from at least a majority of servers.

This algorithm places no constrains on the number of readers and writers, and it performs a modest amount of local computation, resulting in negligible computation overhead. This algorithm can also be used used with quorum systems instead of majorities [40, 44], because the only property of majorities that is used is that any two majorities have a non-empty intersection, just like any two quorums. The failure model for the quorum based solution is that any pattern of crashes is tolerated, provided that the servers in at least one quorums do not crash.

Algorithm ABD-MW established that two rounds are sufficient to implement atomic read and write operations. The question of whether *fast* (single round) implementations are possible was answered in the negative in [17], where it was shown that fast reads are possible only in the single-writer model SWMR. In particular, *fast* MWMR implementations are impossible when the set of readers $\mathcal{R}$ and the set of writers $\mathcal{W}$ contain more than two nodes each.

▶ **Theorem 5** ([17]). *Let $|\mathcal{W}| \geq 2$, $|\mathcal{R}| \geq 2$, and $f \geq 1$. Any atomic register implementation has a run in which some complete read or write operation is not fast.*

Moreover, Georgiou et al. [26] showed that *semifast* implementations (recall from Section 3 that in a semifast implementation either all reads are fast or all the write operations fast) are impossible in the MWMR setting.

▶ **Theorem 6** ([26]). *If $|\mathcal{W}| \geq 2$, $|\mathcal{R}| \geq 2$, and the number of server crashes $f \geq 1$, then semifast atomic register implementation is impossible.*

These impossibility results motivated the development of algorithms that allow some operations to complete in less than two rounds or in less than four communication exchanges. The work from Englert et al. [18] proposed hybrid approaches where some operations complete in *two* and other in *four* communication exchanges. Their algorithm SFW uses quorum systems and enables some reads and writes to be fast. In order to decide whether an operation can terminate after its first round, the algorithm employs two specialized predicates. However, the predicates are computationally hard (NP-hard), and fast write operations are enabled only if the quorum system satisfies certain quorum intersection properties, rendering the algorithm impractical.

Georgiou et al. [24] presented a MWMR algorithm, called CWFR, that allows fast read operations. The algorithm uses a generalization of client-side decision tools, Quorum Views, developed for the SWMR setting [25], to analyze the distribution of a value within a quorum of replies from servers to determine whether fast termination is safe. Since multiple writes can occur concurrently, an iterative technique is used to discover the latest potentially complete write operation. Here read operations terminate in either *two* or *four* communication exchanges. The write protocol is essentially the same as in ABD-MW, taking *four* exchanges to complete. Algorithm CWFR does not impose constrains on participation and it performs a modest amount of local computation, resulting in negligible computation overhead.

Hadjistasi et al. [30] sought a MWMR solution that involves *three* or *four* communication exchanges per operation, and developed algorithm OHMAM, which stands for *One and a Half Rounds Multi-writer Atomic Memory*. The authors adopted the three-exchange protocol from the SWMR algorithm OHSAM to the MWMR setting. The read protocol of OHMAM differs in that it uses tags instead of timestamps. The write protocol is identical to the one that ABD-MW uses and completes in *four* communication exchanges.

The authors then revised the protocol implementing read operations of algorithm OHMAM to yield a protocol that implements read operations that terminate in either *two* or *three* communication exchanges, the resulting algorithm is called OHMAM′. The idea here is to expedite the reader's determination that a majority of servers hold the same tag and its associated value. This is achieved by having the servers send relay messages to each other as well as to the requesting reader. While a reader collects the relays and the read acknowledgments, if it observes in the set of the received relay messages that a majority of servers holds the same timestamp, then it safely returns the associated value, thus terminating in *two* exchanges. If that is not the case, then the reader proceeds similarly to algorithm OHMAM and terminates in *three* communication exchanges. The operations perform insignificant amount of local computation.

Lastly, Georgiou et al. [21], using the SWMR algorithm ERATO as the basis, developed a MWMR algorithm, ERATO-MW. In adopting the single-writer algorithm, the challenge is that the read protocol cannot be used directly because it relies on the fact that if a write is in progress, then the preceding write is complete. Instead the algorithm implements a *three*-exchange read protocol based on [30] in combination with the iterative technique using Quorum Views as in [24]. This technique determines the completion status of a write operation, and also detects the last potentially complete write operation. Read operations complete in either *two* or *three* exchanges. Writes are similar to ABD-MW and take *four* communication exchanges. This algorithm also has a negligible computation overhead.

5 Shared Memory in Dynamic Settings

Additional challenges arise when a shared memory system must be long-lived and must ensure data longevity. A storage system may be able to tolerate failures of some servers, but over a long period it is conceivable that all servers may need to be replaced, because no servers are infallible, and also due to unavoidable changes or planned upgrades. Additionally, in mobile settings, e.g., remote search-and-rescue or military operations, it may be necessary to provide migration of data from one collection of servers to another, so that the data can move as the needs dictate. Whether our concern is data longevity or mobility, the storage system must provide seamless runtime migration of data: one cannot stop the world and reconfigure the system in response to failures and changing environment.

We now survey several approaches for providing consistent shared memory in more dynamic systems, that is, where nodes may not only crash or depart voluntarily, but where new nodes may join the service, and where the entire collection of servers need to be replaced. In general, the set of object replicas can substantially evolve over time, ultimately migrating to a completely different set of replica hosts. Thus, an implementation designed for static settings, e.g., algorithm ABD, cannot be used directly in dynamic settings because it relies on the majority of original replica hosts to always be available. In order to use an ABD-like approach in dynamic settings, one must provide some means for managing the collections of replica hosts, and to ensure that readers and writers contact suitable such collections.

It is noteworthy that dealing with dynamic settings and managing collections of nodes does not directly address the provision of consistency in memory services. Instead, these issues are representative of the broader challenges present in the realm of dynamic distributed computing. It is illustrative that implementations of consistent shared memory services can sometimes be constructed using distributed building blocks, such as those designed for managing collections of participating nodes, for providing suitable communication primitives, and for reaching agreement (consensus) in dynamic distributed settings. A tutorial covering several of these topics is presented by Aguilera et al. [2].

We start by presenting the consensus problem because it provides a natural basis for implementing an atomic memory service by establishing an agreed-upon order of operations, and because consensus is used in other ways in atomic memory implementations. Next we present group communication services (GCS) solutions that use strong communication primitives, such as totally ordered broadcast, to order operations. Finally we focus on approaches that extend the ideas of algorithm ABD to dynamic settings with explicit management of the evolving collections of replica hosts.

Consensus. Reaching agreement in distributed settings is a fundamental problem of computer science. The agreement problem in distributed settings is called *consensus*. Here a collection of processes need to agree on a value, where each process may propose a value for consideration. Any solution must satisfy the following properties: *Agreement:* no two processes decide on different values; *Validity:* the value decided was proposed by some process; *Termination:* all correct processes reach a decision. Consensus is a powerful tool in designing distributed services [39], however, consensus is a notoriously difficult problem to solve in asynchronous systems, where termination cannot be guaranteed in the presence of even a single process crash [20] (this is the seminal FLP impossibility result of Fischer, Lynch, and Paterson); thus consensus must be used with care.

Consensus algorithms can be used directly to implement an atomic data service by enabling the participants to agree on a global total ordering of all operations [36]. The

correctness (atomicity) here is guaranteed regardless of the choice of a specific consensus implementation, but the understanding of the underlying platform characteristics can guide the choice of the implementation for the benefit of system performance (for a *tour de force* of implementations see [39]). Nevertheless, using consensus for each operation is a heavy-handed approach, especially given that perturbations may delay or even prevent termination. Thus, when using consensus, one must avoid invoking it in conjunction with individual memory operations, and make operations independent of the termination of consensus.

We note that achieving consensus is a more difficult problem than implementing atomic read/write objects. In particular, consensus cannot be solved for two or more processes by using atomic read/write registers [31, 38].

Group communication services. Among the most important building blocks for distributed systems are *group communication services* (GCS) [8]. GCSs enable processes at different nodes of a network to operate collectively as a group by means of multicast services that deliver messages to the members of the group, and offer various guarantees about the order and reliability of delivery. The basis of a GCS is a *group membership service*. Each process, at any time, has a unique *view* of the group that includes a list of the processes in the group. Views can change over time, and may become different at different processes. Another important concept introduced by the GCS approach is *virtual synchrony*, where an essential requirement is that processes that proceed together through two consecutive views deliver the same set of messages between these views. This allows the recipients to take coordinated action based on the message, the membership set, and the rules prescribed by the application [8].

GCSs offer one approach for implementing shared memory. For example, one can implement a global totally ordered multicast service on top of a view-synchronous GCS [19]. The ordered multicast is used to impose an order on the memory access operations, yielding atomic memory. The main disadvantage in such solutions is that in GCS implementations, forming a new view takes time, and client memory operations are delayed (or aborted) during the view-formation period.

Another approach is to integrate a GCS with algorithm ABD as done in the dynamic primary configuration GCS of [14] that implements atomic memory by using techniques of [6] within each configuration, where configurations include a group view and a quorum system.

A general methodology for dynamic service replication is presented in [9]. This reconfiguration model unifies the virtual synchrony approach with state machine replication, as used in consensus solutions, in particular, Paxos [36].

DynaStore Algorithm. DynaStore [1] is an implementation of a dynamic atomic memory service for multi-writer/multi-reader objects. The participants start with a default local configuration, that is, some common set of replica hosts. The algorithm supports three kinds of operations: *read*, *write*, and *reconfig*. The read and write operations involve two phases, and in the absence of reconfigurations, the protocol is similar to ABD. If a participant wishes to change its current configuration, it uses the *reconfig* operation and supplies with it a set of incremental changes.

The implementation of *reconfig* involves traversals of DAG's representing possible sequences of changed configurations. In each traversal the DAG may be revised to reflect multiple changes to the same configuration. The assumption that a majority of the involved hosts are not removed and do not crash ensures that there is a path through the DAG that is guaranteed to be common among all hosts. The traversal terminates when a sink node is reached. The

reconfig protocol involves two phases. The goal of the first phase is similar to the Get phase of ABD: discover the latest value-tag pair for the object. The goal of the second phase is similar to the Put phase of ABD: convey the latest value-tag pair to a suitable majority of replica hosts. The main difference is that these two phases are performed in the context of applying the incremental changes to the configuration, while at the same time discovering the changes submitted by other participants. This "bootstraps" possible new configurations. Given that all of this is done by traversing all possible paths—and thus configurations—in the DAG's ensures that the common path is also traversed.

The *read* follows the implementation of *reconfig*, with the differences being: (a) the set of configuration changes is empty, and (b) the discovered value is returned to the client. The *write* also follows the implementation of *reconfig*, with the differences being: (a) the set of changes is empty, (b) a new, higher tag is produced upon the completion of the first phase, and (c) the new value-tag pair is propagated in the second phase.

We note that DynaStore implementation does not incorporate consensus for reconfiguration. On the other hand, reconfigurations are accomplished by additions and removals of individual nodes and this may lead to larger overheads as compared to approaches that evolve the system by replacing a complete configuration with another. Thus the latency of read and write operations are more dependent on the rate of reconfigurations. Finally, in order to guarantee termination, DynaStore assumes that reconfigurations eventually subside.

Rambo Framework. RAMBO is a dynamic memory service supporting MWMR objects [28]; RAMBO stands for Reconfigurable Atomic Memory for Basic Objects. This algorithm uses *configurations*, each consisting of a set of replica hosts plus a quorum system defined over these hosts, and supports *reconfiguration*, by which configurations can be replaced. Notably, any quorum configuration may be installed at any time, and quorums from distinct configurations are not required to have non-empty intersections. The algorithm ensures atomicity in all executions. During quiescent periods when there are no reconfigurations, the algorithm operates similarly to algorithm ABD [6, 40]. To enable long-term operation of the service, quorum configurations can be reconfigured. Reconfigurations are performed concurrently with any ongoing read and write operations, and do not directly affect such operations. Additionally, multiple reconfigurations may be in progress concurrently. Reconfiguration involves two decoupled protocols: (1) introduction of a new configuration by the component called *Recon*, and (2) upgrade to the new configuration and garbage collection of obsolete configuration(s). *Recon* always emits a unique new configuration. Different reconfiguration proposals are reconciled by executing consensus among the members of an existing configuration. Note that termination of read and write operations does not depend on termination of reconfiguration. It is the duty of a decoupled *upgrade* protocol to garbage collect old configurations and propagate the information about the object to the latest locally-known configuration. The main algorithm performs read and write operations using a two-phase strategy. The first phase gathers information from the quorums of active configurations, then the second phase propagates information to the quorums of active configurations. Note that during each phase new configurations may be discovered. To handle this each phase is terminated by a *fixed point* condition that involves a quorum from each active configuration.

Lastly, RAMBO is used as a framework for refinements and optimizations, and several subsequent works focused on practical considerations [29, 12, 22, 23, 33]. *GeoQuorums* [16] is an approach to implementing atomic shared memory on top of a physical platform that is based on mobile nodes moving in arbitrary patterns. The algorithm simplifies reconfiguration of RAMBO by using a finite set of possible configurations, and as the result it avoids the use of consensus. Here it is sufficient for a mobile node to discover the latest configuration, and contact and propagate the latest register information to all configurations.

6 Discussion

We presented several approaches for implement atomically consistent memory services in distributed message-passing systems. Our focus is on atomic consistency because it is an intuitive notion that hides the complexities of underlying implementations, presenting a convenient abstraction to the software builders. This is particularly valuable because of the common perception that the shared-memory paradigm is easier to deal with than the message-passing paradigm in designing distributed algorithms. The solutions presented in this work are representative of the different design choices available for implementing distributed memory services, and we emphasized the trade-offs present in different approaches.

We discussed in detail the issues of resilience and efficiency in the single-writer and multi-writer models in static settings. We then surveyed several approaches that implement consistent shared memory in these settings. In the established implementations frameworks some open problems remain regarding out ability to further improve the efficiency of services that use variable number of exchanges (two, three, and four) in implementing read and write operations. We also anticipate that additional lower bounds will be established to help better understand limitations on efficient implementations. For the static setting, it is also interesting to investigate the possibility of devising consistent implementations with *zero-delay* operations. That is, where operations are able to complete without additional communication, perhaps only relying on the knowledge obtain through prior communications. If the answer is in the negative, then it will still be interesting to understand the possibility of obtaining such implementations for notions of consistency weaker than atomicity, e.g., eventual consistency, or by weakening the power of adversity. As an example of this direction, the work of Chandra et al. [11] assumes a partially synchronous system using synchronized local clocks. Such solutions are particularly interesting for applications that are either read or write dominated.

The algorithms that we surveyed for the static settings may have difference fault-tolerance guarantees and be subject to efficiency trade-offs. This prompted researchers to perform empirical studies of their proposed algorithms [25, 24, 4, 3, 30, 21]. Here a goal is to understand how the analytical results are are reflected in practical efficiency. In addition to simulations, full scale cloud-based experimental evaluations will be certain to yield valuable observations in realistic settings.

In this paper we also surveyed several approaches for providing consistent shared memory in more dynamic systems, that is, where nodes may not only crash or depart voluntarily, but where new nodes may join, and where servers in one configurations can be replaced with entirely new configurations. Providing efficient atomic implementations remains challenging for dynamic settings. Here the expectation is that solutions are found by integrating static algorithms with a reconfiguration framework so that during periods of relative stability one benefits from the efficiency of static algorithms, and where during the more turbulent times performance degrades gracefully when reconfigurations are needed. One of the open questions here is whether consensus is truly necessary for implementing consistent memory services for long-lived dynamic systems.

The technical challenges and performance overheads in the dynamic setting may be the reasons why the existing distributed storage solutions shy away from atomic consistency guarantees. Commercial solutions, such as Google's File System (GFS) [27], Amazon's Dynamo [15], and Facebook's Cassandra [34], provide less-than-intuitive, unproved guarantees. The concepts discussed in section 5 are echoed in the design decisions of production systems. For instance, consensus is used in GFS [27] to ensure agreement on system configuration as it

is done in RAMBO; global time is used in Spanner [13] as it is done in *GeoQuorums*; replica access protocols in Dynamo [15] use quorums as in some approaches surveyed here. These examples provide motivation for pursuing rigorous algorithmic approaches in the study of consistent data services for dynamic networked systems. For a more detailed discussion, we direct the interested reader to related work that surveys atomic shared implementations for dynamic settings [42].

Consistent storage systems continues to be an area of active research and advanced development, and there are good reasons to believe that as high performance memory systems with superior fault-tolerance become available, they will play a significant role in the construction of sophisticated distributed applications. The demand for implementations providing atomic read/write memory will ultimately be driven by the needs of distributed applications that require provable consistency and performance guarantees.

Sparsity – an Algorithmic Perspective

Jaroslav Nešetřil
Computer Science Institute, Charles University, Prague, Czech Republic
nesetril@iuuk.mff.cuni.cz

Abstract

It is a well known experience that for sparse structures one can find fast algorithm for some problems which seem to be otherwise complex. The recently developed theory of sparse classes of graphs (and structures) formalizes this. Particularly the dichotomy Nowhere vs Somewhere Dense presents a very robust tool to study and design algorithms and algorithmic metatheorems. This dichotomy can be characterized in many different ways leading tp broad applications. We survey some of the recent highlights. This is a joint work with Patrice Ossona de Mendez (EHESS Paris and Charles University Prague).

Abstract

A leading idea is to apply techniques from verification and programming theory to machine learning and statistics, to deal with things like compositionality and various notions of correctness and complexity. Probabilistic programming is an example of this. Moreover, this approach leads to new foundational methods in probability theory. This is particularly true in the "non-parametric" aspects, for example in higher-order functions and infinite random graph models.

Abstract

In 2010, the author proposed a program for proving lower bounds in circuit complexity, via faster algorithms for circuit satisfiability and related problems. This talk will give an overview of how the program works, report on the successes of this program so far, and outline open frontiers that have yet to be resolved.

Abstract

We consider the classic d-choice paradigm of Azar et al. [STOC'94] in which m balls are put into n bins sequentially as follows: For each ball we are given a choice of d bins chosen according to d hash functions and the ball is placed in the least loaded of these bins, breaking ties arbitrarily. The interest is in the number of balls in the fullest bin after all balls have been placed.

In this paper we suppose that the d hash functions are simple tabulation hash functions which are easy to implement and can be evaluated in constant time. Generalising a result by Dahlgaard et al. [SODA'16] we show that for an arbitrary constant $d \geq 2$ the expected maximum load is at most $\frac{\lg \lg n}{\lg d} + O(1)$. We further show that by using a simple tie-breaking algorithm introduced by Vöcking [J.ACM'03] the expected maximum load is reduced to $\frac{\lg \lg n}{d \lg \varphi_d} + O(1)$ where φ_d is the rate of growth of the d-ary Fibonacci numbers. Both of these expected bounds match those known from the fully random setting.

The analysis by Dahlgaard et al. relies on a proof by Pătraşcu and Thorup [J.ACM'11] concerning the use of simple tabulation for cuckoo hashing. We require a generalisation to $d > 2$ hash functions, but the original proof is an 8-page tour de force of ad-hoc arguments that do not appear to generalise. Our main technical contribution is a shorter, simpler and more accessible proof of the result by Pătraşcu and Thorup, where the relevant parts generalise nicely to the analysis of d choices.

1 Introduction

Suppose that we are to place $m = O(n)$ balls sequentially into n bins. If the positions of the balls are chosen independently and uniformly at random it is well-known that the maximum load of any bin is[2] $\Theta(\log n/\log\log n)$ whp (i.e. with probability $1 - O(n^{-\gamma})$ for arbitrarily large fixed γ). See for example [10] for a precise analysis.

Another allocation scheme is the ***d*-choice paradigm** (also called the d-choice balanced allocation scheme) first studied by Azar et al. [2]: The balls are inserted sequentially by for each ball choosing d bins, according to d hash functions $h_1, \ldots, h_d$ and placing the ball in the one of these d bins with the least load, breaking ties arbitrarily. Azar et al. [2] showed that using independent and fully random hash functions the maximum load surprisingly drops to at most $\frac{\log\log n}{\log d} + O(1)$ whp. This result triggered an extensive study of this and related types of load balancing schemes. Currently the paper by Azar et al. has more than 700 citations by theoreticians and practitioners alike. The reader is referred to the text book [13] or the recent survey [21] for thorough discussions. Applications are numerous and are surveyed in [11, 12].

An interesting variant was introduced by Vöcking [20]. Here the bins are divided into d groups each of size $g = n/d$ and for each ball we choose a single bin from each group. The balls are inserted using the d-choice paradigm but in case of ties we always choose the leftmost of the relevant bins i.e. the one in the group of the smalles index. Vöcking proved that in this case the maximum load drops further to $\frac{\log\log n}{d\log\varphi_d} + O(1)$ whp.

In this paper we study the use of simple tabulation hashing in the load balancing schemes by Azar et al. and by Vöcking.

1.1 Simple tabulation hashing

Recall that a hash function h is a map from a key universe U to a range R chosen with respect to some probability distribution on R^U. If the distribution is uniform we say that h is fully random but we may impose any probability distribution on R^U.

Simple tabulation hashing was first introduced by Zobrist [23]. In simple tabulation hashing $U = [u] = \{0, 1, \ldots, u-1\}$ and $R = [2^r]$ for some r. We identify R with the $\mathbb{Z}_2$-vector space $(\mathbb{Z}_2)^r$. The keys $x \in U$ are viewed as vectors consisting of $c > 1$ characters $x = (x[0], \ldots, x[c-1])$ with each $x[i] \in \Sigma \stackrel{def}{=} [u^{1/c}]$. We always assume that $c = O(1)$. The simple tabulation hash function h is defined by

$$h(x) = \bigoplus_{i=0}^{c-1} h_i(x[i])$$

where $h_0, \ldots, h_{c-1} : \Sigma \to R$ are chosen independently and uniformly at random from R^Σ. Here $\oplus$ denotes the addition in R which can in turn be interpreted as the bit-wise XOR of the elements $h_i(x[i])$ when viewed as bit-strings of length r.

Simple tabulation is trivial to implement, and very efficient as the character tables $h_0, \ldots, h_{c-1}$ fit in fast cache. Pătraşcu and Thorup [15] considered the hashing of 32-bit keys divided into 4 8-bit characters, and found it to be as fast as two 64-bit multiplications. On computers with larger cache, it may be faster to use 16-bit characters. We note that the c character table lookups can be done in parallel and that character tables are never changed once initialised.

[2] All logarithms in this paper are binary.

In the d-choice paradigm, it is very convenient that all the output bits of simple tabulation are completely independent (the jth bit of $h(x)$ is the XOR of the jth bit of each $h_i(x[i])$). Using (dr)-bit hash values, can therefore be viewed as using d independent r-bit hash values, and the d choices can thus be computed using a single simple tabulation hash function and therefore only c lookups.

1.2 Main results

We will study the maximum load when the elements of a fixed set $X \subset U$ with $|X| = m$ are distributed into d groups of bins $G_1, \dots, G_d$ each of size $g = n/d$ using the d-choice paradigm with independent simple tabulation hash functions $h_1, \dots, h_d : U \to [n/d]$. The d choices thus consist of a single bin from each group as in the scheme by Vöcking but for $x \in X$ we may identify $h_i(x)$ with $(h_i(x), i) \in [n/d] \times [d]$ and thus think of all h_i as mapping to the same set of bins like in the scheme by Azar et al.

Dahlgaard et al. [7] analysed the case $d = 2$ proving that if $m = O(n)$ balls are distributed into two tables each consisting of $n/2$ bins according to the two choice paradigm using two independently chosen simple tabulation hash functions, the maximum load of any bin is $O(\log \log n)$ whp. For $k = O(1)$ they further provided an example where the maximum load is at least $\lfloor k^{c-1}/2 \rfloor \log \log n - O(1)$ with probability $\Omega(n^{-2(k-1)(c-1)})$. Their example generalises to arbitrary fixed $d \geq 2$ so we cannot hope for a maximum load of $(1+o(1))\frac{\log \log n}{\log d}$ or even $100 \times \log \log n$ whp when d is constant. However, as we show in the full version of this paper [1], their result implies that even with $d = O(1)$ choices the maximum load is $O(\log \log n)$ whp.

Dahlgaard et al. also proved that the expected maximum load is at most $\log \log n + O(1)$ when $d = 2$. We prove the following result which generalises this to arbitrary $d = O(1)$.

▶ **Theorem 1.** *Let $d > 1$ be a fixed constant. Assume $m = O(n)$ balls are distributed into d tables each of size n/d according to the d-choice paradigm using d independent simple tabulation hash functions $h_1, \dots, h_d : U \to [n/d]$. Then the expected maximum load is at most $\frac{\log \log n}{\log d} + O(1)$.*

When in the d-choice paradigm we sometimes encounter ties when placing a ball — several bins among the d choices may have the same minimum load. As observed by Vöcking [20] the choice of tie breaking algorithm is of subtle importance to the maximum load. In the fully random setting, he showed that if we use the **Always-Go-Left algorithm** which in case of ties places the ball in the leftmost of the relevant bins, i.e. in the bin in the group of the smallest index, the maximum load drops to $\frac{\log \log n}{d \log \varphi_d} + O(1)$ whp. Here φ_d is the *unique* positive real solution to the equation $x^d = x^{d-1} + \cdots + x + 1$. We prove that his result holds in expectation when using simple tabulation hashing.

▶ **Theorem 2.** *Suppose that we in the setting of Theorem 1 use the Always-Go-Left algorithm for tie-breaking. Then the expected maximum load of any bin is at most $\frac{\log \log n}{d \log \varphi_d} + O(1)$.*

Note that φ_d is the rate of growth of the so called d-ary Fibonacci numbers for example defined by $F_d(k) = 0$ for $k \leq 0$, $F_d(1) = 1$ and finally $F_d(k) = F_d(k-1) + \cdots + F_d(k-d)$ when $k > 1$. With this definition we can write $\varphi_d = \lim_{k\to\infty} \sqrt[k]{F_d(k)}$. It is easy to check that $(\varphi_d)_{d>1}$ is an increasing sequence converging to 2.

1.3 Technical contributions

In proving Theorem 1 we would ideally like to follow the approach by Dahlgaard et al. [7] for the case $d = 2$ as close as possible. They show that if some bin gets load $k + 1$ then

either the hash graph (informally, the d-uniform hypergraph with an edge $\{h_1(x), \ldots, h_d(x)\}$ for each $x \in X$) contains a subgraph of size $O(k)$ with more edges than nodes or a certain kind of "witness tree" T_k. They then bound the probability that either of these events occur when $k = \log\log n + r$ for some sufficiently large constant r. Putting $k = \frac{\log\log n}{\log d} + r$ for a sufficiently large constant r we similarly have three tasks:

(1) Define the d-ary witness trees and argue that if some bin gets load $k+1$ then either **(A)**: the hash graph contains a such, or **(B)**: it contains a subgraph $G = (V, E)$ of size $O(k)$ with $|V| \leq (d-1)|E| - 1$.
(2) Bound the probability of **(A)**.
(3) Bound the probability of **(B)**.

Step (1) and (2) require intricate arguments but the techniques are reminiscent to those used by Dahlgaard et al. in [7] and it is not surprising that their arguments generalise to our setting. Due to space limitations this part of our analysis can be found in the full version of this paper [1].

Our main technical contribution is our work on step (3) as we now describe. Dealing with step (3) in the case $d = 2$ Dahlgaard et al. used the proof by Pătraşcu and Thorup [15] of the result below concerning the use of simple tabulation for cuckoo hashing[3].

▶ **Theorem 3** (Pătraşcu and Thorup [15]). *Fix $\varepsilon > 0$. Let $X \subset U$ be any set of m keys. Let n be such that $n > 2(1+\varepsilon)m$. With probability $1 - O(n^{-1/3})$ the keys of X can be placed in two tables of size $n/2$ with cuckoo hashing using two independent simple tabulation hash functions h_0 and h_1.*

Unfortunately for us, the original proof of Theorem 3 consists of 8 pages of intricate ad-hoc arguments that do not seem to generalise to the d-choice setting. Thus we have had to develop an alternative technique for dealing with step (3) As an extra reward this technique gives a new proof of Theorem 3 which is shorter, simpler and more readable and we believe it to be our main contribution and of independent interest[4].

1.4 Alternatives

We have shown that balanced allocation with d choices with simple tabulation gives the same expected maximum load as with fully-random hashing. Simple tabulation uses c lookups in tables of size $u^{1/c}$ and $c-1$ bit-wise XOR. The experiments from [15], with $u = 2^{32}$ and $c = 4$, indicate this to be about as fast as two multiplications.

Before comparing with alternative hash functions, we note that we may assume that $u \leq n^2$. If u is larger, we can first apply a universal hash function [3] from $[u]$ to $[n^2]$. This yields an expected number of $\binom{n}{2}/n^2 < 1/2$ collisions. We can now apply *any* hash function, e.g., simple tabulation, to the reduced keys in $[n^2]$. Each of the duplicate keys can increase the maximum load by at most one, so the expected maximum load increases by at most $1/2$. If $u = 2^w$, we can use the extremely simple universal hash function from [8], multiplying the key by a random odd w-bit number and performing a right-shift.

Looking for alternative hash functions, it can be checked that $O(\log n)$-independence suffices to get the same maximum load bounds as with full randomness even with high

[3] Recall that in cuckoo hashing, as introduced by Pagh and Rodler [14], we are in the 2-choice paradigm but we require that no two balls collide. However, we are allowed to rearrange the balls at any point and so the feasibility does only depend on the choices of the balls.
[4] We mention in passing that Theorem 3 is best possible: There exists a set X of m keys such that with probability $\Omega(n^{-1/3})$ cuckoo hashing is forced to rehash (see [15]).

probability. High independence hash functions were pioneered by Siegel [17] and the most efficient construction is the double tabulation of Thorup [18]. It gives independence $u^{\Omega(1/c^2)}$ using space $O(cu^{1/c})$ in time $O(c)$. With c a constant this would suffice for our purposes. However, looking into the constants suggested in [18], with 16-bit characters for 32-bit keys, we have 11 times as many character table lookups with double tabulation as with simple tabulation and we loose the same factor in space, so this is not nearly as efficient.

Another approach was given by Woelfel [22] using the hash functions he earlier developed with Dietzfelbinger [9]. He analysed Vöcking's Always-Go-Left algorithm, bounding the error probability that the maximum load exceeded $\frac{\log\log n}{d\log\varphi_d}+O(1)$. Slightly simplified and translated to match our notation, using $d+1$ k-independent hash functions and d lookups in tables of size $n^{2/c}$, the error probability is $n^{1+o(1)-k/c}$. Recall that we may assume $n^{2/c}\geq u^{1/c}$, so this matches the space of simple tabulation with c characters. With, say, $c=4$, he needs 5-independent hashing to get any non-trivial bound, but the fastest 5-independent hashing is the tabulation scheme of Thorup and Zhang [19], which according to the experiments in [15] is at least twice as slow as simple tabulation, and much more complicated to implement.

A final alternative is to compromise with the constant evaluation time. Reingold et al. [16] have shown that using the hash functions from [4] yields a maximum load of $O(\log\log n)$ whp. The functions use $O(\log n\log\log n)$ random bits and can be evaluated in time $O((\log\log n)^2)$. Very recently Chen [5] used a refinement of the hash family from [4] giving a maximum load of at most $\frac{\log\log n}{\log d}+O(1)$ whp and $\frac{\log\log n}{d\log\varphi_d}+O(1)$ whp using the Always-Go-Left algorithm. His functions require $O(\log n\log\log n)$ random bits and can be evaluated in time $O((\log\log n)^4)$. We are not so concerned with the number of random bits. Our main interest in simple tabulation is in the constant evaluation time with a very low constant.

1.5 Structure of the paper

In Section 2 we provide a few preliminaries for the proofs of our main results. In Section 3 we deal with step (3) described under *Technical contributions*. To provide some intuition we first provide the new proof of Theorem 3. Finally, we show how to proceed for general d. For step (1) and (2) as well as the final deduction of Theorem 1 and Theorem 2 the reader is referred to the full version of this paper [1].

2 Preliminaries

First, recall the definition of a hypergraph:

▶ **Definition 4.** A **hypergraph** is a pair $G=(V,E)$ where V is a set and E is a multiset consisting of elements from $\mathcal{P}(V)$. The elements of V are called **vertices** and the elements of E are called **edges**. We say that G is ***d*-uniform** if $|e|=d$ for all $e\in E$.

When using the d-choice paradigm to distribute a set of keys X there is a natural d-uniform hypergraph associated with the keys of X.

▶ **Definition 5.** Given a set of keys $X\subset U$ the **hash graph** is the d-uniform hypergraph on $[n/d]\times[d]$ with an edge $\{(h_1(x),1),\dots,(h_d(x),d)\}$ for each $x\in X$.

When working with the hash graph we will hardly ever distinguish between a key x and the corresponding edge, since it is tedious to write $\{(h_i(x),i)\}_{1\leq i\leq d}$. Statements such as "$P=(x_1,\dots,x_t)$ is a path" or "The keys x_1 and x_2 are adjacent in the hash graph" are examples of this abuse of notation.

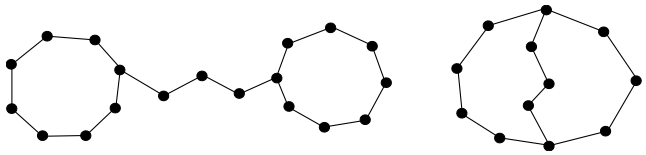

Figure 1 Double cycles - the minimal obstructions for cuckoo hashing.

Now we discuss the independence of simple tabulation. First recall that a **position character** is an element $(j, \alpha) \in [c] \times \Sigma$. With this definition a key $x \in U$ can be viewed as the set of position characters $\{(i, x[i])\}_{i=0}^{c-1}$ but it is sensible to define $h(S) = \bigoplus_{i=1}^{k} h_{j_i}(\alpha_i)$ for any set $S = \{(j_1, \alpha_1), \ldots, (j_k, \alpha_k)\}$ of position characters.

In the classical notion of independence of Carter and Wegman [3] simple tabulation is not even 4-independent. In fact, the keys $(a_0, b_0), (a_0, b_1), (a_1, b_0)$ and (a_1, b_1) are dependent, the issue being that each position character appears an even number of times and so the bitwise XOR of the hash values will be the zero string. As proved by Thorup and Zhang [19] this property in a sense characterises dependence of keys.

▶ **Lemma 6** (Thorup and Zhang [19]). *The keys $x_1, \ldots, x_k \in U$ are dependent if and only if there exists a non-empty subset $I \subset \{1, \ldots, k\}$ such that each position character in $(x_i)_{i \in I}$ appears an even number of times. In this case we have that $\bigoplus_{i \in I} h(x_i) = 0$.*

When each position character appears an even number of times in $(x_i)_{i \in I}$ we will write $\bigoplus_{i \in I} x_i = \emptyset$ which is natural when we think of a key as a set of position characters and $\oplus$ as the symmetric difference. As shown by Dahlgaard et al. [6] the characterisation in Lemma 6 can be used to bound the independence of simple tabulation.

▶ **Lemma 7** (Dahlgaard et al. [6]). *Let $A_1, \ldots, A_{2t} \subset U$. The number of $2t$-tuples $(x_1, \ldots, x_{2t}) \in A_1 \times \cdots \times A_{2t}$ such that $x_1 \oplus \cdots \oplus x_{2t} = \emptyset$ is at most*[5] $((2t-1)!!)^c \prod_{i=1}^{2t} \sqrt{|A_i|}$.

This lemma will be of extreme importance to us. In the full version of this paper [1] proofs of both Lemma 6 and Lemma 7 can be found.

3 Cuckoo hashing and generalisations

The following result is a key ingredient in the proofs of Theorem 1 and Theorem 2.

▶ **Theorem 8.** *Suppose that we are in the setting of Theorem 1 i.e. $d > 1$ is a fixed constant, $X \subset U$ with $|X| = m = O(n)$ and $h_1, \ldots, h_d : U \to [n/d]$ are independent simple tabulation hash functions. The probability that the hash graph contains a subgraph $G = (V, E)$ of size $|E| = O(\log \log n)$ with $|V| \leq (d-1)|E| - 1$ is at most $n^{-1/3+o(1)}$.*

Before giving the full proof however we provide the new proof of Theorem 3 which is more readable and illustrates nearly all the main ideas.

Proof of Theorem 3. It is well known that cuckoo hashing is possible if and only if the hash graph contains no subgraph with more edges than nodes. A minimal such graph is called a **double cycle** and consists of two cycles connected by a path or two vertices connected by

[5] Recall the double factorial notation: If a is a positive integer we write $a!!$ for the product of all the positive integers between 1 and a that have the same parity as a.

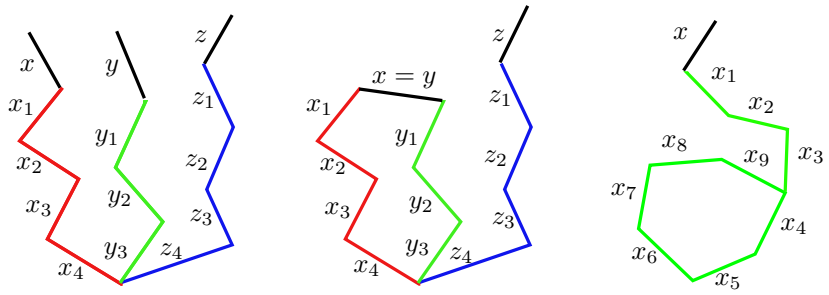

Figure 2 Non-black edges: Two tridents and a lasso. Black edges: Keys that are each dependent on the set of coloured keys.

three disjoint paths (see Figure 1). Hence, it suffices to bound the probability that the hash graph contains a double cycle by $O(n^{-1/3})$.

We denote by g the number of bins in each of the two groups. Thus in this setting $g = n/2 \geq (1+\varepsilon)m$. First of all, we argue that we may assume that the hash graph contains no trail of length at least $\ell = \frac{4}{3}\frac{\log n}{\log(1+\varepsilon)}$ consisting of *independent*. Indeed, the keys of a such can be chosen in at most m^ℓ ways and since we require $\ell - 1$ equations of the form $h_i(x) = h_i(y)$, $i \in \{1,2\}$ to be satisfied and since these events are independent the probability that the hash graph contains such a trail is by a union bound at most

$$\frac{2m^\ell}{g^{\ell-1}} \leq \frac{n}{(1+\varepsilon)^\ell} = n^{-1/3}.$$

Now we return to the double cycles. Let A_ℓ denote the event that the hash graph contains a double cycle of size ℓ consisting of *independent* keys. The graph structure of a such can be chosen in $O(\ell^2)$ ways and the keys (including their positions) in at most m^ℓ ways. Since there are $\ell + 1$ equations of the form $h_i(x) = h_i(y)$, $i \in \{1,2\}$ to be satisfied the probability that the hash graph contains a double cycle consisting of independent keys is at most

$$\sum_{\ell=3}^{m} \mathbb{P}(A_\ell) = O\left(\sum_{\ell=3}^{m} \ell^2 \frac{m^\ell}{g^{\ell+1}}\right) = O\left(\frac{1}{n}\sum_{\ell=3}^{m} \frac{\ell^2}{(1+\varepsilon)^\ell}\right) = O(n^{-1}).$$

The argument above is the same as in the fully random setting. We now turn to the issue of dependencies in the double cycle starting with the following definition.

▶ **Definition 9.** We say that a graph is a **trident** if it consists of three paths P_1, P_2, P_3 of non-zero lengths meeting at a single vertex v. (see the non-black part of Figure 2).

We say that a graph is a **lasso** if it consists of a path that has one end attached to a cycle (see the non-black part of Figure 2).

We claim that in any double cycle D consisting of *dependent* keys we can find one of the following structures (see Figure 2):

- **S1:** A lasso L consisting of independent keys together with a key x not on L and incident to the degree 1 vertex of L such that x is dependent on the keys of L.
- **S2:** A trident T consisting of independent keys together with 3 (not necessarily distinct) keys x, y, z not on T but each dependent on the keys of T and incident to the 3 vertices of degree 1 on T

To see this suppose first that one of the cycles C of D consists of independent keys. In this case any maximal lasso of independent keys in D containing the edges of C is an S_1.

On the other hand if all cycles contained in D consist of dependent keys we pick a vertex of D of degree at least 3 and 3 incident edges. These 3 edges form an independent trident (simple tabulation is 3-independent) and any maximal independent trident contained in D and containing these edges forms an S_2.

Our final step is thus to show that the probability that these structures appear in the hash graph is $O(n^{-1/3})$

The lasso (S_1):

Since the edges of the lasso form an independent trail it by the initial observation suffices to bound the probability that the hash graph contains an S_1 of size ℓ for any $\ell = O(\log n)$.

Fix the size ℓ of the lasso. The number of ways to choose the graph structure of the lasso is $\ell - 2 < \ell$. Denote the set of independent keys of the lasso by $S = \{x_1, \ldots, x_\ell\}$ and let x be the dependent key in S_1. By Lemma 6 we may write $x = \bigoplus_{i \in I} x_i$ for some $I \subset \{1, \ldots, \ell\}$. Fix the size $|I| = t \geq 3$ (which is necessarily odd). By Lemma 7 the number of ways to choose the keys of $(x_i)_{i \in I}$ (including their order) is at most $(t!!)^c m^{(t+1)/2}$ and the number of ways to choose their positions in the lasso is $\binom{\ell}{t}$. The number of ways to choose the remaining keys of S is trivially bounded by $m^{\ell - t}$ and the probability that the choice of independent keys hash to the correct positions in the lasso is at most $2/g^\ell$. By a union bound the probability that the hash graph contains an S_1 for fixed values of ℓ and t is at most

$$\ell (t!!)^c m^{(t+1)/2} m^{\ell - t} \binom{\ell}{t} \frac{2}{g^\ell}.$$

This is maximised for $t = 3$. In fact, when $\ell \leq m^{1/(c+2)}$ and $t \leq \ell - 2$ we have that

$$\frac{((t+2)!!)^c m^{(t+3)/2} m^{\ell - t - 2} \binom{\ell}{t+2}}{(t!!)^c m^{(t+1)/2} m^{\ell - t} \binom{\ell}{t}} = \frac{(t+2)^c}{m} \frac{\binom{\ell - t}{2}}{\binom{t+2}{2}} \leq \frac{\ell^{c+2}}{m} \leq 1.$$

Thus the probability that the hash graph contains an S_1 of size $O(\log n)$ is at most

$$\sum_{\ell=3}^{O(\log n)} \sum_{t=3}^{\ell} \ell 3^c \binom{\ell}{3} \frac{2 m^{\ell - 1}}{g^\ell} = O\left(\sum_{\ell=3}^{O(\log n)} \frac{\ell^5}{n(1+\varepsilon)^{\ell-1}} \right) = O(n^{-1}).$$

The trident (S_2):

Fix the size ℓ of the trident. The number of ways to choose the structure of the trident is bounded by ℓ^2 (once we choose the lengths of two of the paths the length of the third becomes fixed). Let $P_1 = (x_1, \ldots, x_{t_1})$, $P_2 = (y_1, \ldots, y_{t_2})$ and $P_3 = (z_1, \ldots, z_{t_3})$ be the three paths of the trident meeting in $x_{t_1} \cap y_{t_2} \cap z_{t_3}$. As before we may assume that each has length $O(\log n)$. Let S denote the keys of the trident and enumerate $S = \{w_1, \ldots, w_\ell\}$ in some order. Write $x = \bigoplus_{i \in I} w_i$, $y = \bigoplus_{j \in J} w_j$ and $z = \bigoplus_{k \in K} w_k$ for some $I, J, K \subset \{1, \ldots, \ell\}$. By a proof almost identical to that given for the lasso we may assume that $|I| = |J| = |K| = 3$. Indeed, if for example $|I| \geq 5$ we by Lemma 7 save a factor of nearly m^2 when choosing the keys of S and this makes up for the fact that the trident contains no cycles and hence that the probability of a fixed set of independent keys hashing to it is a factor of g larger.

The next observation is that we may assume that $|I \cap J|, |J \cap K|, |K \cap I| \geq 2$. Again the argument is of the same flavour as the one given above. If for example $|I \cap J| = 1$ we by an application of Lemma 7 obtain that the number of ways to choose the keys of $(w_i)_{i \in I}$ is $O(m^2)$. Conditioned on this, the number of ways to choose the keys $(w_j)_{j \in J}$ is $O(m^{3/2})$ by

another application of Lemma 7 with one of the A_i's a singleton. Thus we save a factor of $m^{3/2}$ when choosing the keys of S which will again suffice. The bound gets even better when $|I \cap J| = 0$ where we save a factor of m^2.

Suppose now that x_1 is not a summand of $\bigoplus_{i\in I} w_i$. Write $x = w_a \oplus w_b \oplus w_c$ and let A be the event that the independent keys of S hash to the trident (with the equation involving x_1 and x_2 being $h_2(x_1) = h_2(x_2)$ without loss of generality). Then $\mathbb{P}(A) = \frac{1}{g^{\ell-1}}$. We observe that

$$\mathbb{P}(h_1(x) = h_1(x_1) \,|\, A) = \mathbb{P}(h_1(x_1) = h_1(w_a) \oplus h_1(w_b) \oplus h_1(w_c) \,|\, A) = g^{-1}$$

since A is a conjunction of events of the form $\{h_i(w) = h_i(w')\}$ none of them involving $h_1(x_1)$[6]. A union bound then gives that the probability that this can happen is at most

$$\sum_{\ell=3}^{O(\log n)} \ell^2 \binom{\ell}{3} (3!!)^c m^2 m^{\ell-3} \left(\frac{1}{g}\right)^{\ell} = O\left(\frac{1}{n} \sum_{\ell=3}^{\infty} \frac{\ell^5}{(1+\varepsilon)^{\ell-1}}\right) = O(n^{-1}).$$

Thus we may assume that x_1 is a summand of $\bigoplus_{i\in I} w_i$ and by similar arguments that y_1 is a summand of $\bigoplus_{j\in J} w_j$ and that z_1 is a summand of $\bigoplus_{k\in K} w_k$.

To complete the proof we need one final observation. We can define an equivalence relation on $X \times X$ by $(a, b) \sim (c, d)$ if $a \oplus b = c \oplus d$. Denote by $\mathcal{C} = \{C_1, \ldots, C_r\}$ the set of equivalence classes. One of them, say C_1, consists of the elements $(x, x)_{x\in X}$. We will say that the equivalence class C_i is **large** if $|C_i| \geq m^{2/3}$ and **small** otherwise. Note that

$$\sum_{i=1}^{r} |C_i|^2 = |\{(a, b, c, d) \in X^4 : a \oplus b \oplus c \oplus d = \emptyset\}| \leq 3^c m^2$$

by Lemma 7. In particular the number of large equivalence classes is $O(m^{2/3})$.

If h is a simple tabulation hash function we can well-define a map $\tilde{h} : \mathcal{C} \to R$ by $\tilde{h}(a, b) = h(a) \oplus h(b)$. Since the number of large equivalence classes is $O(m^{2/3})$ the probability that $\tilde{h}_i(C) = 0$ for some large $C \in \mathcal{C}\backslash\{C_1\}$ and some $i \in \{1, 2\}$ is $O(m^{2/3}/n) = O(n^{-1/3})$ and we may thus assume this does not happen.

In particular, we may assume that (x, x_1), (y, y_1) and (z, z_1) each represent small equivalence classes as they are adjacent in the hash graph. Now suppose that y_1 is not a summand in $x = \bigoplus_{i\in I} w_i$. The number of ways to pick $(x_i)_{i\in I}$ is at most $3^c m^2$ by Lemma 7. By doing so we fix the equivalence class of (y, y_1) but not y_1 so conditioned on this the number of ways to pick $(y_j)_{j\in J}$ is at most $m^{2/3}$. The number of ways to choose the remaining keys is bounded by $m^{\ell-4}$ and a union bound gives that the probability of having such a trident is at most

$$\sum_{\ell=3}^{O(\log n)} \ell^2 3 \binom{\ell}{2} 3^c m^2 m^{2/3} m^{\ell-4} \left(\frac{1}{g}\right)^{\ell-1} = O\left(n^{-1/3} \sum_{\ell=3}^{\infty} \frac{\ell^4}{(1+\varepsilon)^{\ell-4/3}}\right) = O(n^{-1/3}),$$

which suffices.

We may thus assume that y_1 is a summand in $\bigoplus_{i\in I} w_i$ and by an identical argument that z_1 is a summand in $\bigoplus_{i\in I} w_i$ and hence $x = x_1 \oplus y_1 \oplus z_1$. But the same arguments apply to y and z reducing to the case when $x = y = z = x_1 \oplus y_1 \oplus z_1$ which is clearly impossible. ◀

[6] If $x_1 = w_a$, say, we don't necessarily get the probability g^{-1}. In this case the probability is $\mathbb{P}(h_1(w_b) = h_1(w_c) \,|\, A)$ and the event $\{h(w_b) = h(w_c)\}$ might actually be included in A in which case the probability is 1. This can of course only happen if the keys w_b and w_c are *adjacent* in the trident so we could impose even further restrictions on the dependencies in S_2.

3.1 Proving Theorem 8

Now we will explain how to prove Theorem 8 proceeding much like we did for Theorem 3. Let us say that a d-uniform hypergraph $G = (V, E)$ is **tight** if $|V| \leq (d-1)|E| - 1$. With this terminology Theorem 8 states that the probability that the hash graph contains a tight subgraph of size $O(\log \log n)$ is at most $n^{-1/3+o(1)}$. It clearly suffices to bound the probability of the existence of a *connected* tight subgraph of size $O(\log \log n)$.

We start with the following two lemmas. The counterparts in the proof of Theorem 3 are the bounds on the probability of respectively an independent double cycle and an independent lasso with a dependent key attached.

▶ **Lemma 10.** *Let A_1 denote the event that the hash graph contains a tight subgraph $G = (V, E)$ of size $O(\log \log n)$ consisting of independent keys. Then $\mathbb{P}(A_1) \leq n^{-1+o(1)}$.*

Proof. Let $\ell = |E|$ be fixed. The number of ways to choose the keys of E is trivially bounded by m^ℓ and the number of ways to choose the set of nodes V in the hash graph is $\binom{n}{(d-1)\ell-1}$. For such a choice of nodes let a_i denote the number of nodes of V in the i'th group. The probability that one of the keys hash to V is then

$$\prod_{i=1}^{d} \frac{da_i}{n} \leq \left(\frac{a_1 + \cdots + a_d}{n}\right)^d \leq \left(\frac{d\ell}{n}\right)^d.$$

By the independence of the keys and a union bound we thus have that

$$\mathbb{P}(A_1) \leq \sum_{\ell=2}^{O(\log \log n)} m^\ell \binom{n}{(d-1)\ell - 1} \left(\frac{d\ell}{n}\right)^{d\ell} \leq \sum_{\ell=2}^{O(\log \log n)} \frac{1}{n} \left(\frac{m}{n}\right)^\ell (d\ell)^{d\ell} = n^{-1+o(1)},$$

as desired. ◀

▶ **Lemma 11.** *Let A_2 be the event that the hash graph contains a subgraph $G = (V, E)$ with $|V| \leq (d-1)|E|$ and $|E| = O(\log \log n)$ such that the keys of E are independent but such that there exists a key $y \notin E$ dependent on the keys of E. Then $\mathbb{P}(A_2) \leq n^{-1+o(1)}$.*

Proof. Let $|E| = \ell$ be fixed and write $E = \{x_1, \ldots, x_\ell\}$. We want to bound the number of ways to choose the keys of E. By Lemma 6, $y = \bigoplus_{i \in I} x_i$ for some $I \subset \{1, \ldots, \ell\}$ with $|I| = r$ for some odd $r \geq 3$. Let r be fixed for now. Using Lemma 7, we see that the number of ways to choose the keys of E is no more than $(r!!)^c m^{\frac{r+1}{2}} m^{\ell - r}$. For fixed ℓ and r the probability is thus bounded by

$$(r!!)^c m^{\ell - \frac{r-1}{2}} \binom{n}{\ell(d-1)} \left(\frac{d\ell}{n}\right)^{d\ell} = n^{-1+o(1)}$$

and a union bound over all $\ell = O(\log \log n)$ and $r \leq \ell$ suffices. ◀

We now generalise the notion of a double cycle starting with the following definition.

▶ **Definition 12.** Let $G = (V, E)$ be a d-uniform hypergraph. We say that a sequence of edges $P = (e_1, \ldots, e_t)$ of G is a **path** if $|e_i \cap e_{i+1}| = 1$ for $1 \leq i \leq t-1$ and $e_i \cap e_j = \emptyset$ when $i < j - 1$.

We say that $C = (e_1, \ldots, e_t)$ is a **cycle** if $t \geq 3$, $|e_i \cap e_{i+1}| = 1$ for all $i \pmod t$ and $e_i \cap e_j = \emptyset$ when $i \neq j \pm 1 \pmod t$.

Next comes the natural extension of the definition of double cycles to d-uniform hypergraphs.

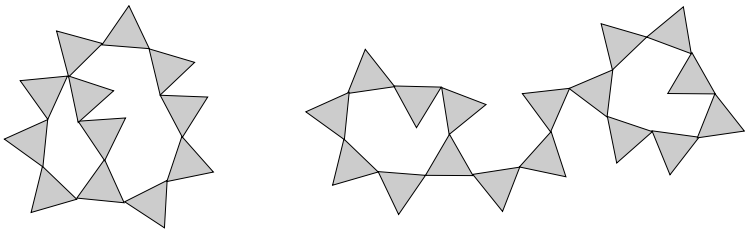

Figure 3 Double cycles in the case $d = 3$. The triangles represent edges of the graph and the corners represent the vertices.

▶ **Definition 13.** A d-uniform hypergraph G is called a **double cycle** if it has either of the following forms (see Figure 3).

- **D1:** It consists of of two vertex disjoint cycles C_1 and C_2 connected by a path $P = (x_1, \ldots, x_t)$ such that $|x_1 \cap V(C_1)| = |x_t \cap V(C_2)| = 1$ and $x_{i+1} \cap V(C_1) = x_i \cap V(C_2) = \emptyset$ for $1 \leq i \leq t-1$. We also allow P to have zero length and $|V(C_1) \cap V(C_2)| = 1$.
- **D2:** It consist of a cycle C and a path $P = (x_1, \ldots, x_t)$ of length $t \geq 2$ such that $|x_1 \cap V(C)| = |x_t \cap V(C)| = 1$ and $x_i \cap V(C) = \emptyset$ for $2 \leq i \leq t-1$. We also allow $t = 1$ and $|x_1 \cap C| = 2$.

Note that a double cycle always has $|V| = (d-1)|E| - 1$.

Now assume that the hash graph contains a connected tight subgraph $G = (V, E)$ of size $O(\log \log n)$ but that neither of the events of Lemma 10 and 11 has occurred. In particular no two edges e_1, e_2 of G has $|e_1 \cap e_2| \geq 2$ and no cycle consists of independent keys.

It is easy to check that under this assumption G contains at least two cycles. Now pick a cycle C_1 of least possible length. Since simple tabulation is 3-independent the cycle consists of at least 4 edges. If there exists an edge x not part of C_1 with $|x \cap V(C_1)| = 2$ we get a double cycle of type D_2. If $|x \cap V(C_1)| \geq 3$ we can use x to obtain a shorter cycle than C_1 which is a contradiction[7]. Using this observation we see that if there is a cycle $C_2 \neq C_1$ such that $|V(C_1) \cap V(C_2)| \geq 2$ then we can find a D_2 in the hash graph. Thus we may assume that any cycle $C_2 \neq C_1$ satisfies $|V(C_2) \cap V(C_1)| \leq 1$.

Now pick a cycle C_2 different from C_1 of least possible length. As before we may argue that any edge x not part of C_2 satisfies that $|x \cap V(C_2)| \leq 1$. Picking a shortest path connecting C_1 and C_2 (possibly the length is zero) gives a double cycle of type D_1.

Next we define tridents (see the non-grey part of Figure 4).

▶ **Definition 14.** We call a d-uniform hypergraph T a **trident** if it consists of paths $P_1 = (x_1, \ldots, x_{t_1})$, $P_2 = (y_1, \ldots, y_{t_2})$ and $P_3 = (z_1, \ldots, z_{t_3})$ of non-zero length such that either:

- There is a vertex v such that $x_{t_1} \cap y_{t_2} \cap z_{t_3} = \{v\}$, v is contained in no other edge of T and no vertex different from v is contained in more than one of the three paths.
- P_1, P_2 and $P_3 \backslash \{z_{t_3}\} = (z_2, \ldots, z_{t_3})$ are vertex disjoint and $(x_1, \ldots, x_{t_1}, z_{t_3}, y_{t_2}, \ldots, y_1)$ is a path.

Like in the proof of of Theorem 3 the existence of a double cycle not containing a cycle of independent keys implies the existence of the following structure (see Figure 4):

[7] Here we use that the length of C_1 is at least 4. If C_1 has length t the fact that x contains three nodes of C_1 only guarantees a cycle of length at most $3 + \lfloor \frac{t-3}{3} \rfloor$.

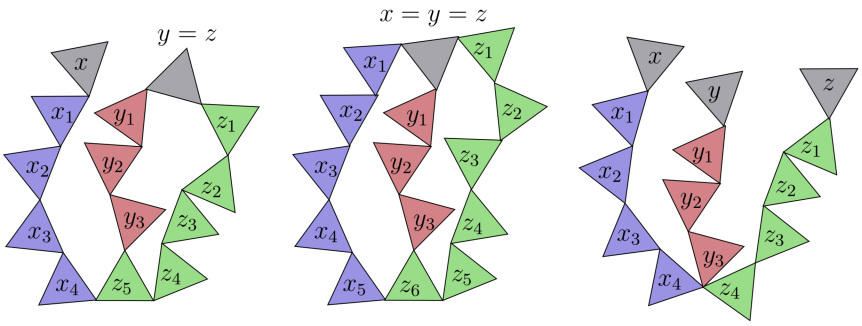

Figure 4 The case $d = 3$. Non-grey edges: Tridents. Grey edges: Keys that are each dependent on the set of non-black keys.

- **S1**: A trident consisting of three paths $P_1 = (x_1, \ldots, x_{t_1})$, $P_2 = (y_1, \ldots, y_{t_2})$ and $P_3 = (z_1, \ldots, z_{t_3})$ such that the keys of the trident are independent and such that there are, not necessarily distinct, keys x, y, z not in the trident extending the paths P_1, P_2 and P_3 away from their common meeting point such that x, y and z are each dependent on the keys in the trident.

We can bound the probability of this event almost identically to how we proceeded in the proof of Theorem 3. The only difference is that when making the ultimate reduction to the case where $x = y = z = x_1 \oplus y_1 \oplus z_1$ this event is in fact possible (see Figure 4). In this case however, there are three *different* hash function h_x, h_y and h_z such that $h_x(x_1) = h_x(x)$, $h_y(y_1) = h_y(x)$ and $h_z(z_1) = h_z(x)$. However, it is easy to bound the probability that this occur: The number of ways to choose the keys (x, x_1, y_1, z_1) is at most $3^c m^2$ by Lemma 7. The number of ways to choose the hash functions is upper bounded by d^3. Since the hash functions $h_1, \ldots, h_d$ are independent the probability that this can happen in the hash graph is by a union bound at most

$$d^3 3^c m^2 \left(\frac{d}{n}\right)^3 = O(n^{-1})$$

which suffices to complete the proof of Theorem 8.

Summing up

For now we have spent most of our energy proving Theorem 8. At this point it is perhaps not clear to the reader why it is important so let us again highlight the steps to Theorem 1. First of all let $k = \frac{\log\log n}{\log d} + r$ for r a sufficiently large constant. The steps are:

(1) Show that if some bin has load k then either the hash graph contains a tight subgraph of size $O(k)$ or a certain kind of witness tree T_k.
(2) Bound the probability that the hash graph contains a T_k by $O((\log\log n)^{-1})$.
(3) Bound the probability that the hash graph contains a tight subgraph of size $O(k)$ by $O((\log\log n)^{-1})$.

We can now cross (3) of the list. In fact, we have a much stronger bound than we require. The remaining steps as well as the final proofs of Theorem 1 and Theorem 2 are dealt with in the full version of this paper [1]. As already mentioned the proofs of all the above steps (except step (3)) are intricate but straightforward generalisations of the methods in [7].

Abstract

Given a graph, does there exist an orientation of the edges such that the resulting directed graph is strongly connected? Robbins' theorem [Robbins, Am. Math. Monthly, 1939] asserts that such an orientation exists if and only if the graph is 2-edge connected. A natural extension of this problem is the following: Suppose that the edges of the graph are partitioned into trails. Can the trails be oriented consistently such that the resulting directed graph is strongly connected?

We show that 2-edge connectivity is again a sufficient condition and we provide a linear time algorithm for finding such an orientation.

The generalised Robbins' theorem [Boesch, Am. Math. Monthly, 1980] for mixed multigraphs asserts that the undirected edges of a mixed multigraph can be oriented to make the resulting directed graph strongly connected exactly when the mixed graph is strongly connected and the underlying graph is bridgeless.

We consider the natural extension where the undirected edges of a mixed multigraph are partitioned into trails. It turns out that in this case the condition of the generalised Robbin's Theorem is not sufficient. However, we show that as long as each cut either contains at least 2 undirected edges or directed edges in both directions, there exists an orientation of the trails such that the resulting directed graph is strongly connected. Moreover, if the condition is satisfied, we may start by orienting an arbitrary trail in an arbitrary direction. Using this result one obtains a very simple polynomial time algorithm for finding a strong trail orientation if it exists, both in the undirected and the mixed setting.

1 Introduction and motivation

Suppose that the mayor of a small town decides to make all the streets one-way such that it is possible to get from any place to any other place without violating the orientations of the streets[5]. If all the streets are initially two-way then Robbins' theorem [10] asserts that this can be done exactly when the corresponding graph is 2-edge connected. If, on the other hand some of the streets were already one-way in the beginning then the generalised Robbins' theorem by Boesch [1] states that it can be done exactly when the corresponding "mixed" graph is strongly connected and the underlying graph is bridgeless.

However, the proofs of both of these results assume that every street of the city corresponds to exactly one edge in the graph. This assumption hardly holds in any city in the world and therefore a more natural assumption is that every street corresponds to a trail (informally, a potentially self-crossing path) in the graph and that the edges of each trail must be oriented consistently[6].

In this paper we consider such graphs having their edges partitioned into trails. We prove that the trails can be oriented to make the resulting directed graph strongly connected exactly if the initial graph is 2-edge connected (note that this is precisely the condition of Robbins' theorem).

Not only do we show that the strong trail orientation problem in undirected 2-edge connected graphs always has a solution, we also provide a linear time algorithm for finding such an orientation. In doing so, we use an interesting combination of techniques that allow us to reduce to a graph with a number of 3-edge connected components that is linear in the number of edges. Using that the average size of these components is constant and that we can piece together solutions for the individual components we obtain an efficient algorithm.

Finally, we will consider the generalised Robbins' theorem in this new setting by allowing some edges to be oriented initially and supposing that the remaining edges are partitioned into trails. We will show that if each cut (V_1, V_2) in the graph has either at least 2 undirected edges going between V_1 and V_2 or at least 1 directed edge in each direction then it is possible to orient the trails making the resulting graph strongly connected. In fact, we show that if this condition is satisfied we may start by orienting an *arbitrary* trail in an *arbitrary* direction. Although this condition is not necessary it does give a simple algorithm for finding a trail orientation if it exists. Indeed, initially the graph may contain undirected edges that are *forced* in one direction by some cut. For finding a trail orientation if it exists we can thus orient forced trails in the forced direction. If there are no forced trails we orient any trail arbitrarily.

[5] The motivation for doing so is that the streets of the town are very narrow and thus it is a great hassle when two cars unexpectedly meet.

[6] This version of the problem was given to us through personal communication with Professor Robert E. Tarjan.

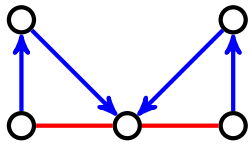

Figure 1 The graph is strongly connected and the underlying graph is 2-edge connected, but irrespective of the choice of orientation of the red trail, the graph will no longer be strongly connected.

Note that in the mixed setting the feasibility depends on the trail decomposition which is not the case for the other results. That the condition from the generalised Robbins' theorem is not sufficient can be seen from Figure 1.

Earlier methods

Several methods have already been applied for solving orientation problems in graphs where the goal is to make the resulting graph strongly connected.

One approach used by Robbins [10] is to use that a 2-edge connected graph has an *ear-decomposition*. An ear decomposition of a graph is a partition of the set of edges into a cycle C and paths $P_1, \ldots, P_t$ such that P_i has its two endpoints but none of its internal vertices on $C \cup \left(\bigcup_{j=1}^{i-1} P_j\right)$. Given the existence of an ear decomposition of a 2-edge connected graph it is easy to prove Robbins' theorem. Indeed, any choice of consistent orientations of the paths and the cycle gives a strongly connected graph.

A second approach introduced by Tarjan [4] gives another simple proof of Robbins' theorem. One can create a DFS tree in the graph rooted at a vertex v and orient all edges in the DFS tree away from v. The remaining edges are all back edges (see [4]) and are oriented towards v. It is easily verified that this gives a strong orientation if the graph is 2-edge connected. A similar approach was used by Chung et al. [2] in the context of the generalized Robbins' theorem for mixed multigraphs.

The above methods not only prove Robbins' theorem, they also provide linear time algorithms for finding strong orientations of undirected or mixed multigraphs.

However, none of the above methods have proven fruitful in our case. In case of the ear decomposition we would need one that is somehow compatible with the partitioning into trails, and this seems hard to guarantee. Similar problems appear when trying a DFS-approach. Neither does the proof by Boesch [1] of Robbins' theorem for mixed multigraphs generalise to prove our result. Most importantly, the corresponding theorem would no longer be true for trail orientations as is shown by the example in Figure 1.

Since the classical linear time algorithms rely on ear-decompositions and DFS searches, and since these approaches do not immediately work for trail partitions, our linear time algorithm will be a completely new approach to solving orientation problems.

Structure of the paper

The structure of this paper is as follows. In section 3 we prove our generalisation of Robbins' theorem for undirected graphs partitioned into trails. In section 4 we study the case of mixed graphs. Finally in section 5 we provide our linear time algorithm for trail orientation in an undirected graph.

2 Preliminaries

Let us briefly review the concepts from graph theory that we will need.

A graph having some subset of its edges oriented is said to be a *mixed* graph. We will write $\{u, v\}$ for an undirected edge between u and v and (u, v) for an edge directed from u to v.

A *walk* in a graph is an alternating sequence of vertices and edges $v_0, e_1, v_1, e_2, \ldots, v_k$, such that for $1 \leq i \leq k$ the edge e_i has v_{i-1} and v_i as its two endpoints. In a directed or mixed graph we further require that either e_i be undirected or directed from v_{i-1} to v_i

A *trail* is a walk without repeated edges. A *path* is a trail without repeated vertices (except possibly $v_0 = v_k$). Finally, a *cycle* is a path for which $v_0 = v_k$.

Next, a mixed multigraph $G = (V, E)$ is called *strongly connected* if for each pair of vertices $u, v \in V$ there exists a walk from u to v. In case the graph is undirected this is equivalent to saying that it consists of exactly one connected component. If $A \subseteq V$ we will say that A is *strongly connected in* G if for each pair of vertices $u, v \in A$ there is a walk in G from u to v.

A *cut* or *edge-cut* (V_1, V_2) in a graph is a partition of its vertices into two non-empty subsets V_1, V_2. We recall the definition of k-edge connectivity. A graph $G = (V, E)$ is said to be *k-edge connected* if and only if $G' = (V, E - X)$ is connected for all $X \subseteq E$ where $|X| < k$. A trivially equivalent condition is that each cut (V_1, V_2) in the graph has at least k edges going between V_1 and V_2.

Finally, if $G = (V, E)$ is a mixed multigraph and $A \subseteq V$ we define G/A to be the graph obtained by contracting A to a single vertex (maintaining duplicate edges and self-loops) and $G[A]$ to be the subgraph of G induced by A. The following simple observation will be used repeatedly in this paper.

▶ **Observation 2.1.** *If $G = (V, E)$ is k-edge connected and $A \subseteq V$ then G/A is k-edge connected. Also, if G is a strongly connected mixed multigraph then G/A is too.*

3 Robbins Theorem Revisited

We are now ready to state and prove our generalisation of Robbins' theorem.

▶ **Theorem 3.1.** *Let $G = (V, E)$ be an undirected multigraph with E partitioned into trails. An orientation of each trail such that the resulting directed graph is strongly connected exists if and only if G is 2-edge connected.*

We note that this theorem could also be proven using a general result from Király and Szigeti [6] which relies on theorems by Nash-Willams [9]. However, our proof is significantly simpler (in fact we believe that restating the theorem by Király and Szigeti and explaining the reduction would be more cumbersome) and more suitable for constructing algorithms.

Proof. If G is not 2-edge connected, such an orientation obviously doesn't exist, so we only need to prove the converse. Suppose therefore that G is 2-edge connected.

Our proof is by induction on the number of edges in G. If there are no edges, the graph consists of a single vertex, and the statement is obviously true. Assume now the statement holds for all graphs with strictly fewer edges than G. Pick an arbitrary edge e that sits at the end of its corresponding trail.

If $G - e$ is 2-edge connected, then by the induction hypothesis there is a strong orientation of $G - e$ that respects the trails of G. Such an orientation clearly extends to the required orientation of G.

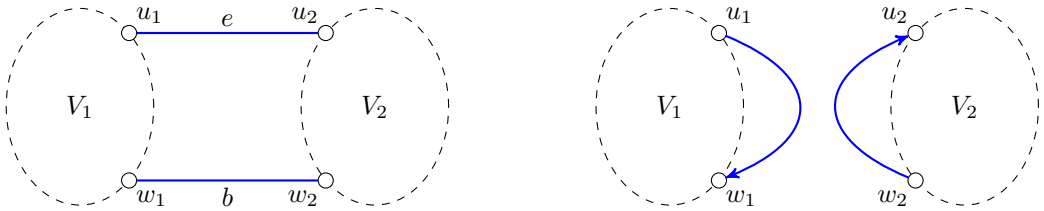

Figure 2 A 2-edge cut and the two graphs $G_1 = G[V_1] \cup \{\{u_1, w_1\}\}$ and $G_2 = G[V_2] \cup \{\{u_2, w_2\}\}$. The orientations of the two new edges are obtained from the strong trail orientations of G_1 and G_2.

If $G - e$ is not 2-edge connected, there exists a bridge b in $G - e$ (see Figure 2). Let V_1, V_2 be the two connected components of $G - \{e, b\}$, and let $e = \{u_1, u_2\}$ and $b = \{w_1, w_2\}$ such that for $i \in \{1, 2\}$, $u_i, w_i \in V_i$ (note that we don't necessarily have that u_i and w_i are distinct for $i \in \{1, 2\}$).

Now for $i \in \{1, 2\}$ construct the graph $G_i = G[V_i] \cup \{\{u_i, w_i\}\}$ (note that $\{u_i, w_i\}$ might be a self-loop but this causes no problems for the argument), and define the trails in G_i to be the trails of G that are completely contained in G_i, together with a single trail combined from the (possibly empty) partial trail of e contained in G_i and ending at u_i, followed by the edge $\{u_i, w_i\}$, followed by the (possibly empty) partial trail of b contained in G_i starting at w_i. Both G_1 and G_2 are 2-edge connected since they can each be obtained as contractions of G with some self-loops deleted. Furthermore, they each have strictly fewer edges than G, so inductively each has a strong orientation that respects the given trails. Further, we can assume that the orientations are such that the new edges are oriented (u_1, w_1) and (w_2, u_2) by flipping the orientation of all edges in either graph if necessary. We claim that this orientation, together with e oriented as (u_1, u_2) and b oriented as (w_2, w_1), is the required orientation of G. To see this first note that (by our choice of flips) this orientation respects the trails. Secondly, suppose $v_1 \in V_1$ and $v_2 \in V_2$ are arbitrary. Since G_1 is strongly connected $G[V_1]$ contains a directed path from v_1 to u_1. Similarly, $G[V_2]$ contains a directed path from u_2 to v_2. Thus G contains a directed path from v_1 to v_2. A similar argument gives a directed path from v_2 to v_1 and since v_1 and v_2 were arbitrary this proves that G is strongly connected and our induction is complete. ◀

The construction in the proof can be interpreted as a naive algorithm for finding the required orientation when it exists.

▶ **Corollary 3.2.** *The one-way trail orientation problem on a graph with n vertices and m edges can be solved in $\mathcal{O}(n + m \cdot f(m, n))$ time, where $f(m, n)$ is the time per operation for fully dynamic bridge finding (a.k.a. 2-edge connectivity).*

At the time of this writing [3], this is $\mathcal{O}(n + m(\log n \log\log n)^2)$. In Section 5 we will provide a less naive algorithm which runs in linear time.

4 Extension to Mixed graphs

Now we will extend our result to the case of mixed graphs. We are going to prove the following.

▶ **Theorem 4.1.** *Let $G = (V, E)$ be a strongly connected mixed multigraph. Then $G - e$ is strongly connected for all undirected $e \in E$ if and only if for any partition $\mathcal{P}$ of the undirected edges of G into trails, and any $T \in \mathcal{P}$, any orientation of T can be extended to a strong trail orientation of $(G, \mathcal{P})$.*

Algorithm 1: Algorithm for mixed graphs.

Input: A mixed multigraph G and a partition $\mathcal{P}$ of the undirected edges of G into trails.

Output: True if $(G, \mathcal{P})$ has a strong trail orientation, otherwise false. If G has a bridge or is not strongly connected, G is left unmodified. Otherwise G is modified, either to have such a strong trail orientation, or to a forced graph that is not strongly connected.

```
if G has a bridge or is not strongly connected then
    return false
end
while |P| > 0 do
    if for some undirected edge e, G − e is not strongly connected then
        Let T ∈ P be the trail containing e.
        if some orientation of T leaves G strongly connected then
            Apply such an orientation of T to G
        else
            return false
        end
    else
        Let T ∈ P be arbitrary.
        Update G by orienting T in an arbitrary direction.
    end
    Remove T from P.
end
return true
```

Suppose $G = (V, E)$ is as in the theorem. We will say that $e \in E$ is *forced* if it is undirected and satisfies that $G - e$ is not strongly connected. This terminology is natural as it is equivalent to saying that there exists a cut (V_1, V_2) in G such that e is the only undirected edge in this cut and such that all the directed edges go from V_1 to V_2. If we want an orientation of the trails making the graph strongly connected we are clearly forced to orient e from V_2 to V_1.

Theorem 4.1 is a proper extension of Theorem 3.1 since if G is undirected and 2-edge connected then no $e \in E$ is forced. Furthermore, the theorem suggests a very simple polynomial time algorithm (see Algorithm 1) for finding a strong orientation of the trails if it exists. Indeed, if the mixed graph contains forced edges we direct the corresponding trails in the forced direction. If there are no forced edges then either the graph is no longer strongly connected in which case we know that a strong trail orientation doesn't exist. Otherwise, we may by Theorem 4.1 orient any trail in an arbitrary direction.

For proving Theorem 4.1 we will need the following lemma.

▶ **Lemma 4.2.** *Let G be a directed graph, and let (A, B) be a cut with exactly one edge crossing from A to B. Then G is strongly connected if and only if G/A and G/B are.*

Proof. Strong connectivity is preserved by contractions, so if G is strongly connected then G/A and G/B both are. For the other direction, let (a_1, b_1) be the edge going from A to B. As G/A is strongly connected and (a_1, b_1) is the only edge going from A to B we can for any edge (b_2, a_2) going from B to A find a path from b_1 to b_2 that stays in B. Since G/B is

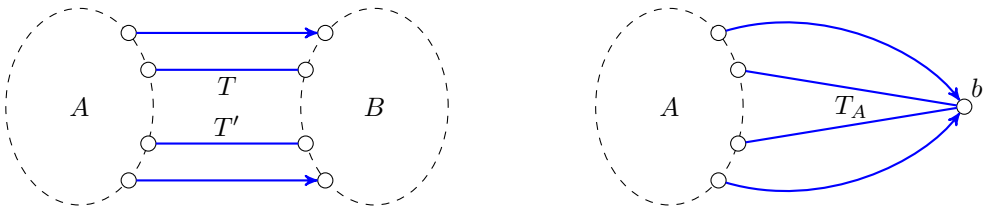

Figure 3 A cut with two undirected edges and all directed edges going from A to B followed by a contraction of B.

strongly connected, it follows that A is strongly connected in G. By a symmetric argument, B is also strongly connected in G and since the cut has edges in both directions (as e.g. G/A is strongly connected), G must be strongly connected. ◀

Now we provide the proof of Theorem 4.1.

Proof of Theorem 4.1. If there exists an undirected edge e such that $G - e$ is not strongly connected, then the trail T containing e can at most be directed one way since e is forced, so there is an orientation of T that does not extend to a strong trail orientation of $(G, \mathcal{P})$. To prove the converse suppose $G - e$ is strongly connected for all undirected $e \in E$.

The proof is by induction on $|\mathcal{P}|$. If $|\mathcal{P}| = 0$ the result is trivial. So suppose $|\mathcal{P}| \geq 1$ and that the theorem holds for all $(G', \mathcal{P}')$ with $|\mathcal{P}'| < |\mathcal{P}|$.

Consider the chosen trail $T \in \mathcal{P}$. If both orientations of T leave a graph where the condition in the theorem is still satisfied we are home by induction. Otherwise, there must exist a cut (A, B) of the following form: (1) T crosses the cut exactly once, (2) exactly one undirected edge from a different undirected trail $T' \in \mathcal{P}$ crosses the cut and (3) every directed edge crossing the cut goes from A to B.

Now suppose there is such a cut (A, B) (see Figure 3). Consider the graph G/B and let b be the node corresponding to B in G/B. Let $\mathcal{P}_A$ consist of all trails in $\mathcal{P}$ that are completely contained in A, together with a single trail T_A combined from the (possibly empty) fragments of T and T', joined at b. Since any cut in G/B corresponds to a cut in G, G/B is strongly connected and remains so after deletion of any single undirected edge. By construction $|\mathcal{P}_A| \leq |\mathcal{P}| - 1$, so by induction any orientation of T_A in G/B extends to a strong orientation of $(G/B, \mathcal{P}_A)$. Let G/A, a, $\mathcal{P}_\mathcal{B}$ and T_B be defined symmetrically, then by the same argument any orientation of T_B in G/A extends to a strong orientation of $(G/A, \mathcal{P}_B)$. Now for any orientation of T, we can choose orientations of T_A and T_B that are compatible. The result then follows by Lemma 4.2. ◀

Theorem 4.1 gives a sufficient condition for the existence of a strong orientation and we deal with the other cases by first orienting all forced edges. However, the generalised Robbins' theorem provides a simple equivalent condition, which we lack. Finding such an equivalent condition in our setting is an essential open problem for strong trail orientations. As seen by the example of Figure 1 such a condition will necessarily have to depend on the structure of the trail partition.

5 Linear time algorithm

In this section we provide our linear time algorithm for solving the trail orientation problem in undirected graphs. For this, we make two crucial observations. First, we show that there is an easy linear time reduction from general graphs or multigraphs to cubic multigraphs.

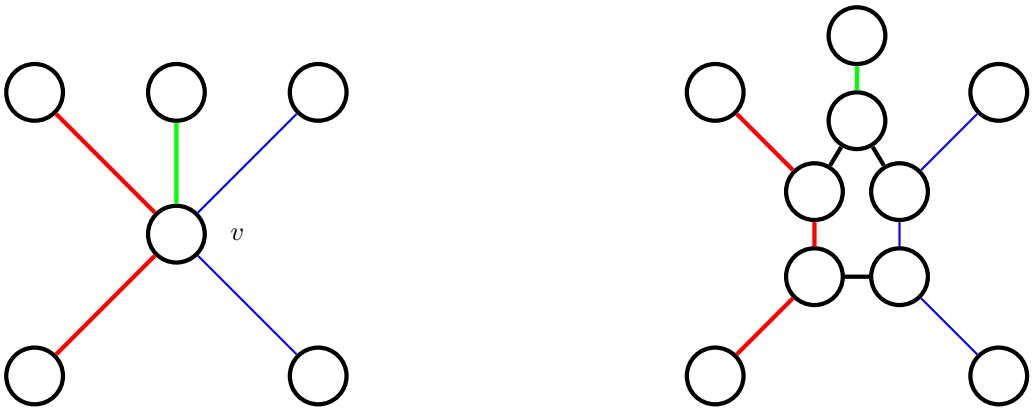

Figure 4 A node of degree 5 turns into a cycle of length 5.

Second, we show that in a cubic multigraph with n vertices, we can in linear time find and delete a set of edges that are at the end of their trails, such that the resulting graph has $\Omega(n)$ 3-edge connected components. We further show that we can compute the required orientation recursively from an orientation of each 3-edge connected component together with the cactus graph of 3-edge connected components. Since the average size of these components is constant, we can compute the orientations of most of them in constant time individually and thus in linear time taken together. The rest contains at most a constant fraction of the vertices, and so a simple geometric sum argument tells us that the total time is also linear.

We start out by making the following reduction.

▶ **Lemma 5.1.** *The one-way trail problem on a 2-edge connected graph or multigraph with n vertices and m edges, reduces in $\mathcal{O}(m+n)$ time to the same problem on a 2-edge connected cubic multigraph with $2m$ vertices and $3m$ edges.*

Proof. Cyclically order the edges adjacent to each vertex such that two edges that are adjacent on the same trail are consecutive in the order. Replace each single vertex v with a cycle of length $\deg(v)$, with each vertex of the new cycle inheriting a corresponding neighbour of v such that the order of the vertices on the cycle corresponds to the cyclic ordering (see Figure 4). Note that for a vertex of degree 2, this creates a pair of parallel edges, so the result may be a multigraph. By the choice of cyclic ordering, we can make the cycle-edge between the two vertices on the same trail belong to that trail. The rest of the cycle edges form new length 1 trails. Clearly the new graph is also 2-edge connected so by Theorem 3.1 it has a strong trail orientation, and any strong trail orientation on this graph translates to a strong trail orientation of the original graph. The new graph has exactly $2m$ vertices and $3m$ edges, and is constructed in $\mathcal{O}(m+n)$ time. ◀

Recall now that a multigraph C is called a *cactus* if it is connected and each edge is contained in at most one cycle. If G is any connected graph we let $C_1, \ldots, C_k$ be its 3-edge connected components. It is well known that if we contract each of these we obtain a cactus graph. For a proof of this result see section 2.3.5 of [8]. As the cuts in a contracted graph are also cuts in the original graph we have that if G is 2-edge connected then the cactus graph is 2-edge connected. The edges of the cactus are exactly the edges of G which are part of a 2-edge cut. We will call these edges *2-edge critical*.

It is easy to check that if a cactus has m edges and n vertices then $m \leq 2(n-1)$. We will be using this result in the proof of the following lemma.

▶ **Lemma 5.2.** *Let $G = (V, E)$ be a cubic 2-edge connected multigraph, let $X \subseteq E$, and let $F \subseteq E$ with $F \supseteq E \setminus X$ minimal (w.r.t inclusion) such that $H = (V, F)$ is 2-edge connected. Then H has at least $\frac{2}{5}|X|$ distinct 3-edge connected components.*

Proof. Let $X_{\text{del}} = X \setminus F$ be the set of edges deleted from G to obtain H, and let $X_{\text{keep}} = X \setminus X_{\text{del}}$ be the remaining edges in X.

By minimality of H there are at least $|X_{\text{keep}}|$ 2-edge-critical edges in H i.e. edges of the corresponding cactus, and thus, if $|X_{\text{keep}}| \geq \frac{4}{5}|X|$, there are at least $\frac{1}{2}|X_{\text{keep}}| + 1 \geq \frac{2}{5}|X| + 1$ distinct 3-edge connected components.

If $|X_{\text{keep}}| \leq \frac{4}{5}|X|$ then $|X_{\text{del}}| \geq \frac{1}{5}|X|$, and since G is cubic and the removal of each edge creates two vertices of degree 2 we must have that H has at least $2|X_{\text{del}}| \geq \frac{2}{5}|X|$ distinct 3-edge connected components. ◀

▶ **Lemma 5.3.** *Let $G = (V, E)$ be a connected cubic multigraph with E partitioned into trails. Then G has a spanning tree that contains all edges that are not at the end of their trail.*

Proof. Let F be the set of edges that are not at the end of their trail. Since G is cubic, the graph (V, F) is a collection of vertex-disjoint paths, and in particular it is acyclic. Since G is connected, F can be extended to a spanning tree. ◀

Note that we can find this spanning tree in linear time e.g. by contracting all edges internal to a trail, finding a spanning tree of the resulting graph, and adding the internal trail edges to the edges of this spanning tree.

▶ **Lemma 5.4.** *Let $G = (V, E)$ be a cubic 2-edge connected multigraph with E partitioned into trails. Let T be a spanning tree of G containing all edges that are not at the end of their trail. Let H be a minimal subgraph of G (w.r.t inclusion) that contains T and is 2-edge connected. Then for any $k \geq 5$, less than $\frac{4}{5}\frac{k}{k-1}|V|$ of the vertices in H are in a 3-edge connected component with at least k vertices.*

Proof. Let X be the set of edges that are not in T. Since G is cubic, $|X| = \frac{1}{2}|V| + 1$. By Lemma 5.2 H has at least $\frac{2}{5}|X| > \frac{1}{5}|V|$ 3-edge connected components. Each such component contains at least one vertex, so the total number of vertices in components of size at least k is less than $\frac{k}{k-1}\left(|V| - \frac{1}{5}|V|\right) = \frac{4}{5}\frac{k}{k-1}|V|$. ◀

▶ **Definition 5.5.** Let C be a 3-edge connected component of some 2-edge connected graph H, whose edges are partitioned into trails. Define $\Gamma_H(C)$ to be the 3-edge connected graph obtained from C by inserting a new edge $\{e_1, f_1\}$ for each min-cut $\{e, f\}$ where $e = \{e_1, e_2\}$ and $f = \{f_1, f_2\}$ and $e_1, f_1 \in C$. Define the corresponding partition of the edges of $\Gamma_H(C)$ into trails by taking every trail that is completely contained in C, together with new trails combined from the fragments of the trails that were broken by the min-cuts together with the new edges that replaced them. See Figure 5.

At this point the idea of the algorithm can be explained. We remove as many of the edges that sit at the end of their trails as possible, while maintaining that the graph is 2-edge connected. Lemma 5.4 guarantees that we obtain a graph H with $\Omega(|V|)$ many 3-edge connected components of size $O(1)$. We solve the problem for each $\Gamma_H(C)$ for every 3-edge connected component. Finally, we combine the solutions for the different components like in the proof of Theorem 3.1.

▶ **Theorem 5.6.** *The one-way trail orientation problem can be solved in $\mathcal{O}(m + n)$ time on any 2-edge connected undirected graph or multigraph with n vertices and m edges.*

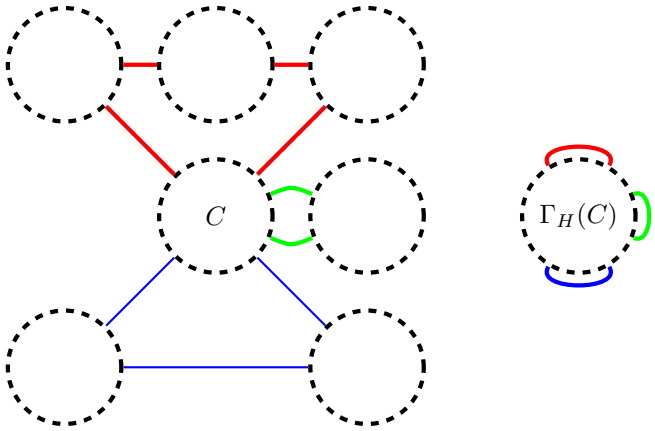

Figure 5 The 3-edge connected components of a 2-edge connected graph. Notice that every edge leaving a 3-edge connected component C becomes part of a cycle if all 3-edge components are contracted. The right hand side shows $\Gamma_H(C)$ where C is the component in the middle.

Proof. By Lemma 5.1, we can assume the graph is cubic. For the algorithm we will use two subroutines. First of all, when we have found a minimum spanning tree T containing the edges that are not on the end of their trail we can use the algorithm of Kelsen et al. [5] to, in linear time, find a minimal (w.r.t. inclusion) subgraph H of G that contains T and is 2-edge connected. Secondly, we will use the algorithm by Mehlhorn et al. [7] to, in linear time, build the cactus graph of 3-edge connected components. The algorithm runs as follows:

1. Construct a spanning tree T of G that contains all edges that are not at the end of their trail.
2. Construct a minimal subgraph H of G that contains T and is 2-edge connected[7].
3. Find the cactus of 3-edge connected components of[8] H.
4. For each 3-edge connected component C_i, construct $\Gamma_H(C_i)$.
5. Recursively compute an orientation for each[9] $\Gamma_H(C_i)$.
6. Combine the orientations from each component to a strong trail orientation of H. A such is also a strong trail orientation of G.

First we will show correctness and then we will determine the running time.

Recall that we can flip the orientation in each $\Gamma_H(C_i)$ and still obtain a strongly connected graph respecting the trails in $\Gamma_H(C_i)$. The way we construct the orientation of the edges of G is by flipping the orientation of each $\Gamma_H(C_i)$ in such a way that each cycle in the cactus graph becomes a directed cycle[10]. This can be done exactly because no edge of the cactus is contained in two cycles. By construction this orientation respects the trails so we need to argue that it gives a strongly connected graph.

For showing that the resulting graph is strongly connected, consider the graph in which every 3-edge connected component is contracted to a single point. This is exactly the cactus of 3-edge connected component of G which is strongly connected as the cycles of the cactus

[7] See Kelsen [5].
[8] See Mehlhorn [7].
[9] Note that $\Gamma_H(C_i)$ is cubic unless it consists of exactly one node. In this case however we don't need to do anything.
[10] In practice this is done by making a DFS (or any other search tree one likes) of the cactus and repeatedly orienting each component in a way consistent with the previous ones.

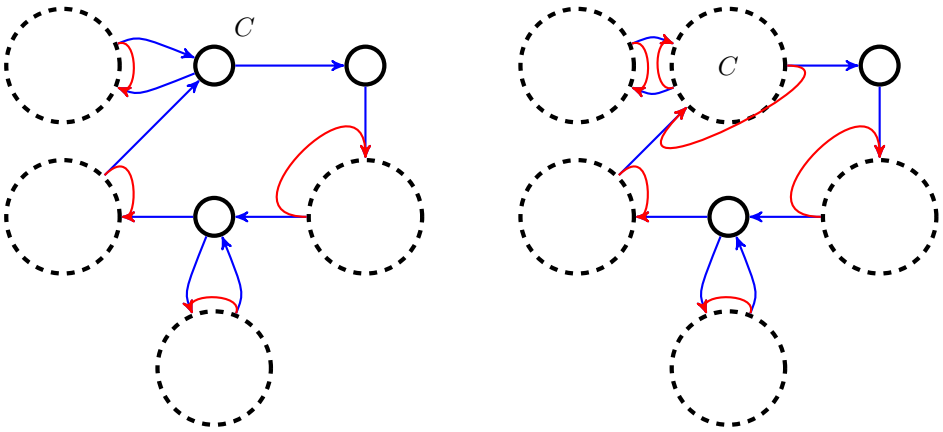

Figure 6 Before and after uncontracting component C. The blue edges are the edges of the cactus i.e. the 2-edge critical edges of H. The red edges are the ones obtained from the 2-edge cuts of H as described in the construction of the $\Gamma_H(C_i)$.

graph have become directed cycles. Now assume inductively that we have uncontracted some of the 3-edge connected components obtaining a graph G_1 which is strongly connected. We then uncontract another component C (see Figure 6) and obtain a new graph G_2 which we will show is strongly connected. If $u, v \in C$, then since $\Gamma_H(C)$ is strongly connected there is a path from u to v in $\Gamma_H(C)$. If this path only contains edges which are edges of C it will also exist in G_2. If the path uses one of the added (now oriented) edges (e_1, f_1), it is because there are edges (e_1, e_2) and (f_2, f_1) forming a cut and thus being part of a cycle in the cactus. In this case we use edge (e_1, e_2) to leave component C and then go from e_2 back to component C which is possible since G_1 was strongly connected. When we get back to the component C we must arrive at f_1 since otherwise there would be two cycles in the cactus containing the edge (e_1, e_2). Hence we succeeded in disposing of the edge (e_1, f_1) with a directed path in G_2. This argument can be used for any of the edges of $\Gamma_H(C)$ that are not in C and thus C is strongly connected in G_2. Since G_1 was strongly connected this suffices to show that G_2 is strongly connected. By induction this implies that after uncontracting all components the resulting graph is strongly connected.

Now for the running time. By Lemma 5.4 each level of recursion reduces the number of vertices in "large" components by a constant fraction, for instance for $k = 10$ we reduce the number of vertices in components of size at least 10 by a factor of $\frac{8}{9}$. Let $f(n)$ be the worst case running time with n nodes for a cubic graph, and pick c large enough such that cn is larger than the time it takes to go through steps 1-4 and 6 as well as computing the orientations in the "small" components. This includes the linear time needed to construct the new set of trails (in 4), and the linear time to reassemble the directed trails (in 6). Let $a_1, \ldots, a_k$ be the number of vertices in the "large" 3-edge connected components. Then $\sum_i a_i \leq \frac{8n}{9}$ and

$$f(n) \leq cn + \sum_i f(a_i).$$

Inductively, we may assume that $f(a_i) \leq 9ca_i$ and thus obtain

$$f(n) \leq cn + \sum_i f(a_i) \leq cn + \sum_i 9ca_i = cn + 8cn = 9cn$$

proving that $f(n) \leq 9cn$ for all n. ◀

Algorithm 2: Linear time algorithm for cubic graphs.

Input: A 2-edge connected undirected cubic multigraph G and a partition $\mathcal{P}$ of the edges of G into trails.

Output: G is modified to a strong trail orientation of $(G, \mathcal{P})$.

```
Construct a spanning tree T of G that contains all edges that are not at the end of
 their trail.
Construct a minimal subgraph H of G that contains T and is 2-edge connected.
Find the cactus C of 3-edge connected components of H.
for each 3-edge connected component C_i in C in DFS preorder do
    Construct G_i = Γ_H(C_i).
    Recursively compute an orientation for G_i.
    if the orientation of G_i is not compatible with its DFS parent then
        Flip orientation of G_i
    end
end
for each edge e deleted from G to create H do
    if no edge on the trail of e has been oriented yet then
        Pick an arbitrary orientation for e.
    else
        Set the orientation of e to follow the trail.
    end
end
```

6 Open problems

We here mention two problems concerning trail orientations which remain open.

First of all, our linear time algorithm for finding trail orientations only works for undirected graphs and it doesn't seem to generalise to the trail orientation problem for mixed graphs. It would be interesting to know whether there also exists a linear time algorithm working for mixed graphs. If so it would complete the picture of how fast an algorithm we can obtain for any variant of the trail orientation problem.

Secondly, our sufficient condition for when it is possible to solve the trail orientation problem for mixed multigraphs is clearly not necessary. It would be interesting to know whether there is a simple necessary and sufficient condition like there is in the undirected case. Since in the mixed case the answer to the problem actually depends on the given trail decomposition and not just on the structure of the mixed graph it is harder to provide such a condition. One can however give the following condition. It is possible to orient the trails making the resulting graph strongly connected if and only if when we repeatedly direct the forced trails end up with a graph satisfying our condition in Theorem 4.1. This condition is not simple and is not easy to check directly. Is there a more natural condition?

Abstract

We present a simple randomized reduction from fully-dynamic integral matching algorithms to fully-dynamic "approximately-maximal" fractional matching algorithms. Applying this reduction to the recent fractional matching algorithm of Bhattacharya, Henzinger, and Nanongkai (SODA 2017), we obtain a novel result for the integral problem. Specifically, our main result is a randomized fully-dynamic $(2+\epsilon)$-approximate integral matching algorithm with small polylog worst-case update time. For the $(2+\epsilon)$-approximation regime only a *fractional* fully-dynamic $(2+\epsilon)$-matching algorithm with worst-case polylog update time was previously known, due to Bhattacharya et al. (SODA 2017). Our algorithm is the first algorithm that maintains approximate matchings with worst-case update time better than polynomial, for any constant approximation ratio. As a consequence, we also obtain the first constant-approximate worst-case polylogarithmic update time maximum weight matching algorithm.

1 Introduction

The maximum matching problem is one of the most widely-studied problems in computer science and operations research, with a long history and theory [5, 38]. On n-vertex and m-edge graphs, the state-of-the art maximum matching algorithms require $O(m\sqrt{n})$ and $O(n^\omega)$ time [40, 41] (here $\omega < 2.37$ is the matrix multiplication exponent [54]). For bipartite graphs, simpler algorithms with the same asymptotic running times are known [34, 41], as well as a faster, $O(m^{10/7} \cdot \text{poly}(\log n))$-time algorithm, due to the recent breakthrough of Mądry[39] for the maximum flow problem. For approximate matchings, it is long- and well-known that a matching admitting no augmenting paths of length $O(1/\epsilon)$ forms a $(1+\epsilon)$-approximate maximum matching (see [34]). The linear-time "blocking flow" subroutines of [34, 40] therefore result in an $O(m/\epsilon)$-time $(1+\epsilon)$-approximate maximum matching.

The maximum weight matching (MWM) problem has also garnered much interest over the years. For general weights, the seminal work of Edmonds [22] shows how to reduce the problem on bipartite graphs to the solution of n non-negative single-source shortest path instances. Relying on Fibonacci Heaps of Fredman and Tarjan [23], this approach yields the current fastest strongly-polynomial running time for the problem, $O(n(m + n\log n))$. Gabow [24] later showed how to obtain the same running time for general graphs. For integer weights $w : E \to \{0, 1, 2, \ldots, N\}$, algorithms nearly matching the state-of-of-the-art for the unweighted problem, with either logarithmic or linear dependence on N, are known.[3] These include an $O(m\sqrt{n}\log(nN))$-time algorithm [25], an $O(Nn^\omega)$-time algorithm [48] and a recent $O(m^{10/7} \cdot \text{poly}(\log n) \cdot \log N)$-time algorithm for bipartite graphs [17]. For approximation algorithms, an algorithm nearly matching the unweighted problem's guarantees is known, yielding a $(1+\epsilon)$-approximate maximum weight matching in $O((m/\epsilon)\log(1/\epsilon))$ time, [21].

All of the above results pertain to the static problem; i.e., where the input is given and we only need to compute a maximum matching on this given input. However, in many applications the graphs considered are inherently *dynamic*, with edges removed or added over time. One could of course address such changes by recomputing a solution from scratch, but this could be wasteful and time-consuming, and such applications may require immediately updating the solution given, as having users wait on a solution to be recomputed may likely be unsatisfactory. Consider for example point to point shortest path computation, a problem routinely solved by navigation systems: for such an application, the temporary closure of some road due to construction should not result in unresponsive GPS applications, busy re-computing the relevant data structures (see e.g.,[7, 36, 33, 19, 20, 51, 52, 10, 26, 28, 2, 31, 29, 30, 32, 3, 4]). Therefore, for such applications we want to update our solution quickly for *every update*, using fast *worst-case* (rather than amortized) update time.

Returning to the maximum matching problem, we note that a maximum matching can be trivially updated in $O(m)$ time. Sankowski [47] showed how to maintain the *value* of the maximum matching in $O(n^{1.495})$ update time.[4] On the other hand, Abboud and Vassilevska Williams [1] and Kopelowitz et al. [37] presented lower bounds based on long-standing conjectures, showing that even maintaining the maximum matching value likely requires $\Omega(m^c)$ update time for some constant $c \geq \frac{1}{3}$.

Given these hardness results for exact solutions, one is naturally inclined to consider fast *approximate* solutions. Trivially updating a maximal matching (and therefore a 2-

[3] Indeed, a black-box reduction of Pettie [46] from maximum weight matching to the maximum matching problem shows that a linear dependence in N is the largest possible gap between these two problems.

[4] We emphasize that this algorithm does not maintain an actual matching, but only the optimal value, and it seems unlikely to obtain such update times for maintaining a matching of this value.

approximate maximum matching) can be done using $O(n)$ worst-case update time. The goal is to obtain sublinear update times – ideally polylogarithmic (or even constant) – with as low an approximation ratio as possible.

The first non-trivial result for fully-dynamic maximum matching is due to Ivkovic and Lloyd [35], who presented a maximal matching algorithm with $O((m+n)^{1/\sqrt{2}})$ amortized update time. Note that this bound is sublinear only for sufficiently sparse graphs. The problem of approximate maximum matchings remained largely overlooked until 2010, when Onak and Rubinfeld [44] presented a fully-dynamic constant-approximate $O(\log^2 n)$ (amortized) update time algorithm. Additional results followed in quick succession.

Baswana et al. [8] showed how to maintain a maximal matching in $O(\log n)$ expected update time, and $O(\log^2 n)$ update time w.h.p. This was recently improved by Solomon [49] who presented a maximal matching algorithm using $O(1)$ update time w.h.p. For deterministic algorithms, Neiman and Solomon [42] showed how to maintain 3/2-approximate matchings deterministically in $O(\sqrt{m})$ update time, a result later improved by Gupta and Peng [27] to obtain $(1+\epsilon)$-approximate matchings in $O(\sqrt{m}/\epsilon^2)$. This result was in turn refined by Peleg and Solomon [45], who obtained the same approximation ratio and update time as [27] with $\sqrt{m}$ replaced by the maximum arboricity of the graph α (which is always at most $\alpha = O(\sqrt{m})$). Bernstein and Stein [11, 12] and Bhattacharya et al. [13] presented faster polynomial update time algorithms (with higher approximation ratios), and Bhattacharya et al. [14] presented a $(2+\epsilon)$-approximate algorithm with $\text{poly}(\log n, \epsilon^{-1})$ update time. See Table 1 for an in-depth tabular exposition of previous work and our results.[5] In §5 we discuss our results for MWM, also widely studied in the dynamic setting (see, e.g. [8, 27, 49, 50]).

Note that in the previous paragraph we did not state whether the update times of the discussed algorithms were worst case or amortized. We now address this point. As evidenced by Table 1, previous fully-dynamic matching algorithms can be broadly divided into two classes according to their update times: polynomial update time algorithms and polylogarithmic *amortized* update time algorithms. The only related polylogarithmic worst-case update time algorithms known to date were *fractional* matching algorithms, due to Bhattacharya et al. [15]. We bridge this gap by presenting the first fully-dynamic integral matching (and weighted matching) algorithm with polylogarithmic worst-case update times and constant approximation ratio. In particular, our approach yields a $(2+\epsilon)$-approximate algorithm, within the $O_\epsilon(\log^3 n)$ time bound of [15], but for *integral* matching.[6]

1.1 Our Contribution

Our main technical result requires the following natural definition of (c,d)-approximately-maximal fractional matchings.

▶ **Definition 1.1** (Approximately-Maximal Fractional Matching)**.** We say that a fractional matching $w : E \to \mathbb{R}^+$ is (c,d)-*approximately-maximal* if every edge $e \in E$ either has fractional value $w_e \geq 1/d$ or has one endpoint v with sum of incident edges' weights at least $W_v \triangleq \sum_{e \ni v} w_e \geq 1/c$ and moreover all edges e' incident on this v have $w_{e'} \leq 1/d$.

[5] For the sake of simplicity we only list bounds here given in terms of n and m. In particular, we do not state the results for arboricity-bounded graphs, which in the worst case (when the arboricity of a graph is $\alpha = \Theta(\sqrt{m})$) are all outperformed by algorithms in this table, with the aforementioned algorithm of Peleg and Solomon [45] being the lone exception to this rule.

[6] Independently of our work, and using a different approach, Charikar and Solomon [16] obtained a $(2+\epsilon)$-approximate dynamic matching algorithm with $O_\epsilon(\log^7 n)$ worst-case update time. For fixed ϵ their algorithm is slower than ours, and is arguably more complicated than our approach.

Note that this definition generalizes maximal fractional matchings (for which $c = d = 1$). The second condition required of v above (i.e., having no incident edges e' with $w_{e'} > 1/d$) may seem a little puzzling, but will prove important later; it can be safely ignored until §2.1 and §3.

Our main qualitative result, underlying our quantitative result, is the following black-box reduction from integral matching algorithms to approximately-maximal fractional matching algorithms, as stated in the following theorem.

▶ **Theorem 1.2.** *Let $\mathcal{A}$ be a fully-dynamic (c,d)-approximately-maximal fractional matching algorithm whose update time $T(n,m)$ and which changes at most $C(n,m)$ edge weights per update, for some $c \geq 1$, $d \geq \frac{6c\cdot\ln(\max\{n,1/\epsilon\})}{\epsilon^2}$, with $\epsilon \leq \frac{1}{2}$. Then, there exists a randomized fully-dynamic* integral *$2c(1+O(\epsilon))$-approximate matching algorithm $\mathcal{A}'$ (with this bound holding both w.h.p and in expectation) with update time $T(n,m)+O(C(n,m)\cdot d/\epsilon^2)$. Moreover, if $T(n,m)$ and $C(n,m)$ are worst-case bounds, so is the update time of Algorithm $\mathcal{A}'$.*

Now, one may wonder whether fully-dynamic (c,d)-approximately-maximal fractional matching algorithms with low worst-case update time and few edge weight changes exist for any non-trivial values of c and d. Indeed, the recent algorithm of Bhattacharya et al. [15] is such an algorithm, as the following lemma asserts.

▶ **Lemma 1.3** ([15])**.** *For all $\epsilon \leq \frac{1}{2}$, there is a fully-dynamic $(1+2\epsilon, \max\{54\log n/\epsilon^3, (3/\epsilon)^{21}\})$-approximately-maximal fractional matching algorithm with $T(n,m) = O(\log^3 n/\epsilon^7)$ worst-case update time, using at most $C(n,m) = O(\log n/\epsilon^2)$ edge weight changes per update in the worst case.*

We highlight the general approach of the algorithm of Bhattacharya et al. [15] in §2.1 to substantiate the bounds given in Lemma 1.3. Plugging the values of c, $T(n,m)$ and $C(n,m)$ of Lemma 1.3 into Theorem 1.2 immediately yields our result, given in the following theorem.

▶ **Theorem 1.4.** *For all $\epsilon \leq \frac{1}{2}$, there exists a randomized fully-dynamic $(2 + O(\epsilon))$-approximate integral matching algorithm (w.h.p and in expectation) with worst-case update time $O(\log^3 n/\epsilon^7 + \log(\max\{n, 1/\epsilon\})/\epsilon^2 \cdot \max\{\log n/\epsilon^3, (3/\epsilon)^{21}\}) = O_\epsilon(\log^3 n)$.*

We recall that until now (barring the aforementioned independent result of Charikar and Solomon [16]), for worst-case polylog update times only *fractional* dynamic algorithms – algorithms which only approximate the *value* of the maximum matching – were known for this problem.

Finally, combined with the recent black-box reduction of Stubbs and Vassilevska Williams [50] from the weighted to the unweighted matching problem, our algorithm also yields the first fully-dynamic constant-approximate maximum weight matching algorithm with polylogarithmic worst-case update time.

▶ **Theorem 1.5.** *For all $\epsilon \leq \frac{1}{2}$, there exists a randomized fully-dynamic $(4+O(\epsilon))$-approximate maximum weight matching algorithm with poly$(\log n, 1/\epsilon)$ worst-case update time. The approximation guarantee holds with high probability and in expectation.*

1.2 Our Techniques

Our framework yielding our main result combines three ingredients: approximately-maximal fractional matchings, kernels and fast $(1+\epsilon)$ matching algorithms for bounded-degree graphs. We give a short exposition of these ingredients and conclude with how we combine all three.

Approximately-Maximal Fractional Matchings. The first ingredient we rely on is (c, d)-approximately-maximal fractional matchings, introduced in the previous section. Recalling that for such solutions, each edge has value at least $1/d$ or one of its endpoints has sum of incident edge values at least $1/c$. This approximate maximality condition implies this fractional matching has high value compared to the maximum matching size; specifically, this fractional matching's size is at least a $1/2 \max\{c, d\}$ fraction of this value (easily verifiable using LP duality). As we shall show, approximate maximality also allows one to use these fractional values to sample a subgraph in the support of this fractional matching which contains a large *integral* matching compared to G, with high probability. We discuss the dynamic fractional matching algorithm of Bhattacharya et al. [15] and show that it maintains an approximately-maximal fractional matching in §2.1.

Kernels. The second ingredient we rely on is the notion of *kernels*, introduced by [13]. Roughly speaking, a kernel is a low-degree subgraph H of G such that each edge of G not taken into H has at least one endpoint whose degree in H is at least $1/c$ times the maximum degree in H. Relying on Vizing's Theorem [53], we show in §2.2 that such a graph has maximum matching size $\mu(H)$ at least $1/(2c + \epsilon)$ of the matching size of G, previously only known for kernels of bipartite graphs, where this is easily verifiable via LP duality.[7] Efficiently maintaining a large matching can therefore be reduced to maintaining a low-degree kernel, given the last ingredient of our approach.

[7] As a byproduct of our proof, we show how the algorithms of Bhattacharya et al. [13] can be made $(2 + \epsilon)$-approximate within the same time bounds. As this is tangential to our main result, we do not elaborate on this.

Bounded-Degree $(1+\epsilon)$-matching. The final ingredient we rely on for our framework is $(1+\epsilon)$ matching algorithms with worst-case update time bounded by the graph's maximum degree, such as the algorithms of Gupta and Peng [27] and Peleg and Solomon [45].

Our approach in a nutshell

Given the above ingredients, our framework is a simple and natural one. Throughout our algorithm's run, we run a fully-dynamic (c, d)-approximately-maximal fractional matching algorithm with efficient worst-case update. Sampling edges independently according to this fractional value (times some logarithmic term in n, to guarantee concentration) allows us to sample a kernel of logarithmic maximum degree, with each non-sampled edge having at least one endpoint with degree at least $1/c$ times the maximum subgraph degree, with high probability. As the obtained subgraph H therefore has a maximum matching of size at least $\approx 1/2c$ times the maximum matching in G, a $(1+\epsilon)$-matching algorithm in H yields a $\approx 2c + O(\epsilon)$ matching in G. We then maintain a $(1+\epsilon)$-matching in H (which by virtue of H's bounded degree we can do in logarithmic worst-case time) following each update to H incurred by a change of some edge's fractional value by the dynamic fractional matching algorithm. The obtained integral algorithm's update time is dominated by two terms: the running time of the fractional algorithm, and the number of edge weight changes per update, times $O(\log n)$. This concludes the high-level analysis of the obtained approximation ratio and update time of our approach, as given in Theorem 1.2.

Wider applicability

We stress that our framework is general, and can use any approximately-maximal fractional matching algorithm. Consequently, any improvement on the running time and number of edge value changes for maintaining approximately-maximal fractional matchings would yield a faster worst-case update time.

2 Preliminaries

In this section we introduce some previous results which we will rely on in our algorithm and its analysis. We start by reviewing the approach of Bhattacharya et al. [15] to obtain efficient fractional algorithms in §2.1. We then discuss the bounded-degree subgraphs we will consider, also known as *kernels*, in §2.2. Finally, we briefly outline the $(1+\epsilon)$-approximate $O(\Delta/\epsilon^2)$ worst case update time algorithms we will rely on for our algorithm, in §2.3.

2.1 Hierarchical Partitions

In this section we review the approximately-maximal fractional matchings maintained by Bhattacharya et al. [15]. At a high level, this algorithm relies on the notion *hierarchical partitions*, in which vertices are assigned some *level* (the partition here is given by the level sets), and edges are assigned a fractional value based on their endpoints' levels. Specifically, an edge is assigned a value exponentially small in its vertices' maximum level. The levels (and therefore the edge weights) are updated in a way as to guarantee feasibility, as well as guaranteeing that a vertex v of high level has high sum of incident edge weights, W_v. These conditions are sufficient to guarantee approximate maximality, as we shall soon show.

The hierarchical partitions considered by Bhattacharya et al. [15], termed simply *nice partitions*, is described as follows. In the definition constants β, K, L and a function $f(\beta) = 1 - 3/\beta$ are used, satisfying the following.

$$\beta \geq 5,\ K = 20,\ f(\beta) = 1 - 3/\beta,\ L = \lceil \log_\beta n \rceil. \tag{1}$$

In our case, for some $\epsilon \leq \frac{1}{2}$, we will let $\beta = \frac{3}{\epsilon} (\geq 5)$. As we will be shooting for $O(1)$-approximation algorithms with polylogarithmic update time and our reduction's update time has polynomial dependence on ϵ^{-1}, we will assume without loss of generality that $\epsilon = \Omega(\frac{3}{\sqrt[20]{n}})$, and so for n large enough, we have $K \leq L$.

▶ **Definition 2.1** (A nice partition [15]). In a *nice partition* of a graph $G = (V, E)$, each vertex v is assigned an integral *level* $\ell(v)$ in the set $\{K, K+1, \ldots, L\}$. In addition, for each vertex $v \in V$ and edge $e \ni v$ the *shadow-level of v with respect to e*, denoted by $\ell_v(e)$, is a (positive) integer satisfying $\ell(v) - 1 \leq \ell_v(e) \leq \ell(v) + 1$. Moreover, for each vertex v, we have

$$\max_{e \ni v} \ell_v(e) - \min_{e \ni v} \ell_v(e) \leq 1. \tag{2}$$

The level of an edge $e = (u, v)$ is taken to be the maximum shadow-level of an endpoint of e with respect to e; i.e., $\ell(u, v) = \max\{\ell_u(e), \ell_v(e)\}$. Let $W_v = \sum_{e \in v} w_e$ be the sum of weights of edges incident on a vertex v. Then,

1. For every edge $e \in E$, it holds that $w_e = \beta^{-\ell(e)}$.
2. For every node $v \in V$, it holds that $W_v < 1$.
3. For every node $v \in V$ with level $\ell(v) > K$, it holds that $W_v \geq f(\beta)$.

The intuition behind this definition in Bhattacharya et al. [15] is to mimic the hierarchical partition of Bhattacharya et al. [13], termed (α, β)-*decompositions* there. (α, β)-decompositions are the special case of nice partitions where the shadow-level of a vertex v with respect to each edge $e \ni v$ is precisely equal to the vertex's level; i.e, $\ell_v(e) = \ell(v)$ (with α denoting $f(\beta)/\beta$). The advantage of this more relaxed notion of shadow-level is to allow a vertex to move between levels "slowly", only notifying *part* of its incident edges of its level change between updates, and therefore only updating some of its edges' weights. This allows for maintaining this partition with fast worst-case update time, as shown in Bhattacharya et al. [15] (more on this below).

This above intuition concerning nice partitions will not prove important for our analysis. The crucial property we will rely on is given by the following lemma, which asserts that the fractional matching associated with a nice partition is approximately-maximal.

▶ **Lemma 2.2.** *Let $\epsilon \leq \frac{1}{2}$. Consider a nice partition with parameter $\beta = 3/\epsilon \geq 6 \geq 5$, and so $f(\beta) = 1 - \epsilon$. Then, the fractional matching associated with this nice partition is $(1 + 2\epsilon, \max\{54 \log n/\epsilon^3, (3/\epsilon)^{21}\})$-approximately-maximal.*

Proof. Let $K' = \max\{\lceil \log_\beta(18c \log n/\epsilon^2) \rceil, K+1\}$ and $d = \beta^{K'} \leq \max\{54 \log n/\epsilon^3, (3/\epsilon)^{21}\}$. For any edge e, if $\ell(e) = \max_{v \in e}\{\ell_v(e)\} \leq K'$, then by definition $w_e = \beta^{-\ell(e)} \geq \beta^{-K'} = \frac{1}{d}$. Alternatively, if $w_e < \frac{1}{d}$ then $\ell(e) > K'$ and therefore by integrality of $\ell(e)$, we have $\ell(e) \geq K' + 1$. Now, let v be $\arg\max_{v \in e}\{\ell_v(e)\} \geq K' + 1$. Then, by definition of shadow-levels and $K' > K$, we have $\ell(v) \geq \ell_v(e) - 1 \geq K' > K$ and so by Property 3 of a nice partition we have $W_v > f(\beta) = 1 - \epsilon \geq \frac{1}{1+2\epsilon}$ (as $\epsilon \leq \frac{1}{2}$). But on the other hand, by Equation (2), we also know that for every edge $e' \ni v$,

$$\ell_v(e') \geq \min_{e' \ni v} \ell_v(e') \geq \max_{e' \ni v} \ell_v(e') - 1 \geq \ell_v(e) - 1 \geq K' > K.$$

Therefore, by definition of the edge weights, each edge $e' \ni v$ satisfies $w_{e'} \leq \beta^{-K'} \leq \frac{1}{d}$. ◀

The recent result of Bhattacharya et al. [15] for maintaining nice partitions in polylogarithmic worst-case update time together with Lemma 2.2 immediately implies Lemma 1.3, restated below. We substantiate these bounds with the dependence on ϵ stated explicitly in the full version of this paper [6], as Bhattacharya et al. [15] had $\epsilon = O(1)$ and so their results do not state these dependencies explicitly.

▶ **Lemma 1.3** ([15]). *For all $\epsilon \leq \frac{1}{2}$, there is a fully-dynamic $(1+2\epsilon, \max\{54 \log n/\epsilon^3, (3/\epsilon)^{21}\})$-approximately-maximal fractional matching algorithm with $T(n,m) = O(\log^3 n/\epsilon^7)$ worst-case update time, using at most $C(n,m) = O(\log n/\epsilon^2)$ edge weight changes per update in the worst case.*

As we shall show, approximately-maximal fractional matchings allow us to sample a bounded-degree subgraph H of G containing a large matching compared to the maximum matching size in G, $\mu(G)$. For this we will require the notion of *kernels*, defined in §2.2.

2.2 Kernels

In this section we review the concept of kernels, first introduced by Bhattacharya et al. [13].

▶ **Definition 2.3** (Kernels [13]). A (c,d)-*kernel* of a graph G is a subgraph H of G satisfying:
1. For each vertex $v \in V$, the degree of v in H is at most $d_H(v) \leq d$.
2. For each edge $(u,v) \in E \setminus H$, it holds that $\max\{d_H(u), d_H(v)\} \geq d/c$.

The interest in finding a bounded-degree subgraph H of G may seem natural, as one may expect to be able to compute a matching quickly in H due to its sparsity (we elaborate more on this point in §2.3). The interest in satisfying the second property, on the other hand, may seem a little cryptic. However, combining both properties implies that the matching number of H, $\mu(H)$, is large in comparison with the matching number of G, $\mu(G)$.

▶ **Lemma 2.4.** *Let H be a (c,d)-kernel of G for some $c \geq 1$. Then $\mu(H) \geq \frac{1}{2c(1+1/d)} \cdot \mu(G)$.*

Proof. Let M^* be some maximum matching in G (i.e., $|M^*| = \mu(G)$). Consider the following fractional matching solution:

$$f_{u,v} = \begin{cases} \frac{1}{d} & (u,v) \in H \setminus M^* \\ \max\{1 - \frac{d_h(u)+d_H(v)-2}{d}, 0\} & (u,v) \in H \cap M^*. \end{cases}$$

This is a feasible fractional matching due to the degree bound of H and the fractional values assigned to edges of a vertex v incident on an edge $e \in H \cap M^*$ being at most $\frac{d_H(v)-1}{d} + \frac{d-d_H(v)+1}{d} = 1$. To show that this fractional matching has high value, consider the variables $y_v = \sum_u f_{u,v}$. On the one hand, by the handshake lemma, $\sum_{u,v} f_{u,v} = \frac{1}{2}\sum_v y_v$. On the other hand, each edge (u,v) of $M^* \cap H$ has $y_u + y_v \geq 1 \geq \frac{1}{c}$ by construction and each edge of $M^* \setminus H$ has at least one endpoint v of degree $d_H(v) \geq \frac{d}{c}$, implying that $y_u + y_v \geq \frac{d}{c} \cdot \frac{1}{d} = \frac{1}{c}$ for each $(u,v) \in M^* \setminus H$. As each vertex v neighbors at most one edge of the (optimal) matching M^*, we obtain

$$\sum_e f_e = \frac{1}{2} \cdot \sum_v y_v \geq \frac{1}{2c} \cdot |M^*| = \frac{1}{2c} \cdot \mu(G).$$

Now, to show that H contains a large *integral* matching, we rely on Vizing's Theorem [53], which asserts that every multigraph of maximum degree Δ and maximum edge multiplicity μ has a proper $\Delta + \mu$ edge-coloring; i.e., a partition of the edge multiset into $\Delta + \mu$ edge-disjoint

matchings. To use this theorem, we construct a multigraph on the same vertex set V with each edge e replaced by $f_e \cdot d$ parallel copies (note that $f_e \cdot d$ is integral). By construction, the number of edges in this multigraph is $\sum_e f_e \cdot d$. By feasibility of f, we have that this multigraph has maximum degree d. By Vizing's Theorem, the simple subgraph obtained by ignoring parallel edges corresponding to edges in $H \cap M^*$ can be edge colored using $d+1$ colors. But for each edge $e = (u, v) \in H \cap M^*$, such a coloring uses at most $d_H(u) - 1 + d_H(v) - 1$ distinct colors on edges other than (u, v) incident on u or v. To extend this $d+1$ edge coloring to a proper coloring of the multigraph, we color the $\max\{d - (d_H(u) - 1 + d_H(v) - 1), 0\}$ multiple edges (u, v) in this multigraph using some $\max\{d - (d_H(u) - 1 + d_H(v) - 1), 0\}$ colors of the palette of size $d + 1$ not used on the other edges incident on u and v. We conclude that this multigraph, which is contained in H and has $\sum_e f_e \cdot d$ edges, is $d+1$ edge colorable and therefore H contains an integral matching of size at least

$$\frac{1}{d+1} \cdot \sum_e f_e \cdot d = \frac{1}{1+1/d} \cdot \sum_e f_e \geq \frac{1}{2c(1+1/d)} \cdot \mu(G). \qquad \blacktriangleleft$$

Lemma 2.4 and the algorithm of §2.3 immediately imply that the algorithms of Bhattacharya et al. [13] can be made $(2+\epsilon)$-approximate within the same time bounds (up to poly$(1/\epsilon)$ terms). As this was previously also observed in Bhattacharya et al. [14], we do not elaborate on this point here.

2.3 Nearly-Maximum Matchings in Degree-Bounded Graphs

In this short subsection we highlight one final component we will rely on for our reduction: fast nearly-optimal matching algorithms with worst-case update time bounded by G's maximum degree. Such algorithms were given by Peng and Gupta [27] and Peleg and Solomon [45]. More precisely, we have the following lemma.

▶ **Lemma 2.5** ([27, 45]). *There exists a dynamic $(1+\epsilon)$-approximate matching algorithm with worst-case $O(\Delta/\epsilon^2)$ update time in dynamic graphs of maximum degree at most Δ.*

The bound for the algorithm of [45] follows as $\alpha \leq \Delta$ always, while the bound for the algorithm of [27] is immediate by inspecting this algorithm, as observed in [45].

3 Sampling Using Approximately-Maximal Matchings

In what follows we will show that sampling edges independently with probability roughly proportional to their assigned value according to an approximately-maximal fractional matching yields a kernel of logarithmic maximum degree with high probability.

▶ **Lemma 3.1.** *Let $\epsilon \leq \frac{1}{2}$. Let $w : E \to \mathbb{R}^+$ be a (c, d)-approximately-maximal fractional matching with $c \geq 1$ and $d \geq \frac{6c \cdot \ln(\max\{n, 1/\epsilon\})}{\epsilon^2}$. Then, a subgraph H obtained by sampling each edge e independently with probability*

$$\min\{1, w_e \cdot d\} \tag{3}$$

is a $(c(1+O(\epsilon)), (1+\epsilon)d)$-kernel of G with probability at least $1 - \frac{2}{\max\{n, 1/\epsilon\}}$.

Proof. For any vertex $v \in V$, denote by D_v the random variable which corresponds to v's degree in H. As before, denote by $W_v = \sum_{e \ni v} w_e \leq 1$ the sum of edge weights of edges incident on v.

First, we prove the degree upper bound; i.e., Property 1 of a kernel. As w is a fractional matching, we know that $W_v \leq 1$. Therefore, by Equation (3), we have that $\mathbb{E}[D_v] \leq d$. By standard Chernoff bounds, as $d \geq \frac{6c \cdot \ln(\max\{n,1/\epsilon\})}{\epsilon^2}$ and $c \geq 1$, we find that

$$\Pr[D_v \geq (1+\epsilon) \cdot d] \leq \exp\left(\frac{-\epsilon^2 \cdot d}{3}\right) \leq \frac{1}{\max\{n,1/\epsilon\}^{2c}} \leq \frac{1}{\max\{n,1/\epsilon\}^2}.$$

Next, we prove that any edge not sampled into H will, with high probability, be incident on some high-degree vertex in H; i.e., we show that H satisfies Property 2 of a kernel. First, note that an edge e with $w_e \geq 1/d$ will be sampled with probability one, given our sampling probability given in Equation (3), therefore trivially satisfying Property 2 of a kernel. Conversely, an edge e with $w_e < 1/d$ has some endpoint v with $W_v \geq 1/c$ and all edges e' incident on v have $w_{e'} \leq 1/d$, since w is (c,d)-approximately maximal. Therefore, by Equation (3) each edge e' incident on v is sampled with probability precisely $w_{e'} \cdot d$. Consequently, we have that $\mu_v = \mathbb{E}[D_v] = W_v \cdot d \geq d/c$. By standard Chernoff bounds, as $\mu_v \geq d/c \geq \frac{6\ln(\max\{n,1/\epsilon\})}{\epsilon^2}$, we find that

$$\Pr[D_v \leq (1-\epsilon) \cdot d/c] \leq \Pr[D_v \leq (1-\epsilon) \cdot \mu_v] \leq \exp\left(\frac{-\epsilon^2 \cdot \mu_v}{2}\right) \leq \frac{1}{\max\{n,1/\epsilon\}^3}.$$

Taking a union bound over the $O(n^2)$ possible bad events corresponding to violating a property of a $(c(1+\epsilon)/(1-\epsilon)), d(1+\epsilon))$-kernel, we find that probability at least $1 - \frac{2}{\max\{n,1/\epsilon\}}$:

1. For each vertex $v \in V$, it holds that $d_H(v) \leq (1+\epsilon) \cdot d$.
2. For each edge $(u,v) \in E \setminus H$, it holds that $\max\{d_H(u), d_H(v)\} \geq (1-\epsilon) \cdot d/c$.

In other words, H is a $(c(1+\epsilon)/(1-\epsilon), d(1+\epsilon))$-kernel of G with high probability. ◀

4 Our Reduction

Given the previous sections, we are now ready to describe our reduction from fully-dynamic integral matching to approximately-maximal fractional matching and analyzing its performance, given by Theorem 1.2, restated here.

▶ **Theorem 1.2.** *Let $\mathcal{A}$ be a fully-dynamic (c,d)-approximately-maximal fractional matching algorithm whose update time $T(n,m)$ and which changes at most $C(n,m)$ edge weights per update, for some $c \geq 1$, $d \geq \frac{6c \cdot \ln(\max\{n,1/\epsilon\})}{\epsilon^2}$, with $\epsilon \leq \frac{1}{2}$. Then, there exists a randomized fully-dynamic* integral *$2c(1+O(\epsilon))$-approximate matching algorithm $\mathcal{A}'$ (with this bound holding both w.h.p and in expectation) with update time $T(n,m)+O(C(n,m)\cdot d/\epsilon^2)$. Moreover, if $T(n,m)$ and $C(n,m)$ are worst-case bounds, so is the update time of Algorithm $\mathcal{A}'$.*

Proof. Our reduction works as follows. Whenever an edge e is added/removed from G, we update the (c,d)-approximately-maximal fractional matching, using algorithm $\mathcal{A}$, in time $T(n,m)$. We then sample each of the at most $C(n,m)$ edges e whose value is changed, independently, with probability given by Equation (3). To control the maximum degree in the sampled subgraph H', every vertex v maintains a list of at most $(1+\epsilon) \cdot d$ sampled edges "allowable" for use in H. (This list can be maintained dynamically in $O(1)$ time per update in H' in a straightforward manner.) We let H be the graph induced by the sampled edges "allowed" by both their endpoints. Finally, we use a $(1+\epsilon)$-matching algorithm as in Lemma 2.5 to maintain a matching in the sampled subgraph H.

By Lemma 3.1 the subgraph H is a $(c(1+O(\epsilon)), (1+\epsilon)d)$-kernel of G with high probability (note that by the same lemma, all sampled edges of H' will appear in our H). By Lemma 2.4,

this means that with high probability this kernel H has matching number at least

$$\mu(H) \geq \frac{1}{2c(1+O(\epsilon))(1+1/d))} \cdot \mu(G) \geq \frac{1}{2c(1+O(\epsilon))} \cdot \mu(G),$$

where the second inequality follows from $d \geq \frac{6c \cdot \ln(\max\{n,1/\epsilon\})}{\epsilon^2} \geq \frac{1}{\epsilon}$. As the above lower bound on $\mu(H)$ holds with probability at least $1-2\epsilon$ by Lemma 3.1 and Lemma 2.4, we have that $\mathbb{E}[\mu(H)] \geq (1-2\epsilon) \cdot \frac{1}{2c(1+O(\epsilon))} \cdot \mu(G) \geq \frac{1}{2c(1+O(\epsilon))} \cdot \mu(G)$. Therefore, a $(1+\epsilon)$-approximate matching in H is itself a $2c(1+O(\epsilon))$-approximate matching in G w.h.p and in expectation. Now, each of the $C(n,m)$ changes to edge weights of the fractional matching incurs at most three updates to the kernel H: for every edge e whose weight changes, this edge can be added/removed to/from H if it is sampled in/out; in the latter case both of e's endpoints can have a new edge added to their "allowable" edge list in place of e, and therefore possibly added to H, in case the endpoints had less than $(1+\epsilon)d$ sampled edges. In either case, the number of edges added to H is at most a constant per edge weight update. But on the other hand, the $(1+\epsilon)$-approximate matching algorithm implied by Lemma 2.5 requires $O(d/\epsilon^2)$ worst-case time per update in H, by H's worst-case degree bound. Consequently, our algorithm maintains a $2c(1+O(\epsilon))$-approximate integral matching (w.h.p and in expectation) in $T(n,m) + O(C(n,m) \cdot d/\epsilon^2)$ update time; moreover, this update time is worst case if the bounds on $T(n,m)$ and $C(n,m)$ are themselves worst case. ◀

5 Applications to Maximum Weight Matching

In this section we highlight the consequences of our results for fully-dynamic maximum weight matching. First, we discuss a new reduction of Stubbs and Vassilevska Williams [50].

▶ **Lemma 5.1** ([50]). *Let $\mathcal{A}$ be an fully-dynamic α-approximate maximum cardinality matching algorithm with update time $T(n,m)$. Then, there exists a fully-dynamic $2\alpha(1+\epsilon)$-approximate maximum cardinality matching algorithm with update time $O(T(n,m) \cdot \frac{\log(n/\epsilon)}{\epsilon})$. Furthermore, if Algorithm $\mathcal{A}$ is deterministic, so is the new one, and if Algorithm $\mathcal{A}$'s update time is worst case, so is the new algorithm's update time.*

This reduction (which we elaborate on shortly), together with the state of the art dynamic maximum matching algorithms, implies most of the best currently best bounds for dynamic maximum weight matching, in Table 2.

A somewhat more involved and worse update time bound than that given in Lemma 5.1 was presented in [50], as that paper's authors sought to obtain a persistent matching, in a sense that this matching should not change completely after a single step (i.e., no more than $O(T(n,m))$ changes to the matching per edge update, if $T(n,m)$ is the algorithm's update time). However, a simpler and more efficient reduction yielding a non-persistent matching algorithm with the performance guarantees of Lemma 5.1 is implied immediately from the driving observation of Stubbs and Vassilevska Williams [50] (and indeed, is discussed in [50]). This observation, previously made by Crouch and Stubbs [18] in the streaming setting, is as follows: denote by E_i the edges of weights in the range $((1+\epsilon)^i, (1+\epsilon)^{i+1}]$, and let M_i be an α-approximate matching in $G[E_i]$. Then, greedily constructing a matching by adding edges from each M_i in decreasing order of i yields a $2\alpha(1+\epsilon)$-approximate maximum weight matching. Adding to this observation the observation that if we are content with a $(1+\epsilon)$-approximate (or worse) maximum weight matching we may safely ignore all edges of weight less than ϵ/n of the maximum edge weight (a trivial lower bound on the maximum weight matching's weight), we find that we can focus on the ranges $((n/\epsilon)^i, (n/\epsilon)^{i+2}]$, for some $i \in \mathbb{Z}$, noting that each edge belongs to at most two such ranges.

Table 2 Our Results and Previous State-of-the-Art for Fully-Dynamic MWM.

$1+\epsilon$	$O(\sqrt{m}\log C\epsilon^{-O(1/\epsilon)})$	✓	✓	Gupta and Peng (FOCS '13) [27]

In each such range $((n/\epsilon)^i, (n/\epsilon)^{i+2}]$, the argument of [18, 50] implies that maintaining α-approximate matchings in the sub-ranges $((1+\epsilon)^j, (1+\epsilon)^{j+1}]$ for integral ranges and combining these greedily result in a $2\alpha(1+\epsilon)$-approximate maximum weight matching in the range $((n/\epsilon)^i, (n/\epsilon)^{i+2}]$. Therefore, in the range containing a $(1+\epsilon)$-approximate MWM (such a range exists, by the above), this approach maintains a $2\alpha(1+O(\epsilon))$-approximate MWM. The only possible difficulty is combining these matchings greedily *dynamically*. This is relatively straightforward to do in $O(\log(n/\epsilon)/\epsilon)$ worst-case time per change of the α-approximate matching algorithm, however, implying the bound of Lemma 5.1.

As seen in Table 2, this reduction of Stubbs and Vassilevska Williams [50] implies a slew of improved bounds for fully-dynamic approximate maximum weight matching. Plugging in our bounds of Theorem 1.4 for fully-dynamic maximum matching into the reduction of Lemma 5.1 similarly yields the first constant-approximate maximum weight matching with polylogarithmic *worst-case* update time, given in Theorem 1.5 below.

▶ **Theorem 1.5.** *For all $\epsilon \leq \frac{1}{2}$, there exists a randomized fully-dynamic $(4+O(\epsilon))$-approximate maximum weight matching algorithm with poly$(\log n, 1/\epsilon)$ worst-case update time. The approximation guarantee holds with high probability and in expectation.*

6 Conclusion and Future Work

In this work we presented a simple randomized reduction from $(2c+\epsilon)$-approximate fully-dynamic matching to fully-dynamic (c,d)-approximately-maximal fractional matching with a slowdown of d. Using the recent algorithm of Bhattacharya et al. [15], our work yields the first fully-dynamic matching algorithms with faster-than-polynomial worst-case update time for any constant approximation ratio; specifically, it yields a $(2+O(\epsilon))$-approximate matching with polylog worst case update time. Our work raises several natural questions and future research directions to explore.

Faster Fractional Algorithms. Given our reduction, in order to obtain faster $(2+\epsilon)$-approximate matching algorithms, it would suffice to improve the update time for fully-dynamic $(1+\epsilon, O_\epsilon(\log n))$-approximately-maximal fractional matching algorithm compared to the algorithm of Bhattacharya et al. [15]. Large enough improvements in the update time, number of edge weight changes and parameter d of $(1+\epsilon, d)$-approximately-maximal

fractional matching algorithms used would result in even better bounds. We note however that our current approach does not seem to allow for sub-logarithmic update bounds, due to its update time's dependence on $d \geq \log n$, so obtaining worst-case sub-logarithmic bounds may require different ideas.

More Efficient/Deterministic Reduction. Given the above, one may ask whether the dependence on d may be removed in a black-box reduction such as ours, yielding randomized integral matching algorithms with the same running time as their fractional counterparts. One may further wonder whether or not one can obtain a *deterministic* counterpart to our black-box reduction from integral matching to approximately-maximal fractional matching. Such a reduction with polylogarithmic overhead would yield for example a deterministic $(2+\epsilon)$-approximate algorithm with worst-case polylogarithmic update time.

Maximal Matching. Finally, a natural question from our work and prior work is whether or not a *maximal* matching can be maintained in worst-case polylogarithmic time (also implying a 2-approximate minimum vertex cover within the same time bounds). We leave this as a tantalizing open question.

Abstract

A noticeable fraction of Algorithms papers in the last few decades improve the running time of well-known algorithms for fundamental problems by logarithmic factors. For example, the $O(n^2)$ dynamic programming solution to the Longest Common Subsequence problem (LCS) was improved to $O(n^2/\log^2 n)$ in several ways and using a variety of ingenious tricks. This line of research, also known as *the art of shaving log factors*, lacks a tool for proving negative results. Specifically, how can we show that it is unlikely that LCS can be solved in time $O(n^2/\log^3 n)$?

Perhaps the only approach for such results was suggested in a recent paper of Abboud, Hansen, Vassilevska W. and Williams (STOC'16). The authors blame the hardness of shaving logs on the hardness of solving satisfiability on boolean formulas (Formula-SAT) faster than exhaustive search. They show that an $O(n^2/\log^{1000} n)$ algorithm for LCS would imply a major advance in circuit lower bounds. Whether this approach can lead to tighter barriers was unclear.

In this paper, we push this approach to its limit and, in particular, prove that a well-known barrier from complexity theory stands in the way for shaving five additional log factors for fundamental combinatorial problems. For LCS, regular expression pattern matching, as well as the Fréchet distance problem from Computational Geometry, we show that an $O(n^2/\log^{7+\varepsilon} n)$ runtime would imply new Formula-SAT algorithms.

Our main result is a reduction from SAT on formulas of size s over n variables to LCS on sequences of length $N = 2^{n/2} \cdot s^{1+o(1)}$. Our reduction is essentially as efficient as possible, and it greatly improves the previously known reduction for LCS with $N = 2^{n/2} \cdot s^c$, for some $c \geq 100$.

Vassilevska Williams for helpful discussions regarding regular expressions. We also thank an anonymous reviewer for ideas leading to shaving off a second log-factor for Formula-Pair.

1 Introduction

Since the early days of Algorithms research, a noticeable fraction of papers each year *shave log factors* for fundamental problems: they reduce the best known upper bound on the time complexity from $T(n)$ to $T(n)/\log^c n$, for some $c > 0$. While in some cases a cynic would call such results "hacks" and "bit tricks", there is no doubt that they often involve ingenious algorithmic ideas and suggest fundamental new ways to look at the problem at hand. In his survey, Timothy Chan calls this kind of research "The Art of Shaving Logs" [37]. In many cases, we witness a race of shaving logs for some problem, in which a new upper bound is found every few months, without giving any hints on when this race is going to halt. For example, in the last few years, the upper bound for combinatorial Boolean Matrix Multiplication dropped from $O(n^3/\log^2 n)$ [16], to $O(n^3/\log^{2.25} n)$ [20], to $O(n^3/\log^3 n)$ [38], and most recently to $O(n^3/\log^4 n)$ [99]. Perhaps the single most important missing technology for this kind of research is a tool for proving *lower bounds*.

Consider the problem of computing the Longest Common Subsequence (LCS) of two strings of length n. LCS has a simple $O(n^2)$ time dynamic programming algorithm [93, 46]. Several approaches have been utilized in order to shave log factors such as the "Four Russians" technique [16, 61, 74, 23, 58], utilizing bit-parallelism [10, 47, 62], and working with compressed strings [48, 54]. The best known upper bounds are $O(n^2/\log^2 n)$ for constant size alphabets [74], and $O(n^2 \log\log n/\log^2 n)$ for large alphabets [58]. But can we do better? Can we solve LCS in $O(n^2/\log^3 n)$ time? While the mathematical intrigue is obvious, we remark that even such mild speedups for LCS could be significant in practice. Besides its use as the *diff* operation in unix, LCS is at the core of highly impactful similarity measures between biological data. A heuristic algorithm called BLAST for a generalized version of LCS (namely, the Local Alignment problem [87]) has been cited more than sixty thousand times [14]. While such heurisitics are much faster than the near-quadratic time algorithms above, they are not guaranteed to return an optimal solution and are thus useless in many applications, and biologists often fall back to (highly optimized implementations of) the quadratic solutions, see, e.g. [71, 72].

How would one show that it is hard to shave logs for some problem? A successful line of work, inspired by NP-hardness, utilizes "fine-grained reductions" to prove statements of the form: a small improvement over the known runtime for problem A implies a breakthrough algorithm for problem B, refuting a plausible hypothesis about the complexity of B. For example, it has been shown that if LCS can be solved in $O(n^{2-\varepsilon})$ time, where $\varepsilon > 0$, then there is a breakthrough $(2-\delta)^n$ algorithm for CNF-SAT, and the Strong Exponential Time Hypothesis (SETH, defined below) is refuted [2, 29]. Another conjecture that has been used to derive interesting lower bounds states that the 3-SUM problem[2] cannot be solved in $O(n^{2-\varepsilon})$ time. It is natural to ask: can we use these conjectures to rule out log-factor improvements for problems like LCS? And even more optimistically, one might hope to base the hardness of LCS on a more standard assumption like $\mathsf{P} \neq \mathsf{NP}$. Unfortunately, we can formally prove that these assumptions are not sharp enough to lead to any consequences for log-factor improvements, if only Turing reductions are used. In Section 3 we prove the

[2] 3-SUM asks, given a list of n numbers, to find three that sum to zero. The best known upper bound is $O(n^2(\log\log n)^2/\log n)$ for real numbers [59, 53, 56] and $O(n^2(\log\log n/\log n)^2)$ for integers [21].

following theorem which also shows that an $O(f(n)/\log^c(f(n)))$ time algorithm for problem A cannot imply, via a fine-grained reduction, an $O(g(n)^{1-\varepsilon})$ algorithm for problem B, unless B is (unconditionally) solvable in $O(g(n)^{1-\delta})$ time.

▶ **Theorem 1.1** (Informally). *If for some $c > 0$ there is a fine-grained reduction proving that LCS is not in $O(n^2/\log^c n)$ time unless SETH fails, then SETH is false.*

Note that it also does not suffice to simply make SETH stronger by postulating a higher running time lower bound for CNF-SAT, since *superpolynomial improvements are known* for this problem [81, 34, 49, 8]. Similarly, we cannot base a study of log-factor improvements on the APSP conjecture, since *superlogarithmic improvements are known* for APSP [97]. (However, 3SUM could be a candidate to base higher lower bounds on, since only log-factor improvements are known [59, 53, 56, 21], see Section A of the full version for a discussion.)

Thus, in a time when super-linear lower bounds for problems like LCS are far out of reach, and our only viable approach to obtaining such negative results is reductions-based, we are left with two options. We could either leave the study of log-factor improvements in limbo, without a technology for proving negative results, or we could search for natural and convincing assumptions that are more fine-grained than SETH that could serve as the basis for the negative results we desire. Such assumptions were recently proposed by Abboud, Hansen, Vassilevska Williams and Williams [3]. The authors blame the hardness of shaving logs on the hardness of solving satisfiability on boolean formulas (Formula-SAT) faster than exhaustive search[3], by polynomial factors (which are log-factors in the runtime), a task for which there are well known "circuit lower bound" barriers in complexity theory. They show that an $O(n^2/\log^{1000} n)$ algorithm for LCS would imply a major advance in circuit lower bounds. In the final section of this paper, we give a more detailed argument in favor of this approach. Whether one should expect it to lead to *tight* barriers, i.e. explaining the lack of $O(n^2/\log^3 n)$ algorithms for LCS or any other natural problem, was completely unclear.

The Machine Model

We use the *Word-RAM* model on words of size $\Theta(\log n)$, where there is a set of operations on words that can be performed in time $O(1)$. Most papers do not fix the concrete set of allowed operations, and instead refer to "typical Boolean and arithmetic operations". In this paper, we choose a set of operations $\mathcal{P}$ that is *robust* with respect to changing the word size: For any operation $\circ \in \mathcal{P}$, given two words a, b (of size $\Theta(\log n)$) we can compute $a \circ b$ in time $(\log n)^{1+o(1)}$ on a Word RAM with word size $\Theta(\log \log n)$ and operation set $\mathcal{P}$. In other words, if we split a, b into $\Theta(\log n/\log \log n)$ words of size $\Theta(\log \log n)$ then $a \circ b$ can still be computed very efficiently.

This robustness in particular holds for the following standard set of operations: initializing a cell with a constant, bitwise AND, OR, NOT, shift, addition, subtraction, multiplication, and division with remainder (since multiplication and division have near-linear time algorithms).

The results in this paper will get gradually weaker as we relax the restriction on near-linear time per operation to higher runtimes, however, even with this restriction, to the best of our knowledge this model captures all log shaving results in the literature (on the "standard" Word RAM model without fancy word operations).

[3] In [3] the authors focus on SAT on Branching Programs (BPs) rather than formulas, but due to standard transformations between BPs and formulas, the two problems are equivalent up to polynomial factors. Focusing on Formula-SAT will be crucial to the progress we make in this paper.

Formula-SAT

A boolean formula over n input variables can be viewed as a tree in which every leaf is marked by an input variable or its negation and every internal node or *gate* represents some basic boolean operation. Throughout this introduction we will only talk about *deMorgan* formulas, in which every gate is from the set $\{\wedge, \vee\}$. The *size* of the formula is defined to be the number of leaves in the tree.

In the Formula-SAT problem we are given a formula F of size s over n inputs, and we have to decide whether there is an input $\{0,1\}^n$ that makes it output 1. A naive algorithm takes $O(2^n \cdot s)$ time, since evaluating the formula on some input takes $O(s)$ time. Can we do better? We will call a SAT algorithm *non-trivial*[4] if it has a runtime at most $O(\frac{2^n}{n^\varepsilon})$, for some $\varepsilon > 0$.

It seems like a clever algorithm must look at the given formula F and try to gain a speedup by analyzing it. The more complicated F can be, the harder the problem becomes. Indeed, Dantsin and Hirsch [49] survey dozens of algorithms for SAT on CNF formulas which exploit their structure. For k-CNF formulas of size s there are $2^n s/2^{\Omega(n/k)}$ time algorithms (e.g. [81]), and for general CNF formulas the bound is $2^n s/2^{\Omega(n/\log \Delta)}$ where $\Delta = s/n$ is the clause-to-variable ratio [34, 49, 8]. The popular SETH [66, 35] essentially says that this is close to optimal, and that there is no $2^n s/2^{\Omega(n)}$ algorithm for CNF-SAT. For arbitrary deMorgan formulas, the upper bounds are much worse. A FOCS'10 paper by Santhanam [84] and several recent improvements [41, 43, 42, 70, 91] solve Formula-SAT on formulas of size $s = n^{3-16\varepsilon}$ in time $2^n s^{O(1)}/2^{n^\varepsilon}$, which is non-trivial only for $s = o(n^3)$, and going beyond cubic seems extremely difficult. This leads us to the first barrier which we will transform into a barrier for shaving logs.

▶ **Hypothesis 1.2.** *There is no algorithm that can solve SAT on deMorgan formulas of size $s = n^{3+\Omega(1)}$ in $O(\frac{2^n}{n^\varepsilon})$ time, for some $\varepsilon > 0$, in the Word-RAM model.*

Perhaps the main reason to believe this hypothesis is that despite extensive algorithmic attacks on variants of SAT (perhaps the most extensively studied problem in computer science) over decades, none of the ideas that anyone has ever come up with seem sufficient to refute it. Recent years have been particularly productive in non-trivial algorithms designed for special cases of Circuit-SAT [84, 86, 64, 35, 98, 22, 40, 67, 63, 44, 83, 57] (in addition to the algorithms for deMorgan formulas above) and this hypothesis still stands.

A well-known "circuit lower bounds" barrier seems to be in the way for refuting Hypothesis 1.2: can we find an explicit boolean function that cannot be computed by deMorgan formulas of cubic size? Functions that require formulas of size $\Omega(n^{1.5})$ [89] and $\Omega(n^2)$ [69] have been known since the 60's and 70's, respectively. In the late 80's, Andreev [15] proved an $\Omega(n^{2.5})$ which was later gradually improved to $\Omega(n^{2.55})$ by Nisan and Wigderson [65] and to $\Omega(n^{2.63})$ by Paterson and Zwick [79] until Håstad proved his $n^{3-o(1)}$ lower bound in FOCS'93 [60] (a recent result by Tal improves the $n^{o(1)}$ term [90]). All these lower bound results use the "random restrictions" technique, first introduced in this context by Subbotovskaya in 1961 [89], and it is known that a substantially different approach must be taken in order to go beyond the cubic barrier. What does this have to do with Formula-SAT algorithms? Interestingly, this same "random restrictions" technique was crucial to *all* the non-trivial Formula-SAT algorithms mentioned above. This is not a coincidence, but only one out of

[4] Some works on SAT algorithms used this term for runtimes of the form $2^n \mathrm{poly}(s)/n^{\omega(1)}$. In our context, we need to be a bit more fine-grained.

the many examples of the intimate connection between the task of designing non-trivial algorithms for SAT on a certain class $\mathcal{F}$ of formulas or circuits and the task of proving lower bounds against $\mathcal{F}$. This connection is highlighted in many recent works and in several surveys [85, 78, 96]. The intuition is that both of these tasks seem to require identifying a strong structural property of functions in $\mathcal{F}$. There is even a formal connection shown by Williams [95], which in our context implies that solving Formula-SAT on formulas of size $O(n^{3.1})$ in $O(2^n/n^{10})$ time (which is only slightly stronger than refuting Hypothesis 1.2) is sufficient in order to prove that there is a function in the class E^{NP} that cannot be computed by formulas of size $O(n^{3.1})$ (see [3] for more details). This consequence would be the first polynomial progress on the fundamental question of worst case formula lower bounds since Håstad's result.

1.1 Our Results: New Reductions

Many recent papers have reduced CNF-SAT to fundamental problems in P to prove SETH-based lower bounds (e.g. [80, 82, 6, 4, 27, 18, 7, 1, 33, 5, 19, 75, 39]). Abboud et al. [3] show that even SAT on formulas, circuits, and more, can be efficiently reduced to combinatorial problems in P. In particular, they show that Formula-SAT on formulas of size s over n inputs can be reduced to an instance of LCS on sequences of length $N = O(2^{n/2} \cdot s^{1000})$. This acts as a barrier for shaving logs as follows. A hypothetical $O(N^2/\log^c N)$ time algorithm for LCS can be turned into an algorithm for Formula-SAT in time

$$n^{1+o(1)} \cdot (2^{n/2} \cdot s^{1000})^2/(\log 2^{\Omega(n)})^c = O(2^n \cdot s^{2000}/n^{c-1}),$$

which for a large enough $c \geq 2001$ would refute Hypothesis 1.2. The first $n^{1+o(1)}$ factor in the runtime comes from the jump from n to $N = 2^n$ and our Word-RAM machine model: whenever the LCS algorithm wants to perform a unit-cost operation on words of size $\Theta(\log N)$ (this is much more than the word size of our SAT algorithm which is only $\Theta(\log n) = \Theta(\log \log N)$), the SAT algorithm can simulate it in $(\log N)^{1+o(1)} = n^{1+o(1)}$ time in the Word-RAM model with words of size $\Theta(\log n)$.

Our main result is a *much* more efficient reduction to LCS. For large but constant size alphabets, we get a near-linear dependence on the formula size, reducing the s^{1000} factor to just $s^{1+o(1)}$.

▶ **Theorem 1.3.** *Formula-SAT on formulas of size s on n inputs can be reduced to an instance of LCS on two sequences over an alphabet of size σ of length $N = 2^{n/2} \cdot s^{1+O(1/\log\log\sigma)}$, in $O(N)$ time.*

Thus, if LCS on sequences of length N and alphabet of size $\omega(1)$ can be solved in $O(N^2/\log^c N)$ time, then Formula-SAT can be solved in $2^n \cdot \frac{s^{2+o(1)}}{n^c} \cdot n^{1+o(1)}$ time. Recall that the known upper bound for LCS is $O(n^2/\log^c n)$ for any constant alphabet size, with $c = 2$, and we can now report that the barrier of cubic formulas stands in the way of improving it to $c > 7$ (see Corollary 1.6 below).

The novelty in the proof of Theorem 1.3 over [3] is discussed in Section 2. As an alternative to Theorem 1.3, in Section D of the full version we present another reduction to LCS which is much simpler than all previously known reductions, but uses a larger alphabet.

Fréchet Distance

An important primitive in computational geometry is to judge how similar are two basic geometric objects, such as polygonal curves, represented as sequences of points in d-dimensional Euclidean space. Such curves are ubiquitous, since they arise naturally as trajectory data of

moving objects, or as time-series data of stock prices and other measures. The most popular similarity measure for curves in computational geometry is the Fréchet distance, also known as dog-leash-distance. For formal definitions see Section F of the full version. The Fréchet distance has found many applications (see, e.g., [76, 26, 30]) and developed to a rich field of research with many generalizations and variants (see, e.g., [11, 17, 13, 51, 36, 45, 32, 50, 73, 68]).

This distance measure comes in two variants: the continuous and the discrete. A classic algorithm by Alt and Godau [12, 55] computes the continuous Fréchet distance in time $O(n^2 \log n)$ for two given curves with n vertices. The fastest known algorithm runs in time $O(n^2(\log\log n)^2)$ (on the Word RAM) [31]. If we only want to decide whether the Fréchet distance is at most a given value δ, this algorithm runs in time $O(n^2(\log\log n)^2/\log n)$. For the discrete Fréchet distance, the original algorithm has running time $O(n^2)$ [52], which was improved to $O(n^2 \log\log n/\log n)$ by Agarwal et al. [9]. Their algorithm runs in time $O(n^2 \log\log n/\log^2 n)$ for the decision version. It is known that both versions of the Fréchet distance are SETH-hard [27]. However, this does not rule out log factor improvements. In particular, no reduction from versions of SETH on formulas or branching programs is known.

In this paper we focus on the *decision version of the discrete Fréchet distance* (which we simply call "Fréchet distance" from now on). We show that Fréchet distance suffers from the same barriers for shaving logs like LCS. In particular, this reduction allows us to base the usual $\Omega(n^{2-\varepsilon})$ lower bound on a weaker assumption than SETH, such as NC-SETH (see the discussion in [3]). This is the first NC-SETH hardness for a problem that does not admit alignment gadgets (as in [29]).

▶ **Theorem 1.4.** *Formula-SAT on formulas of size s on n inputs can be reduced to an instance of the Fréchet distance on two curves of length $N = O(2^{n/2} \cdot s)$, in $O(N)$ time.*

Regular Expression Pattern Matching

Our final example is the fundamental *Regular Expression Pattern Matching* problem: Decide whether a given regular expression of length m matches a substring of a text of length n. Again, there is a classical $O(nm)$ algorithm [92], and the applicability and interest in this problem resulted in algorithms shaving log factors; the first one by Myers [77] was improved by Bille and Thorup [24] to time $O(mn/\log^{1.5} n)$. Recently, Backurs and Indyk proved an $n^{2-o(1)}$ SETH lower bound [19], and performed an impressive study of the exact time complexity of the problem with respect to the complexity of the regular expression. This study was essentially completed by Bringmann, Grønlund, and Larsen [28], up to $n^{o(1)}$ factors. In Section E of the full version we show that this problem is also capable of efficiently simulating formulas and thus has the same barriers as LCS and Fréchet distance.

▶ **Theorem 1.5.** *Formula-SAT on formulas of size s on n inputs can be reduced to an instance of Regular Expression Pattern Matching on text and pattern of length $N = O(2^{n/2} \cdot s \log s)$ over a constant size alphabet, in $O(N)$ time.*

Consequences of the Cubic Formula Barrier

We believe that SAT on formulas can be tightly connected to many other natural problems in P. As we discuss in the next section, such reductions seem to require problem-specific engineering and are left for future work. The main point of this paper is to demonstrate the possibility of basing such ultra fine-grained lower bounds on one common barrier. Our conditional lower bounds are summarized in the following corollary, which shows that current log-shaving algorithms are very close to the well-known barrier from complexity theory of cubic formula lower bounds.

▶ **Corollary 1.6.** *For all $\varepsilon > 0$, solving any of the following problems in $O(n^2/\log^{7+\varepsilon} n)$ time refutes Hypothesis 1.2, and solving them in $O(n^2/\log^{17+\varepsilon} n)$ time implies that E^{NP} cannot be computed by non-uniform formulas of cubic size:*

- *LCS over alphabets of size $\omega(1)$*
- *The Fréchet distance on two curves in the plane*
- *Regular Expression Pattern Matching over constant size alphabets.*

The main reason that our lower bounds above are not tight (the gap between 2 and 7) is that we need to start from SAT on *cubic* size formulas rather than linear size ones, due to the fact that clever algorithms do exist for smaller formulas. We remark that throughout the paper we will work with a class of formulas we call $\mathcal{F}_1$ (see Section 2 below), also known as bipartite formulas, that are more powerful than deMorgan formulas yet our reduction to LCS can support them as well. This makes our results stronger, since $\mathcal{F}_1$-Formula-SAT could be a harder problem than SAT on deMorgan formulas. In fact, in an earlier version of the paper we had suggested the hypothesis that $\mathcal{F}_1$-Formula-SAT does not have non-trivial algorithms even on *linear size* formulas. This stronger hypothesis would give higher lower bounds. However, Avishay Tal (personal communication) told us about such a non-trivial algorithm for formulas of size up to $n^{2-\Omega(1)}$ using tools from quantum query complexity. We are optimistic that one could borrow such ideas or the "random restrictions" technique from SAT algorithms in order to shave more logs for combinatorial problems such as LCS. This is an intriguing direction for future work.

2 Technical Overview and the Reduction to LCS

We first define the class of frmulas $\mathcal{F}_1$. A formula F of size s over n variables $x_1, \ldots, x_n$ is in the class $\mathcal{F}_1$ iff it has the following properties. The gates in the first layer (nodes in the tree whose children are all leaves) compute arbitrary functions $C : \{0,1\}^{n/2} \to \{0,1\}$, as long as C can be computed in $2^{o(n)}$ time and all children of a gate are marked with variables in $\{x_1, \ldots, x_{n/2}\}$ or with variables in $\{x_{n/2+1}, \ldots, x_n\}$ but not with both. W.l.o.g. we can assume that the inputs are only connected to nodes in the first layer. The gates in the other layers compute deMorgan gates, i.e., OR and AND gates. The size of F is considered to be the *number of gates in the first layer*. Since F is a formula and thus has fanout 1, our size measure is up to constant factors equal to the total number of all gates except the inputs. Note that the complexity of the functions in the first layer and their number of incoming wires, i.e. the number of leaves in the tree, do not count towards the size of F.

All the reductions from SAT to problems in P mentioned in the introduction start with a split-and-list reduction to some "pair finding" problem. In the SETH lower bounds, CNF-SAT is reduced to the Orthogonal-Vectors problem of finding a pair $a \in A, b \in B, A, B \subseteq \{0,1\}^d$ that are orthogonal [94]. When starting from Formula-SAT, we get a more complex pair-finding problem. In Section B of the full version we show a simple reduction from SAT on formulas from the class $\mathcal{F}_1$ (which contains deMorgan formulas) to the following problem.

▶ **Definition 2.1** (Formula-Pair Problem)**.** Given a deMorgan formula over $2m$ variables $F = F(x_1, \ldots, x_m, y_1, \ldots, y_m)$ (each appearing once in F), and two sets of vectors $A, B \subseteq \{0,1\}^m$ of size n, decide if there is a pair $a \in A, b \in B$ such that $F(a_1, \ldots, a_m, b_1, \ldots, b_m) =$ true.

In Section B of the full version we show a Four-Russians type algorithm that solves Formula-Pair in $O(n^2 m/\log^2 n)$ time, and even when $m = |F| = (\log n)^{1+o(1)}$ no $O(n^2/\log^{1+\varepsilon} n)$ upper bound is known. By our reduction, such an upper bound would

imply a non-trivial algorithm for SAT on formulas from $\mathcal{F}_1$. Moreover, Hypothesis 1.2 implies that we cannot solve Formula-Pair in $O(n^2/\log^{\varepsilon} n)$ time, for $m = (\log n)^{3+\Omega(1)}$. In the next sections, we reduce Formula-Pair to LCS, from which Theorem 1.3 follows. A simpler reduction using much larger alphabet size can be found in Section D of the full version.

▶ **Theorem 2.2.** Formula-Pair *on formulas of size s and lists of size n can be reduced to an instance of LCS on two strings over alphabet of size $\sigma \geq 2$ of length $O(n \cdot s^{1+O(1/\log\log\sigma)})$, in linear time.*

The reduction constructs strings x, y and a number ρ such that $\mathrm{LCS}(x, y) \geq \rho$ holds if and only if the given Formula-Pair instance (F, A, B) is satisfiable. The approach is similar to the reductions from Orthogonal-Vectors to sequence alignment problems (e.g. [6, 27, 18, 2, 29]). The big difference is that our formula F can be much more complicated than a CNF, and so we will need more powerful gadgets. Sequence gadgets that are able to simulate the evaluation of deMorgan formulas were (implicitly) constructed in [3] with a recursive approach. Our main contribution is an *extremely efficient* implementation of such gadgets with LCS.

The main part of the reduction is to construct *gate gadgets*: for any vectors $a, b \in \{0,1\}^m$ and any gate g of F, we construct strings $x(g, a)$ and $y(g, b)$ whose LCS determines whether gate g evaluates to true for input (a, b) to F (see Section 2.1). Once we have this, to find a pair of vectors $a \in A, b \in B$ satisfying F, we combine the strings $x(r, a), y(r, b)$, constructed for the root r of F, using a known construction of so-called alignment gadgets [2, 29] from previous work (see Section C.1 of the full version).

Let us quickly explain how [3] constructed gate gadgets and the main ideas that go into our new construction. There are two kinds of gadgets, corresponding to the two types of gates in F: AND and OR gates. Since the AND gadgets will be relatively simple, let us consider the OR gadgets. Fix two inputs a, b, and let $g = (g_1 \vee g_2)$ be an OR gate, and assume that we already constructed gate gadgets for g_1, g_2, namely $x_1 = x(g_1, a), y_1 = y(g_1, b), x_2 = x(g_2, a), y_2 = y(g_2, b)$ so that for $i \in \{1, 2\}$ we have that $\mathrm{LCS}(x_i, y_i)$ is large if the gate g_i outputs true on input (a, b), and it is smaller otherwise. In [3], these gadgets were combined as follows. Let β be an upper bound on the total length of the gadgets x_i, y_i. We add a carefully chosen padding of 0's and 1's, so that any optimal matching of the two strings will have to match *either* x_1, y_1 or x_2, y_2 but not both.

$$\begin{aligned} x &:= \quad 0^{4\beta}\ x_1\ 1^{\beta}\ x_2\ 0^{4\beta} \\ y &:= \quad y_1\ 1^{\beta} 0^{4\beta} 1^{\beta}\ y_2 \end{aligned}$$

One then argues that, in any optimal LCS matching of x, y, the $0^{4\beta}$ block of y must be matched either left or right. If it's matched left, then the total score will be equal to $4\beta + \beta + LCS(x_2, y_2)$ while if it's matched right, we will get $4\beta + \beta + LCS(x_1, y_1)$. Thus, $LCS(x, y)$ is determined by the OR of g_1, g_2. The blowup of this construction is a multiplicative factor of 11 with every level of the formula, and the length of the gadget of the root will end up roughly $11^{\mathrm{depth}(F)}$. To obtain our tight lower bounds, we will need to decrease this blowup to $1 + \varepsilon_\sigma$ at every level, where ε_σ goes to 0 when the alphabet size σ tends to infinity. With the above construction, decreasing the length of the padding will allow the optimal LCS matching to cheat, e.g. by matching y_1 to both x_1 and x_2, and no longer corresponding to the OR of g_1, g_2.

Our first trick is an ultra-efficient OR gadget in case we are allowed unbounded alphabet size. We take x_1, y_1 and transform all their letters into a new alphabet Σ^{g_1}, and we take x_2, y_2 and transform their letters into a disjoint alphabet Σ^{g_2}. Then our OR gadget does not

require any padding at all:

$$x := x_1\ x_2$$
$$y := y_2\ y_1$$

The crossing structure of this construction means that any LCS matching that matches letters from x_1, y_1 cannot also match letters from x_2, y_2, and vice versa, while the disjoint alphabets make sure that there can be no matches between x_1, y_2 or x_2, y_1. With such gadgets we can encode a formula of size s with $O(s)$ letters, for details see Section D of the full version.

But how would such an idea work for *constant size alphabets*? Once we allow x_1 and y_2 to share even a single letter, this argument breaks. Natural attempts to simulate this construction with smaller alphabets, e.g. by replacing each letter with a random sequence, do not seem to work, and we do not know how to construct such an OR gadget with a smaller alphabet *in a black box way*. The major part of our proof will be a careful examination of the formula and the sub-gadgets g_1, g_2 in order to reduce the alphabet size to a large enough constant, while using padding that is only $1 + \varepsilon_\sigma$ times the length of the sub-gadgets. We achieve this by combining this crossing gadget with a small padding that will reuse letters from alphabets that were used much deeper in the formula, and we will argue that the noise we get from recycling letters is dominated by our paddings, in any optimal matching.

We remark that the reduction of [3] can be implemented in a generic way with any problem that admits *alignment gadgets* as defined in [29], giving formula-gadgets of size $s^{O(1)}$. The list of such problems includes LCS and Edit-Distance on binary strings. However, to get gadgets of length $s^{1+o(1)}$ it seems that problem-specific reductions are necessary. A big open question left by our work is to find the most efficient reduction from Formula-SAT to Edit-Distance. A very efficient OR gadget, even if the alphabet is unbounded, might be (provably) impossible. Can we use this intuition to shave more log factors for Edit-Distance?

Fréchet Distance falls outside the alignment gadgets framework of [29] and no reduction from Formula-SAT was known before. In Section F of the full version we prove such a reduction by a significant boosting of the SETH-lower bound construction of [27]. In order to implement recursive AND/OR gadgets, our new proof utilizes the geometry of the curves, in contrast to [27] which only used ten different points in the plane.

In the remainder of this section we present the details of the reduction to LCS. Some missing proofs can be found in Section C of the full version.

2.1 Implementing Gates

Fix vectors $a, b \in \{0,1\}^m$ (where $2m$ is the number of inputs to F). In this section we prove the following lemma which demonstrates our main construction.

▶ **Lemma 2.3.** *For any sufficiently large $\sigma > 0$ let $\tau = (\log \sigma)^{1/4}$. We can inductively construct, for each gate g of F, strings $x(g) = x(g,a)$ and $y(g) = y(g,b)$ over alphabet size $5\sigma^2$ and a number $\rho(g)$ such that for $L(g) := \mathrm{LCS}(x(g), y(g))$ we have (1) $L(g) \leq \rho(g)$ and (2) $L(g) = \rho(g)$ if and only if gate g evaluates to true on input (a,b) to F. Moreover, we have $|x(g)| = |y(g)| = n(g) \leq 6\tau \cdot |F_g|(1 + 7/\tau)^{\mathrm{depth}(F_g)}$, where F_g is the subformula of F below g.*

In this construction, we use disjoint size-5 alphabets $\Sigma_1, \ldots, \Sigma_{\sigma^2}$, determining the total alphabet size as $5\sigma^2$. Each gate g is assigned an alphabet $\Sigma_{f(g)}$. We fix the function f later.

In the following, consider any gate g of F, and write the gate alphabet as $\Sigma_{f(g)} = \{0,1,2,3,4\}$. For readability, we write $x = x(g)$ and similarly define y, n, L, ρ. If g has fanin 2, write g_1, g_2 for the children of g. Moreover, let $x_1 = x(g_1)$ and similarly define y_1, n_1, L_1, ρ_1 and $x_2, y_2, n_2, L_2, \rho_2$.

Input Gate

The base case is an input bit a_i to F (input bits b_j are symmetric). Interpreting a_i as a string of length 1 over alphabet $\{0,1\}$, note that $\mathrm{LCS}(a_i, 1) = a_i$. Hence, the strings $x = a_i$ and $y = 1$, with $n = \rho = 1$, trivially simulate the input bit a_i.

AND Gates

Consider an AND gate g and let $\beta := \lceil (n_1 + n_2)/\tau^2 \rceil$. We construct strings x, y as

$$\begin{aligned} x &:= x_1\, 0^\beta\, 1^\beta\, x_2 \\ y &:= y_1\, 0^\beta\, 1^\beta\, y_2 \end{aligned}$$

▶ **Lemma 2.4.** *If* $\mathrm{LCS}(x_2, y_1), \mathrm{LCS}(x_1, y_2) \leq \beta/4$ *and the symbols* $0, 1$ *appear at most* $\beta/16$ *times in each of* x_1, x_2, y_1, *and* y_2, *then we have* $L = \mathrm{LCS}(x, y) = 2\beta + L_1 + L_2$.

Later we will choose the gate alphabets $\Sigma_{f(g)}$ such that the precondition of the above lemma is satisfied. Setting $\rho := 2\beta + \rho_1 + \rho_2$ we thus inductively obtain (1) $L \leq \rho$ and (2) $L = \rho$ if and only if g_1 and g_2 both evaluate to true. Thus, we correctly simulated the AND gate g. It remains to prove the lemma.

Proof. Clearly, we have $L \geq \mathrm{LCS}(x_1, y_1) + \mathrm{LCS}(0^\beta, 0^\beta) + \mathrm{LCS}(1^\beta, 1^\beta) + \mathrm{LCS}(x_2, y_2) = 2\beta + L_1 + L_2$. For the other direction, consider any LCS z of x, y. If z does not match any symbol of the left half of x, $x_1 0^\beta$, with any symbol of the right half of y, $1^\beta y_2$, and it does not match any symbol of the right half of x, $1^\beta x_2$, with any symbol of the left half of y, $y_1 0^\beta$, then we can split both strings in the middle and obtain $L = |z| \leq \mathrm{LCS}(x_1 0^\beta, y_1 0^\beta) + \mathrm{LCS}(1^\beta x_2, 1^\beta y_2)$. Greedy suffix/prefix matching now yields $L \leq \big(\mathrm{LCS}(x_1, y_1) + \beta\big) + \big(\beta + \mathrm{LCS}(x_2, y_2)\big) = 2\beta + L_1 + L_2$.

In the remaining case, there is a matching from some left half to some right half. By symmetry, we can assume that there is a matching from the left half of x to the right half of y. We can moreover assume that z matches a symbol of x_1 with a symbol of $1^\beta y_2$, since the case that z matches a symbol of y_2 with a symbol of $x_1 0^\beta$ is symmetric. Now no symbol in 0^β in x can be matched with a symbol in 0^β in y. We obtain a rough upper bound on $L = |z|$ by summing up the LCS length of all remaining $4 \cdot 4 - 1 = 15$ pairs of a part $x' \in \{x_1, 0^\beta, 1^\beta, x_2\}$ in x and a part $y' \in \{y_1, 0^\beta, 1^\beta, y_2\}$ in y. This yields $L \leq L_1 + L_2 + \beta + 2 \cdot \beta/4 + 8 \cdot \beta/16 = 2\beta + L_1 + L_2$, finishing the proof. ◀

OR Gates

Consider an OR gate g and again let $\beta := \lceil (n_1 + n_2)/\tau^2 \rceil$. We first make the LCS target values equal by adding $4^{|\rho_1 - \rho_2|}$ to the shorter of x_2/y_2 and x_1/y_1, i.e., we set $x_1' := 4^{\max\{0, \rho_2 - \rho_1\}} x_1$ and similarly $y_1' := 4^{\max\{0, \rho_2 - \rho_1\}} y_1$, $x_2' := 4^{\max\{0, \rho_1 - \rho_2\}} x_2$, $y_2' := 4^{\max\{0, \rho_1 - \rho_2\}} y_2$. Note that the resulting strings satisfy $L_1' := \mathrm{LCS}(x_1', y_1') \leq \rho' := \max\{\rho_1, \rho_2\}$ and $L_1' = \rho'$ if and only if g_1 evaluates to true, and similarly $L_2' := \mathrm{LCS}(x_2', y_2') \leq \rho'$ and $L_2' = \rho'$ if and only if g_2 evaluates to true. We construct the strings x, y as

$$\begin{aligned} x &:= 0^\beta 1^\beta\, x_1'\, 2^\beta 3^\beta\, x_2'\, 0^\beta 1^\beta \\ y &:= 2^\beta 3^\beta\, y_2'\, 0^\beta 1^\beta\, y_1'\, 2^\beta 3^\beta \end{aligned}$$

▶ **Lemma 2.5.** *If* $\mathrm{LCS}(x_2, y_1), \mathrm{LCS}(x_1, y_2) \leq \beta/8$ *and the symbols* $0, 1, 2, 3$ *appear at most* $\beta/48$ *times in each of* x_1, x_2, y_1, *and* y_2, *then* $L = \mathrm{LCS}(x, y) = 4\beta + \max\{L_1', L_2'\}$.

Later we will choose the gate alphabets $\Sigma_{f(g)}$ such that the precondition of the above lemma is satisfied. Setting $\rho := 4\beta + \rho' = 4\beta + \max\{\rho_1, \rho_2\}$ we thus inductively obtain (1) $L \leq \rho$ and (2) $L = \rho$ if and only if at least one of g_1 and g_2 evaluates to true, so we correctly simulated the OR gate g. The proof of the Lemma is in Section C of the full version.

Analyzing the Length

Note that the above constructions inductively yields strings $x(g), y(g)$ simulating each gate g. We inductively prove bounds for $n(g)$ and $\rho(g)$. See Section C of the full version.

▶ **Lemma 2.6.** *We have* $n(g) \leq 6\tau \cdot |F_g|(1+7/\tau)^{\mathrm{depth}(F_g)}$ *and* $\rho(g) \leq 6|F_g|(1+7/\tau)^{\mathrm{depth}(F_g)}$ *for any gate* g*, where* F_g *is the subformula of* F *below* g*.*

Fixing the Gate Alphabets

Now we fix the gate alphabet $\Sigma_{f(g)}$ for any gate g. Again let $\Sigma_{(i,j)}$, $i, j \in [\sigma]$, be disjoint alphabets of size 5, and let $\Sigma := \bigcup_{i,j} \Sigma_{(i,j)}$. For any gate g of F, we call its distance to the root the *height* $h(g)$. For any h, order the gates with height h from left to right, and let $\iota(g)$ be the index of gate g in this order, for any gate g with height h. Note that $(h(g), \iota(g))$ is a unique identifier of gate g. We define $f(g) := (h(g) \bmod \sigma, \iota(g) \bmod \sigma)$, i.e., we set the gate alphabet of g to $\Sigma_{f(g)} = \Sigma_{(h(g) \bmod \sigma, \iota(g) \bmod \sigma)}$. Note that the overall alphabet Σ has size $5\sigma^2$. Recall that we set $\tau := (\log \sigma)^{1/4}$.

It remains to show that the preconditions of Lemmas 2.4 and 2.5 are satisfied. Specifically, consider a gate g with children g_1, g_2. As before, let x, y, n be the strings and string length constructed for gate g, and let x_i, y_i, n_i be the corresponding objects for g_i, $i \in \{1, 2\}$. We need to show:

(1) $\mathrm{LCS}(x_2, y_1), \mathrm{LCS}(x_1, y_2) \leq (n_1 + n_2)/(8\tau^2)$, and
(2) each $c \in \Sigma_{f(g)}$ appears at most $(n_1 + n_2)/(48\tau^2)$ times in each of x_1, x_2, y_1, and y_2.

We call a gate g' in the subformula F_g *d-deep* if $h(g') \geq h(g) + d$, and *d-shallow* otherwise. For each symbol c in x or y we can trace our construction to find the gate g' in F_g at which we introduced c to x or y. In other words, each symbol in x, y *stems* from some gate g' below g.

First consider (2). Observe that all symbols in x, y stemming from σ-shallow gates do not belong to the gate alphabet $\Sigma_{f(g)}$, since the function $f(g')$ has $(h(g') \bmod \sigma)$ as the first component, which repeats only every σ levels. Thus, if a symbol $c \in \Sigma_{f(g)}$ occurs in x_i or y_i, then this occurence stems from a σ-deep gate. We now argue that only few symbols in x, y stem from deep gates. For any $d > 0$, let N_d be the number of symbols in x (or, equivalently, y) steming from d-deep gates. Note that N_d is equal to the total string length $\sum n(g')$, summed over all gates g' in F_g with height $h(g') = h(g) + d$. Observe that our construction increases the string lengths in each step by at least a factor $1 + 1/\tau^2$, i.e., $N_d \geq (1 + 1/\tau^2)N_{d+1}$ holds for any d. It follows that $N_\sigma \leq N_1/(1 + 1/\tau^2)^{\sigma-1} = (n_1 + n_2)/(1 + 1/\tau^2)^{\sigma-1}$. Hence, each symbol in $\Sigma_{f(g)}$ appears at most $(n_1+n_2)/(1+1/\tau^2)^{\sigma-1}$ times in each of x_1, x_2, y_1, y_2. Since $\tau = (\log \sigma)^{1/4}$, we have $(1 + 1/\tau^2)^{\sigma-1} = 2^{\Omega(\sigma/\sqrt{\log \sigma})} \geq 48\sqrt{\log \sigma} = 48\tau^2$ for sufficiently large σ. This proves (2).

For (1), remove all $\log(\sigma)$-deep symbols from x_1 and y_2 to obtain strings x_1', y_2'. Note that we removed exactly $N_{\log \sigma}$ symbols from each of x_1, y_2. This yields $\mathrm{LCS}(x_1, y_2) \leq 2N_{\log \sigma} + \mathrm{LCS}(x_1', y_2')$. For x_1', y_2', we claim that any $\log(\sigma)$-shallow gates $g_1' \neq g_2'$ in F_g have disjoint alphabets $\Sigma_{f(g_1')}, \Sigma_{f(g_2')}$. Indeed, if $h(g_1') \neq h(g_2')$ then since the first component $(h(g') \bmod \sigma)$ of $f(g')$ repeats only every σ levels we have $f(g_1') \neq f(g_2')$. If $h(g_1') = h(g_2') =: h$,

then note that each gate g' in height h has a unique label $\iota(g') \bmod \sigma$, since there are σ such labels and there are at most $2^{h-h(g)} < \sigma$ gates with height h in F_g. Hence, x'_1 and y'_2 use disjoint alphabets, and we obtain $\mathrm{LCS}(x'_1, y'_2) = 0$. Thus, $\mathrm{LCS}(x_1, y_2) \leq 2N_{\log\sigma}$. As above, we bound $N_{\log\sigma} \leq (n_1+n_2)/(1+1/\tau^2)^{\log\sigma-1}$, so that $\mathrm{LCS}(x_1, y_2) \leq 2(n_1+n_2)/(1+1/\tau^2)^{\log\sigma-1}$. Since $\tau = (\log\sigma)^{1/4}$, we have $(1+1/\tau^2)^{\log\sigma-1}/2 = 2^{\Omega(\sqrt{\log\sigma})} \geq 8\sqrt{\log\sigma} = 8\tau^2$ for sufficiently large σ. This yields (1), since the strings x_2, y_1 are symmetric, finishing the proof of Lemma 2.3.

Finalizing the Proof

Let us sketch how we complete the proof of Theorem 2.2. The full details are in Section C.1 of the full version. First, for all vectors $a \in A, b \in B$ we construct gate gadgets for the output gate of the formula, i.e. *formula gadgets*, by invoking Lemma 2.3. Then we combine all these gadgets by applying a standard alignment gadget [2, 29] to get our final sequences of length $O\big(n\tau|F|(1+7/\tau)^{\mathrm{depth}(F)}\big)$ and with alphabet of size $O(\sigma^2)$. The LCS of the final sequence will be determined by the existence of a satisfying pair. Since a priori the depth of F could be as large as $|F|$, the factor $(1+7/\tau)^{\mathrm{depth}(F)}$ in our length bound is not yet satisfactory. Thus, as a preprocessing before the above construction, we decrease the depth of F using a depth-reduction result of Bonet and Buss [88, 25]: for all $k \geq 2$ there is an equivalent formula F' with depth at most $(3k\ln 2)\log|F|$ and size $|F'| \leq |F|^{1+1/(1+\log(k-1))}$. Choosing the parameters correctly, we get final sequences of length $O\big(n|F|^{1+O(1/\log\log\sigma)}\big)$.

3 On the Limitations of Fine-Grained Reductions

With the increasingly complex web of reductions and conjectures used in the "Hardness in P" research, one might oppose to our use of nonstandard assumptions. Why can't we base the hardness of shaving logs on one of the more established assumptions such as SETH, or even better, on $\mathsf{P} \neq \mathsf{NP}$? We conclude the paper with a proof that such results are not possible if one is restricted to fine-grained reductions, which is essentially the only tool we have in this line of research.

Let A be a problem with best known upper bound of $T_A(n)$ on inputs of size n, and let B be a problem with best known upper bound of $T_B(n)$ on inputs of size n. Throughout this section we assume that these runtime are non-decreasing functions, such as 2^n or n^2. A fine-grained reduction from "solving A in time $T_A(n)/g(n)$" to "solving B in time $T_B(n)/f(n)$" proves that improving $T_B(n)$ to $T_B(n)/f(n)$ improves T_A to $T_A(n)/g(n)$. Formally, it is an algorithm X that solves A and it is allowed to call an oracle for problem B, as long as the following bound holds. Let n_i be the size of the instance in the i^{th} call to problem B that our algorithm performs, where $i \leq t$ for some value t, and let $T_X(n)$ be the runtime of X excluding the time it takes to answer all the instances of problem B. It must be that $T_X(n) + \sum_{i=1}^{t} T_B(n_i)/f(n_i) \leq T_A(n)/g(n)$. This is a natural adaptation of the definition of fine-grained reductions from previous works, where the improvements were restricted to be by polynomial factors. We can now give a formal version of Theorem 1.1 from the introduction.

▶ **Theorem 3.1.** *If for some $c, \varepsilon > 0$ and all $k \geq 2$ there is a fine-grained reduction from solving k-SAT in time $\mathrm{poly}(n,m)2^n/2^{\varepsilon n}$ to solving LCS in time $O(n^2/\log^c n)$, then SETH is false.*

Proof. Assume there was a fine-grained reduction from k-SAT to LCS as above. This means that there is an algorithm X for k-SAT that makes t calls to LCS with instances of size $n_1, \ldots, n_t$ such that $T_X(n) + \sum_{i=1}^{t} n_i^2/\log^c n_i = O(\mathrm{poly}(n,m)2^n/2^{\varepsilon n})$. But then consider

algorithm X' which simulates X and whenever X makes a call to the LCS oracle with an instance of size n_i, our algorithm will execute the known quadratic time solution for LCS. Let n_{max} be the size of the largest instance we call, and note that $n_{max} < 2^n$. Simple calculations show that X' solves k-SAT and has a running time of $T_X(n) + \sum_{i=1}^{t} n_i^2 = O\big(\text{poly}(n,m)2^n/2^{\varepsilon n}\big) \cdot \log^c n_{max} = O(\text{poly}(n,m)2^n/2^{\varepsilon n})$ for all k, refuting SETH. ◀

Abstract

We give faster and simpler approximation algorithms for the $(1,2)$-TSP problem, a well-studied variant of the traveling salesperson problem where all distances between cities are either 1 or 2.

Our main results are two approximation algorithms for $(1,2)$-TSP, one with approximation factor $8/7$ and run time $O(n^3)$ and the other having an approximation guarantee of $7/6$ and run time $O(n^{2.5})$. The $8/7$-approximation matches the best known approximation factor for $(1,2)$-TSP, due to Berman and Karpinski (SODA 2006), but considerably improves the previous best run time of $O(n^9)$. Thus, ours is the first improvement for the $(1,2)$-TSP problem in more than 10 years. The algorithm is based on combining three copies of a minimum-cost cycle cover of the input graph together with a relaxed version of a minimum weight matching, which allows using "half-edges". The resulting multigraph is then edge-colored with four colors so that each color class yields a collection of vertex-disjoint paths. The paths from one color class can then be extended to an $8/7$-approximate traveling salesperson tour. Our algorithm, and in particular its analysis, is simpler than the previously best $8/7$-approximation.

The $7/6$-approximation algorithm is similar and even simpler, and has the advantage of not using Hartvigsen's complicated algorithm for computing a minimum-cost triangle-free cycle cover.

1 Introduction

The metric traveling salesperson problem (TSP) is one of the most fundamental combinatorial optimization problems. Given a complete undirected graph G with a metric cost function c on the edges of G, the goal is to find a tour $\mathcal{T}$ (i.e., a Hamiltonian cycle) of minimum cost in G, where the cost of $\mathcal{T}$ is the sum of costs of the edges traversed by $\mathcal{T}$. Four decades ago, Christofides [8] devised a polynomial-time algorithm that always outputs a tour with cost at most $3/2$ times the cost of an optimal tour. Improving this factor remains a major open problem in the area of approximation algorithms.

[1] Supported by ERC Starting Grant 306465 (BeyondWorstCase) and DFG grant MN 59/4-1.
[2] Supported by Polish National Science Center grant UMO-2013/11/B/ST6/01748.

The metric TSP is well-known to be NP-hard; it is one of Karp's 21 NP-complete problems [16]. In fact, Karp showed that the special case of metric TSP in which all distances between the cities are either 1 or 2, i.e., the cost function is of the form $c : E(G) \to \{1, 2\}$, is NP-hard. This special case is generally known as the $(1, 2)$-TSP problem. Notice that any instance of $(1, 2)$-TSP satisfies the triangle inequality. The $(1, 2)$-TSP problem has been considered in numerous papers [1, 2, 4, 10, 12, 16, 18, 19, 21, 24].

After Karp established the NP-hardness of $(1, 2)$-TSP, Papadimitriou and Yannakakis showed the problem to be APX-hard [24]. The currently best known inapproximability bound for $(1, 2)$-TSP is 535/534 [18]. A certain restriction of $(1, 2)$-TSP was considered by Fernandez de la Vega and Karpinski [10]. It was this restriction of $(1, 2)$-TSP that Trevisan [27] reduced from to establish the inapproximability of TSP in $\mathbb{R}^{\log n}$ under any ℓ_p metric. This hardness complemented Arora's breakthrough result [3] that TSP in $\mathbb{R}^2$ admits a PTAS under any ℓ_p metric.

One can also view the $(1, 2)$-TSP problem as the problem of finding a traveling salesperson tour that uses the maximum number of 1-edges in the given instance; here and throughout the paper, we will refer to edges of cost i as *i-edges*, for $i \in \{1, 2\}$. Alternatively, $(1, 2)$-TSP may be seen as a generalization of the Hamiltonian Cycle problem with non-edges represented by 2-edges.

Both $(1, 2)$-TSP and $(1, 2)$-ATSP (i.e., when the underlying graph G is a complete directed graph) are well-studied from the approximation point of view. For $(1, 2)$-TSP, it is NP-hard to obtain a performance guarantee better than 535/534 [18]. Papadimitriou and Yannakakis [24] gave a 7/6-approximation algorithm for $(1, 2)$-TSP; their algorithm works by successively merging cycles of a triangle-free cycle cover of the graph which they obtained by running Hartvigsen's algorithm [14]. The approximation factor was improved by Bläser and Ram [5] to 65/56, and to 8/7 by Berman and Karpinski [4]. Berman and Karpinski [4] used a local search approach: starting from a path cover they employ local improvements according to certain criteria, and finally connect the paths arbitrarily to a tour. Their algorithm takes time $O(n^9)$ for n-city instances.

1.1 Our Results

Our main results are novel approximation algorithms for $(1, 2)$-TSP that obtain the approximation ratios of 8/7 and 7/6, respectively.. The 8/7-approximation matches the best approximation factor known for $(1, 2)$-TSP, obtained by Berman and Karpinski [4], while improving the run time from $O(n^9)$ to $O(n^3)$. This is the first improvement for this classical problem in over 10 years.

▶ **Theorem 1.** *The (1,2)-TSP problem admits an 8/7-approximation in time $O(n^3)$, and a 7/6-approximation in time $O(n^{2.5})$.*

In this extended abstract we focus on presenting the 7/6-approximation algorithm, which is the simpler of our two algorithms. It is worth noting that it does not rely on Hartvigsen's involved algorithm [14] for computing a minimum-cost triangle-free cycle cover; in contrast, the 7/6-approximation by Papadimitriou and Yannakakis [24] relies on Hartvigsen's algorithm. (Papadimitriou and Yannakakis also gave an 11/9-approximation algorithm that does not use Hartvigsen's algorithm.) We defer the full details of our 8/7-approximation algorithm to the full version of this paper.

Outline of the approach. The idea of the 7/6-approximation algorithm is as follows. We start with computing a minimum cost cycle cover $\mathcal{C}_{\min}$ of the input graph G. Recall that a *cycle cover* of a graph G is a collection of simple cycles of G such that each vertex belongs to

exactly one cycle. Notice that the cost of $\mathcal{C}_{\min}$ is a lower bound on $\mathsf{opt}(G,c)$, where $\mathsf{opt}(G,c)$ denotes the cost of an optimal traveling salesperson tour in the graph G with cost function c. The cost of a minimum cost perfect matching $M_{\min}$ of G is also a lower bound, but this time on $\mathsf{opt}(G,c)/2$. This leads to our key idea of constructing a multigraph $\hat{G}$ on $V(G)$ from two copies of $\mathcal{C}_{\min}$ and one copy of $M_{\min}$. It readily follows that the cost of $\hat{G}$ satisfies $c(\hat{G}) \leq \frac{5}{2}\mathsf{opt}(G,c)$.

Next, we would like to color each edge of $\hat{G}$ with one of three colors so that each color class consists of vertex-disjoint paths, i.e., we would like to "path-3-color" $\hat{G}$. Given a path-3-coloring of $\hat{G}$, the paths of the color class that contains the maximum number of 1-edges can be patched in an arbitrary manner to form a traveling salesperson tour of weight not exceeding $\frac{7}{6}\mathsf{opt}(G,c)$. The exact calculation is given in Sect. 3.1.

However, we observe that not every multigraph $\hat{G}$ obtained from $\mathcal{C}_{\min}$ and $M_{\min}$ in the above way is path-3-colorable. For example, a subgraph of $\hat{G}$ obtained from a 4-cycle (called a *square*) $C \in \mathcal{C}_{\min}$ such that two edges of $M_{\min}$ connect vertices of C cannot be path-3-colored. The reason is that $\hat{G}$ has two copies of each edge of C and additionally two more edges coming from $M_{\min}$, and clearly it is not possible to color these ten edges with three colors without creating a monochromatic cycle.

Similarly, a subgraph of $\hat{G}$ obtained from a 3-cycle (called a *triangle*) $C \in \mathcal{C}_{\min}$ such that one of the edges of $M_{\min}$ connects vertices of C cannot be path-3-colored. An edge of $M_{\min}$ connecting two vertices of a cycle $C \in \mathcal{C}_{\min}$ is going to be called an *internal edge* of C).

While triangles of the above sort can be handled, by flipping edges, squares with two internal edges of $M_{\min}$ are problematic. Moreover, there are problem instances where every perfect matching of weight at most $\mathsf{opt}/2$ uses two internal edges of some square of $\mathcal{C}_{\min}$.

To get around this obstacle, we relax the notion of a matching and allow it to contain "half-edges". A *half-edge* of an edge e is, informally speaking, half of the edge e that contains exactly one of its endpoints. The notion of half-edges has been introduced by Paluch et al. [23]. We call such a relaxed matching $M^{\frac{1}{2}}$ with half-edges *perfect* if every vertex of the graph has exactly one edge or half-edge of $M^{\frac{1}{2}}$ incident to it. Now, we would like to compute a minimum-cost perfect matching $M^{\frac{1}{2}}_{\min}$ with half-edges, such that the half-edges can appear in a controlled way. In particular, for each 4-cycle of $\mathcal{C}_{\min}$ the matching uses correspondingly at most three "internal" half-edges; here, a half-edge of edge e is *internal* for a cycle C if is derived from an edge of G whose both endpoints belong to C. In such a matching the problem described above cannot occur. In Sect. 3.2 we show that $M^{\frac{1}{2}}_{\min}$ can be computed in time $O(n^{2.5})$, and that its weight is at most $\mathsf{opt}(G,c)/2$.

Next, from two copies of $\mathcal{C}_{\min}$ and one copy of $M^{\frac{1}{2}}_{\min}$ we will build a multigraph $\hat{G}$ whose cost is at most $\frac{5}{2}\mathsf{opt}(G,c)$ and that, after some modifications, is path-3-colorable, which yields the desired 7/6-approximation algorithm for (1,2)-TSP.

Modifying the multigraph $\hat{G}$. Before the multigraph $\hat{G}$ can be path-3-colored, it needs to be modified in certain ways. First, $\hat{G}$ should not contain any half-edges; so we replace all half-edges by an appropriate number of "whole" edges. Second, while coloring $\hat{G}$ we can restrict ourselves to coloring of edges of cost 1. Third, we remove some 1-edges if some optimal solution contains 2-edges; the exact relationship between the required number of 1-edges in $\hat{G}$ and the number of 2-edges in $\mathsf{opt}(G,c)$ is given in Sect. 3.1.

Fourth, before $\hat{G}$ can be path-3-colored, we need to "flip" certain edges and half-edges. For example, a subgraph of $\hat{G}$ obtained from a triangle $C \in \mathcal{C}_{\min}$ and one internal edge of C contained in $M^{\frac{1}{2}}_{\min}$ cannot be path-3-colored, and we need to flip this edge to the edge of $\hat{G}$ outside of C. The algorithm for path-3-coloring essentially comes from Dudycz et al. [9].

1.2 Related Work

Despite extensive research, the best approximation algorithm for metric TSP is still Christofides' algorithm [8] from 1976, which has a performance guarantee of 3/2. Generally the bound 3/2 is not believed to be tight. However, the currently largest known lower bound on the performance guarantee obtainable in polynomial time is as low as 123/122 [17]. A promising approach to improving upon the factor of 3/2 for metric TSP is to round a linear programming relaxation known as the Held-Karp relaxation [15], that is widely conjectured to have an integrality gap upper bounded by 4/3. However, even for the graphic TSP, the best known approximation upper bound of 7/5 due to Sebő and Vygen [26] does not match this conjectured upper bound of 4/3.

Another LP relaxation for TSP is the *subtour elimination LP*, which has constraints prescribing any vertex to be incident to exactly two edges of the TSP tour and constraints ruling out incomplete subtours (hence the name) by forcing edges to leave any non-empty proper subset of nodes. The best known integrality gap lower bound of the subtour elimination LP for $(1,2)$-TSP is 10/9, due to Williamson [29]. Qian et al. [25] showed an integrality gap upper bound of 19/15 for $(1,2)$-TSP (in a revised version, they improve the integrality gap upper bound to 5/4 and to 26/21 for fractionally Hamiltonian instances), and of 7/6 if the integrality gap is attained by a basic solution of the fractional 2-matching polytope. With the additional assumption that a certain type of modification maintains the 2-vertex connectedness of the support graph, they were able to show a tight integrality gap of 10/9. For fractionally Hamiltonian instances (i.e., where the optimal value of the LP relaxation of the subtour elimination formulation equals the order of the instance), Mnich and Mömke [21] prove integrality upper bounds of 5/4 in the general case and of 10/9 in the case of subcubic support graphs.

For $(1,2)$-ATSP, it is NP-hard to obtain a performance ratio better than 207/206 [18]. The first non-trivial approximation algorithm for $(1,2)$-ATSP was given by Vishwanathan [28], with an approximation factor of 17/12. This was improved to 4/3 by Bläser and Manthey [7]. The currently best approximation factor is 5/4, and is due to Bläser [6] and Paluch [22]. For fractionally Hamiltonian instances of $(1,2)$-ATSP, Mnich and Mömke [21] prove an integrality upper bound of 7/6.

The approach of using half-edges for solving variants of TSP was first used by Paluch et al. [23], who used it to give a 2/3-approximation for Max-ATSP. Later, Paluch [22] used half-edges to improve the approximation guarantee to 3/4 for the special case of Max-ATSP where all edge costs are either zero or one. Recently, Dudycz et al. [9] used half-edges to give a 4/5-approximation for Max-TSP.

2 Preliminaries

An instance of the $(1,2)$-TSP problem consists of pair (G,c), where G is a complete undirected graph and $c : E(G) \to \{1,2\}$ is an edge cost function, where each edge $e \in E(G)$ has a cost of $c(e) \in \{1,2\}$. A *tour* for the instance (G,c) is a subset $T \subseteq E(G)$ of edges of G that forms a Hamiltonian cycle of G, that is, the edges of T form a cycle that visits each vertex of G exactly once; the *cost* of T is defined as $c(T) = \sum_{e \in T} c(e)$. The goal is to find an *optimal* tour opt for (G,c), which is a tour of minimum cost. For a real number r, a tour T for an instance (G,c) is *r-approximate* if $c(T)/c(\mathsf{opt}) \leq r$.

For a graph G, a *cycle* is a sequence $C = (v_0, \ldots, v_{\ell-1})$ for some $\ell \geq 3$ of pairwise distinct vertices $v_i \in V$ such that $\{v_i, v_{i+1 \pmod \ell}\} \in E$ for $i \in \{0, \ldots, \ell-1\}$. We refer to ℓ as the *length* of C, and denote it by $\ell(C)$. For an integer ℓ, an *ℓ-cycle* is a cycle of length exactly ℓ,

and an $(\leq \ell)$-*cycle* is a cycle of length at most ℓ. For the sake of convenience, we also refer to 3-, 4-, 5- and 6-cycles as triangles, squares, pentagons and hexagons, respectively.

Let C be an ℓ-cycle of G. We say that C is *short* if $\ell \leq 6$. Further, an ℓ'-cycle C' of G with $\ell' < \ell$ is a *subcycle* of C if $V(C') \subset V(C)$. Note that C and C' can visit the vertices of $V(C')$ in different order. An edge $e = \{u, u'\}$ is a *native edge* of C if u, u' are two consecutive vertices of C, and a *diagonal* of C if u, u' are two non-consecutive vertices of C. When e is a native edge or a diagonal of C, we say that e is an *internal edge* of C. Finally, we call a cycle C a *1-cycle* if $c(e) = 1$ for all $e \in E(C)$; notice that there is no confusion of this notion with ℓ-cycles as we consider simple undirected graphs without loops.

Cycle covers. Our algorithm utilizes the concept of cycle covers. A *cycle cover* of G is a collection of cycles of G such that each vertex of G belongs to exactly one cycle of the collection. Thus, a Hamiltonian cycle of G is a cycle cover of G that consists of a single cycle. Cycle covers of undirected graphs are also known as 2-factors, because every vertex is incident to exactly two edges.

A cycle cover of G is *triangle-free* if each of its cycles has a length of at least 4. An essential ingredient of our 8/7-approximation algorithm is the following result by Hartvigsen [14]; the algorithm can be implemented to run in time $O(n^3)$ for an n-vertex graph [13].

▶ **Proposition 2** ([14]). *There is an algorithm that, given a complete graph G with edge costs $c : E(G) \to \{1, 2\}$, in strongly polynomial time computes a triangle-free cycle cover of G with minimum cost under c.*

***b*-matchings.** We will use the classical notion of *b-matchings* in graphs, which are a generalization of matchings. Let H be a graph. For a vector $b = (b_v)_{v \in V(H)} \in \mathbb{N}^{|V(H)|}$ where each coordinate corresponds to a vertex of H, a *b-matching* in H is a collection of edges $E(b) \subseteq E(H)$ that contains at most b_v edges incident to any vertex $v \in V(H)$. Notice that a b-matching with $b_v = 1$ for all $v \in V(H)$ is a classical matching in H.

A b-matching in H is said to be *maximum* if among all b-matchings in H it contains a maximum number of edges. Maximum matchings as well as maximum cost b-matchings can be computed in polynomial time. We refer to Lovász and Plummer [20] for further background on b-matchings.

We are interested in computing a b-matching in a graph H where each vertex $v \in V(H)$ has a lower bound ℓ_v and an upper bound b_v - we say that a vertex v has capacity interval $[\ell_v, b_v]$; the b-matching $E(\ell, b) \subseteq E(G)$ then contains at least ℓ_v edges and at most b_v edges incident to any vertex $v \in V(H)$. Such b-matchings can also be computed efficiently:

▶ **Proposition 3** ([11]). *There is an algorithm that, given a graph H and capacity intervals $[\ell_v, b_v]$, in time $O(\sqrt{\sum_{v \in V(H)} b_v} |E(H)|)$, computes a largest subgraph H' of H for which $\ell_v \leq d_{H'}(v) \leq b_v$ for every $v \in V(H')$.*

It is possible to reduce the problem of computing a b-matching with capacity intervals to the computation of a matching in which each vertex has capacity interval $[0, 1]$ or $[1, 1]$, i.e., a matching in which every vertex with capacity interval $[1, 1]$ is required to be matched; we defer the details to the full version of the paper.

Half-edges. Intuitively, half-edges correspond to halves of the edges of a graph and incident to only one vertex of the graph. Formally, from an instance (G, c) of $(1, 2)$-TSP we construct an *extended instance* (G', c') from (G, c), as follows. We start by setting $V(G') = V(G)$ and

$E(G') = E^1(G)$, where $E^1(G)$ denotes the subset of $E(G)$ containing all 1-edges. Next, for each edge $e = \{u, u'\} \in E^1(G)$ we add to $V(G')$ a new vertex v_e, and to $E(G')$ the edges $\{u, v_e\}, \{v_e, u'\}$. We refer to the vertices v_e as *extended vertices*, and to the remaining vertices of G' as *basic vertices*. We denote the new edges of E' as *half-edges* and the other edges as *basic edges*. Put concisely, G' is the *extended graph* of G with $V(G') = V(G) \cup \{v_e \mid e \in E^1(G)\}$, $E(G') = E^1(G) \cup \{\{u, v_e\}, \{v_e, u'\} \mid e = \{u, u'\} \in E^1(G)\}$.

A *matching with half-edges* $M^{\frac{1}{2}}$ in G' is a collection of edges in G', in which each vertex has degree 0 or 1 Intuitively, a matching with half-edges in G' corresponds to a relaxation of a matching in G, where we can take halves of the edges, incident to only one vertex, to the matching. We define the cost of a matching with half-edges $M^{\frac{1}{2}}$ in G' as $c'(M^{\frac{1}{2}}) = \frac{1}{2}|\{v \in V(G) : v \text{ is matched in } M^{\frac{1}{2}}\}| + |\{v \in V(G) : v \text{ is unmatched in } M^{\frac{1}{2}}\}|$. In other words, a basic vertex that is unmatched in $M^{\frac{1}{2}}$ contributes twice as much cost to $c'(M^{\frac{1}{2}})$ as a matched basic vertex. (We might say that we treat an unmatched basic vertex as if it was matched to a half-edge of a basic 2-edge in a perfect matching with half-edges in a graph G'' in which we also add basic 2-edges and their half-edges.) Therefore, any maximum matching with half-edges in G' has minimum cost.

3 A Fast and Simple 7/6-Approximation Algorithm for (1,2)-TSP

3.1 Outline of the Algorithm

We give an outline of our 7/6-approximation algorithm for $(1, 2)$-TSP, which is listed as Algorithm 1. For an instance (G, c) of the problem and a fixed tour $\mathcal{T}$ of G, let $\alpha_{\mathcal{T}}$ and $\beta_{\mathcal{T}}$ denote the number of 1-edges and 2-edges, respectively, in $\mathcal{T}$.

▶ **Observation 4.** *It holds that* $c(\mathcal{T}) = \alpha_{\mathcal{T}} + 2\beta_{\mathcal{T}} = \alpha_{\mathcal{T}} + 2(|V(G)| - \alpha_{\mathcal{T}}) = 2|V(G)| - \alpha_{\mathcal{T}}$.

Let G_1 denote the subgraph of G containing all 1-edges. In step 1 of the algorithm we compute a path-cycle cover $\mathcal{C}_{\min}$ of minimum cost in (G, c), using the algorithm from Proposition 3. A *path-cycle cover* of G is any b-matching of G_1 such that each vertex v has capacity interval $[0, 2]$. The cost of a path-cycle cover $\mathcal{C}$ of G is defined as $2n - |\mathcal{C}|$. Let $\mathcal{C}_{\min}$ denote a minimum cost path-cycle cover of G. Then, clearly, its cost is a lower bound on $c(\mathsf{opt})$.

In step 2 we use $\mathcal{C}_{\min}$ to construct a minimum cost matching with half-edges (and some additional properties) $M^{\frac{1}{2}}$; this construction is described in Sect. 3.2. In Sect. 3.3 we describe step 3, i.e., the construction of the graph G^1 from $\mathcal{C}_{\min}$ and $M^{\frac{1}{2}}$. In step 4 we path-3-color G^1, for which we use a modification of a path-3-coloring proposed by Dudycz et al. [9] for Max-TSP.

In summary, the algorithm works as follows:

Algorithm 1 Computing a 7/6-approximate solution for an instance (G, w) of (1,2)-TSP.

Input: An instance (G, c) of (1,2)-TSP.
Output: A tour $\mathcal{T}$ of G with cost $c(\mathcal{T}) \leq \frac{7}{6}c(\mathsf{opt})$.

1: Find a minimum-cost path-cycle cover $\mathcal{C}_{\min}$ of (G, c).
2: Find a minimum cost matching with half-edges (and some additional properties) $M^{\frac{1}{2}}$.
3: Based on $\mathcal{C}_{\min}$ and $M^{\frac{1}{2}}$, construct a multigraph G^1 on vertex set $V(G)$ with at least $\frac{5}{2}\alpha_{\mathsf{opt}} - \beta_{\mathsf{opt}}$ edges of cost 1 from G.
4: Path-3-color the edges of G^1.
5: Extend the set of edges of G^1 from the largest color class arbitrarily to a tour $\mathcal{T}$ of G.
6: **return** $\mathcal{T}$

▶ **Lemma 5.** *Algorithm 1 gives a 7/6-approximate solution for (1,2)-TSP.*

Proof. Let alg be a solution output by Algorithm 1 on input (G, c), and let α_{alg} and β_{alg} be the number of 1-edges resp. 2-edges in alg. Then

$$\alpha_{\mathsf{alg}} \geq \frac{\frac{5}{2}\alpha_{\mathsf{opt}} - \beta_{\mathsf{opt}}}{3} = \frac{5}{6}\alpha_{\mathsf{opt}} - \frac{1}{3}\beta_{\mathsf{opt}} \ .$$

By multiplying by 6 and using that $n = \alpha_{\mathsf{opt}} + \beta_{\mathsf{opt}}$, we obtain

$$6\alpha_{\mathsf{alg}} \geq 7\alpha_{\mathsf{opt}} - 2n = 7\alpha_{\mathsf{opt}} - 2(\alpha_{\mathsf{opt}} + \beta_{\mathsf{opt}}) = 5\alpha_{\mathsf{opt}} - 2\beta_{\mathsf{opt}} \ .$$

Subtracting $14n$ from both sides, and substituting $2(\alpha_{\mathsf{opt}} + \beta_{\mathsf{opt}})$ for $2n$ on the right hand side yields $12n - 6\alpha_{\mathsf{alg}} \leq 14n - 7\alpha_{\mathsf{opt}}$, which is equivalent to the desired result of

$$\frac{c(\mathsf{alg})}{c(\mathsf{opt})} = \frac{2n - \alpha_{\mathsf{alg}}}{2n - \alpha_{\mathsf{opt}}} \leq \frac{7}{6} \ . \qquad \blacktriangleleft$$

3.2 Computing a Minimum Cost Matching with Half-Edges

In this section we describe the construction of a minimum-cost matching with half-edges (and some additional properties) $M^{\frac{1}{2}}$ in the extended instance (G', c'), as defined in Sect. 2. Recall that a square is a 4-cycle. We refer to a diagonal of cost i as an *i-diagonal*, for $i = 1, 2$.

Intuitively, we want to ensure that $M^{\frac{1}{2}}$ matches at least one vertex of each 1-square of $\mathcal{C}_{\min}$ with some vertex from outside the square or leaves at least one vertex of a 1-square unmatched. As we want to find such a matching $M^{\frac{1}{2}}$ efficiently, and we want the cost of $M^{\frac{1}{2}}$ to be at most $c(\mathsf{opt})/2$, we allow $M^{\frac{1}{2}}$ to contain half-edges. However, we will only allow half-edges in a controlled manner. The idea is to allow a half-edge $\{u, v_e\}$ within $M^{\frac{1}{2}}$ only when the corresponding edge e is a native edge of a 1-square of $\mathcal{C}_{\min}$. Also, we want to allow at most one half-edge per each 1-square of $\mathcal{C}_{\min}$. For technical reasons (due to parity issues), we have to relax these simple conditions to a more complex set of conditions.

▶ **Definition 6.** A matching with half-edges $M^{\frac{1}{2}}$ in (G', c') is *good* for $\mathcal{C}_{\min}$ if it satisfies the following properties.

($M^{\frac{1}{2}}$.1) For each half-edge $\{u, v_e\} \in M^{\frac{1}{2}}$, except at most one *special half-edge*, the edge e is a native edge of a 1-square of $\mathcal{C}_{\min}$. Also, each 1-square of $\mathcal{C}_{\min}$ is incident to at most one half-edge of $M^{\frac{1}{2}}$.

($M^{\frac{1}{2}}$.2) For every 1-square $C \in \mathcal{C}_{\min}$ (i) there is a 1-edge $e_C \in M^{\frac{1}{2}}$ incident to C such that the other endpoint of e_C is incident to a cycle of $\mathcal{C}_{\min}$ different from C, or (ii) at least one of the vertices of C is unmatched in $M^{\frac{1}{2}}$.

($M^{\frac{1}{2}}$.3) $M^{\frac{1}{2}}$ may contain a special half-edge $\{u, v_e\}$ only if $|V(G)|$ is odd and $\mathcal{C}_{\min}$ does not contain a 2-edge. The following conditions are satisfied for the special half-edge $\{u, v_e\}$:

- **a.** e is an edge of a fixed odd-length 1-cycle $C_0 \in \mathcal{C}_{\min}$ called a *special cycle*.
- **b.** If $\mathcal{C}_{\min}$ contains a cycle of length at least 7, then C_0 has length at least 7.
- **c.** If C_0 is a triangle or pentagon and $\mathcal{C}_{\min}$ consists of at least two cycles, then at least two vertices of C_0 are incident to external edges of $M^{\frac{1}{2}}$, or some vertex of C_0 is unmatched in $M^{\frac{1}{2}}$.

▶ **Lemma 7.** *Consider an instance (G, c) of $(1, 2)$-TSP with minimum-cost path-cycle cover $\mathcal{C}_{\min}$ and extended instance (G', c'). A matching $M^{\frac{1}{2}}$ of minimum cost among all matchings with half-edges $M^{\frac{1}{2}}$ which are good for $\mathcal{C}_{\min}$ can be computed in time $O(n^{2.5})$ where $n = |V(G)|$.*

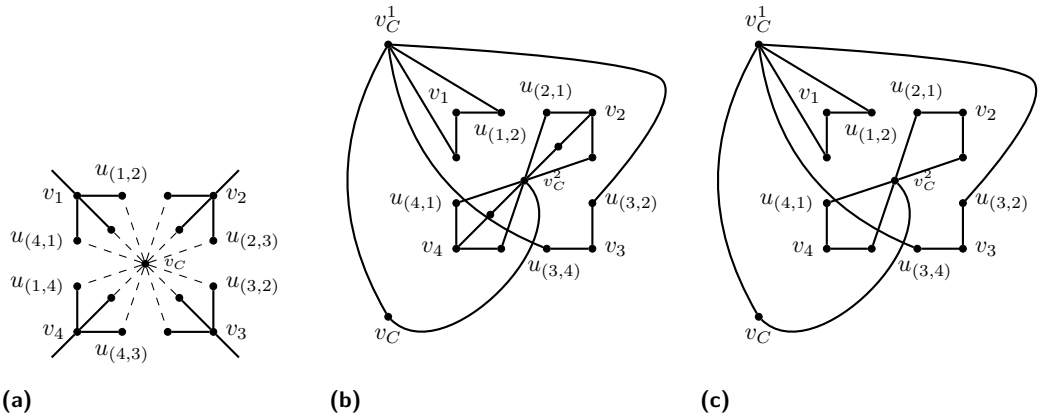

Figure 1 The gadget for modifying a 1-square $\{v_1, v_2, v_3, v_4\}$ of $\mathcal{C}_{\min}$ which has (a) two 1-diagonals, (b) one 1-diagonal $\{v_2, v_4\}$, and (c) no 1-diagonals.

Proof. First, from the instance (G, c) we create an unweighted graph G_0'' with a vertex capacity interval for each vertex of G_0''. We do that by locally and independently modifying each 1-square in $\mathcal{C}_{\min}$. The modification introduces new vertices and edges, as well as vertex capacity intervals $[\ell_v, u_v]$ for each vertex $v \in V(G_0'')$.

We start by setting $V(G_0'') = V(G)$, and assigning the capacity interval $[0, 1]$ to each vertex. For each edge $e \in E(G)$ which is not an internal 1-edge of a 1-square of $\mathcal{C}_{\min}$, we add e to $E(G_0'')$. Then, for each 1-square $C = (v_1, \ldots, v_4) \in \mathcal{C}_{\min}$ we proceed as follows. For each internal 1-edge $e_{\{i,j\}} = \{v_i, v_j\} \in E(G)$ of C (note that we consider both the native 1-edges and the 1-diagonals of C here), we introduce two new vertices $u_{(i,j)}, u_{(j,i)}$ with capacity intervals $[1, 1]$, and two new edges $\{v_i, u_{(i,j)}\}, \{u_{(j,i)}, v_j\}$. We call these added vertices *subdivision vertices*.

The exact type of further modification depends on whether the number of 1-diagonals of C in (G, c) is two, one, or zero.

- **If C has two 1-diagonals:** (See Fig. 1a) Introduce a vertex v_C of capacity interval $[9, 12]$; then connect v_C to all 12 subdivision vertices $u_{(i,j)}, u_{(j,i)}$.
- **If C has exactly one 1-diagonal $\{v_2, v_4\}$:** (See Fig. 1b) Introduce two vertices v_C^1, v_C^2 of capacity intervals $[3, 4]$ and $[5, 5]$, respectively, and one vertex v_C of capacity interval $[0, 1]$. Connect v_{C_1} to each vertex $u_{(i,j)}, u_{(j,i)}$ that is a neighbour of v_1 or v_3, and connect v_{C_2} to each vertex $u_{(i,j)}, u_{(j,i)}$ that is a neighbour of v_2 or v_4. Further, add two edges $\{v_C, v_C^1\}, \{v_C, v_C^2\}$.
- **If C is a square with no 1-diagonal:** (See Fig. 1c) Introduce two vertices v_C^1 and v_C^2 of capacity interval $[3, 3]$ and one vertex v_C of capacity interval $[0, 1]$. Connect v_{C_1} to each vertex $u_{(i,j)}, u_{(j,i)}$ that is a neighbour of v_1 or v_3, and connect v_{C_2} to each vertex $u_{(i,j)}, u_{(j,i)}$ that is a neighbour of v_2 or v_4. Further, add twoedges $\{v_C, v_C^1\}, \{v_C, v_C^2\}$.

This completes the construction of the graph G_0'' with vertex capacity intervals $[\ell_v, u_v]$ for each $v \in V(G_0'')$.

The cost of a b-matching M_0'' in G_0'' is defined as $c'(M_0'') = \frac{1}{2}|\{v \in V(G) : v \text{ is matched in } M_0''\}| + |\{v \in V(G) : v \text{ is unmatched in } M_0''\}|$. For the graph G_0'' and vertex capacity intervals $[\ell_v, u_v]$ for each $v \in V(G_0'')$, we compute a minimum-cost b-matching M_0'' that respects the vertex capacity intervals or, equivalently a b-matching that respects the vertex capacity intervals and minimizes the number of basic vertices unmatched in M_0''.

▶ **Claim 1.** *For the graph G_0'' and vertex capacity intervals $[\ell_v, u_v]$ for each $v \in V(G_0'')$, a minimum-cost b-matching M_0'' that respects the vertex capacity intervals can be computed in $O(n^{2.5})$ time.*

We defer the proof of Claim 1 to the full version of this paper.

▶ **Claim 2.** *The b-matching M_0'' in G_0'' can be transformed into a matching with half-edges $M^{\frac{1}{2}}$ which is good for $\mathcal{C}_{\min}$, has the same cost as M_0'', and contains no special half-edge.*

Proof of Claim 2. We construct the matching $M^{\frac{1}{2}}$ as follows. For any edge $e = \{u, v\} \in E(G_0'')$ such that both u, v are basic vertices of G_0'' (i.e., they correspond to the vertices of G, and not to the vertices introduced during the gadget construction), we add the edge e to $M^{\frac{1}{2}}$. Then, consider each 1-square $C = \{v_1, .., v_4\} \in \mathcal{C}_{\min}$ and a gadget corresponding to it. If there are some two vertices $v_i, v_j \in C$ such that both v_i and v_j are matched by the b-matching with subdivision vertices, and the edge $e = \{v_i, v_j\}$ in G' is a 1-edge, we add e to $M^{\frac{1}{2}}$. We construct such pairings greedily. For all vertices v_i which are matched by the b-matching with subdivision vertices, and which have not been paired, we add a half-edge $\{v_i, v_e\}$ to $M^{\frac{1}{2}}$, where $e = \{v_i, v_{(i \mod 4)+1}\}$.

The degree of each basic vertex $v \in V(G_0'')$ in $M^{\frac{1}{2}}$ is the same as the degree of v in the b-matching. The degree of each extended vertex $v \in V(G_0'')$ in $M^{\frac{1}{2}}$ is either 0 or 1. Therefore, $M^{\frac{1}{2}}$ is a matching with half-edges. Also, is it easy to see that the cost of $M^{\frac{1}{2}}$ is the same as the cost of the b-matching. We now have to prove that $M^{\frac{1}{2}}$ is good for $\mathcal{C}_{\min}$. As we did not denote any half-edge of $M^{\frac{1}{2}}$ as special, we only need to check properties 1 and 2 of Definition 6.

Consider a 1-square $C = \{v_1, \ldots, v_4\} \in \mathcal{C}_{\min}$. From the gadgets construction we can see that the vertex capacities for v_C, v_C^1, v_C^2 enforce that at most three of the vertices $\{v_1, \ldots, v_4\}$ are matched with a subdivision vertex. Therefore, at least one of the vertices $\{v_1, \ldots, v_4\}$ is matched by the b-matching via an edge not belonging to the gadget, i.e., an external 1-edge or at least one vertex of C is unmatched in M_0''. Therefore, Property 2 holds.

From the construction of $M^{\frac{1}{2}}$, each half-edge of $M^{\frac{1}{2}}$ corresponds to a native edge $e = \{v_i, v_{(i \mod 4)+1}\}$ of a 1-square. To prove Property 1, we need to show that each 1-square $C \in \mathcal{C}_{\min}$ is incident to at most one half-edge. We already know that at most three of the vertices $\{v_1, \ldots, v_4\}$ of C are matched with a subdivision vertex. If there are three, some two of them are incident to neighboring vertices of C, and will be transformed into one native edge in $M^{\frac{1}{2}}$, which will result in only one half-edge of $M^{\frac{1}{2}}$ incident to C. If exactly two of the vertices $\{v_1, \ldots, v_4\}$ of C were matched with a subdivision vertex, they yield two half-edges within $M^{\frac{1}{2}}$ only if they are incident with the opposite corners of C, and the corresponding diagonal has cost 2. We show that the construction of the gadgets prevents this from happening.

First, consider the case when C has no 1-diagonal, see Fig. 1c. Assume, without loss of generality, that exactly the vertices v_1, v_3 are matched by the b-matching with the subdivision vertices. Then, as the capacity interval of v_C^1 is $[3, 3]$, and the capacity interval of v_C is $[0, 1]$, v_C must be matched with v_C^1, and v_C^1 must be matched with 2 of the subdivision vertices. Then, as the capacity interval of v_C^2 is $[3, 3]$, v_C^2 must be matched with 3 subdivision vertices. But that leaves one subdivision vertex unmatched, and it therefore cannot happen.

Now, consider the case when C has exactly one 1-diagonal $\{v_2, v_4\}$, see Fig. 1b. Assume that exactly the vertices v_1, v_3 are matched by the b-matching with the subdivision vertices. Then, by the capacity intervals of v_C^1 and v_C, again v_C must be matched with v_C^1, and v_C^1 must be matched with 2 of the subdivision vertices. Then, as the capacity interval of v_C^2 is $[5, 5]$, v_C^2 must be matched with 5 subdivision vertices. But that leaves one subdivision vertex unmatched, and it therefore cannot happen.

Each 1-square of $\mathcal{C}_{\min}$ is incident to at most one half-edge, and therefore Property 1 holds and the matching $M^{\frac{1}{2}}$ is good. This completes the proof of Claim 2. ◀

▶ **Claim 3.** *Any matching with half-edges $M^{\frac{1}{2}}$ which is good for $\mathcal{C}_{\min}$ and contains no special half-edge can be transformed into a b-matching M_0'' in G_0'' of the same cost.*

Proof of Claim 3. Consider a matching with half-edges $M^{\frac{1}{2}}$ which is good for $\mathcal{C}_{\min}$ and contains no special half-edge. We will construct a corresponding b-matching for $M^{\frac{1}{2}}$. For any edge $e = \{u, v\} \in M^{\frac{1}{2}}$ which is not a half-edge or a 1-edge of a 1-square, e is also present in the graph G_0'', and we add e to the b-matching. Now, consider any half-edge $\{u, v_e\} \in M^{\frac{1}{2}}$, where $e = \{u, u'\}$. From Property 1 of Definition 6, e is a native edge of a square $C \in \mathcal{C}_{\min}$. In the b-matching, we connect u with any subdivision edge neighbouring with it. Last, for any edge $\{u_i, u_j\}$ which is a 1-edge of a 1-square, we take the two edges $\{u_i, u_{(i,j)}\}$ and $\{u_{(j,i)}, u_j\}$ into the b-matching. From Property 2 of Definition 6, at most 3 subdivision edges corresponding to any 1-square $C \in \mathcal{C}_{\min}$ have been matched by this procedure. Moreover, if there were two or three, then some two of them must be incident to two endpoints of a 1-edge of C (either a native edge, or a diagonal).

We now show how to extend this matching to a b-matching. For any 1-square $C \in \mathcal{C}_{\min}$ with two 1-diagonals, we match v_C with the at least 9 unmatched subdivision vertices.

This completes the proof of Claim 3. ◀

If $|V(G)|$ is odd and $\mathcal{C}_{\min}$ contains only 1-edges, we also build another unweighted graph G_1'' from G', in which we find a b-matching M_1''. The graph G_1'' is quite similar to G_0''. The details of constructing G_1'' and computing M_1'' are given in the full version.

From M_1'' we obtain a matching $M_1^{\frac{1}{2}}$ with half-edges good for $\mathcal{C}_{\min}$. If $|V(G)|$ is odd and $\mathcal{C}_{\min}$ does not contain any 2-edge, we set as $M^{\frac{1}{2}}$ that one of the matching $M^{\frac{1}{2}}$ and $M_1^{\frac{1}{2}}$ that has smaller cost. This completes the proof. ◀

▶ **Lemma 8.** *Any minimum-cost matching $M^{\frac{1}{2}}$ of (G', c') that is good for $\mathcal{C}_{\min}$ satisfies $c'(M^{\frac{1}{2}}) \leq c(\mathsf{opt})/2$.*

Proof. Let (G'', c'') denote the extension of the graph G, in which we add two half-edges of each edge of G, also those of cost 2. Each edge e of G has cost $c''(e) = c(e)$ in G''. Each half-edge of a 1-edge $e \in G$ has cost $\frac{1}{2}$ and each half-edge of a 2-edge $e \in G$ has cost 2. The cost of a matching M in G'' is defined in the usual way as $c''(M) = \sum_{e \in M} c''(e)$. We notice that for any matching M in G'' it holds $c''(M) = c'(M')$, where $M' = M \cap E(G')$.

To prove the lemma, we partition the edges of a fixed but arbitrary tour opt of minimum cost in (G, c) into two perfect matchings $M_1 \cup M_2$ in (G'', c'') with half-edges, each of which constitutes in (G', c') a matching with half-edges, which is good for $\mathcal{C}_{\min}$.

To this end, let $\mathcal{S}_2$ denote the set of squares in $\mathcal{C}_{\min}$ such that opt uses two of its internal 1-edges. Similarly, let $\mathcal{S}_3$ denote the set of squares in $\mathcal{C}_{\min}$ such that opt uses three of its internal 1-edges. Let us note that if $\mathcal{S}_2 \cup \mathcal{S}_3 \neq \emptyset$, then partitioning opt into two perfect matchings might yield a matching or matchings that are not good for $\mathcal{C}_{\min}$. Therefore, for each square $C \in \mathcal{S}_2 \cup \mathcal{S}_3$, we take one of its internal 1-edges e_C belonging to opt, and split e_s into two half-edges. For each such edge e_C, we place one of its half-edges into M_1 and place its other half-edge into M_2.

If the parities of $|\mathcal{S}_2 \cup \mathcal{S}_3|$ and $|V(G)|$ are the same, then this way we have already decomposed opt into two perfect matchings with half-edges M_1 and M_2. Assume, without loss of generality, that $c'(M_1) \leq c'(M_2)$. From M_1 we construct a matching M' in G'. We first initialize $M' = M_1$. This way, the condition $c'(M') \leq c'(\mathsf{opt})/2$ is clearly satisfied.

However, M' potentially is not a perfect matching with half-edges, as it might contain a half-edge of a diagonal of a square $C \in \mathcal{S}_2$. We can, however, replace such a half-edge with a half-edge of an edge of C, without increasing the cost of M'.

If the parities of $|\mathcal{S}_2 \cup \mathcal{S}_3|$ and $|V(G)|$ differ and opt uses a 2-edge, then we choose any such 2-edge $e \in \mathsf{opt}$ and split it into two half-edges. Otherwise, if $\mathcal{S}_2 \cup \mathcal{S}_3$ is empty, $|V(G)|$ is odd. Then any path-cycle cover of G must contain at least one odd cycle C. We split any edges of opt which is incident to a vertex of C into two half-edges. We decompose opt into two perfect matchings M_1 and M_2. Since $c'(M_1) = c'(M_2)$, we may choose that one which contains a half-edge incident to a vertex of C.

The remaining case is when the parities of $|\mathcal{S}_2 \cup \mathcal{S}_3|$ and $|V(G)|$ differ, each edge of opt has cost 1 and $\mathcal{S}_2 \cup \mathcal{S}_3$ is non-empty. Then we choose one square $C \in S_2 \cup S_3$ and do not split any of its edges. At least one of the perfect matchings M_1, M_2 from the decomposition of opt is such that it does not use two internal edges of C. Since again $c'(M_1) = c'(M_2)$, we may choose that one, which does not use two internal edges of C. ◀

3.3 Constructing the Multigraph

We will now construct a multigraph G^1 from the path-cycle cover $\mathcal{C}_{\min}$, and the minimum-cost matching $M^{\frac{1}{2}}$ that is good for $\mathcal{C}_{\min}$. We set $V(G^1) = V(G)$. The idea is to take into G^1 two copies of each 1-edge of $\mathcal{C}_{\min}$, and one copy of each 1-edge and of each 1/2-half-edge of $M^{\frac{1}{2}}$. However, to ensure that we will be able to color the graph at a later stage, and as we do not have the extended vertices v_e in $V(G^1)$ to accommodate half-edges, we first need to modify the matching $M^{\frac{1}{2}}$ into a collection of edges M. The set M does not have to be a matching—it may contain multiple edges incident to the same vertex, and even multiple copies of the same edge of G. Also, we need to ensure that the multigraph G^1 has at least $\frac{5}{2}\alpha_{\mathsf{opt}} - \beta_{\mathsf{opt}}$ edges of cost 1 in (G, c), i.e., that the set M has at least $\frac{1}{2}\alpha_{\mathsf{opt}} - \beta_{\mathsf{opt}}$ edges of cost 1 in (G, c).

We start by setting M to be the collection of edges and half-edges of $M^{\frac{1}{2}}$. Then we modify M by executing the following sequence of steps:

(O1) For every 1-triangle (u, v, w) of $\mathcal{C}_{\min}$ for which $\{u, v\} \in M$ and $\{w, t\} \in M$ for some t, we remove the edge $\{u, v\}$ from M, and instead we add a second copy of $\{w, t\}$ into M. Notice that if we perform a similar operation with the cycle of $\mathcal{C}_{\min}$ containing the vertex t, it will result in the third copy of $\{w, t\}$ being added to the graph.

(O2) For every 1-triangle (u, v, w) of $\mathcal{C}_{\min}$ for which $\{u, v\} \in M$ and w is unmatched in M, we remove the edge $\{u, v\}$ from M.

(O3) For every 1-square (u, v, w, z) of $\mathcal{C}_{\min}$ for which $\{u, v\}, \{w, v_e\} \in M$ and $\{z, t\} \in M$ for some t, we remove $\{w, v_e\}$ from M, and instead we add a second copy of $\{z, t\}$ into M. Notice that in this case we really need half of the additional edge $\{z, t\}$, so if we perform such operation twice for $\{z, t\}$ (i.e., the component containing t is also a 1-square), we have to add only one, and not two copies of $\{z, t\}$. We also perform the same operation if $\{u, v\}$ is a diagonal, and not a native edge of the square.

(O4) For every 1-square (u, v, w, z) of $\mathcal{C}_{\min}$ for which $\{u, v\}, \{w, v_e\} \in M$ and z is unmatched in M, we remove the half-edge $\{w, v_e\}$ from M. As before, we perform the same operation if $\{u, v\}$ is a diagonal, and not a native edge of the square.

(O5) For every 1-square (u, v, w, z) of $\mathcal{C}_{\min}$ for which $\{u, v_e\} \in M$ and no other edge or diagonal of the square (or its half) is in M, we remove $\{u, v_e\}$ from M and instead we add $\{u, v\}$ into M where $e = \{u, v\}$.

(O6) If the matching M contains a special half-edge $\{u, v_e\}$, then we add e to M.

After these operations, there are no half-edges left in M. We now construct the multigraph G^1 by setting $V(G^1) = V(G)$, and by adding to G^1 two copies of each 1-edge of $\mathcal{C}_{\min}$ and all edges of M. We can show a lower bound on the number of edges of G^1.

▶ **Lemma 9.** *The multigraph G^1 has at least $\frac{5}{2}\alpha_{\mathsf{opt}} - \beta_{\mathsf{opt}}$ edges which are 1-edges of (G, c).*

Proof. The minimum-cost path-cycle cover $\mathcal{C}_{\min}$ contains at least α_{opt} edges of cost 1 in (G, c). Therefore, two copies of $\mathcal{C}^1_{\min}$ contain at least $2\alpha_{\mathsf{opt}}$ edges. The matching $M^{\frac{1}{2}}$ has cost at most $c(opt)/2$. Therefore, the number of 1-edges in $M^{\frac{1}{2}}$ is at least $\alpha_{\mathsf{opt}}/2$, where half-edges count as half of an edge each. We further have that $\beta_{\mathsf{opt}} \geq \beta_M$, where β_M denotes the number of basic verices unmatched in $M^{\frac{1}{2}}$.

The only modifications that decrease the number of edges in G^1 are operations 2 and 4. However, for each triangle or square for which we remove one 1-edge or 1/2-half-edge, we can uniquely charge it to an unmatched basic vertex. Thus, the number of such deletions is at most β_M and can be charged against β_{opt}. Consequently, we always have at least $\frac{5}{2}\alpha_{\mathsf{opt}} - \beta_{\mathsf{opt}}$ edges in the resulting multigraph G^1. ◀

The multigraph G^1 can be essentially path-3-colored using the path-3-coloring procedure by Dudycz et al. [9]. The multigraph colored by Dudycz et al. [9] is built from two copies of a maximum-cost cycle cover and a maximum cost perfect matching. Several not very serious modifications are needed in order to deal with double and triple edges of M; note that the existence of such edges means that some vertices in G^1 have degree greater than 5. Again, details are deferred to the full version of the paper.

4 A New 8/7-Approximation Algorithm for (1,2)-TSP

The 8/7-approximation algorithm is quite similar to the algorithm with an approximation factor of 7/6. Instead of a minimum-cost path-cycle cover $\mathcal{C}_{\min}$ of (G, c) we use a minimum-cost *triangle-free* cycle cover $\mathcal{C}^t_{\min}$. We also compute a minimum-cost matching $M^{\frac{1}{2}}$ with half-edges with additional properties. To obtain an 8/7-approximation, $M^{\frac{1}{2}}$ has to additionally satisfy the condition that for every 1-hexagon C from $\mathcal{C}^t_{\min}$ at least one of the vertices of C must be incident to an external edge of $M^{\frac{1}{2}}$ or be unmatched in $M^{\frac{1}{2}}$. Next, we build a multigraph G^1 that consists of three copies of $\mathcal{C}^t_{\min}$ and one copy of $M^{\frac{1}{2}}$. We do some flipping of edges and half-edges and path-4-color the multigraph G^1. Path-4-coloring is based on the same ideas as path-3-coloring but is a little more complicated. We defer the details to the full version of this paper.

Abstract

Let $T = \{\triangle_1, \ldots, \triangle_n\}$ be a set of of n pairwise-disjoint triangles in $\mathbb{R}^3$, and let B be a convex polytope in $\mathbb{R}^3$ with a constant number of faces. For each i, let $C_i = \triangle_i \oplus r_i B$ denote the Minkowski sum of $\triangle_i$ with a copy of B scaled by $r_i > 0$. We show that if the scaling factors $r_1, \ldots, r_n$ are chosen randomly then the expected complexity of the union of $C_1, \ldots, C_n$ is $O(n^{2+\varepsilon})$, for any $\varepsilon > 0$; the constant of proportionality depends on ε and the complexity of B. The worst-case bound can be $\Theta(n^3)$.

We also consider a special case of this problem in which T is a set of points in $\mathbb{R}^3$ and B is a unit cube in $\mathbb{R}^3$, i.e., each C_i is a cube of side-length $2r_i$. We show that if the scaling factors are chosen randomly then the expected complexity of the union of the cubes is $O(n \log^2 n)$, and it improves to $O(n \log n)$ if the scaling factors are chosen randomly from a "well-behaved" probability density function (pdf). We also extend the latter results to higher dimensions. For any fixed odd value of d, we show that the expected complexity of the union of the hypercubes is $O(n^{\lfloor d/2 \rfloor} \log n)$ and the bound improves to $O(n^{\lfloor d/2 \rfloor})$ if the scaling factors are chosen from a "well-behaved" pdf. The worst-case bounds are $\Theta(n^2)$ in $\mathbb{R}^3$, and $\Theta(n^{\lceil d/2 \rceil})$ in higher dimensions.

1 Introduction

We advance the state of the art regarding the complexity of the union of combinatorial objects in dimensions $d \geq 3$ beyond worst-case analysis. To that end we study the union complexity of Minkowski sums of pairwise disjoint triangles with a randomly scaled copies of a fixed convex polytope, and Minkowski sums of points with cubes of random sizes. We hope that our techniques will be useful in future studies of such stochastic arrangements.

Specifically, let $T = \{\triangle_1, \ldots, \triangle_n\}$ be a collection of n pairwise-disjoint triangles in $\mathbb{R}^3$, and let B be a fixed convex polytope in $\mathbb{R}^3$ with a constant number of faces. We consider the setup where we are given a sequence $\mathbf{r} = \langle r_1, \ldots, r_n \rangle$ of non-negative scaling factors (or *sizes*), and we let $C_i = \triangle_i \oplus r_i B$ denote the Minkowksi sum of $\triangle_i$ with a copy of B scaled by r_i, for $i = 1, \ldots, n$. Each C_i is a convex polytope with a constant number of faces. Let $\mathcal{C} = \{C_1, \ldots, C_n\}$, and let $\mathcal{U} = \mathcal{U}(T, \mathbf{r}) = \bigcup_{i=1}^{n} C_i$ denote their union. We also use $\mathcal{U}(\mathcal{C})$ to denote $\mathcal{U}(T, \mathbf{r})$.

The *combinatorial complexity* of $\mathcal{U}$ is the total number of faces of all dimensions on the boundary $\partial\mathcal{U}$ of $\mathcal{U}$. Each vertex of $\partial\mathcal{U}$ is a vertex of some set C_i, an intersection point between an edge of some C_i and a face of another C_j, or an intersection point of three faces of three distinct C_i's. By Euler's formula, the overall complexity of $\partial\mathcal{U}$ is proportional to the number of vetices on $\partial\mathcal{U}$. Therefore we measure the combinatorial complexity of $\mathcal{U}$ by the number of its vertices, and denote this quantity by $\psi(T, \mathbf{r})$.

Our goal is to obtain an upper bound on the *expected* value of $\psi(T, \mathbf{r})$, under a suitable stochastic model for choosing the scaling factors $\mathbf{r}$ for the members of $\mathcal{C}$. We refer to this problem as the *stochastic Minkowski-sum union* problem. Our expected bounds are significantly better than the worst case bounds (for any such union), indicating that inputs which are not adversarial are likely to have lower union complexity.

Another motivation for our analysis is for an efficient computation of the most vulnerable location of an attack in a three-dimensional scene. Concretely, we use the model where we have a scene consisting of objects, modeled as a collection of pairwise disjoint triangles. An attack occurs at some point, and the probability of a triangle to be hit decreases as its distance from the attacking point increases (up to some threshold). We want to compute a point of attack in which we maximize the expected number of triangles that we hit. The same technique to approximately solve this problem, as done in the planar case [1, 2], leads to questions about the complexity of the union of Minkowski sums of the input triangles with balls of random radii. The case studied here replaces the ball by a convex polytope, which we choose to approximate the Euclidean ball. The results obtained in this paper lead to improved solution to the vulnerability problem, by roughly one factor of n.
We consider two stochastic models for choosing the sequence $\mathbf{r} = \langle r_1, \ldots, r_n \rangle$ of scaling factors:

The density model. We are given an arbitrary probability density (or mass) function (pdf) π over the non-negative reals; for each $1 \leq i \leq n$, we take r_i to be a random value drawn independently from the distribution determined by π.

The permutation model. We are given a sequence $\Theta = \langle \theta_1, \ldots, \theta_n \rangle$ of n arbitrary non-negative real numbers, with $\theta_1 \leq \theta_2 \leq \cdots \leq \theta_n$. We draw a random permutation σ on $[1 : n]$, where all permutations are equally likely to be chosen, and assign $r_i := \theta_{\sigma(i)}$ to $\triangle_i$, for each $i = 1, \ldots, n$.

For the density model, let $\psi(T, \pi)$ denote the expected value of $\psi(T, \mathbf{r})$, where the expectation is taken over the random choices of $\mathbf{r}$, drawn from π in the manner specified above. Set $\psi(n) = \max \psi(T, \pi)$, where the maximum is taken over all probability density (mass) functions and over all sets T of n pairwise-disjoint triangles in $\mathbb{R}^3$. For the permutation model, in an analogous manner, we let $\psi(T, \Theta)$ denote the expected value of $\psi(T, \mathbf{r})$, where the expectation is taken over the choices of $\mathbf{r}$, obtained by randomly shuffling the members of Θ. Then, with a slight overloading of the notation, we define $\psi(n) = \max \psi(T, \Theta)$, where the maximum is over all possible choices of the multi-set Θ and over all sets T of n pairwise-disjoint triangles in $\mathbb{R}^3$. Our goal is to prove sharp bounds on $\psi(n)$ under these two models.

As noted in [2], the permutation model is more general than the density model, in the sense that an upper bound on $\psi(n)$ in the permutation model immediately implies the same bound on $\psi(n)$ in the density model. Although we mostly focus on the permutation model, we also show that some of our bounds can be improved, by a logarithmic factor, in the density model if the underlying pdf is "well behaved," in a sense to be made precise below.

Related work. There is extensive work on bounding the complexity of the union of a set of geometric objects, especially in $\mathbb{R}^2$ and $\mathbb{R}^3$, and optimal or near-optimal bounds have been obtained for many interesting cases. We refer the reader to the survey paper by Agarwal *et al.* [18] for a comprehensive summary of most of the known results on this topic.

The complexity of the union of n arbitrary shapes of constant complexity in $\mathbb{R}^2$ is $\Theta(n^2)$, but the bound improves to near linear for a large class of well behaved planar objects; see [18]. Analogously, the complexity of the union of n arbitrary shapes of constant complexity in $\mathbb{R}^3$ is $\Theta(n^3)$. Over more than a decade, a series of papers have considered geometric objects in $\mathbb{R}^3$ that have some special properties, and derived *near-quadratic* bounds on the complexity of their union. These cases include: a family of arbitrary convex polytopes[4] [8], a family of cylinders (of arbitrary radii) [12], (arbitrarily aligned) congruent cubes in three dimensions [19], a family of fat tetrahedra [13], a family of κ-round objects [4], and Minkowski sums of a family of pairwise-disjoint convex polytopes with a fixed convex polytope [7] or with a fixed ball [3]. Quadratic lower bounds are known for all these cases.

The case of the union of axis-parallel cubes is a highly-structured special instance. If the cubes are *isothetic* (that is, they are all congruent), the complexity of their union is[5] $O(n)$. In dimension d, Boissonnat *et al.* [10] proved that the complexity of the union of n isothetic hypercubes is $\Theta\left(n^{\lfloor d/2 \rfloor}\right)$. If the hypercubes are (axis-parallel but) of arbitrary sizes, the complexity of their union is $\Theta\left(n^{\lceil d/2 \rceil}\right)$ in $\mathbb{R}^d$. These two bounds coincide for even values of d, but there is a gap, by a factor of d, for odd values of d.

There is a rich literature on bounding the complexity of geometric structures under a stochastic model in which the locations of points are drawn randomly from a distribution; see [14, 20, 21] and references therein. The complexity of the union of a set of objects in a semi-stochastic model, in which the locations of the objects were arbitrary but their scaling factors were chosen randomly, was first studied by the authors (with Har-Peled) in [2]. They investigated two planar variants of the stochastic Minkowski-sum union problem. In the first variant, one is given a set S of n pairwise-disjoint line segments in $\mathbb{R}^2$, and one replaces each $e \in S$ by the Minkowski sum $e \oplus r_i B$, where B is the unit disk and the scaling factors r_i are

[4] Here the bound is cubic in the number of polytopes but is only near linear in the number of facets.

[5] In contrast, the complexity of the union of congruent balls in $\mathbb{R}^3$ is quadratic in the worst case; see, e.g., [18].

randomly chosen under either of the above two models. It is shown in [2] that the expected complexity of the union of these sums is $O(n \log n)$. In the second variant, S is a collection of arbitrary pairwise-disjoint convex sets (of constant complexity) in the plane, and then the expected complexity of the union of the corresponding random Minkowski sums (again, with randomly scaled copies of the unit disk) is shown in [2] to be $O(n^{1+\varepsilon})$, for any $\varepsilon > 0$. In both cases, the bounds are a significant improvement over the worst case quadratic bound, and almost match the linear upper bound when all scaling factors are equal—the Minkowski sums then form a collection of *pseudo-disks*. Here we study related random arrangements in higher dimensions, a situation that required some new ideas in order to apply some exisiting techniques.

In a different, but closely related context, Har-Peled and Raichel [16] proved that the expected complexity of the multiplicatively weighted Voronoi diagram of a set of points or line segments in $\mathbb{R}^2$ is $O(n \operatorname{polylog}(n))$ if the weights are randomly chosen under the permutation model.[6] Recall that if the weights are arbitrarily chosen, then the worst-case complexity of the weighted Voronoi diagram is quadratic [9]. Chang *et al.* [11] studied various generalizations of multiplicatively weighted Voronoi diagrams and proved sharp bounds on their expected complexity.

Our results. We have two main results in this paper:

Union of hypercubes. We first study (in Section 2) the interesting special case of the stochastic Minkowski-sum union problem in which each triangle is a point in $\mathbb{R}^3$ and B is an axis-aligned cube in $\mathbb{R}^3$ of side-length 2. That is, we have a set $P = \{p_1, \ldots, p_n\}$ of n points in $\mathbb{R}^3$, and $B = \{x \in \mathbb{R}^3 \mid \|x\|_\infty \leq 1\}$, and for each $i \leq n$, $C_i = r_i B + p_i$ is a cube of side-length $2r_i$ centered at p_i. In other words, we study the complexity of the union of n cubes C_i each having a random (according to each of our models) L_∞ diameter and a fixed center. In fact, we study this problem not only in $\mathbb{R}^3$ but in $\mathbb{R}^d$ for general d. The reader should note that all our definitions (e.g. of $\psi(P, \Theta)$) extend to $\mathbb{R}^d$. Hypercubes in $\mathbb{R}^d$ arise in many applications and the following result indicates that if their diameters are not chosen in an adversarial manner then the complexity of their union is likely to be smaller than the worst case, by nearly a factor of n. Specifically, we prove:

▶ **Theorem 1.1.** *Let P be a set of n points in $\mathbb{R}^d$, let B be the axis-aligned hypercube of side-length 2 in $\mathbb{R}^d$ centered at the origin, and let Θ be a multi-set of scaling factors. Under the permutation model, $\psi(P, \Theta) = O(n \log^2 n)$ for $d = 3$, and $\psi(P, \Theta) = O(n^{\lfloor d/2 \rfloor} \log n)$ for any fixed odd value of $d > 3$. The same bounds hold for the density model.*

Tame distributions. We call a pdf π, with Π as its cdf (cumulative distribution function), *tame* if for every $x > 0$ and for every integer $k \geq 0$,

$$1 - \Pi(kx) \leq (1 - \Pi(x))^k. \tag{1}$$

It is an easy exercise to verify that (1) is satisfied for a large class of pdfs, including uniform, exponential, (one-sided) normal, and log-normal distributions. If the scaling factors are chosen from a tame pdf, then the bounds can be improved by a logarithmic factor:

▶ **Theorem 1.2.** *Let P be a set of n points in $\mathbb{R}^d$, and let B be the hypercube of side-length 2 centered at the origin. If the scaling factors are drawn randomly from a tame pdf π, then $\psi(P, \pi) = O(n \log n)$ for $d = 3$ and $\psi(P, \pi) = O(n^{\lfloor d/2 \rfloor})$ for any fixed odd value of $d > 3$.*

---

[6] Given a point set $P = \{p_1, \ldots, p_n\}$ and a weight $w_i > 0$ for each point p_i, the Voronoi cell of p_i in the multiplicatively weighted Voronoi diagram is $\{x \in \mathbb{R}^d \mid w_i \|x - p_i\| \leq w_j \|x - p_j\| \, \forall j \leq n\}$.

By Theorems 1.1 and 1.2, the expected complexity of the union of a set of axis-aligned hypercubes, whose sizes are chosen randomly, is almost the same as when their sizes are equal. The overall structure of the proof of both theorems is the same, and consists of two stages. The first stage bounds the expected number of *outer* vertices on the union, i.e., the vertices that lie on a $(d-2)$-face or a lower-dimensional face of one of the hypercubes. This is where we had to develop a new technique to exploit the randomness of the input. The second stage then obtains a bound on the number of *inner* vertices, namely vertices formed by the intersection of d facets of d distinct hypercubes, by adapting the argument in [10] and using the bound, derived earlier, on the expected number of outer vertices.

The stochastic Minkowski-sum union problem. Next, we study (in Section 3) the general case in which T is a set of pairwise disjoint triangles in $\mathbb{R}^3$ and B is a convex polytope in $\mathbb{R}^3$ with $O(1)$ faces, and prove the following near-quadratic upper bound:

▶ **Theorem 1.3.** *Let T be a collection of n pairwise-disjoint triangles in $\mathbb{R}^3$, let Θ be a multi-set of scaling factors, and let B be a convex polytope with $O(1)$ vertices. Then the value of $\psi(T,\Theta)$ under the permutation model is $O(n^{2+\varepsilon})$, for any fixed constant $\varepsilon > 0$; the constant of proportionality depends on ε and the complexity of B. The same bound holds for the density model.*

If all sizes r_i are equal, the complexity of $\mathcal{U}$ is $O(n^2 \log n)$ [7], where the constant of proportionality depends on the complexity of B. On the other hand, for a bad layout of the triangles of T and a bad (non-random) choice of sizes, the complexity of $\mathcal{U}$ can be $\Theta(n^3)$; see Section 3 for a lower-bound construction. (The bound in Theorem 1.3 is coarse enough so that drawing the scaling factors from a tame pdf does not seem to affect it.

2 Union of Hypercubes

In this section we prove Theorems 1.1 and 1.2. For a point $x \in \mathbb{R}^d$, we use $\|x\|_\infty$ to denote the L_∞-norm of x. For a compact set $S \subset \mathbb{R}^d$, let $d_\infty(x,S) = \min_{y\in S} \|x-y\|_\infty$. A hypercube C of L_∞-*radius* (or *radius* for brevity) r centered at c is the set $C = \{x \in \mathbb{R}^d \mid \|x-c\|_\infty \le r\}$; the *side-length* of this hypercube is $2r$. Let $P = \{p_1, \ldots, p_n\}$ be a set of n points in $\mathbb{R}^d$, and let B be the (axis-aligned) hypercube of radius 1 centered at the origin. Given a sequence $\mathbf{r} = \langle r_1, \ldots, r_n\rangle$ of non-negative scaling factors, we define, for each $i \le n$, $C_i = r_i B + p_i$ to be a hypercube of radius r_i centered at p_i. Let $\mathcal{C} = \{C_1, \ldots, C_n\}$, and let $\mathcal{U} = \mathcal{U}(\mathcal{C}) = \bigcup_{i=1}^n C_i$ denote the union of the hypercubes.

For simplicity, we assume that the hypercubes of $\mathcal{C}$ are in *general position*, in the sense that no two facets of any pair of hypercubes lie in a common hyperplane. This assumption is made only to simplify the analysis, and the general, possibly degenerate case can be reduced to the general-position setup by means of a suitable small perturbation.

A vertex v in the arrangement $\mathcal{A}(\mathcal{C})$ of $\mathcal{C}$ is the intersection of d facets of the hypercubes in $\mathcal{C}$ and each of these facets is orthogonal to a different coordinate axis. These facets need not belong to distinct hypercubes. We refer to v as an *inner* vertex if the d facets on which it lies belong to d distinct hypercubes, and as an *outer* vertex if at least two of these facets belong to the same hypercube. The *level* of v is j if it lies in the interior of exactly j hypercubes of $\mathcal{C}$; the level of every vertex on $\partial\mathcal{U}$ is 0. For $j \ge 0$, let $\mathcal{I}_j(\mathcal{C})$ (resp. $\mathcal{O}_j(\mathcal{C})$) denote the number of inner (resp. outer) vertices at level j in $\mathcal{A}(\mathcal{C})$.

If the sequence $\mathbf{r}$ of scaling factors is chosen randomly, using either the permutation model or the density model, $\mathcal{I}_j(\mathcal{C})$ and $\mathcal{O}_j(\mathcal{C})$ are random variables. For a sequence Θ of scaling factors, let $\bar{\mathcal{I}}_j(P,\Theta) = \mathsf{E}[\mathcal{I}_j(\mathcal{C})]$ denote the expected value of $\mathcal{I}_j(\mathcal{C})$ in the permutation

model, over a random permutation of Θ. For any $n > 0$ and for any $j \leq n - d$, let $\bar{\mathcal{I}}_j(n) = \max \bar{\mathcal{I}}_j(P, \Theta)$ denote the expected number of inner vertices of level j under the permutation model, where the maximum is taken over all point sets of size n. We define $\bar{\mathcal{O}}_j(P, \Theta)$ and $\bar{\mathcal{O}}_j(n)$ similarly. By definition (recall the terminology introduced earlier), $\psi(P, \Theta) = \bar{\mathcal{I}}_0(P, \Theta) + \bar{\mathcal{O}}_0(P, \Theta)$ and $\psi(n) \leq \bar{\mathcal{I}}_0(n) + \bar{\mathcal{O}}_0(n)$.

Finally, in the density model, which we use explicitly only when the scaling factors are chosen randomly from a tame pdf π, we define $\bar{\mathcal{I}}_j(P, \pi)$ and $\bar{\mathcal{O}}_j(P, \pi)$ as the expected number of inner and outer level-j vertices, respectively, and we also define $\bar{\mathcal{I}}_j(n)$ and $\bar{\mathcal{O}}_j(n)$ as the maximum value of these respective quantities, where the maximum is taken over all sets P of n points and all tame pdf's.[7]

Our goal is to bound $\bar{\mathcal{I}}_0(n)$ and $\bar{\mathcal{O}}_0(n)$. Our strategy is first to derive an upper bound for $\bar{\mathcal{O}}_0(n)$, either for the permutation model or for the density model for a tame pdf, and then use either of these bounds in a charging scheme that leads to a corresponding bound on $\bar{\mathcal{I}}_0(n)$. The following lemma will be crucial in proving the bound on $\bar{\mathcal{I}}_0(n)$.

▶ **Lemma 2.1.** $\bar{\mathcal{O}}_1(n) = O(\bar{\mathcal{O}}_0(n))$.

To keep the presentation simple, we first bound $\bar{\mathcal{O}}_0(n)$ in $\mathbb{R}^3$ (Section 2.1) and then extend the argument to higher dimensions (Section 2.2). Finally, we prove an upper bound on $\bar{\mathcal{I}}_0(n)$ in $\mathbb{R}^d$, for any odd dimension $d \geq 3$ (Section 2.3).

2.1 Outer vertices in 3D

An outer vertex of $\mathcal{U}(\mathcal{C})$ in $\mathbb{R}^3$ is either a vertex of a cube in $\mathcal{C}$ or the intersection point of an edge of a cube C_i with a face of another cube C_j. There are $O(n)$ vertices of the first type, so it suffices to bound the expected number of the second type of outer vertices.

We fix a point, say p_1, of P and an edge e of the cube $C_1 = p_1 + r_1 B$ centered at p_1. We bound the expected number of outer vertices of $\mathcal{U}$ lying on e. Note that e is not a fixed segment in $\mathbb{R}^3$—its physical location in $\mathbb{R}^3$ as well as its length depend on the value of r_1. Nevertheless, we can combinatorially define e so that it refers to a fixed edge (one of the 12 possible edges) of C_1. For simplicity, we assume that e is parallel to the z-axis. We bound the expected number of vertices lying on e, first for the permutation model, and then for the density model for a tame pdf.

The permutation model. We are given a sequence $\Theta = \langle 0 \leq \theta_1 \leq \cdots \leq \theta_n \rangle$ of n arbitrary non-negative scaling factors. We choose a random permutation σ on $[1 : n]$, and assign $r_i := \theta_{\sigma(i)}$.

Let $\mu(e, P, \Theta)$ denote the expected number of connected components of $\partial\mathcal{U} \cap e$. The expected number of outer vertices on e is at most $2\mu(e, P, \Theta)$. For a fixed value $\theta_i \in \Theta$ for r_1, let $\mu(e, P, \Theta \mid r_1 = \theta_i)$ denote the conditional expected number of connected components of $\partial\mathcal{U} \cap e$ assuming that $r_1 = \theta_i$. With this fixed choice of r_1, e is a segment of length $2\theta_i$, lying at a fixed location in $\mathbb{R}^3$. Observe that

$$\mu(e, P, \Theta) = \frac{1}{n} \sum_{i=1}^{n} \mu(e, P, \Theta \mid r_1 = \theta_i). \tag{2}$$

The following probabilistic lemma is the main technical tool used in the analysis in $\mathbb{R}^3$.

[7] One can also take the maximum over all pdfs, but then the various expectations are at most the corresponding quantities under the permutation model, and no better bounds are known so far. We will therefore be interested only in tame pdfs.

▶ **Lemma 2.2.** *For any* $1 \le k \le n$, $\mu(e, P, \Theta \mid r_1 = \theta_{n-k+1}) \le \frac{4n}{k}$.

Proof. Let $r = \theta_{n-k+1}$. Let e^+ (resp. e^-) denote the top (resp. bottom) half of e, i.e., the portion lying above (resp. below) p_1. Further partition e^+ into two parts e_1^+ and e_2^+, each of length $r/2$, and similarly partition e^-. We bound the expected number of connected components of $\mathcal{U}$ lying on e_1^+, e_2^+, e_1^- and e_2^- separately. Let $e' = e_1^+$, the bounds for the other parts of e are derived analogously.

Let $P(e^*) = \langle p_{i_1}, p_{i_2}, \ldots, p_{i_{n-1}} \rangle$ denote the sorted sequence of the points of $P \setminus \{p_1\}$ by increasing values of $\delta_i = d_\infty(p_i, e')$. We fix an assignment $r_2, \ldots, r_n$ of scaling factors (which is a permutation of $\Theta \setminus \{r\}$) to the points of $P \setminus \{p_1\}$, so that p_i is assigned the scaling factor r_i, for $i = 2, \ldots, n$. Let p_{i_j} be the first point in the sequence $P(e^*)$ for which $r_{i_j} \ge r$. If $\delta_{i_j} \le r/2$ then, since $|e'| = r/2$, it follows by the triangle inequality that $e' \subseteq C_{i_j}$ and there are no connected components of $\mathcal{U}$ on e'.

So assume that $\delta_{i_j} > r/2$. Then, since the sequence $P(e^*)$ is sorted by distance to e', it follows that $\delta_{i_\ell} > r/2$ for every $\ell \ge j$. Hence, any cube C_{i_ℓ}, for $\ell \ge j$, will intersect e' only if $r_{i_\ell} \ge r/2$. But then $e' \cap C_{i_\ell}$ must contain an endpoint of e'. It follows that all the cubes C_{i_ℓ}, for $\ell \ge j$, can contribute at most one connected component to $\partial\mathcal{U} \cap e'$. The cubes C_{i_ℓ}, for $\ell < j$, can increase the number of components by at most $j - 1$, so in total we get at most j connected components of $\mathcal{U}$ on e'.

As argued in [2, Lemma 3.3] (see also [15]), the expected value of the index j of the first appearance of one of $k-1$ distinguished elements in a random permutation of $n-1$ elements is n/k, so the expected value of j is n/k. This gives an average of at most n/k connected components of $\partial\mathcal{U} \cap e'$. From this the lemma follows. ◀

Plugging Lemma 2.2 into (2), we obtain $\mu(e, P, \Theta) = O(\log n)$. Summing this bound over all $O(n)$ edges of cubes in $\mathcal{C}$ and using Lemma 2.1, we obtain the following.

▶ **Corollary 2.3.** *Let P be a set of n points in $\mathbb{R}^3$, and let Θ be a multi-set of n non-negative scaling factors. Then $\bar{\mathcal{O}}_0(P, \Theta), \bar{\mathcal{O}}_1(P, \Theta) = O(n \log n)$.*

The density model for tame distributions. Next, we show that if the scaling factors of the cubes in $\mathcal{C}$ are chosen randomly and independently from a tame pdf then the expected number of outer vertices on a fixed edge g of any cube, say for concreteness the cube C_1 centered at p_1, is only $O(1)$. For simplicity, we assume that p_1 is at the origin. Let π be a tame pdf and Π its cdf. By definition, $1 - \Pi(kx) \le (1 - \Pi(x))^k$ for all $x > 0$ and for each $k \ge 1$. Adapting the previous notation, let $\mu(g, P, \pi)$ denote the expected number of connected components on $\partial\mathcal{U} \cap g$.

▶ **Lemma 2.4.** $\mu(g, P, \pi) \le 2e^3/(e-1)$.

Proof. Assume, as before, that g is parallel to the z-axis, and let g^+ (resp. g^-) denote the top (resp. bottom) half of g, i.e., the portion of g lying above (resp. below) p_1. Recall that g^+ is a random segment whose length and location depend on the value of r_1, the scaling factor assigned to p_1. We bound $\mu(g^+, P, \pi)$, the expected number of connected components of $\partial\mathcal{U} \cap g^+$. A symmetric argument will bound $\mu(g^-, P, \pi)$, and the sum of these two quantities will bound $\mu(g, P, \pi)$.

Set $\alpha = \Pi^{-1}(1 - 1/e)$ and let $I_k = [k\alpha, (k+1)\alpha)$, for $k = 0, 1, \ldots$. For a fixed value of r_1 we partition g^+ into $\ell + 1$ intervals, $\Delta_0, \ldots, \Delta_\ell$, such that, for $k < \ell$, the projection of Δ_k on the z-axis is I_k and the projection of Δ_ℓ is contained in I_ℓ. For convenience we define Δ_k, for $k > \ell$, to be an empty interval. Note that ℓ is a random variable whose value depends

on r_1. Let $\mu(\Delta_k) := \mu(\Delta_k, P, \pi)$ denote the expected number of connected components of $\partial\mathcal{U} \cap \Delta_k$. Then

$$\mu(g^+, P, \pi) \leq \sum_{k=0}^{\infty} \mu(\Delta_k). \tag{3}$$

The probability that Δ_k is not empty is equal to $\Pr[r_1 \geq k\alpha]$, which is

$$\Pr[r_1 \geq k\alpha] = 1 - \Pi(k\alpha) \leq (1 - \Pi(\alpha))^k = e^{-k}. \tag{4}$$

Fix a value of r_1 for which Δ_k is not empty. Let $P(\Delta_k) = \langle p_{i_1}, p_{i_2}, \ldots, p_{i_{n-1}} \rangle$ denote the sorted sequence of the points of $P \setminus \{p_1\}$ by increasing values of $\delta_i = d_\infty(p_i, \Delta_k)$. Fix an assignment $r_2, \ldots, r_n$ of scaling factors to the points of $P \setminus \{p_1\}$, so that p_i is assigned the scaling factor r_i, drawn from π, for $i = 2, \ldots, n$.

Let p_{i_j} be the first point in the sequence $P(\Delta_k)$ for which $r_{i_j} \geq 2\alpha$. If $\delta_{i_j} \leq \alpha$ then since $|\Delta_k| \leq \alpha$ it follows by the triangle inequality that $\Delta_k \subseteq C_{i_j}$, and there are no connected components of $\mathcal{U}$ on Δ_k.

So let us assume that $\delta_{i_j} > \alpha$. Then, since the sequence $P(\Delta_k)$ is sorted by distance to Δ_k, it follows that $\delta_{i_\ell} \geq \alpha$ for every $\ell \geq j$. Thus, for a cube C_{i_ℓ}, for $\ell \geq j$, to intersect Δ_k, we must have that $r_{i_\ell} \geq \alpha$. But then $\Delta_k \cap C_{i_\ell}$ must contain an endpoint of Δ_k. It follows that all the cubes C_{i_ℓ}, for $\ell \geq j$, can contribute at most one connected component to $\partial\mathcal{U} \cap \Delta_k$. The cubes C_{i_ℓ}, for $\ell < j$, can increase the number of components by at most $j - 1$, so in total we get at most j connected components of $\mathcal{U}$ on Δ_k.

Notice that j is a geometric random variable, where the success probability of each trial is $p = 1 - \Pi(2\alpha) \leq (1 - \Pi(\alpha))^2 = 1/e^2$. The expectation of j is thus $1/p = e^2$. Therefore $\mu(\Delta_k \mid \Delta_k \neq \emptyset) \leq e^2$.

Combining this with the bound on the probability that Δ_k is not empty, in Equation (4), we get that $\mu(\Delta_k) = \Pr[\Delta_k \neq \emptyset] \cdot \mu(\Delta_k \mid \Delta_k \neq \emptyset) \leq e^{-k+2}$. Substituting these bounds into Equation (3), the lemma follows. ◀

Putting everything together and using Lemma 2.1, we obtain the following:

▶ **Lemma 2.5.** *Let P be a set of n points in $\mathbb{R}^3$ and π a tame pdf. Then $\bar{\mathcal{O}}_0(P, \pi), \bar{\mathcal{O}}_1(P, \pi) = O(n)$.*

2.2 Outer vertices in higher odd dimensions

We now bound $\bar{\mathcal{O}}_0(n)$ in $\mathbb{R}^d$, for any fixed odd value $d > 3$. We fix a point of P, say, p_1, and a $(d-2)$-dimensional face f of C_1. We bound the expected number of outer vertices lying on f. As in the previous case, we first obtain the bound for the permutation model and then for the density model (with a tame pdf).

The permutation model. Let Θ denote a fixed set of scaling factors, and let $\mu(\mathsf{f}, P, \Theta)$ denote the expected number of vertices of $\mathcal{U}$ lying on f. We bound the conditional expectation $\mu(\mathsf{f}, P, \Theta \mid r_1 = \theta_i)$, assuming that the scaling factor of p_1 is θ_i, and then use (2) to bound $\mu(\mathsf{f}, P, \Theta)$.

Recall that once the value r_1 is fixed to θ_i, the hypercube $C_1 = p_1 + r_1 B$ is also fixed, and so is its face f. The problem is therefore to bound the expected number of outer vertices lying on a fixed $(d-2)$-dimensional hypercube f. A naive approach, based on induction on d within f does not work. We use instead a different approach.

The following lemma is analogous to Lemma 2.2.

▶ **Lemma 2.6.** *For any* $1 \leq k \leq n$, $\mu(\mathsf{f}, P, \Theta \mid r_1 = \theta_{n-k+1}) = O\left(\frac{n^{\lfloor d/2 \rfloor}}{k}\right)$.

Proof. The proof is similar to that of Lemma 2.2. Let $r = \theta_{n-k+1}$. We partition f into 4^{d-2} hypercubes (subfaces) each of radius $r/4$. Fix such a smaller hypercube g. Let $\mu(\mathsf{g}, P, \Theta \mid r_1 = r)$ be the expected number of outer vertices of $\mathcal{U}$ incident to g, conditioned on the choice of r_1.

Let $\delta_i = d_\infty(p_i, f)$ and let $P(\mathsf{g}) = \langle p_{i_1}, p_{i_2}, \ldots, p_{i_{n-1}} \rangle$ denote the sorted sequence of the points of $P \setminus \{p_1\}$ by increasing values of $\delta_i = d_\infty(p_i, \mathsf{g})$. We fix an assignment $r_2, \ldots, r_n$ of scaling factors from $\Theta \setminus \{r\}$ to the points of $P \setminus \{p_1\}$, so that p_i is assigned the scaling factor r_i, for $i = 2, \ldots, n$. Let $\hat{\mathcal{C}} = \{C_i := p_i + r_i B \mid p_i \in P \setminus \{p_1\}\}$ be the resulting set of hypercubes. Let $U_\mathsf{g} = \mathcal{U}(\hat{\mathcal{C}}) \cap \mathsf{g}$. Our goal is to bound the number of vertices of U_g. Let F be the $(d-2)$-dimensional flat spanned by g. For a hypercube $C_i \in \hat{\mathcal{C}}$, let $K_i = C_i \cap F$. If nonempty, K_i is a $(d-2)$-dimensional hypercube of radius r_i.

Let p_{i_j} be the first point in the sequence $P(\mathsf{g})$ for which $r_{i_j} \geq r$. Set $\mathcal{K}_< = \{K_{i_\ell} \mid \ell < j \wedge K_{i_\ell} \neq \emptyset\}$ and $\mathcal{K}_\geq = \{K_{i_\ell} \mid \ell \geq j \wedge K_{i_\ell} \neq \emptyset\}$. By definition, $|\mathcal{K}_<| < j$ and $U_\mathsf{g} = \mathcal{U}(\mathcal{K}_< \cup K_\geq) \cap \mathsf{g}$.

If $\delta_{i_j} \leq r/2$ then, since the side-length of g is $r/2$, it follows by the triangle inequality that $f \subseteq C_{i_j}$ and the number of vertices in U_g is 0. So assume that $\delta_{i_j} > r/2$. Then, since the p_i's are sorted by their distance to g, it follows that $\delta_{i_\ell} > r/2$ for every $\ell \geq j$. Hence, for a cube C_{i_ℓ} with $\ell \geq j$ to intersect g we must have $r_{i_\ell} > r/2$.

▶ **Lemma 2.7.** *Let* g *be a* $(d-2)$*-dimensional hypercube of radius* $r/4$*. For any* $(d-2)$*-dimensional hypercube* K *of radius at least* $r/4$*, there is another hypercube* $\tilde{K}$ *of radius exactly* $r/4$ *such that* $K \cap \mathsf{g} = \tilde{K} \cap \mathsf{g}$.

Since all hypercubes in $\mathcal{K}_\geq$ have radius at least $r/4$, we obtain, by applying Lemma 2.7 to all of them, a collection $\tilde{\mathcal{K}}_\geq = \{\tilde{K}_i \mid K_i \in \mathcal{K}_\geq\}$ such that $\mathcal{U}(\mathcal{K}_\geq) \cap \mathsf{g} = \mathcal{U}(\tilde{\mathcal{K}}_\geq) \cap \mathsf{g}$. It follows that $U_\mathsf{g} = \mathcal{U}(\mathcal{K}_< \cup \tilde{\mathcal{K}}_\geq) \cap \mathsf{g}$. It therefore suffices to bound the number of vertices of $\tilde{U}_\mathsf{g} = \mathcal{U}(\mathcal{K}_< \cup \tilde{\mathcal{K}}_\geq)$, and also the number of vertices of $\tilde{U}_\mathsf{g} \cup \mathsf{g}$ (in order to upper bound the number of vertices in U_g which are on the boundary of g). We bound the number of vertices of $\tilde{U}_\mathsf{g}$, the analysis for $\tilde{U}_\mathsf{g} \cup \mathsf{g}$ is similar.

We call a vertex v of $\tilde{U}_\mathsf{g}$ *pure* if it does not lie on the boundary of any hypercube in $\mathcal{K}_<$, otherwise we call it *mixed*. A pure vertex is also a vertex of $\mathcal{U}(\tilde{\mathcal{K}}_\geq)$. Since $\tilde{\mathcal{K}}_\geq$ is a set of at most n congruent hypercubes in $\mathbb{R}^{d-2}$, the number of vertices in $\mathcal{U}(\tilde{\mathcal{K}}_\geq)$ is $O(n^{\lfloor (d-2)/2 \rfloor}) = O(n^{\lfloor d/2 \rfloor - 1})$.

Each mixed vertex of $\tilde{U}_f$ is incident to at least one facet of a hypercube in $\mathcal{K}_<$. Fix such a facet ϕ, and let Φ be the $(d-3)$-dimensional flat spanned by ϕ. For each hypercube $K \in \mathcal{K}_< \cup \tilde{\mathcal{K}}_\geq$, let $K^* = K \cap \Phi$ be the (possibly empty) $(d-3)$-dimensional hypercube contained in Φ. Set $\mathcal{K}^* = \{K^* \mid K \in \mathcal{K}_< \cup \tilde{\mathcal{K}}_\geq\}$. A mixed vertex incident on ϕ is also a vertex of $\mathcal{U}(\mathcal{K}^*)$. Since $d-3$ is even, the result in [10] implies the number of such vertices is (always) $O\left(n^{(d-3)/2}\right) = O\left(n^{\lfloor d/2 \rfloor - 1}\right)$. Multiplying the bound by the number of facets in the hypercubes of $\mathcal{K}_<$, the total number of mixed vertices is $O(|\mathcal{K}_<| n^{\lfloor d/2 \rfloor - 1})$. Hence, the total number of vertices in U_g is $O(|\mathcal{K}_<| n^{\lfloor d/2 \rfloor - 1} + n^{\lfloor d/2 \rfloor - 1}) = O(jn^{\lfloor d/2 \rfloor - 1})$. As in the proof of Lemma 2.2, the expected value of j (assuming that $r_1 = \theta_{n-k+1}$) is $O(n/k)$. Hence, $\mu(\mathsf{g}, P, \Theta \mid r_1 = \theta_{n-k+1}) = O\left(\frac{n^{\lfloor d/2 \rfloor}}{k}\right)$. The lemma follows by summing this over all 4^{d-2} subfaces g in the subdivision of f. ◀

Plugging Lemma 2.6 in (2), we obtain that $\mu(\mathsf{f}, P, \Theta) = \frac{1}{n} \sum_{k=1}^{n} O\left(\frac{n^{\lfloor d/2 \rfloor}}{k}\right) = O\left(n^{\lfloor d/2 \rfloor - 1} \log n\right)$. Finally, summing this bound over all points of P and using Lemma 2.1, we obtain the main result of this section:

▶ **Lemma 2.8.** *Let P be a set of n points in $\mathbb{R}^d$ for some fixed odd value of $d > 3$, and let Θ be a multi-set of scaling factors. Then $\bar{\mathcal{O}}_0(P,\Theta), \bar{\mathcal{O}}_1(P,\Theta) = O\left(n^{\lfloor d/2 \rfloor} \log n\right)$.*

The density model for tame distributions. Next, we show (see the full version for details) that if the scaling factors of the cubes in $\mathcal{C}$ are chosen randomly and independently from a tame pdf π (whose cdf is denoted by Π) then the expected number of outer vertices on a fixed $(d-2)$-dimensional face f of any cube, say of C_1, is $O\left(n^{\lfloor d/2 \rfloor - 1}\right)$. That is,

▶ **Lemma 2.9.** $\mu(\mathsf{f}, P, \pi) = O(n^{\lfloor d/2 \rfloor - 1})$.

Putting everything together, using Lemma 2.1, we obtain the following:

▶ **Lemma 2.10.** *Let P be a set of n points in $\mathbb{R}^d$ for some fixed odd value of $d > 3$, and let π be a tame pdf. Then $\bar{\mathcal{O}}_0(P,\Theta), \bar{\mathcal{O}}_1(P,\Theta) = O\left(n^{\lfloor d/2 \rfloor}\right)$.*

2.3 Inner vertices

We now bound the expected number of inner vertices in $\mathcal{U}(\mathcal{C})$ in $\mathbb{R}^d$ under both the permutation model and the density model for tame distributions. We first consider a fixed assignment of scaling factors to the points of P, so $\mathcal{C} = \{C_1, \ldots, C_n\}$ is a fixed set of n hypercubes in $\mathbb{R}^d$. We obtain a recurrence for $\mathcal{I}_0(\mathcal{C})$ for this fixed $\mathcal{C}$, by closely following the charging scheme proposed in Boissonnat *et al.* [10], which shows that there are many distinct outer vertices of level 0 plus vertices (inner or outer) of level 1 in the neighborhood of any inner vertex of $\mathcal{U}(\mathcal{C})$. This gives an upper bound on $\mathcal{I}_0(\mathcal{C})$ in terms of $\mathcal{I}_1(\mathcal{C})$, $\mathcal{O}_0(\mathcal{C})$, and $\mathcal{O}_1(\mathcal{C})$. Next, we consider a random assignment of scaling factors and obtain a recurrence for $\bar{\mathcal{I}}_0(n)$ in terms of $\bar{\mathcal{I}}_1(n)$, $\bar{\mathcal{O}}_0(n)$, and $\bar{\mathcal{O}}_1(n)$, from the recurrence for $\mathcal{I}_0(\mathcal{C})$. We use results from Sections 2.1 and 2.2 to bound the last two terms, and we use a counting argument to bound $\bar{\mathcal{I}}_1(n)$ in terms of $\bar{\mathcal{I}}_0(n-1)$.

The charging scheme. Let v be an inner vertex of $\partial\mathcal{U}$, lying on d facets $\mathbf{f} = \{f_1, \ldots, f_d\}$ of a set $\mathbf{C} = \{C_1, \ldots, C_d\}$ of d distinct hypercubes, such that f_i is a facet of C_i orthogonal to the x_i-axis. For each $i \leq d$, let γ_i denote the intersection segment of the $d-1$ facets in $\mathbf{f} \setminus \{f_i\}$. The segment γ_i is parallel to the x_i-axis. The vertex v is incident to all d segments $\gamma_1, \ldots, \gamma_d$. For each i, we trace the segment γ_i from v entering the hypercube C_i (recall that v lies on the x_i-orthogonal facet f_i of C_i) until we encounter another vertex, w_i, of the arrangement $\mathcal{A}(\mathcal{C})$ of $\mathcal{C}$. Three cases can arise:

- **(i)** The vertex w_i lies on the facet of C_i opposite to f_i (i.e., the other facet of C_i orthogonal to the x_i-axis). This event can happen only if C_i is smaller than all the other $d-1$ hypercubes in $\mathbf{C}$, i.e., it can happen for at most one index i.
- **(ii)** The vertex w_i is an outer vertex at level 1 (it is contained in C_i), lying on a $(d-2)$-face of one of the hypercubes $C_j \in \mathbf{C} \setminus \{C_i\}$.
- **(iii)** The vertex w_i is an inner vertex at level 1 (it is contained in C_i), lying on the boundary of another hypercube $C_0 \in \mathcal{C} \setminus \mathbf{C}$.

In the first case, we simply ignore this segment γ_i and the vertex w_i—at most one of the d segments will be ignored. In cases (ii) and (iii), v charges w_i one unit. This way, each inner vertex v of $\mathcal{U}$ receives at least $d-1$ units of charge.

An outer vertex w at level 1, lying on a $(d-2)$-face ϕ of C_j, can be reached from an inner vertex only along one of the two corresponding facets of C_j (in a direction normal to the other facet containing ϕ), so w is charged at most twice by a type (ii) event.

An inner vertex w at level 1 can be charged at most d times, once along each of its d incident intersection segments. Suppose w is charged s times. If $s \leq 1$, then w pays one unit of charge for its unique charging inner vertex (or does not pay at all). If $s > 1$, we distribute $s-1$ of the s units of charge to nearby outer vertices at level 0 or 1 so that each outer vertex is charged at most once (at most one inner vertex can pass a charge to it), and w also pays only one unit of charge. The charge distribution scheme culminates in the following recurrence.

$$(d-1)\mathcal{I}_0(\mathcal{C}) \leq \mathcal{I}_1(\mathcal{C}) + 3\mathcal{O}_1(\mathcal{C}) + \mathcal{O}_0(\mathcal{C}). \tag{5}$$

Recurrence for a fixed assignment. We now obtain a recurrence for $\mathcal{I}_0(\mathcal{C})$ by using the following lemma; see [10] for the easy proof.

▶ **Lemma 2.11.** $\displaystyle\sum_{i=1}^{n} \mathcal{I}_0(\mathcal{C} \setminus \{C_i\}) = (n-d)\mathcal{I}_0(\mathcal{C}) + \mathcal{I}_1(\mathcal{C}).$

Using Lemma 2.11 and (5), we obtain the following recurrence.

$$\begin{aligned}(n-1)\mathcal{I}_0(\mathcal{C}) &= (n-d)\mathcal{I}_0(\mathcal{C}) + (d-1)\mathcal{I}_0(\mathcal{C}) \\ &\leq (n-d)\mathcal{I}_0(\mathcal{C}) + \mathcal{I}_1(\mathcal{C}) + 3\mathcal{O}_1(\mathcal{C}) + \mathcal{O}_0(\mathcal{C}) \qquad \text{(Eq. (5))} \\ &= \sum_{i=1}^{n} \mathcal{I}_0(\mathcal{C} \setminus \{C_i\}) + 3\mathcal{O}_1(\mathcal{C}) + \mathcal{O}_0(\mathcal{C}) \qquad \text{(Lemma 2.11).}\end{aligned} \tag{6}$$

Recurrence for a random assignment. We remind the reader that so far the analysis has been applied to a fixed assignment of scaling factors to the points of P, that is, to a fixed set $\mathcal{C}$ of hypercubes. We now want to replace (6) by the expectations of the terms appearing there, with respect to a random assignment of the scaling factors. By linearity of expectation,

$$(n-1)\mathsf{E}[\mathcal{I}_0(\mathcal{C})] \leq \sum_{i=1}^{n} \mathsf{E}[\mathcal{I}_0(\mathcal{C} \setminus \{C_i\})] + 3\mathsf{E}[\mathcal{O}_1(\mathcal{C})] + \mathsf{E}[\mathcal{O}_0(\mathcal{C})]. \tag{7}$$

For a fixed choice of the scaling factor r_i of C_i, the assignment of the remaining scaling factors to the elements of $\mathcal{C} \setminus \{C_i\}$ is a random permutation (of the $n-1$ elements in $\Theta \setminus \{r_i\}$) under the permutation model, and a random assignment under the density model. The conditional expected value of $\mathcal{I}_0(\mathcal{C} \setminus \{C_i\})$ over any fixed choice of r_1 is thus at most $\bar{\mathcal{I}}_0(n-1)$, and therefore the same also holds for the unconditional expected value of $\mathcal{I}_0(\mathcal{C} \setminus \{C_i\})$. Hence, we obtain the following:

$$(n-1)\bar{\mathcal{I}}_0(n) \leq n\bar{\mathcal{I}}_0(n-1) + 3\bar{\mathcal{O}}_1(n) + \bar{\mathcal{O}}_0(n). \tag{8}$$

Dividing both sides by $n(n-1)$ and setting $\chi(m) = \frac{1}{m}\bar{\mathcal{I}}_0(m)$, we obtain

$$\chi(n) \leq \chi(n-1) + \frac{1}{n(n-1)}(3\bar{\mathcal{O}}_1(n) + \bar{\mathcal{O}}_0(n)). \tag{9}$$

We now substitute the bounds on $\bar{\mathcal{O}}_0(n)$ and $\bar{\mathcal{O}}_1(n)$ from Section 2.1 and Section 2.2 for both the permutation model and the density model for tame distributions. For example, for the permutation model in $\mathbb{R}^3$, $\bar{\mathcal{O}}_0(n), \bar{\mathcal{O}}_1(n) = O(n \log n)$. Therefore, we obtain $\chi(n) \leq \chi(n-1) + \frac{b \log n}{n}$, where $b > 0$ is a constant. Hence, $\chi(n) = O(\log^2 n)$ and $\bar{\mathcal{I}}_0(n) = O(n \log^2 n)$ in this case. For any fixed odd $d > 3$ and still under the permutation model, we obtain

$\chi(n) \leq \chi(n-1) + b'n^{\lfloor d/2 \rfloor - 2} \log n$, where b' is another constant. Since $d > 3$, the solution of the above recurrence is $\chi(n) = O(n^{\lfloor d/2 \rfloor - 1} \log n)$ and thus $\bar{\mathcal{I}}_0(n) = O(n^{\lfloor d/2 \rfloor} \log n)$. This completes the proof of Theorem 1.1.

If the scaling factors of all points are chosen from a tame pdf, the bounds for $\bar{\mathcal{O}}_0(n), \bar{\mathcal{O}}_1(n)$ can be obtained using Lemmas 2.5 and 2.10. This implies that in this case $\bar{\mathcal{I}}_0(n) = O(n \log n)$ for $d = 3$ and $\bar{\mathcal{I}}_0(n) = O(n^{\lfloor d/2 \rfloor})$ for any fixed $d > 3$. This completes the proof of Theorem 1.2.

3 Union of Stochastic Minkowski Sums

We now consider the general (three-dimensional) stochastic Minkowski-sum union problem defined in the introduction, i.e., we now have a set $T = \{\triangle_1, \ldots, \triangle_n\}$ of n pairwise-disjoint triangles in $\mathbb{R}^3$ and a convex polytope B with $O(1)$ vertices. Let $\mathbf{r} = \langle r_1, \ldots, r_n \rangle$ be a sequnce of n non-negative scaling factors. $C_i = \triangle_i \oplus r_i B$ is a convex polytope with $O(1)$ vertices. Set $\mathcal{C} = \{C_i \mid 1 \leq i \leq n\}$. Let $\Theta = \langle \theta_1, \ldots, \theta_n \rangle$ be a sequence of n scaling factors. Our goal is to bound the expected number of vertices in $\mathcal{U}(T, \mathbf{r})$, denoted by $\psi(T, \Theta)$, when $\mathbf{r}$ is chosen from Θ using the permutation model, i.e., we choose a random permutation σ of $[1 : n]$ and set $r_i = \theta_{\sigma(i)}$. For simplicity, we assume that T, B, Θ are such that $\mathcal{C}$ is in general position for any permutation of Θ. Let $\mathcal{F}(T, \mathbf{r})$ denote the complement of $\mathcal{U}(T, \mathbf{r})$.

As in Section 2, we first analyze a certain conditional expectation and then bound the overall expected value $\psi(T, \Theta)$. A crucial ingredient in our analysis is the following technical lemma, adapted from Aronov and Sharir [5, Slicing Theorem] (see also [6, Chopping Theorem]).

▶ **Lemma 3.1.** *Let $R \subseteq T$ be a subset of t triangles and let $\mathbf{r} = \langle r, r, \ldots, r \rangle$. Then (a) the complexity of $\mathcal{U}(T, \mathbf{r})$ is $O(t^2 \log t)$, and (b) there exists a decomposition $\mathcal{F}^{\nabla}$ of $\mathcal{F} := \mathcal{F}(R, \mathbf{r})$ into $O(t^2 \log t)$ tetrahedra with pairwise-disjoint interiors.*

We note that each tetrahedron in $\mathcal{F}^{\nabla}$ is defined by at most s triangles of T, where s is a constant that specifies the (maximum) number of input triangles that are needed to define the features (vertices, edges, and facets) of the corresponding tetrahedron. Moreover, any s or fewer triangles define at most $O(1)$ tetrahedra. We thus obtain the following lemma:

▶ **Lemma 3.2.** *The overall number of tetrahedra that can ever arise in the decomposition $\mathcal{F}^{\nabla}(R, \mathbf{r})$ for any subset $R \subseteq T$, where all the scaling factors in $\mathbf{r}$ are equal, is $O(n^s)$.*

The recursive partition scheme. We now follow, or rather adapt, the recursive scheme used in [2]. Specifically, fix a parameter t, whose value will be determined later, and put $\rho = \theta_{n-t}$, the $(t+1)$-st largest scaling factor in Θ. Let $\Theta^<$ be the sequence of the $n - t$ smallest values in Θ. We fix a subset $T^> \subseteq T$ of t triangles, and set $T^< = T \setminus T^>$. Let $\psi(T, \Theta \mid T^>)$ denote the conditional expected complexity of $\mathcal{U}$ conditioned over the subset of those permutations σ that assign the t largest scaling factors in Θ to the triangles of $T^>$; the restriction of a random permutation from this subset to $[1 : n - t]$ (i.e., the part of the permutation that assigns the scaling factors of $\Theta^<$ to the triangles in $T^<$) is a random permutation, i.e., each permutation of $[1 : n - t]$ is equally likely to arise.

We first obtain a bound on $\psi(T, \Theta \mid T^>)$. For each $\triangle_i \in T$, put $\bar{C}_i = \triangle_i \oplus \rho B$. Set $\bar{\mathcal{C}}^> = \{\bar{C}_i \mid \triangle_i \in T^>\}$ and $\bar{\mathcal{U}} := \mathcal{U}(\bar{\mathcal{C}}^>)$. Let $\bar{\mathcal{F}}$ denote the complement of $\bar{\mathcal{U}}$. Since the $\triangle_i$'s are pairwise disjoint and we now add the same convex polytope ρB to each of them, Lemma 3.1(a) implies that $\bar{\mathcal{U}}$ has $O(t^2 \log t)$ complexity. Moreover, by Lemma 3.1(b), there exists a decomposition, denoted as $\bar{\mathcal{F}}^{\nabla}$, of $\bar{\mathcal{F}}$ into $O(t^2 \log t)$ tetrahedra with pairwise-disjoint interiors. For each tetrahedron τ of $\bar{\mathcal{F}}^{\nabla}$, let $T^<_\tau = \{\triangle_i \in T^< \mid \bar{C}_i \cap \tau \neq \emptyset\}$; set $n_\tau = |T^<_\tau|$.

Note that $\bar{\mathcal{U}}$, $\bar{\mathcal{F}}$, $\bar{\mathcal{F}}^{\nabla}$, and the sets $T_\tau^<$ are independent of the choice of permutation; they only depend on ρ and the set $T^>$.[8]

We now fix a permutation σ, and thus an assignment of scaling factors, such that the largest t scaling factors are assigned to the triangles of $T^>$. Thus the scaling factors of all triangles in $T^<$ (resp. $T^>$) are at most (resp. at least) ρ. Therefore $C_i \subseteq \bar{C}_i$ for each $\triangle_i \in T^<$ and $C_i \supseteq \bar{C}_i$ for each $\triangle_i \in T^>$. Consequently, $\bar{\mathcal{U}} \subseteq \mathcal{U}(\mathcal{C})$.

For a cell $\tau \in \bar{\mathcal{F}}^{\nabla}$, set $\mathcal{C}_\tau^< = \{C_i \mid T_i \in T_\tau^<\}$. Clearly, no other triangle $\triangle_i \in T^<$ can have its real expansion C_i meet τ. We define $\mathcal{C}_\tau = \{C_i \cap \tau \mid \triangle_i \in T_\tau^< \cup T^>\}$, and set $\mathcal{U}_\tau = \mathcal{U}(\mathcal{C}_\tau)$. By construction,

$$\mathcal{U} = \mathcal{U}(\mathcal{C}) = \bar{\mathcal{U}} \cup \bigcup_{\tau \in \bar{\mathcal{F}}^{\nabla}} \mathcal{U}_\tau. \tag{10}$$

We call a vertex v of $\mathcal{U}$ *internal* if v does not lie on the boundary of any polytope C_i with $T_i \in T^>$, and we call v *external* otherwise. The number of external vertices is trivially $O(tn^2)$, so it suffices to bound the number of internal vertices of $\mathcal{U}$. Since $\bar{\mathcal{U}} \subseteq \mathcal{U}$, every internal vertex lies in $\bar{\mathcal{F}}$. Suppose v lies in the tetrahedron τ of $\bar{\mathcal{F}}^{\nabla}$. Then by (10), v is a vertex of $\mathcal{U}_\tau$. Furthermore, v is an internal vertex, so it is not incident on any C_i for $T_i \in T^>$, and thus v is a vertex of $\mathcal{U}(\mathcal{C}_\tau^<)$. The total number of internal vertices in τ is bounded by the combinatorial complexity of $\mathcal{U}(\mathcal{C}_\tau^<)$, denoted by $\psi(T_\tau^<, \mathbf{r}_\tau)$ (as defined in the introduction), where $\mathbf{r}_\tau$ is the set of scaling factors of the triangles in T_τ, Hence, the total number of internal vertices on $\mathcal{U}$ is $\sum_{\tau \in \bar{\mathcal{F}}^{\nabla}} \psi(T_\tau^<, \mathbf{r}_\tau)$, and (10) implies that the total number vertices $\psi(T, \mathbf{r})$ on $\mathcal{U}$ satisfies $\psi(T, \mathbf{r}) \leq \sum_{\tau \in \bar{\mathcal{F}}^{\nabla}} \psi(T_\tau^<, \mathbf{r}_\tau) + O(tn^2)$.

Expected number of vertices. We now bound the expected complexity of $\mathcal{U}$, conditioned on a fixed choice of $T^>$. That is, we condition the analysis on the subset of those permutations σ that assign the t largest scaling factors in Θ to the triangles of $T^>$. The set $\Theta_\tau^<$ of scaling factors assigned to the triangles in $T_\tau^<$ is not fixed, but, since $T_\tau^<$ is a fixed set, conditioned only on the choice of $T^>$, the set $\Theta_\tau^<$ is a *random subset* of $\Theta^< = \{\theta_1, \ldots, \theta_{n-t}\}$ of the fixed size n_τ. Moreover, the assignment (under the original random permutation σ) of these scaling factors to the triangles in $T_\tau^<$ is a *random* permutation of $\Theta_\tau^<$. Hence, conditioning further on the choice of $\Theta_\tau^<$, the expected value of $\psi(T_\tau^<, \mathbf{r}_\tau)$ is $\psi(T_\tau^<, \Theta_\tau^<) \leq \psi(n_\tau)$. Hence, the last expression also bounds the unconditional expected complexity of $\mathcal{U}(\mathcal{C}_\tau^-)$, albeit still conditioned on a fixed choice of $T^>$. Summing this over all tetrahedra of $\bar{\mathcal{F}}^{\nabla}$, we obtain that $\psi(T, \Theta \mid T^>) \leq \sum_{\tau \in \bar{\mathcal{F}}^{\nabla}} \psi(n_\tau) + O(tn^2)$.

To bound the unconditional expected value $\psi(T, \Theta)$ we notice that the subset $T^>$ of the triangles that are assigned the t largest scaling factors is a random subset of T. Since $T^>$ is a random sample of T of size t and since, by Lemma 3.2, there are only $O(n^s)$ tetrahedra that can appear in the decomposition $\bar{\mathcal{F}}^{\nabla}$, the following lemma is a consequence of a standard random-sampling argument; see [17, Section 4.6] for a proof.

▶ **Lemma 3.3.** *For any constant $c > 0$, with probability $1 - O\left(\frac{1}{n^c}\right)$, every (open) tetrahedron τ of $\bar{\mathcal{F}}^{\nabla}$ intersects at most $\frac{c'n}{t} \log n$ of the sets of $\bar{\mathcal{C}}^<$, where c' is a constant that depends on both c.*

Choosing $c = 3$ in Lemma 3.3, with probability $1 - O\left(\frac{1}{n^3}\right)$ our $T^>$ is such that $n_\tau \leq \frac{c'n}{t} \log n$ for every $\tau \in \bar{\mathcal{F}}^{\nabla}$. With probability $O\left(\frac{1}{n^3}\right)$, $T^>$ may fail to satisfy this property,

[8] Clearly, $\bar{\mathcal{U}}$ and $\bar{\mathcal{F}}$ are uniquely determined. For $\bar{\mathcal{F}}^{\nabla}$, the statement means that if we follow an agreed-upon implementation of the construction in the proof of Lemma 3.1, $\bar{\mathcal{F}}^{\nabla}$ is also uniquely determined.

but, since the complexity of $\mathcal{U}(\mathcal{C})$ is always $O(n^3)$ (again, with a constant of proportionality that depends on the complexity of B), the contribution of these "bad" choices of $T^>$ to $\psi(T, \Theta)$ is $O(1)$. If n is below some appropriate constant n_0, we can use a trivial bound of $O(n^3)$ for the complexity of $\mathcal{U}$. Altogether, we obtain the following recurrence,

$$\psi(n) \leq \begin{cases} a_0 n^3 & \text{for } n \leq n_0, \\ a_1 t^2 \log t \cdot \psi\left(\frac{c'n}{t} \log n\right) + a_2 n^2 t & \text{for } n > n_0, \end{cases} \tag{11}$$

where n_0, a_0, a_1, a_2, c' are suitable constants. With appropriate choice of parameters, the solution of this recurrence is $\psi(n) \leq An^{2+\varepsilon}$, for any $\varepsilon > 0$, where A depends on ε and on the other constants appearing in the recurrence. This proves Theorem 1.3.

Abstract

In this work we construct tests that allow a classical user to certify high dimensional entanglement in uncharacterized and possibly noisy quantum devices. We present a family of non-local games $\{G_n\}$ that for all n certify states with entanglement of formation $\Omega(n)$. These tests can be derived from *any* bipartite non-local game with a classical-quantum gap. Furthermore, our tests are noise-tolerant in the sense that fault tolerant technologies are not needed to play the games; entanglement distributed over noisy channels can pass with high probability, making our tests relevant for realistic experimental settings. This is in contrast to, e.g., results on self-testing of high dimensional entanglement, which are only relevant when the noise rate goes to zero with the system's size n. As a corollary of our result, we supply a lower-bound on the entanglement cost of any state achieving a quantum advantage in a bipartite non-local game. Our proof techniques heavily rely on ideas from the work on classical and quantum parallel repetition theorems.

1 Introduction

Non-local games offer a powerful method to experimentally study the properties and behavior of uncharacterized quantum systems. In a non-local game, an experimenter can play a game with two non-communicating players (representing spatially separated quantum systems) via classical interaction only. Based on the outcome of the game, the experimenter draws conclusions about, e.g., whether the players used an entangled quantum state to win the

game. This idea dates back to John Bell's seminal paper [7], in which he presents a game to test the non-classicality of nature. Today, such games are not only relevant for our understanding of the foundations of quantum physics but are at the heart of device-independent quantum information processing, where a classical user can certify that an unknown quantum device is performing a desired computational or cryptographic task (such as, e.g., device-independent quantum key distribution [4, 37, 45, 34, 2] or delegated quantum computation [42, 24, 22, 35, 17]).

In this work we ask the following question:

Is it possible to classically test for high dimensional entanglement, even in the presence of noise?

Whereas Bell's original test is a classical method to certify the *presence* of entanglement, we are instead interested in non-local games that would allow us to quantify the *amount*. In particular, we are interested in certifying the amount of entanglement of *noisy quantum systems*.

Designing noise-tolerant tests for high dimensional entanglement is an important and timely challenge for both computer science and physics. First, our understanding of complexity theory indicates that unless $\mathsf{BQP} \subseteq \mathsf{BPP}$ (i.e., quantum computers are classically simulable), general quantum computations must involve highly entangled states. Thus if we hope to achieve super-classical speedups in quantum computers, at the very least we must be able to generate high dimensional entanglement.

Second, we are seeing increasingly sophisticated experiments involving quantum information, from loophole-free Bell tests [26, 43, 23] to small scale quantum computers [10, 29]. However, full-fledged quantum fault tolerance appears to be a faraway prospect; in the near-term, our explorations of complex quantum states will be done using noisy gates and little (if any) error correction. Despite this obstacle, researchers have been enthusiastically proposing uses of noisy quantum computers, from approximate optimization to investigation of exotic physics phenomena. Interesting questions will emerge in tandem with these efforts, namely: how can one verify that a noisy quantum computer has succeeded in these proposed experiments? Finding noise-tolerant tests to certify high dimensional entanglement is a prerequisite step towards verifying other complex quantum behavior in this noisy regime.

1.1 What do we mean by certifying entanglement?

There are a variety of ways to formulate this task; our work is most directly motivated by recent work on *self-tests*, which are games that certify the presence of entanglement *of a specific form*. The works of [33, 14, 16, 20, 35] construct families of games $\{G_n\}$ where any optimal quantum strategy for G_n must use a large amount of entanglement, e.g., a tensor product of n EPR pairs. These self-testing results are also *robust*, in that near-optimal strategies must use states that are near a specific highly entangled state. However, these tests will also reject a natural class of highly entangled states such as $\sigma^{\otimes n}$ where σ has fidelity $1-\nu$ with a single EPR pair. Here, think of ν as a small (but fixed) noise parameter that represents the level of imperfection of a state preparation process.

Thus, even though $|EPR\rangle\langle EPR|^{\otimes n}$ can be used to pass the tests of [33, 14, 16, 20, 35] with high probability, the "similar-looking" state $\sigma^{\otimes n}$ will fail with high probability. A key observation we wish to emphasize in this paper is that robustness of a self-test is *not* equivalent to noise tolerance!

More formally, the robust self-tests in the above works show the following: let $\mathrm{qval}(G_n)$ denote the optimal quantum winning probability for the game G_n. Then there exists a

function $f(n,\varepsilon)$ and an *ideal state* ρ_n^* such that for all ε, any quantum strategy that achieves a winning probability of at least $\text{qval}(G_n)-\varepsilon$ must use a state ρ that is $f(n,\varepsilon)$-close to ρ_n^*. In these works, ρ_n^* is a state whose entanglement grows with n (like a maximally entangled state on n qubits). "Closeness" can be defined in terms of the fidelity of the two states up to local isometries acting on each of the players' systems.

Given a game G_n as above, an experiment to test the entanglement of an unknown state ρ can be the following: play the game G_n using ρ, and check whether the game is won.[3] In order to obtain a non-trivial guarantee about ρ, we require that $f(n,\varepsilon)<1$; one can think of this function as specifying the amount of experimental imperfection/noise that can be tolerated by the *test* itself. In the works of [33, 14, 16, 20], the function $f(n,\varepsilon)$ scales as $a\cdot n^b\cdot\varepsilon^c$ for constants a,b,c. Thus we get no guarantees about ρ unless ε scales as $1/\operatorname{poly}(n)$. In other words, as we increase the amount of entanglement we want to certify, the test becomes less tolerant of noise!

The strongest self-testing result (in this context) is presented in the work of Natarajan and Vidick [35]. There, a self-test for n EPR pairs is given where the associated function is $f(n,\varepsilon)=O(\sqrt{\varepsilon})$. While the closeness parameter is independent of the parameter n, such $f(n,\varepsilon)$ still requires that, in order to pass the test with high probability, the players share a state ρ that is *globally* $O(\sqrt{\varepsilon})$-close to $|EPR\rangle\langle EPR|^{\otimes n}$. Using a state like $\sigma^{\otimes n}$ where σ has $1-\nu$ fidelity with a single EPR pair would fail their test with high probability, because $\sigma^{\otimes n}$ has *exponentially small* fidelity $(1-\nu)^n\approx e^{-n/\nu}$ with $|EPR\rangle\langle EPR|^{\otimes n}$.

In this paper we seek an entanglement test that is both *sound* — meaning that any strategy that passes the test with good probability must have high entanglement — and also *noise tolerant*, meaning that they do not reject noisy implementations of an ideal strategy. The self-tests above are sound, but they are not noise tolerant. Part of the difficulty stems from the fact that it is not even clear how one should *formulate* the soundness guarantee of a desired noise-tolerant self-testing result.

1.2 Noise model

As discussed above, we wish to define a testing procedure that can also certify entanglement in noisy entangled states. While our work can be used to certify different types of noisy states, we briefly discuss a specific noise model here for the sake of concreteness. The noise model that we have in mind produces a state of the form $\sigma^{\otimes n}$ where each σ has fidelity $1-\nu$ with some optimal state defined via the considered non-local game. Such a state can be produced, e.g., by sending many copies of the optimal state via noisy channels.

We emphasize that by saying that this is the noise model that we consider we merely mean that we require that our tests will be able to certify the entanglement of $\sigma^{\otimes n}$. However, we do not assume that all of the states on which the procedure is applied must have this form (i.e., the soundness part of the statement is independent of the considered noise model).

1.3 Results and contributions

In this work, instead of trying to certify the presence of a specific state like in self-testing statements, we address the question of certifying an entanglement measure. This allows us to sidestep the difficulty of formulating a noise-tolerant self-testing result.

[3] In an experiment one actually needs to prepare many identical and independent copies of ρ and play the game G_n many times. Then the average winning probability can be calculated, and high amount of entanglement is certified (with high probability) if the average winning probability is at least $\text{qval}(G_n)-\varepsilon$.

We present a family of simple non-local games $\{G_n\}$ where each game G_n certifies that the shared state of the players has $\Omega(n)$ bits of *entanglement of formation*. The entanglement of formation, denoted by $E_F(\rho)$, is a well-studied entanglement measure for bipartite mixed states that, in the case of pure states, is equal to the entanglement entropy. As the name suggests, the entanglement of formation captures, roughly speaking, the amount of entanglement needed in order to produce a given state ρ. It is also closely related to another important, perhaps more well known, entanglement measure which will be of use below – the *entanglement cost* $E_C(\rho)$. The entanglement cost of a mixed state roughly describes how many EPR pairs are needed to create ρ via local operations and classical communication [9]. We provide a more thorough discussion of the entanglement measures relevant for our work in Section 1.4.

The family of non-local games that we consider are the so called *threshold games*. Before stating our main result, we define these games. Let G be a two-player non-local game with classical value[4] $\mathrm{cval}(G)$ and quantum value $\mathrm{qval}(G)$. Given an integer $n \geq 1$ and a noise threshold $0 \leq \nu < \mathrm{qval}(G) - \mathrm{cval}(G)$, define the threshold game $G^n_{\mathrm{qval}(G)-\nu}$ to be a game where the two-players now play n independent instances of G in parallel, and win if they win at least $\mathrm{qval}(G) - \nu$ fraction of instances of G.

The main theorem of this paper is as follows:

▶ **Theorem 1** (Main theorem). *Let G be a two-player game with a classical-quantum gap: i.e., $\Delta := \mathrm{qval}(G) - \mathrm{cval}(G) > 0$. Let $0 \leq \nu < \Delta$ be a noise parameter.*

Completeness (Noise tolerance). *Let $n \geq 1$ be an integer. Consider a quantum strategy for G that succeeds with probability $\mathrm{qval}(G) - \eta$ for $0 \leq \eta < \nu$. Playing this strategy n times independently in parallel in the threshold game $G^n_{\mathrm{qval}(G)-\nu}$ succeeds with probability at least $1 - \exp(-(\nu - \eta)^2 n/3)$.*[5]

Soundness (Entanglement certification). *There exist constants $0 < c_1, c_2 < 1$ such that for sufficiently large $n > \frac{1}{c_1}$, any strategy that wins the threshold game $G^n_{\mathrm{qval}(G)-\nu}$ with probability $\kappa \geq \exp(-c_1 n)$ must use a quantum state ρ such that its entanglement of formation satisfies $E_F(\rho) \geq c_2 \kappa^2 n$.*

The constants c_1, c_2 depend only on Δ, ν, and the number of possible answers in G.

To gain a better understanding of our theorem we now give an example. Consider the famous CHSH game, which has classical value $\mathrm{cval}(CHSH) = 3/4$ and quantum value $\mathrm{qval}(CHSH) \approx 0.854$. Any strategy for winning a single instance of CHSH with probability $\mathrm{qval}(CHSH) - \eta$ for some parameter $0 \leq \eta < 0.1$ must use some entangled state σ. An "honest" strategy for playing the threshold game $CHSH^n_{.854-2\eta}$ would be to play each instance of $CHSH$ independently using $\sigma^{\otimes n}$ as the entangled resource state. Via a simple Chernoff-Hoeffding bound it is easy to see that this strategy will pass $CHSH^n_{.854-2\eta}$ with overwhelming probability. Thus this game is noise-tolerant. The entanglement of formation of $\sigma^{\otimes n}$ is indeed $\Omega(n)$.

But what about other strategies? Is there a state with entanglement of formation $o(n)$ that can be used to win $CHSH^n_{.854-2\eta}$ sufficiently well? Theorem 1 shows that this is not possible.

---

[4] The classical value of a game is the maximum winning probability when the players employ classical strategies, i.e., do not use entanglement. Similarly, the quantum value of a game is the optimal winning probability when using quantum strategies.

[5] Alternatively, a simpler (but slightly weaker) statement is that playing a strategy the succeeds with probability $\mathrm{qval}(G) - \nu$ in G n times independently in parallel succeeds in the threshold game $G^n_{\mathrm{qval}(G)-\nu}$ with probability $\frac{1}{2}$. This is sufficient for an experiment certifying entanglement.

We list several features of Theorem 1:

1. It holds for *any* two-player game G. In other words, any game with a classical-quantum gap can be "lifted" to another game that tests for large entanglement in a noise-tolerant manner.
2. The players are able to pass our test with high probability by holding a tensor product of noisy few-qubit states (such as $\sigma^{\otimes n}$ where σ has fidelity $1-\nu$ with an EPR pair for any amount). The theorem gives non-trivial guarantees for any $0 \leq \nu < \mathrm{qval}(G) - \mathrm{cval}(G)$, i.e., it is robust to *any* amount of noise up to the classical limit.
3. It gives non-trivial guarantees even for strategies whose success probability is far from optimal; for any constant κ, Theorem 1 still guarantees that $E_F(\rho) \in \Omega(n)$.[6]

Theorem 1 thus shows that by playing the simple threshold game $G^n_{\mathrm{qval}(G)-\nu}$ with an uncharacterized device we can classically test for large amounts of entanglement (as measured by the entanglement of formation), even when the device is highly noisy, as current devices are. As far as we are aware, previous results [33, 14, 16, 35, 18] cannot be used to derive conclusions which are quantitively strong as Theorem 1, even when considering more complex games and proof techniques.[7]

Our main theorem presented above can be easily used to derive another quantitive relation between the advantage in a non-local game G and the *entanglement cost* required to achieve this advantage. Specifically, we prove the following.

▶ **Theorem 2.** *Let G be a two-player game with a classical-quantum gap: i.e., $\Delta := \mathrm{qval}(G) - \mathrm{cval}(G) > 0$. Let $0 \leq \nu < \Delta$ be a noise parameter. Then, for any state σ that can be used to win G with probability at least $\mathrm{qval}(G) - \nu$, its entanglement cost satisfies $E_C(\sigma) \geq c_2/4$, where c_2 is the constant from Theorem 1.*

Put in other words: the minimum entanglement cost[8] needed to obtain a super-classical success probability in a non-local game only depends on the classical-quantum gap as well as the number of possible answers in the game.

As we explain in Section 1.4, even given the full description of a state σ, calculating $E_C(\sigma)$ is not easy and no "single letter" formula is known to describe it. Theorem 2 gives a simple lower bound on $E_C(\sigma)$ in terms of σ's advantage in any non-local game G.

The only lower-bound with a similar flavour which was known before is the one given in [46]. There, a (tight) relation between $E_F(\sigma)$ and σ's winning probability in the CHSH game was derived. Self-testing results can, of course, also be used to achieve similar bounds (by taking into account the continuity of the considered entanglement measures), but so far most of the results are non-trivial for a very limited amount of noise and only apply to specific two-player games. In contrast, Theorem 2 holds for any non-local game and amount of noise.

1.4 Why entanglement of formation?

In this section we motivate and explain the relations between the entanglement measures certified by our tests in Theorem 1 and Theorem 2.

[6] However, the constants c_1 and c_2 are probably not optimal and can be improved.

[7] This is not to say that our work supersedes the mentioned works; these derived self-testing statements which certify the *state* and not just its *entanglement* as we do here.

[8] For any σ, $E_F(\sigma) \geq E_C(\sigma)$. Thus, Theorem 2 could have been phrased in terms of the entanglement of formation as well.

Myriad entanglement measurements have been studied by researchers, each possessing various properties [38, 28]. For pure bipartite states $|\psi\rangle^{\mathsf{AB}}$, the coarsest quantity describing entanglement is the *entanglement rank*, which is simply the Schmidt rank of $|\psi\rangle$. However, this is not a very useful measure of entanglement as one can have a state arbitrarily close to a product state, yet have high entanglement rank.

A more natural measure of entanglement is the *entanglement entropy* $E(\psi)$, which is the von Neumann entropy of the reduced density matrix of $|\psi\rangle$ on system A or equivalently B [8, 39]. In fact, the entanglement entropy is the *unique* entanglement measure for pure bipartite states that satisfies a few natural axioms, such as monotonicity under local operations and classical communication (LOCC) and asymptotic continuity [28].

For mixed states the situation is more complicated — there is no clear "best" entanglement measure. The most natural and operational entanglement measures are considered to be the *entanglement cost* E_C and the *distillable entanglement* E_D. In fact, for any entanglement measure M satisfying some natural properties we have that $E_D \leq M \leq E_C$ [28]. Thus the entanglement cost and distillable entanglement are in a sense "extremal" entanglement measures. For pure states, both E_C and E_D are equal to the entanglement entropy.

In the following we focus on E_C. Informally, the entanglement cost of a bipartite quantum state ρ_{AB} describes the number of maximally entangled states required to produce ρ using only LOCC. As LOCC cannot increase entanglement, the pre-shared maximally entangled states describe the sole source of entanglement in such a process and hence quantify how entangled ρ is in a meaningful way.[9]

Formally, the entanglement cost is defined as the following asymptotic quantity:

$$E_C(\rho) = \inf\left\{ r : \lim_{n\to\infty} \left(\inf_{\Lambda} \|\rho^{\otimes n} - \Lambda(\Phi^+_{2^{rn}})\|_1 \right) = 0 \right\} ,$$

where the infimum ranges over all LOCC maps Λ and $\Phi^+_{2^{rn}}$ is the maximally entangled state of rank 2^{rn}. That is, it is the maximal possible rate r at which one can convert $\Phi^+_{2^{rn}}$ into $\rho^{\otimes n}$ with vanishing error in the limit $n \to \infty$.

Computing $E_C(\rho)$ is considered to be a difficult task in general. Due to this reason one usually considers a closely related entanglement measure called the *entanglement of formation*. It is formally defined as follows [9]:

$$E_F(\rho) = \inf\left\{ \sum_i p_i E(\Psi_i) : \rho = \sum_i p_i |\Psi_i\rangle\langle\Psi_i| \right\} .$$

That is, $E_F(\rho)$ is the minimum average entanglement entropy over all pure-state decompositions of ρ.

The entanglement of formation derives its relevance from its relation to the entanglement cost $E_C(\rho)$ discussed above. It describes the rate in which maximally entangled states are converted to ρ using a specific type of LOCC protocols [51] (whereas $E_C(\rho)$ is the minimum over all LOCC protocols). Furthermore, [25] showed that the entanglement cost is equal to the *regularised* entanglement of formation:

$$E_C(\rho) = E_F^{\infty}(\rho) = \lim_{n\to\infty} (E_F(\rho^{\otimes n})/n).$$

[9] Another way of thinking about the operational meaning of entanglement cost is by considering the task of entanglement dilution. There, the goal is to start with initial noiseless entanglement and dilute it to create a target state ρ using LOCC.

For some time it was conjectured that the entanglement of formation is additive and hence $E_C(\rho) = E_F(\rho)$. Today it is known that this is not the case and that the limit in the above equation is needed in general [11].

It is not known how to compute $E_F^\infty(\rho)$ for general ρ, in part because of the infinite limit. The "single-letter" quantity $E_F(\rho)$ does not appear to be much easier to compute because of the minimisation over all possible decompositions of ρ. To date, it can be done only for states with high symmetry [44, 48] or of low dimension [49, 50, 3]. One can imagine that the task of calculating or bounding $E_F(\rho)$ only becomes harder if one does not have full information about ρ as in the scenario considered in the current work.

In the light of the above, one can see our work as giving a way to lower bound those complex entanglement measures for an unknown state ρ in a device-independent manner. Of course, this is not a general method that works for all states ρ, but rather it works for any state ρ that can be used to gain an advantage in non-local games (or, in other words, violate some Bell inequality). Specifically, Theorem 1 gives a lower bound on E_F for high dimensional (while perhaps noisy) states that can be used to pass the threshold game $G^n_{\mathrm{qval}(G)-\nu}$ for some two-player game G. Theorem 2 gives a lower bound on E_C for any state achieving a quantum advantage in a two-player game G. In particular, for any given state one can choose the game G such that the lower bounds on E_F and E_C are maximal.

1.5 Proof technique

The proof idea is simple: if the entanglement of formation of the players' shared state in the threshold game $G^n_{\mathrm{qval}(G)-\nu}$ is $o(n)$ and the players win with non-negligible probability, then this strategy can be transformed into a strategy for the original game G that uses *no* entanglement, yet still wins with probability strictly greater than $\mathrm{cval}(G)$, which would be a contradiction.

This is argued as follows. Consider a two-player game G where the first player receives a question x and produces answer a, and the second player receives question y and responds with answer b. The players win if $V(x, y, a, b) = 1$ for some predicate V. Let $\mathrm{qval}(G) > \mathrm{cval}(G)$.

Now suppose there is a quantum strategy that wins $G^n_{\mathrm{qval}(G)-\nu}$ with decent probability. A simple probabilistic argument implies that conditioned on an event E of winning roughly $\mathrm{qval}(G) - \nu$ fraction of some subset $S \subseteq [n]$ of instances, the players will win the j'th instance with probability close to $\mathrm{qval}(G)$, for an average $j \in [n]$. Another way of phrasing this statement is: Let $(\mathbf{X}_j, \mathbf{Y}_j)$ denote the questions to the two players in the j'th instance of G, and let $(\mathbf{A}_j, \mathbf{B}_j)$ denote their answers. Let $\mathsf{P}_{\mathbf{X}_j\mathbf{Y}_j\mathbf{A}_j\mathbf{B}_j|E}$ denote the joint distribution of questions and answers of the j'th coordinate in this hypothetical strategy, conditioned on the event E. Then sampling a tuple $(\mathbf{X}_j, \mathbf{Y}_j, \mathbf{A}_j, \mathbf{B}_j)$ from $\mathsf{P}_{\mathbf{X}_j\mathbf{Y}_j\mathbf{A}_j\mathbf{B}_j|E}$ will satisfy the game predicate V with probability $\mathrm{qval}(G) - \varepsilon > \mathrm{cval}(G)$.

Next, we will prove the following three statements (roughly speaking): (1) $\mathsf{P}_{\mathbf{X}_j\mathbf{Y}_j|E} \approx \mathsf{P}_{\mathbf{X}_j\mathbf{Y}_j}$, (2) $\mathsf{P}_{\mathbf{A}_j|\mathbf{X}_j\mathbf{Y}_jE} \approx \mathsf{P}_{\mathbf{A}_j|\mathbf{X}_jE}$, and (3) $\mathsf{P}_{\mathbf{B}_j|\mathbf{X}_j\mathbf{Y}_j\mathbf{A}_jE} \approx \mathsf{P}_{\mathbf{B}_j|\mathbf{Y}_jE}$, where "$\approx$" denotes closeness in statistical distance. Notice that without the conditioning event E, the first item would be trivial and the second item would follow exactly from the non-signaling condition between the players. To prove the third item, we use the fact that the hypothetical strategy for the threshold game uses $o(n)$ bits of entanglement; intuitively this implies that each instance of G can only use $o(1)$ bits of entanglement.

Putting these three items together, we obtain a classical strategy for G: the first player receives question $\mathbf{X}_j$, and samples an answer $\mathbf{A}_j$ from the distribution $\mathsf{P}_{\mathbf{A}_j|\mathbf{X}_jE}$. The second player receives question $\mathbf{Y}_j$ and samples from $\mathsf{P}_{\mathbf{B}_j|\mathbf{Y}_jE}$. The joint distribution of their questions and answers will be close to $\mathsf{P}_{\mathbf{X}_j\mathbf{Y}_j\mathbf{A}_j\mathbf{B}_j|E}$, but that implies that they will win G with probability $\mathrm{qval}(G) - \varepsilon > \mathrm{cval}(G)$, which is a contradiction.

The proof strategy and the techniques used are heavily inspired by the proofs of the *parallel repetition theorem* in classical complexity theory [41, 27, 40], and subsequently the work on the *quantum parallel repetition problem*. This problem asks for a bound on $\mathrm{qval}(G^n)$ if $\mathrm{qval}(G) < 1$, where G^n is like the threshold game except we demand that the players win *all* instances of G. It is conjectured that $\mathrm{qval}(G^n)$ decays exponentially with n, although the best general upper bound is that $\mathrm{qval}(G^n)$ decays polynomially with n when $\mathrm{qval}(G) < 1$ [52]. Nearly all of the works that study the quantum parallel repetition problem [30, 15, 5, 6] share the proof strategy of transforming a "too-good-to-be-true" strategy for the repeated game G^n into a "too-good-to-be-true" strategy for the single game G, namely a quantum strategy with success probability better than $\mathrm{qval}(G)$, a contradiction. These works all use information-theoretic machinery in the proof, and in this work we use the same tools.

The full proof can be found at `https://arxiv.org/abs/1712.09368`.

1.6 Related work

Our work is the first that addresses directly the question of certifying the entanglement of formation of high dimensional states in a noise-tolerant way (while the case of a single CHSH game was already considered in [46] as mentioned above).

Any robust self-testing result can be used to certify any continuous entanglement measures (e.g. the entanglement of formation); but as explained before, such results cannot accommodate the kinds of noise considered here. In addition to the self-testing results mentioned before [33, 14, 16, 20, 35, 18], the only other self-testing result that certifies asymptotically growing amounts of entanglement is from the work of Reichardt, Unger and Vazirani [42], who show how to verify quantum computations using classical resources only. At the heart of their result is a *sequential* protocol where the experimenter plays many rounds of the CHSH game with the two players in order to certify the presence of many EPR pairs. However, like the other self-testing results, the protocol of [42] is also not noise-tolerant in the sense considered here.

If one cares just about certifying high *entanglement rank* of a state (rather than certifying an entanglement measure such as E_F, or precisely characterizing the state as in self-testing), then we can combine the following two independent results to address the question of noise-tolerant, device-independent testing of asymptotically growing amounts of entanglement: The work of [40] shows that the *classical* value of a threshold game $G^n_{\mathrm{cval}(G)+\delta}$ decays exponentially fast with n (if $\mathrm{cval}(G) < 1$). The work of [31] shows that the maximum quantum success probability in a game F using dimension-d entanglement is at most $d\,\mathrm{cval}(F)$. Letting F be a threshold game, we obtain that d must be exponentially large in any quantum strategy whose winning probability is say at least a small constant. Since the threshold game is noise-tolerant (i.e. it can be won with high probability with noisy strategies), this gives a noise-tolerant test for *entanglement rank*. This same argument can be modified to show that the 1/2-*Rényi entropy* of the state[10] must be linear in n.

Our test lower bounds a stronger entanglement measure, the entanglement of formation, which in the pure state case is the entanglement entropy and therefore a lower bound on the 1/2-Rényi entropy. There can be arbitrarily large gaps between the von Neumann entropy and the 1/2-Rényi entropy of a pure state.

[10] The 1/2-Rényi entropy of a pure state $|\psi\rangle$ is $2\log(\sum_i \lambda_i^{1/2})$ where λ_i are the eigenvalues of the reduced density matrix of $|\psi\rangle$ on either side.

The broader goal of certifying the dimension of a quantum system in a device-independent manner has been heavily studied under the heading of *dimension witnesses*. Much of the work on dimension witnesses has focused on finding Bell inequalities such that achieving the optimal violation requires an entangled state of a certain dimension [12, 36, 13]. Many of these works construct and design dimension witnesses using a combination of analytical and numerical techniques.

1.7 Future work

Some open problems and future directions include:

1. Quantitatively improve our results. The constants c_1, c_2 in Theorem 1 are small; for the CHSH game, the constant c_1 is on the order of 10^{-6} and thus in order for our Theorem to give any guarantees, $\sim 10^6$ CHSH games would have to be played. Even though recent experiments are capable of producing such a large amount of states (in [32], for example, order of 10^{10} signals were produced), an improvement of the constants can lead to the ability of certifying *much* more entanglement in such experiments. Our analysis is likely far from tight and significant quantitative improvements can probably be gained by tailoring the analysis to a specific game, such as the CHSH game.
2. To get a non-trivial bound on the entanglement of formation, this requires that the success probability κ is at least $\sim 1/\sqrt{n}$. Can this dependence on κ be improved?
3. Can one prove a version of Theorem 1 for some non-local games G that allows one to lower bound other measures of entanglement, such as distillable entanglement[11] or quantum conditional entropy? The results of [47, 21] indicate that this cannot be done for arbitrary amount of noise for all games since there are Bell inequalities that can be violated while using states with un-distillable entanglement or positive conditional entropy.
4. Can one prove a self-testing result for a growing number of EPR pairs that is also noise-tolerant in the sense described above? A concrete goal would be to characterize all near-optimal strategies for the threshold game $CHSH^n_{.854-\nu}$. The results of [19] hint that by sticking to the current measures of distance considered in self-testing results any characterization of near-optimal strategies for $CHSH^n_{.854-\nu}$, in the regime of high amount of noise, must include also non-entangled states. Hence, we do not expect self-testing results (as they are phrased today) to allow for certification of entanglement in the presence of arbitrary noise using threshold games.

A Complete Dichotomy for Complex-Valued Holant^c

Miriam Backens[1]
Department of Computer Science, University of Oxford, UK
miriam.backens@cs.ox.ac.uk

Abstract

Holant problems are a family of counting problems on graphs, parametrised by sets of complex-valued functions of Boolean inputs. Holant^c denotes a subfamily of those problems, where any function set considered must contain the two unary functions pinning inputs to values 0 or 1. The complexity classification of Holant problems usually takes the form of dichotomy theorems, showing that for any set of functions in the family, the problem is either #P-hard or it can be solved in polynomial time. Previous such results include a dichotomy for real-valued Holant^c and one for Holant^c with complex symmetric functions, i.e. functions which only depend on the Hamming weight of the input.

Here, we derive a dichotomy theorem for Holant^c with complex-valued, not necessarily symmetric functions. The tractable cases are the complex-valued generalisations of the tractable cases of the real-valued Holant^c dichotomy. The proof uses results from quantum information theory, particularly about entanglement. This full dichotomy for Holant^c answers a question that has been open for almost a decade.

1 Introduction

Holant problems are a framework for the analysis of counting problems defined on graphs. They encompass and generalise other counting complexity frameworks like counting constraint satisfaction problems (#CSP) [9, 10] and counting graph homomorphisms [10, 4].

A Holant instance is defined by assigning a function from a specified set to each vertex of a graph, with the edges incident on that vertex corresponding to inputs of the function. The counting problem is a sum-of-products computation: multiplying all the function values

[1] The research leading to these results has received funding from EPSRC via grant EP/L021005/1 and from the European Research Council under the European Union's Seventh Framework Programme (FP7/2007-2013) ERC grant agreement no. 334828. and then summing over the different assignments of input values to the edges [10]. A more rigorous definition can be found in Section 2. In this work, we consider only complex-valued functions of Boolean inputs. Throughout, all numbers are assumed to be algebraic [4].

Problems expressible in the Holant framework include counting matchings or counting perfect matchings, counting vertex covers [10], and counting Eulerian orientations [14]. A Holant problem can also be thought of as the problem of contracting a tensor network; from that perspective, each function corresponds to a tensor with one index for each input [7].

The main goal in the analysis of Holant problems is the derivation of dichotomy theorems, showing that all problems in a certain family are either polynomial time solvable or #P-hard. Families of Holant problems are often defined by assuming that the function sets contain specific functions, which are said to be 'freely available'. As an example, the problem #CSP($\mathcal{F}$) for a function set $\mathcal{F}$ effectively corresponds to the Holant problem $\textsc{Holant}\left(\mathcal{F} \cup \{=_n |\ n \in \mathbb{N}_{\geq 1}\}\right)$, where $(=_1) : \{0,1\} \to \mathbb{C}$ is the function that is 1 on both inputs, and, for $n \geq 2$, $(=_n) : \{0,1\}^n \to \mathbb{C}$ is the function satisfying:

$$(=_n)(x_1, x_2, \ldots, x_n) = \begin{cases} 1 & \text{if } x_1 = x_2 = \ldots = x_n \\ 0 & \text{otherwise.} \end{cases} \tag{1}$$

The problem $\textsc{Holant}^c\left(\mathcal{F}\right)$ is the Holant problem where the unary functions pinning edges to values 0 or 1 are available in addition to the elements of $\mathcal{F}$:

$$\textsc{Holant}^c\left(\mathcal{F}\right) = \textsc{Holant}\left(\mathcal{F} \cup \{\delta_0, \delta_1\}\right), \tag{2}$$

with $\delta_0(0) = 1$, $\delta_0(1) = 0$ and $\delta_1(0) = 0$, $\delta_1(1) = 1$ [9]. Another important family is $\textsc{Holant}^*$, in which all unary functions are freely available [6].

Known Holant dichotomies include a full dichotomy for $\textsc{Holant}^*$ [6], dichotomies for $\textsc{Holant}^c$ with symmetric functions, i.e. where all functions in the sets considered depend only on the Hamming weight of the input [9], and a dichotomy for real-valued $\textsc{Holant}^c$, where functions need not be symmetric but must take values in $\mathbb{R}$ instead of $\mathbb{C}$ [11]. There is also a dichotomy for symmetric $\textsc{Holant}$ [5] and a dichotomy for non-negative real-valued $\textsc{Holant}$ [18]. Both existing results about $\textsc{Holant}^c$ are proved via dichotomies for #CSP problems with complex-valued, not necessarily symmetric functions: in the first case, a dichotomy for general #CSP problems, and in the second case, a dichotomy for $\#\mathrm{CSP}_2^c$, a subfamily of #CSP in which each variable must appear an even number of times and variables can be pinned to 0 or 1.

While many dichotomies have been derived for functions taking values in some smaller set, we consider complex-valued functions to be the natural setting for Holant problems. This is motivated in part by connecting Holant problems to quantum computation, where complex numbers naturally arise: the problem of strongly classically simulating a quantum circuit with fixed input and output states can immediately be expressed as a Holant problem. The second justification for considering complex numbers is that many tractable sets find a more natural expression over $\mathbb{C}$. An example of this are the 'affine functions' (see Section 3.1): they were originally discovered as several distinct tractable sets for a smaller codomain, but their definition is vastly more straightforward when expressed in terms of complex values [10]. Thirdly, some problems parametrised in terms of real values are naturally connected by *complex-valued* holographic transformations (defined in Section 2.1): for example, the problem of counting Eulerian orientations on 4-regular graphs is expressed in the Holant framework in this way [5, 14].

We therefore build on the existing work to derive a $\textsc{Holant}^c$ dichotomy for complex-valued, not necessarily symmetric functions. In the process, we employ notation and results from quantum information theory. This approach was first used in a recent paper [2]

to derive a dichotomy for Holant^+, in which four unary functions are freely available, including the ones available in Holant^c: $\text{Holant}^+(\mathcal{F}) = \text{Holant}(\mathcal{F} \cup \{\delta_0, \delta_1, \delta_+, \delta_-\})$, where $\delta_+(x) = 1$ for both inputs (i.e. it is the same as the unary equality function[2]) and $\delta_-(x) = (-1)^x$.

A core part of quantum theory, and also of the quantum approach to Holant problems, is the notion of entanglement. A pure[3] quantum state of n qubits, the quantum equivalents of bits, is represented by a vector in the space $(\mathbb{C}^2)^{\otimes n}$, which consists of n tensor copies of $\mathbb{C}^2$. Such a vector is called *entangled* if it cannot be written as a tensor product of vectors from each copy of $\mathbb{C}^2$.

An n-ary function $f : \{0,1\}^n \to \mathbb{C}$ can be considered as a vector in $\mathbb{C}^{2^n}$ by treating each input as an element of an orthonormal basis for that space and using the function values as coefficients in a linear combination of those basis vectors (cf. Section 2). This vector space $\mathbb{C}^{2^n}$ is isomorphic to $(\mathbb{C}^2)^{\otimes n}$, allowing functions to be brought into correspondence with quantum states. We thus call a function entangled if the associated vector is entangled. Identifying this property in Holant problems lets us apply some of the large body of work on quantum entanglement [19, 13, 12, 17] to Holant problems. The resulting complexity classification of Holant problems remains non-quantum, we simply employ a different set of mathematical tools in their analysis.

In the Holant^+ dichotomy, it was shown how to construct a gadget for an entangled ternary function, given an n-ary entangled function with $n \geq 3$ and using the freely-available unary functions. Furthermore, in most cases it was shown to be possible to realise a ternary symmetric function from this [2]. We show how to adapt those constructions to the Holant^c framework, where only two unary functions are freely available. This does not always work, yet if the construction fails, it is always the case that either the problem is tractable by the Holant^* dichotomy or it is equivalent to $\#\text{CSP}_2^c$ using techniques from [11]. With these adaptations, we therefore extend the dichotomy theorem for real-valued Holant^c to arbitrary complex-valued functions.

In the following, Section 2 contains the formal definition of Holant problems and an overview over common strategies used in classifying their complexity. We recap existing results in Section 3. The new dichotomy and its constituent lemmas are proved in Section 4. Section 5 contains the conclusions and outlook.

2 Holant problems

Holant problems are a framework for counting complexity problems defined on graphs, first introduced in the conference version of [10]. Let $G = (V, E)$ be a graph with vertices V and edges E, which may contain self-loops and multiple edges between the same pair of vertices, and let $\mathcal{F}$ be a set of complex-valued functions of Boolean inputs. Throughout, when we refer to complex numbers we mean algebraic complex numbers. Let π be a function that assigns to each degree-n vertex v in the graph an n-ary function $f_v \in \mathcal{F}$ and also assigns one edge incident on the vertex to each input of the function. This determines a complex value

[2] The availability of the function δ_+ is indeed important to the Holant^+ dichotomy proof. This is a difference between the Holant framework and #CSP, where a constraint equal to δ_+ would have no effect.

[3] There are also *mixed* quantum states, which have a different mathematical representation, and which are not considered here.

associated with the tuple $(\mathcal{F}, G, \pi)$, called the *Holant* and defined as follows:

$$\text{Holant}_{(\mathcal{F},G,\pi)} = \sum_{\sigma:E\to\{0,1\}} \prod_{v\in V} f\left(\sigma|_{E(v)}\right). \tag{3}$$

Here, σ is an assignment of a Boolean value to each edge in the graph and $\sigma|_{E(v)}$ is the restriction of σ to the edges incident on vertex v. The tuple $(\mathcal{F}, G, \pi)$ is called a *signature grid*.

The associated counting problem is Holant $(\mathcal{F})$: given a signature grid $(\mathcal{F}, G, \pi)$ for the fixed set of functions $\mathcal{F}$, find $\text{Holant}_{(\mathcal{F},G,\pi)}$.

It is often useful to think of the functions, also called signatures, as vectors or tensors [7]. The n-ary functions can be put in one-to-one correspondence with vectors in $\mathbb{C}^{2^n}$ as follows: pick an orthonormal basis for $\mathbb{C}^{2^n}$ and label its elements $\{|x\rangle\}_{x\in\{0,1\}^n}$, i.e. each basis vector is labelled by one of the 2^n n-bit strings.[4] Then assign to each $f : \{0,1\}^n \to \mathbb{C}$ the vector $|f\rangle = \sum_{x\in\{0,1\}^n} f(x)\,|x\rangle$. Conversely, any vector $|\psi\rangle \in \mathbb{C}^{2^n}$ corresponds to an n-ary function $\psi : \{0,1\}^n \to \mathbb{C} :: x \mapsto \langle x|\psi\rangle$, where $\langle\cdot|\cdot\rangle$ denotes the inner product of two vectors.[5] The product of two functions of disjoint sets of variables corresponds to the tensor product of the associated vectors, i.e. if $h(x_1,\ldots,x_n,y_1,\ldots,y_m) = f(x_1,\ldots,x_n)g(y_1,\ldots,y_m)$ then $|h\rangle = |f\rangle \otimes |g\rangle$. Where no confusion arises, we drop the tensor product symbol and sometimes even combine labels into a single 'ket' $|\cdot\rangle$: for example, instead of writing $|0\rangle \otimes |0\rangle$, we may write $|0\rangle\,|0\rangle$ or $|00\rangle$. If g is a unary signature, we sometimes write $\langle g|_l\,|f\rangle$ to indicate that the l-th input of f is connected to a vertex with signature g.

The vector perspective is particularly useful for bipartite Holant problems, which arise on bipartite graphs if we assign functions from two different signature sets to the vertices in the two different partitions. Then the Holant becomes the inner product between two vectors corresponding to the two partitions. Formally: let $G = (V, W, E)$ be a bipartite graph with vertex partitions V and W, and let $\mathcal{F}, \mathcal{G}$ be two sets of signatures. Suppose π is a function that assigns elements of $\mathcal{F}$ to vertices from V and elements of $\mathcal{G}$ to vertices from W and otherwise acts as described above. Then:

$$\text{Holant}_{(\mathcal{F}|\mathcal{G},G,\pi)} = \left(\bigotimes_{v\in V}(|f_v\rangle)^T\right)\left(\bigotimes_{w\in W}|g_w\rangle\right), \tag{4}$$

where we assume the two tensor products are arranged so that the appropriate components of the two vectors meet. The bipartite Holant problem over signature sets $\mathcal{F}$ and $\mathcal{G}$ is denoted by Holant $(\mathcal{F} \mid \mathcal{G})$.

Any Holant instance can be made bipartite without changing the value of the Holant by inserting an additional vertex in the middle of each edge and assigning it the binary equality signature $=_2$. Thus, Holant $(\mathcal{F}) \equiv_T$ Holant $(\mathcal{F} \mid \{=_2\})$, i.e. the two problems have the same complexity.

In the following, we use the function and vector perspectives on signatures interchangeably.

2.1 Complexity classification

Most complexity results about the Holant problem take the form of *dichotomies*, showing that for all signature sets in a specific family, the problem is either #P-hard or in FP. Such a dichotomy is not expected to be true for all counting complexity problems: if FP $\neq$ #P, then there are problems in #P $\setminus$ FP which are not #P-hard [6].

[4] The $|\cdot\rangle$ notation for vectors is the Dirac or bra-ket notation commonly used in quantum theory.

[5] Strictly speaking, this notation refers to the complex inner product, i.e. $\langle x|$ is the conjugate transpose of $|x\rangle$, but the distinction is irrelevant if all coefficients of $|x\rangle$ are real.

We write $A \leq_T B$ if there exists a polynomial-time reduction from problem B to problem A and $A \equiv_T B$ if $(A \leq_T B) \wedge (B \leq_T A)$. A number of polynomial-time reduction techniques are commonly used in Holant problems.

The technique of *holographic reductions* is the origin of the name Holant. Let M be a 2 by 2 invertible complex matrix and define $M \circ f = M^{\otimes \operatorname{arity}(f)} |f\rangle$, where $M^{\otimes 1} = M$ and $M^{\otimes n+1} = M \otimes M^{\otimes n}$. Furthermore, let $M \circ \mathcal{F} = \{M \circ f \mid f \in \mathcal{F}\}$. This is called a *holographic transformation*. Let $\mathcal{F}$ and $\mathcal{G}$ be two signature sets. Then:

$$\textsc{Holant}\left(\mathcal{F} \mid \mathcal{G}\right) \equiv_T \textsc{Holant}\left(M \circ \mathcal{F} \mid (M^{-1})^T \circ \mathcal{G}\right) \tag{5}$$

and, in fact, $\text{Holant}_{(\mathcal{F}|\mathcal{G},G,\pi)} = \text{Holant}_{(M\circ\mathcal{F}|(M^{-1})^T\circ\mathcal{G},G,\pi')}$; this is Valiant's Holant Theorem [20].

A second technique is that of *gadgets*. Consider a subgraph of some signature grid, which is connected to the larger graph by n edges. This subgraph can be replaced by a single degree-n vertex with an appropriate signature without changing the value of the overall Holant. Thus, if there exists some subgraph with signatures taken from $\mathcal{F}$ such that the effective signature for that subgraph is g, then [6]:

$$\textsc{Holant}\left(\mathcal{F} \cup \{g\}\right) \leq_T \textsc{Holant}\left(\mathcal{F}\right). \tag{6}$$

We say g is *realisable* over $\mathcal{F}$. As multiplying a signature by a non-zero constant does not change the complexity of a Holant problem, we also consider g realisable if we can construct a gadget with effective signature cg for some $c \in \mathbb{C} \setminus \{0\}$. In bipartite signature grids, we may distinguish between left-hand side (LHS) gadgets and right-hand side (RHS) gadgets, which can be used as if they are signatures for the left and right partitions, respectively.

Finally, there is the technique of *polynomial interpolation*. Let $\mathcal{F}$ be a set of signatures and suppose g is a signature that cannot be realised over $\mathcal{F}$. If, given any signature grid over $\mathcal{F} \cup \{g\}$, it is possible to set up a family of signature grids over $\mathcal{F}$ such that the Holant for the original problem instance can be determined efficiently from the Holant values of the family by solving a linear system, then g is said to be *interpolatable* over $\mathcal{F}$. We do not directly use polynomial interpolation here, though the technique is employed by many of the results we build upon. A rigorous definition of polynomial interpolation can be found in [10].

2.2 Properties of signatures

A signature is called *symmetric* if its value as a function depends only on the Hamming weight of the inputs – in other words, it is invariant under any permutation of the inputs. Symmetric functions are often written in the short-hand notation $f = [f_0, f_1, \ldots, f_n]$, where f_k is the value f takes on inputs of Hamming weight k.

A signature is *degenerate* if it can be written as a tensor product of unary signatures. Conversely, using language from quantum theory, a signature is *entangled* if it cannot be written as a tensor product of unary signatures. This corresponds to the notion of *non-degenerate* signatures in the Holant literature. For example, $|01\rangle + |11\rangle$ is not entangled because it can be rewritten as $(|0\rangle + |1\rangle) \otimes |1\rangle$. On the other hand, the binary equality signature $|00\rangle + |11\rangle$ is entangled. If $k \geq 2$, a k-ary signature can be partially decomposable into a tensor product, e.g. $|0\rangle \otimes (|00\rangle + |11\rangle)$. We say a signature is *genuinely entangled* if there is no way of decomposing it as a tensor product of signatures of any arity. A genuinely entangled signature of arity at least 3 is said to be *multipartite entangled* (as opposed to the bipartite entanglement in a signature of arity 2). A non-genuinely entangled signature has multipartite entanglement if it has a tensor factor corresponding to a genuinely entangled signature of arity at least 3 and a set of signatures has multipartite entanglement if it contains a signature that does.

Among genuinely entangled ternary signatures, we distinguish two types, also known as 'entanglement classes' [12]. Each entanglement class contains signatures that are related via local holographic transformations, i.e. two states $|f\rangle, |g\rangle$ are in the same entanglement class if and only if there exist some 2 by 2 invertible matrices A, B, C such that $(A \otimes B \otimes C)|f\rangle = |g\rangle$.

In quantum theory, the two entanglement classes are named after their representative states: the ternary equality signature $|000\rangle + |111\rangle$, called the GHZ-state, and the ternary perfect matching signature $|001\rangle + |010\rangle + |100\rangle$, called the W state. We say that a signature has GHZ type if it is equivalent to the GHZ state under local holographic transformations and that a signature has W type if it is equivalent to the GHZ state under local holographic transformations. In the Holant literature, GHZ-type signatures are called the *generic case* and W type signatures are called the *double-root case* [9].

The two types of ternary genuinely entangled signatures can be distinguished as follows [17]. Let f be a ternary signature and write:

$$|f\rangle = \sum_{k,\ell,m \in \{0,1\}} a_{k\ell m} |k\ell m\rangle, \tag{7}$$

where $a_{k\ell m} \in \mathbb{C}$ for all $k, \ell, m \in \{0, 1\}$. Then $|f\rangle$ has GHZ type if the following polynomial in the coefficients is non-zero:

$$(a_{000}a_{111} - a_{010}a_{101} + a_{001}a_{110} - a_{011}a_{100})^2 - 4(a_{010}a_{100} - a_{000}a_{110})(a_{011}a_{101} - a_{001}a_{111}). \tag{8}$$

The signature $|f\rangle$ has W type if the above polynomial is zero, and furthermore each of the following three expressions is satisfied:

$$(a_{000}a_{011} \neq a_{001}a_{010}) \vee (a_{101}a_{110} \neq a_{100}a_{111}) \tag{9}$$

$$(a_{001}a_{100} \neq a_{000}a_{101}) \vee (a_{011}a_{110} \neq a_{010}a_{111}) \tag{10}$$

$$(a_{011}a_{101} \neq a_{001}a_{111}) \vee (a_{010}a_{100} \neq a_{000}a_{110}). \tag{11}$$

If the polynomial (8) is zero and at least one of the above expressions evaluates to false, then the signature is not genuinely entangled.

There are many other classes of entangled signatures for higher arities [21, 15, 16, 3], but those are not directly relevant to this paper.

Given a set of signatures that contains multipartite entanglement in the Holant^c framework, we can assume without loss of generality that we have a genuinely multipartite-entangled signature. To see this, consider a non-zero signature $|\psi\rangle$ that has multipartite entanglement, and suppose $|\psi\rangle = |\psi_1\rangle \otimes |\psi_2\rangle$. Then at least one of the tensor factors must have multipartite entanglement, assume this is $|\psi_1\rangle$. Now, $|\psi\rangle$ is non-zero, so $\langle x|\psi_2\rangle$ must be non-zero for some bit string x. Thus we can realise $|\psi_1\rangle$ by connecting all inputs associated with $|\psi_2\rangle$ to $|0\rangle$ or $|1\rangle$, as appropriate.

3 Existing results

It is difficult to determine the complexity of the general Holant problem. Thus, all existing dichotomies make use of one or more simplifying assumptions: either they assume the availability of certain signatures in all signature sets considered [7, 6, 2], or they only consider signature sets containing functions taken from more restricted families, e.g. symmetric functions [9, 5] or functions taking only real [11] or even non-negative real values [18].

Among others, the following variants of the Holant problem have been considered:

- Holant* $(\mathcal{F})$ = Holant $(\mathcal{F} \cup \mathcal{U})$, where $\mathcal{U}$ is the set of all unary signatures [6],

- $\text{Holant}^+(\mathcal{F}) = \text{Holant}(\mathcal{F} \cup \{\delta_0, \delta_1, \delta_+, \delta_-\})$, where $\delta_+(x) = 1$ and $\delta_-(x) = (-1)^x$ [2], and
- $\text{Holant}^c(\mathcal{F}) = \text{Holant}(\mathcal{F} \cup \{\delta_0, \delta_1\})$ [9, 11].

Several variants of complex-weighted Boolean counting constraint satisfaction problems (#CSP) have also been expressed in the Holant framework. These include:

- $\#\text{CSP}(\mathcal{F}) = \text{Holant}(\mathcal{F} \mid \mathcal{G})$, where $\mathcal{G} = \{=_n \mid n \in \mathbb{N}_{\geq 1}\}$ is the set containing all equality signatures [10], and
- $\#\text{CSP}_2^c(\mathcal{F}) = \text{Holant}(\mathcal{F} \mid \{\delta_0, \delta_1\} \cup \{=_{2n} \mid n \in \mathbb{N}_{\geq 1}\})$ [11].

The $\#\text{CSP}_2^c$ problems assume availability of the signatures pinning inputs to 0 or 1, respectively, as well as equality signatures of even arity.

Existing results include full dichotomies for Holant^* [6], Holant^+ [2], #CSP [10], and $\#\text{CSP}_2^c$ [11]. There are also dichotomies for Holant^c with symmetric complex-valued signatures [6], Holant^c with arbitrary real-valued signatures [11], Holant with symmetric complex-valued signatures [5], and Holant with arbitrary non-negative real-valued signatures [18].

3.1 Preliminary definitions

The following definitions will be used throughout the dichotomy theorems. Write:

$$T = \begin{pmatrix} 1 & 0 \\ 0 & e^{i\pi/4} \end{pmatrix}, \qquad X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \qquad \text{and} \qquad K = \begin{pmatrix} 1 & 1 \\ i & -i \end{pmatrix}, \tag{12}$$

where $i^2 = -1$. Then let:

- $\mathcal{T}$ be the set of all unary and binary signatures,
- $\mathcal{E}$ be the set of all signatures that are non-zero only on two inputs x and $\bar{x}$, where $\bar{x}$ denotes the bit-wise complement of x, also called *generalised equality signatures*,
- $\mathcal{M}$ be the set of all signatures that are non-zero only on inputs of Hamming weight at most 1,
- $\mathcal{A}$ be the set of all *affine signatures*, i.e. functions of the form $f(x) = ci^{l(x)}(-1)^{q(x)}\chi$, where $c \in \mathbb{C}$, $l(x)$ is a linear Boolean function, $q(x)$ is a quadratic Boolean function, and χ is the indicator function for an affine space, and
- $\mathcal{L}$ be the set of all signatures f with the property that, for any bit string x in the support of f:

$$\left(\bigotimes_{j=1}^{\text{arity}(f)} T^{x_j} \right) |f\rangle \in \mathcal{A}, \tag{13}$$

where x_j is the j-th bit of x. Elements of $\mathcal{L}$ are called *local affine signatures*.

Denote by $\langle \mathcal{F} \rangle$ the closure of the signature set $\mathcal{F}$ under tensor products. It is straightforward to see that $\mathcal{A} = \langle \mathcal{A} \rangle$ and $\mathcal{L} = \langle \mathcal{L} \rangle$, i.e. these signature sets are already closed under tensor products. If n is a positive integer, we denote by $[n]$ the set $\{1, 2, \ldots, n\}$.

3.2 Dichotomies for Holant variants

The Holant dichotomies generally build upon each other. Dichotomies with fewer freely-available signatures refer to dichotomies for problems with more freely-available signatures, as all tractable cases of the latter must also be tractable cases of the former: removing signatures can never make the problem harder.

▶ **Theorem 1** (Theorem 2.2, [6]). *Let $\mathcal{F}$ be any set of complex valued functions in Boolean variables. The problem* $\text{Holant}^*(\mathcal{F})$ *is polynomial time computable if:*

- $\mathcal{F} \subseteq \langle \mathcal{T} \rangle$, *or*
- $\mathcal{F} \subseteq \langle O \circ \mathcal{E} \rangle$, *where O is a complex orthogonal 2 by 2 matrix, or*
- $\mathcal{F} \subseteq \langle K \circ \mathcal{E} \rangle$, *or*
- $\mathcal{F} \subseteq \langle K \circ \mathcal{M} \rangle$ *or* $\mathcal{F} \subseteq \langle KX \circ \mathcal{M} \rangle$.

In all other cases, $\text{Holant}^*(\mathcal{F})$ *is #P-hard.*

▶ **Theorem 2** (Theorem 6, [9]). *Let $\mathcal{F}$ be a set of complex symmetric signatures.* $\text{Holant}^c(\mathcal{F})$ *is #P-hard unless $\mathcal{F}$ satisfies one of the following conditions, in which case it is tractable:*

- $\text{Holant}^*(\mathcal{F})$ *is tractable, or*
- *there exists a 2 by 2 matrix $S \in \mathcal{S}$ such that $\mathcal{F} \subseteq S \circ \mathcal{A}$, where:*

$$\mathcal{S} = \left\{ S \,\middle|\, (S^T)^{\otimes 2}(=_2), S^T\delta_0, S^T\delta_1 \in \mathcal{A} \right\}. \tag{14}$$

▶ **Theorem 3** (Theorem 4.1, [11]). *A $\#\text{CSP}_2^c(\mathcal{F})$ problem has a polynomial time algorithm if one of the following holds: $\mathcal{F} \subseteq \langle \mathcal{E} \rangle$, $\mathcal{F} \subseteq \mathcal{A}$, $\mathcal{F} \subseteq T \circ \mathcal{A}$, or $\mathcal{F} \subseteq \mathcal{L}$. Otherwise, it is #P-hard.*

The preceding results all apply to complex-valued signatures, but the following theorem is restricted to real-valued ones.

▶ **Theorem 4** (Theorem 5.1, [11]). *Let $\mathcal{F}$ be a set of real-valued signatures. Then* $\text{Holant}^c(\mathcal{F})$ *is #P-hard unless $\mathcal{F}$ is a tractable family for* Holant^* *or* $\#\text{CSP}_2^c$.

3.3 Complexity results for ternary signatures

In addition to the above-mentioned Holant dichotomies, there are also some dichotomies specific to symmetric signatures on three-regular graphs. For signature sets containing a ternary GHZ-type signature, there is furthermore a direct relationship to #CSP, which allows a more general complexity classification. When deriving the Holant^c dichotomy, our general approach will be to attempt to construct a gadget for a genuinely entangled ternary signature and then use the following results.

▶ **Theorem 5** (Theorem 3.4, [9]). $\text{Holant}([y_0, y_1, y_2] | [x_0, x_1, x_2, x_3])$ *is #P-hard unless the signatures $[x_0, x_1, x_2, x_3]$ and $[y_0, y_1, y_2]$ satisfy one of the following conditions, in which case the problem is in FP:*

- $[x_0, x_1, x_2, x_3]$ *is degenerate, or*
- *there is a 2 by 2 matrix M such that:*
  - $[x_0, x_1, x_2, x_3] = M \circ [1, 0, 0, 1]$ *and* $(M^T)^{-1} \circ [y_0, y_1, y_2]$ *is in* $\mathcal{A} \cup \langle \mathcal{E} \rangle$,
  - $[x_0, x_1, x_2, x_3] = M \circ [1, 1, 0, 0]$ *and* $(M^T)^{-1} \circ [y_0, y_1, y_2]$ *is of the form* $[0, *, *]$,
  - $[x_0, x_1, x_2, x_3] = M \circ [0, 0, 1, 1]$ *and* $(M^T)^{-1} \circ [y_0, y_1, y_2]$ *is of the form* $[*, *, 0]$,

with $*$ denoting an arbitrary complex number.

The signature $|000\rangle + |111\rangle$ is invariant under holographic transformations of the form $\left(\begin{smallmatrix} 1 & 0 \\ 0 & \omega \end{smallmatrix}\right)$, where $\omega^3 = 1$. Therefore, a binary signature is considered to be ω-normalised if $y_0 = 0$, or there does not exist a primitive $(3t)$-th root of unity λ, where $gcd(t, 3) = 1$, such that $y_2 = \lambda y_0$. Similarly, a unary signature $[a, b]$ is ω-normalised if $a = 0$, or there does not exist a primitive $(3t)$-th root of unity λ, where $gcd(t, 3) = 1$, such that $b = \lambda a$ [9].

▶ **Theorem 6** (Theorem 4.1, [9]). *Let $\mathcal{G}_1, \mathcal{G}_2$ be two sets of signatures and let $[y_0, y_1, y_2]$ be a ω-normalised and non-degenerate signature. In the case of $y_0 = y_2 = 0$, further assume that $\mathcal{G}_1$ contains a unary signature $[a, b]$ which is ω-normalised and satisfies $ab \neq 0$. Then:*

$$\text{Holant}\left(\{[y_0, y_1, y_2]\} \cup \mathcal{G}_1 \mid \{[1, 0, 0, 1]\} \cup \mathcal{G}_2\right) \equiv_T \#\text{CSP}(\{[y_0, y_1, y_2]\} \cup \mathcal{G}_1 \cup \mathcal{G}_2). \quad (15)$$

More specifically, $\text{Holant}\left(\{[y_0, y_1, y_2]\} \cup \mathcal{G}_1 \mid \{[1, 0, 0, 1]\} \cup \mathcal{G}_2\right)$ *is #P-hard unless*

$$\{[y_0, y_1, y_2]\} \cup \mathcal{G}_1 \cup \mathcal{G}_2 \subseteq \langle \mathcal{E} \rangle \quad \text{or} \quad \{[y_0, y_1, y_2]\} \cup \mathcal{G}_1 \cup \mathcal{G}_2 \subseteq \mathcal{A}, \quad (16)$$

in which cases the problem is in FP.

The following lemmas show how to realise symmetric genuinely entangled ternary signatures from non-symmetric ones. They do not rely on any unary signatures.

▶ **Lemma 7** (Lemma 18, [2]). *Let $|\psi\rangle$ be a ternary GHZ-type signature, i.e. $|\psi\rangle = (A \otimes B \otimes C)\,|\text{GHZ}\rangle$ for some invertible 2 by 2 matrices A, B, C. Then at least one of the three possible symmetric triangle gadgets constructed from three copies of $|\psi\rangle$ is non-degenerate, unless $|\psi\rangle \in K \circ \mathcal{E}$ and is furthermore already symmetric.*

▶ **Lemma 8** (Lemma 19, [2]). *Let $|\psi\rangle$ be a ternary W-type signature, i.e. $|\psi\rangle = (A \otimes B \otimes C)\,|W\rangle$ for some invertible 2 by 2 matrices A, B, C. If $|\psi\rangle \in K \circ \mathcal{M}$ (or $|\psi\rangle \in KX \circ \mathcal{M}$), assume that we also have a binary entangled signature $|\phi\rangle$ that is not in $K \circ \mathcal{M}$ (or $KX \circ \mathcal{M}$, respectively). Then we can realise a symmetric genuinely entangled ternary signature.*

3.4 Results about 4-ary signatures

Besides the above results about ternary signatures, we will also make use of the following result about realising or interpolating the 4-ary equality signature from a more general 4-ary signature.

▶ **Lemma 9** (Lemma 2.38, [8]). *Suppose $\mathcal{F}$ contains a signature f of arity 4 with:*

$$|f\rangle = a\,|0000\rangle + b\,|0011\rangle + c\,|1100\rangle + d\,|1111\rangle\,, \quad (17)$$

where $M = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ has full rank. Then $\text{Pl-Holant}(\{=_4\} \cup \mathcal{F}) \leq_T \text{Pl-Holant}(\mathcal{F})$.

Here, Pl-Holant refers to the Holant problem for planar graphs; the lemma can also be used in the non-planar setting.

▶ **Lemma 10** (Lemma 5.2, [11]). *Suppose $\mathcal{F}$ contains a 4-ary generalised equality signature f, i.e. $f \in \mathcal{F} \cap \mathcal{E}$ and $arity(f) = 4$. Then* $\text{Holant}\,(\mathcal{F}) \equiv_T \#\text{CSP}_2(\mathcal{F})$*, the counting constraint satisfaction problem in which each variable appears an even number of times.*

4 The dichotomy

Our dichotomy proof uses techniques from the Holant$^+$ dichotomy [2] and from the real-valued Holant^c dichotomy [11], as well as some new results.

The core strategy in the hardness part of the Holant$^+$ dichotomy proof is to realise a symmetric genuinely entangled ternary signature f and a symmetric entangled binary signature g for which $\text{Holant}\,(\{f\} \mid \{g\})$ is known to be #P-hard. The techniques for realising low-arity signatures utilise knowledge from quantum information theory. They rely crucially on having access to the four unary signatures $\delta_0, \delta_1, \delta_+$ and δ_-, and do not seem directly adaptable to the Holant^c setting.

The dichotomy proof for real-valued Holant^c contains arity-reduction techniques that require only δ_0, δ_1, and self-loops. Yet there are two main barriers to extending this result to complex-valued signatures: firstly, some of the hardness results for genuinely entangled ternary signatures in [11] only apply to real values. Secondly, some cases of the dichotomy proof rely on being able to interpolate all unary signatures using techniques that have only been shown to work for real-valued signatures.

In the present work, our strategy is similar to that in the Holant$^+$ dichotomy: we attempt to realise symmetric genuinely entangled ternary signatures. There are now two cases in which this is not possible: either there is no multipartite entanglement, in which case the problem is in FP, or all genuinely entangled signatures in the closure of $\mathcal{F} \cup \{\delta_0, \delta_1\}$ under gadgets have even arity, in which case the smallest signature that can give hardness has arity 4. For arity reduction, we adapt techniques from [11], modifying them to work for complex values. If all genuinely entangled signatures have even arity, we show analogously to [11] that is is always possible to realise a 4-ary signature of a specific form, which can then be used to realise or interpolate $=_4$. Furthermore, we adapt symmetrisation techniques for genuinely entangled ternary signatures from [2] to work in the Holant^c setting. Thus, we never need to interpolate arbitrary unary signatures. In one subcase, we do require unary signatures other than δ_0 and δ_1, but we give a new construction for realising sufficiently many such signatures by gadgets.

In this extended abstract, we give sketch proofs of the new results; full proofs may be found in the full version of the paper [1].

4.1 Hardness proofs involving a genuinely entangled ternary signature

First, we prove two lemmas that give a complexity classification for Holant^c problems in the presence of any genuinely entangled ternary signature with complex coefficients.

▶ **Lemma 11.** *Let $f \in \mathcal{F}$ be a genuinely entangled ternary signature. Then* Holant$^c(\mathcal{F})$ *is #P-hard unless:*

- Holant$^*(\mathcal{F})$ *is tractable, or*
- $\mathcal{F} \subseteq S \circ \mathcal{A}$ *for some $S \in \mathcal{S}$, as defined in* (14).

In both of those cases, the problem Holant$^c(\mathcal{F})$ *is tractable.*

Proof (sketch). Let $\mathcal{F}' = \mathcal{F} \cup \{\delta_0, \delta_1\}$. We distinguish cases according to whether f is symmetric or not, and according to its entanglement class.

If f is symmetric and has GHZ type, there exists an invertible holographic transformation M that maps f to $=_3$. Transform the Holant problem to bipartite form by adding an extra vertex carrying the signature $=_2$ in the middle of each edge. It is straightforward to see that allowing the signatures δ_0 and δ_1 on both partitions does not affect the complexity, i.e.:

$$\text{Holant}^c(\mathcal{F}) \equiv_T \text{Holant}(\{=_2\} \mid \mathcal{F}') \equiv_T \text{Holant}(\{=_2, \delta_0, \delta_1\} \mid \mathcal{F}'). \tag{18}$$

Apply Valiant's Holant theorem with the holographic transformation M identified above:

$$\text{Holant}(\{=_2, \delta_0, \delta_1\} \mid \mathcal{F}') \equiv_T \text{Holant}\left((M^{-1})^T \circ \{=_2, \delta_0, \delta_1\} \mid M \circ \mathcal{F}'\right). \tag{19}$$

As $(=_3) \in M \circ \mathcal{F}'$ by construction, the problem now has the same form as the LHS of (15), with $[y_0, y_1, y_2] = (M^{-1})^T \circ (=_2)$, $\mathcal{G}_1 = (M^{-1})^T \circ \{\delta_0, \delta_1\}$, and $\mathcal{G}_2 = M \circ \mathcal{F}'$. With a bit of effort, it can be shown that the conditions of Theorem 6 regarding ω-normalisation and unary signatures are always satisfiable by choosing M appropriately; hence:

$$\text{Holant}^c(\mathcal{F}) \equiv_T \#\text{CSP}\left((M^{-1})^T \circ \{=_2, \delta_0, \delta_1\} \cup M \circ \mathcal{F}'\right). \tag{20}$$

Now, as stated in Theorem 6, this problem is #P-hard unless $(M^{-1})^T \circ \{=_2, \delta_0, \delta_1\} \cup M \circ \mathcal{F}'$ is a subset of $\langle \mathcal{E} \rangle$ or a subset of $\mathcal{A}$. With some additional work, these conditions can be shown to correspond to $\text{Holant}^c(\mathcal{F})$ being tractable if $\mathcal{F} \subseteq \langle O \circ \mathcal{E} \rangle$ for some orthogonal 2×2 matrix O, if $\mathcal{F} \subseteq \langle K \circ \mathcal{E} \rangle$, or if $\mathcal{F} \subseteq S \circ \mathcal{A}$ for some $S \in \mathcal{S}$. For all other $\mathcal{F}$ containing a symmetric GHZ-type signature, $\text{Holant}^c(\mathcal{F})$ is #P-hard.

If f is symmetric and has W type, then:

- If $f \notin K \circ \mathcal{M} \cup KX \circ \mathcal{M}$, $\text{Holant}(\{=_2\} \mid \{f\})$ is #P-hard by Theorem 5.
- If $\mathcal{F} \subseteq K \circ \mathcal{M}$ or $\mathcal{F} \subseteq KX \circ \mathcal{M}$, the problem is tractable by the Holant^* dichotomy.
- If $f \in K \circ \mathcal{M}$ but $\mathcal{F} \not\subseteq K \circ \mathcal{M}$, the problem is #P-hard by Lemma 12 below, and analogously with KX instead of K.

If f is not symmetric and $f \notin K \circ \mathcal{M} \cup KX \circ \mathcal{M}$, it is possible to realise a symmetric genuinely entangled ternary signature using Lemmas 7 and 8, so the case reduces to the above.

Finally, if f is not symmetric and $f \in K \circ \mathcal{M}$ (or $f \in KX \circ \mathcal{M}$), then either $\mathcal{F} \subseteq K \circ \mathcal{M}$ (or $\mathcal{F} \subseteq KX \circ \mathcal{M}$) and $\text{Holant}^c(\mathcal{F})$ is in FP, or the problem is hard by Lemma 12 below. This covers all cases. ◀

▶ **Lemma 12.** *Let $f \in \mathcal{F} \cap K \circ \mathcal{M}$ be a genuinely entangled ternary signature, and assume $\mathcal{F} \not\subseteq K \circ \mathcal{M}$. Then $\text{Holant}^c(\mathcal{F})$ is #P-hard. The same holds if $f \in \mathcal{F} \cap KX \circ \mathcal{M}$ and $\mathcal{F} \not\subseteq KX \circ \mathcal{M}$.*

Proof (sketch). We show hardness by either realising a symmetric genuinely entangled ternary signature that is not in $K \circ \mathcal{M} \cup KX \circ \mathcal{M}$ or by realising a symmetric binary entangled signature g such that $\text{Holant}(\{f\} \mid \{g\})$ is #P-hard according to Theorem 5.

The basic approach is the same as in [2], but the techniques need some modification to work in the Holant^c setting. In particular, we show how to realise new unary signatures by gadgets using f, δ_0, δ_1, and self-loops. With these gadgets, we then realise the signatures given above. ◀

These two lemmas show that we can classify the complexity of $\text{Holant}^c(\mathcal{F})$ whenever $\mathcal{F}$ contains a genuinely entangled ternary signature.

4.2 Main theorem

We now have all the components required to prove the main dichotomy for Holant^c. The proof strategy is to realise certain genuinely entangled signatures of low arity. Then:

- If $\mathcal{F} \subseteq \langle \mathcal{T} \rangle$, the problem is known to be tractable.
- If $\mathcal{F}$ contains a genuinely entangled ternary signature, its complexity can be determined by Lemmas 11 and 12.
- If $=_4$ can be realised or interpolated over $\mathcal{F}$, then $\text{Holant}^c(\mathcal{F}) \equiv_T \#\text{CSP}_2^c(\mathcal{F})$ by Lemma 10, so its complexity is determined by Theorem 3.

The arity reduction technique is adapted from that used in the real-valued Holant^c dichotomy [11], with modifications that ensure it works for all complex-valued signatures.

▶ **Theorem 13.** *Let $\mathcal{F}$ be a set of complex-valued signatures. Then $\text{Holant}^c(\mathcal{F})$ is #P-hard unless:*

- *$\mathcal{F}$ is a tractable family for Holant^*,*
- *there exists $S \in \mathcal{S}$ such that $\mathcal{F} \subseteq S \circ \mathcal{A}$, or*
- *$\mathcal{F} \subseteq \mathcal{L}$.*

In all of the exceptional cases, $\text{Holant}^c(\mathcal{F})$ is tractable.

Proof (sketch). If $\mathcal{F}$ is one of the tractable families for Holant*, $\mathcal{F} \subseteq S \circ \mathcal{A}$ for some $S \in \mathcal{S}$, or $\mathcal{F} \subseteq \mathcal{L}$, tractability of Holant$^c(\mathcal{F})$ follows using the same algorithms as employed in the dichotomy proofs for Holant* [6], #CSP [10] (possibly after a holographic transformation), or #CSP$_2^c$ [11]. So assume otherwise. In particular, this implies that $\mathcal{F} \not\subseteq \langle \mathcal{T} \rangle$, i.e. $\mathcal{F}$ has multipartite entanglement.

Without loss of generality, we may focus on genuinely entangled signatures (cf. Section 2.2). So assume that there is some genuinely entangled signature $f \in \mathcal{F}$ of arity $n \geq 3$. If the signature has arity 3, we are done by Lemma 11. Hence assume $n \geq 4$.

As in [11], we now determine the minimum Hamming distance between any pair of bit strings in the support of f, and distinguish cases according to this value. We show that, using f, δ_0, δ_1, and self-loops, it is always possible to realise either a genuinely entangled ternary signature or a 4-ary signature of the form $a\,|0000\rangle + b\,|1100\rangle + c\,|0011\rangle + d\,|1111\rangle$ where $a, b, c, d \in \mathbb{C}$ and $ad - bc \neq 0$. In the former case, we can determine the complexity by Lemmas 11 and 12. In the latter case, we can realise or interpolate the 4-ary equality signature by Lemma 9; then, by Lemma 10, Holant$^c(\mathcal{F}) \equiv_T$ #CSP$_2^c(\mathcal{F})$.

Thus, whenever $\mathcal{F}$ is not one of the tractable families listed in the theorem statement, the problem is #P-hard. ◀

5 Conclusions

Building on the existing dichotomies for real-valued Holant^c and for complex-valued Holant$^+$, we have derived a dichotomy for complex-valued Holant^c. The tractable cases are the complex generalisations of the tractable cases of the real-valued Holant^c dichotomy. The question of a dichotomy for complex-valued, not necessarily symmetric Holant^c had been open since the definition of the family Holant^c in 2009. Several steps in the dichotomy proof use knowledge from quantum information theory, particularly about entanglement. We expect this approach of bringing together Holant problems and quantum information theory to yield further insights into both areas of research in the future. The ultimate goals include a dichotomy for general Holant problems on the one hand, building up on existing results for symmetric functions [5] and non-negative real-valued, not necessarily symmetric functions [18]. On the other hand, we hope to gain further understanding of the complexity of classically simulating quantum circuits.

Abstract

The problem of online checkpointing is a classical problem with numerous applications which had been studied in various forms for almost 50 years. In the simplest version of this problem, a user has to maintain k memorized checkpoints during a long computation, where the only allowed operation is to move one of the checkpoints from its old time to the current time, and his goal is to keep the checkpoints as evenly spread out as possible at all times.

At ICALP'13 Bringmann et al. studied this problem as a special case of an online/offline optimization problem in which the deviation from uniformity is measured by the natural discrepancy metric of the worst case ratio between real and ideal segment lengths. They showed this discrepancy is smaller than $1.59 - o(1)$ for all k, and smaller than $\ln 4 - o(1) \approx 1.39$ for the sparse subset of k's which are powers of 2. In addition, they obtained upper bounds on the achievable discrepancy for some small values of k.

In this paper we solve the main problems left open in the ICALP'13 paper by proving that $\ln 4$ is a tight upper and lower bound on the asymptotic discrepancy for all large k, and by providing tight upper and lower bounds (in the form of provably optimal checkpointing algorithms, some of which are in fact better than those of Bringmann et al.) for all the small values of $k \leq 10$.

1 Introduction and Notation

Most programs perform some irreversible operations, and thus they can only be run in a forward direction. However, in many cases we would like to roll back a computation to an earlier point in time. When the computation is short, we can just rerun the computation from the beginning, but when the computation requires many days, a better strategy is to memorize several copies of the full state of the computation at various times. These memorized states (called *checkpoints*) make it possible to roll the computation back from time T to any earlier time $T' < T$ by restarting the computation from the last available checkpoint which was memorized before T'. This checkpointing technique is extremely useful in many real life applications: For example, when we want to interactively debug a new program we may want to randomly access earlier points in the execution in order to find the source of a problem; in fault tolerant computer systems we may want to undo the effect of faulty hardware; and during lengthy simulations of physical systems we may want to explore the effect of changing some parameter such as the temperature at some earlier point in time without rerunning the simulation from the beginning.

In principle, we can try to memorize the full state of the computation after each step, but for long computations this requires an unrealistic amount of memory. Instead, we assume that we have some bounded amount of memory which suffices to keep k checkpoints. At time T, these checkpoints are spread within the time interval $[0, T]$, dividing it into $k + 1$ subintervals between consecutive checkpoints (where the endpoints 0 and T can be viewed as virtual checkpoints which require no additional memory). As T increases, the last subinterval gets longer, and at some point we may want to relocate one of the old checkpoints by reusing its memory to store the current state of the computation. A checkpointing algorithm can thus be viewed as an infinite pebbling game in which we place k pebbles on the positive side of the time axis, and then repeatedly perform update operations which move one of the pebbles to the right of all the other pebbles.

The first paper dealing with this problem seems to be "Rollback and Recovery Strategies for Computer Programs" [5], published in 1972, while the first paper which tried to solve it optimally was "On the Optimum Checkpoint Interval" [7], published in 1979. Over the years, dozens of academic research papers were published in this area, most notably [8] in 1984, [3] in 1994, and [1, 4] in 2013. However, many of these papers either dealt with concrete applications of the problem in other areas (especially in distributed computing where the notion of a timeline is different), or used other optimization criteria (which make their optimal solutions incomparable with ours). The mathematical problem we are dealing with in this paper was mentioned in [1] and studied in [4] which was published at ICALP'13, and we closely follow their model and notation.

At any time T, we define a *snapshot* as the ordered sequence of current checkpoint locations $S = (T_1, \ldots, T_k)$. Within each snapshot, we refer to the checkpoints by their *freshness index* p, where checkpoint 1 stores the oldest state and checkpoint k stores the newest state. Starting from an initial snapshot $S_k = (t_1, t_2, \ldots, t_k)$, we define for every

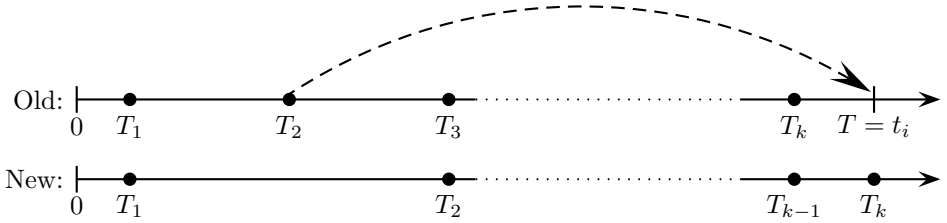

Figure 1 Transition from old to new snapshot for the update action $(t_i, 2)$.

$i \geq k+1$ the i-th *update action* as a pair (t_i, p_i) in which p_i is the freshness index of the checkpoint whose memory we want to reuse by moving it to time t_i. A typical example of how one snapshot is transformed into another snapshot by an update operation is described in Fig. 1. The effect of the i-th update action is to unify the two consecutive subintervals which were separated by the p_i-th oldest active checkpoint at time $T = t_i$, and to create a new subinterval which ends at t_i. Note that with this notation, each update action affects multiple freshness indices within the snapshot; in particular, the freshness index of active checkpoint T_j for $1 \leq j < p_i$ is left unchanged, and is decreased by one for $p_i < j \leq k$. To demonstrate this point, consider a sequence of updates in which $p_i = 1$ for all $i \geq k+1$: it updates the k memory locations in a round robin way since it always updates the oldest active checkpoint by overwriting it with the newest checkpoint, shifting all freshness indices by one. On the other hand, a sequence of updates in which $p_i = k$ for all $i \geq k+1$ keeps updating the same memory location, pushing its associated checkpoint further and further to the right, with no change to the other checkpoints.

In this model, the time complexity of rolling back a computation from time T to time T' is assumed to be proportional to the distance between T' and the last checkpoint that precedes T' in the snapshot at time T, and thus its worst case happens when we decide to roll back to just before the end of the longest subinterval. A *checkpointing algorithm* (t, p) consists of a monotonically increasing and unbounded sequence of update times $t = \{t_i\}_{i=1}^{\infty}$ and a pattern sequence $p = \{p_i\}_{i=k+1}^{\infty}$, forming an initial snapshot and an infinite sequence of update actions; its goal is to make the length of this longest subinterval as short as possible. Clearly, no checkpointing algorithm can make this length shorter than the subinterval length in a perfectly uniform partition of $[0, T]$, which is $T/(k+1)$. We say that a snapshot $S = (T_1, \ldots, T_k)$ of a k-checkpoint algorithm $\textsc{Alg} = (t, p)$ is *q-compliant* at time T if the $k+1$ subintervals defined by S satisfy $T_j - T_{j-1} \leq qT/(k+1)$ for $j = 1, \ldots, k+1$,[3] and that $\textsc{Alg}$ is *q-efficient* if its snapshots are q-compliant at all times $T \geq t_k$. Finally, the *efficiency* of a checkpointing algorithm is defined as the smallest q for which it is q-efficient.

Notice that the problem of efficient checkpointing can be viewed as a special case of an online/offline optimization problem: If we knew in advance the time T at which we would like to roll back the computation, we could make each subinterval as small as $T/(k+1)$. However, in the online version of the problem, we do not know T in advance, and thus we have to position the checkpoints so that they will be roughly equally spaced at all times. The efficiency of the solution is the ratio between what we can achieve in the online and offline cases, respectively, and the goal of the *online checkpointing problem* is to find the smallest possible efficiency q_k achievable by the best k-checkpoint algorithm for any given k.

[3] We write $T_0 = 0$ and $T_{k+1} = T$ for convenience.

Clearly, $q_k \geq 1$ for all $k \geq 2$, and cannot be too close to 1 since any snapshot in which all subintervals have roughly the same length will be transformed by the next update operation to a snapshot in which one of the subintervals will be the union of two previous subintervals, and thus will be about twice as long as the other subintervals.[4] On the other hand, there is a very simple subinterval doubling algorithm from [1, Section 3.1] which is 2-efficient: Assuming WLOG that k is even, the algorithm starts with the snapshot $(1, 2, 3, \ldots, k)$, and performs the sequence of update actions $(k+2, 1), (k+4, 2), \ldots, (2k, k/2)$, yielding the snapshot $(2, 4, 6, \ldots, 2k)$. Since this snapshot is the same as the original snapshot up to a scaling factor of 2, we can continue with update actions $(2k+4, 1), (2k+8, 2), \ldots, (4k, k/2)$ and so on. This is a *cyclic* algorithm, repeating the same sequence of freshness indices again and again but with times which form a geometric progression. As in each snapshot there are only two possible lengths for the subintervals of the form x and $2x$, all the snapshots in this algorithm are 2-compliant, and thus the algorithm is 2-efficient.

The best strategy for keeping the checkpoints as uniform as possible at all times is thus to keep in each snapshot a variety of subinterval lengths, so that the algorithm will always be able to join two relatively short adjacent subintervals into a single subinterval which is not too long. This can be viewed as a generalization of the algorithm that creates Fibonacci numbers: Whereas the standard algorithm is always adding the last two numbers and placing their sum on the right, in our case we can add any two consecutive numbers in the sequence, replacing them by their sum and adding any number we want on the right. Analyzing this problem is surprisingly difficult, and so far there had been no tight bounds on the best possible efficiencies q_k of online checkpointing algorithms in this model.

The main results in [4] are two online checkpointing algorithms whose asymptotic efficiencies are $\ln 4 + o(1) \approx 1.39$ for the sparse subset of k's which are powers of 2, and 1.59 for general k. In addition, they proved in their model the first nontrivial asymptotic lower bound of $2 - \ln 2 - o(1) \approx 1.30$. However, since the upper and lower bounds did not match, it was not clear whether the checkpointing algorithms they proposed were asymptotically optimal. For small values of $k < 60$ they presented concrete checkpointing algorithms whose efficiencies were all below 1.55, but again it was not clear whether they were optimal.

In this paper we solve the main open problems related to the mathematical formulation of the problem which was defined and studied in [4]. In particular, we develop a new checkpointing algorithm with an asymptotic efficiency of $\ln 4$ for all values of k, and prove its optimality by providing a matching asymptotic lower bound. For all the small values of $k < 10$ we develop optimal checkpointing algorithms by proving tight upper and lower bounds on the achievable efficiency for these k's. This analysis enables us to show that for some values of k (such as $k = 8$), the algorithms presented in [4] are in fact suboptimal.

The rest of this paper is organized as follows. In Section 2 we go over basic observations about checkpointing algorithms (some from [4], some new). In Section 3 we focus on moderately small values of k and provide optimal algorithms for $k \leq 10$. In Section 4 we construct a recursive algorithm of asymptotically optimal efficiency $\ln 4 + o(1)$. In Section 5 we prove a matching asymptotic lower bound of $\ln 4 - o(1)$. In Section 6 we provide concluding remarks.

Most proofs were omitted from this extended abstract due to space constraints.

[4] Actually $q_k \geq (k+1)/k$ since subinterval $k+1$ has zero length upon updating, as noted in [1, Theorem 3].

2 Basic Observations

By definition, a k-checkpoint $\textsc{Alg} = (t, p)$ is q-efficient if and only if its snapshots at all times $T \geq t_k$ are q-compliant. However, as noted in [1, Lemma 2] (and also [4, Lemma 1]), it suffices to verify compliance only at the discrete times $T \in \{t_i\}_{i=k}^{\infty}$. It makes sense thus to only consider "standard" snapshots S_i taken at time t_i for $i \geq k$. Moreover, as shown in [4, Lemma 2], besides compliance of the initial snapshot S_k, it suffices to verify compliance of just two subintervals of S_i for every $i > k$ — subinterval k, that ends in the new checkpoint t_i, and subinterval p_i, created by merging two consecutive subintervals.

The following two observations about the sequence $p = (p_i)_{i=k+1}^{\infty}$ were mentioned in [4, Section 6] without proof.

▶ **Fact 1.** *Without loss of generality we can assume a k-checkpoint algorithm updates the least recent checkpoint infinitely often (i.e., $\liminf_{i\to\infty} p_i = 1$).*

▶ Remark 2. An important consequence of Fact 1 is that we can essentially ignore the compliance of the initial snapshot S_k by *rebasing*, i.e., running the algorithm until all checkpoints present in S_k are overwritten and treating the then-current snapshot as the new initial $(t_1, \ldots, t_k)$.

▶ **Fact 3.** *Without loss of generality we can assume a k-checkpoint algorithm never updates the most recent checkpoint (i.e., $p_i < k$ for all $i \geq 1$).*

▶ Remark 4. Fact 3 means that the two last checkpoints in snapshot S_i are t_{i-1} and t_i, and thus subinterval k is q-compliant if and only if $t_{i-1} - t_i \leq qt_i/(k+1)$, that is, $t_i \leq G \cdot t_{i-1}$, where $G = G(q) := (k+1)/(k+1-q)$. We refer to this condition by saying that the update times sequence $t = (t_i)_{i=1}^{\infty}$ should be *G-subgeometric*.

Next we introduce the notion of *cyclic* algorithms. Upper bounds on q_k presented in this paper, as well as in [1, 4], are all achieved by cyclic algorithms. Given a positive integer n and a real number $\gamma > 1$, a k-checkpoint algorithm $\textsc{Alg} = (t, p)$ is *(n, γ)-cyclic* if $t_{n+i} = \gamma \cdot t_i$ for all $i \geq 1$ and $p_i = p_{n+i}$ for all $i \geq k+1$. It has been observed in [4, Lemma 5] that any q-efficient (n, γ)-cyclic algorithm must satisfy $\gamma \leq G^n$ (to see this, apply subgeometry n times). An (n, γ)-cyclic algorithm is called *(n, G)-geometric* when $\gamma = G^n$ (and thus $t_{i+1} = G \cdot t_i$ for $i \geq k$).

We finish this subsection with two observations about the exponential growth of update times in efficient algorithms, relevant for upper and lower bounds on q_k.

The first one is an improvement of [4, Lemma 8]:

▶ **Fact 5.** *Any q-efficient k-checkpoint algorithm $\textsc{Alg} = (t, p)$ satisfies, without loss of generality, $t_{i+2} > t_i \cdot G$ for all $i \geq k$.*

An immediate corollary of Fact 5 is that $t_{i+j} > t_i \cdot G^{\lfloor j/2 \rfloor}$ for $j \geq 0$; in particular, $t_{i+j} > t_i \cdot G^2$ for $j \geq 4$. Our next observation says when we can get $t_{i+3} > t_i \cdot G^2$.

▶ **Fact 6.** *Let $S = (T_1, \ldots, T_k)$ be a snapshot of some q-efficient k-checkpoint algorithm $\textsc{Alg} = (t, p)$ such that $T_j = t_i$ and $T_{j+1} = t_{i+3}$ for some $j = 1, \ldots, k-1$. Thus, without loss of generality, $t_{i+3} > t_i \cdot G^2$.*

3 Optimal Algorithms for Small Values of k

3.1 Round-robin and $k \leq 5$

We now analyze the efficiency of the ROUND-ROBIN algorithm, which is geometric and always updates the oldest checkpoint (i.e., $p_i = 1$ for all $i \geq k+1$).[5] Besides serving as a first example, ROUND-ROBIN is optimal for $k \leq 3$ and will make an appearance within the asymptotically optimal algorithm RECURSIVE of Section 4.

▶ **Proposition 7.** *The efficiency of k-checkpoint* ROUND-ROBIN *is $q = (k+1)\,r$, where r is the smallest real root of $x = (1-x)^{k-1}$.*

▶ Remark. ROUND-ROBIN is pretty bad for large k; indeed, $(k+1)\,r \approx \ln k - \ln\ln k$ is asymptotically inferior to the simple bound $q_k \leq 2$ from the introduction.

The case $k = 2$ is made obvious by Fact 3, since without loss of generality ROUND-ROBIN is the *only* 2-checkpoint algorithm to consider. Thus $q_2 = 1.5$.

▶ **Proposition 8.** *For $k = 3$ we have $q_3 = 4r_3 \approx 1.52786$, where $r_3 = \frac{3-\sqrt{5}}{2} \approx 0.38197$ is the smaller root of $x^2 - 3x + 1 = 0$.*

Proof. For the upper bound, ROUND-ROBIN is $4r_3$-efficient. For the lower bound, consider a $4r$-efficient 3-checkpoint algorithm and a snapshot $S_i = (x, y, t_i)$. By subgeometry we must have $t_i \leq y/(1-r) \leq x/(1-r)^2$ and for subinterval 1 to be compliant we need $x \leq rt_i$, which together imply $(1-r)^2 \leq r$, i.e., $r^2 - 3r + 1 \leq 0$. Thus $r \geq r_3$. ◀

ROUND-ROBIN is no longer optimal for $k > 3$. Indeed, cyclic algorithms with better efficiency were described in [4, Figure 3] for $k = 4, 5, 6, 7, 8$. These provide upper bounds on $q_4, \ldots, q_8$, respectively. Nevertheless, no formal proof of optimality was provided.

▶ Remark. These algorithms were found by the use of linear programming, which is thoroughly discussed in the next subsection.

For $k = 4, 5$ the optimal algorithms are 2-cyclic; $k = 5$ is geometric while $k = 4$ is not.

▶ **Proposition 9.** *For $k = 4$ we have $q_4 = 5r_4 \approx 1.53989$, where $r_4 = (2 + 2\cos(2\pi/7))^{-1} \approx 0.307979$ is the smallest root of $x^3 - 5x^2 + 6x - 1 = 0$. Moreover, the efficiency of any geometric 4-checkpoint algorithm is at least $5\tilde{r}_4 \approx 1.58836$, where $\tilde{r}_4 \approx 0.31767 > r_4$ is the real root of $x^3 - 3x^2 + 4x - 1 = 0$.*

▶ **Proposition 10.** *For $k = 5$ we have $q_5 = 6r_5 \approx 1.47073$, where $r_5 \approx 0.24512$ is the (only) real root of $x^3 - 4x^2 + 5x - 1 = 0$.*

3.2 Casting the problem as a linear program

Fix $\lambda \geq 1$ and an update pattern $p = (p_i)_{i=k+1}^{\infty}$. Can we choose a sequence $t = (t_i)_{i=1}^{\infty}$ of update times such that the resulting k-checkpoint algorithm $\text{ALG} = (t, p)$ is λ-efficient?

Each snapshot S_i consists of a particular subset of the variables t, and using p we can determine exactly which. Furthermore, all constraints (e.g., monotonicity, subgeometry, compliance) can be expressed as linear inequalities. This gives rise to an infinite linear program $L = L(\lambda; p)$, which is feasible whenever a λ-efficient algorithm with the prescribed

[5] The case $k = 3$ of ROUND-ROBIN was considered in [4, Theorem 1] under the name SIMPLE.

pattern p exists. Note that all constraints are homogeneous, so to avoid the zero solution we add the non-homogeneous condition $t_k = 1$.

In addition, we are not interested in solutions where t is bounded. This can happen, for instance, when $p_i = k - 1$ for all $i \geq k + 1$.[6] Luckily, by using Fact 5 we can restrict our attention to exponentially increasing sequences t, so we add to L the linear inequalities from Facts 5 and 6. Now L is feasible if and only if a λ-efficient algorithm with the prescribed pattern p exists; in other words, q_k is the infimum[7] over $\lambda \geq 1$ for which there exists a pattern p such that $L(\lambda; p)$ is feasible.

As an infinite program, L is not too convenient to work with. We can thus limit our attention to finite subprograms $L(\lambda; (p_{k+1}, \ldots, p_{k+n}))$ for some $n \in \mathbb{N}$, which only involve the $k + n$ variables $t_1, \ldots, t_{k+n}$ and the relevant $3k + 6n$ constraints. Finite subprograms can no longer ensure the existence of a λ-efficient algorithm, but can be used to prove lower bounds on q_k in the following way. Write $\Sigma = \{1, \ldots, k - 1\}$ and consider the set Σ^* of strings, i.e, finite sequences over Σ.

▶ **Definition.** A string $B \in \Sigma^*$ is called a *λ-witness* if $L(\lambda; B)$ is infeasible. A string set $\mathcal{B} \subset \Sigma^*$ is called *blocking* if any infinite sequence p over Σ contains some $B \in \mathcal{B}$ as a substring.

▶ **Fact 11.** *If there exists a blocking set of λ-witnesses for some $\lambda \geq 1$, then $q_k > \lambda$.*

▶ Remark. The lower bound of Fact 11 holds for all algorithms, cyclic or not.

We now describe a strategy to approximate q_k to arbitrary precision. For the lower bound we use Fact 11; for the upper bound, we limit our focus to cyclic algorithms. Given $\gamma > 1$ and a string $P \in \Sigma^*$ of length n, we can augment $L(\lambda; P)$ with k equality constraints $\{t_{i+n} = \gamma \cdot t_i\}_{i=1}^{k}$; call the resulting program $L^*(\lambda, \gamma; P)$. This is a finite linear program, which we can computationally solve given λ, γ, and P. Although $\gamma \leq G^n$ is not known to us, we can first compute an approximation $\tilde{\gamma}$ of γ by solving $L_{10n}\left(\gamma; P^{10}\right)$, and then solve $L^*(\lambda, \tilde{\gamma}; P)$. Using binary search, we can compute a numerical approximation $\tilde{\lambda}$ of the minimal λ for which $L^*(\lambda, \tilde{\gamma}; P)$ is feasible. Lastly, we can enumerate short strings $P \in \Sigma^*$ in a BFS/DFS-esque manner and take the best $\tilde{\lambda}$ obtained.

To demonstrate this strategy, we computed $q_2, \ldots, q_{10}$ up to 7 decimal digits, using a Python program employing GLPK [6] via CVXOPT [2] (see Table 1; starred values of k are geometric algorithms).

At first it seems that Fact 11 cannot be used to pinpoint q_k exactly, since any finite blocking set $\mathcal{B}$ of $(q_k - \epsilon)$-witnesses for some $\epsilon > 0$ leaves an interval of uncertainty of length ϵ. The following proposition eliminates this uncertainly.

▶ **Proposition 12.** *For every string $B \in \Sigma^*$ there is finite set $\Lambda_B \subset \mathbb{R}$ such that the feasibility of $L(\lambda; B)$ for some $\lambda \geq 1$ only depends on the relative order between λ and members of Λ_B. In particular, there exists some $\epsilon > 0$ such that if $L(\lambda; B)$ is feasible and B is a $(\lambda - \epsilon)$-witness, then B is also a λ'-witness for all $\lambda - \epsilon < \lambda' < \lambda$.*

Proof. Fix $B \in \Sigma^*$. Treating λ as a parameter, note that the subprogram $L(\lambda; B)$ is feasible if and only if its feasible region, the convex polytope $\mathcal{P}(\lambda; B)$, is nonempty. Decreasing λ shrinks $\mathcal{P}(\lambda; B)$ until some critical λ_B for which $\mathcal{P}(\lambda_B; B)$ is reduced to a single vertex, at which a subset of the linear constraints are satisfied with equality. Hence λ_B is a solution of

[6] This may not seem a valid pattern to consider, given Fact 1; however, when solving a finite subprogram we might have to consider an arbitrarily long prefix of the pattern with no occurrences of 1.

[7] This infimum is actually a minimum, by [4, Theorem 8] and also by Proposition 12.

Table 1 Computationally-verified bounds on q_k for $2 \leq k \leq 10$.

some polynomial equation determined by the relevant constraints. The set of constraints is finite, thus there are finitely many polynomial equations that can define λ_B, and we can take Λ_B as the set of all their roots. Now take ϵ to be smaller than the distance between any two distinct elements of Λ_B. ◀

▶ Remark. Note that when ϵ is small enough, we can actually retrieve the polynomial equations defining λ and γ from the polytope $\mathcal{P}^*\left(\tilde{\lambda}, \tilde{\gamma}; B\right)$; using this method we get an algebraic representation of q_k rather than a rational approximation. To demonstrate, $q_9 = 10r_9$, where $r_9 \approx 0.1473072131$ is the smallest real root of $x^8-7x^7+22x^6-40x^5+39x^4-17x^3+10x^2-8x+1$.

4 Asymptotically Optimal Upper Bounds

In this section we describe a family of geometric k-checkpoint algorithms. Despite our experience from Table 1—that only for $k = 2, 3, 5$ optimal algorithms are geometric—this family is rich enough to be asymptotically optimal, i.e., $(1 + o(1))\, q_k$-efficient.

4.1 A recursive geometric algorithm

Fix a real number $G > 1$ and an integer $m \geq 0$. We describe a k-checkpoint algorithm RECURSIVE(G, K), where K is an $(m + 2)$-subset $\{0, \ldots, k\}$ whose elements are

$$k = k_0 > k_1 > k_2 > \cdots > k_m > k_{m+1} = 0.$$

RECURSIVE(G, K) is $(2^m, G)$-geometric, and its update pattern p is defined as $p_{k+i} = 1 + k_{\mu(i)+1}$, where $\mu(i)$ is the largest $\mu \leq m$ for which 2^μ divides i. It is easy to see that p is 2^m-periodic, and we can just refer to $P = (p_{k+i})_{i=1}^{2^m}$. As per Remark 2, via rebasing there is no need to define the initial snapshot S_k explicitly.

▶ **Example.** For $K = \{0, 2, 4, 9, 19\}$ we get $P = (10, 5, 10, 3, 10, 5, 10, 1)$.

True to its name, RECURSIVE(G, K) can be viewed also as a recursive algorithm: the base case $m = 0$ (i.e., $K = \{0, k\}$) is simply k-checkpoint ROUND-ROBIN; for $m \geq 1$, RECURSIVE(G, K) alternates between updating the $(k_1 + 1)$-st oldest checkpoint and between acting according to the inner k_1-checkpoint algorithm RECURSIVE$\left(G^2, K \setminus \{k\}\right)$.

Let us elaborate a bit more on the recursive step. In every snapshot $S_i = (T_1, \ldots, T_k)$ we have $T_j = G^{i+j}$ for $k_1 + 1 \leq j \leq k$ since we never update checkpoints younger than $k_1 + 1$. In every *odd* snapshot S_i we have just updated the $(k_1 + 1)$-st oldest checkpoint,

so $T_{k_1} = G^{i+k_1-1}$ while $T_{k_1+1} = G^{i+k_1+1}$. This means that $\log_G T_j$ for $j = 1, \ldots, k_1$ all have the same parity as $i + k_1 - 1$ in any snapshot S_i. We thus treat $S' = (T_1, \ldots, T_{k_1})$ as a snapshot of a k_1-checkpoint algorithm, which operates at half speed and never sees half of the checkpoints. The inner algorithm can rightfully be called $\textsc{Recursive}\left(G^2, K \setminus \{k\}\right)$, as the common ratio of the update times sequence for the checkpoints that do make it to the inner algorithm is G^2, and taking only the even locations of P yields a 2^{m-1} periodic sequence p' such that $p'_{k+i} = p_{k+2i} = 1 + k_{\mu(2i)+1} = 1 + k_{\mu(i)+2}$.

4.2 Analyzing the recursive algorithm

First we determine exactly how efficient $\textsc{Recursive}(G, K)$ can be for any G and K, and then we work with a particular choice.

Denote by $r(G, K)$ the maximum of

$$1 - G^{-1}; \tag{1a}$$

$$\max\left\{G^{-e(\ell)}\left(G^{2^\ell} - G^{-2^\ell}\right)\right\}_{\ell=0}^{m-1}; \text{ and} \tag{1b}$$

$$G^{2^m - e(m)}, \tag{1c}$$

where $e(\ell) = \sum_{j=0}^{\ell} 2^j (k_j - k_{j+1})$ for $\ell = 0, 1, \ldots, m$.

▶ **Theorem 13.** *Given G and K, the efficiency of $\textsc{Recursive}(G, K)$ is $(k+1)r(G, K)$.*

Given an integer $k \geq 2$, let $m = \lfloor \log_2 k \rfloor - 1$. Define $K^* = \{k_0, \ldots, k_{m+1}\}$ by $k_j = \lfloor 2^{-j} k \rfloor$ for $j = 0, \ldots, m$ and $k_{m+1} = 0$. Note that $k_0 = k$ and that $k_m \in \{2, 3\}$.

▶ **Theorem 14.** $\textsc{Recursive}(G, K^*)$ *is q-efficient for large enough k, where $G = e^{q/(k+1)}$ and $q = \left(1 + \frac{3}{\log_2 k}\right) \frac{k+1}{k} \ln 4 = (1 + o(1)) \ln 4$.*

Proof. By Theorem 13, it suffices to verify that $(k+1)r(G, K^*) < q$, that is, $r(G, K^*) \leq \ln G$ for sufficiently large k. Clearly (1a) holds since $1 - G^{-1} < \ln G$ for all $G > 1$. It remains to verify (1b) and (1c), handled by Propositions 15 and 16 respectively. ◀

▶ **Proposition 15.** *For $k \geq 2^{13}$ and G as above, $G^{-e(\ell)}\left(G^{2^\ell} - G^{-2^\ell}\right) < \ln G$ for all $\ell = 0, \ldots, m-1$.*

▶ **Proposition 16.** *For $k \geq 5$ and G as above, $G^{2^m - e(m)} < \ln G$.*

▶ Remark. Theorem 14 chooses G suboptimally. Empirical evidence shows that, for all $k \geq 2$, the optimal $G = G^*$ for $\textsc{Recursive}(G, K^*)$ satisfies (1a) and one of (1b) and (1c). In other words, it is the smallest root of either $1 - x^{-1} = x^{2^m - e(m)}$ or $1 - x^{-1} = x^{-e(\ell)}\left(x^{2^\ell} - x^{-2^\ell}\right)$ for some $\ell = 0, \ldots, m-1$.

▶ Remark. With additional effort the constant 3 in Theorem 14 can be improved by a factor of almost 6 to $\tau := -\log_2 \ln 2 \approx 0.53$. The major obstacle is that cases $\ell = m-2$ and $\ell = m-1$ of (1b) need to be done separately since the appropriate $f(x, z)$ in the proof of Proposition 15 is negative for $z < \log_2(\ln 4 / (1 - \ln 2)) \approx 2.1756$. No proof is possible for $\tau' < \tau$ since then (1c) would be violated for large enough $k = 2^{m+2} - 1$.

▶ Remark. We verified that the algorithm $\textsc{Recursive}(G^*, K^*)$ is $(1 + \tau / \log_2 k) \frac{k+1}{k} \ln 4$-efficient for $2 \leq k \leq 2^{13}$ as well.

5 Asymptotically Optimal Lower Bounds

In this section we prove lower bounds on q_k, focusing on asymptotic lower bounds in which k grows to infinity.

We start by reproving the simple asymptotic lower bound $q_k \geq 2 - \ln 2 - o(1)$ of [4, Theorem 6], and then improve it to $q_k \geq \ln 4$, which is asymptotically optimal via the matching upper bound of Section 4.

5.1 Stability and bounding expressions

Obtaining lower bounds requires viewing the problem from a different perspective. It will sometimes be more convenient to refer to a certain physical checkpoint, without considering its temporary freshness index p in the checkpoint sequence at some snapshot S (which is variable and depends on S).

Given a k-checkpoint algorithm, we define a function $BE(s)$ and use it to bound its efficiency from below. The parameter s is related to the notion of stability, which we now define.

▶ **Definition.** Fix a k-checkpoint algorithm. A checkpoint updated at time T is called s-stable, for some $s = 1, \ldots, k-1$, if at least s previous checkpoints are updated before the next time it is updated.

By Fact 1 we can assume all checkpoints get updated eventually; this means that in a snapshot $S = (T_1, \ldots, T_k)$, where T_k is a time by which all checkpoints have been updated from the initial snapshot, we have that the checkpoint updated at time T_{k-s} is s-stable for $s = 1, \ldots, k-1$.

For convenience, the proofs in this section assume the update times sequence is normalized by a constant. This is captured by the following definition.

▶ **Definition.** A k-checkpoint algorithm is called s-normalized if an s-stable checkpoint is updated at time $R_0 = 1$.

Given an s-normalized k-checkpoint algorithm, we define a sequence of times $1 = R_0 < R_1 < \cdots < R_s$ as follows: R_i for $i \geq 1$ is the time at which the i-th checkpoint is *removed* from $(0, 1]$. In other words, R_1 is the time $T > R_0$ at which some checkpoint is updated; R_2 is the time $T > R_1$ at which we update the next checkpoint that was previously updated in $(0, 1]$ (but not at $T > 1$), and so forth. Note that the checkpoint updated at time R_0 is not updated at any time R_i for $i = 1, \ldots, s$ by the definition of stability. Now we are ready to define $BE(s)$.

▶ **Definition.** The T-truncated bounding expression of an s-normalized k-checkpoint algorithm is $BE_T(s) = \sum_{i=1}^{s} U_i$, where $U_i = \min\{T, R_i\}$.

The bounding expression plays a crucial role in proving lower bounds, based on Proposition 17 below. We note that the truncated bounding expression only depends on the algorithm's behavior until time T, and hence the bounds that can be obtained from it are not tight for $k > 3$. Nevertheless, the lower bound we obtain using BE_2 in Corollary 22 is asymptotically optimal, since the gap between it and the upper bound of Theorem 14 tends to zero as k grows to infinity.

▶ Remark. It is possible to analyze BE_T beyond $T = 2$ and obtain tight lower bounds for larger values of k. However, there is no asymptotic improvement and the analysis becomes increasingly more technical as k grows.

5.2 Asymptotic lower bound of $2 - \ln 2 \approx 1.3068$

To simplify the analysis, we assume k is even. It can be extended to cover odd values of k as well, but this gives no asymptotic improvement since $q_{k+1} \leq q_k \cdot \frac{k+2}{k+1}$ for all k, so we only lose an error term of $O(1/k)$, which is of the same order as the error terms in Corollaries 20 and 22.

To simplify our notation we write $b = q/(k+1)$ throughout this section.

▶ **Proposition 17.** *Any $(k/2)$-normalized $b(k+1)$-efficient k-checkpoint algorithm satisfies $BE_2(k/2) \geq 1/b$.*

Proof. At time $R_0 = 1$, the time interval $(0, 1]$ contains k subintervals of length $\leq b$, giving rise to the inequality $b \cdot k \geq 1$. At time R_1, a checkpoint is removed from $(0, 1]$ and it now contains one subinterval of length $\leq b \cdot R_1$ (two previous subintervals, each of length $\leq b$, were merged), and $k-2$ subintervals of length $\leq b$, giving $b \cdot (k - 2 + R_1) \geq 1$.

At time R_2, an additional checkpoint is removed from the time interval $(0, 1]$, hence it must contain an subinterval of length $\leq b \cdot R_2$ formed by merging two previous subintervals. We obtain $b \cdot (k - 4 + R_1 + R_2) \geq 1$, since the remaining $k-3$ subintervals must include $k-4$ subintervals of length $\leq b$ and one (additional) subinterval of length at most $\leq b \cdot R_1$. Note that this claim holds regardless of which checkpoint is updated at R_2, and it holds in particular in case one of the subintervals merged at time R_2 contains the subintervals merged at R_1 (in fact, this case gives the stronger inequality $b \cdot (k - 3 + R_2) \geq 1$).

In general, for $j = 1, 2, \ldots, k/2$, at time R_j the time interval $(0, 1]$ must contain j distinct subintervals of lengths $\leq b \cdot R_i$ for $i = 1, 2, \ldots, j$, and $k - 2j$ subintervals of length $\leq b$. This gives the inequality $k - 2j + \sum_{i=1}^{j} R_i \geq 1/b$.

Let $j \leq k/2$ be the largest index such that $R_j \leq 2$, so $U_i = R_i$ for all $1 \leq i \leq j$ and $U_i = 2$ for all $j < i \leq k/2$. Now at time R_j we have

$$1/b \leq k - 2j + \sum_{i=1}^{j} R_i = (k/2 - j) \cdot 2 + \sum_{i=1}^{j} U_i = \sum_{i=j+1}^{k/2} U_i + \sum_{i=1}^{j} U_i = BE_2(k/2). \quad \blacktriangleleft$$

Now we need an upper bound on the bounding expression. For the simpler lower bound of $2 - \ln 2$ we use the following proposition.

▶ **Proposition 18.** *Any $(k/2)$-normalized $b(k+1)$-efficient k-checkpoint algorithm satisfies $R_i \leq 1/(1 - bi)$ for $i = 1, \ldots, k/2$.*

Proof. At time $T = 1/(1 - bi)$, all subintervals are of length at most $bT = b/(1 - bi)$. Since $T - R_0 = 1/(1 - bi) - 1 = bi/(1 - bi)$, for any $\epsilon > 0$ the time interval $(R_0, T + \epsilon]$ must consist of at least $i + 1$ subintervals, implying that the i-th checkpoint was removed from the time interval $(0, 1]$ by time T. ◀

▶ **Proposition 19.** *Let $b < \frac{1}{2}$. Any $(k/2)$-normalized $b(k+1)$-efficient k-checkpoint algorithm satisfies $b \cdot BE_2(k/2) \leq \ln 2 + b/(1 - 2b) + bk - 1$.*

▶ **Corollary 20.** *For all even $k \geq 4$ we have $q_k \geq 2 - \ln 2 - o(1)$.*

Proof. Fix a $(k/2)$-normalized q_k-efficient k-checkpoint algorithm, and let $b = q_k/(k+1) < \frac{1}{2}$. By Propositions 17 and 19 we have

$$q_k = bk + b \geq 2 - \ln 2 - \frac{b}{1 - 2b} + b = 2 - \ln 2 - \frac{2b^2}{1 - 2b} \geq 2 - \ln 2 - \frac{8}{(k+1)(k-3)}. \quad \blacktriangleleft$$

5.3 Improved asymptotic lower bound of $\ln 4 \approx 1.3863$

We now improve the asymptotic lower bound to $\ln 4$. This result is a simple corollary of the following lemma, which gives a tighter upper bound on the bounding expression. Recall that $q = b(k+1)$ and thus $G = (k+1)/(k+1-q) = 1/(1-b)$.

▶ **Lemma 21.** *For any s-normalized $b(k+1)$-efficient k-checkpoint algorithm such that $1 \le s \le k/2$ and $G^{k/2} \le 2$ we have $b \cdot BE_2(s) \le G^s - 1$.*

▶ **Corollary 22.** *For all even $k \ge 2$ we have $(1 - q_k/(k+1))^{-k/2} \ge 2$. In particular, $q_k > \ln 4$.*

Proof. Write $b = q_k/(k+1)$ and assume for the sake of contradiction that $G^{k/2} < 2$. By Lemma 21 and Proposition 17 we have $1 \le b \cdot BE_2(k/2) \le G^{k/2} - 1$ for a $k/2$-normalized q_k-efficient k-checkpoint algorithm, so $G^{k/2} \ge 2$, contradicting our assumption. Now

$$\frac{q_k}{k+1} = b \ge 1 - 2^{-2/k} = 1 - e^{-(\ln 4)/k} \ge \frac{\ln 4}{k} - \frac{1}{2}\left(\frac{\ln 4}{k}\right)^2 = \left(1 - \frac{\ln 2}{k}\right)\frac{\ln 4}{k},$$

hence $q_k \ge \left(1 + (1 - \ln 2)/k - (\ln 2)/k^2\right)\ln 4 > \ln 4$. The last inequality is true when $k > \ln 2/(1 - \ln 2) \approx 2.26$, but we already know that $q_2 = 1.5 > \ln 4$. ◀

6 Concluding Remarks and Open Problems

In this paper we solved the main open problem in online checkpointing algorithms, which is to find tight asymptotic upper and lower bounds on their achievable efficiency. In addition, we developed efficient techniques for determining tight upper and lower bounds on q_k for small values of k, which enabled us to develop provably optimal concrete algorithms for all $k \le 10$. However, determining the values of q_k for larger values of k remains a computationally challenging problem, and finding more efficient ways to compute these values remains an interesting open problem.

A Tables

The best algorithms our LP approach of Section 3.2 found for $k = 11, 12, \ldots, 20$ are described in Table 2. These are (perhaps non-tight) upper bounds on $q_{11}, \ldots, q_{20}$. Observe how some of the patterns are reminiscent of the pattern used in the algorithm RECURSIVE of Section 4.

Fast Reed-Solomon Interactive Oracle Proofs of Proximity

Abstract

The family of Reed-Solomon (RS) codes plays a prominent role in the construction of quasilinear probabilistically checkable proofs (PCPs) and interactive oracle proofs (IOPs) with perfect zero knowledge and polylogarithmic verifiers. The large concrete computational complexity required to prove membership in RS codes is one of the biggest obstacles to deploying such PCP/IOP systems in practice.

To advance on this problem we present a new interactive oracle proof of proximity (IOPP) for RS codes; we call it the *Fast RS IOPP* (FRI) because (i) it resembles the ubiquitous Fast Fourier Transform (FFT) and (ii) the arithmetic complexity of its prover is strictly linear and that of the verifier is strictly logarithmic (in comparison, FFT arithmetic complexity is quasi-linear but not strictly linear). Prior RS IOPPs and PCPs of proximity (PCPPs) required super-linear proving time even for polynomially large query complexity.

For codes of block-length N, the arithmetic complexity of the (interactive) FRI prover is less than $6 \cdot N$, while the (interactive) FRI verifier has arithmetic complexity $\leq 21 \cdot \log N$, query complexity $2 \cdot \log N$ and constant soundness – words that are δ-far from the code are rejected with probability $\min\{\delta \cdot (1 - o(1)), \delta_0\}$ where δ_0 is a positive constant that depends mainly on the code rate. The particular combination of query complexity and soundness obtained by FRI is better than that of the quasilinear PCPP of [Ben-Sasson and Sudan, SICOMP 2008], even with the tighter soundness analysis of [Ben-Sasson et al., STOC 2013; ECCC 2016]; consequently, FRI is likely to facilitate better concretely efficient zero knowledge proof and argument systems.

Previous concretely efficient PCPPs and IOPPs suffered a constant *multiplicative* factor loss in soundness with each round of "proof composition" and thus used at most $O(\log \log N)$ rounds. We show that when δ is smaller than the unique decoding radius of the code, FRI suffers only a negligible *additive* loss in soundness. This observation allows us to increase the number of "proof composition" rounds to $\Theta(\log N)$ and thereby reduce prover and verifier running time for fixed soundness.

1 Introduction

The family of Reed-Solomon (RS) codes is a fundamental object of study in algebraic coding theory and theoretical computer science [56]. For an evaluation set S of N elements in a finite field $\mathbb{F}$ and a rate parameter $\rho \in (0,1]$, the code $\mathsf{RS}[\mathbb{F}, S, \rho]$ is the space of functions $f : S \to \mathbb{F}$ that are evaluations of polynomials of degree $d < \rho N$ [56]. The *RS proximity problem* assumes a verifier has oracle access to $f : S \to \mathbb{F}$, and asks that verifier to distinguish, with "large" confidence and "small" query complexity, between the case that f is a codeword of $\mathsf{RS}[\mathbb{F}, S, \rho]$ and the case that f is δ-far in relative Hamming distance from all codewords. This problem has been addressed in several different computational models (surveyed next and summarized in Table 1), and is also the focus of this paper.

RS proximity testing: When no additional data is provided to the verifier, the RS proximity problem is commonly called a *testing* problem, and has been first defined and addressed by Rubinfeld and Sudan in [58] (cf. [32]). In this case, one can see that $d+1$ queries are necessary and sufficient to solve the problem: codewords are accepted by their tester with probability 1 whereas functions that are δ-far from the code are rejected with probability $\geq \delta$. Since no additional information is provided to the verifier in this model, we may say that a prover attempting to convince the verifier that $f \in \mathsf{RS}[\mathbb{F}, S, \rho]$ spends zero computational effort, zero rounds of interaction and produces a proof of length zero.

RS proximity verification – PCPP model: Probabilistically checkable proofs of proximity (PCPP) [21, 30] relax the testing problem to a setting in which the verifier is given oracle access also to an auxiliary proof, called a PCPP and denoted π. This PCPP is produced by the prover, which is given $f \in \mathsf{RS}[\mathbb{F}, S, \rho]$ as input. The time required to produce π is the *prover complexity* and $|\pi|$ is called the *proof length*[1]; similarly, *verifier complexity* is the total time required to generate queries and check query-answers. The techniques used to prove the celebrated PCP Theorem [2, 3] also show that the proximity problem can be solved with constant query complexity and proof length and prover complexity $N^{O(1)}$, or with proof length $N^{1+\epsilon}$ and query complexity $(\log N)^{O(1/\epsilon)}$ [5]. The current state of the art in the PCPP model gives proofs of length $\tilde{O}(N) \stackrel{\triangle}{=} N \cdot \log^{O(1)} N$ with constant query complexity [23, 28] and prover complexity $\tilde{O}(N)$ [16]; verifier complexity is $\mathsf{poly} \log N$ [20, 50].

RS proximity verification – IOPP model: Interactive oracle proofs of proximity (IOPP), formally introduced in [13] and, independently, in [57] (under the name "probabilistically checkable interactive proofs of proximity"), generalize IPs, PCPs and interactive PCPs (IPCP) [42]. As in an IP and IPCP, several rounds of interaction are used in which the prover sends messages $\pi_1, \pi_2, \ldots, \pi_r$ in response to successive verifier messages. As in a PCP and

[1] Typically π is a sequence of elements in $\mathbb{F}$. Therefore, proof length is measured over the alphabet $\mathbb{F}$.

Table 1 Comparison of RS proximity protocols. For concreteness, all results are stated for binary additive RS codes with rate $\rho = 1/8$ evaluated over a sufficiently large set $S, |S| = N$ satisfying $N/|\mathbb{F}| < 0.001$ with proximity parameter $\delta < \delta_0$ (cf. Theorem 2) and soundness at least 0.99δ; i.e., the rejection probability of δ-far words is at least 0.99δ for $\delta < \delta_0$ (in particular, smaller δ leads to smaller soundness). Exponents for the 4th row taken from [16]; the various exponents c in the 5th and 6th row have not been estimated in prior works but are greater than the respective exponents in the 4th row.

IPCP, the verifier is not required to read prover messages in entirety but rather may query them at random locations (in an IPCP, verifier must read the full messages $\pi_2, \ldots$ but may query π_1 randomly); the query complexity is the total number of entries read from f and $\pi_1, \pi_2, \ldots, \pi_{\mathsf{r}}$. The prover is provided with $f \in \mathsf{RS}[\mathbb{F}, S, \rho]$ as input and *prover complexity* is the total time required to produce all (prover) messages[2], while *proof length* is generalized from the PCPP setting to the IOPP setting and defined as $|\pi_1| + \ldots + |\pi_{\mathsf{r}}|$. IOPPs can be used to "replace" PCPP proof composition with more rounds of interaction, and thereby reduce proof length and prover complexity without compromising soundness (see Section 1.3). In particular, the IOPP version of the aforementioned PCPP constructions reduces proof length to $O(N)$ with no change to soundness and/or query complexity [8, 13]. In spite of the shorter proof length, prover complexity in prior works was $\Theta(N\,\mathsf{poly}\log N)$ due to a limitation on the number of proof-composition rounds, explained in Section 2.1.

1.1 Main results

We present a new IOPP for RS codes, called the Fast RS IOPP (FRI) because of its resemblance to the Fast Fourier Transform (FFT) [26]; its analysis relies on the quasi-linear RS-PCPP [23] (see Section 2.1). FRI is the first RS-IOPP to have (i) *strictly linear* arithmetic complexity for the prover with (ii) *strictly logarithmic* arithmetic complexity for the verifier and (iii) *constant* soundness. We start by recalling IOPP systems as described in [12, Section 3.2], after informally summarizing the main complexity parameters of IOPs (introduced and discussed thoroughly in [19]).

1.1.1 IOP

An *Interactive Oracle Proof (IOP)* system S is defined by a pair of interactive randomized algorithms $\mathsf{S} = (\mathsf{P}, \mathsf{V})$, where P denotes the prover and V the verifier. On input x of length N, the number of rounds of interaction is denoted by $\mathsf{r}(N)$ and called the *round complexity* of the system. During a single round the prover sends a message to which the verifier is

[2] Notice that prover complexity does not include the time needed to produce f.

given oracle access, and the verifier responds with a message to the prover. The *proof length*, denoted $\ell(N)$, is the sum of lengths of all messages sent by the prover. The *query complexity* of the protocol, denoted $\mathsf{q}(N)$, is the number of entries read by V from the various prover messages; since the verifier has oracle access to those messages, typically $\mathsf{q}(N) \ll \ell(N)$. (For the FRI system $q(N) = O(\log \ell(N))$). We denote by $\langle \mathsf{P} \leftrightarrow \mathsf{V} \rangle(x)$ the output of V after interacting with P on input x; this output is either accept or reject. An IOP is said to be *transparent* (or have *public randomness*) if all messages sent from the verifier are public random coins and all queries are determined by public coins, which are broadcast to the prover (such protocols are also known as Arthur-Merlin protocols [4]).

1.1.2 IOPP

As its name suggests, an *IOP of proximity (IOPP)* is the natural generalization of a PCP of Proximity (PCPP) to the IOP model. An IOPP for a family of codes[3] $\mathcal{C}$ is a pair (P, V) of randomized algorithms, called *prover* and *verifier*, respectively. Both parties receive as common input a specification of a code $C \in \mathcal{C}$ which we view as a set of functions $C = \{f : S \to \Sigma\}$ for a finite set S and alphabet Σ. We also assume that the verifier has oracle access to a function $f^{(0)} : S \to \Sigma$ and that the prover receives the same function as explicit input. The number of rounds of interaction, or *round complexity*, is denoted by r, *query complexity* is denoted by q.

▶ **Definition 1** (Interactive Oracle Proof of Proximity (IOPP) [12])**.** An r-round Interactive Oracle Proof of Proximity (IOPP) $\mathsf{S} = (\mathsf{P}, \mathsf{V})$ is a $(\mathsf{r}+1)$-round IOP. We say S is an (r-round) IOPP for the error correcting code $C = \{f : S \to \Sigma\}$ with soundness $\mathbf{s}^- : (0, 1] \to [0, 1]$ with respect to distance measure Δ, if the following conditions hold:

- **First message format:** the first prover message, denoted $f^{(0)}$, is a purported codeword of C, i.e., $f^{(0)} : S \to \Sigma$
- **Completeness:** $\Pr\left[\langle \mathsf{P} \leftrightarrow \mathsf{V} \rangle = \mathsf{accept} \mid \Delta\left(f^{(0)}, C\right) = 0\right] = 1$; this means that for every $f^{(0)} \in C$ the protocol terminates in acceptance.
- **Soundness:** For any P^*, $\Pr\left[\langle \mathsf{P}^* \leftrightarrow \mathsf{V} \rangle = \mathsf{reject} \mid \Delta\left(f^{(0)}, C\right) = \delta\right] \geq \mathbf{s}^-(\delta)$

The sum of lengths of all prover messages, except for $f^{(0)}$, is the IOPP *proof length*; the time required to generate all messages except for $f^{(0)}$ is the *prover complexity*. The IOPP *query complexity* is the total number of queries to all messages, including $f^{(0)}$ and the *decision complexity* is the computational complexity (see following remark) required by the verifier to reach its verdict, once the queries and query answers are provided as inputs.

▶ Remark (Computational model for decision complexity). The computational model in which decision complexity is computed is left undefined. A natural default is to use *boolean circuit complexity*. However, later we study families of linear codes in which each IOPP query is answered by a field element. The natural computational model in this case is that of *arithmetic complexity*, i.e., for a linear code C over a finite field $\mathbb{F}$, it is the number of arithmetic operations over $\mathbb{F}$ made by the verifier to reach its decision.

1.1.3 Main Theorem

The finite field of size q is denoted here by $\mathbb{F}_q$; when q is clear from context we omit it. A field is called *binary* if $q = 2^m, m \in \mathbb{N}$. A subset S of a binary field is an *additive coset* if it is a coset of a subgroup of the additive group $\mathbb{F}^+$, i.e., if S is an additive shift of an

[3] The definition of an IOPP can be generalized to arbitrary languages; we study an IOPP for a specific family of codes so prefer to limit the scope of our definition accordingly.

$\mathbb{F}_2$-linear space contained in $\mathbb{F}_q$. The *binary additive RS code family* is the collection of codes $\mathsf{RS}[\mathbb{F}, S, \rho]$ where $\mathbb{F}$ is a binary field and S an additive coset. This family of codes is one for which quasilinear PCPP were defined in [23], and our main theorem is stated for it (see Table 1).

▶ **Theorem 2** (Main – FRI properties)**.** *The binary additive RS code family of rate* $\rho = 2^{-\mathcal{R}}, \mathcal{R} \geq 2, \mathcal{R} \in \mathbb{N}$ *has an IOPP (*FRI*) with the following properties, where* $N = |S|$ *denotes block-length (which equals the prover-side input length for a fixed* $\mathsf{RS}[\mathbb{F}, S, \rho]$ *code) and* $\rho N > 16$*:*

- ***Prover*** *Complexity is less than* $6N$ *arithmetic operations in* $\mathbb{F}$*; proof length is less than* $N/3$ *field elements and round complexity is at most* $\frac{\log N}{2}$*;*
- ***Verifier complexity*** *Query complexity is* $2 \log N$*; the verifier decision is computed using at most* $21 \log N$ *arithmetic operations over* $\mathbb{F}$*;*
- ***Soundness:*** *There exists* $\delta_0 \geq \frac{1}{4}(1 - 3\rho) - \frac{1}{\sqrt{N}}$ *such that every* f *that is* δ*-far in relative Hamming distance from the code, is rejected with probability at least* $\min\{\delta, \delta_0\} - \frac{3N}{|\mathbb{F}|}$*;*
- ***Parallelization:*** *Each prover-message can be computed in* $O(1)$ *time on a Parallel Random Access Machine (PRAM) with common read and exclusive write (CREW), assuming a single* $\mathbb{F}$ *arithmetic operation takes unit time.*

▶ Remark (Space complexity). Given the ith prover message as input, each symbol of the $(i+1)$th prover message can be computed with space complexity $O(\log |\mathbb{F}|)$, i.e., the space required to hold a constant number of field elements.

This follows immediately from the fact that each prover message is computed in $O(1)$ arithmetic operations on a parallel machine.

Generalizing Theorem 2 to arbitrary rate $\rho \in (0, 1]$ can be done as described in [23, Proposition 6.13] (cf. remark 6.2 there); this leads to slightly larger constants in the prover and verifier complexity. For practical applications like ZK-IOPs [14, 12], rates of the form stated in the theorem above suffice.

▶ Remark (FRI for "smooth codes"). We call a multiplicative group $H \subset \mathbb{F}_q$ *smooth* if its order ($|H|$) is 2^k for $k \in \mathbb{N}$. The family of *smooth* RS codes of rate ρ is the set of $\mathsf{RS}[\mathbb{F}_q, H, \rho]$ codes in which H is a smooth multiplicative group. Theorem 2 holds *also* with respect to the family of smooth RS codes, with somewhat smaller constants than 6 and 21 for the prover and verifier arithmetic complexity (see full version of this paper [10]); see Section 2.1 for a high-level overview of the smooth case and full version of this paper [10] for more details on modifying the protocol to this case. The protocol can be further generalized to groups of order c^k for constant c (perhaps with different arithmetic complexity constants), details omitted.

The soundness bound of Theorem 2 is nearly tight for $\delta \leq \delta_0$. We conjecture that a similar bound holds for all δ. See full version of this paper [10] for a more detailed version of the conjecture that implies it, and a discussion of Equation (1)

▶ **Conjecture 3.** *The soundness limit* δ_0 *of Theorem 2 approaches* $1 - \rho$*. Specifically, for all* $\delta \leq 1 - \rho$*, the rejection probability of any* f *that is* δ*-far from the RS-code of rate* ρ *and block-length* N *over* $\mathbb{F}$*, is at least*

$$\delta - \frac{2 \log N}{\sqrt{|\mathbb{F}|}}. \tag{1}$$

1.2 Applications to transparent zero knowledge implementations

Prover-efficient IOPPs of the kind presented here are crucially needed to facilitate *practical* ZK argument systems that are (i) *transparent* (public randomness), (ii) *universal* – apply to any computation – and (iii) *(doubly) scalable* – have quasi-linear proving time *and* poly-logarithmic verification time, simultaneously. In a follow-up paper we use the FRI protocol (among other things) to realize in code the first ZK system (called a ZK-STARK there) that achieves the three properties listed above [11]. The concrete efficiency of that protocol, which relies to a large degree on the efficiency of the FRI protocol presented here, allows one to construct ZK arguments of knowledge (ZK-ARKs) for computational statements, where verifying the computational integrity of the statement using the ZK-STARK verifier is stricly faster than naïve verification via re-exectution, and the communication compelxity is strictly smaller than the size of the non-deterministic witness supporting the claim. The ZK-STARK prover is $\approx 50\times$ faster than the previous state-of-the-art transparent system, code-named SCI [7] (that system does not have ZK), and $\approx 10\times$ faster than state-of-the-art ZK-SNARKs [17] (which are not transparent); see [11, Figure 5] for details.

In the remainder of this section we explain, briefly, how our system could be incorporated in a larger practical ZK system (like the ZK-STARK mentioned earlier). In Section 1.3 we discuss the range of block-lengths that are relevant in applications, and the resulting communication complexity arising from their use.

The seminal works of Babai et al. [6, 5] showed that verifying the correctness of an arbitrary nondeterministic computation running for $T(N)$ steps can be achieved by a verifier running in time $\mathsf{poly}(N, \log T(N))$ in the PCP model. Kilian's construction transforms such PCPs into a 4-round ZK argument in which the total communication complexity and verifier running time are bounded by $\mathsf{poly}\log T(N)$ [43] (cf. [44, 40, 41]), assuming a family of collision-resistant hash functions. Micali further compressed this system into a non-interactive computationally sound (CS) proof system, assuming both prover and verifier share access to the same random function [48]; this is typically realized in practice using a hash function like SHA2 and relying on the Fiat-Shamir heuristic [31]. No implementation of these marvelous techniques has appeared during the quarter century that has passed since they were first published. This is explained, in part, by concerns about the efficiency of these constructions for concrete programs and run-times. Among the numerous components involved in building these systems, a significant computational bottleneck is that of computing solutions to the Reed-Muller (RM) proximity problem, also known as "low degree testing" of multivariate polynomials.

Quasilinear PCPs based on RS codes have prover complexity that is asymptotically more efficient than RM codes which lead to PCPs with super-quasi-linear length, and a number of works have explored the concrete efficiency of these RS-based protocols [16, 8]. Recently, Ben-Sasson et al. suggested an IOP with perfect zero knowledge (PZK) for NP [14], later extended to NEXP [12], in which prover complexity is quasilinear and verifier complexity is $\mathsf{poly}(N, \log T(N))$; this PZK-IOP can be compiled, using Kilian's technique, into an interactive ZK argument with succinct[4] communication complexity, or, using Micali's technique (cf. [61]), into a *non-interactive random oracle proof (NIROP)* as defined in [19]. In light of this, the practicality of Kilian- and Micali-type ZK argument systems with polylogarithmic verifiers should be reconsidered.

To add motivation, a number of interesting practical succinct argument systems (with and without zero-knowledge) have been reported recently (see [62] for an excellent updated survey

[4] Here, as in past works, "succinct" is synonymous to "polylogarithmic".

of the subject and [7] for a comparison of PCP/IOP-based solutions to other approaches). A particular system based on the *quadratic span programs* (QSP) of Gennaro et al. [33] (cf. [17]) has been used by Ben-Sasson et al. to build a decentralized anonymous payment (DAP) system called "Zerocash" [15], later deployed as a practical commercial crypto-currency called "Zcash" [52, 38]. However, the QSP based ZK system used in Zerocash/Zcash, called a "preprocessing SNARK" [24], requires a setup phase that involves *private* randomness; additionally, it relies on rather strong cryptographic "knowledge of exponent" assumptions, and quantum computers can create pseudo-proofs of falsities in polynomial time for such systems [60] (cf. [54]). In contrast, the aforementioned succinct interactive and non-interactive (NIROP) systems based on quasilinear PZK-IOPs require only public randomness for their setup, and the only cryptographic assumption required to realize them[5] is the existence of a family of collision resistant hash functions [43], in particular, they are not known to be breakable by quantum computers in polynomial time. Therefore, there is great interest in understanding whether succinct (interactive and non-interactive) ZK argument systems which require only public randomness (and resistant to known polynomial time quantum algorithms) can be *practically* built and used, say, by Zcash. Ben-Sasson et al. [7] describe such an implemented system, called "succinct computational integrity (SCI)" which is not ZK and has comparatively large communication complexity[6]. As mentioned above, the RS proximity solution described in Theorem 2 is already used within an implemented ZK system [11].

1.3 Concrete degree, communication, and round complexity

In this section we *briefly* discuss the "size" of RS codes that would be needed for various practical applications and the effect of logarithmic round complexity on security. Due to space limitations, and because the focus of this paper is *theoretical* (within the information theoretic IOP model), we omit implementation details and point the interested reader to full version of this paper [10]; cf. [7, 14].

The message length of RS codes of degree $d = \rho \cdot N - 1$ is precisely d, so we start by recounting the range of degrees (message sizes) that seem practically relevant. Later we calculate the communication complexity arising from using the FRI protocol to argue proximity to codes of practically relevant block-lengths, and end by discussing the practical implications of an IOPP with $\log d$ rounds. Throughout this section $\rho = 1/8$ ($N = 8 \cdot d$) because this setting is used in prior [7] and future [11] works.

1.3.1 RS block-length of systems realized in code

The recently realized IOP-based argument system called SCI ("Scalable Computational Integrity") reduces computational statements, like *"the output of program P on input x equals y after T steps"* to a *pair* of RS-proximity testing problems. SCI uses an IOP version of the quasilinear PCP of [23], which could be replaced with FRI. Programs bench-marked by SCI were executed on a simple MIPS-like virtual machine called *TinyRAM* [18]. Generally speaking, RS degree increases in size with the number of TinyRAM machine cycles T.

[5] To reach a (non-interactive) computationally sound (CS) proof [49], the "random oracle" is assumed, and realized in practice by relying on the Fiat-Shamir heuristic. In particular, this approach as well is not known to be breakable by quantum computers in polynomial time.

[6] Communication complexity in SCI is on the order of tens of megabytes long, compared with QSP based zk-SNARKs that are shorter than 300 Bytes.

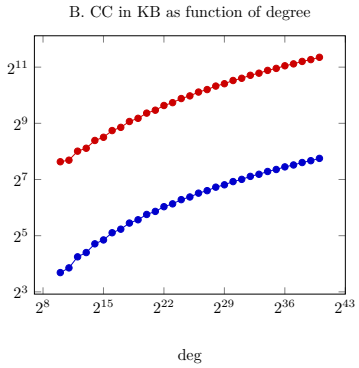

Figure 1 A. Degree of RS code arising from the *exhaustive subset sum* program [7, Appendix C], as a function of the number of TinyRAM machine cycles. B. Communication complexity (CC) as a function of degree, using $\lambda = 160$ bits, field size 2^{64}, soundness error $\epsilon = 2^{-80}$, and maximal proximity parameter $\delta = 1 - \rho$. The higher (red) graph corresponds to proven soundness (see full version of this paper [10]) and the lower (blue) corresponds to conjectured soundness (Conjecture 3). Both plots use code rate $\rho = 1/8$.

Figure 1.A plots the degree d as a function of T for a specific simple program, showing that $d \approx T \cdot 2^{21}$.

For crypto-currency applications requiring zero knowledge, block-length will be dominated by the type of cryptographic primitives required, and the number of times they are invoked within a computational statement. For instance, *ZK contingent payments* [47] require a single hash, and Zerocash's *Pour circuit* [15] uses 64 hash invocations, leading in that work to RS codewords (over a prime field) with degree (=number of gates) approximately 2^{22}. Our new work in progress shows that a single hash invocation requires RS block-length between $2^{12} = 4096$ (for a Davies–Meyer hash based on AES128) to 2^{19} (for SHA2), meaning that degrees in the range $d \in [2^{12}, 2^{26}]$ are relevant for existing crypto-currency (ZK) applications [11].

1.3.2 Estimated communication complexity and argument length

The practical realization of interactive proof systems (see Section 1.2) into interactive argument systems [43] and CS proofs [49] can be extended to the IOPP model, in which multiple rounds of interaction are used [19]. Using Kilian's scheme [43], during the ith round the prover sends the root $\mathsf{root}^{(i)}$ of a Merkle hash tree $\mathsf{Tree}^{(i)}$ whose leaves are labeled by entries of $f^{(i)}$, and the verifier replies with randomness. Using Micali's scheme [49], the (non-interactive) prover queries the random oracle with $\mathsf{root}^{(i)}$ to "simulate" the verifier's ith message. When verifier queries to $f^{(i)}$ are answered by the prover, each answer is accompanied by an *authentication path* (AP) that shows the query answer is consistent with $\mathsf{root}^{(i)}$. Let $\mathsf{CC}_{\delta,\epsilon}(N)$ denote the prover-side communication complexity (in bits) of an argument/CS proof realized by applying the Kilian/Micali scheme to FRI, where δ is the proximity parameter and ϵ is the error bound, i.e., words that are δ-far from the RS code are rejected with probability $< \epsilon$. Then

$$\mathsf{CC}_{\delta,\epsilon}(N) = \mathsf{q}_{\delta,\epsilon} \cdot \log |\mathbb{F}| + \mathsf{AP}_{\delta,\epsilon} \cdot \lambda \tag{2}$$

where $\mathsf{q}_{\delta,\epsilon}$ denotes total query complexity in the IOP model to reach soundness $\geq 1 - \epsilon$ for proximity parameter δ, $\mathsf{AP}_{\delta,\epsilon}$ is the number of nodes in the sub-forest of the Merkle trees $\mathsf{Tree}^{(0)}, \ldots, \mathsf{Tree}^{(\mathsf{r})}$ induced by all authentication paths, and λ is the number of output bits of

the hash function used to construct the Merkle trees. In our preliminary results [11] we use $\lambda = 160$, $\epsilon = 2^{-80}$, $|\mathbb{F}| = 2^{64}$ and $\rho = 1/8$. Figure 1.B plots the communication complexity for this setting under the proven soundness of Theorem 2 and the (better) soundness of Conjecture 3. In both cases we use maximally large distance $\delta = 1 - \rho = 7/8$ to show the concrete difference in communication complexity between the proven and conjectured soundness. This plot also motivates the quest for improving the soundness analysis of Theorem 2.

1.3.3 Round complexity considerations

Assuming that a crypto-currency block-chain serves as a time-stamping service for public messages and a public beacon of randomness, one may use block-chains to simulate verifier messages. Several block-chains (including Zcash) generate blocks every 2.5 minutes, which means that a FRI proof for $d = 2^k$ will take roughly $k \cdot \frac{5}{4}$ minutes to complete, or less than 1 hour[7] for $d < 2^{40}$.

For fixed d, the round complexity stated in Theorem 2 is $\frac{1}{2}\log d$, but the more refined version (see [10]) gives a trade-off between query (q) and round (r) complexity, of the form $\mathsf{r} = \log d / \log \mathsf{q}$, allowing further reduction in round complexity in exchange for larger communication complexity.

Finally, the Random Oracle model used by Micali to "compress" interactive argument systems (like Kilian's) into CS proofs applies equally to multi-round IOPs like FRI, with negligible impact on argument length; see [19, Remark 1.6] for a detailed discussion. Practically speaking, those who treat hash functions like SHA2 as realizations of the RO model (a position taken by Bitcoin and other crypto-currency miners), might feel comfortable compiling IOP protocols like FRI into succinct non-interactive arguments, as described in [19].

1.4 Related works

High-rate LTCs Locally testable codes (LTCs) are error correcting codes for which – by definition – prover complexity and proof length equal 0 (as stated for the case of RS codes by Rubinfeld and Sudan [58]); in other words, when focusing solely on prover complexity, LTCs offer an optimal solution (zero complexity). Nevertheless, as discussed in Section 1.2, the specific question of small prover complexity for RS codes is highly relevant because of the its applications to practical ZK-IOPs.

Classical "direct" constructions of LTCs, such as the Hadamard code studied by Blum, Luby and Rubinfeld [25] and the $\log N$-variate RM codes used in early PCP constructions [1, 5] have sub-constant rate, thus lead to long proofs and large PCP prover complexity.

More recently, there has been remarkable progress on constructing locally testable codes (LTCs) with small query complexity and large soundness. Kopparty et al. obtained such codes with rate approaching 1 [45] and Gopi et al. presented LTCs that reach the Gilbert Varshamov bound [36]. These LTCs have super-polylogarithmic query complexity. Additionally, in contrast to RS codes, we are not aware of PCP constructions with similar parameters nor do we know how to convert these LTCs into PCPs.

PCPs and IOPs: A number of recent works have considered PCP constructions with small proof length and query complexity. In addition to the aforementioned works on quasi-linear PCPs, Moshkovitz and Raz constructed PCPs with optimally small query complexity

[7] Compare this with Bitcoin's "best practice" of waiting 1 hour for confirmations, or 3 days required to clear standard checks.

(measured in bits) and proofs of length $N^{1+o(1)}$ [51], where N denotes the length of the NP statement (like a 3CNF) for which the PCP is constructed, achieving better soundness than Hr astad's result [37]. A different line of works attempts to optimize the *bit-length* of PCP proofs; the state of the art, due to Ben-Sasson et al., achieves PCPs of bit-length $O(N)$ and query complexity N^{ϵ} [22]. In the IOP model, which generalizes PCPs by allowing more rounds of interaction, Ben-Sasson et al. presented a 2-round IOP with bit-length $O(N)$, constant query complexity (measured in bits) and constant soundness [13]. (Prover arithmetic complexity in all of these systems is super-linear.)

Soundness amplification: A number of results in the PCP literature have suggested techniques for improving soundness of general PCP constructions, including the parallel repetition theorem of Raz [55], the gap amplification technique of Dinur [28] and direct-product testing, introduced by Goldreich and Safra [34] (cf. [29, 39]). These techniques lead to excellent soundness bounds with small query complexity. The concrete prover complexity of PCPs and PCPPs associated with these methods has not been studied in prior works but prover complexity is at least super-linear, and often polynomially large.

Doubly-efficient "proofs for muggles": A recent line of works, initiated by Goldwasser, Kalai and Rothblum [35], revisits the IP model which is equivalent to PSPACE [46, 59], focusing on *doubly efficient* systems in which the prover runs in polynomial time (as opposed to polynomial space, as in the aforementioned results) and verifier runs in nearly linear time. The state of the art along this line is due to Reingold et al. [57], they construct doubly-efficient IP protocols with a constant number of rounds for a family of languages in P. Prover complexity in this line of works is at least super-linear, and typically polynomially large and verifier complexity is super-polylogarithmic, and often super-linear as well (cf. [27, 57]).

2 Overview of the FRI IOPP and its soundness

In this section we consider the task of building an IOPP for a "smooth" RS code (defined below). We start in Section 2.1 by considering the *completeness* case, where we describe the interaction between the verifier and an *honest prover* attempting to prove membership in the RS code of a valid codeword $f^{(0)}$. The IOPP protocol is explained in similarity to the Inverse Fast Fourier Transform (IFFT) [26]. Then, in Section 2.2, we consider the *soundness* case, where we assume $f^{(0)}$ is far in relative Hamming distance from the code and need to prove lower bounds on the verifier's rejection probability. Soundness analysis is the most challenging aspect of our work (as it is for all prior PCPP/IOPP works). Our analysis uses the soundness analysis of the quasilinear RS-PCPP [23] for the case of "large" Hamming distance (beyond the unique decoding radius of the code), and presents a novel, tighter, analysis for "small" Hamming distance (below that radius).

2.1 FRI overview and similarity to the Fast Fourier Transform (FFT)

We start by describing the protocol in similarity to the IFFT algorithm; that algorithm is also related to the quasi-linear PCPP for RS codes of [23], and towards the end of this section we explain the connection between FRI and that quasi-linear PCPP.

Let $\omega^{(0)}$ generate a *smooth* multiplicative group of order $N = 2^n$ (see Remark 1.1.3), denoted $L^{(0)}$, that is contained in a field $\mathbb{F}$; in signal processing applications $\omega^{(0)}$ is a complex root of unity of order 2^n and $\mathbb{F}$ is the field of complex numbers (we shall use a different setting). Assume the prover claims that $f^{(0)} : L^{(0)} \to \mathbb{F}$ is a member of $\mathsf{RS}[\mathbb{F}, L^{(0)}, \rho]$, i.e., $f^{(0)}$ is the evaluation of an unknown polynomial $P^{(0)}(X) \in \mathbb{F}[X], \deg(P) < \rho 2^n$; for simplicity we assume $\rho = 2^{-\mathcal{R}}$ and $\mathcal{R}$ is a positive integer. The task of the verifier is to distinguish between

low-degreeness ($f^{(0)} \equiv P^{(0)}$ for some low degree $P^{(0)}$) and cases where $f^{(0)}$ is far from all polynomials of degree $< \rho 2^n$. Recalling the IFFT, if $f^{(0)} \equiv P^{(0)}$ there exist polynomials $P_0^{(1)}, P_1^{(1)} \in \mathbb{F}[Y]$ such that $\max\left\{\deg\left(P_0^{(1)}\right), \deg\left(P_1^{(1)}\right)\right\} < \frac{1}{2}\rho 2^n$ and

$$\forall x \in L^{(0)} \;\; f^{(0)}(x) = P^{(0)}(x) = P_0^{(1)}(x^2) + x \cdot P_1^{(1)}(x^2),$$

or, letting $Q^{(1)}(X,Y) \stackrel{\triangle}{=} P_0^{(1)}(Y) + X \cdot P_1^{(1)}(Y)$ and defining $q^{(0)}(X) \stackrel{\triangle}{=} X^2$, we have

$$P^{(0)}(X) \equiv Q^{(1)}(X, Y) \mod Y - q^{(0)}(X) \tag{3}$$

where $\deg_X\left(Q^{(1)}\right) < 2$ and $\deg_Y\left(Q^{(1)}\right) < \frac{1}{2}\rho 2^n$. The map $x \mapsto q^{(0)}(x)$ is 2-to-1 on $L^{(0)}$ because $q^{(0)}(x) = q^{(0)}(-x)$, and the output of this map is the multiplicative group generated by $\omega^{(1)} = \left(\omega^{(0)}\right)^2$, this group has order 2^{n-1}, denote it by $L^{(1)}$. Moreover, for every $x^{(0)} \in \mathbb{F}$ and $y \in L^{(1)}$, the value of $Q^{(1)}\left(x^{(0)}, y\right)$ can be computed by querying two entries of $f^{(0)}$ because $\deg_X\left(Q^{(1)}\right) < 2$ (the two entries are the two roots of the polynomial $y - q^{(0)}(X)$).

Our verifier thus samples $x^{(0)} \in \mathbb{F}$ uniformly at random and requests the prover to send as its first oracle a function $f^{(1)} : L^{(1)} \to \mathbb{F}$ that is supposedly the evaluation of $Q^{(1)}\left(x^{(0)}, Y\right)$ on $L^{(1)}$. Assuming $f^{(0)} \in \mathsf{RS}[\mathbb{F}, L^{(0)}, \rho]$, the discussion above shows that $f^{(1)} \in \mathsf{RS}[\mathbb{F}, L^{(1)}, \rho]$. Notice that there exists a 3-query test for the consistency of $f^{(0)}$ and $f^{(1)}$, we call it the *round consistency test*:

1. sample a pair of distinct elements $s_0, s_1 \in L^{(0)}$ such that $s_0^2 = s_1^2 = y$; in other words, sample a uniform $y \in L^{(1)}$ and let s_0, s_1 be the two roots of the polynomial $y - X^2$;
2. query $f^{(0)}(s_0), f^{(0)}(s_1)$ and $f^{(1)}(y)$, denote the query answers by α_0, α_1 and β, respectively;
3. interpolate the "line" through (s_0, α_0) and (s_1, α_1), i.e., find the polynomial $p(X)$ of degree at most 1 that satisfies $p(s_0) = \alpha_0$ and $p(s_1) = \alpha_1$; notice p is unique and well-defined because $s_0 \neq s_1$;
4. accept if and only if $p\left(x^{(0)}\right) = \beta$ and otherwise reject;

Tallying the costs of the first round, the verifier sends a single field element ($x^{(0)}$) and the prover responds with a message (oracle) $f^{(1)} : L^{(1)} \to \mathbb{F}$ evaluated on a domain that is half the size of $L^{(0)}$; testing the consistency of $f^{(0)}$ and $f^{(1)}$ requires three field elements per test (repeating the test boosts soundness). We thus reduced a single proximity problem of size 2^n and rate ρ to a single analogous problem of size 2^{n-1} and same rate. Repeating the process for $\mathsf{r} = n - \mathcal{R}$ rounds leads to a function $f^{(\mathsf{r})}$ that is supposedly of constant degree and evaluated over a domain of constant size $2^{\mathcal{R}}$, so at this point the prover sends the single constant that describes the function, and the verifier uses it as $f^{(\mathsf{r})}$ in the last round consistency test, the one that tests consistency of $f^{(\mathsf{r}-1)}$ and $f^{(\mathsf{r})}$.

Applying inductive analysis to all r rounds, if $f^{(0)} \in \mathsf{RS}[\mathbb{F}, L^{(0)}, \rho]$ (and the prover is honest) then all r round consistency tests pass with probability 1 and $f^{(\mathsf{r})}$ is indeed a constant function. In other words, the protocol we described has perfect completeness.

▶ Remark (FRI as a "biased" version of quasi-linear RS-PCPP). The quasi-linear PCPP of [23] is quite similar to FRI, including the degree-reduction (from $P^{(0)}$ to $P^{(1)}$) obtained by requesting the prover to evaluate a bivariate polynomial $Q(X,Y)$ on a collection of axis-parallel lines. There are two main differences between FRI and that PCPP:

1. the quasilinear PCPP is non-interactive, and thus the prover evaluates $Q^{(1)}(X,Y)$ on a large subset of $\mathbb{F} \times \mathbb{F}$, whereas the FRI protocol uses interaction to reduce proving time, by requesting the prover to apply recursion only to the axis-parallel lines selected by the verifier.

2. the polynomial $q^{(0)}(X)$ used in [23] has degree $\approx \sqrt{\deg\left(P^{(0)}\right)}$ and thus $Q^{(1)}(X,Y)$ has degree $\approx \sqrt{\deg\left(P^{(0)}\right)}$ in each of its variables. In contrast, the polynomial $q^{(0)}$ used by FRI has *constant* degree, and so the degrees of $Q^{(1)}$ are very biased (constant degree in X vs. $\deg\left(P^{(0)}\right)/2$ in Y). This leads to larger recursion depth for FRI but also avoids the necessity to apply recursive low-degree testing to each of the axes (the X-axis) because of its constant degree.

2.1.1 Differences between informal and actual protocol

The differences between the informal and formal protocols are mostly technical; we list them now. The field $\mathbb{F}$ is finite and *binary*, i.e., of characteristic 2; nevertheless the construction and analysis can be immediately applied to RS codes evaluated over smooth multiplicative groups (of order 2^n), as explained informally above (cf. Remark 1.1.3). In binary fields, the natural evaluation domains (like $L^{(0)}, L^{(1)}$ above) are cosets of *additive* groups (not multiplicative ones), i.e, $L^{(i)}$ is an affine shift of a linear space over $\mathbb{F}_2$. The map $q^{(0)}(X) = X^2$ is *not* 2-to-1 on $L^{(0)}$ (in binary fields it is a 1-to-1 map, a Frobenius automorphism of $\mathbb{F}$ over $\mathbb{F}_2$) so we use a different polynomial $q^{(0)}(X)$ that is many-to-one on $L^{(0)}$ and such that the set $L^{(1)} = \left\{y = q^{(0)}(x) \mid x \in L^{(0)}\right\}$ is a coset of an *additive* group, like $L^{(0)}$, but of smaller size ($|L^{(1)}| \ll |L^{(0)}|$); the polynomial $q^{(0)}$ is known as an *affine subspace* polynomial, belonging to the class of *linearized* polynomials. We use $q^{(0)}$ of degree 4 instead of 2 because this reduces the number of rounds from n to $n/2$ with no increase in total query complexity; notice that a similar reduction could be applied in the multiplicative setting by using $q^{(0)} = X^4$ (but we preferred simplicity to efficiency in the informal exposition above). Finally, the actual protocol performs all queries only after the prover has sent all of $f^{(1)}, \ldots, f^{(\mathsf{r})}$. Thus, we construct a protocol with two phases. The first phase, called the COMMIT phase, involves r *rounds*. At the beginning of the ith round the prover has sent oracles $f^{(0)}, \ldots, f^{(i-1)}$, and during this ($i$th) round the verifier samples and sends $x^{(i)}$ and the prover responds by sending the next oracle $f^{(i)}$. During the second phase, called the QUERY phase, the verifier applies the *round consistency test* to all r rounds. To save query complexity *and boost soundness*, the query made to $L^{(i)}$ is used to test *both* consistency of $f^{(i-1)}$ vs. $f^{(i)}$ *and* consistency of $f^{(i)}$ vs. $f^{(i+1)}$.

2.2 Soundness analysis – overview

Proof composition is a technique introduced by Arora and Safra [3] in the context of PCPs, adapted to PCPPs in [21, 30] and optimized for the special case of the RS code in [23]. Informally, it reduces proximity testing problems over a large domain to similar proximity testing problems over significantly smaller domains. The process reducing $f^{(0)}$ to $f^{(1)}$ above is a special case of proof composition, and each invocation of it incurs two costs on behalf of the verifier. The first is the *query complexity* needed to check consistency of $f^{(0)}$ and $f^{(1)}$ (the "round consistency test") and the second is the reduction in *distance*, which affects the *soundness* of the protocol. Assuming $f^{(0)}$ is $\delta^{(0)}$-far from all codewords in relative Hamming distance, for proof composition to work one should prove that with high probability $f^{(1)}$ is $\delta^{(1)}$-far from all codewords where $\delta^{(1)}$ depends on $\delta^{(0)}$; larger values of $\delta^{(1)}$ imply higher (better) soundness and smaller communication complexity. A benefit of the FRI protocol is that with high probability $\delta^{(1)} \geq (1 - o(1))\delta^{(0)}$, i.e., the reduction in distance in our protocol is *negligible*. In contrast, prior RS proximity PCPP and IOPP solutions follow the construction and analysis of [23] which in turn is based on the bivariate testing Theorem of

Polischuk and Spielman [53] and incur a *constant multiplicative loss* in distance per round of proof composition ($\delta^{(1)} \leq \delta^{(0)}/2$). This loss limited the number of proof composition rounds to $\leq \log N$ and thus required replacing $q^{(0)}(X) = X^2$ with a higher degree polynomial, like $q^{(0)}(X) = X^{2^{n/2}}$. The higher degree of $q^{(0)}$ results in $Q^{(1)}(X, Y)$ having *balanced* X- and Y-degrees, namely

$$\deg_X \left(Q^{(1)}\right) \approx \deg_Y \left(Q^{(1)}\right) \approx 2^{n/2}.$$

Moving to $q^{(0)}(X)$ of *constant* degree as in FRI gives a *biased RS-IOPP* (because $\deg_X(Q^{(1)}) \ll \deg_Y(Q^{(1)})$). The main benefit of this bias is that one side of the recursive process (that of X) terminates immediately and consequently *removes* the constant multiplicative soundness loss incurred in prior works, replacing it with a negligible additive loss. More to the point, we show that for $\delta^{(0)}$ less than the unique decoding radius of the code ($\delta^{(0)} < (1-\rho)/2$), with high probability (namely, $1 - \frac{O(1)}{|\mathbb{F}|}$) the sum of (i) the round consistency error and (ii) the "new" distance $\delta^{(1)}$ is at least as large as the "old" distance $\delta^{(0)}$. This statement is relatively straightforward to prove in case the prover is *honest*, i.e., when $f^{(1)}(y) = Q^{(1)}\left(x^{(0)}, y\right)$ for all $y \in L^{(1)}$ (in this case there is no round consistency error). The challenging part of the proof is to show this also holds for non-honest provers and arbitrary $f^{(1)}$; see full version of this paper [10] for more details.

NP-Hardness of Coloring 2-Colorable Hypergraph with Poly-Logarithmically Many Colors

Amey Bhangale[1]
Weizmann Institute of Science, Rehovot, Israel
amey.bhangale@weizmann.ac.il

Abstract

We give very short and simple proofs of the following statements: Given a 2-colorable 4-uniform hypergraph on n vertices,

1. It is NP-hard to color it with $\log^{\delta} n$ colors for some $\delta > 0$.
2. It is *quasi*-NP-hard to color it with $O\left(\log^{1-o(1)} n\right)$ colors.

In terms of NP-hardness, it improves the result of Guruswam, Håstad and Sudani [SIAM Journal on Computing, 2002], combined with Moshkovitz-Raz [Journal of the ACM, 2010], by an 'exponential' factor. The second result improves the result of Saket [Conference on Computational Complexity (CCC), 2014] which shows *quasi*-NP-hardness of coloring a 2-colorable 4-uniform hypergraph with $O\left(\log^{\gamma} n\right)$ colors for a sufficiently small constant $1 \gg \gamma > 0$.

Our result is the first to show the NP-hardness of coloring a c-colorable k-uniform hypergraph with poly-logarithmically many colors, for *any* constants $c \geq 2$ and $k \geq 3$.

Finally, I would like to thank all the anonymous reviewers for their comments which helped in improving the presentation significantly.

1 Introduction

A k-uniform hypergraph $\mathcal{H}(\mathcal{V}, \mathcal{E})$ is a collection of vertices $\mathcal{V}$ and a family $\mathcal{E}$ of subsets of size k of the vertices. Let n denote the number of vertices $|\mathcal{V}|$. A coloring of $\mathcal{H}$ with c colors is a mapping $\chi : \mathcal{V} \to [c]$. A coloring χ is said to be a valid c-coloring if for every $e \in \mathcal{E}$, χ assigns at least two different colors to the vertices in e. The *chromatic number* of a hypergraph is the minimum c for which a valid c-coloring exists.

It is easy to find a 2-coloring of a 2-colorable graph. Deciding whether a graph is 3-colorable or not is a well known NP-complete problem [7]. In an approximate graph (or hypergraph) coloring problem, given a graph which is c colorable, the algorithm is allowed to use more than c colors to properly color the given graph. The best known polynomial-time algorithms to color a 3-colorable graph require $n^{\Omega(1)}$ colors. However, the known NP-hardness results can only rule out coloring a 3-colorable graph with 4 colors [11, 10]. This also implies that coloring a t-colorable graph with $t + 2\lfloor t/3 \rfloor - 1$ colors is NP-hard. Garey and Johnson [7] proved NP-hardness of $(2t-5)$-coloring a t-colorable graph, for all $t \geq 6$. Recently,

[1] Research supported by Irit Dinur's ERC-CoG grant 772839.

Brakensiek-Guruswami [4] showed that for all $t \geq 3$, it is NP-hard to find a c-coloring when $c \leq 2t - 2$.

For hypergraphs with uniformity 3 and more, the situation is completely different when the hypergraph is 2-colorable. The best known approximation algorithm for coloring a 2-colorable hypergraph is with n^{ϵ} color for some explicit $\epsilon \in (0, 1)$. It is easy to see that if t-coloring of c-colorable k-uniform hypergraphs is hard, then it also implies a similar hardness result for k'-uniform hypergraphs for any $k' > k$ up to polynomial-time reductions i.e. coloring a c-colorable k'-uniform hypergraph with t colors is also hard. Therefore, the wishful inapproximability result is to get n^{ϵ} coloring hardness for 2-colorable 3-uniform hypergraphs for some $\epsilon > 0$.

Two directions have been pursued in literature. One is getting better and better hardness results in terms of colorability, where the uniformity of a hypergraph is any constant k and the guarantee is that the hypergraph is colorable with constantly many colors. The other is getting hardness results for smaller values of k . Both the directions are equally interesting and have been looked into for several years. Table 1 summarizes the known inapproximability results: For *e.g.* Guruswami *et al.* [9] (the first row) showed that given a 2-colorable 4-uniform hypergraph, there is no polynomial-time algorithm to color it with $O\left(\frac{\log\log n}{\log\log\log n}\right)$ many colors unless $\mathsf{NP} \subseteq \mathsf{DTIME}\left(n^{O(\log\log n)}\right)$. We would like to point out that the condition $\mathsf{NP} \subsetneq \mathsf{DTIME}\left(n^{O(\log\log n)}\right)$ from [9] can be replaced with $\mathsf{P} \neq \mathsf{NP}$, if one carries out the reduction of [9] starting with the PCP of [17].

We prove the following results:

▶ **Theorem 1.** *Assuming* $\mathsf{NP} \nsubseteq \mathsf{DTIME}(n^{O(\log\log n)})$*, there is no polynomial-time algorithm that colors a* 2*-colorable* 4*-uniform hypergraph on* n *vertices with* $O\left(\frac{\log n}{\log\log n}\right)$ *colors.*

Although an explicit constant in the exponent of $\log n$ was not mentioned in [19], it is less than 0.01. Therefore, Theorem 1 improves the best known inapproximability result by Saket [19] by a large polynomial factor, in terms of coloring with few colors. However, both the results are incomparable (See Remark 1).

Our second result shows NP-hardness of coloring a 2-colorable 4-uniform hypergraph.

▶ **Theorem 2.** *Assuming* $\mathsf{P} \neq \mathsf{NP}$*, there is no polynomial-time algorithm that colors a* 2*-colorable* 4*-uniform hypergraph on* n *vertices with* $\log^{\delta} n$ *colors for some* $\delta > 0$*.*

Theorem 2 improves the best known inapproximability result by Guruswami *et al.*[9] by an'exponential' factor, in terms of coloring with few colors. In fact, our result is the first to show the NP-hardness of coloring a c-colorable k-uniform hypergraph with $\texttt{poly}(\log n)$ colors for any constants $c \geq 2$ and $k \geq 3$.

An independent set in a hypergraph is defined as a set of vertices such that no hyperedge lies entirely within the set. In a valid coloring of a hypergraph, the vertices colored with the same color form an independent set. Thus, saying that a hypergraph does not contain an independent set of size n/c is stronger than saying that it cannot be colored with c colors.

In terms of approximating the size of the maximum independent set, Khot-Saket [15] showed that given an *almost* 2-colorable 4-uniform hypergraph, it is quasi-NP-hard to find an independent set of fractional size $2^{(\log n)^{1-\gamma}}$, for any $\gamma > 0$. More concretely, they show that it is quasi-NP-hard to distinguish between cases when a 4-uniform hypergraph has an independent set of size at least $\left(\frac{n}{2} - o(n)\right)$ vs. when it has no independent set of size $n/2^{(\log n)^{1-\gamma}}$, for any $\gamma > 0$.

▶ Remark. With the exception of results from this paper and Dinur *et al.*(denoted by ** in Table 1), all the remaining results give stronger inapproximability results than showing non

Table 1 Known inapproximability results for hypergraph coloring (for ** see Remark 1).

c-colorability in *soundness*. Namely, they show it is hard to distinguish between cases when a hypergraph satisfies the property in the *completeness* column vs. when there does not exist an independent set of size at least $1/s$, where s is the quantity in the *soundness* column.

1.1 Proof Overview

Our inapproximability result is obtained by constructing a *probabilistically checkable proof* where the locations are the vertices of a hypergraph and every check denotes a hyperedge of the hypergraph. Typically, the PCP is constructed by composing the so-called *outer verifier* with the *inner verifier*. Our starting point is a basic outer verifier that one gets from the PCP Theorem [6, 1, 2], along with Raz's parallel repetition theorem [18]. We can view it as an instance of a *Label Cover*. A Label Cover instance consists of a bipartite graph $G(U, V, E)$ where every edge is associated with a projection constraint $\pi_e : [R] \to [L]$ (See section 2.1). The inner verifier consists of encoding of labels of the vertices in a specific format and performing a test on the encoding.

A typical hardness of approximation result uses the *Long Code* encoding where the encoding of a k bit binary (or q-ary) string has an entry for every $f : \{0,1\}^k \to \{0,1\}$ (or $f : [q]^k \to [q]$ for $q \geq 2$). This blows up a string of length k into a string of length 2^{2^k}. Such an encoding is used in the construction of PCP by Guruswami *et al.* [9] and they managed to show a $\approx \log\log n$ lower bound on the inapproximability of coloring a 2-colorable 4-uniform

hypergraph. Khot [12] used a different encoding based on *Split Code* to get the hardness of poly-logarithmic number of colors, but for q-colorable 4-uniform hypergraph where $q \geq 5$. Saket [19] improved the result of Guruswami *et al.* [9] and showed the inapproximability of coloring with $O((\log n)^{\delta})$ colors for a very small constant $0 < \delta \ll 1$. Saket also used the Long Code encoding, but the hypergraph is formed using a different inner verifier compared to [9]. In a more recent series of works [8, 14, 21], efficient encodings were designed based on so-called *Short Code* which was used to break the poly-logarithmic barrier. It is not clear how to use this Short Code encoding to prove better inapproximability for 2-colorable 4-uniform hypergraphs. In all the previous constructions of PCPs based on Short Code, either the alphabet size is at least 3 (the guarantee on the hypergraph colorability in the completeness case) or the number of queries (the uniformity of the constructed hypergraph) is at least 6 if the alphabet size is restricted to 2 (See Table 1).

Our reduction is along the lines of the reduction in [5] which showed that coloring a 2-colorable 3-uniform hypergraph with $(\log \log n)^{1/3}$ colors is quasi-NP-hard. We give a very brief outline of their reduction first: This reduction also encodes a label in the outer verifier with a (rather large) subset of the Long Code encoding of size $2^{2^k - \mathtt{poly}(k)}$. They were able to construct a PCP over a binary alphabet which only queries 3 bits, giving the hardness for the above mentioned coloring problem. The encoding consists of all the locations in the Long Code encoding which correspond to a *slice* of $\{0,1\}^{2^k}$ of hamming weight m, where m is roughly $2^k/2$. The reduction crucially used two important properties of a specific graph, known as *Kneser graph*, on these locations. The first is that the chromatic number of the graph is *large* and the second is that in all the colorings of this graph with strictly fewer colors than the chromatic number, there is a *large* color class containing a monochromatic edge. The reduction also needed a multi-layered version of Label Cover, which gives the hardness of $(\log \log n)^{1/3}$ colors based on $\mathsf{NP} \not\subseteq \mathsf{DTIME}(n^{(\log n)^{O(1)}})$.

In our construction of the PCP, we start with a basic outer verifier and use a very short encoding of the labels of the outer verifier. More specifically, to get an inapproximability of c-colorability, we use an encoding of size roughly 2^{kc}, which is much shorter than the Long Code encoding 2^{2^k} or the encoding used in [5] for $c \ll 2^k$. This short encoding is the reason for improvement in the inapproximability. Of course, the whole analysis needs to work for such a short encoding. For the analysis to work, we need to query one more bit from the composed PCP, giving a hardness result for 4-uniform hypergraphs.

The subset of locations in the Long Code that we use corresponds to the vertex set of the *Schrijver graph* (See section 2.2 for the definition). It has much fewer number of vertices than the Kneser graph on the same slice. Moreover, the Schrijver graph also has a property that its chromatic number is large. Unfortunately, it is known to be a *vertex-critical graph* [2]. Thus, the property analogous to the second property of the Kneser graph mentioned previously no longer holds for the Schrijver graph. However, if we are allowed to query one more bit, then given an efficient coloring of the constructed 4-uniform hypergraph, it is possible to list-decode, from the coloring, a small list of possible labelings to the vertices of the outer verifier. The structure of the hyperedges in our 4-uniform hypergraph ensures that the lists are *consistent* with each other i.e. there is a way to assign labels to the vertices of the Label Cover instance from the list, which satisfies many constraints of the Label Cover instance.

[2] A vertex-critical graph is a graph G in which every vertex is a critical element, that is, if its deletion decreases the chromatic number of G.

$\log^{\delta} n$ NP-hardness

As highlighted earlier, the size of the encoding we use is 2^{kc} and if we start with the NP-hardness of the Label Cover given by [17], which has better parameters in the subconstant soundness regime, we can run the whole reduction in polynomial-time if we set $c = \log^{\delta} n$ for small enough $\delta > 0$. Therefore, we get the required inapproximability result proving Theorem 2.

$\Omega\left(\frac{\log n}{\log\log n}\right)$ *quasi*-NP-hardness

The soundness parameter of the Label Cover instance given by [17] has an *inverse exponential* dependence on the alphabet size of the instance (See Theorem 5). To get the improved $\log^{1-o(1)} n$ coloring hardness, we start with the usual Label Cover instance derived from the combination of the PCP Theorem and the parallel repetition theorem. In this case, there is an *inverse polynomial* dependence on the soundness parameter and the alphabet size which enables us to prove a better hardness factor. One drawback of using this Label Cover instance is that the instance size grows polynomially with the number of parallel repetitions. More concretely, an instance of size n becomes an instance of size $n^{O(r)}$ with r repetitions. Thus, it restricts us to assume $\mathsf{NP} \not\subseteq \mathsf{DTIME}\left(n^{O(\log\log n)}\right)$ instead of $\mathsf{P} \neq \mathsf{NP}$, as we need $r = \Omega(\log\log n)$ repetitions.

1.2 $\log^{\delta} n$ NP-hardness via Independent set analysis?

We discuss here informally why the previous approaches could not reach $\mathtt{poly}(\log n)$ factor NP-hardness for approximating hypergraph coloring. Since all the previous approaches (except [5]) get the inapproximability result by showing the hardness of approximating an independent set, we focus on those works here. To get NP-hardness of $\mathtt{poly}(\log n)$-coloring by showing the NP-hardness of approximating an independent set by $1/\mathtt{poly}(\log n)$ factor, usually the soundness of the outer verifier (or the Label Cover instance) that one needs is at most $1/\mathtt{poly}(\log n)$. The outer verifier of [17] has an exponential dependence on the label set size and the inverse of the soundness parameter. Thus, the label set size which is required for such reductions is at least $2^{\mathtt{poly}(\log n)}$. The analysis of [8] uses the Short Code encoding where the degree is $\omega(1)$. Therefore, the blowup in the reduction size is $2^{\mathtt{poly}(\log n)^{\omega(1)}}$, which is super polynomial.

One can use a Short Code encoding where the degree is constant so that the blow-up is limited to $2^{\mathtt{poly}(\log n)^{O(1)}}$. [14] used a Quadratic Code where the degree is 2. One can possibly use the Quadratic Code encoding or Short Code encoding of constant degree and get a hypergraph of polynomial size starting with a Label Cover instance with $1/\mathtt{poly}(\log n)$ soundness. Unfortunately, the analysis of [14] crucially needed an outer verifier with certain properties. It is not yet known how to get a Label Cover instance by a *polynomial-time reduction* starting from a 3SAT instance, with similar properties that were needed in [14] and with $1/\mathtt{poly}(\log n)$ soundness (the latter was done in [17]).

2 Preliminaries

We denote a set $\{1, 2, \ldots, n\}$ by $[n]$. Bold face letters $\mathbf{a}, \mathbf{b}, \mathbf{c} \ldots$ are used to denote strings and subscripts are used to denote the elements at the respective locations in a string. By an abuse of notation, we will use $\mathbf{a} \in \{0,1\}^n$ as a binary string of length n as well as a subset of $[n]$ given by $\{i \in [n] \mid \mathbf{a}_i = 1\}$. We will denote by $2^{[n]}$ the set of all subsets of $[n]$ and by $\binom{[n]}{k}$ the set of all subsets of $[n]$ of size k. We denote the quantity $O(n^k)$, where $k \in \mathbb{R}^+$ by $\mathtt{poly}(n)$.

2.1 Label Cover

Now, we define a Label Cover instance which is the starting point of our reduction.

▶ **Definition 3** (Label Cover)**.** A Label Cover instance $\mathcal{L} = (U, V, E, [R], [L], \phi)$ consists of a bi-regular bipartite graph on *two* sets of variables $U \cup V$. The range of variables in U is denoted by $[R]$ and that in V by $[L]$. Every $(x, y) \in E$, has a constraint $\phi_{x\to y} : [R] \to [L]$. Moreover, every constraint between a pair of variables is a projection constraint i.e. a labeling to x uniquely defines a labeling to y that satisfies the constraint $\phi_{x\to y}$.

For brevity, we say $x \sim y$, or 'x is a neighbor of y' if $\phi_{x\to y} \in \phi$. We say that a Label Cover instance is ϵ-satisfiable, if there exists a labeling to the variables which satisfies at least ϵ fraction of the constraints between U and V.

We have the following NP-hardness result which follows from the PCP Theorem [6, 1, 2] along with Raz's parallel repetition theorem [18].

▶ **Theorem 4.** *For any parameter $l \in \mathbb{N}$, there exists a reduction from a 3-SAT instance of size n to a Label Cover instance with $n^{O(\ell)}$ variables over a range of size $2^{O(\ell)}$. The Label Cover instance has the following completeness and soundness conditions:*

- *If the 3-SAT instance is satisfiable, then there exists an assignment to the Label Cover instance that satisfies all the constraints.*
- *If the 3-SAT instance is not satisfiable, then every assignment to the Label Cover instance satisfies at most $2^{-\Omega(\ell)}$ fraction of the constraints.*

Moreover, the reduction runs in time $n^{O(\ell)}$.

For our NP-hardness result, we need the following reduction from a 3-SAT instance to a Label Cover instance by [17], which gives better parameters for *subconstant soundness*.

▶ **Theorem 5.** *There exist absolute constants $c', c'' > 1$ such that for every n and $\epsilon > 0$ (ϵ can be any function of n), there exists a reduction from a 3-SAT instance of size n to a Label Cover instance with $n^{1+o(1)} \cdot \left(\frac{1}{\epsilon}\right)^{c'}$ variables over a range of size $2^{\left(\frac{1}{\epsilon}\right)^{c''}}$. The Label Cover instance has the following completeness and soundness conditions:*

- *If the 3-SAT instance is satisfiable, then there exists an assignment to the Label Cover instance that satisfies all the constraints.*
- *If the 3-SAT instance is not satisfiable, then every assignment to the Label Cover instance satisfies at most ϵ fraction of the constraints.*

Moreover, the reduction runs in time $\texttt{poly}(n, \frac{1}{\epsilon})$.

2.2 Schrijver Graphs

In this section, we define a Schrijver graph of order n, k, denoted by $SG(n, k)$, where $n \geq 3, k < n$ and $n - k$ is even, which we use as a gadget in our reduction. The vertex set of this Schrijver graph, denoted by $V_{SG}(n, k)$, is a subset of $\{0, 1\}^n$. An element $\mathbf{a} \in \{0, 1\}^n$ belongs to $V_{SG}(n, k)$ iff

1. The hamming weight of $\mathbf{a}$ is $\frac{n-k}{2}$.
2. There exists no $i \in [n]$ such that both $\mathbf{a}_i = 1$ and $\mathbf{a}_{(i+1) \mod (n+1)} = 1$.

In other words, if we denote a cycle graph on $\{1, 2, \ldots, n\}$ by C_n, then the vertex set $V(n, k)$ corresponds to all independent sets in C_n of size $\frac{n-k}{2}$. The edge set of $SG(n, k)$ is as follows:

$$E_{SG}(n, k) = \{(\mathbf{a}, \mathbf{b}) \mid \mathbf{a} \cap \mathbf{b} = \emptyset\}.$$

Vertices $\mathcal{V}$. Each vertex $x \in U$ in the Label Cover instance $\mathcal{L}$ is replaced by a cloud of size $|V_{SG}(R,k)|$ denoted by $C[x] := x \times V_{SG}(R,k)$. We refer to a vertex from the cloud $C[x]$ by a pair $(x, \mathbf{a})$, where $\mathbf{a} \in V_{SG}(R,k)$. The vertex set of the hypergraph $\mathcal{H}$ is given by

$$\mathcal{V} = \cup_{x \in U} C[x].$$

Hyperedges $\mathcal{E}$. The hyperedges of $\mathcal{H}$ are given by sets $\{(x,\mathbf{a}),(x,\mathbf{b}),(y,\mathbf{c}),(y,\mathbf{d})\}$ such that the following conditions hold:

1. There exists a common neighbor z of x and y in V.
2. For every $\alpha, \beta \in [R]$ such that $\phi_{x\to z}(\alpha) = \phi_{y\to z}(\beta)$, $\{\mathbf{a}_\alpha, \mathbf{b}_\alpha, \mathbf{c}_\beta, \mathbf{d}_\beta\}$ are not all the same i.e. $|\{\mathbf{a}_\alpha, \mathbf{b}_\alpha, \mathbf{c}_\beta, \mathbf{d}_\beta\}| = 2$.

Figure 1 Reduction to a 4-uniform hypergraph $\mathcal{H}(\mathcal{V},\mathcal{E})$

In other words, $\mathbf{a} \sim \mathbf{b}$ in $SG(n,k)$ iff their supports are disjoint.

We need two properties of the Schrijver graph $SG(n,k)$, first of which is easy to prove.

▶ **Claim 6** ([5]). $|V_{SG}(n,k)| \leq \binom{n}{k}$.

Proof. Map every vertex $\mathbf{x} \in V_{SG}(n,k)$ to $\tilde{\mathbf{x}} \in \{0,1\}^n$ by setting $\tilde{\mathbf{x}}_i = \tilde{\mathbf{x}}_{i+1 \mod (n+1)} = 1$ iff $\mathbf{x}_i = 1$ and rest of the coordinates to 0. Clearly, this is an injective map from $V_{SG}(n,k)$ to the set $\binom{[n]}{n-k}$. ◀

The second property of $SG(n,k)$ is its chromatic number. The following theorem from [20] gives the exact chromatic number of $SG(n,k)$ which builds on the beautiful proofs by Lovász [16] and Bárány [3].

▶ **Theorem 7** ([20]). *The chromatic number of $SG(n,k)$ is $k+2$.*

3 Main Reduction

We give a reduction from a Label Cover instance $\mathcal{L} = (U, V, E, [R], [L], \phi)$ with a parameter $R > L$ and a parameter k, both of which we will set later, to a 4-uniform hypergraph $\mathcal{H}(\mathcal{V},\mathcal{E})$. We also assume that $R - k$ is even. The reduction is given in Figure 1.

The completeness is easy to prove:

▶ **Lemma 8** (Completeness). *If the Label Cover instance is satisfiable then the hypergraph $\mathcal{H}$ is 2-colorable.*

Proof. Let $A : U \cup V \to [R] \cup [L]$ be the perfectly satisfiable labeling to the Label Cover instance $\mathcal{L}$. The 2-coloring of the hypergraph $\mathcal{H}$ is given by assigning a vertex $(x,\mathbf{a}) \in C[x]$ with a color $\mathbf{a}_{A(x)}$. We show that this is a valid 2-coloring of $\mathcal{H}$. Suppose not, in which case, there exists a monochromatic hyperedge. Let that hyperedge be $\{(x,\mathbf{a}),(x,\mathbf{b}),(y,\mathbf{c}),(y,\mathbf{d})\}$. Let z be the common neighbor responsible for adding this edge. It must be that $\phi_{x\to z}(A(x)) \neq \phi_{y\to z}(A(y))$ and hence A is not a perfectly satisfiable assignment, which is a contradiction. ◀

We now show the soundness of the reduction.

▶ **Lemma 9** (Soundness). *If the Label Cover instance is not $\frac{1}{(k+1)k^2}$ satisfiable then the hypergraph is not even $k+1$-colorable.*

Proof. In this case, we show that if the hypergraph is $(k+1)$-colorable, then there exists a labeling to the Label Cover instance that satisfies at least $\frac{1}{(k+1)k^2}$ fraction of the constraints between the two layers U and V.

Suppose the hypergraph is $(k+1)$-colorable. Fix a $k+1$ coloring χ of the hypergraph. Consider the Schrijver Graph $SG(R,k)$ defined on the cloud $C[x]$ where $x \in U$. By Theorem 7, there exists a monochromatic edge i.e $\chi((x,\mathbf{a})) = \chi((x,\mathbf{b}))$ where $(\mathbf{a},\mathbf{b}) \in E_{SG}(R,k)$. Label a cloud $C[x]$ (and hence the vertex x) $c \in [k+1]$ if that edge is c-colored (breaking ties arbitrarily). Out of $|U|$ vertices, there exists at least $1/(k+1)$ fraction of the vertices with the same color. Let that color be c'.

From now on, we denote the c' colored vertices of U by U'. We know from the bi-regularity of the Label Cover instance that the total number of constraints between U' and V is at least $\frac{1}{k+1}$ fraction of the constraints between layers U and V. Thus, if we show that we can satisfy at least $\frac{1}{k^2}$ fraction of the constraints between U' and V, then we are done. This will satisfy $\frac{1}{(k+1)k^2}$ fraction of the constraints between layers U and V.

List-Labeling

We define the list-labeling A to the vertices in U' as follows: For $x \in U'$, in the induced Schrijver Graph on $C[x]$, there exists a monochromatic edge with color c'. Let that edge be $\{(x,\mathbf{a}),(x,\mathbf{b})\}$. Let $A(x) = [R] \setminus (\mathbf{a} \cup \mathbf{b})$.

▶ **Observation 10.** *For every $x \in U'$, $|A(x)| = k$.*

We need a simple fact as follows:

▶ **Fact 11.** *For every pairwise intersecting family $\mathcal{F} \subseteq \binom{[n]}{k}$, there exists $i \in [n]$ which is present in at least $1/k$ fraction of the sets in $\mathcal{F}$.*

Proof. Suppose not. Consider $A = \{a_1, a_2, \ldots, a_k\} \in \mathcal{F}$ and the sub-families $\mathcal{A}_i = \{A' \in \mathcal{F} \mid a_i \in A'\}$ for $i \in [k]$. By assumption, we have $|\mathcal{A}_i| < |\mathcal{F}|/k$. By the union bound, $|\cup_i \mathcal{A}| \leq \sum_i |\mathcal{A}_i| < |\mathcal{F}|$. Thus, there exists $B \in \mathcal{F} \setminus (\cup_i \mathcal{A}_i)$ and $A \cap B = \emptyset$, a contradiction. ◀

The following two claims finish the proof.

▶ **Claim 12.** *For every $x, y \in U'$ that have a common neighbor z in V,*

$$\phi_{x\to z}(A(x)) \cap \phi_{y\to z}(A(y)) \neq \emptyset.$$

Proof. For contradiction, suppose there exist $x, y \in U'$ and a common neighbor z such that $\phi_{x\to z}(A(x)) \cap \phi_{y\to z}(A(y)) = \emptyset$. Let $\{(x,\mathbf{a}),(x,\mathbf{b})\}$ and $\{(y,\mathbf{c}),(y,\mathbf{d})\}$ be the monochromatic c'-colored edges that were used to define A on x and y respectively. Since, $\phi_{x\to z}(A(x)) \cap \phi_{y\to z}(A(y)) = \emptyset$, we know that $\phi_{x\to z}([R] \setminus (\mathbf{a} \cup \mathbf{b}))$ and $\phi_{y\to z}([R] \setminus (\mathbf{c} \cup \mathbf{d}))$ are disjoint. This means that for every $\alpha, \beta \in [R]$ such that $\phi_{x\to z}(\alpha) = \phi_{y\to z}(\beta)$, we have $\mathbf{a}_\alpha, \mathbf{b}_\alpha, \mathbf{c}_\beta, \mathbf{d}_\beta$, not all of which are 1 (this follows from $\mathbf{a}_\alpha, \mathbf{b}_\alpha$ not both equal to 1 as they form an edge in the Schrijver graph $SG(R,k)$). Also, not all of $\mathbf{a}_\alpha, \mathbf{b}_\alpha, \mathbf{c}_\beta, \mathbf{d}_\beta$ are 0, since otherwise $\alpha \in A(x)$ and $\beta \in A(y)$ and hence $\phi_{x\to y}(A(x)) \cap \phi_{y\to z}(A(y)) \neq \emptyset$. Thus, $\{(x,\mathbf{a}),(x,\mathbf{b}),(y,\mathbf{c}),(y,\mathbf{d})\}$ is a valid hyperedge in $\mathcal{H}$, which is monochromatic with color c'. This contradicts the fact that χ is a valid $k+1$ coloring of $\mathcal{H}$. ◀

Now, consider the following randomized labeling B:

$$\forall z \in V, \qquad B(z) \leftarrow \arg\max_{i \in [L]} |\{x \mid (x \in U') \wedge (z \sim x) \wedge i \in \phi_{x \to z}(A(x))\}|$$

$$\forall x \in U', \qquad B(x) \leftarrow \text{ A uniformly random label from } A(x).$$

In other words, $B(z)$ for $z \in V$ is a label $i \in [L]$ which is the most common projection (w.r.t. $\phi_{x \to z}$) of the labels $A(x)$, where $x \sim z$ and $x \in U'$.

▶ **Claim 13.** *The randomized labeling B satisfies at least $\frac{1}{k^2}$ fraction of the constraints between U' and V in expectation.*

Proof. Fix $z \in V$ and let $X = \{x_1, x_2, \ldots, x_t\}$ be the neighbors of z in U' which satisfy $B(z) \in \phi_{x_i \to z}(A(x_i))$. Thus, X constitutes at least $1/k$ fraction of z's neighbors in U' using Claim 12 and Fact 11. The edge (x_i, z) is satisfied by the labeling $(B(x_i), B(z))$ with probability $1/|A(x_i)| = 1/k$ using Observation 10. Thus, in expectation, the randomized labeling satisfies at least $1/k^2$ fraction of the constraints between z and U'. Finally, by linearity of expectation, B satisfies at least $1/k^2$ fraction of the constraints between U' and V. ◀

Thus, the partial labeling B satisfies at least $\frac{1}{(k+1)k^2}$ fraction of the constraints between U and V in expectation. ◀

3.1 Setting of parameters

Proof of Theorem 1: Starting with a 3-SAT instance of size n, we first reduce it to a Label Cover instance given by Theorem 4 with parameter $\ell = c_0 \log\log n$ for a large constant $c_0 > 1$, so that the soundness of the Label Cover instance is $2^{-\Omega(\ell)} \ll \Omega(\log^{-3} n)$. We will set $k = \log n$. Thus, the number of vertices in the hypergraph $\mathcal{H}$ is $N = n^{O(\ell)} \cdot 2^{O(\ell) \cdot k} = n^{O(\log\log n)}$ and the reduction runs in time $n^{O(\log\log n)}$. Therefore, assuming $\mathsf{NP} \not\subseteq \mathsf{DTIME}(n^{O(\log\log n)})$, there is no polynomial-time algorithm to color a 2-colorable 4-uniform hypergraph on N vertices with $O\left(\frac{\log N}{\log\log N}\right)$ colors. ◀

Proof of Theorem 2: Starting with a 3-SAT instance of size n, we first reduce it to a Label Cover instance given by Theorem 5 with parameter $\epsilon = (\log n)^{-4\delta}$ for a sufficiently small constant $\delta > 0$. Thus, the soundness of the Label Cover instance is $(\log n)^{-4\delta}$, the alphabet size is $|\Sigma| = 2^{(\log n)^{c'\delta}}$ and the size of the Label Cover instance is $n^{1+o(1)} \cdot (\log n)^{c''\delta}$ for some absolute constants $c', c'' > 1$. We will set $k = (\log n)^{\delta}$. Thus, the number of vertices in the hypergraph $\mathcal{H}$ is $N \leq n^{1+o(1)} \cdot (\log n)^{c''\delta} \cdot |\Sigma|^k = n^{1+o(1)} \cdot (\log n)^{c''\delta} \cdot 2^{(\log n)^{4c'\delta+\delta}} = n^{1+o(1)}$, for small enough δ. Also, the overall reduction starting from an instance of 3-SAT of size n runs in time $\mathtt{poly}(n)$. Therefore, it is NP-hard to color a 2-colorable 4-uniform hypergraph on N vertices with $\log^{\delta} N$ colors for some $\delta > 0$. ◀

4 Conclusion

Long Code has been used extensively to prove inapproximability results. Many inapproximability results benefit from *puncturing/derandomization* of the Long Code constructions. Most of them are algebraic in nature *e.g.* Hadamard code, Split code, Short code etc. We made an attempt to find a puncturing of the Long Code which is more combinatorial in nature. We believe that such combinatorial puncturings might find new applications in the

hardness of approximation as well as in other areas which use the Long Code or similar objects.

We conclude with a couple of obvious interesting open problems:

1. Can we show that coloring a 2-colorable 3-uniform hypergraph with $\omega(\log\log n)$ colors is NP-hard, or even *quasi*-NP-hard?
2. Can we go beyond $\texttt{poly}(\log n)$ coloring NP-hardness factor for coloring a c-colorable k-uniform hypergraph for some constants $c \geq 2$ and $k \geq 3$?

Abstract

We study sublinear algorithms for two fundamental graph problems, MAXCUT and correlation clustering. Our focus is on constructing core-sets as well as developing streaming algorithms for these problems. Constant space algorithms are known for *dense* graphs for these problems, while $\Omega(n)$ lower bounds exist (in the streaming setting) for sparse graphs.

Our goal in this paper is to bridge the gap between these extremes. Our first result is to construct core-sets of size $\widetilde{O}(n^{1-\delta})$ for both the problems, on graphs with average degree n^{δ} (for any $\delta > 0$). This turns out to be optimal, under the exponential time hypothesis (ETH). Our core-set analysis is based on studying random-induced sub-problems of optimization problems. To the best of our knowledge, all the known results in our parameter range rely crucially on near-regularity assumptions. We avoid these by using a biased sampling approach, which we analyze using recent results on concentration of quadratic functions. We then show that our construction yields a 2-pass streaming $(1+\varepsilon)$-approximation for both problems; the algorithm uses $\widetilde{O}(n^{1-\delta})$ space, for graphs of average degree n^{δ}.

1 Introduction

Sublinear algorithms are a powerful tool for dealing with large data problems. The range of questions that can be answered accurately using sublinear (or even polylogarithmic) space or time is enormous, and the underlying techniques of sketching, streaming, sampling and core-sets have been proven to be a rich toolkit.

When dealing with large graphs, the sublinear paradigm has yielded many powerful results. For many NP-hard problems on graphs, classic results from property testing [20, 7] imply extremely efficient sublinear approximations. In the case of dense graphs, these results (and indeed older ones of [10, 16]) provide constant time/space algorithms. More recently, graph sketching techniques have been used to obtain efficient approximation algorithms for cut problems on graphs [2, 3] in a streaming setting. These algorithms use space that is nearly linear in n (the number of vertices) and are sublinear in the number of edges as long as $|E| = \omega(n)$ (this is called the "semi-streaming" setting).

By way of lower bounds, recent results have improved our understanding of the limits of sketching and streaming. In a sequence of results [22, 23, 25], it was shown that for problems like matching and MaxCut in a streaming setting, $\Omega(n)$ space is necessary in order to obtain any approximation better than a factor 2 in one round. (Note that a factor 2 is trivial by simply counting edges.) Furthermore, Andoni et al. [9] showed that any sketch for all the cuts in a graph must have size $\Omega(n)$.

While these lower bounds show that $O(n)$ space is the best possible for approximating problems like MaxCut in general, the constructions used in these bounds are quite specialized. In particular, the graphs involved are sparse, i.e., have $\Theta(n)$ edges. Meanwhile, as we mentioned above, if a graph is *dense* ($\Omega(n^2)$ edges), random sampling is known to give $O(1)$ space and time algorithms. The question we study in this paper is if there is a middle ground: can we get truly sublinear (i.e., $o(n)$) algorithms for natural graph problems in between (easy) dense graphs and (hard) sparse graphs?

Our main contribution is to answer this in the affirmative. As long as a graph has average degree n^δ for some $\delta > 0$, truly sub-linear space $(1+\epsilon)$ approximation algorithms are possible for problems such as MaxCut and correlation clustering.[1] Indeed, we show that a biased sample of vertices forms a "core-set" for these problems. A core-set for an optimization problem (see [1]), is a subset of the input with the property that a solution to the subset provides an approximation to the solution on the entire input.

Our arguments rely on understanding the following fundamental question: given a graph G, is the induced subgraph on a random subset of vertices a core-set for problems such as MaxCut? This question of sub-sampling and its effect on the value of an optimization problem is well studied. Results from property testing imply that a uniformly random sample of constant size suffices for many problems on *dense* graphs. [16, 6] generalized these results to the case of arbitrary k-CSPs. More recently, [12], extending a result in [14], studied the setting closest to ours. For graphs, their results imply that when the maximum and minimum degrees are both $\Theta(n^\delta)$, then a random induced subgraph with $\widetilde{O}(n^{1-\delta})$ acts as a core-set for problems such as MaxCut. Moreover, they showed that for certain lifted relaxations, subsampling does *not* preserve the value of the objective. Finally, using more modern techniques, [31] showed that the *cut norm* of a matrix (a quantity related to the MaxCut) is preserved up to a constant under random sampling, improving on [16, 6]. While powerful, we will see that these results are not general enough for our setting. Thus we propose a new, conceptually simple technique to analyze sub-sampling, and present it in the context of MaxCut and correlation clustering.

1.1 Our Results

As outlined above, our main result is to show that there exist core-sets of size $\widetilde{O}(n^{1-\delta})$ for MaxCut and correlation clustering for graphs with $\Omega(n^{1+\delta})$ edges (where $0 < \delta \leq 1$). This

[1] We consider the max-agreement version of correlation clustering (see Section 2).

then leads to a two-pass streaming algorithm for MaxCut and correlation clustering on such graphs, that uses $\widetilde{O}(n^{1-\delta})$ space and produces a $1+\varepsilon$ approximation.

This dependence of the core-set size on δ is optimal up to logarithmic factors, by a result of [15]. Specifically, [15] showed that any $(1+\varepsilon)$ approximation algorithm for MaxCut on graphs of average degree n^{δ} must have running time $2^{\Omega(n^{1-\delta})}$, assuming the exponential time hypothesis (ETH). Since a core-set of size $o(n^{1-\delta})$ would trivially allow such an algorithm (we can perform exhaustive search over the core-set), our construction is optimal up to a logarithmic factor, assuming ETH.

Our streaming algorithm for correlation clustering can be viewed as improving the semi-streaming (space $\tilde{O}(n)$) result of Ahn et al. [4], while using an additional pass over the data. Also, in the context of the lower bound of Andoni et al. [9], our result for MaxCut can be interpreted as saying that while a sketch that approximately maintains *all* cuts in a graph requires an $\Omega(n)$ size, one that preserves the MaxCut can be significantly smaller, when the graph has a polynomial average degree.

At a technical level, we analyze the effect of sampling on the value of the MaxCut and correlation clustering objectives. As outlined above, several techniques are known for such an analysis, but we give a new and conceptually simple framework that (a) allows one to analyze *non-uniform* sampling for the first time, and (b) gets over the assumptions of near-regularity (crucial for [14, 12]) and density (as in [16, 6]). We expect the ideas from our analysis to be applicable to other settings as well, especially ones for which the 'linearization' framework of [10] is applicable.

The formal statement of results, an outline of our techniques and a comparison with earlier works are presented in Section 3.

1.2 Related Work

MaxCut and correlation clustering are both extremely well-studied problems, and thus we will only mention the results most relevant to our work.

Dense graphs. A graph is said to be dense if its average degree is $\Omega(n)$. Starting with the work of Arora et al. [10], many NP hard optimization problems have been shown to admit a PTAS when the instances are dense. Indeed, a small random induced subgraph is known to be a core-set for problems such as MaxCut, and indeed all k-CSPs [20, 6, 16, 29]. The work of [10] relies on an elegant *linearization* procedure, while [16, 6] give a different (and more unified) approach based on "cut approximations" of a natural tensor associated with a CSP.

Polynomial density. The focus of our work is on graphs that are *in between* sparse (constant average degree) and dense graphs. These are graphs whose density (i.e., average degree) is n^{δ}, for some $0 < \delta < 1$. Fotakis et al. [15] extended the approach of [10] to this setting, and obtained $(1+\varepsilon)$ approximation algorithms with run-time $\exp(\widetilde{O}(n^{1-\delta}))$. They also showed that it was the best possible, under the exponential time hypothesis (ETH). By way of core-sets, in their celebrated work on the optimality of the Goemans-Williamson rounding, Feige and Schechtman [14] showed that a random sample of $\widetilde{O}(n^{1-\delta})$ is a core-set for MaxCut, if the graphs are *almost regular* and have an average degree n^{δ}. This was extended to other CSPs by [12]. These arguments seem to use near-regularity in a crucial way, and are based on restricting the number of possible 'candidates' for the maximum cut.

Streaming algorithms and lower bounds. In the streaming setting, there are several algorithms [2, 27, 18, 3, 19, 26] that produce cut or spectral sparsifiers with $O(\frac{n}{\epsilon^2})$ edges using $\tilde{O}(\frac{n}{\epsilon^2})$ space. Such algorithms preserve every cut within $(1+\epsilon)$-factor (and therefore

also preserve the max cut). Andoni et al. [9] showed that such a space complexity is essential; in fact, [9] show that any sketch for all the cuts in a graph must have bit complexity $\Omega(\frac{n}{\epsilon^2})$ (not necessarily streaming ones). However, this does not rule out the possibility of being able to find a *maximum* cut in much smaller space.

For MaxCut, Kapralov et al. [24] and independently Kogan et al. [28] proved that any streaming algorithm that can approximate the MaxCut value to a factor better than 2 requires $\tilde{\Omega}(\sqrt{n})$ space, even if the edges are presented in random order. For adversarial orders, they showed that for any $\epsilon > 0$, a one-pass $(1+\epsilon)$-approximation to the max cut value must use $n^{1-O(\epsilon)}$ space. Very recently, Kapralov et al. [25] went further, showing that there exists an $\epsilon^* > 0$ such that every randomized single-pass streaming algorithm that yields a $(1+\epsilon^*)$-approximation to the MAXCUT size must use $\Omega(n)$ space.

Correlation clustering. Correlation clustering was formulated by Bansal et al. [11] and has been studied extensively. There are two common variants of the problem – maximizing agreement and minimizing disagreement. While these are equivalent for exact optimization (their sum is a constant), they look very different under an approximation lens. Maximizing agreement typically admits constant factor approximations, but minimizing disagreement is much harder. In this paper, we focus on the maximum-agreement variant of correlation clustering and in particular we focus on $(1+\epsilon)$-approximations. Here, Ailon and Karnin [5] presented an approximation scheme with sublinear query complexity (which also yields a semi-streaming algorithm) for dense instances of correlation clustering. Giotis and Guruswami [17] described a sampling based algorithm combined with a greedy strategy which guarantees a solution within (ϵn^2) additive error. (Their work is similar to the technique of Mathieu and Schudy [29].) Most recently, Ahn et al. [4] gave a single-pass semi-streaming algorithm for max-agreement. For bounded weights, they provide an $(1+\epsilon)$-approximation streaming algorithm and for graphs with arbitrary weights, they present a $0.766(1-\epsilon)$-approximation algorithm. Both algorithms require $(n\epsilon^{-2})$ space. The key idea in their approach was to adapt multiplicative-weight-update methods for solving the natural SDPs for correlation clustering in a streaming setting using linear sketching techniques.

2 Definitions

▶ **Definition 1** (MaxCut). Let $G = (V, E, w)$ be a graph with weights $w\colon E \to \mathbb{R}^+$. Let (A, B) be a partition of V and let $w(A, B)$ denote the sum of weights of edges between A and B. Then $\text{MaxCut}(G) = \max_{(A,B) \text{ partition of } V} w(A, B)$.

For ease of exposition, we will assume that the input graph for MaxCut is unweighted. Our techniques apply as long as all the weights are $O(1)$. Also, we denote by Δ the average degree, i.e., $\sum_{i,j} w_{ij}/|V|$.

Moving now to correlation clustering, let $G = (V, E, c^+, c^-)$ be a graph with edge weights c^+_{ij} and c^-_{ij} where for every edge ij we have $c^+_{ij}, c^-_{ij} \geq 0$ and only one of them is nonzero. For every edge $ij \in E$, we define $\eta_{ij} = c^+_{ij} - c^-_{ij}$ and for each vertex, $d_i = \sum_{i \in \Gamma(j)} |\eta_{ij}|$. We will also assume that all the weights are bounded by an absolute constant in magnitude (for simplicity, we assume it is 1). We define the "average degree" Δ (used in the statements that follow) of a correlation clustering instance to be $(\sum_i d_i)/n$.

▶ **Definition 2** (MAX-AGREE correlation clustering). Given $G = (V, E, c^+, c^-)$ as above, consider a partition of V into *clusters* $C_1, C_2, \ldots, C_k$, and let χ_{ij} be an indicator that is 1 if i an j are in the same cluster and 0 otherwise. The MAX-AGREE score of this clustering is given by $\sum_{ij} c^+_{ij}\chi_{ij} + \sum_{ij} c^-_{ij}(1-\chi_{ij})$. The goal is to find a partition *maximizing* this score. The maximum value of the score over all partitions of V will be denoted by $CC(G)$.

Note that the objective value can be simplified to $\sum_{ij} c_{ij}^- + \eta_{ij}\chi_{ij} = C^- + \sum_{ij} \eta_{ij}\chi_{ij}$, where C^- denotes the sum $\sum_{ij} c_{ij}^-$.

We will also frequently use concentration bounds; these are stated in full version of the paper.

3 Technical overview

We now present an outline of our main ideas. Suppose we have a graph $G = (V, E)$. First, we define a procedure VERTEX SAMPLE. This takes as input probabilities p_i for every vertex, and produces a random weighted induced subgraph.

Procedure vertex sample ($\{p_i\}_{i\in V}$). Sample a set S' of vertices by selecting each vertex v_i with probability p_i independently. Define H to be the induced subgraph of G on the vertex set S'. For $i, j \in S'$, define $w_{ij} = \frac{1}{p_i p_j \Delta^2}$.[2]

Intuitively, the edge weights are chosen so that the total number of edges remains the same, in expectation. Next, we define the notion of an importance score for vertices. Let d_i denote the degree of vertex i.

▶ **Definition 3.** The *importance score* h_i of a vertex i is defined as $h_i = \min\{1, \frac{\max\{d_i, \epsilon\Delta\}}{\Delta^2 \alpha_\epsilon}\}$, where α_ϵ is an appropriately chosen parameter (for MAXCUT, we set it to $\frac{\epsilon^4}{C \log n}$, and for correlation clustering, we set it to $\frac{\epsilon^8}{C \log n}$, where C is an absolute constant).

The main result is now the following:

▶ **Theorem 4** (Core-set). *Let $G = (V, E)$ have an average degree Δ. Suppose we apply* VERTEX SAMPLE *with probabilities $p_i \in [h_i, 2h_i]$ to obtain a weighted graph H. Then H has $\widetilde{O}(\frac{n}{\Delta})$ vertices and the quantities* MAXCUT(H) *and $CC(H)$ are within a $(1+\epsilon)$ factor of the corresponding quantities* MAXCUT(G) *and $CC(G)$, w.p. at least $1 - \frac{1}{n^2}$.*

While the number of vertices output by the vertex sample procedure is small, we would like a core-set of small "total size". This is ensured by the following.

Procedure edge sample (H). Given a weighted graph H with total edge weight W, sample each edge $e \in E(H)$ independently with probability $p_e := \min(1, \frac{8|S'|w_e}{\varepsilon^2 W})$, to obtain a graph H'. Now, assign a weight w_e/p_e to the edge e in H'.

The procedure samples roughly $|S'|/\varepsilon^2$ edges, with probability proportional to the edge weights. The graph is then re-weighted in order to preserve the total edge weight in expectation, yielding:

▶ **Theorem 5** (Sparse core-set). *Let G be a graph with n vertices and average degree $\Delta = n^\delta$. Let H' be the graph obtained by first applying* VERTEX SAMPLE *and then applying* EDGE SAMPLE. *Then H' is a ϵ-core-set for* MAXCUT *and CC, having size $\widetilde{O}(\frac{n}{\Delta}) = \widetilde{O}(n^{1-\delta})$.*

We then show how to implement the above procedures in a streaming setting. This gives:

▶ **Theorem 6** (Streaming algorithm). *Let G be a graph on n vertices and average degree $\Delta = n^\delta$, whose edges arrive in a streaming fashion in adversarial order. There is a two-pass streaming algorithm with space complexity $\widetilde{O}(\frac{n}{\Delta}) = \widetilde{O}(n^{1-\delta})$ for computing a $(1+\epsilon)$-approximation to* MAXCUT(G) *and $CC(G)$.*

[2] In correlation clustering, we have edge weights to start with, so the weight in H will be $w_{ij} \cdot c_{ij}^+$ (or c_{ij}^-).

Of these, Theorem 4 is technically the most challenging. Theorem 5 follows via standard edge sampling methods akin to those in [2] (which show that w.h.p., every cut size is preserved). It is presented in full version of the paper, for completeness. The streaming algorithm, and a proof of Theorem 6, are presented in Section 6. In the following section, we give an outline of the proof of Theorem 4.

3.1 Proof of the sampling result (theorem 4): an outline

In this outline we will restrict ourselves to the case of MaxCut as it illustrates our main ideas. Let G be a graph as in the statement of the theorem, and let H be the output of the procedure VERTEX SAMPLE.

Showing that $\textsc{MaxCut}(H)$ is at least $\textsc{MaxCut}(G)$ up to an $\varepsilon n\Delta$ additive term is easy. We simply look at the projection of the maximum cut in G to H (see, for instance, [14]). Thus, the challenge is to show that a sub-sample cannot have a significantly larger cut, w.h.p. The natural approach of showing that every cut in G is preserved does not work as 2^n cuts is too many for the purposes of a union bound.

There are two known ways to overcome this. The first approach is the one used in [20, 14] and [12]. These works essentially show that in a graph of average degree Δ, we need to consider only roughly $2^{n/\Delta}$ cuts for the union bound. If all the degrees are roughly Δ, then one can show that all these cuts are indeed preserved, w.h.p. There are two limitations of this argument. First, for non-regular graphs, the variance (roughly $\sum_i pd_i^2$, where p is the sampling probability) can be large, and we cannot take a union bound over $\exp(n/\Delta)$ cuts. Second, the argument is combinatorial, and it seems difficult to generalize this to analyze non-uniform sampling.

The second approach is via *cut decompositions*, developed in [16, 6]. Here, the adjacency matrix A is decomposed into $\text{poly}(1/\varepsilon)$ rank-1 matrices, plus a matrix that has a small *cut norm*. It turns out that solving many quadratic optimization problems (including MaxCut) on A is equivalent (up to an additive $\varepsilon n\Delta$) to solving them over the sum of rank-1 terms (call this A'). Now, the adjacency matrix of H is an induced square sub-matrix of A, and since we care only about A' (which has a simple structure), [6] could show that $\textsc{MaxCut}(H) \leq \textsc{MaxCut}(G) + \varepsilon n^2$, w.h.p. To the best of our knowledge, such a result is not known in the "polynomial density" regime (though the cut decomposition still exists).

Our technique. We consider a new approach. While inspired by ideas from the works above, it also allows us to reason about non-uniform sampling in the polynomial density regime. Our starting point is the result of Arora et al. [10], which gives a method to estimate the MaxCut using a collection of linear programs (which are, in turn, derived using a sample of size n/Δ). Now, by a double sampling trick (which is also used in the approaches above), it turns out that showing a sharp concentration bound for the value of an *induced sub-program* of an LP as above, implies Theorem 4. As it goes via a linear programming and not a combinatorial argument, analyzing non-uniform sampling turns out to be quite direct. Let us now elaborate on this high level plan.

Induced sub-programs. First, we point out that an analysis of induced sub-programs is also an essential idea in the work of [6]. The main difference is that in their setting, only the variables are sub-sampled (and the number of constraints remains the same). In our LPs, the constraints correspond to the vertices, and thus there are fewer constraints in the sampled LP. This makes it harder to control the value of the objective. At a technical level,

while a duality-based argument using Chernoff bounds for linear forms suffices in the setting of [6], we need the more recent machinery on concentration of quadratic functions.

We start by discussing the estimation technique of [10].

Estimation with Linear Programs. The rough idea is to start with the natural quadratic program for MaxCut: $\max \sum_{(i,j)\in E} x_i(1-x_j)$, subject to $x_i \in \{0,1\}$.[3] This is then "linearized" using a seed set of vertices sampled from G. We refer to Section 4 for details. For now, $\textsc{Est}(G)$ is a procedure that takes a graph G and a set of probabilities $\{\gamma_i\}_{i\in V(G)}$, samples a seed set using γ, and produces an estimate of MaxCut (G).

Now, suppose we have a graph G and a sample H. We can imagine running $\textsc{Est}(G)$ and $\textsc{Est}(H)$ to obtain good estimates of the respective MaxCut values. But now suppose that in both cases, we could use precisely the same seed set. Then, it turns out that the LPs used in $\textsc{Est}(H)$ would be 'induced' sub-programs (in a sense we will detail in Section 5) of those used in $\textsc{Est}(G)$, and thus proving Theorem 4 reduces to showing a sufficiently strong concentration inequality for sub-programs.

The key step above was the ability to use same seed set in the Est procedures. This can be formalized as follows.

Double sampling. Consider the following two strategies for sampling a *pair* of subsets (S, S') of a universe $[n]$ (here, $q_v \le p_v$ for all v):

- Strategy A: choose $S' \subseteq [n]$, by including every v w.p. p_v, independently; then for $v \in S'$, include them in S w.p. q_v/p_v, independently.
- Strategy B: pick $S \subseteq [n]$, by including every v w.p. q_v; then iterate over $[n]$ once again, placing $v \in S'$ with a probability equal to 1 if $v \in S$, and p_v^* if $v \notin S$.

▶ **Lemma 7.** *Suppose* $p_v^* = p_v(1 - \frac{q_v}{p_v})/(1-p_v)$. *Then the distribution on pairs* (S, S') *obtained by strategies A and B are identical.*

The proof is by a direct calculation and the details can be found in full version.

Proof of Theorem 4. To show the theorem, we use p_v as in the statement of the theorem, and set q to be the uniform distribution $q_v = \frac{16 \log n}{\varepsilon^2 \Delta}$. The proof now proceeds as follows. Let S' be a set sampled using the probabilities p_v. These form the vertex set of H. Now, the procedure Est on H (with sampling probabilities q_v/p_v) samples the set S (as in strategy A). By the guarantee of the estimation procedure (Corollary 5.1.2 in full version), we have $\textsc{MaxCut}(H) \approx \textsc{Est}(H)$, w.h.p. Next, consider the procedure Est on G with sampling probabilities q_v. Again, by the guarantee of the estimation procedure (Corollary 5.1.1), we have $\textsc{MaxCut}(G) \approx \textsc{Est}(G)$, w.h.p.

Now, we wish to show that $\textsc{Est}(G) \approx \textsc{Est}(H)$. By the equivalence of the sampling strategies, we can now take the strategy B view above. This allows us to assume that the Est procedures use the same S, and that we pick S' *after* picking S. This reduces our goal to one of analyzing the value of a random induced sub-program of an LP, as mentioned earlier. The details of this step are technically the most involved, and are presented in Section 5. This completes the proof of the theorem. (Note that the statement also includes a bound on the number of vertices of H. This follows immediately from the choice of p_v.) ◀

[3] This is a valid formulation, because for every $x_i \neq x_j$ that is an edge contributes 1 to the objective, and $x_i = x_j$ contribute 0.

4 Estimation via linear programming

We now present the estimation procedure Est used in our proof. It is an extension of [10] to the case of weighted graphs and non-uniform sampling probabilities.

Let $H = (V, E, w)$ be a weighted, undirected graph with edge weights w_{ij}, and let $\gamma : V \to [0, 1]$ denote sampling probabilities. The starting point is the quadratic program for MaxCut: max $\sum_{ij \in E} w_{ij} x_i (1 - x_j)$, subject to $x_i \in \{0, 1\}$. The objective can be re-written as $\sum_{i \in V} x_i (d_i - \sum_{j \in \Gamma(i)} w_{ij} x_j)$, where d_i is the weighted degree, $\sum_{j \in \Gamma(i)} w_{ij}$. The key idea now is to "guess" the value of $\rho_i := \sum_{j \in \Gamma(i)} w_{ij} x_j$, by using a seed set of vertices. Given a guess, the idea is to solve the following linear program, which we denote by $LP_\rho(V)$.

$$\begin{aligned} \text{maximize} \quad & \sum_i x_i (d_i - \rho_i) - s_i - t_i \\ \text{subject to} \quad & \rho_i - t_i \le \sum_{j \in \Gamma(i)} w_{ij} x_j \le \rho_i + s_i \\ 0 \le x_i \le 1, \qquad & s_i, t_i \ge 0. \end{aligned}$$

The variables are x_i, s_i, t_i. Note that if we fix the x_i, the optimal s_i, t_i will satisfy $s_i + t_i = |\rho_i - \sum_{j \in \Gamma(i)} w_{ij} x_j|$. Also, note that if we have a perfect guess for ρ_i's (coming from the MaxCut), the objective can be made $\ge$ MaxCut(H).

Estimation procedure. The procedure Est is the following: first sample a set $S \subseteq V$ where each $i \in V$ is included w.p. γ_i independently. For every partition $(A, S \setminus A)$ of S, set $\rho_i = \sum_{j \in \Gamma(i) \cap A} \frac{w_{ij}}{\gamma_j}$, and solve $LP_\rho(V)$ (in what follows, we denote this LP by $LP^\gamma_{A, S \setminus A}(V)$, as this makes the partition and the sampling probabilities clear). Return the maximum of the objective values.

Our result here is a sufficient condition for having Est$(H) \approx$ MaxCut(H).

▶ **Theorem 8.** *Let H be a weighted graph on n vertices, with edge weights w_{ij} that add up to W. Suppose the sampling probabilities γ_i satisfy the condition*

$$w_{ij} \le \frac{W \varepsilon^2}{8 \log n} \frac{\gamma_i \gamma_j}{\sum_u \gamma_u} \quad \text{for all } i, j. \tag{1}$$

Then, we have Est$(H, \gamma) \in$ MaxCut$(H) \pm \varepsilon W$*, with probability at least $1 - 1/n^2$ (where the probability is over the random choice of S).*

The proof consists of claims showing the upper and lower bound separately. The technical details are presented in full version. Finally, to show Theorem 4 (as outlined in Section 3.1), we need to apply Theorem 8 with specific values for γ and w_{ij}. The related corollaries are stated in full version of the paper.

5 Random induced linear programs

We will now show that the Est on H has approximately the same value as the estimate on G (with appropriate γ values). First, note that Est(G) is $\max_{A \subseteq S} LP^\gamma_{A, S \setminus A}(G)$, where $\gamma_i = q_i$. To write the LP, we need the constants ρ_i, defined by the partition $(A, S \setminus A)$ as $\rho_i := \sum_{j \in \Gamma(i) \cap A} \frac{1}{q_j}$. For the graph H, the estimation procedure uses an identical program, but the sampling probabilities are now $\alpha_i := q_i / p_i$, and the estimates ρ, which we now denote by $\widetilde{\rho}_i$, are defined by $\widetilde{\rho}_i := \sum_{j \in \Gamma(i) \cap A} \frac{p_j w_{ij}}{q_j}$. Also, by the way we defined w_{ij}, $\widetilde{\rho}_i = \frac{\rho_i}{p_i \Delta^2}$.

$$\begin{aligned}
\max \quad & \sum_{i\in G}[x_i(d_i-\rho_i)-(s_i+t_i)] \\
\text{s.t.} \quad & \sum_{j\in\Gamma(i)} x_j \le \rho_i + s_i, \quad \forall i\in[n] \\
& -\sum_{j\in\Gamma(i)} x_j \le -\rho_i + t_i, \quad \forall i\in[n] \\
& 0\le x_i\le 1 \quad \forall i\in[n]
\end{aligned}$$

(a) The LP on the full graph

$$\begin{aligned}
\max \quad & \sum_{i\in S'}[x_i(\widetilde{d}_i-\widetilde{\rho}_i)-(\tilde{s}_i+\tilde{t}_i)] \\
\text{s.t.} \quad & \sum_{j\in\Gamma(i)\cap S'} w_{ij}x_j \le \widetilde{\rho}_i + \tilde{s}_i, \quad \forall i\in S' \\
& -\sum_{j\in\Gamma(i)\cap S'} w_{ij}x_j \le -\widetilde{\rho}_i + \tilde{t}_i, \quad \forall i\in S' \\
& 0\le x_i\le 1, \quad \tilde{s}_i,\tilde{t}_i\ge 0 \quad \forall i\in S'
\end{aligned}$$

(b) The sampled LP

Figure 1 The two LPs.

$$\begin{aligned}
\text{minimize} \quad & \sum_{i\in G} u_i+\rho_i z_i \quad \text{s.t.} \\
& u_i + \sum_{j\in\Gamma(i)} z_j \ge d_i-\rho_i \quad \forall i\in V \\
& u_i\ge 0, \quad -1\le z_i\le 1 \quad \forall i\in V
\end{aligned}$$

(a) The dual of $LP^{\gamma}_{A,S\setminus A}(G)$

$$\begin{aligned}
\text{minimize} \quad & \sum_{i\in S'}[\tilde{u}_i+\widetilde{\rho}_i\tilde{z}_i] \quad \text{s.t.} \\
& \tilde{u}_i + \sum_{j\in\Gamma(i)\cap S'} w_{ij}\tilde{z}_j \ge \widetilde{d}_i-\widetilde{\rho}_i \quad \forall i\in S' \\
& \tilde{u}_i\ge 0, \quad -1\le \tilde{z}_i\le 1 \quad \forall i\in S'.
\end{aligned}$$

(b) The dual of the induced program $LP^{\alpha}_{A,S\setminus A}(H)$.

Figure 2 The dual LPs.

The degrees are now $\widetilde{d}_i := \sum_{j\in\Gamma(i)\cap S'} w_{ij} = \sum_{j\in\Gamma(i)\cap S'} \frac{1}{p_i p_j \Delta^2}$. The two LPs are shown in Figure 1. Our aim in this section is to show the following:

▶ **Theorem 9.** *Let G be an input graph, and let (S,S') be sampled as described in Section 3.1. Then, with probability $\ge 1-\frac{1}{n^2}$, we have*

$$\max_{A\subseteq S} LP^{\gamma}_{A,S\setminus A}(G) \ge \Delta^2 \cdot \max_{A\subseteq S} LP^{\alpha}_{A,S\setminus A}(H) - \varepsilon n\Delta.$$

Proof outline. To prove the theorem, the idea is to take the "strategy B" viewpoint of sampling (S,S'), i.e., fix S, and sample S' using the probabilities p^*. Then, we only need to understand the behavior of an "induced sub-program" sampled with the probabilities p^*. This is done by considering the duals of the LPs, and constructing a feasible solution to the induced dual whose cost is not much larger than the dual of the full program, w.h.p. This implies the result, by linear programming duality.

Let us thus start by understanding the dual of $LP^{\gamma}_{A,S\setminus A}(G)$ given A, shown in Figure 2a. We note that for any given z, the optimal choice of u_i is $\max\{0, d_i-\rho_i-\sum_{j\in\Gamma(i)} z_j\}$; thus we can think of the dual solution as being the vector z. The optimal u_i may thus be bounded by $2d_i$, a fact that we will use later. Next, we write down the dual of the induced program, $LP^{\alpha}_{A,S\setminus A}(H)$, as shown in Figure 2b. Following the outline above, we will construct a feasible solution to LP (2b), whose cost is close to the optimal dual solution to LP (2a). The construction we consider is very simple: if z is the optimal dual solution to (2a), we set $\tilde{z}_i = z_i$ for $i\in S'$ as the candidate solution to (2b). This is clearly feasible, and thus we only

need to compare the solution costs. The dual objective values are as follows

$$\mathsf{Dual}_G = \sum_{i \in V} \rho_i z_i + \max\{0,\ d_i - \rho_i - \sum_{j \in \Gamma(i)} z_j\} \tag{2}$$

$$\mathsf{Dual}_H \leq \sum_{i \in S'} \widetilde{\rho}_i z_i + \max\{0,\ \widetilde{d}_i - \widetilde{\rho}_i - \sum_{j \in \Gamma(i) \cap S'} w_{ij} z_j\} \tag{3}$$

Note that there is a $\leq$ in (3), as $\tilde{z}_i = z_i$ is simply one feasible solution to the dual (which is a minimization program). Next, our goal is to prove that w.p. at least $1 - \frac{1}{n^2}$,

$$\max_{A \subseteq S} \mathsf{Dual}_H \leq \frac{1}{\Delta^2} \cdot \max_{A \subseteq S} \mathsf{Dual}_G + \frac{\varepsilon n}{\Delta}.$$

Note that here, the probability is over the choice of S' *given* S (as we are taking view-B of the sampling). The first step in proving the above is to move to a slight variant of the quantity Dual_H, which is motivated by the fact that $\mathbf{Pr}[Y_i = 1]$ is not quite p_i, but p_i^* (as we have conditioned on S). Let us define $\widetilde{\rho}_i^* := \frac{\rho_i}{p_i^* \Delta^2}$ (recall that $\widetilde{\rho}_i$ is $\frac{\rho_i}{p_i \Delta^2}$), and $w_{ij}^* := \frac{1}{p_i^* p_j^* \Delta^2}$. So also, let $d_i^* := \sum_{j \in \Gamma(i)} Y_j w_{ij}^*$. Then, define

$$\mathsf{Dual}_H^* := \sum_{i \in S'} \widetilde{\rho}_i^* z_i + \max\{0,\ \widetilde{d}_i^* - \widetilde{\rho}_i^* - \sum_{j \in \Gamma(i) \cap S'} w_{ij}^* z_j\}. \tag{4}$$

A straightforward lemma is as follows. The proof is presented in full version of the paper.

▶ **Lemma 10.** *Let (S, S') be sampled as in Section 3.1. Then w.p. at least $1 - \frac{1}{n^4}$, we have that for all $z \in [-1, 1]^n$ and for all partitions $(A, S \setminus A)$ of S,*[4] *$|\mathsf{Dual}_H - \mathsf{Dual}_H^*| \leq \frac{\varepsilon n}{2\Delta}$.*

Thus our goal is to show the following (where condition (b) on S is a technical one needed to bound ρ_i).

▶ **Lemma 11.** *Let S satisfy the conditions (a) $|S| \leq \frac{20 n \log n}{\varepsilon^2 \Delta}$, and (b) for all $i \in V$, $\sum_{j \in \Gamma(i) \cap S} \frac{1}{q_j} \leq 2(d_i + \varepsilon\Delta)$. Then, w.p. $\geq 1 - \frac{1}{n^4}$ over the choice of S' given S, we have*

$$\max_{A \subseteq S} \mathsf{Dual}_H^* \leq \frac{1}{\Delta^2} \cdot \max_{A \subseteq S} \mathsf{Dual}_G + \frac{\varepsilon n}{2\Delta}.$$

Proof of Theorem 9. The conditions we assumed on S in Lemma 11 hold w.p. at least $1 - \frac{1}{n^4}$ (via a simple application of Bernstein's inequality). Thus the conclusion of the lemma holds w.p. at least $1 - \frac{2}{n^4}$. Combining this with Lemma 10, we have that $\max_A \mathsf{Dual}_H \leq \frac{1}{\Delta^2} \max_A \mathsf{Dual}_G + \frac{\varepsilon n}{\Delta}$ w.p. at least $1 - \frac{3}{n^4}$. The theorem then follows via LP duality. ◀

It thus suffices to prove Lemma 11 via a concentration bound on a quadratic function that is not quite a quadratic *form*. Details can be found in full version of the paper.

6 A 2-pass streaming algorithm

We now show how our main core set result can be used to design a streaming algorithm for MaxCut. The algorithm works in two passes: the first pass builds a core-set S of size $\widetilde{O}(n/\Delta)$ as prescribed by Theorem 4 and the second pass builds the induced weighted graph $G[S]$ and computes its max cut. This algorithm works under edge insertion/deletion.

[4] Note that the partition defines the ρ_i.

6.1 Pass 1: Building a core set

To construct S, Theorem 4 states that each vertex must be sampled with probability p_i, where $p_i \geq h_i$ and $h_i = \min(1, \frac{\max(d_i, \epsilon\Delta)}{\Delta^2 \alpha_\epsilon})$ is the importance score of a vertex. As the goal is to only choose a small number of vertices, we will also make sure that $p_i \leq 2h_i$. The challenge here is two-fold: we need to sample (roughly) proportional to the degree d_i, which can only be computed *after* the stream has passed, and we also need the actual value of p_i (or a close enough estimate of it) in order to correctly reweight edges in the second pass.

The degree d_i of a vertex i is the "count" of the number of times i appears in the edge stream. To sample with probability proportional to d_i we will therefore make use of streaming algorithms for ℓ_1-sampling [30, 8, 21]. We borrow some notation from [8].

▶ **Definition 12.** Let $\rho > 0, f \in [1, 2]$. A (ρ, f)-approximator to $\tau > 0$ is a quantity $\hat{\tau}$ such that $\tau/f - \rho \leq \hat{\tau} \leq f\tau + \rho$

▶ **Lemma 13** ([21] (rephrased from [8])). *Given a vector $x \in \mathbb{R}^n$ and parameters $\epsilon, \delta > 0, c > 0$ there exists an algorithm A that uses space $O(\log(1/\epsilon)\epsilon^{-1} \log^2 n \log(1/\delta))$ and generates a pair (i, v) from a distribution D_x on $[1 \ldots n]$ such that with probability $1 - \delta$*

- *$D_x(i)$ is a $(\frac{1}{n^c}, 1 + \epsilon)$-approximator to $|x_i|/\|x\|_1$*
- *v is a $(0, 1 + \epsilon)$-approximator to x_i*

where c is a fixed constant.

We will also need to maintain heavy hitters: all vertices of degree at least Δ^2 (up to constants). To do this, we will make use of the standard CountMin sketch [13]. For completeness, we state its properties here.

▶ **Lemma 14** ([13]). *Fix parameters $k, \delta > 0$. Then given a stream of m updates to a vector $x \in \mathbb{R}^n$ there is a sketch CM of size $O(k \log \delta^{-1}(\log m + \log n))$ and a reconstruction procedure $f : [n] \to \mathbb{R}$ such that with probability $1 - \delta$, for any x_i, $|x_i - f(i)| \leq \|x\|_1/k$*

Outline. We will have a collection of r, roughly n/Δ ℓ_1-samplers. These samplers will together give a good estimate ($(1+\varepsilon)$-approximation) of the importance h_i for all the vertices that have a *small* degree (which we define to be $< \alpha_\varepsilon \Delta^2$). Then, we use the CM sketch to maintain the degrees of all the 'high degree' vertices, i.e., those with degrees $\geq \alpha_\varepsilon \Delta^2$. Taken together, we obtain the desired sampling in the first pass.

▶ **Definition 15.** Given two sets of pairs of numbers S, S', let

$$S \cup_{\max} S' = \{(x, \max_{(x',y) \in S \cup S', x' = x} y)\}.$$

▶ **Lemma 16.** *Let $S = \{(i, v_i)\}$ be the set returned by Algorithm 1. Then*

- *S has size $\widetilde{O}\left(\frac{n}{\Delta}\right)$.*
- *Each $i \in [n]$ is sampled with probability p_i that is $(0, 1 + \epsilon)$ approximated by v_i and that $(n^{-c}, 1 + \epsilon)$-approximates h_i.*

Proof sketch. Consider any vertex i with $d_i \geq \Delta^2 \alpha_\epsilon$. By Lemma 14, such a vertex will report a count of at least $f(i) = (1 - \zeta)\Delta^2 \alpha_\epsilon$ and thus is guaranteed to be included in S_h. Its reported score $v_i = 1$ satisfies the requirement of the Lemma. Secondly, consider any vertex with degree $d_i < \epsilon\Delta$. For such a vertex, $h_i = \epsilon/\Delta\alpha_\epsilon$ and thus it is included in S_l with the desired probability and v_i.

Finally, consider a vertex i with $\epsilon\Delta \leq d_i < \Delta^2 \alpha_\epsilon$. The probability that none of the ℓ_1-samplers yield i is $(1 - d_i/n\Delta)^r$, and since $d_i/n\Delta \ll 1$, this can be approximated as $(1 - rd_i/n\Delta)$. Thus, the probability of seeing i is $rd_i/n\Delta = d_i/\Delta^2 \alpha_\epsilon$ as desired. ◀

Algorithm 1 Given n and average degree Δ

Initialize $S_l, S_m, S_h \leftarrow \emptyset$, and $\zeta = \alpha_\varepsilon$.
Sample elements from $[1 \dots n]$ each with probability $\epsilon/\Delta\alpha_\epsilon$. For each sampled i add $(i, \epsilon/\Delta\alpha_\epsilon)$ to S_l.
Fix $\zeta > 0$. Initialize a CountMin sketch CM with size parameter $k = n/\Delta\zeta^2$. Let f be the associated reconstruction procedure.
Initialize $r = O(n/\Delta\alpha_\epsilon)$ copies $A_1 \dots A_r$ of the algorithm A from Lemma 13.
for each stream update (i, w) (a vertex to which current edge is incident, and weight) **do**
  Update each $A_j, 1 \le j \le r$. Update CM.
for $j = 1$ to r **do**
  Sample (i, v) from A_j. $S_m = S_m \cup_{\max} \{(i, v)\}$
$S_h = \{(i, 1) \mid f(i) \ge (1 - \zeta)\Delta^2\alpha_\epsilon\}$
return $S_l \cup_{\max} S_m \cup_{\max} S_h$

▶ **Corollary 17.** *For each* $(i, v_i) \in S, h_i \le v_i \le 2h_i$.

6.2 Pass 2: Building the induced weighted graph

The first pass produces a set S of $\widetilde{O}(n/\Delta)$ vertices together with estimates v_i for their importance score h_i. If we weight each edge ij in $G[S]$ by $w_{ij} = 1/v_i v_j \Delta^2$, Theorem 4, along with Corollary 17 guarantee that a MaxCut in the resulting weighted graph is a good approximation of the true max cut. Thus, knowing S, constructing the re-weighted $G[S]$ in the second pass is trivial if we had space proportional to the number of edges in $G[S]$. Unfortunately this can be quadratic in $|S|$, so our goal is to implement the edge sampling of Theorem 5 in the second pass. This is done as follows: we maintain a set of edges E'. Every time we encounter an edge ij with $i, j \in S$, we check to see if it is already in E'. If not, we toss a coin and with probability $p_{ij} = \min(1, w_{ij} \log n/\epsilon^2)$ we insert $(i, j, w_{ij}/p_{ij})$ into E'. By Lemma 7.1 in full version of the paper, the size of E' is $\widetilde{O}(n/\Delta)$, and the resulting graph yields a $(1 + \epsilon)$ approximation to the MaxCut.

7 Correlation Clustering

Our argument for correlation clustering parallels the one for MaxCut. The MAX-AGREE variant of correlation clustering, while not a CSP (as the number of clusters is arbitrary), almost behaves as one. We start with two simple observations. The first is that we can restrict the number of clusters to $1/\varepsilon$, for the purposes of a $(1 + \varepsilon)$ approximation (See full version of the paper). Next, observe that the optimum objective value is at least $\max\{C^+, C^-\} \ge n\Delta/2$. This is simply because placing all the vertices in a single cluster gives a value C^+, while placing them all in different clusters gives C^-. Thus, it suffices to focus on additive approximation of $\varepsilon n\Delta$. Once we fix the number of clusters k, we can write correlation clustering as a quadratic program in a natural way: for each vertex i, have k variables $x_{i\ell}$, which is supposed to indicate if i is given the label ℓ. We then have the constraint that $\sum_\ell x_{i\ell} = 1$ for all i. The objective function then has a clean form:

$$\sum_{ij}[\sum_{\ell=1}^{k} x_{i\ell}(1 - x_{j\ell})c^-_{ij} + x_{i\ell}x_{j\ell}c^+_{ij}] = \sum_{ij}\sum_{\ell} x_{i\ell}c^-_{ij} + x_{i\ell}x_{j\ell}\eta_{ij} = \sum_{i,\ell} x_{i\ell}(\rho_{i\ell} + d^-_i),$$

where $x_{i\ell} = 1$ iff vertex $i \in C_\ell$, and $\rho_{i\ell} = \sum_{j\in\Gamma(i)} x_{j\ell}\eta_{ij}$ and $d^-_i = \sum_j c^-_{ij}$.

Note the similarity with the program for MaxCut. We will show that the framework from Section 3.1 carries over with minor changes. The details of the new Est procedure can be found in full version of the paper (it requires one key change: we now need to consider k-partitions of the seed set in order to find ρ). The duality based proof is slightly more involved; however we can use the same rough outline. The proof is presented in full version of the paper.

Abstract

The *k-Even Set* problem is a parameterized variant of the *Minimum Distance Problem* of linear codes over $\mathbb{F}_2$, which can be stated as follows: given a generator matrix $\mathbf{A}$ and an integer k, determine whether the code generated by $\mathbf{A}$ has distance at most k. Here, k is the parameter of the problem. The question of whether k-Even Set is fixed parameter tractable (FPT) has been repeatedly raised in literature and has earned its place in Downey and Fellows' book (2013) as one of the "most infamous" open problems in the field of Parameterized Complexity.

In this work, we show that k-Even Set does not admit FPT algorithms under the (randomized) Gap Exponential Time Hypothesis (Gap-ETH) [Dinur'16, Manurangsi-Raghavendra'16]. In fact, our result rules out not only exact FPT algorithms, but also any constant factor FPT approximation algorithms for the problem. Furthermore, our result holds even under the following weaker assumption, which is also known as the *Parameterized Inapproximability Hypothesis* (PIH) [Lokshtanov et al.'17]: no (randomized) FPT algorithm can distinguish a satisfiable 2CSP instance from one which is only 0.99-satisfiable (where the parameter is the number of variables).

We also consider the parameterized *k-Shortest Vector Problem (SVP)*, in which we are given a lattice whose basis vectors are integral and an integer k, and the goal is to determine whether the norm of the shortest vector (in the ℓ_p norm for some fixed p) is at most k. Similar to k-Even Set, this problem is also a long-standing open problem in the field of Parameterized Complexity. We show that, for any $p > 1$, k-SVP is hard to approximate (in FPT time) to some constant factor, assuming PIH. Furthermore, for the case of $p = 2$, the inapproximability factor can be amplified to any constant.

1 Introduction

The study of error-correcting codes gives rise to many computational problems. One of the most fundamental among these is the problem of computing the distance of a linear code. In this problem, which is commonly referred to as the *Minimum Distance Problem* (MDP), we are given as input a generator matrix $\mathbf{A} \in \mathbb{F}_2^{n \times m}$ of a binary[4] linear code and an integer k. The goal is to determine whether the code has distance at most k. Recall that the distance of a linear code is $\min_{\mathbf{0} \neq \mathbf{x} \in \mathbb{F}_2^m} \|\mathbf{Ax}\|_0$ where $\|\cdot\|_0$ denotes the 0-norm (aka the Hamming norm).

The study of MDP dates back to at least 1978 when Berlekamp et al. [8] conjectured that it is NP-hard. This conjecture remained open for almost two decades until it was positively resolved by Vardy [46, 47]. Later, Dumer et al. [22] strengthened this result by showing that even *approximately* computing the minimum distance of the code is hard. Specifically, they showed that, unless NP = RP, no polynomial time algorithm can distinguish between a code with distance at most k and one whose distance is greater than $\gamma \cdot k$ for any constant $\gamma \geqslant 1$. Furthermore, under stronger assumptions, the ratio can be improved to superconstants and even almost polynomial. Dumer et al.'s result has been subsequently derandomized by Cheng and Wan [11] and further simplified by Austrin and Khot [6] and Micciancio [36].

While the aforementioned results rule out not only efficient algorithms but also efficient approximation algorithms for MDP, there is another popular technique in coping with NP-hardness of problems which is not yet ruled out by the known results: *parameterization*.

In parameterized problems, part of the input is an integer designated as the parameter of the problem, and the goal is now not to find a polynomial time algorithm but a *fixed parameter tractable (FPT)* algorithm. This is an algorithm whose running time can be upper bounded by some (computable) function of the parameter in addition to some polynomial in the input length. Specifically, for MDP, its parameterized variant[5] k-MDP has k as the parameter and the question is to decide if the code generated by $\mathbf{A}$ has distance at most k in time $T(k) \cdot \text{poly}(mn)$ where T can be any computable function that depends only on k.

The parameterized complexity of k-MDP was first posed as an open problem by Downey et al. [21][6,7] who showed that parameterized variants of several other coding-theoretic problems, including the Nearest Codeword Problem and the Nearest Vector Problem[8] which we will discuss in more details in Section 1.1.1, are W[1]-hard. Thereby, assuming the widely believed W[1] $\neq$ FPT hypothesis, these problems are rendered intractable from the parameterized perspective. Unfortunately, Downey et al. fell short of proving such hardness for k-MDP and left it as an open problem:

[4] Note that MDP can be defined over larger fields as well; we discuss more about this in Section 3.
[5] Throughout Sections 1 and 2, for a computational problem Π, we denote its parameterized variant by k-Π, where k is the parameter of the problem.
[6] k-MDP is formulated differently in [21] where the input is the parity-check matrix instead of the generator matrix. Since we can efficiently compute one given the other, the two formulations are equivalent.
[7] k-MDP is commonly referred to as *k-Even Set* due to its graph theoretic interpretation (see [21]).
[8] The Nearest Vector Problem is also referred to in the literature as the Closest Vector Problem.

▶ **Open Question 1.** *Is k-MDP fixed parameter tractable?*

Although almost two decades have passed, the above question remains unresolved to this day, despite receiving significant attention from the community. In particular, the problem was listed as an open question in the seminal book of Downey and Fellows [19] and has been reiterated numerous times over the years [15, 23, 25, 20, 12, 14, 9, 13, 31]. In fact, in their second book [20], Downey and Fellows even include this problem as one of the six "most infamous" open questions in the area of Parameterized Complexity.

Another question posted in [21] that remains open is the parameterized *Shortest Vector Problem (k-SVP)* in lattices. The input of k-SVP (in the ℓ_p norm) is an integer $k \in \mathbb{N}$ and a matrix $\mathbf{A} \in \mathbb{Z}^{n \times m}$ representing the basis of a lattice, and we want to determine whether the shortest (non-zero) vector in the lattice has length at most k, i.e., whether $\min_{\mathbf{0} \neq \mathbf{x} \in \mathbb{Z}^m} \|\mathbf{Ax}\|_p \leqslant k$. Again, k is the parameter of the problem. Note that, similar to [21], we require the basis of the lattice to be integer-valued, which is sometimes not enforced in the literature (e.g. [45, 3]). This is because, if $\mathbf{A}$ is allowed to have rational entries, then parameterization is meaningless because we can simply scale $\mathbf{A}$ down by a large multiplicative factor.

The (non-parameterized) Shortest Vector Problem (SVP) has been intensively studied, motivated partly due to the fact that both algorithms and hardness results for the problem have numerous applications. Specifically, the celebrated LLL algorithm for SVP [28] can be used to factor rational polynomials, and to solve integer programming (parameterized by the number of unknowns) [29] and many other computational number-theoretic problems (see e.g. [38]). Furthermore, the hardness of (approximating) SVP has been used as the basis of several cryptographic constructions [3, 4, 39, 40]. Since these topics are out of scope of our paper, we refer the interested readers to the following surveys for more details: [41, 37, 38, 42].

On the computational hardness side of the problem, van Emde-Boas [45] was the first to show that SVP is NP-hard for the ℓ_∞ norm, but left open the question of whether SVP on the ℓ_p norm for $1 \leqslant p < \infty$ is NP-hard. It was not until a decade and a half later that Ajtai [2] showed, under a randomized reduction, that SVP for the ℓ_2 norm is also NP-hard; in fact, Ajtai's hardness result holds not only for exact algorithms but also for $(1 + o(1))$-approximation algorithms as well. The $o(1)$ term in the inapproximability ratio was then improved in a subsequent work of Cai and Nerurkar [10]. Finally, Micciancio [33] managed to achieve a factor that is bounded away from one. Specifically, Micciancio [33] showed (again under randomized reductions) that SVP on the ℓ_p norm is NP-hard to approximate within a factor of $\sqrt[p]{2}$ for every $1 \leqslant p < \infty$. Khot [27] later improved the ratio to any constant, and even to $2^{\log^{1/2-\varepsilon}(nm)}$ under a stronger assumption. Haviv and Regev [26] subsequently simplified the gap amplification step of Khot and, in the process, improved the ratio to almost polynomial. We note that both Khot's and Haviv-Regev reductions are also randomized and it is still open to find a deterministic NP-hardness reduction for SVP in the ℓ_p norms for $1 \leqslant p < \infty$ (see [35]); we emphasize here that such a reduction is not known even for the exact (not approximate) version of the problem. For the ℓ_∞ norm, the following stronger result due to Dinur is known [16]: SVP in the ℓ_∞ norm is NP-hard to approximate to within $n^{\Omega(1/\log\log n)}$ factor (under a *deterministic* reduction).

Very recently, fine-grained studies of SVP have been initiated [7, 1]. The authors of [7, 1] showed that SVP for any ℓ_p norm cannot be solved (or even approximated to some constant strictly greater than one) in subexponential time assuming the existence of a certain family of lattices[9] and the (randomized) *Gap Exponential Time Hypothesis (Gap-ETH)* [17, 32], which states that no randomized subexponential time algorithm can distinguish between a satisfiable 3CNF formula and one which is only 0.99-satisfiable.

[9] This assumption is needed only for $p \leqslant 2$. For $p > 2$, their hardness is conditional only on Gap-ETH.

As with MDP, Downey et al. [21] were the first to question the parameterized tractability of k-SVP (for the ℓ_2 norm). Once again, Downey and Fellows included k-SVP as one of the open problems in both of their books [19, 20], albeit, in their second book, k-SVP was in the "tough customers" list instead of the "most infamous" list that k-MDP belonged to. And again, as with Open Question 1, this question remains unresolved to this day:

▶ **Open Question 2.** *Is k-SVP fixed parameter tractable?*

1.1 Our Results

The main result of this paper is a resolution to the previously mentioned Open Question 1 and 2: more specifically, we prove that k-MDP and k-SVP (on ℓ_p norm for any $p > 1$) do not admit any FPT algorithm, assuming the aforementioned (randomized) Gap-ETH. In fact, our result is slightly stronger than stated here in a couple of ways:

- We rule out not only exact FPT algorithms but also FPT approximation algorithms.
- Second, our result works even under the so-called *Parameterized Inapproximability Hypothesis (PIH)* [30], which asserts that no (randomized) FPT algorithm[10] can distinguish between a satisfiable 2CSP instance and one which is only 0.99-satisfiable, where the parameter is the number of variables. It is known that Gap-ETH implies PIH.

With this in mind, we can state our results starting with the parameterized intractability of k-MDP, more concretely (but still informally), as follows:

▶ **Theorem 3.** *Assuming PIH, for any $\gamma \geqslant 1$ and any computable function T, no $T(k) \cdot poly(nm)$-time algorithm, on input $(\mathbf{A}, k) \in \mathbb{F}_2^{n \times m} \times \mathbb{N}$, can distinguish between*

- *the distance of the code generated by $\mathbf{A}$ is at most k, and,*
- *the distance of the code generated by $\mathbf{A}$ is more than $\gamma \cdot k$.*

While our above result rules out FPT approximation algorithms with *any* constant approximation ratio for k-MDP, we can only prove FPT inapproximability with *some* constant ratio for k-SVP in ℓ_p norm for $p > 1$, with the exception of $p = 2$ for which the ratio in our result can be amplified to any constant. These are stated more precisely below.

▶ **Theorem 4.** *For any $p > 1$, there exists a constant $\gamma_p > 1$ such that, assuming PIH, for any computable function T, no $T(k) \cdot poly(nm)$-time algorithm, on input $(\mathbf{A}, k) \in \mathbb{Z}^{n \times m} \times \mathbb{N}$, can distinguish between*

- *the ℓ_p norm of the shortest vector of the lattice generated by $\mathbf{A}$ is $\leqslant k$, and,*
- *the ℓ_p norm of the shortest vector of the lattice generated by $\mathbf{A}$ is $> \gamma_p \cdot k$.*

▶ **Theorem 5.** *Assuming PIH, for any computable function T and constant $\gamma \geqslant 1$, no $T(k) \cdot poly(nm)$-time algorithm, on input $(\mathbf{A}, k) \in \mathbb{Z}^{n \times m} \times \mathbb{N}$, can distinguish between*

- *the ℓ_2 norm of the shortest vector of the lattice generated by $\mathbf{A}$ is $\leqslant k$, and,*
- *the ℓ_2 norm of the shortest vector of the lattice generated by $\mathbf{A}$ is $> \gamma \cdot k$.*

We remark that our results do not yield hardness for SVP in the ℓ_1 norm and this remains an interesting open question. Section 3 contains discussion on this problem. We also note that, for Theorem 4 and onwards, we are only concerned with $p \neq \infty$; this is because, for $p = \infty$, the problem is NP-hard to approximate even when $k = 1$ [45]!

[10] The original formulation from [30] is slightly different in that it states that the problem is W[1]-hard.

1.1.1 Nearest Codeword Problem and Nearest Vector Problem

As we shall see in Section 2, our proof proceeds by first showing FPT hardness of approximation of the non-homogeneous variants of k-MDP and k-SVP called the *k-Nearest Codeword Problem* (k-NCP) and the *k-Nearest Vector Problem* (k-NVP) respectively. For both k-NCP and k-NVP, we are given a target vector $\mathbf{y}$ (in $\mathbb{F}_2^n$ and $\mathbb{Z}^n$, respectively) in addition to $(\mathbf{A}, k)$, and the goal is to find whether there is any $\mathbf{x}$ (in $\mathbb{F}_2^m$ and $\mathbb{Z}^m$, respectively) such that the (Hamming and ℓ_p, respectively) norm of $\mathbf{Ax} - \mathbf{y}$ is at most k.

As an intermediate step of our proof, we show that the k-NCP and k-NVP problems are hard to approximate[11]. This should be compared to [21], in which the authors show that both problems are W[1]-hard. The distinction here is that our result rules out not only exact algorithms but also approximation algorithms, at the expense of the stronger assumption than that of [21]. Indeed, if one could somehow show that k-NCP and k-NVP are W[1]-hard to approximate (to some constant strictly greater than one), then our reduction would imply W[1]-hardness of k-MDP and k-SVP (under randomized reductions). Unfortunately, no such W[1]-hardness of approximation of k-NCP and k-NVP is known yet.

We end this section by remarking that the computational complexity of both (non-parameterized) NCP and NVP are also thoroughly studied (see e.g. [34, 18, 44, 5, 24] in addition to the references for MDP and SVP), and indeed the inapproximability results of these two problems form the basis of hardness of approximation for MDP and SVP.

2 Proof Overview

In the non-parameterized setting, all the aforementioned inapproximability results for both MDP and SVP are shown in two steps: first, one proves the inapproximability of their inhomogeneous counterparts (i.e. NCP and NVP), and then reduces them to MDP and SVP. We follow this general outline. That is, we first show, via relatively simple reductions from PIH, that both k-NCP and k-NVP are hard to approximate. Then, we reduce k-NCP and k-NVP to k-MDP and k-SVP respectively. In this second step, we employ Dumer et al.'s reduction [22] for k-MDP and Khot's reduction [27] for k-SVP. While the latter works almost immediately in the parameterized regime, there are several technical challenges in adapting Dumer et al.'s reduction to our setting. The remainder of this section is devoted to presenting all of our reductions and to highlight such technical challenges and changes in comparison with the non-parameterized settings.

The starting point of all the hardness results in this paper is Gap-ETH. As mentioned earlier, it is well-known that Gap-ETH implies PIH, i.e., PIH is weaker than Gap-ETH. Hence, for the rest of this section, we may start from PIH instead of Gap-ETH.

2.1 Parameterized Intractability of k-MDP from PIH

We start this subsection by describing the Dumer et al.'s (henceforth DMS) reduction [22]. The starting point of the DMS reduction is the NP-hardness of approximating NCP to any constant factor [5]. Let us recall that in NCP we are given a matrix $\mathbf{A} \in \mathbb{F}_2^{n \times m}$, an integer k, and a target vector $\mathbf{y} \in \mathbb{F}_2^n$, and the goal is to determine whether there is any $\mathbf{x} \in \mathbb{F}_2^m$ such that $\|\mathbf{Ax} - \mathbf{y}\|_0$ is at most k. Arora et al. [5] shows that for any constant $\gamma \geqslant 1$, it is NP-hard to distinguish the case when there exists $\mathbf{x}$ such that $\|\mathbf{Ax} - \mathbf{y}\|_0 \leqslant k$ from the case when for all $\mathbf{x}$ we have that $\|\mathbf{Ax} - \mathbf{y}\|_0 > \gamma k$. Dumer et al. introduce the notion of "locally

[11] While our k-MDP result only applies for $\mathbb{F}_2$, our result for k-NCP holds for any finite field $\mathbb{F}_q$ too.

dense codes" to enable a gadget reduction from NCP to MDP. Informally, a locally dense code is a linear code $\mathbf{L}$ with minimum distance d admitting a ball $\mathcal{B}(\mathbf{s}, r)$ centered at $\mathbf{s}$ of radius[12] $r < d$ and containing a large (exponential in the dimension) number of codewords. Moreover, for the gadget reduction to MDP to go through, we require not only the knowledge of the code, but also the center $\mathbf{s}$ and a linear transformation $\mathbf{T}$ used to index the codewords in $\mathcal{B}(\mathbf{s}, r)$, i.e., $\mathbf{T}$ maps $\mathcal{B}(\mathbf{s}, r) \cap \mathbf{L}$ onto a smaller subspace. Given an instance $(\mathbf{A}, \mathbf{y}, k)$ of NCP, and a locally dense code $(\mathbf{L}, \mathbf{T}, \mathbf{s})$ whose parameters (such as dimension and distance) we will fix later, Dumer et al. build the following matrix:

$$\mathbf{B} = \begin{bmatrix} \mathbf{ATL} & -\mathbf{y} \\ \vdots & \vdots \\ \mathbf{ATL} & -\mathbf{y} \\ \mathbf{L} & -\mathbf{s} \\ \vdots & \vdots \\ \mathbf{L} & -\mathbf{s} \end{bmatrix} \begin{matrix} \left.\vphantom{\begin{matrix} \mathbf{ATL} & -\mathbf{y} \\ \vdots & \vdots \\ \mathbf{ATL} & -\mathbf{y} \end{matrix}}\right\} a \text{ copies} \\ \left.\vphantom{\begin{matrix} \mathbf{L} & -\mathbf{s} \\ \vdots & \vdots \\ \mathbf{L} & -\mathbf{s} \end{matrix}}\right\} b \text{ copies} \end{matrix}, \tag{1}$$

where a, b are some appropriately chosen positive integers. If there exists $\mathbf{x}$ such that $\|\mathbf{Ax} - \mathbf{y}\|_0 \leqslant k$ then consider $\mathbf{z}'$ such that $\mathbf{TLz}' = \mathbf{x}$ (we choose the parameters of $(\mathbf{L}, \mathbf{T}, \mathbf{s})$, in particular the dimensions of $\mathbf{L}$ and $\mathbf{T}$ such that all these computations are valid). Let $\mathbf{z} = \mathbf{z}' \circ 1$ (where $\circ$ is used to denote the concatenation operation on vectors), and note that $\|\mathbf{Bz}\|_0 = a\|\mathbf{Ax} - \mathbf{y}\|_0 + b\|\mathbf{Lz} - \mathbf{s}\|_0 \leqslant ak + br$. In other words, if $(\mathbf{A}, \mathbf{y}, k)$ is a YES instance of NCP then $(\mathbf{B}, ak + br)$ is a YES instance of MDP. On the other hand if we had that for all $\mathbf{x}$, the norm of $\|\mathbf{Ax} - \mathbf{y}\|_0$ is more than γk for some constant[13] $\gamma > 2$, then it is possible to show that for all $\mathbf{z}$ we have that $\|\mathbf{Bz}\|_0 > \gamma'(ak + br)$ for any $\gamma' < \frac{2\gamma}{2+\gamma}$. The proof is based on a case analysis of the last coordinate of $\mathbf{z}$. If that coordinate is 0, then, since $\mathbf{L}$ is a code of distance d, we have $\|\mathbf{Bz}\|_0 \geqslant bd > \gamma'(ak + br)$; if that coordinate is 1, then the assumption that $(\mathbf{A}, \mathbf{y}, k)$ is a NO instance of NCP implies that $\|\mathbf{Bz}\|_0 > a\gamma k > \gamma'(ak + br)$. Note that this gives an inapproximability for MDP of ratio $\gamma' < 2$; this gap is then further amplified by a simple tensoring procedure.

We note that Dumer et al. were not able to find a deterministic construction of locally dense codes with all of the above described properties. Specifically, they gave an efficient deterministic construction of $\mathbf{L}$, but only gave a randomized algorithm that finds $\mathbf{T}$ and $\mathbf{s}$ w.h.p. Therefore, their hardness result relies on the assumption that NP $\neq$ RP, instead of the more standard NP $\neq$ P assumption. Later, Cheng and Wan [11] and Micciancio [36] provided constructions for such (families of) locally dense codes with an explicit center, and thus showed the constant ratio inapproximability of MDP under the assumption of NP $\neq$ P.

Trying to follow the DMS reduction in order to show the parameterized intractability of k-MDP, we face the following three immediate obstacles. First, there is no inapproximability result known for k-NCP, for any constant factor greater than 1. Note that to use the DMS reduction, we need the parameterized inapproximability of k-NCP, for an approximation factor which is greater than two. Second, the construction of locally dense codes of Dumer et al. only works when the distance is linear in the block length (which is a function of the size of the input). However, we need codes whose distance are bounded above by a function of the parameter of the problem (and does not depend on the input size). This is because

[12] Note that for the ball to contain more than a single codeword, we must have $r \geqslant d/2$.

[13] Note that in the described reduction, we need the inapproximability of NCP to a factor greater than two, even to just reduce to the *exact* version of MDP.

the DMS reduction converts an instance $(\mathbf{A}, \mathbf{y}, k)$ of k-NCP to an instance $(\mathbf{B}, ak + br)$ of $(ak + br)$-MDP, and for this reduction to be an FPT reduction, we need $ak + br$ to be a function only depending on k, i.e., d, the distance of the code $\mathbf{L}$ (which is at most $2r$), must be a function only of k. Third, recall that the DMS reduction needs to identify the vectors in the ball $\mathcal{B}(\mathbf{s}, r) \cap \mathbf{L}$ with all the potential solutions of k-NCP. Notice that the number of vectors in the ball is at most $(nm)^{O(r)}$ but the number of potential solutions of k-NCP is exponential in m (i.e. all $\mathbf{x} \in \mathbb{F}_2^m$). However, this is impossible since $r \leqslant d$ is bounded above by a function of k!

We overcome the first obstacle by proving the constant inapproximability of k-NCP under PIH. Specifically, assuming PIH, we first show the parameterized inapproximability of k-NCP for some constant factor greater than 1, and then boost the gap using a composition operator (self-recursively). Note that in order to follow the DMS reduction, we need the inapproximability of k-NCP for some constant factor greater than 2; in other words, the gap amplification for k-NCP is necessary, even if we are not interested in showing the inapproximability of k-NCP for all constant factors.

We overcome the third obstacle by introducing an intermediate problem in the DMS reduction, which we call the *sparse nearest codeword problem*. The sparse nearest codeword problem is a promise problem which differs from k-NCP in only one way: in the YES case, we want to find $\mathbf{x} \in \mathcal{B}(\mathbf{0}, k)$ (rather than from the entire space $\mathbb{F}_2^m$), such that $\|\mathbf{Ax} - \mathbf{y}\|_0 \leqslant k$. In other words, we only allow sparse $\mathbf{x}$ as a solution. We show that k-NCP can be reduced to the sparse nearest codeword problem.

Finally, we overcome the second obstacle by introducing a variant of locally dense codes, which we call *sparse covering codes*. Roughly speaking, we show that any code which nears the Hamming bound (aka sphere-packing bound) in the high rate regime is a sparse covering code. Then we follow the DMS reduction with the new ingredient of sparse covering codes (replacing locally dense codes) to reduce the sparse nearest codeword problem to k-MDP.

We note that overcoming the second and third obstacles are our main technical contributions. Specifically, our result on sparse covering codes might be of independent interest.

The full reduction goes through several intermediate steps, which we will describe in more detail in the coming paragraphs. Throughout this section, for any gap problem, if we do not specify the gap in the subscript, then it implies that the gap can be any arbitrary constant. For every $\varepsilon \geqslant 0$, we denote by $\text{Gap2CSP}_\varepsilon$ the gap problem where we have to determine if a given 2CSP instance Γ, i.e., a graph $G = (V, E)$ and a set of constraints $\{C_{uv}\}_{(u,v)\in E}$ over an alphabet set Σ, has an assignment to its vertices that satisfies all the constraints or if every assignment violates more than ε fraction of the constraints. Here each C_{uv} is simply the set of all $(\sigma_u, \sigma_v) \in \Sigma \times \Sigma$ that satisfy the constraint. The parameter of the problem is $|V|$. PIH asserts that there exists some constant $\varepsilon > 0$ such that no randomized FPT algorithm can solve $\text{Gap2CSP}_\varepsilon$.

Reducing Gap2CSP$_\varepsilon$ to GapMLD$_\gamma$. We start by showing the parameterized inapproximability of k-NCP for some constant ratio. Instead of working with k-NCP, we work with its equivalent formulation (by converting the generator matrix given as input into a parity-check matrix) which in the literature is referred to as the *maximum likelihood decoding problem*[14]. We define the gap version of this problem (i.e., a promise problem), denoted by GapMLD_γ (for some constant $\gamma \geqslant 1$) as follows: on input $(\mathbf{A}, \mathbf{y}, k)$, distinguish between the YES case

[14] The two formulations are equivalent but we use different names for them to avoid confusion when we use *Sparse Nearest Codeword Problem* later on.

where there exists $\mathbf{x} \in \mathcal{B}(\mathbf{0}, k)$ such that $\mathbf{Ax} = \mathbf{y}$, and the NO case where for all $\mathbf{x} \in \mathcal{B}(\mathbf{0}, \gamma k)$ we have $\mathbf{Ax} \neq \mathbf{y}$. It is good to keep in mind that this is equivalent to asking whether there exist k columns of $\mathbf{A}$ whose sum is equal to $\mathbf{y}$ or whether any $\leqslant \gamma k$ columns of $\mathbf{A}$ do not sum up to $\mathbf{y}$.

Next, we sketch the reduction from an instance $(G = (V, E), \Sigma, \{C_{uv}\}_{(u,v)\in E})$ of Gap2CSP$_\varepsilon$ to an instance $(\mathbf{A}, \mathbf{y}, k)$ of GapMLD$_{1+\varepsilon/3}$. The matrix $\mathbf{A}$ has $|V||\Sigma| + \sum_{(u,v)\in E} |C_{uv}|$ columns and $|V| + |E| + 2|E||\Sigma|$ rows. The first $|V||\Sigma|$ columns of $\mathbf{A}$ are labelled with $(u, \sigma_u) \in V \times \Sigma$, and the remaining columns are labeled by (e, σ_u, σ_v) where $e = (u, v) \in E$ and $(\sigma_u, \sigma_v) \in C_{uv}$.

Before we continue with our description of $\mathbf{A}$, let us note that, in the YES case where there is a satisfying assignment $\phi : V \to \Sigma$, our intended solution for our GapMLD instance is to pick the $(u, \phi(u))$-column for every $u \in V$ and the $((u, v), \phi(u), \phi(v))$-column for every $(u, v) \in E$. Notice that $|V| + |E|$ columns are picked, and indeed we set $k = |V| + |E|$. Moreover, we set the first $|V| + |E|$ coordinates of $\mathbf{y}$ to be one and the rest to be zero.

We also identify the first $|V|$ rows of $\mathbf{A}$ with $u \in V$, the next $|E|$ rows with $e \in E$, and the remaining $2|E||\Sigma|$ rows with $(e, \sigma, b) \in E \times \Sigma \times \{0, 1\}$. Figure 1 provides an illustration of $\mathbf{A}$. The rows of $\mathbf{A}$ will be designed to serve the following purposes: the first $|V|$ rows will ensure that, for each $u \in V$, at least one column of the form $(u, \cdot)$ is picked, the next $|E|$ rows will ensure that, for each $e \in E$, at least one column of the form $(e, \cdot, \cdot)$ is picked, and finally the remaining $2|E||\Sigma|$ rows will "check" that the constraint is indeed satisfied.

Specifically, each u-row for $u \in V$ has only $|\Sigma|$ non-zero entries: those in column (u, σ_u) for all $\sigma_u \in \Sigma$. Since our target vector $\mathbf{y}$ has $\mathbf{y}_u = 1$, we indeed have that at least one column of the form $(u, \cdot)$ must be selected for every $u \in V$. Similarly, each e-row for $e = (u, v) \in E$ has $|C_{uv}|$ non-zero entries: those in column (e, σ_u, σ_v) for all $(\sigma_u, \sigma_v) \in C_{uv}$. Again, these make sure that at least one column of the form $(e, \cdot, \cdot)$ must be picked for every $e \in E$.

Finally, we will define the entries of the last $2|E||\Sigma|$ rows. To do so, let us recall that, in the YES case, we pick the columns $(u, \phi(u))$ for all $u \in V$ and $((u, v), \phi(u), \phi(v))$ for all $(u, v) \in E$. The goal of these remaining rows is to not only accept such a solution but also prevent any solution that picks columns $(u, \sigma_u), (v, \sigma_v)$ and $((u, v), \sigma'_u, \sigma'_v)$ where $\sigma_u \neq \sigma'_u$ or $\sigma_v \neq \sigma'_v$. In other words, these rows serve as a "consistency checker" of the solution. Specifically, the $|\Sigma|$ rows of the form $((u, v), \cdot, 0)$ will force σ_u and σ'_u to be equal whereas the $|\Sigma|$ rows of the form $((u, v), \cdot, 1)$ will force σ_v and σ'_v to be equal. For convenience, we will only define the entries for the $((u, v), \cdot, 0)$-rows; the $((u, v), \cdot, 1)$-rows can be defined similarly. Each $((u, v), \sigma, 0)$-row has only one non-zero entry within the first $|V||\Sigma|$ rows: the one in the (u, σ)-column. For the remaining columns, the entry in the $((u, v), \sigma, 0)$-row and the (e, σ_0, σ_1)-column is non-zero if and only if $e = (u, v)$ and $\sigma_0 = \sigma$.

It should be clear from the definition that our intended solution for the YES case is indeed a valid solution because, for each $((u, v), \phi(u), 0)$-row, the two non-zero entries from the columns $(u, \phi(u))$ and $((u, v), \phi(u), \phi(v))$ cancel each other out. On the other hand, for the NO case, the main observation is that, for each edge $(u, v) \in E$, if only one column of the form $(u, \cdot)$, one of the form $(v, \cdot)$ and one of the form $((u, v), \cdot, \cdot)$ are picked, then the assignment corresponding to the picked columns satisfy the constraint C_{uv}. In particular, it is easy to argue that, if we can pick $(1 + \varepsilon/3)(|V| + |E|)$ columns that sum up to $\mathbf{y}$, then all but ε fraction of all constraints fulfill the previous conditions, meaning that we can find an assignment that satisfies $1 - \varepsilon$ fraction of the constraints. Thus, we have also proved the soundness of the reduction.

Gap Amplification for GapMLD$_\gamma$. We have sketched the proof of the hardness of GapMLD$_\gamma$ for *some* constant $\gamma \geqslant 1$, assuming PIH. The next step is to amplify the gap and arrive at the

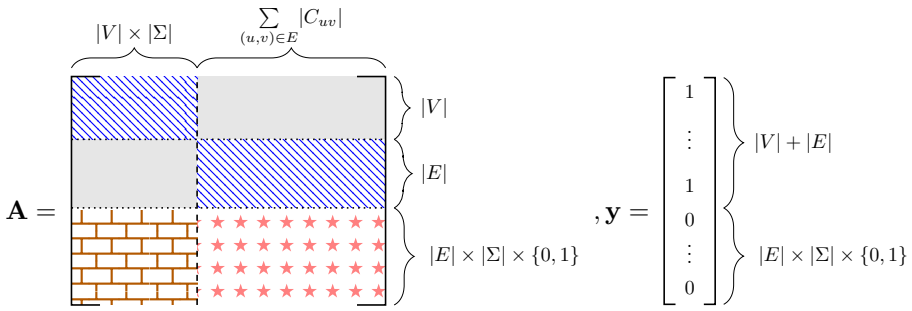

Figure 1 An illustration of $\mathbf{A}$ and $\mathbf{y}$. All entries in shaded areas are zero. Each *row* in the brick pattern area has one non-zero entry in that area, and each *column* in the star pattern area has two non-zero entries in the area. Finally, each column has one non-zero entry in the lines pattern areas.

hardness for GapMLD$_\gamma$ for *every* constant $\gamma \geqslant 1$. To do so, we define an operator $\oplus$ over every pair of instances of GapMLD$_\gamma$ with the following property: if two instances $(\mathbf{A}_1, \mathbf{y}_1, k_1)$ and $(\mathbf{A}_2, \mathbf{y}_2, k_2)$ are both YES instances, then $(\mathbf{A}, \mathbf{y}, k) := (\mathbf{A}_1, \mathbf{y}_1, k_1) \oplus (\mathbf{A}_2, \mathbf{y}_2, k_2)$ is a YES instance for GapMLD$_{\gamma'}$ where $\gamma' \approx \gamma^2$. On the other hand, if both $(\mathbf{A}_1, \mathbf{y}_1, k_1)$ and $(\mathbf{A}_2, \mathbf{y}_2, k_2)$ are NO instances, then $(\mathbf{A}, \mathbf{y}, k)$ is a NO instance for GapMLD$_{\gamma'}$. Hence, we can apply $\oplus$ repeatedly to the GapMLD$_\gamma$ instance from the previous step (with itself) and amplify the gap to be any arbitrarily large constant. The definition of $\oplus$, while simple, is slightly tedious to formalize and we defer it to the full version of this paper.

Reducing GapMLD to GapSNC. Now we introduce the *sparse nearest codeword problem* that we had briefly talked about. We define the gap version of this problem, denoted by GapSNC$_\gamma$ (for some constant $\gamma \geqslant 1$) as follows: on input $(\mathbf{A}', \mathbf{y}', k)$, distinguish between the YES case where there exists $\mathbf{x} \in \mathcal{B}(\mathbf{0}, k)$ such that $\|\mathbf{A}'\mathbf{x} - \mathbf{y}'\|_0 \leqslant k$, and the NO case where for all $\mathbf{x}$ (in the entire space), we have $\|\mathbf{A}'\mathbf{x} - \mathbf{y}'\|_0 > \gamma k$. We highlight that the difference between k-NCP and GapSNC$_\gamma$ is that, in the YES case of the latter, we are promised that $\mathbf{x} \in \mathcal{B}(\mathbf{0}, k)$. We sketch below the reduction from an instance $(\mathbf{A}, \mathbf{y}, k)$ of GapMLD$_\gamma$ to an instance $(\mathbf{A}', \mathbf{y}', k)$ of GapSNC$_\gamma$. Given $\mathbf{A}, \mathbf{y}$, let

$$\mathbf{A}' = \begin{bmatrix} \mathbf{A} \\ \vdots \\ \mathbf{A} \\ \mathrm{Id} \end{bmatrix} \Big\} \gamma k + 1 \text{ copies}, \qquad \mathbf{y}' = \begin{bmatrix} \mathbf{y} \\ \vdots \\ \mathbf{y} \\ \mathbf{0} \end{bmatrix} \Big\} \gamma k + 1 \text{ copies}.$$

Notice that for any $\mathbf{x}$ (in the entire space), we have $\|\mathbf{A}'\mathbf{x} - \mathbf{y}'\|_0 = (\gamma k + 1)\|\mathbf{A}\mathbf{x} - \mathbf{y}\|_0 + \|\mathbf{x}\|_0$, and thus both the completeness and soundness of the reduction easily follow.

Sparse Covering Codes. Before reducing GapSNC to GapMDP$_{1.99}$ we need to introduce in more detail the notion of *sparse covering codes* that we previously mentioned.

A sparse covering code (SCC) is a linear code $\mathbf{L}$ of block length h with minimum distance d admitting a ball $\mathcal{B}(\mathbf{s}, r)$ centered at $\mathbf{s}$ of radius $r < d$ and containing a large (i.e., about h^k, where $k = \Omega(d)$) number of codewords. Moreover, for our reduction to go through, we require not only $\mathbf{L}$ and $\mathbf{s}$, but also a linear transformation $\mathbf{T}$ used to index the codewords in $\mathcal{B}(\mathbf{s}, r)$, i.e., $\mathbf{T}(\mathcal{B}(\mathbf{s}, r) \cap \mathbf{L})$ needs to contains the ball of radius k centered at $\mathbf{0}$. Similar to

how Dumer et al. only managed to show the probabilistic existence of the center, we too cannot find an explicit $\mathbf{s}$ for the SCCs that we construct, but instead provide an efficiently samplable distribution such that, for any $\mathbf{x} \in \mathcal{B}(\mathbf{0}, k)$, the probability (over $\mathbf{s}$ sampled from the distribution) that $\mathbf{x} \in \mathbf{T}(\mathcal{B}(\mathbf{s}, r) \cap \mathbf{L})$ is non-negligible. This is what makes our reduction from GapSNC to $\text{GapMDP}_{1.99}$ randomized. We will not elaborate more on this issue here, but focus on the (probabilistic) construction of such codes. For convenience, we will assume throughout this overview that k is much smaller than d, i.e., $k = 0.001d$.

Recall that the Hamming (aka sphere-packing) bound states that a binary code of block length h and distance d can have at most $2^h/|\mathcal{B}(\mathbf{0}, \lceil \frac{d-1}{2} \rceil)|$ codewords, because the balls of radius $\lceil \frac{d-1}{2} \rceil$ centered at the codewords do not intersect. Our main theorem regarding the existence of SCC is that any code that is "near" the Hamming bound is a sparse covering code with $r = \lceil \frac{d-1}{2} \rceil + k \approx 0.501d$. Here "near" means that the number of codewords must be at least $2^h/|\mathcal{B}(\mathbf{0}, \lceil \frac{d-1}{2} \rceil)|$ divided by $f(d) \cdot \text{poly}(h)$ for some function f that depends only on d. (Equivalently, this means that the message length must be at least $h - (d/2 + O(1)) \log h$.) The BCH code over binary alphabet is an example of a code satisfying such a condition.

While we do not sketch the proof of the theorem here, we note that the idea is to set $\mathbf{T}$ and the distribution over $\mathbf{s}$ in such a way that the probability that $\mathbf{x}$ lies in $\mathbf{T}(\mathcal{B}(\mathbf{s}, r) \cap \mathbf{L})$ is at least the probability that a random point in $\mathbb{F}_2^h$ is within distance $r - k = \lceil \frac{d-1}{2} \rceil$ of some codeword. The latter is non-negligible since $\mathbf{L}$ nears the Hamming bound.

Finally, we remark that our proof here is completely different from the DMS proof of existence of locally dense codes. Specifically, DMS uses a group-theoretic argument to show that, when a code exceeds the Gilbert–Varshamov bound, there must be a center $\mathbf{s}$ such that $\mathcal{B}(\mathbf{s}, r)$ contains many codewords. Then, they pick a random linear map $\mathbf{T}$ and show that w.h.p. $\mathbf{T}(\mathcal{B}(\mathbf{s}, r) \cap \mathbf{L})$ is the entire space. Note that this second step does not use any structure of $\mathcal{B}(\mathbf{s}, r) \cap \mathbf{L}$; their argument is simply that, for any sufficiently large subset Y, a random linear map $\mathbf{T}$ maps Y to an entire space w.h.p. However, such an argument fails for us, due to the fact that, in SCC, we want to cover a ball $\mathcal{B}(\mathbf{0}, k)$ rather than the whole space, and it is not hard to see that there are very large subsets Y such that no linear map $\mathbf{T}$ satisfies $\mathbf{T}(Y) \supseteq \mathcal{B}(\mathbf{0}, k)$. A simple example of this is when Y is a subspace of $\mathbb{F}_2^h$; in this case, even when Y is as large as $\exp(\text{poly}(h))$, no desired linear map $\mathbf{T}$ exists.

Reducing GapSNC_γ to $\text{GapMDP}_{1.99}$. Next, we prove the hardness of $\text{GapMDP}_{\gamma'}$ for all constant $\gamma' \in [1, 2)$, assuming PIH, using a gadget constructed from sparse covering codes.

Given an instance $(\mathbf{A}, \mathbf{y}, k)$ of GapSNC_γ for some $\gamma > 2$ and a SCC $(\mathbf{L}, \mathbf{T}, \mathbf{s})$ we build an instance $(\mathbf{B}, ak + br)$ of $\text{GapMDP}_{\gamma'}$ where $\gamma' < \frac{2\gamma}{2+\gamma}$, by following the DMS reduction (which was previously described; see (1)). If $\|\mathbf{Ax} - \mathbf{y}\|_0 \leqslant k$ for some $\mathbf{x} \in \mathcal{B}(\mathbf{0}, k)$, then consider $\mathbf{z}'$ such that $\mathbf{TLz}' = \mathbf{x}$; the existence of such a $\mathbf{z}'$ is guaranteed by the definition of SCC. Consider $\mathbf{z} = \mathbf{z}' \circ 1$, and note that $\|\mathbf{Bz}\|_0 = a\|\mathbf{Ax} - \mathbf{y}\|_0 + b\|\mathbf{Lz} - \mathbf{s}\|_0 \leqslant ak + br$. In other words, as in the DMS reduction, if $(\mathbf{A}, \mathbf{y}, k)$ is a YES instance of NCP, then $(\mathbf{B}, ak + br)$ is a YES instance of MDP. On the other hand, similar to the DMS reduction, if we had that $\|\mathbf{Ax} - \mathbf{y}\|_0 > \gamma k$ for all $\mathbf{x}$, then $\|\mathbf{Bz}\|_0 > \gamma'(ak + br)$ for all $\mathbf{z}$. The parameterized intractability of $\text{GapMDP}_{1.99}$ is obtained by setting $\gamma = 400$ in the above reduction.

Gap Amplification for $\text{GapMDP}_{1.99}$. It is well known that the distance of the tensor product of two linear codes is the product of the distances of the individual codes. We can use this proposition to reduce GapMDP_γ to GapMDP_{γ^2} for any $\gamma \geqslant 1$. In particular, we can obtain, for any constant γ, the intractability of GapMDP_γ starting from $\text{GapMDP}_{1.99}$ by just recursively tensoring the input code $\lceil \log_{1.99} \gamma \rceil$ times.

2.2 Parameterized Intractability of k-SVP from PIH

We begin this subsection by briefly describing Khot's reduction. The starting point of Khot's reduction is the NP-hardness of approximating NVP in every ℓ_p norm to any constant factor [5]. Let us recall that in NVP in the ℓ_p norm, we are given a matrix $\mathbf{A} \in \mathbb{Z}^{n\times m}$, an integer k, and a target vector $\mathbf{y} \in \mathbb{Z}^n$, and the goal is to determine whether there is any $\mathbf{x} \in \mathbb{Z}^m$ such that$\|\mathbf{Ax} - \mathbf{y}\|_p^p$ is at most k. The result of Arora et al. [5] states that for any constant $\gamma \geqslant 1$, it is NP-hard to distinguish the case when there exists $\mathbf{x}$ such that $\|\mathbf{Ax} - \mathbf{y}\|_p^p \leqslant k$ from the case when for all (integral) $\mathbf{x}$ we have that $\|\mathbf{Ax} - \mathbf{y}\|_p^p > \gamma k$. Khot's reduction proceeds in four steps. First, he constructs a gadget lattice called the "BCH Lattice" using BCH Codes. Next, he reduces NVP in the ℓ_p norm (where $p \in (1, \infty)$) to an instance of SVP on an intermediate lattice by using the BCH Lattice. This intermediate lattice has the following property. For any YES instance of NVP the intermediate lattice contains multiple copies of the witness of the YES instance; For any NO instance of NVP there are also many "annoying vectors" (but far less than the total number of YES instance witnesses) which look like witnesses of a YES instance. However, since the annoying vectors are outnumbered, Khot reduces this intermediate lattice to a proper SVP instance, by randomly picking a sub-lattice via a random homogeneous linear constraint on the coordinates of the lattice vectors (this annihilates all the annoying vectors while retaining at least one witness for the YES instance). Thus he obtains some constant factor hardness for SVP. Finally, the gap is amplified via "Augmented Tensor Product". It is important to note that Khot's reduction is randomized, and thus his result of inapproximability of SVP is based on NP $\neq$ RP.

Trying to follow Khot's reduction, in order to show the parameterized intractability of k-SVP, we face only one obstacle: there is no known parameterized inapproximability of k-NVP for any constant factor greater than 1. Let us denote by $\text{GapNVP}_{p,\eta}$ for any constant $\eta \geqslant 1$ the gap version of k-NVP in the ℓ_p norm. Recall that in $\text{GapNVP}_{p,\eta}$ we are given a matrix $\mathbf{A} \in \mathbb{Z}^{n\times m}$, a target vector $\mathbf{y} \in \mathbb{Z}^n$, and a parameter k, and we would like to distinguish the case when there exists $\mathbf{x} \in \mathbb{Z}^m$ such that $\|\mathbf{Ax} - \mathbf{y}\|_p^p \leqslant k$ from the case when for all $\mathbf{x} \in \mathbb{Z}^m$ we have that $\|\mathbf{Ax} - \mathbf{y}\|_p^p > \eta k$. As it turns out, our reduction from $\text{Gap2CSP}_\varepsilon$ to GapSNC (with arbitrary constant gap), having GapMLD_γ and GapMLD as intermediate steps, can be translated to show the constant inapproximability of GapNVP_p (under PIH) in a straightforward manner. We will not elaborate on this part of the proof any further here and defer the detailed proof to the full version of this paper.

Once we have established the constant parameterized inapproximability of GapNVP_p, we follow Khot's reduction, and everything goes through as it is to establish the inapproximability for some factor of the gap version of k-SVP in the ℓ_p norm (where $p \in (1, \infty)$). We denote by $\text{GapSVP}_{p,\gamma}$ for some constant $\gamma(p) \geqslant 1$ the gap version of k-SVP (in the ℓ_p norm) where we are given a matrix $\mathbf{B} \in \mathbb{Z}^{n\times m}$ and a parameter $k \in \mathbb{N}$, and we would like to distinguish the case when there exists a non-zero $\mathbf{x} \in \mathbb{Z}^m$ such that $\|\mathbf{Bx}\|_p^p \leqslant k$ from the case when for all $\mathbf{x} \in \mathbb{Z}^m \setminus \{\mathbf{0}\}$ we have that $\|\mathbf{Bx}\|_p^p > \gamma k$. Let $\gamma^* := \frac{2^p}{2^{p-1}+1}$. Following Khot's reduction, we obtain the inapproximability of $\text{GapSVP}_{p,\gamma^*}$ (under PIH). To obtain inapproximability of GapSVP_2 for all constant ratios, we use the tensor product of lattices; the argument needed here is slightly more subtle than the similar step in MDP because, unlike distances of codes, the ℓ_2 norm of the shortest vector of the tensor product of two lattices is not necessarily equal to the product of the ℓ_2 norm of the shortest vector of each lattice. Fortunately, Khot's construction is tailored so that the resulting lattice is "well-behaved" under tensoring [27, 26], and gap amplification is indeed possible for such instances.

We remark here that, for the (non-parameterized) inapproximability of SVP, the techniques of [27, 26] allow one to successfully amplify gaps for ℓ_p norm where $p \neq 2$ as well. Unfortunately, this does not work in our settings, as it requires the distance k to be dependent on nm which is not possible for us since k is the parameter of the problem.

3 Discussion and Open Questions

While our results give an evidence of intractability of k-MDP and k-SVP, there are still many questions that remain open. First and foremost, it is still open whether the hardness of both problems can be based on more standard assumptions, such as ETH or W[1] $\neq$ FPT. On this front, we would like to note that the only reason we need PIH is to arrive at the inapproximability of the non-homogeneous variants of the problems, which is needed for us even if we want to only rule out exact FPT algorithms for k-MDP and k-SVP. Hence, if one could prove the hardness of approximation for these problems under weaker assumptions, then the inapproximability of k-MDP and k-SVP would still follow.

Another obvious question is whether k-SVP in the ℓ_1 norm is in FPT. Khot's reduction unfortunately does not work for ℓ_1; indeed, in [26], the hardness of approximating SVP in the ℓ_1 norm is shown by embedding SVP instances in ℓ_2 to instances in ℓ_1 using an earlier result of Regev and Rosen [43]. This embedding inherently does not work in the FPT regime either, as it produces non-integral lattices. Similar issue applies to an earlier hardness result for SVP on ℓ_1 of [33], whose reduction produces irrational bases.

An additional question regarding k-SVP is whether we can prove inapproximability for *every* constant factor for $p \neq 2$. As described earlier, the gap amplification techniques of [27, 26] require the distance k to be dependent on the input size nm, and hence are not applicable for us. To the best of our knowledge, it is unknown whether this dependency is necessary. If they are indeed required, it would be interesting to come up with different gap amplification techniques that also work for our settings.

Furthermore, k-MDP can be defined for linear codes in $\mathbb{F}_p$ for any larger field of size $p > 2$ as well. It turns out that our result does not rule out FPT algorithms for k-MDP over $\mathbb{F}_p$ with $p > 2$. The issue here is that, in our proof of existence of Sparse Covering Codes, we need the co-dimension of the code to be small compared to its distance. In particular, the co-dimension $h - m$ has to be at most $(d/2 + O(1)) \log_p h$ where d is the distance. While the BCH code over binary alphabet satisfies this property, we are not aware of any linear codes that satisfy this for larger fields. It is an intriguing open question to determine whether such codes exist, or whether the reduction can be made to work without existence of such codes.

Since the current reductions for both k-MDP and k-SVP are randomized, it is still an intriguing open question whether we can find deterministic reductions from PIH to these problems. As stated in the introduction, even in the non-parameterized setting, NP-hardness of SVP through deterministic reductions is not known. On the other hand, MDP is known to be NP-hard even to approximate under deterministic reductions; in fact, even the DMS reduction [22] that we employ can be derandomized, as long as one has a deterministic construction for Locally Dense Codes [11, 36]. In our settings, if one can deterministically construct Sparse Covering Codes, we would also get a deterministic reduction for k-MDP.

Finally, another interesting research direction is to prove more concrete running time lower bounds for k-MDP and k-SVP. For instance, k-MDP can be trivially solved (exactly) in $N^{O(k)}$ time, where $N = nm$ is the input size. On the other hand, while not stated explicitly above, our proof implies that k-MDP cannot be solved (or even approximated) in time $N^{o(k^c)}$ for some small constant $c > 0$, assuming Gap-ETH. Would it be possible to improve this running time lower bound to the tight $N^{o(k)}$? Similar questions also apply to k-SVP.

Abstract

A *rollercoaster* is a sequence of real numbers for which every maximal contiguous subsequence – increasing or decreasing – has length at least three. By translating this sequence to a set of points in the plane, a rollercoaster can be defined as an x-monotone polygonal path for which every maximal sub-path, with positive- or negative-slope edges, has at least three vertices. Given a sequence of distinct real numbers, the rollercoaster problem asks for a maximum-length (not necessarily contiguous) subsequence that is a rollercoaster. It was conjectured that every sequence of n distinct real numbers contains a rollercoaster of length at least $\lceil n/2 \rceil$ for $n > 7$, while the best known lower bound is $\Omega(n/\log n)$. In this paper we prove this conjecture. Our proof is constructive and implies a linear-time algorithm for computing a rollercoaster of this length. Extending the $O(n \log n)$-time algorithm for computing a longest increasing subsequence, we show how to compute a maximum-length rollercoaster within the same time bound. A maximum-length rollercoaster in a permutation of $\{1, \ldots, n\}$ can be computed in $O(n \log \log n)$ time.

The search for rollercoasters was motivated by orthogeodesic point-set embedding of caterpillars. A *caterpillar* is a tree such that deleting the leaves gives a path, called the *spine*. A *top-view caterpillar* is one of maximum degree 4 such that the two leaves adjacent to each vertex lie on opposite sides of the spine. As an application of our result on rollercoasters, we are able to

find a planar drawing of every n-vertex top-view caterpillar on every set of $\frac{25}{3}(n+4)$ points in the plane, such that each edge is an orthogonal path with one bend. This improves the previous best known upper bound on the number of required points, which is $O(n \log n)$. We also show that such a drawing can be obtained in linear time, when the points are given in sorted order.

1 Introduction

A *run* in a sequence of real numbers is a maximal contiguous subsequence that is increasing or decreasing. A *rollercoaster* is a sequence of real numbers such that every run has length at least three.[7] For example the sequence $(8, 5, 1, 3, 4, 7, 6, 2)$ is a rollercoaster with runs $(8, 5, 1)$, $(1, 3, 4, 7)$, $(7, 6, 2)$, which have lengths 3, 4, 3, respectively. The sequence $(8, 5, 1, 7, 6, 2, 3, 4)$ is not a rollercoaster because its run $(1, 7)$ has length 2. Given a sequence $S = (s_1, s_2, \ldots, s_n)$ of n distinct real numbers, the rollercoaster problem is to find a maximum-size set of indices $i_1 < i_2 < \cdots < i_k$ such that $(s_{i_1}, s_{i_2}, \ldots, s_{i_k})$ is a rollercoaster. In other words, this problem asks for a longest rollercoaster in S, i.e., a longest subsequence of S that is a rollercoaster.

One can interpret S as a set P of points in the plane by translating each number $s_i \in S$ to a point $p_i = (i, s_i)$. With this translation, a rollercoaster in S translates to a "rollercoaster" in P, which is a polygonal path whose vertices are points of P and such that every maximal sub-path, with positive- or negative-slope edges, has at least three points. See Figure 1(a). Conversely, for any point set in the plane, the y-coordinates of the points, ordered by their x-coordinates, form a sequence of numbers. Therefore, any rollercoaster in P translates to a rollercoaster of the same length in S.

The best known lower bound on the length of a longest rollercoaster is $\Omega(n/\log n)$ due to Biedl et al. [4], who posed the following conjecture; see Appendix B in the full version of [4].

▶ **Conjecture 1.** *Every sequence of $n > 7$ distinct real numbers contains a rollercoaster of length at least $\lceil n/2 \rceil$.*

Conjecture 1 can be viewed as a statement about patterns in permutations, a topic with a long history, and the subject of much current research. For example, the Eulerian polynomials, introduced by Euler in 1749, are the generating function for the number of descents in permutations. For surveys of recent work, see, for example, Linton et al. [13] and Kitaev [12]. Specifically, Conjecture 1 is related to the following seminal result of Erdős and Szekeres [7] in the sense that they prove the existence of an increasing or a decreasing subsequence of length at least $a + 1$ for $n = a^2 + 1$, which is essentially a rollercoaster with one run.

[7] The term "rollercoaster permutation" has also been used to refer to a permutation that, together with all its subsequences, has maximum number of changes from increasing to decreasing and vice versa; see e.g. [1].

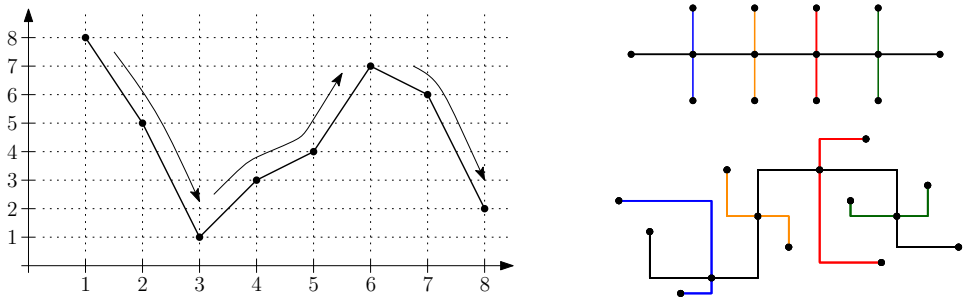

Figure 1 (a) Translating the sequence $(8, 5, 1, 3, 4, 7, 6, 2)$ to a set of points. (b) A planar L-shaped drawing of a top-view caterpillar.

▶ **Theorem 2** (Erdős and Szekeres, 1935). *Every sequence of $ab + 1$ distinct real numbers contains an increasing subsequence of length at least $a + 1$ or a decreasing subsequence of length at least $b + 1$.*

Hammersley [11] gave an elegant proof of the Erdős–Szekeres theorem that is short, simple, and based on the pigeonhole principle. The Erdős–Szekeres theorem also follows from the well-known decomposition of Dilworth (see [17]). The following is a restatement of Dilworth's decomposition for sequences of numbers.

▶ **Theorem 3** (Dilworth, 1950). *Any finite sequence S of distinct real numbers can be partitioned into k ascending sequences where k is the maximum length of a descending sequence in S.*

Besides its inherent interest, the study of rollercoasters is motivated by point-set embedding of caterpillars [4]. A *caterpillar* is a tree such that deleting the leaves gives a path, called the *spine*. An *ordered caterpillar* is a caterpillar in which the cyclic order of the edges incident to each vertex is specified. A *top-view caterpillar* is an ordered caterpillar where all vertices have degree 4 or 1 such that the two leaves adjacent to each spine vertex lie on opposite sides of the spine; see Figure 1(b). Planar orthogonal drawings of trees on a fixed set of points in the plane have been explored recently, see e.g., [4, 10, 15]; in these drawings every edge is drawn as an orthogonal path between two points, and the edges are non-intersecting. A *planar L-shaped drawing* is a simple type of planar orthogonal drawing in which every edge is an orthogonal path of exactly two segments. Such a path is called an *L-shaped edge*. For example see the top-view caterpillar in Figure 1(b) together with a planar L-shaped drawing on a given point set. Biedl et al. [4] proved that every top-view caterpillar on n vertices has a planar L-shaped drawing on every set of $O(n \log n)$ points in the plane that is in *general orthogonal position*, meaning that no two points have the same x- or y-coordinate.

1.1 Our Contributions

In Section 2 we study rollercoasters and prove Conjecture 1. In fact we prove something stronger: every sequence of n distinct numbers contains two rollercoasters of total length n. Our proof is constructive and yields a linear-time algorithm for computing such rollercoasters. We also extend our result to rollercoasters whose runs are of length at least k, for $k > 3$. Then we present an $O(n \log n)$-time algorithm for computing a longest rollercoaster, extending

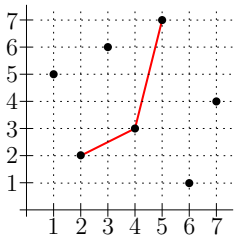
the classical algorithm for computing a longest increasing subsequence. This algorithm can be implemented in $O(n \log \log n)$ time if each number in the input sequence is an integer that fits in a constant number of memory words. Then we give an estimate on the number of permutations of $\{1, \ldots, n\}$ that are rollercoasters. In Section 3 we prove, by using Conjecture 1, that every n-vertex top-view caterpillar has a planar L-shaped drawing on every set of $\frac{25}{3}(n+4)$ points in the plane in general orthogonal position.

2 Rollercoasters

In this section we investigate lower bounds for the length of a longest rollercoaster in a sequence of numbers. We also study algorithmic aspects of computing such rollercoasters. First we prove Conjecture 1: any sequence of n distinct real numbers contains a rollercoaster of length at least $\lceil n/2 \rceil$. Observe that the length 4 sequence $(3, 4, 1, 2)$ has no rollercoaster, so we will restrict to $n \geqslant 5$ in the remainder of this section. Also, due to the following proposition we assume that $n \geqslant 8$.

▶ **Proposition 1.** *Every sequence of $n \in \{5, 6, 7\}$ distinct real numbers contains a rollercoaster of length at least 3. This bound is tight in the worst case.*

Proof. By applying Theorem 2 with $a = b = 2$ we get that every sequence of at least $ab + 1 = 5$ distinct numbers contains an increasing or a decreasing subsequence of length at least 3. This subsequence is a rollercoaster of length at least 3. For the tightness of this bound, consider the sequence $(5, 2, 6, 3, 7, 1, 4)$, depicted in the figure below. It has length 7 and its longest rollercoaster has length 3.



◀

We refer to a polygonal path as a *chain*. We define an *ascent* (resp., a *descent*) as an increasing (resp., a decreasing) sequence. We define a *k-ascent* (resp., a *k-descent*) as an ascent (resp., a descent) with at least k elements. We also use k-ascent and k-descent to refer to increasing and decreasing chains with at least k points, respectively. With this definition, a rollercoaster is a sequence in which every run is either a 3-ascent or a 3-descent. We refer to the rightmost run of a rollercoaster as its *last run*.

2.1 A Proof of Conjecture 1

In this section we prove the following theorem, which is a restatement of Conjecture 1. Our proof is constructive, and yields a linear-time algorithm for finding such a rollercoaster.

▶ **Theorem 4.** *Every sequence of $n \geqslant 8$ distinct real numbers contains a rollercoaster of length at least $\lceil n/2 \rceil$; such a rollercoaster can be computed in linear time. The lower bound of $\lceil n/2 \rceil$ is tight in the worst case.*

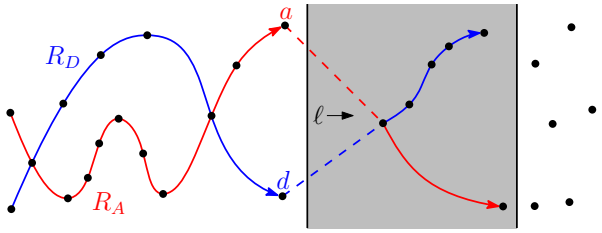


Figure 2 One iteration of algorithm: Constructing two pseudo-rollercoasters.

Consider a sequence with $n \geqslant 8$ distinct real numbers, and let P be its point-set translation with points $p_1, \ldots, p_n$ that are ordered from left to right. We define a *pseudo-rollercoaster* as a sequence in which every run is a 3-ascent or a 3-descent, except possibly the first run. That is, the first run of a pseudo-rollercoaster could be of length at most two, while the other runs are of length at least three. We present an algorithm that computes two pseudo-rollercoasters R_1 and R_2 in P such that $|R_1| + |R_2| \geqslant n$; the length of the longer one is at least $\lceil n/2 \rceil$. Then with a more involved proof we show how to extend this longer pseudo-rollercoaster to obtain a rollercoaster of length at least $\lceil n/2 \rceil$; this will prove the lower bound.

2.1.1 An Algorithm

First we provide a high-level description of our algorithm as depicted in Figure 2. Our algorithm is iterative, and proceeds by sweeping the plane by a vertical line ℓ from left to right. We maintain the following invariant:

▶ **Invariant.** *At the beginning of every iteration we have two pseudo-rollercoasters whose union is the set of all points to the left of ℓ and such that the last run of one of them is an ascent and the last run of the other one is a descent. Furthermore, these two last runs have a point in common.*

During every iteration we move ℓ forward and try to extend the current pseudo-rollercoasters. If this is not immediately possible with the next point, then we move ℓ farther and stop as soon as we are able to split all the new points into two chains that can be appended to the current pseudo-rollercoasters to obtain two new pseudo-rollercoasters that satisfy the invariant. See Figure 2.

Now we present our iterative algorithm in detail.

The First Iteration: We take the leftmost point p_1, and initialize each of the two pseudo-rollercoasters by p_1 alone. We may consider one of the pseudo-rollercoasters to end in an ascent and the other pseudo-rollercoaster to end in a descent. The two runs share p_1.

An Intermediate Iteration: By the above invariant we have two pseudo-rollercoasters R_A and R_D whose union is the set of all points to the left of ℓ and such that the last run of one of them, say R_A, is an ascent and the last run of R_D is a descent. Furthermore, the last run of R_A and the last run of R_D have a point in common. During the current iteration we make sure that every swept point will be added to R_A or R_D or both. We also make sure that at the end of this iteration the invariant will hold for the next iteration. Let a and d denote the rightmost points of R_A and R_D, respectively; see Figure 2. Observe that a lies above d. Let p_i be the first point to the right of ℓ. If p_i is above a, we add p_i to R_A to complete this iteration. Similarly, if p_i is below d, we add p_i to R_D to complete this iteration. In either

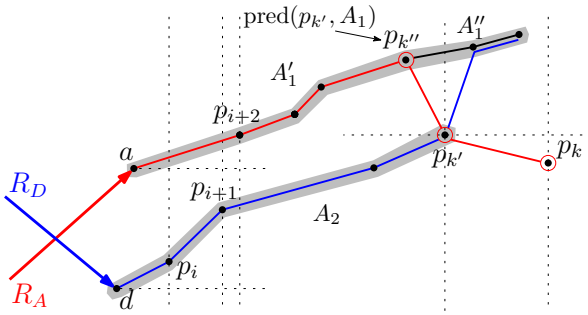

Figure 3 Illustration of an intermediate iteration of the algorithm.

case we get two pseudo-rollercoasters that satisfy the invariant for the next iteration. Thus we may assume that p_i lies below a and above d.

Consider the next point p_{i+1}. (If there is no such point, go to the last iteration; see below.) Suppose by symmetry that p_{i+1} lies above p_i as depicted in Figure 3. Then d, p_i, p_{i+1} forms a 3-ascent. Continue considering points $p_{i+2}, \ldots, p_k$ until for the first time, there is a 3-descent in $a, p_i, \ldots, p_k$. In other words, k is the smallest index for which $a, p_i, \ldots, p_k$ contains a descending chain of length 3. (If we run out of points before finding a 3-descent, then go to the last iteration.)

Without p_k there is no descending chain of length 3. Thus the longest descending chain has two points, and by Theorem 3, the sequence $P' = a, p_i, p_{i+1}, \ldots, p_{k-1}$ is the union of two ascending chains. We give an algorithm to find two such chains A_1 and A_2 with A_1 starting at a and A_2 starting at p_i. The algorithm also finds the 3-descent ending with p_k. For every point $q \in A_2$ we define its A_1-*predecessor* to be the rightmost point of A_1 that is to the left of q. We denote the A_1-predecessor of q by $\text{pred}(q, A_1)$.

The algorithm is as follows: While moving ℓ forward, we denote by r_1 and r_2 the rightmost points of A_1 and A_2, respectively; at the beginning $r_1 = a$, $r_2 = p_i$, and $\text{pred}(p_i, A_1) = a$. Moreover, we maintain this invariant that $\text{pred}(r_2, A_1)$ is above r_2. Let p be the next point to be considered. If p is above r_1 then we add p to A_1. If p is below r_1 and above r_2, then we add p to A_2 and set $\text{pred}(p, A_1) = r_1$; notice that this assignment satisfies the invariant. If p is below r_2, then we find our desired first 3-descent formed by (in backwards order) $p_k = p$, $p_{k'} = r_2$, and $p_{k''} = \text{pred}(r_2, A_1)$. See Figure 3. This algorithm runs in time $O(k - i)$, which is proportional to the number of swept points.

We add point d to the start of chain A_2. The resulting chains A_1 and A_2 are shaded in Figure 3. Observe that A_2 ends at $p_{k'}$. Also, all points of P' that are to the right of $p_{k'}$ (if there are any) belong to A_1, and lie to the right of $p_{k''}$, and form an ascending chain. Let A_1'' be this ascending chain. Let A_1' be the sub-chain of A_1 up to $p_{k''}$; see Figure 3. Now we form one pseudo-rollercoaster (shown in red) consisting of R_A followed by A_1' and then by the descending chain $p_{k''}, p_{k'}, p_k$. We form another pseudo-rollercoaster (shown in blue) consisting of R_D followed by A_2 and then by A_1''. We need to verify that the ascending chain added after d has length at least 3. This chain contains d, p_i and $p_{k'}$. This gives a chain of length at least 3 unless $k' = i$, but in this case $p_{k''} = a$, so p_{i+1} is part of A_1'' (because p_{i+1} is above p_i) and consequently part of this ascending chain. Thus we have constructed two longer pseudo-rollercoasters whose union is the set of all points up to point p_k, one ending with a 3-ascent and one with a 3-descent and such that the last two runs share the point $p_{k'}$. Figure 4(a) shows an intermediate iteration.

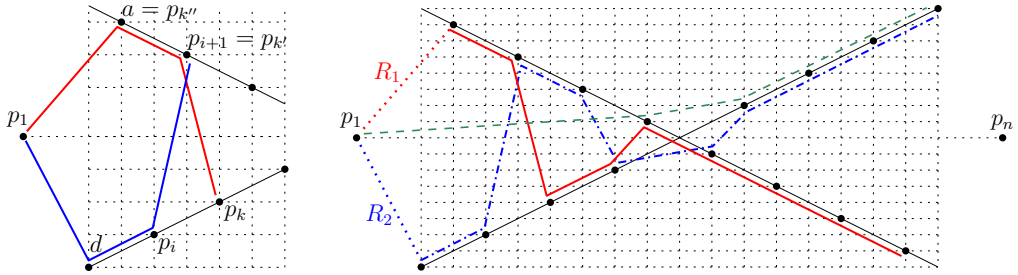

Figure 4 (a) An intermediate iteration. (b) A point set for which any rollercoaster of length at least $n/4 + 3$ does not contain p_1 and p_n. The green (dashed) rollercoaster, which contains p_1, has length $n/4 + 2$. The red (solid) and blue (dash-dotted) chains are the two rollercoasters returned by our algorithm.

The Last Iteration: If there are no points left, then we terminate the algorithm. Otherwise, let p_i be the first point to the right of ℓ. Let a and d be the endpoints of the two pseudo-rollercoasters obtained so far, such that a is the endpoint of an ascent and d is the endpoint of a descent. Notice that p_i is below a and above d, because otherwise this iteration would be an intermediate one. Moreover, the remaining points $p_i, \ldots, p_n$ do not contain a 3-ascent together with a 3-descent, again, because otherwise this iteration would be an intermediate one. If p_i is the last point, i.e., $i = n$, then we discard this point and terminate this iteration. Assume that $i \neq n$, and suppose by symmetry that the next point p_{i+1} lies above p_i. In this setting, by Theorem 3 and as described in an intermediate iteration, with the remaining points, we can get two ascending chains A_1 and A_2 such that A_2 contains at least two points. By connecting A_1 to a and A_2 to d we get two pseudo-rollercoasters whose union is all the points (in this iteration we do not need to maintain the invariant).

Final Refinement: At the end of algorithm, we obtain two pseudo-rollercoasters R_1 and R_2 that share p_1 and such that their union contains all points of P, except possibly p_n. Thus, $|R_1| + |R_2| \geqslant n$, and the length of the longer one is at least $\lceil \frac{n}{2} \rceil$.

Recall that every run of pseudo-rollercoasters R_1 and R_2 is a 3-ascent or a 3-descent, except possibly the first run. If the first run of R_1 (resp., R_2) contains only two points, then we remove p_1 to obtain a rollercoaster $\mathcal{R}_1$ (resp., $\mathcal{R}_2$). Therefore, we obtain two rollercoasters whose union contains all points, except possibly p_1 and p_n.

This is the end of our algorithm. In the next section we analyze the length of the resulting rollercoaster, the tightness of the claimed lower bound, and the running time of the algorithm.

2.1.2 Length and Running-Time Analysis

Our algorithm computes two rollercoasters $\mathcal{R}_1$ and $\mathcal{R}_2$ consisting of all points of P, except possibly p_1 and p_n. Thus, the total length of these rollercoasters is at least $n - 2$, and the length of the longer one is at least $\lceil \frac{n-2}{2} \rceil$. In the full version of the paper (see [3]) we show how to improve this bound to $\lceil \frac{n}{2} \rceil$ by revisiting the first and last iterations of our algorithm with some case analysis.

We note that there are point sets, with n points, for which every rollercoaster of length at least $n/4 + 3$ does not contain any of p_1 and p_n; see e.g., the point set in Figure 4(b). To verify the tightness of the $\lceil n/2 \rceil$ lower bound, consider a set of n points in the plane where

$\lceil n/2 \rceil$ of the points lie on a positive-slope line segment in the $(-,+)$-quadrant and the other $\lfloor n/2 \rfloor$ points lie on a positive-slope line segment in the $(+,-)$-quadrant.

To verify the running time, notice that the first iteration and final refinement take constant time, and the last iteration is essentially similar to an intermediate iteration. As described in an intermediate iteration the time complexity to find a 3-ascent and a 3-descent for the first time, together with the time complexity to compute chains A_1', A_1'', and A_2 is $O(k-i)$, which is linear in the number of swept points $p_i, \ldots, p_k$. Based on this and the fact that every point is considered only in one iteration, our algorithm runs in $O(n)$ time.

2.2 An Extension

In this section we extend our result to k-rollercoasters. A *k-rollercoaster* is a sequence of real numbers in which every run is either a k-ascent or a k-descent.

▶ **Theorem 5.** *Let $k \geqslant 4$ be an integer. Then every sequence of $n \geqslant (k-1)^2+1$ distinct real numbers contains a k-rollercoaster of length at least $\frac{n}{2(k-1)} - \frac{3k}{2}$. Moreover, for every $n > 0$ there exists a sequence of n distinct real numbers whose longest k-rollercoaster has length at most $\lceil \frac{n}{k-1} \rceil$.*

Proof. Our proof of the lower bound follows the same iterative approach of the proof of Theorem 4. Consider a sequence of n distinct real numbers and its point-set translation $p_1, \ldots, p_n$. We sweep the plane by a line ℓ, and maintain two k-rollercoasters R_A and R_D to the left of ℓ such that the last run of R_A is an ascent and the last run of R_D is a descent. In each iteration, except the last one, we move ℓ forward and stop as soon as we see a k-ascent A and a k-descent D in the swept points. Then we attach D to R_A, and A to R_D. To achieve the claimed lower bound, we make sure that the total length of A and D is at least $1/(k-1)$ times the number of swept points.

Consider an intermediate iteration where p_i lies below the rightmost point of R_A and above the rightmost point of R_D. Let m be the number of swept points in this iteration and let $P' = (p_i, p_{i+1} \ldots, p_{i+m-2}, p_{i+m-1})$ be the sequence of these points. Notice that $m \geqslant 2k-1$ because we need to sweep at least $2k-1$ points to get a k-ascent and a k-descent, which may share one point. Our strategy for stopping ℓ ensures that P' contains a k-ascent and a k-descent, while $P'' = (p_i, \ldots, p_{i+m-2})$ may contain only one of them but not both. Without loss of generality assume that P'' does not contain a k-descent. Since $m-1 \geqslant 2k-2$, there exists an integer $\alpha \geqslant 2$ for which

$$(\alpha-1)(k-1) < m-1 \leqslant \alpha(k-1). \tag{1}$$

The left-hand side of Inequality (1) implies that P'' has at least $(\alpha-1)(k-1)+1$ points. Having this and our assumption that P'' does not contain a k-descent, Theorem 2 implies that P'' contains an increasing subsequence of length at least α. We take the longest increasing and the longest decreasing subsequences in P' as A and D, respectively. Observe that $|A| \geqslant \max\{k, \alpha\}$ and $|D| = k$. This and the right-hand side of Inequality (1) imply that

$$|A| + |D| \geqslant \alpha + k \geqslant \frac{m-1}{k-1} + k > \frac{m}{k-1},$$

which means that the total length of A and D is at least $1/(k-1)$ times the number of swept points. In the last iteration if we sweep at most $(k-1)^2$ points then we discard all of them. But if we sweep $m > (k-1)^2$ points then by an argument similar to the one above there exists an integer α, with $\alpha \geqslant m/(k-1)$, for which we get either an α-ascent or an α-descent, which contains at least $1/(k-1)$ fraction of the swept points.

The first iteration is similar to the one in the proof of Theorem 4: we assume the existence of an ascent and a descent that end at the first point. At the end of algorithm if the first run of any of R_A and R_D contains k' points, for some $k' < k$, then by removing $k' - 1 (\leqslant k-2)$ points from its first run we get a valid k-rollercoaster. The total length of the resulting two k-rollercoasters is

$$|R_A| + |R_D| \geqslant \frac{n-(k-1)^2}{k-1} - 2(k-2),$$

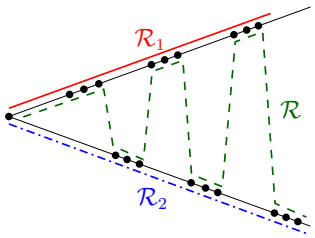
where the length of the longer one is at least

$$\frac{n-(k-1)^2}{2(k-1)} - (k-2) > \frac{n}{2(k-1)} - \frac{3(k-1)}{2}.$$

This finishes our proof of the lower bound. To verify the upper bound, consider a set of n points that are placed in the main-diagonal cells of a $(k-1) \times (k-1)$ grid, such that every cell contains at most $\lceil \frac{n}{k-1} \rceil$ points that are placed on a positive-slope line. ◀

2.3 Algorithms for a Longest Rollercoaster

In this section we study algorithmic aspects of computing a longest rollercoaster in a given sequence S of n distinct real numbers. By Theorem 4 we can compute a rollercoaster of length at least $\lceil n/2 \rceil$ in $O(n)$ time. However this rollercoaster may not necessarily be a longest one. If we run our algorithm of Section 2.1.1 on the point set in the figure below, then it returns two rollercoasters $\mathcal{R}_1$ and $\mathcal{R}_2$ each of length at most $\lceil \frac{n}{2} \rceil$ while the longest rollercoaster $\mathcal{R}$ has length n. In this section, first we adapt the existing $O(n \log n)$-time algorithm for computing a longest increasing subsequence in S to compute a longest rollercoaster in S within the same time bound. Then we show that if S is a permutation of $\{1, \ldots, n\}$, then we can compute a longest rollercoaster in $O(n \log \log n)$ time.



First we recall Fredman's version of the $O(n \log n)$-time algorithm for computing a longest increasing subsequence [9]; for more information about longest increasing subsequence, see Romik [14]. We maintain an array $R[i]$, which initially has $R[1] = S[1]$ and is empty otherwise. Then as i proceeds from 2 to n, we find the largest l for which $R[l] < S[i]$, and set $R[l+1] = S[i]$; if $S[i]$ is smaller than all elements of R, then $l = 0$. This insertion ensures that every element $R[l]$ stores the smallest element of $S[1..i]$ in which an increasing subsequence of length l ends. After all elements of S have been processed, the index of the last non-empty element of R is the largest length of an increasing sequence; the corresponding sequence can also be retrieved from R. Notice that R is always sorted during the above process. So, the proper location of $S[i]$ in R can be computed in $O(\log n)$ time by a predecessor search, which can be implemented as a binary search. Therefore, this algorithm runs in $O(n \log n)$ time.

To compute a longest rollercoaster we need to extend this approach. We maintain six arrays $R(w, h)$ with $w \in \{\text{inc}, \text{dec}\}$ and $h \in \{2, 3_+, 3'_+\}$ where inc stands for "increasing", dec stands for "decreasing", and both 3_+ and $3'_+$ stand for any integer that is at least 3 (we will see the difference between 3_+ and $3'_+$ later when we fill the arrays). We define a

w-h-rollercoaster to be a rollercoaster whose last run has h points and is increasing if $w = \text{inc}$ and decreasing if $w = \text{dec}$. We insert $S[i]$ into arrays $R(\text{inc}, h)$ such that after this insertion the following invariants hold:

- The array $R(\text{inc}, 2)[l]$ stores the smallest element of $S[1..i]$ in which an inc-2-rollercoaster of length l ends. The array $R(\text{dec}, 2)[l]$ stores the largest element of $S[1..i]$ in which a dec-2-rollercoaster of length l ends.
- The array $R(\text{inc}, 3_+)[l]$ stores the smallest element of $S[1..i]$ in which an inc-3_+-rollercoaster of length l ends. The array $R(\text{dec}, 3_+)[l]$ stores the largest element of $S[1..i]$ in which an dec-3_+-rollercoaster of length l ends.
- The array $R(\text{inc}, 3'_+)[l]$ stores the largest element of $S[1..i]$ in which an inc-3_+-rollercoaster of length l ends. The array $R(\text{dec}, 3'_+)[l]$ stores the smallest element of $S[1..i]$ in which a dec-3_+-rollercoaster of length l ends. These arrays will be used when the last run of the current rollercoaster changes from an ascent to a descent, and vice versa.

We insert $S[i]$ into arrays $R(\text{dec}, h)$ so to maintain analogous aforementioned invariants. To achieve these invariants we insert $S[i]$ as follows:

- $R(\text{inc}, 2)$: Find the largest index l such that $R(\text{dec}, 3'_+)[l] < S[i]$. If $S[i] < R(\text{inc}, 2)[l+1]$ then update $R(\text{inc}, 2)[l+1] = S[i]$.
- $R(\text{inc}, 3_+)$: Find the largest indices l_1 and l_2 such that $R(\text{inc}, 2)[l_1] < S[i]$ and $R(\text{inc}, 3_+)[l_2] < S[i]$. Let $l = \max\{l_1, l_2\}$. If $S[i] < R(\text{inc}, 3_+)[l+1]$ then update $R(\text{inc}, 3_+)[l+1] = S[i]$.
- $R(\text{inc}, 3'_+)$: Find the largest index l_1 and l_2 such that $R(\text{inc}, 2)[l_1] < S[i]$ and $R(\text{inc}, 3'_+)[l_2] < S[i]$. Let $l = \max\{l_1, l_2\}$. If $S[i] > R(\text{inc}, 3'_+)[l+1]$ then update $R(\text{inc}, 3'_+)[l+1] = S[i]$.
- The arrays $R(\text{dec}, h)$ are updated in a similar fashion.

Since our arrays $R(w, h)$ are not necessarily sorted, we cannot perform a predecessor search to find proper locations of $S[i]$. To insert $S[i]$ we need to *find* the largest index l such that $R(w, h)[l]$ is smaller (or, alternatively, larger) than $S[i]$ for some w and h, and also need to *update* contents of these arrays. Thereby, if A is an $R(w, h)$ array, we need to perform the following two operations on A:

- FindMax$(A, S[i])$: Find the largest index l such that $A[l] > S[i]$ (or $A[l] < S[i]$).
- Update$(A, l, S[i])$: Set $A[l] = S[i]$.

We implement each $R(w, h)$ as a Fenwick tree [8], which supports FindMax and Update in $O(\log n)$ time. Thus, the total running time of our algorithm is $O(n \log n)$. After all elements of S have been processed, the largest length of a rollercoaster is the largest value l for which $R(w, 3_+)[l]$ or $R(w, 3'_+)[l]$ is not empty; the corresponding rollercoaster can also be retrieved from arrays $R(w, h)$, by keeping the history of the way the elements of these arrays were computed, and then rolling back the computation.

A Longest Rollercoaster in Permutations: Here we consider a special case where our input sequence S consists of n distinct integers, each of which can be represented using at most c memory words for some constant $c \geqslant 1$, in a RAM model with logarithmic word size. In linear time, we can sort S, using Radix Sort, and then hash it to a permutation of $\{1, \ldots, n\}$. This reduces the problem to finding a longest rollercoaster in a permutation of $\{1, \ldots, n\}$. The longest increasing subsequence of such a sequence can be computed in $O(n \log \log n)$ time by using a van Emde Boas tree [18], which supports predecessor search and updates in $O(\log \log n)$ time.[8] To compute a longest rollercoaster in the same time, we need a data

[8] We note that a longest increasing subsequence of a permutation can also be computed in $O(n \log \log k)$ time (see [5]) where k is the largest length of an increasing sequence. However, in our case, the largest

structures that supports FindMax and Update in permutations in $O(\log\log n)$ time. In the full version of the paper (see [3]) we show how to obtain such a data structure by using van Emde Boas trees combined with some other structures.

▶ **Lemma 6.** *Let A be an array with n elements from the set $\{0, 1, \ldots, n\}$ such that each non-zero number occurs at most once in A. We can construct, in linear time, a data structure that performs* FindMax *and* Update *operations in $O(\log\log n)$ amortized time.*

With Lemma 6 in hand, we can compute a longest rollercoaster in S in $O(n \log\log n)$ time. We note that this algorithm can also compute a longest increasing subsequence by maintaining only the array $R(\text{inc}, 3_+)$.

Notice that both of our algorithms (for general sequences and for permutations) can be generalized to compute a longest k-rollercoaster in $O(kn \log n)$ time and in $O(kn \log\log n)$ time, respectively. A straightforward way is to maintain $2k$ arrays $R(w, h)$ with $w \in \{\text{inc}, \text{dec}\}$ and $h \in \{2, \ldots, k-1, k_+, k'_+\}$ and fill them in a way analogous to what we did for rollercoasters. The following theorem summarizes our results in this section.

▶ **Theorem 7.** *Let $k \geqslant 3$ be an integer. Then a longest k-rollercoaster in every sequence of n distinct real numbers can be computed in $O(kn \log n)$ time, and a longest k-rollercoaster in every permutation of $\{1, \ldots, n\}$ can be computed in $O(kn \log\log n)$ time.*

2.4 Counting Rollercoaster Permutations

In this section we estimate the number $r(n)$ of permutations of $\{1, 2, \ldots, n\}$ that are rollercoasters. A brief table follows:

n	1	2	3	4	5	6	7	8	9	10	11	12	13	14
$r(n)$	1	0	2	2	14	42	244	1208	7930	52710	40580	3310702	29742388	285103536

This is sequence A277556 in the *On-Line Encyclopedia of Integer Sequences* [16].

The first step is to rephrase the condition that a permutation is a rollercoaster in the language of ascents and descents. Given a length-n permutation $\pi = \pi_1\pi_2\cdots\pi_n$, its *descent word* $u(\pi)$ is defined to be $u_1u_2\cdots u_{n-1}$ where $u_i = \mathbf{a}$ if $\pi_i < \pi_{i+1}$ and $\mathbf{b}$ otherwise. For example if $\pi = 2, 4, 6, 1, 3, 5$, then $u(\pi) = \mathbf{aabaa}$. Notice that π is a rollercoaster if and only if every maximal contiguous subsequence of $u(\pi)$, that consists of only $\mathbf{a}$'s or $\mathbf{b}$'s, has length at least two. In other words, π is a rollercoaster if and only if $u(\pi)$ does not have an isolated $\mathbf{a}$ or an isolated $\mathbf{b}$; in fact $u(\pi)$ does not contain patterns $\{\mathbf{aba}, \mathbf{bab}\}$, and also begins and ends with either $\mathbf{aa}$ or $\mathbf{bb}$. The set of all such descent words $u(\pi)$ is given by the expression

$$(\mathbf{aaa}^* + \mathbf{bbb}^*)^*.$$

This expression specifies that every increasing run and every decreasing run must contain at least three elements. Since this description is a regular expression, one can, in principle, obtain the asymptotic behavior of $r(n)$ using the techniques of [2], but the calculations appear to be formidable.

Instead, we follow the approach of Ehrenborg and Jung [6]. This is based on specifying sets of permutations through pattern avoidance. We say a word w *avoids* a set of words S if no contiguous subword of w belongs to S. Although rollercoasters are not specifiable in terms of a finite set of avoidable patterns, they "almost are". Consider the patterns

length of a rollercoaster is $\Omega(n)$.

$\{\mathbf{aba}, \mathbf{bab}\}$. Every descent word of a rollercoaster must avoid both these patterns, and every word avoiding these patterns that *also* begins and ends with either **aa** or **bb** is the descent word of some rollercoaster. Let $s(n)$ be the number of permutations of length n whose descent word avoids $\{\mathbf{aba}, \mathbf{bab}\}$. Then $r(n) = \Theta(s(n))$. From [6, Prop. 5.2] we know that $s(n) \sim c \cdot n! \cdot \lambda^{n-3}$ where $\lambda \doteq 0.6869765032\cdots$ is the root of a certain equation. It follows that $r(n) \sim c' \cdot n! \cdot \lambda^{n-3}$ where c' is a constant, approximately 0.204.

3 Caterpillars

In this section we study the problem of drawing a top-view caterpillar, with L-shaped edges, on a set of points in the plane that is in general orthogonal position. Recall that a top-view caterpillar is an ordered caterpillar of degree 4 such that the two leaves adjacent to each vertex lie on opposite sides of the spine; see Figure 1(b) for an example. The best known upper bound on the number of required points for a planar L-shaped drawing of the n-vertex top-view caterpillar is $O(n \log n)$, for all n; this bound is due to Biedl et al. [4]. We use Theorem 4 and improve this bound to $\frac{25}{3}n+O(1)$.

In every planar L-shaped drawing of a top-view caterpillar, every node of the spine, except for the two endpoints, must have its two incident spine edges aligned either horizontally or vertically. Such a drawing of the spine (which is essentially a path) is called a *straight-through* drawing. It has been proved in [4] that every n-vertex path has an x-monotone straight-through drawing on any set of at least $c \cdot n \log n$ points, for some constant c. The following theorem improves this bound.

▶ **Theorem 8.** *Any path of n vertices has an x-monotone straight-through drawing on any set of at least $3n-3$ points in the plane that is in general orthogonal position.*

Proof. Fix an arbitrary set of $3n-3$ points. As in the proof of Theorem 4, find two pseudo-rollercoasters that together cover all but the last point and that both contain the first point. Append the last point to both sets; we hence obtain two subsequences R_1, R_2 with $|R_1| + |R_2| \geqslant 3n-1$ and for which all but the first and last run have length at least 3.

We may assume $|R_1| \geqslant \frac{3}{2}n - \frac{1}{2}$, and will find the straight-through drawing within it. To do so, consider any run r of R_1 that is neither the first nor the last run, and that has even length (hence length at least 4). By removing from r one point that is not shared with an adjacent run, we turn it into a run of odd length. Let R' be the subsequence that results after applying this to every such run of R_1; then R' satisfies that every run except the first and last one has odd length. Observe that we can find an x-monotone straight-through drawing of length $|R'|$ on this, see e.g. the black path in Figure 5 that is drawn on the black points.

It remains to argue that $|R'| \geqslant n$. Let $r_1, \ldots, r_\ell$ be the runs of R_1, and assign to each run r_i all but the last point of r_i (the last point of r_i is counted with r_{i+1}, or not counted at all if $i = \ell$). Therefore $|r_1| + \cdots + |r_\ell| = |R_1|-1 \geqslant \frac{3}{2}n - \frac{3}{2}$. For each r_i with $2 \leqslant i \leqslant \ell-1$, we remove a point only if $|r_i| \geqslant 3$, hence we keep at least $\frac{2}{3}|r_i|$ points. Therefore $|R'| \geqslant |r_1|+|r_\ell|+\sum_{2\leqslant i\leqslant \ell-1} \frac{2}{3}|r_i| = \sum_{1\leqslant i\leqslant \ell} \frac{2}{3}|r_i| + \frac{1}{3}(|r_1|+|r_\ell|) \geqslant \frac{2}{3}\cdot(\frac{3}{2}n - \frac{3}{2}) + \frac{1}{3}(2+1) = n$ as desired. ◀

To draw top-view caterpillars, we essentially use Theorem 8 and place the spine on the resulting straight-through x-monotone path. But we will get a slightly better factor if we analyze the number of points directly.

▶ **Theorem 9.** *For every n, the n-vertex top-view caterpillar has a planar L-shaped drawing on any set of $\frac{25}{3}(n+4)$ points in the plane that is in general orthogonal position. Such a*

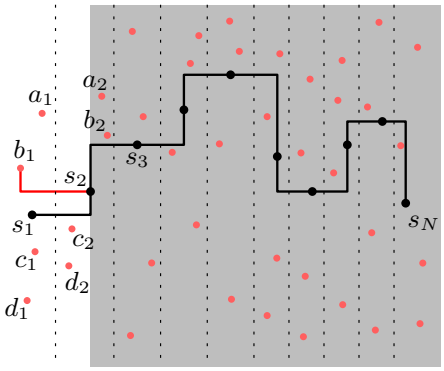


Figure 5 An x-monotone straight-through drawing of an N-vertex path. Red (lighter shade) points are reserved.

drawing can be computed in $O(n)$ time, provided that the input points are given in sorted order.

Proof. Fix any $\frac{25}{3}(n+4)$ points P in general orthogonal position. Partition P, by vertical lines, into $\frac{5}{3}(n+4)$ sets, each of them containing five points. We call every such set a *5-set*. Let P' be the set of the mid-points (with respect to y-coordinates) of every 5-set. We have $|P'| \geqslant \frac{5}{3}(n+4)$, so by Theorem 4 it contains a rollercoaster R of length at least $\frac{5}{6}(n+4)$.

Let $s_1, \ldots, s_N$ (for $N \geqslant \frac{5}{6}(n+4)$) be the points of R, ordered from left to right. For every $i \in \{1, \ldots, N\}$, consider the 5-set containing s_i and let its other points be a_i, b_i, c_i, d_i from top to bottom; we call these the *reserved points*. The main idea is to draw the spine of the caterpillar along R and the leaves at reserved points, though we will deviate from this occasionally. Let the spine consist of vertices $v_1, v_2, \ldots, v_\ell$, where v_1 and v_ℓ are leaves while $v_2, v_3, \ldots$ are vertices of degree 4. We process the vertices in order along the spine, and maintain the following invariant:

▶ **Invariant.** *At time $k \geqslant 1$, vertex v_{2k} is drawn on a point s_i that is not an extremal vertex of a run of R. Edge (v_{2k}, v_{2k-1}) attaches vertically at v_{2k}. All vertices $v_1, \ldots, v_{2k-1}$, all their incident leaves, and one incident leaf of v_{2k} are drawn on points to the left of s_i.*

By a suitable reflection we may assume that s_2 is above s_1. To initiate this process, we draw v_1 on s_1, v_2 on s_2, and one leaf incident to s_2 on b_1. See Figure 5. Clearly the invariant holds for v_2. Now assume that vertex v_{2k} has been placed at s_i, and we want to place v_{2k+1} and v_{2k+2} next. We know that s_i is in the middle of some run of R; up to symmetry we may assume that it is an ascending run. Let s_j be the last point of this run of R; by the invariant $j > i$. We distinguish cases:

Case 1: $j \leqslant i + 4$. See Figure 6(a). We will completely ignore the 5-sets containing $s_{i+1}, \ldots, s_{j-1}$. Recall that there are two reserved points a_j and b_j above s_j. We place v_{2k+1} at b_j and v_{2k+2} at s_{j+1}. We connect leaves as follows: The leaves incident to v_{2k+1} are placed at a_j and s_j. To place one leaf each incident to v_{2k} and v_{2k+2}, we use the two points c_j and d_j, using the one farther left for v_{2k}. Clearly the invariant holds.

Observe that there are at most five 5-sets (corresponding to $s_{i+1}, \ldots, s_{j+1}$) that were parsed, and we have used two for placing spine-vertices. Therefore, we have used at least $\frac{2}{5}$th of the parsed 5-sets.

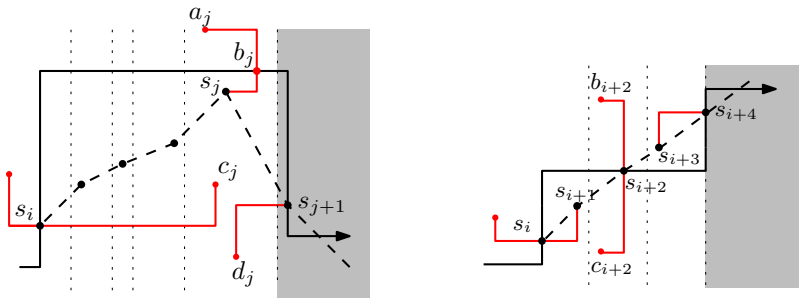

Figure 6 Placing the next two spine-vertices. (a) $j \leqslant i+4$. (b) $j > i+4$. The dashed line indicates R, the solid line is the spine.

Case 2: $j > i+4$. See Figure 6(b). We ignore the reserved points corresponding to s_{i+1} and s_{i+3}. We place v_{2k+1} at s_{i+2} and v_{2k+2} at s_{i+4}. Note that by case-assumption s_{i+4} is *not* the end of the run, so this satisfies the invariant. We connect, as leaves, s_{i+1} to v_{2k} (at s_i), and s_{i+3} to v_{2k+2} (at s_{i+4}). The two leaves of v_{2k+1} can be placed in the 5-set of s_{i+2}. We have used four 5-sets and placed two spine-vertices, and have therefore used half of the parsed 5-sets.

This is the end of one iteration. In every iteration, we have used at least $\frac{2}{5}$th of the parsed 5-sets. Since there were $\frac{5}{6}(n+4)$ 5-sets, we hence can place $\frac{1}{3}(n+4)$ spine-vertices. Since the spine of the n-vertex top-view caterpillar has $\frac{1}{3}(n+4)$ vertices, our claim about the size of the input point set follows. If the input points are given in sorted order, we can find the rollercoaster in linear time, and then we do one scan of the points to find a planar L-shaped drawing. Thus, our claim about the running time follows. ◀

Abstract

Reoptimization is a setting in which we are given an (near) optimal solution of a problem instance and a local modification that slightly changes the instance. The main goal is that of finding an (near) optimal solution of the modified instance.

We investigate one of the most studied scenarios in reoptimization known as *Steiner tree reoptimization*. Steiner tree reoptimization is a collection of strongly NP-hard optimization problems that are defined on top of the classical Steiner tree problem and for which several constant-factor approximation algorithms have been designed in the last decade. In this paper we improve upon all these results by developing a novel technique that allows us to design *polynomial-time approximation schemes*. Remarkably, prior to this paper, no approximation algorithm better than recomputing a solution from scratch was known for the elusive scenario in which the cost of a single edge decreases. Our results are best possible since none of the problems addressed in this paper admits a fully polynomial-time approximation scheme, unless P = NP.

1 Introduction

Reoptimization is a setting in which we are given an instance I of an optimization problem together with an (near) optimal solution S for I and a local modification that, once applied to I, generates a new instance I' which slightly differs from I. The main goal is that of finding an (near) optimal solution of I'. Since reoptimization problems defined on top of NP-hard problems are usually NP-hard, the idea beyond reoptimization is to compute a good approximate solution of I' by exploiting the structural properties of S. This approach leads to the design of reoptimization algorithms that, when compared to classical algorithms that compute feasible solutions from scratch, are less expensive in terms of running time or output solutions which guarantee a better approximation ratio. Thus, reoptimization finds applications in many real settings (like scheduling problems or network design problems) where prior knowledge is often at our disposal and a problem instance can arise from a local modification of a previous problem instance (for example, a scheduled job is canceled or some links of the network fail).

The term reoptimization was mentioned for the first time in the paper of Schäffter [33], where the author addressed an NP-hard scheduling problem with forbidden sets in the scenario of adding/removing a forbidden set. Since then, reoptimization has been successfully applied to other NP-hard problems including: the Steiner tree problem [8, 11, 13, 14, 15, 29, 30, 35], the traveling salesman problem and some of its variants [1, 5, 7, 12, 15, 16, 17, 18, 19, 32],

1.1 Our results

In this paper we address *Steiner tree reoptimization*. Steiner tree reoptimization is a collection of optimization problems that are built on top of the famous *Steiner tree problem* (*STP* for short), a problem that given an edge-weighted graph as input, where each vertex can be either terminal or Steiner, asks to find a minimum-cost tree spanning all the terminals. More precisely, we study the four local modifications in which the cost of an edge changes (it can either increase or decrease) or a vertex changes its status (from Steiner to terminal and viceversa).[2] All the problems addressed are strongly NP-hard [14, 15], which implies that none of them admits a fully polynomial-time approximation scheme, unless $\mathsf{P} = \mathsf{NP}$.

In this paper we improve upon all the constant-factor approximation algorithms that have been developed in the last 10 years by designing *polynomial-time approximation schemes*. More precisely, if S is a ρ-approximate solution of I, then all our algorithms compute a $(\rho + \epsilon)$-approximate solution of I'. For the scenarios in which the cost of an edge decreases or a terminal vertex becomes Steiner, our polynomial-time approximation schemes hold under the assumption that $\rho = 1$, i.e., the provided solution is optimal. We observe that this assumption is somehow necessary since Goyal and Mömke (see [30]) proved that in both scenarios, unless $\rho = 1$, any σ-approximation algorithm for the reoptimization problem would be also a σ-approximation algorithm for the *STP*! Remarkably, prior to this paper, no approximation algorithm better than recomputing a solution from scratch was known for the elusive scenario in which the cost of a single edge decreases.

The state of the art of Steiner tree reoptimization is summarized in Table 1. We observe that the only problem that remains open is the design of a reoptimization algorithm for the scenario in which a vertex, that can be either terminal or Steiner, is added to the graph. In fact, as proved by Goyal and Mömke [30], the scenario in which a vertex is removed from the graph is as hard to approximate as the *STP* (think of the removal of a vertex that is connected to each terminal by an edge of cost 0).

1.2 Used techniques

All the polynomial-time approximation schemes proposed in this paper make a clever use of the following three algorithms:

- the algorithm Connect that computes a Steiner tree in polynomial time by augmenting a Steiner forest having a constant number of trees with a minimum-cost set of edges. This algorithm has been introduced by Böckenhauer et al. in [14] and has been subsequently used in several other papers on Steiner tree reoptimization [11, 13, 30, 35];
- the algorithmic proof of Borchers and Du [20] that, for every $\xi > 0$, converts a Steiner tree S into a $f(\xi)$-*restricted Steiner tree* S_ξ, for some function $f(\xi)$ that depends on ξ only, whose cost is a $(1 + \xi)$-factor away from the cost of S. This algorithm has been used for the first time in Steiner tree reoptimization by Goyal and Mömke [30];

[1] In this paper we focus only on reoptimization problems that are NP-hard.

[2] We observe that the insertion of an edge can be modeled by decreasing the cost of the edge from $+\infty$ to its real value. Analogously, the deletion of an edge can be modeled by increasing the cost of the edge to $+\infty$.

Table 1 The state of the art of the approximability of Steiner tree reoptimization before and after our paper. The value σ is the best approximation ratio we can achieve for *STP* (actually $\sigma = \ln 4 + \epsilon \approx 1.387$ [26]). If we substitute $\sigma = \ln 4 + \epsilon$, we get $\frac{10\sigma-7}{7\sigma-4} \approx 1.204$, $\frac{7\sigma-4}{4\sigma-1} \approx 1.256$, and $\frac{5\sigma-3}{3\sigma-1} \approx 1.246$. The bound of $\frac{5\sigma-3}{3\sigma-1}$ for the scenario in which the cost of an edge decreases holds when the modified edge can affect only its cost in the shortest-path metric closure. To increase readability, all the bounds are provided for the case in which $\rho = 1$. Local modifications marked with an asterisk are those for which the condition $\rho = 1$ is necessary as otherwise the reoptimization problem would be as hard to approximate as the *STP*. Finally, the question mark means that the problem is still open.

Local modification	**before our paper**	**after our paper**
a terminal becomes a Steiner vertex*	$\frac{10\sigma-7}{7\sigma-4} + \epsilon$ [30]	$1 + \epsilon$
a Steiner vertex becomes terminal	$\frac{10\sigma-7}{7\sigma-4} + \epsilon$ [30]	$1 + \epsilon$
an edge cost increases	$\frac{7\sigma-4}{4\sigma-1} + \epsilon$ [30]	$1 + \epsilon$
an edge cost decreases*	$\frac{5\sigma-3}{3\sigma-1}$ [8]	$1 + \epsilon$
a vertex is added to the graph*	?	?
a vertex is deleted from the graph	as hard as the *STP* [30]	as hard as the *STP* [30]

- a novel algorithm, that we call BuildST, that takes a $f(\xi)$-restricted Steiner forest S_ξ of S with q trees, generated with the algorithm of Borchers and Du, and a positive integer h as inputs and computes a minimum-cost Steiner tree S' w.r.t. the set of all the feasible solutions that can be obtained by swapping up to h *full components* of S_ξ with a minimum-cost set of edges (that is computed using the algorithm Connect). The running time of this algorithm is polynomial when all the three parameters $f(\xi), q$, and h are bounded by a constant.

We prove that the approximation ratio of the solution S' returned by the algorithm BuildST is $\rho+\epsilon$ (i) by showing that the cost of S' is at most the cost of other feasible solutions $S_1, \ldots, S_\ell$ and (ii) by proving useful upper bounds to the cost of each S_i's. Intuitively, each S_i is obtained by swapping up to h suitable full components, say H_i, of a suitable $f(\xi)$-restricted version of a forest in S, say S_ξ, with a minimal set of full components, say H'_i, of a $g(\xi)$-restricted version of a fixed optimal solution OPT'. This implies that we can easily bound the cost of each S_i w.r.t. the cost of S_ξ, the cost of H_i, and the cost of H'_i. Unfortunately, none of these bounds can be used by itself to prove the claim. We address this issue by carefully defining H_{i+1} as a function of both OPT' and H'_i, and H'_i as a function of both S_ξ and H_i. This trick allows us to derive better upper bounds: we prove that the cost of each S_i is at most $\rho g(\xi)^2$ times the cost of OPT' plus the i-th term of a telescoping sum. As each term of the telescoping sum can be upper bounded by $g(\xi)$ times the cost of OPT', the bound of $(\rho + \epsilon)$ on the approximation ratio of S' then follows by averaging the costs of the S_i's and because of the choices of the parameters.

The paper is organized as follows: in Section 2 we provide the basic definitions and some preliminaries; in Section 3 we describe the three main tools that are used in all our algorithms; in Sections 4 and 5 we describe and analyze the algorithms for the cases in which a Steiner vertex becomes terminal and the cost of an edge increases, respectively. Due to the lack of space, the local modifications in which a terminal becomes a Steiner vertex and the cost of an edge decreases can be found in the full version of the paper.

2 Basic definitions and preliminaries

The Steiner tree problem (*STP* for short) is defined as follows:

- the input is a triple $I = \langle G, c, R\rangle$ where $G = (V(G), E(G))$ is a connected undirected graph with $|V(G)| = n$ vertices, c is a function that associates a real value $c(e) \geq 0$ to each edge $e \in E(G)$, and $R \subseteq V(G)$ is a set of *terminal* vertices;
- the problem asks to compute a minimum-cost Steiner tree of I, i.e., a tree that spans R and that minimizes the overall sum of its edge costs.

The vertices in $V(G) \setminus R$ are also called *Steiner* vertices. With a slight abuse of notation, for any subgraph H of G, we denote by $c(H) := \sum_{e\in E(H)} c(e)$ the cost of H.

In *Steiner tree reoptimization* we are given a triple $\langle I, S, I'\rangle$ where I is an *STP* instance, S is a ρ-approximate Steiner tree of I, and I' is another *STP* instance which slightly differs from I. The problem asks to find a ρ-approximate Steiner tree of I'.

For a forest F of G (i.e., with $E(F) \subseteq E(G)$) and a set of edges $E' \subseteq E(G)$, we denote by $F + E'$ a (fixed) forest yielded by the addition of all the edges in $E' \setminus E(F)$ to F, i.e., we scan all the edges of E' one by one in any (fixed) order and we add the currently scanned edge to the forest only if the resulting graph remains a forest. Analogously, we denote by $F - E'$ the forest yielded by the removal of all the edges in $E' \cap E(F)$ from F. We use the shortcuts $F + e$ and $F - e$ to denote $F + \{e\}$ and $F - \{e\}$, respectively. Furthermore, if F' is another forest of G we also use the shortcuts $F + F'$ and $F - F'$ to denote $F + E(F')$ and $F - E(F')$, respectively. For a set of vertices $U \subseteq V(G)$, we define $F + U := (V(F) \cup U, E(F))$ and use the shortcut $F + v$ to denote $F + \{v\}$.

W.l.o.g., in this paper we tacitly assume that all the leaves of a Steiner tree are terminals: if a Steiner tree S contains a leaf which is not a terminal, then we can always remove such a leaf from S to obtain another Steiner tree whose cost is upper bounded by the cost of S. Analogously, we tacitly assume that all the leaves of a Steiner forest (i.e., a forest spanning all the terminals) are terminals. A *full component* of a Steiner forest F – so a Steiner tree as well – is a maximal (w.r.t. edge insertion) subtree of F whose leaves are all terminals and whose internal vertices are all Steiner vertices. We observe that a Steiner forest can always be decomposed into full components. A *k-restricted* Steiner forest is a Steiner forest where each of its full components has at most k terminals.

In the rest of the paper, for any superscript s (the empty string is included), we denote by I^s an *STP* instance (we tacitly assume that $I^s = \langle G^s, c^s, R^s\rangle$ as well as that G^s has n vertices), by OPT^s a fixed optimal solution of I^s, by d^s the shortest-path metric induced by c^s in G^s (i.e, $d^s(u, v)$ is equal to the cost of a shortest path between u and v in G^s w.r.t. cost function c^s), by K^s the complete graph on $V(G^s)$ with edge costs d^s, and by K^s_n the complete graph obtained by adding $n - 1$ copies of K^s to K^s and where the cost of an edge between a vertex and any of its copies is equal to 0. With a little abuse of notation, we use d^s to denote the cost function of K^s_n. Moreover, we say that a subgraph H of K^s_n *spans* a vertex $v \in V(G^s)$ if H spans – according to the standard terminology used in graph theory – any of the n copies of v. Finally, with a little abuse of notation, we denote by I^s_n the *STP* instance $I^s_n = \langle K^s_n, d^s, R^s\rangle$.

Let I be an *STP* instance. We observe that any forest F of G is also a forest of K such that $d(F) \leq c(F)$. Moreover, any forest $\bar{F}$ of K can be transformed in polynomial time into a forest F of G spanning $V(\bar{F})$ and such that $c(F) \leq d(\bar{F})$. In fact, F can be build from an empty graph on $V(G)$ by iteratively adding – according to our definition of graph addition – a shortest path between u and v in G, for every edge $(u, v) \in E(\bar{F})$.

We also observe that any forest F of K can be viewed as a forest of K_n. Conversely, any forest F of K_n can be transformed in polynomial time into a forest of K spanning $V(F)$ and having the same cost of F: it suffices to identify each of the 0-cost edges of F between any vertex and any of its copies. Therefore, we have polynomial-time algorithms that convert any forest F of any graph in $\{G, K, K_n\}$ into a forest F' of any graph in $\{G, K, K_n\}$ such that F' always spans $V(F)$ and the cost of F' (according to the cost function associated with the corresponding graph) is less than or equal to the cost of F (according to the cost function associated with the corresponding graph). All these polynomial-time algorithms will be implicitly used in the rest of the paper; for example, we can say that a Steiner tree of I_n is also a Steiner tree of I or that a forest of I_n that spans v is also a forest of I that spans v. However, we observe that some of these polynomial-time algorithms do no preserve useful structural properties; for example, when transforming a k-restricted Steiner tree of I_n into a Steiner tree of I we may lose the property that the resulting tree is k-restricted. Therefore, whenever we refer to a structural property of a forest, we assume that such a property holds only w.r.t. the underlying graph the forest belongs to.

3 General tools

In this section we describe the three main tools that are used by all our algorithms.

The first tool is the algorithm Connect that has been introduced by Böckenhauer et al. in [14]. This algorithm takes an *STP* instance I together with a Steiner forest F of I as inputs and computes a minimum-cost set of edges of G whose addition to F yields a Steiner tree of I. The algorithm Connect reduces the *STP* instance to a smaller *STP* instance, where each terminal vertex corresponds to a tree of F, and then uses the famous Dreyfus-Wagner algorithm (see [28]) to find an optimal solution of the reduced instance.[3] If F contains q trees, the running time of the algorithm Connect is $O^*(3^q)$;[4] this implies that the algorithm has polynomial running time when q is constant. The call of the algorithm Connect with input parameters I and F is denoted by Connect(I, F).

The second tool is the algorithmic proof of Borchers and Du on k-restricted Steiner trees [20] that has already been used in Steiner tree reoptimization in the recent paper of Goyal and Mömke [30]. In their paper, Borchers and Du proved that, for every *STP* instance I and every $\xi > 0$, there exists a k-restricted Steiner tree S_ξ of I_n, with $k = 2^{\lceil 1/\xi \rceil}$, such that $d(S_\xi) \leq (1+\xi)c(OPT)$. As the following theorem shows, the algorithmic proof of Borchers and Du immediately extends to any (not necessarily optimal!) Steiner tree of I_n.

▶ **Theorem 1** ([20]). *Let I be an STP instance, S a Steiner tree of I, and $\xi > 0$ a real value. There is a polynomial time algorithm that computes a k-restricted Steiner tree S_ξ of I_n, with $k = 2^{\lceil 1/\xi \rceil}$, such that $d(S_\xi) \leq (1+\xi)c(S)$.*

The call of Borchers and Du algorithm with input parameters I, S, and ξ, is denoted by RestrictedST(I, S, ξ). By construction, the algorithm of Borchers and Du also guarantees the following properties:

(a) if v is a Steiner vertex that has degree at least 3 in S, then S_ξ spans v;

(b) if the degree of a terminal t in S is 2, then the degree of t in S_ξ is at most 4.

As shown in the following corollary, these two properties are useful if we want that a specific vertex of S would also be a vertex of the k-restricted Steiner tree S_ξ of I_n.

[3] We refer to Hougardy [31] for further exact algorithms for the *STP*.

[4] The O^* notation hides polynomial factors.

Algorithm 1: The pseudocode of the algorithm BUILDST(I, F, h).

```
1 if F contains less than h full components then return CONNECT(I, (R, ∅));
2 S' ←⊥;
3 for every set H of up to h full components of F do
4 |   F̄ ← F − H;
5 |   S̄ ← CONNECT(I_n, F̄);
6 |   if S' =⊥ or c(S̄) < c(S') then S' ← S̄;
7 return S';
```

▶ **Corollary 2.** *Let I be an STP instance, S a Steiner tree of I, v a vertex of S, and $\xi > 0$ a real value. There is a polynomial time algorithm that computes a k-restricted Steiner tree S_ξ of I_n, with $k = 2^{2+\lceil 1/\xi \rceil}$, such that $d(S_\xi) \leq (1+\xi)c(S)$ and $v \in V(S_\xi)$.*

Proof. The cases in which $v \in R$ has already been proved in Theorem 1. Moreover, the claim trivially holds by property (a) when v is a Steiner vertex of degree greater than or equal to 3 in S. Therefore we assume that v is a Steiner vertex of degree 2 in S. Let $I' = \langle G, c, R \cup \{v\} \rangle$. In this case, the call of RESTRICTEDST(I', S, ξ) outputs a k'-restricted Steiner tree S_ξ of I'_n, with $k' = 2^{\lceil 1/\xi \rceil}$, such that $d(S_\xi) \leq (1+\xi)c(S)$. Since v is a terminal in I', by property (b) the degree of v in S_ξ is at most 4; in other words, v is contained in at most 4 full components of S_ξ. Therefore, S_ξ is a k-restricted Steiner tree of I, with $k = 4k' = 2^{2+\lceil 1/\xi \rceil}$. ◀

The call of Borchers and Du algorithm with parameters I, S, ξ, and v is denoted by RESTRICTEDST(I, S, ξ, v).

The third tool, which is the novel idea of this paper, is the algorithm BUILDST (see Algorithm 1 for the pseudocode). The algorithm BUILDST takes as inputs an *STP* instance I, a Steiner forest F of I_n, and a positive integer value h. The algorithm computes a Steiner tree of I by selecting, among several feasible solutions, the one of minimum cost. More precisely, the algorithm computes a feasible solution for each forest $\bar{F}$ that is obtained by removing from F up to h of its full components. The Steiner tree of I associated with $\bar{F}$ is obtained by the call of CONNECT$(I_n, \bar{F})$. If F contains a number of full components which is strictly less than h, then the algorithm computes a minimum-cost Steiner tree of I from scratch. The call of the algorithm BUILDST with input parameters I, F, and h is denoted by BUILDST(I, F, h). The proof of the following lemma is immediate.

▶ **Lemma 3.** *Let I be an STP instance, F a Steiner forest of I_n, $\bar{F}$ a Steiner forest of I_n that is obtained from F by removing up to h of its full components, and H a minimum-cost subgraph of K_n such that $\bar{F} + H$ is a Steiner tree of I. Then the cost of the Steiner tree of I returned by the call of* BUILDST(I, F, h) *is at most $c(\bar{F}) + c(H)$.*

Moreover, the following lemmas hold.

▶ **Lemma 4.** *Let I be an STP instance and F a forest of G spanning R. If F contains q trees, then every minimal (w.r.t. the deletion of entire full components) subgraph H of any graph in $\{G, K, K_n\}$ such that $F + H$ is a Steiner tree of I contains at most $q - 1$ full components.*

Proof. Since H is minimal, each full component of H contains at least 2 vertices each of which respectively belongs to one of two distinct trees of F. Therefore, if we add the full components of H to F one after the other, the number of connected components of the resulting graph strictly decreases at each iteration because of the minimality of H. Hence, H contains at most $q - 1$ full components. ◀

Algorithm 2: A Steiner vertex $t \in V(G) \setminus R$ becomes a terminal.

```
1 ξ ← ε/10;
2 h ← 2^{2⌈2/ε⌉⌈1/ξ⌉};
3 S_ξ ← RestrictedST(I, S, ξ);
4 S' ← BuildST(I', S_ξ + t, h);
5 return S';
```

▶ **Lemma 5.** *Let I be an STP instance and F a Steiner forest of I_n of q trees. If each tree of F is k-restricted, then the call of* BuildST(I, F, h) *outputs a Steiner tree of I in time $O^*(|R|^h 3^{q+hk})$.*

Proof. If F contains at most h full components, then the number of terminals is at most $q + hk$ and the call of Connect$(I, (R, \emptyset))$ outputs a Steiner tree of I in time $O^*(3^{q+hk})$. Therefore, we assume that F contains a number of full components that is greater than or equal to h. In this case, the algorithm BuildST(I, F, h) computes a feasible solution for each forest that is obtained by removing up to h full components of F from itself. As the number of full components of F is at most $|R|$, the overall number of feasible solutions evaluated by the algorithm is $O(|R|^{h+1})$. Let $\bar{F}$ be any forest that is obtained from F by removing h of its full components. Since F is k-restricted, $\bar{F}$ contains at most $q + hk$ trees. Therefore the call of Connect$(I_n, \bar{F})$ requires $O^*(3^{q+hk})$ time to output a solution. Hence, the overall time needed by the call of BuildST(I, F, h) to output a solution is $O^*(|R|^h 3^{q+hk})$. ◀

For the rest of the paper, we denote by $\langle I, S, I' \rangle$ an instance of the Steiner tree reoptimization problem. Furthermore, we also assume that $\rho \leq 2$ as well as $\epsilon \leq 1$, as otherwise we can use classical time-efficient algorithms to compute a 2-approximate solution of I'.

4 A Steiner vertex becomes a terminal

In this section we consider the local modification in which a Steiner vertex $t \in V(G) \setminus R$ becomes a terminal. Clearly, $G' = G$, $c' = c$, $d' = d$, whereas $R' = R \cup \{t\}$. Therefore, for the sake of readability, we will drop the superscripts from G', c', and d'.

Let $\xi = \epsilon/10$ and $h = 2^{2\lceil 2/\epsilon \rceil \lceil 1/\xi \rceil}$. The algorithm, whose pseudocode is reported in Algorithm 2, computes a Steiner tree of I' first by calling RestrictedST(I, S, ξ) to obtain a k-restricted Steiner tree S_ξ of I_n, with $k = 2^{\lceil 1/\xi \rceil}$, and then by calling BuildST$(I', S_\xi + t, h)$. Intuitively, the algorithm *guesses* the full components of S_ξ to be replaced with the corresponding full components of a suitable k'-restricted version of a new (fixed) optimal solution, for suitable values of k'.

▶ **Theorem 6.** *Let $\langle I, S, I' \rangle$ be an instance of Steiner tree reoptimization, where S is a ρ-approximate solution of I and I' is obtained from I by changing the status of a single vertex from Steiner to terminal. Then Algorithm 2 computes a $(\rho + \epsilon)$-approximate Steiner tree of I' in polynomial time.*

Proof. Theorem 1 implies that the computation of S_ξ requires polynomial time. Since S_ξ is a Steiner tree of I_n, $S_\xi + t$ is a Steiner forest of I'_n of at most two trees (observe that S_ξ may already contain t). Therefore, using Lemma 5 and the fact that h is a constant value, the call of BuildST$(I', S_\xi + t, h)$ outputs a solution S' in polynomial time. Hence, the overall time complexity of Algorithm 2 is polynomial.

In the following we show that Algorithm 2 returns a $(\rho + \epsilon)$-approximate solution. Let S'_ξ denote the Steiner tree of I'_n that is returned by the call of RestrictedST(I', OPT', ξ). Let

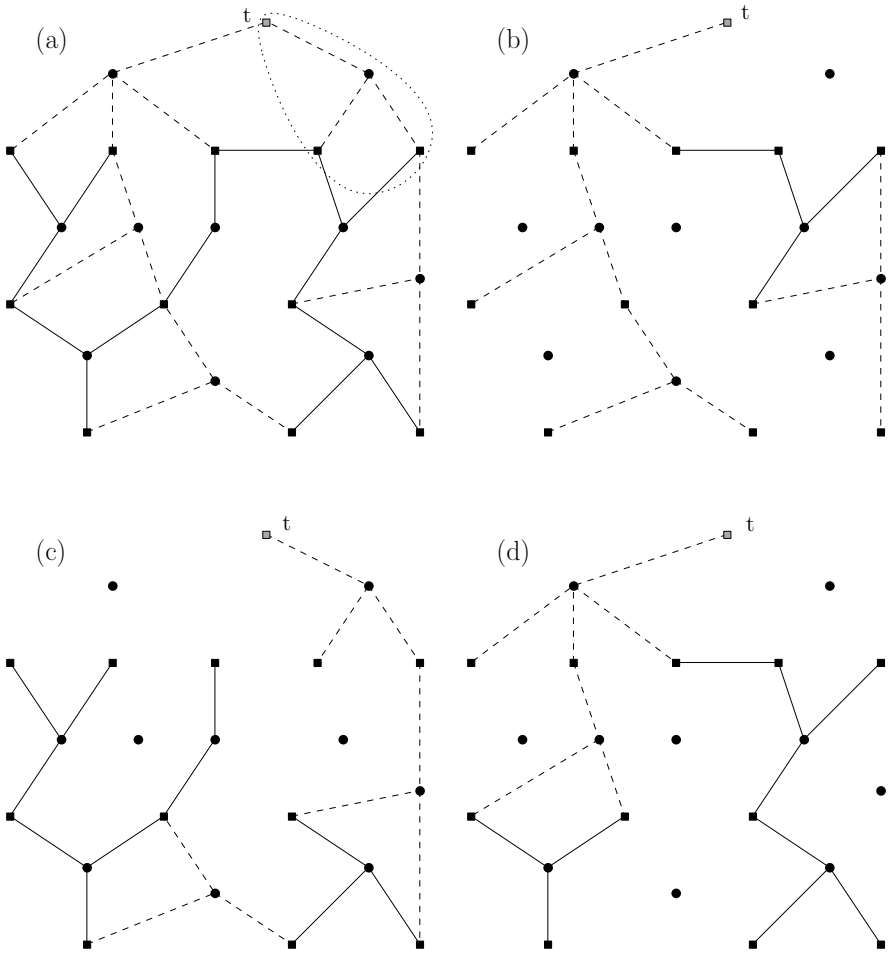

Figure 1 An example that shows how H_i and H'_i are defined. In (a) it is depicted a Steiner tree reoptimization instance where square vertices represent the terminals, while circle vertices represent the Steiner vertices. The Steiner vertex t of I that becomes a terminal in I' is represented as a terminal vertex of grey color. Solid edges are the edges of S_ξ, while dashed edges are the edges of S'_ξ. The full component H'_0 of S'_ξ is highlighted in (a). The forests $S'_\xi - H'_0$ and H_1 are shown in (b). The forests $S_\xi - H_1$ and H'_1 are shown in (c). Finally, the forests $S'_\xi - H'_1$ and H_2 are shown in (d).

H'_0 be a full component of S'_ξ that spans t (ties are broken arbitrarily). For every $i = 1, \ldots, \ell$, with $\ell = \lceil 2/\epsilon \rceil$, we define:

- H_i as the forest consisting of a minimal set of full components of S_ξ whose addition to $S'_\xi - H'_{i-1}$ yields a Steiner tree of I_n (see Figure 1 (b) and (d));
- H'_i as the forest consisting of a minimal set of full components of S'_ξ whose addition to $S_\xi - H_i$ yields a Steiner tree of I'_n (see Figure 1 (c)).

For the rest of the proof, we denote by S_i the Steiner tree of I' yielded by the addition of H'_i to $S_\xi - H_i$.

Let $k = 2^{\lceil 1/\xi \rceil}$ and observe that both S_ξ and S'_ξ are k-restricted Steiner trees of I_n and I'_n, respectively (see Theorem 1). Therefore H'_0 spans at most k terminals. Furthermore, by repeatedly using Lemma 4, H_i contains at most k^{2i-1} full components and spans at most k^{2i} terminals, while H'_i contains at most k^{2i} full components and spans at most k^{2i+1} terminals.

This implies that the number of the full components of H_i, with $i = 1, \ldots, \ell$, is at most

$$k^{2i-1} \leq k^{2\ell} = 2^{2\lceil 2/\epsilon \rceil \lceil 1/\xi \rceil} = h.$$

Therefore, by Lemma 3, the cost of the solution returned by the call of $\textsc{BuildST}(I', S_\xi + t, h)$ is at most $c(S_i)$. As a consequence

$$c(S') \leq \frac{1}{\ell} \sum_{i=1}^{\ell} c(S_i). \tag{1}$$

Now we prove an upper bound to the cost of each S_i. Let $\Delta_{OPT} = (1+\xi)c(OPT') - c(OPT)$. As any Steiner tree of I' is also a Steiner tree of I, $c(OPT') \geq c(OPT)$; therefore $\Delta_{OPT} \geq 0$. Since the addition of H_i to $S'_\xi - H'_{i-1}$ yields a Steiner tree of I, the cost of this tree is lower bounded by the cost of OPT. As a consequence, using Theorem 1 in the second inequality that follows, $c(OPT) \leq d(S'_\xi) - d(H'_{i-1}) + d(H_i) \leq (1+\xi)c(OPT') - d(H'_{i-1}) + d(H_i)$, i.e.,

$$d(H_i) \geq d(H'_{i-1}) - \Delta_{OPT}. \tag{2}$$

Using Theorem 1 in the first inequality that follows we have that

$$d(S_\xi) \leq (1+\xi)c(S) \leq \rho(1+\xi)c(OPT) \leq \rho(1+\xi)^2 c(OPT') - \Delta_{OPT}. \tag{3}$$

Using both (2) and (3) in the second inequality that follows, we can upper bound the cost of S_i with

$$c(S_i) \leq d(S_\xi) - d(H_i) + d(H'_i) \leq \rho(1+\xi)^2 c(OPT') - d(H'_{i-1}) + d(H'_i). \tag{4}$$

Observe that the overall sum of the last two terms on the right-hand side of (4) for every $i \in \{1, \ldots, \ell\}$ is a telescoping sum. As a consequence, if for every $i \in \{1, \ldots, \ell\}$ we substitute the term $c(S_i)$ in (1) with the corresponding upper bound in (4), and use Theorem 1 to derive that $d(H'_\ell) \leq d(S'_\xi) \leq (1+\xi)c(OPT')$, we obtain

$$c(S') \leq \frac{1}{\ell} \sum_{i=1}^{\ell} c(S_i) \leq \rho(1+\xi)^2 c(OPT') + \frac{1+\xi}{\ell} c(OPT') \leq (\rho + \epsilon) c(OPT'),$$

where last inequality holds by the choice of ξ and ℓ, and because $\rho \leq 2$ and $\epsilon \leq 1$. This completes the proof. ◀

5 The cost of an edge increases

In this section we consider the local modification in which the cost of an edge $e = (u, v) \in E(G)$ increases by $\Delta > 0$. More formally, we have that $G' = G$, $R' = R$, whereas, for every $e' \in E(G)$,

$$c'(e') = \begin{cases} c(e) + \Delta & \text{if } e' = e; \\ c(e') & \text{otherwise.} \end{cases}$$

For the sake of readability, in this section we drop the superscripts from G' and R'. Furthermore, we denote by c_{-e} the edge-cost function c restricted to $G - e$ and by d_{-e} the corresponding shortest-path metric.

Algorithm 3: The cost of an edge $e = (u, v)$ increases by $\Delta > 0$.

$\xi \leftarrow \epsilon/10$;
$h \leftarrow 2^{2(1+\lceil 1/\xi \rceil)\lceil 2/\epsilon \rceil}$;
if $e \notin E(S)$ **then**
  $S' \leftarrow S$;
else
  let S_u and S_v be the tree of $S - e$ containing u and v, respectively;
  $I_u \leftarrow \langle G - e, c_{-e}, V(S_u) \cap R \rangle$;
  $I_v \leftarrow \langle G - e, c_{-e}, V(S_v) \cap R \rangle$;
  $S_{u,\xi} \leftarrow \textsc{RestrictedST}(I_u, S_u, \xi, u)$;
  $S_{v,\xi} \leftarrow \textsc{RestrictedST}(I_v, S_v, \xi, v)$;
  $S_\xi \leftarrow S_{u,\xi} + S_{v,\xi}$;
  $S' \leftarrow \textsc{BuildST}(I', S_\xi, h)$;
  if $c'(S) \leq c'(S')$ **then** $S' \leftarrow S$;
return S';

Let $\xi = \epsilon/10$ and $h = 2^{2(1+\lceil 1/\xi \rceil)\lceil 2/\epsilon \rceil}$. The algorithm, whose pseudocode is reported in Algorithm 3, first checks whether $e \in E(S)$. If this is not the case, then the algorithm returns S. If $e \in E(S)$, then let S_u and S_v denote the two trees of $S - e$ containing u and v, respectively. The algorithm first computes a k-restricted Steiner tree $S_{u,\xi}$ (resp., $S_{v,\xi}$), with $k = 2^{2+\lceil 1/\xi \rceil}$, of S_u (resp., S_v) such that $u \in V(S_{u,\xi})$ (resp., $v \in V(S_{v,\xi})$). Then the algorithm computes a solution S' via the call of $\textsc{BuildST}(I', S_{u,\xi} + S_{v,\xi}, h)$, and, finally, it returns the cheapest solution between S and S'. As we will see, the removal of e from S is necessary to guarantee that the cost of the processed Steiner forest of I' (i.e., $S - e$) is upper bounded by the cost of OPT'.

▶ **Theorem 7.** *Let $\langle I, S, I' \rangle$ be an instance of Steiner tree reoptimization, where S is a ρ-approximate solution of I and I' is obtained from I by increasing the cost of a single edge. Then Algorithm 3 computes a $(\rho + \epsilon)$-approximate Steiner tree of I' in polynomial time.*

Proof. Corollary 2 implies that the computation of both $S_{u,\xi}$ and $S_{v,\xi}$ requires polynomial time. Therefore, using Lemma 5 and the fact that h is a constant value, the call of $\textsc{BuildST}(I', S_\xi, h)$ outputs a solution S' in polynomial time. Hence, the overall time complexity of Algorithm 3 is polynomial.

In the following we show that Algorithm 3 returns a $(\rho+\epsilon)$-approximate solution. Observe that the local modification does not change the set of feasible solutions, i.e., a tree is a Steiner tree of I iff it is a Steiner tree of I'. This implies that OPT' is a Steiner tree of I as well. Thanks to this observation, if $e \notin E(S)$ we have that

$$c'(S) = c(S) \leq \rho c(OPT) \leq \rho c(OPT') \leq \rho c'(OPT'),$$

i.e., the solution returned by the algorithm is a ρ-approximate solution. Moreover, if $e \in E(OPT')$, then $c'(OPT') = c(OPT') + \Delta$ or, equivalently, $c(OPT') = c'(OPT') - \Delta$. As a consequence,

$$c'(S) \leq c(S) + \Delta \leq \rho c(OPT) + \Delta \leq \rho c(OPT') + \Delta \leq \rho c'(OPT'),$$

i.e., once again, the solution returned by the algorithm is a ρ-approximate solution. Therefore, in the rest of the proof, we assume that $e \in E(S)$ as well as $e \notin E(OPT')$.

Let S'_ξ denote the Steiner tree of $\langle K_n, d_{-e}, R \rangle$ that is returned by the call of $\textsc{RestrictedST}(\langle G - e, c_{-e}, R \rangle, OPT', \xi)$. Using Theorem 1 and the fact that $e \notin E(OPT')$ we have that

$$d_{-e}(S'_\xi) \leq (1 + \xi) c_{-e}(OPT') = (1 + \xi) c'(OPT'). \tag{5}$$

Let H'_0 be a full component of S'_ξ whose addition to S_ξ yields a Steiner tree of I'_n (ties are broken arbitrarily). For every $i = 1, \ldots, \ell$, with $\ell = \lceil 2/\epsilon \rceil$, we define:

- H_i as the forest consisting of a minimal set of full components of S_ξ such that the addition of H_i and e to $S'_\xi - H'_{i-1}$ yields a Steiner tree of I_n;[5]
- H'_i as the forest consisting of a minimal set of full components of S'_ξ whose addition to $S_\xi - H_i$ yields a Steiner tree of I'_n.

For the rest of the proof, we denote by S_i the Steiner tree of I' obtained by augmenting $S_\xi - H_i$ with H'_i. Observe that S_i does not contain e. Therefore

$$c'(S_i) \leq c_{-e}(S_i) \leq d_{-e}(S_\xi) - d_{-e}(H_i) + d_{-e}(H'_i). \tag{6}$$

Let $k = 2^{2+\lceil 1/\xi \rceil}$ and $r = 2^{\lceil 1/\xi \rceil}$. Observe that S_ξ is a k-restricted Steiner forest of I_n (see Corollary 2), while S'_ξ is an r-restricted Steiner tree of I'_n (see Theorem 1). Therefore, H'_0 spans at most r terminals. Moreover, by repeatedly using Lemma 4, H_i contains at most $k^{i-1}r^i$ full components and spans at most $k^i r^i$ terminals, while H'_i contains at most $k^i r^i$ full components and spans at most $k^i r^{i+1}$ terminals. This implies that the number of full components of H_i, with $i = 1, \ldots, \ell$, is at most

$$k^{i-1}r^i \leq k^\ell r^\ell = 2^{2(1+\lceil 1/\xi \rceil)\lceil 2/\epsilon \rceil} = h.$$

Therefore, by Lemma 3, the cost of the solution returned by the call of BuildST(I', S_ξ, h) is at most the cost of S_i. As a consequence

$$c'(S') \leq \frac{1}{\ell} \sum_{i=1}^{\ell} c'(S_i). \tag{7}$$

Now we prove an upper bound to the cost of each S_i, with $i \in \{1, \ldots, \ell\}$. Let $\Delta_{OPT} = (1+\xi)c'(OPT') - c(OPT)$ and observe that $\Delta_{OPT} \geq 0$. Since the addition of H_i and e to $S'_\xi - H'_{i-1}$ yields a Steiner tree of I, the cost of this tree is lower bounded by the cost of OPT. As a consequence, using (5) together with Theorem 1 in the third inequality that follows,

$$\begin{aligned} c(OPT) &\leq d(S'_\xi - H'_{i-1}) + d(H_i) + d(e) \leq d_{-e}(S'_\xi - H'_{i-1}) + d_{-e}(H_i) + c(e) \\ &= d_{-e}(S'_\xi) - d_{-e}(H'_{i-1}) + d_{-e}(H_i) + c(e) \\ &\leq (1+\xi)c'(OPT') - d_{-e}(H'_{i-1}) + d_{-e}(H_i) + c(e), \end{aligned}$$

from which we derive

$$d_{-e}(H_i) \geq d_{-e}(H'_{i-1}) - \Delta_{OPT} - c(e). \tag{8}$$

Using Corollary 2 twice in the first inequality that follows we have that

$$\begin{aligned} d_{-e}(S_\xi) &= d_{-e}(S_{u,\xi}) + d_{-e}(S_{v,\xi}) \leq (1+\xi)c_{-e}(S_u) + (1+\xi)c_{-e}(S_v) \\ &= (1+\xi)c(S) - (1+\xi)c(e) \leq \rho(1+\xi)c(OPT) - c(e) \\ &\leq \rho(1+\xi)^2 c'(OPT') - \Delta_{OPT} - c(e). \end{aligned} \tag{9}$$

Starting from (6) and using both (8) and (9) in the second inequality that follows, we can upper bound the cost of S_i, for every $i \in \{1, \ldots, \ell\}$, with

$$c'(S_i) \leq d_{-e}(S_\xi) - d_{-e}(H_i) + d_{-e}(H'_i) \leq \rho(1+\xi)^2 c'(OPT') - d_{-e}(H'_{i-1}) + d_{-e}(H'_i). \tag{10}$$

[5] We observe that the existence of H_i is guarantee by the fact that $S_\xi + e$ is a Steiner tree of I_n: in fact, $S_\xi = S_{u,\xi} + S_{v,\xi}$ is a forest of two trees such that $u \in S_{u,\xi}$ and $v \in S_{v,\xi}$.

As a consequence, if for every $i \in \{1, \ldots, \ell\}$ we substitute the term $c'(S_i)$ in (7) with the corresponding upper bound in (10), and use (5) to derive $d_{-e}(H'_\ell) \leq d_{-e}(S'_\xi) \leq (1 + \xi)c'(OPT')$, we obtain

$$c'(S') \leq \frac{1}{\ell} \sum_{i=1}^{\ell} c'(S_i) \leq \rho(1+\xi)^2 c'(OPT') + \frac{1+\xi}{\ell} c'(OPT') \leq (\rho + \epsilon)c'(OPT'),$$

where last inequality holds by the choice of ξ and ℓ, and because $\rho \leq 2$ and $\epsilon \leq 1$. This completes the proof. ◀

Abstract

A common way to accelerate shortest path algorithms on graphs is the use of a bidirectional search, which simultaneously explores the graph from the start and the destination. It has been observed recently that this strategy performs particularly well on scale-free real-world networks. Such networks typically have a heterogeneous degree distribution (e.g., a power-law distribution) and high clustering (i.e., vertices with a common neighbor are likely to be connected themselves). These two properties can be obtained by assuming an underlying hyperbolic geometry.

To explain the observed behavior of the bidirectional search, we analyze its running time on hyperbolic random graphs and prove that it is $\tilde{\mathcal{O}}(n^{2-1/\alpha} + n^{1/(2\alpha)} + \delta_{\max})$ with high probability, where $\alpha \in (0.5, 1)$ controls the power-law exponent of the degree distribution, and $\delta_{\max}$ is the maximum degree. This bound is sublinear, improving the obvious worst-case linear bound. Although our analysis depends on the underlying geometry, the algorithm itself is oblivious to it.

1 Introduction

Finding shortest paths between nodes in a network is among the most basic graph problems. Besides being of independent interest, many algorithms use shortest path queries as a subroutine. On unweighted graphs, such queries can be answered in linear time using a *breadth-first search (BFS)*. Though this is optimal in the worst case, it is not efficient enough when dealing with large networks or problems involving many shortest path queries.

A way to heuristically improve the run time, is to use a *bidirectional BFS* [16]. It runs two searches, simultaneously exploring the graph from the start and the destination. The shortest path is then found once the two search spaces touch. Though this heuristic does not improve the worst-case running time, recent experiments by Borassi and Natale [6] suggest that it achieves a significant speedup on scale-free real-world networks. They also try to explain the observed run times by proving that the bidirectional BFS runs in sublinear expected time on different random graph models. Though this is a great result, we do not think that it provides a satisfying explanation for the good practical performance for two reasons.

First, the bidirectional search performs particularly well on networks with a heterogeneous degree distribution (i.e., few vertices with high degree, many vertices with low degree). A common assumption is that the degree distribution follows a *power-law*, i.e., the number of vertices of degree k is proportional to $k^{-\beta}$. The constant β is called the *power-law exponent* and is typically between 2 and 3. The above mentioned proof predicts a shorter execution time for homogeneous graphs (e.g., for Erdős-Rényi graphs) than for heterogeneous graphs (e.g., for Chung-Lu graphs), which contradicts the observed behavior.

Second, the proof relies on the independence of edges. In fact, this is the only assumption, which makes the same proof hold for multiple different models. However, this assumption is unrealistic for most real-world networks. The dependence between edges is typically measured with the *clustering coefficient*. The *local clustering coefficient* of a vertex v is the probability that two randomly chosen neighbors of v are adjacent. The clustering coefficient of the graph is the average of all local coefficients. The assumption of independent edges thus implies a clustering coefficient close to 0. In contrast, the three best performing instances in [6, Figure 2] have comparatively high clustering coefficients 0.47, 0.49, and 0.57 [14].

In this paper, we analyze the bidirectional BFS on hyperbolic random graphs, which are generated by randomly placing vertices in the hyperbolic plane and connecting each pair that is geometrically close. This model was introduced by Krioukov et al. [13] with the aim to generate graphs that closely resemble real-world networks. Hyperbolic random graphs in particular have a power-law degree distribution and high clustering [12, 13]. Moreover, as these properties emerge naturally from the hyperbolic geometry, the model is conceptually simple, which makes it accessible to mathematical analysis. It has thus gained popularity in different research areas and has been studied from different perspectives.

From the network-science perspective, the goal is to gather knowledge about real-world networks. This is for example achieved by assuming that a real-world network has a hidden underlying hyperbolic geometry, which can be revealed by embedding it into the hyperbolic plane [1, 5]. From the mathematical perspective, the focus lies on studying structural properties. Beyond degree distribution and clustering [12], the diameter [11], the component structure [4], the clique size [3], and separation properties [2] have been studied successfully.

Finally, there is the algorithmic perspective, which is the focus of this paper. Usually algorithms are analyzed by proving worst-case running times. Though this is the strongest possible performance guarantee, it is rather pessimistic as practical instances rarely resemble worst-case instances. Techniques leading to a more realistic analysis include parameterized

or average case complexity. The latter is based on the assumption that instances are drawn from a certain probability distribution. Thus, its explanatory power depends on how realistic the distribution is. For hyperbolic random graphs, the maximum clique can be computed in polynomial time [3], and there are several algorithmic results based on the fact that hyperbolic random graphs have sublinear tree width [2]. Moreover, there is a compression algorithm that can store a hyperbolic random graph using on $O(n)$ bits in expectation [8, 15]. Finally, a close approximation of the shortest path between two nodes can be found using greedy routing, which visits only $\mathcal{O}(\log \log n)$ nodes for most start-destination pairs [9]. The downside of all these algorithms is that they need to know the underlying geometry, i.e., the coordinates of each vertex. Unfortunately, this is a rather unrealistic assumption for real-world networks. To the best of our knowledge, we present the first analysis of an algorithm on hyperbolic random graphs that is oblivious to the underlying geometry.

Contribution and Outline. After an introduction to hyperbolic random graphs in Section 2, we analyze the bidirectional BFS in Section 3. We first prove in Section 3.1 that a certain greedy strategy for deciding when to alternate between the forward and the backward search is not much worse than any other alternation strategy. We note that this result is interesting in its own right and does not depend on the input. In Section 3.2 we analyze the bidirectional BFS on hyperbolic random graphs. We show that, for any pair of vertices, it computes a shortest path in $\tilde{\mathcal{O}}(n^{2-1/\alpha} + n^{1/(2\alpha)} + \delta_{\max})$ time with high probability[1], where $\alpha \in (0.5, 1)$ controls the power-law exponent and $\delta_{\max}$ is the maximum degree of the graph (which is $\tilde{\mathcal{O}}(n^{1/(2\alpha)})$ almost surely [12]). We note that drawing the hyperbolic random graph is the only random choice here; once this is done our analysis always assumes the worst case. Thus, the bound in particular holds for every start-destination pair. Section 4 contains concentration bounds that were left out in Section 3 to improve readability. In Section 5, we conclude by comparing our theoretical results to empirical data.

2 Preliminaries

Let $G = (V, E)$ be an undirected, unweighted, and connected graph. We denote the number of vertices and edges with n and m, respectively. With $N(v) = \{w \in V \mid \{v, w\} \in E\}$, we denote the *neighborhood* of a vertex $v \in V$. The *degree* of v is $\deg(v) = |N(v)|$. We denote the maximum degree with $\delta_{\max}$. The soft O-notation $\tilde{\mathcal{O}}$ suppresses poly-logarithmic factors.

The Hyperbolic Plane. The major difference between hyperbolic and Euclidean geometry is the exponential expansion of the hyperbolic plane. A circle of radius r has area $2\pi(\cosh(r)-1)$ and circumference $2\pi \sinh(r)$, with $\cosh(x) = (e^x + e^{-x})/2$ and $\sinh(x) = (e^x - e^{-x})/2$, both growing as $e^x/2 \pm o(1)$. To identify points, we use radial coordinates with respect to a designated origin O and a ray starting at O. A point p is uniquely determined by its *radius* r, which is the distance to O, and the *angle* (or *angular coordinate*) φ between the reference ray and the line through p and O. In illustrations, we use the *native representation*, obtained by interpreting the hyperbolic coordinates as polar coordinates in the Euclidean plane, see Figure 1 (left). Due to the exponential expansion, line segments bend towards the origin O. Let $p_1 = (r_1, \varphi_1)$ and $p_2 = (r_2, \varphi_2)$ be two points. The *angular distance* between p_1 and p_2 is the angle between the rays from the origin through p_1 and p_2. Formally, it is

[1] *With high probability* and *almost surely* refer to probabilities $1 - O(1/n)$ and $1 - o(1)$, respectively.

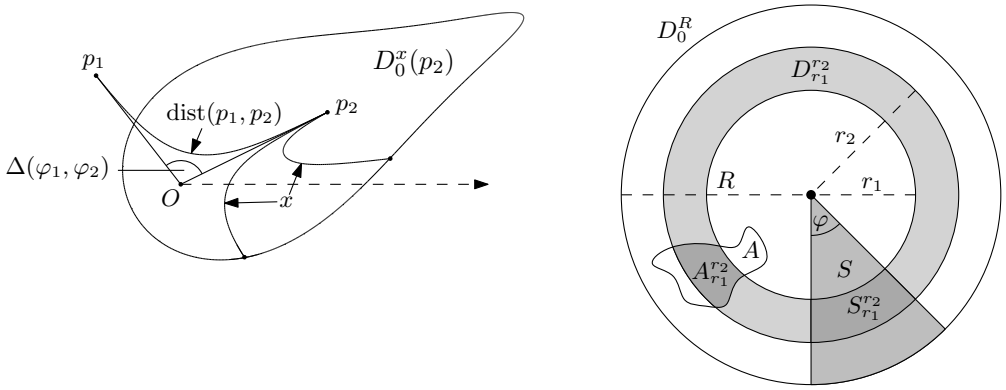

Figure 1 Left: A circle and several line segments in the native representation of the hyperbolic plane. A disk of radius x is centered at p_2. Right: Geometric shapes and their intersections.

$\Delta(\varphi_1, \varphi_2) = \pi - |\pi - |\varphi_1 - \varphi_2||$. The hyperbolic distance $\text{dist}(p_1, p_2)$ is given by

$$\cosh(\text{dist}(p_1, p_2)) = \cosh(r_1)\cosh(r_2) - \sinh(r_1)\sinh(r_2)\cos(\Delta(\varphi_1, \varphi_2)).$$

Note how the angular coordinates make simple definitions cumbersome as angles are considered modulo 2π, leading to a case distinction depending on where the reference ray lies. Whenever possible, we implicitly assume that the reference ray was chosen such that we do not have to compute modulo 2π. Thus, the above angular distance between p_1 and p_2 simplifies to $|\varphi_1 - \varphi_2|$. A third point $p = (r, \varphi)$ *lies between* p_1 and p_2 if $\varphi_1 \leq \varphi \leq \varphi_2$ or $\varphi_2 \leq \varphi \leq \varphi_1$.

Throughout the paper, we regularly use different geometric shapes, which are mostly based on disks centered at the origin O, as can be seen in Figure 1 (right). With $D_{r_1}^{r_2}$ we denote the set of points that have radius between r_1 and r_2. Note that D_0^r is the disk of radius r centered at O. The restriction of a disk D_0^r to all points with angular coordinates in a certain interval is called *sector*, which we usually denote with the letter S. Its *angular width* is the length of this interval. For an arbitrary set of points A, $A_{r_1}^{r_2}$ denotes the restriction of A to points with radii in $[r_1, r_2]$, i.e., $A_{r_1}^{r_2} = A \cap D_{r_1}^{r_2}$.

Hyperbolic Random Graphs. A *hyperbolic random graph* is generated by drawing n points uniformly at random in a disk of the hyperbolic plane and connecting pairs of points whose distance is below a threshold. More precisely, the model depends on two parameters C and α. The generated graphs have a power-law degree distribution with power-law exponent $\beta = 2\alpha + 1$ and with an average degree depending on C. The n points are sampled within the disk D_0^R of radius $R = 2\log n + C$. For each vertex, the angular coordinate is drawn uniformly from $[0, 2\pi]$. The radius r is sampled according to the probability density function

$$f(r) = \frac{1}{2\pi}\frac{\alpha\sinh(\alpha r)}{\cosh(\alpha R) - 1} = \Theta(e^{\alpha(r-R)}), \tag{1}$$

for $r \in [0, R]$. For $r > R$, $f(r) = 0$. Two vertices are connected by an edge if and only if their hyperbolic distance is less than R. The above probability distribution is a natural choice as the probability for a vertex ending up in a certain region is proportional to its area (at least for $\alpha = 1$). Note that the exponential growth in r reflects the fact that the area of a disk grows exponentially with the radius. It follows that a hyperbolic random graph typically has few vertices with high degree close to the center of the disk and many vertices with low degree near its boundary. The following lemma is common knowledge; see the full version of the paper for a proof.

▶ **Lemma 1.** *Let G be a hyperbolic random graph. Furthermore, let v_1, v_2 be two nodes with radii $r_1 \leq r_2 \leq R$, respectively, and with the same angular coordinate. Then $N(v_2) \subseteq N(v_1)$.*

Given two vertices with fixed radii r_1 and r_2, their hyperbolic distance grows with increasing angular distance. The maximum angular distance such that they are still adjacent [12, Lemma 3.1] is

$$\theta(r_1, r_2) = \arccos\left(\frac{\cosh(r_1)\cosh(r_2) - \cosh(R)}{\sinh(r_1)\sinh(r_2)}\right) = 2e^{\frac{R-r_1-r_2}{2}}(1 + \Theta(e^{R-r_1-r_2})). \tag{2}$$

The probability that a sampled node falls into a given subset $A \subseteq D_0^R$ of the disk is given by its probability measure $\mu(A) = \int_A f(r)\,\mathrm{d}r$, which can be thought of as the area of A. There are two types of regions we encounter regularly: disks D_0^r with radius r centered at the origin and disks $D_0^R(r, \varphi)$ of radius R centered at a point (r, φ). Note that the measure of $D_0^R(r, \varphi)$ gives the probability that a random vertex lies in the neighborhood of a vertex with position (r, φ). Gugelmann et al. [12, Lemma 3.2] showed that

$$\mu(D_0^r) = e^{\alpha(r-R)}(1 + o(1)), \text{ and} \tag{3}$$

$$\mu(D_0^R(r, \varphi)) = \Theta(e^{-r/2}). \tag{4}$$

For a given region $A \subseteq D_0^R$ of the disk, let $X_1, \dots, X_n$ be random variables with $X_i = 1$ if $i \in A$ and $X_i = 0$ otherwise. Then $X = \sum_{i=1}^n X_i$ is the number of vertices lying in A. By the linearity of expectation, we obtain that the expected number of vertices in A is $\mathbb{E}[X] = \sum_{i=1}^n \mathbb{E}[X_i] = n\mu(A)$. To bound the number of vertices in A *with high probability*, we regularly use the following Chernoff bound.

▶ **Theorem 2** (Chernoff Bound [10, A.1])**.** *Let $X_1, \dots, X_n$ be n independent random variables with $X_i \in \{0, 1\}$ and let X be their sum. For any $\delta > 0$,*

$$\Pr[X > (1 + \delta)\mathbb{E}[X]] < \exp\left(-\frac{\delta^2}{3}\mathbb{E}[X]\right).$$

▶ **Corollary 3.** *Let $X_1, \dots, X_n$ be n independent random variables with $X_i \in \{0, 1\}$ and let X be their sum. Let $f(n) = \Omega(\log n)$. If $f(n)$ is an upper bound for $\mathbb{E}[X]$, then for any constant c there is a constant c' such that $X \leq c' f(n)$ holds with probability $1 - \mathcal{O}(n^{-c})$.*

3 Bidirectional BFS

In this section, we analyze the running time of the bidirectional BFS on hyperbolic random graphs. Our results are summarized in the following main theorem.

▶ **Theorem 4.** *Let G be a hyperbolic random graph. With high probability the shortest path between any two vertices in G can be computed in $\tilde{\mathcal{O}}(n^{2-1/\alpha} + n^{1/(2\alpha)} + \delta_{\max})$ time.*

To prove this, we make use of the hyperbolic geometry in the following way; see Figure 2. As long as the two searches visit only low-degree vertices, all explored vertices lie within a small region, i.e., the searches operate locally. Once the searches visit high-degree vertices closer to the center of the hyperbolic disk (gray area in Figure 2), it takes only few steps to complete the search, as hyperbolic random graphs have a densely connected core. Thus, we split our analysis in two phases: a first phase in which both searches advance towards the center and a second phase in which both searches meet in the center. Note that this strategy

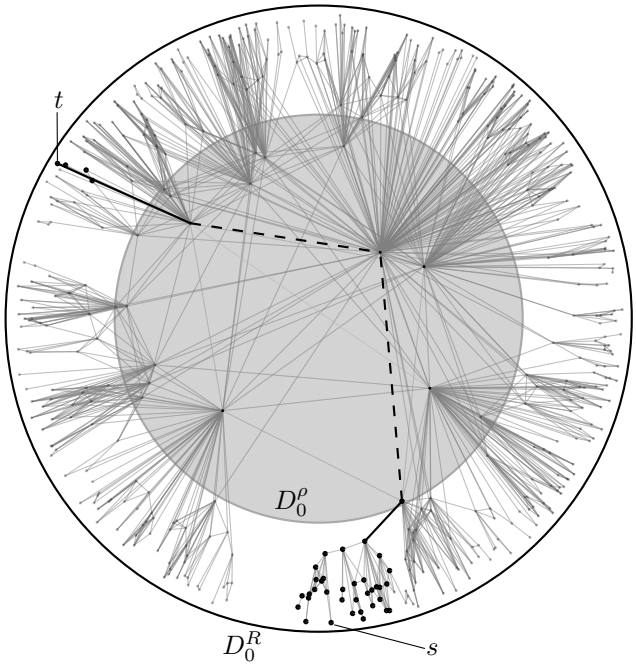

Figure 2 Visualization of the two phases of each BFS in a hyperbolic random graph. Nodes that are visited during the first phase are bold. The bold black edges denote the first encounter of a node in the inner disk D_0^ρ (gray region). This corresponds to the first step in the second phase. The last step then leads to a common neighbor via the dashed edges.

assumes that we know the coordinates of the vertices as we would like to stop a search once it reached the center. To resolve this issue, we first show in Section 3.1 that there exists an alternation strategy that is oblivious to the geometry but performs not much worse than any other alternation strategy. We note that this result is independent of hyperbolic random graphs and thus interesting in its own right. Afterwards, in Section 3.2, we actually analyze the bidirectional search in hyperbolic random graphs.

3.1 Bidirectional Search and Alternation Strategies

In an unweighted and undirected graph $G = (V, E)$, a BFS finds the shortest path between two vertices $s, t \in V$ by starting at s and exploring the graph level after level, where the ith level L_i^s contains the vertices with distance i to s. More formally, the BFS starts with the set $L_0^s = \{s\}$ on level 0. Assuming the first i levels $L_1^s, \dots, L_i^s$ have been computed already, one obtains the next level L_{i+1}^s as the set of neighbors of vertices in level L_i^s that are not contained in earlier layers. Computing L_{i+1}^s from L_i^s is called an *exploration step*, which is obtained by *exploring the edges* between vertices in L_i^s and L_{i+1}^s.

The bidirectional BFS runs two BFSs simultaneously. The *forward search* starts at s and the *backward search* starts at t. The shortest path between the two vertices can then be obtained, once the search spaces of the forward and backward search touch. Since the two searches cannot actually be run simultaneously, they alternate depending on their progress. When exactly the two searches alternate is determined by the *alternation strategy*. Note that we only swap after full exploration steps, i.e., we never explore only half of level i of one search before continuing with the other. This has the advantage that we can be certain to know the shortest path once a vertex is found by both searches.

In the following we define the *greedy alternation strategy* as introduced by Borassi and Natale [6] and show that it is not much worse than any other alternation strategy. Assume the latest layers of the forward and backward searches are L_i^s and L_j^t, respectively. Then the next exploration step of the forward search would cost time proportional to $c_i^s := \sum_{v \in L_i^s} \deg(v)$, while the cost for the backward search is $c_j^t := \sum_{v \in L_j^t} \deg(v)$. The *greedy alternation strategy* then greedily continues with the search that causes the fewer cost in the next exploration step, i.e., it continues with the forward search if $c_i^s \leq c_j^t$ and with the backward search otherwise.

▶ **Theorem 5.** *Let G be a graph with diameter d. If there exists an alternation strategy such that the bidirectional BFS explores $f(n)$ edges, then the bidirectional BFS with greedy alternation strategy explores at most $d \cdot f(n)$ edges.*

Proof. Let A be the alternation strategy that explores only $f(n)$ edges. First note that the number of explored edges only depends on the number of layers explored by the two different searches and not on the actual order in which they are explored. Thus, if the greedy alternation strategy is different from A, we can assume without loss of generality that the greedy strategy performed more exploration steps in the forward search and fewer in the backward search compared to A. Let c^s and c^t be the number of edges explored by the forward and backward search, respectively, when using the greedy strategy. Moreover, let j be the last layer of the backward search (which is actually not explored) and, accordingly, let c_j^t be the number of edges the next step in the backward search would have explored. Then $c^t + c_j^t \leq f(n)$ as, when using A, the backward search still explores layer j. Moreover, the forward search with the greedy strategy explores at most $c^t + c_j^t$ (and therefore at most $f(n)$) edges in each step, as exploring the backward search would be cheaper otherwise. Consequently, each step in the forward and backward search costs at most $f(n)$. As there are at most d steps in total, we obtain the claimed bound. ◀

3.2 Bidirectional Search in Hyperbolic Random Graphs

To analyze the size of the search space of the bidirectional BFS in hyperbolic random graphs, we separate the whole disk D_0^R into two partitions. One is the *inner disk* D_0^ρ centered at the origin. Its radius ρ is chosen in such a way that any two vertices in D_0^ρ have a common neighbor with high probability. The second part is the *outer band* D_ρ^R, the remainder of the whole disk. A single BFS now explores the graph in two phases. In the first phase, the BFS explores vertices in the outer band. The phase ends, when the next vertex to be encountered lies in the inner disk. Once both BFSs completed the first phase, they only need at most two more steps for their search spaces to share a vertex. One step to encounter the vertex in the inner disk and another step to meet at their common neighbor that any two vertices in the inner disk have with high probability; see Figure 2.

For our analysis we assume an alternation strategy in which each search stops once it explored one additional layer after finding the first vertex in the inner disk D_0^ρ. Of course, this cannot be implemented without knowing the underlying geometry of the network. However, by Theorem 5 the search space explored using the greedy alternation strategy is only a poly-logarithmic factor larger, as the diameter of hyperbolic random graphs is poly-logarithmic with high probability [11]. The following lemma shows for which choice of ρ the above sketched strategy works.

▶ **Lemma 6.** *Let G be a hyperbolic random graph. With high probability, G contains a vertex that is adjacent to every other vertex in D_0^ρ, for $\rho = \frac{1}{\alpha}(\log n - \log\log n)$.*

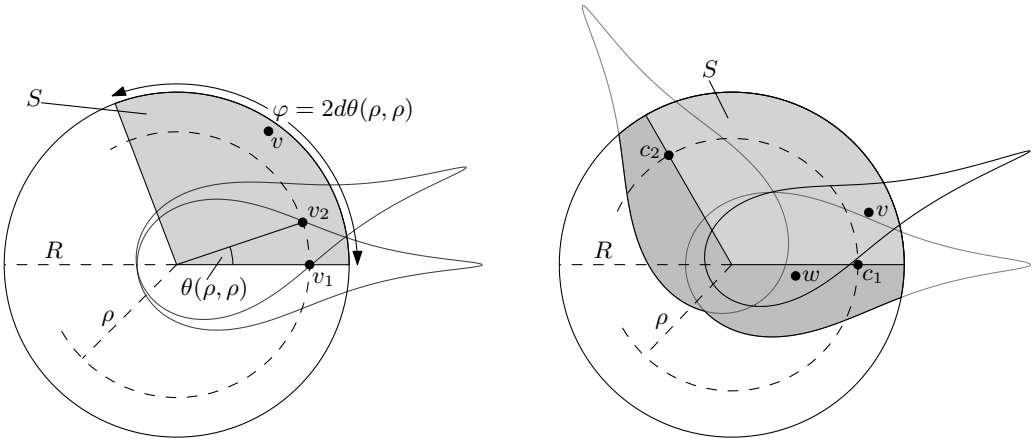

Figure 3 Left: The sector S of angular width φ contains the search space of a BFS in the outer band D_ρ^R starting at v. The vertices v_1 and v_2 are at maximum angular distance to still be adjacent. Right: Neighbor w of vertex v is in S (gray) or a neighbor of c_1 or c_2 (dark gray).

Proof. Assume v is a vertex with radius at most $R-\rho$. Note that the distance between two points is upper bounded by the sum of their radii. Thus, every vertex in D_0^ρ has distance at most R to v, and is therefore adjacent to v. Hence, to prove the claim, it suffices to show the existence of this vertex v with radius at most $R-\rho$. As described in Section 2, the probability for a single vertex to have radius at most $R-\rho$ is given by the measure $\mu(D_0^{R-\rho})$. Using Equation (3) we obtain

$$\begin{aligned}\mu(D_0^{R-\rho}) &= e^{-\alpha\rho}(1+o(1)) \\ &= \frac{\log n}{n}(1+o(1)).\end{aligned}$$

Thus, the probability that none of the n vertices lies in $D_0^{R-\rho}$ is $O((1-\frac{\log n}{n})^n) = O(\frac{1}{n})$. Hence, there is at least one vertex with radius at most $R-\rho$ with high probability. ◀

In the following, we first bound the search space explored in the first phase, i.e., before we enter the inner disk D_0^ρ. Afterwards we bound the search space explored in the second phase, which consists of two exploration steps. The first one to enter D_0^ρ and the second one to find a common neighbor, which exists due to Lemma 6.

3.2.1 Search Space in the First Phase

To bound the size of the search space in the outer band, we make use of the network geometry in the following way. For two vertices in the outer band to be adjacent, their angular distance has to be small. Moreover, the number of exploration steps is bounded by the diameter of the graph. Thus, the maximum angular distance between vertices visited in the first phase cannot be too large. Note that following lemma restricts the search to a sublinear portion of the disk, which we later use to show that also the number of explored edges is sublinear.

▶ **Lemma 7.** *With high probability, all vertices a BFS on a hyperbolic random graph explores before finding a vertex with radius at most* $\rho = \frac{1}{\alpha}(\log n - \log\log n)$ *lie within a sector of angular width* $\tilde{\mathcal{O}}(n^{1-1/\alpha})$.

Proof. For an illustration of the proof see Figure 3 (left). Recall from Section 2 that $\theta(r_1, r_2)$ denotes the maximum angular distance between two vertices of radii r_1 and r_2 such that

they are still adjacent. As this angle increases with decreasing radii, $\theta(r_1, r_2) \leq \theta(\rho, \rho)$ holds for all vertices in the outer band D_ρ^R.

Now assume we start a BFS at a vertex $v \in D_\rho^R$ and perform d exploration steps without leaving the outer band D_ρ^R. Then no explored vertex has angular distance more than $d\theta(\rho, \rho)$ from v. Thus, the whole search space lies within a disk sector of angular width $2d\theta(\rho, \rho)$. The number of steps d is at most poly-logarithmic as the diameter of a hyperbolic random graph is poly-logarithmic with high probability [11]. Using Equation (2) for $\theta(\rho, \rho)$, we obtain

$$\begin{aligned}\theta(\rho, \rho) &= 2e^{\frac{R-2\rho}{2}}(1 + \Theta(e^{R-2\rho})) \\ &= 2e^{C/2}n^{1-1/\alpha}\log^{1/\alpha} n(1 + \Theta((\log n/n^{1-\alpha})^{2/\alpha}) \\ &= \mathcal{O}(n^{1-1/\alpha}\log^{1/\alpha} n),\end{aligned}$$

which proves the claimed bound. ◀

Note that the expected number of vertices in a sector S of angular width φ is linear in $n\varphi$ due to the fact that the angular coordinate of each vertex is chosen uniformly at random. Thus, Lemma 7 already shows that the expected number of vertices visited in the first phase of the BFS is $\tilde{\mathcal{O}}(n^{2-1/\alpha})$, which is sublinear in n. It is also not hard to see that this bound holds with high probability (see Corollary 3). To also bound the number of explored edges, we sum the degrees of vertices in S. It is not surprising that this yields the same asymptotic bound in expectation, as the expected average degree in a hyperbolic random graph is constant. However, showing that this value is concentrated around its expectation is more involved. Though we can use techniques similar to those that have been used to show that the average degree of the whole graph is constant with high probability [7, 12], the situation is complicated by the restriction to a sublinear portion of the disk. Nonetheless, we obtain the following theorem.

▶ **Theorem 8.** *Let G be a hyperbolic random graph. The degrees of vertices in every sector of angular width φ sum to $\tilde{\mathcal{O}}(\varphi n + \delta_{\max})$ with high probability if $\varphi = \Omega(n^{1-1/\alpha}\log n)$.*

We note that $\delta_{\max}$ has to be included here, as the theorem states a bound for every sector, and thus in particular for sectors containing the vertex of maximum degree. Recall, that $\delta_{\max} = \tilde{\mathcal{O}}(n^{1/(2\alpha)})$ holds almost surely [12]. Moreover, we note that the condition $\varphi = \Omega(n^{1-1/\alpha}\log n)$ is crucial for our proof, i.e., the angular width of the sector has to be sufficiently large for the concentration bound to hold. Fortunately, this matches the bound found in Lemma 7. As the proof for Theorem 8 is rather technical, we defer it to Section 4. Together with Lemma 7, we obtain the following corollary.

▶ **Corollary 9.** *On a hyperbolic random graph, the first phase of the bidirectional search explores with high probability only $\tilde{\mathcal{O}}(n^{2-1/\alpha} + \delta_{\max})$ many edges.*

3.2.2 Search Space in the Second Phase

The first phase of the BFS is completed when the next vertex to be encountered lies in the inner disk. Thus, the second phase consists of only two exploration steps. One step to encounter the vertex in the inner disk and another step to meet the other search. Thus, to bound the running time of the second phase, we have to bound the number of edges explored in these two exploration steps. To do this, let V_1 be the set of vertices encountered in the first phase. Recall that all these vertices lie within a sector S of angular width $\varphi = \tilde{\mathcal{O}}(n^{1-1/\alpha})$ (Lemma 7). The number of explored edges in the second phase is then bounded by the sum of

degrees of all neighbors $N(V_1)$ of vertices in V_1. To bound this sum, we divide the neighbors of V_1 into two categories: $N(V_1) \cap S$ and $N(V_1) \setminus S$. Note that we already bounded the sum of degrees of vertices in S for the first phase (see Theorem 8), which clearly also bounds this sum for $N(V_1) \cap S$. Thus, it remains to bound the sum of degrees of vertices in $N(V_1) \setminus S$.

To bound this sum, we introduce two *hypothetical vertices* (i.e., vertices with specific positions that are not actually part of the graph) c_1 and c_2 such that every vertex in $N(V_1) \setminus S$ is a neighbor of c_1 or c_2. Then it remains to bound the sum of degrees of neighbors of these two vertices. To define c_1 and c_2, recall that the first phase was not only restricted to the sector S but also to points with radius greater than ρ, i.e., all vertices in V_1 lie within S_ρ^R. The hypothetical vertices c_1 and c_2 are basically positioned at the corners of this region, i.e., they both have radius ρ, and they assume the maximum and minimum angular coordinate within S, respectively. Figure 3 (right) shows these positions. We obtain the following.

▶ **Lemma 10.** *Let G be a hyperbolic random graph and let $v \in S_\rho^R$ for a sector S. Then, every neighbor of v lies in S or is a neighbor of one of the hypothetical vertices c_1 or c_2.*

Proof. Let $v = (r, \varphi) \in S_\rho^R$ and $w \in N(v) \setminus S$. Without loss of generality, assume that c_1 lies between v and w, as is depicted in Figure 3 (right). Now consider the point $v' = (\rho, \varphi)$ obtained by moving v to the same radius as c_1. According to Lemma 1 we have $N(v) \subseteq N(v')$. In particular, it holds that $w \in N(v')$ and therefore $\operatorname{dist}(v', w) \leq R$. Since v' and c_1 have the same radial coordinate and c_1 is between v' and w, it follows that $\operatorname{dist}(c_1, w) \leq R$. ◀

By the above argumentation, it remains to sum the degrees of neighbors of c_1 and c_2. It is not hard to see that the degrees of the neighbors of a node with radius r sum to $\mathcal{O}(ne^{-(\alpha-1/2)r})$ in expectation. For c_1 and c_2, which both have radius ρ, the degrees of their neighbors thus sum to $\tilde{\mathcal{O}}(n^{1/(2\alpha)})$ in expectation. Note that this matches the claimed bound in Theorem 4. However, to actually prove Theorem 4, we need to show that this bound holds with high probability for every possible angular coordinates of c_1 and c_2. Again, showing this concentration bound is rather technical and thus deferred to Section 4. Together with the bounds on the sum of degrees in a sector of width $\varphi = \tilde{\mathcal{O}}(n^{1-1/\alpha})$ (Theorem 8), we obtain the following corollary, which concludes the proof of Theorem 4.

▶ **Corollary 11.** *On a hyperbolic random graph, the second phase of the bidirectional search explores with high probability only $\tilde{\mathcal{O}}(n^{2-1/\alpha} + n^{1/(2\alpha)} + \delta_{\max})$ many edges.*

4 Concentration Bounds for the Sum of Vertex Degrees

Here we prove the concentration bounds that were announced in the previous section. For the first phase, we already know that the search space is contained within a sector S of sublinear width (Lemma 7). Thus, the running time in the first phase is bounded by the sum of vertex degrees in this sector. Moreover, all edges explored in the second phase also lie within the same sector S or are incident to neighbors of the two hypothetical vertices c_1 and c_2 (Lemma 10). Thus, the running time of the second phase is bounded by the sum of vertex degrees in S and in the neighborhood of c_1 and c_2. We start by proving Theorem 8 to bound the sum of degrees in a given sector. Afterwards, we consider the neighborhood of c_1 and c_2. To improve readability, we restate Theorem 8 here.

▶ **Theorem 8.** *Let G be a hyperbolic random graph. The degrees of vertices in every sector of angular width φ sum to $\tilde{\mathcal{O}}(\varphi n + \delta_{\max})$ with high probability if $\varphi = \Omega(n^{1-1/\alpha} \log n)$.*

Due to space constraints, we only sketch the proof by explaining the overall strategy and stating the core lemmas. A full proof can be found in the full version of the paper. The proof of Theorem 8 basically works as follows. For each degree, we want to compute the number of vertices of this degree and multiply it with the degree. As all vertices with a certain degree have roughly the same radius, we can separate the disk into small bands, one for each degree. Then summing over all degrees comes down to summing over all bands and multiplying the number of vertices in this band with the corresponding degree. If we can prove that each of these values is highly concentrated (i.e., probability $1 - O(n^{-2})$), we obtain that the sum is concentrated as well (using the union bound). Unfortunately, this fails in two situations. For large radii the degree is too small to be concentrated around its expected value. Moreover, for small radii, the number of vertices within the corresponding band (i.e., the number of high degree vertices) is too small to be concentrated.

To overcome this issue, we partition the sector S into three parts. An inner part $S_0^{\rho_1}$, containing all points of radius at most ρ_1, an outer part $S_{\rho_2}^R$, containing all points of radius at least ρ_2, and a central part $S_{\rho_1}^{\rho_2}$, containing all points in between. We choose ρ_2 in such a way that the smallest degree in the central part $S_{\rho_1}^{\rho_2}$ is $\Omega(\log n)$, which ensures that all vertex degrees in $S_{\rho_1}^{\rho_2}$ are concentrated. Moreover, we choose ρ_1 such that the number of vertices with maximum degree in $S_{\rho_1}^{\rho_2}$ is $\Omega(\log n)$, which ensures that for each vertex degree, the number of vertices with this degree is concentrated. To achieve this, we set

$$\rho_1 = 2\log n - \frac{\log(\varphi n) - \log\log n}{\alpha} \quad \text{and} \quad \rho_2 = \frac{\log n}{\alpha},$$

and show concentration separately for the three parts.

The Inner Part of a Sector. The inner part $S_0^{\rho_1}$ contains vertices of high degree. It is not hard to see that there are only poly-logarithmically many vertices with radius at most ρ_1. Thus, we obtain the following lemma.

▶ **Lemma 12.** *Let G be a hyperbolic random graph. For every sector S of angular width φ, the degrees of the nodes in $S_0^{\rho_1}$ sum to $\tilde{\mathcal{O}}(\delta_{\max})$ with high probability.*

The Central Part of a Sector. For each possible vertex degree k, we want to compute the number of vertices with this degree in the central part $S_{\rho_1}^{\rho_2}$. First note, that by Equation (4) a vertex with fixed radius has expected degree $\Theta(k)$ if this radius is $2\log(n/k)$. Motivated by this, we define $r_k = 2\log(n/k)$. To bound the sum of degrees in the central part $S_{\rho_1}^{\rho_2}$, we use that vertices with radius significantly larger than r_k also have a smaller degree. More formally, one can show that there exists a constant ε such that all vertices of degree k have radius at most $r_k + \varepsilon$ with high probability. From this, we can derive a bound $g(k)$ for the number of vertices with degree at least k by bounding the number of vertices with radius at most $r_k + \varepsilon$. Then summing the vertex degrees boils down to integrating over $g(k)$, which yields the following lemma.

▶ **Lemma 13.** *Let G be a hyperbolic random graph. For every sector S of angular width φ, the degrees of the nodes in $S_{\rho_1}^{\rho_2}$ sum to $\mathcal{O}(\varphi n^{3-2\alpha-1/(2\alpha)})$ with high probability.*

Note that $3 - 2\alpha - 1/(2\alpha) \leq 1$ for $\alpha \in [0.5, 1]$. Thus, the lemma in particular shows that $S_{\rho_1}^{\rho_2}$ contains at most $\mathcal{O}(\varphi n)$ edges, as claimed in Theorem 8.

The Outer Part of a Sector. The outer part $S_{\rho_2}^R$ contains many vertices, all of which have low expected degree. To bound their sum with high probability, we consider the coordinates of the vertices as random variables and the sum of their degrees as a function in these

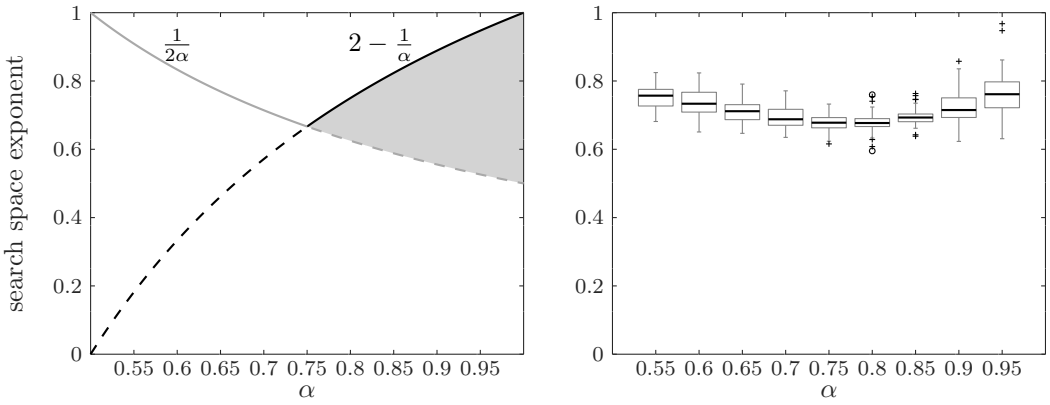

Figure 4 Left: The exponent of our theoretical bound depending on α. Right: The corresponding empirically measured search spaces. The data was obtained by generating 20 hyperbolic random graphs with average degree roughly 8 for each shown α and each $n \in \{100\text{k}, 200\text{k}, 300\text{k}\}$. For each graph we sampled 300k start-destination pairs and report the maximum number of edges explored in one search. The numbers are normalized with the total number of edges m of the graph such that x is plotted for a search space of size m^x.

variables. Then, our plan to show concentration is to apply a method of average bounded differences [10, Theorem 7.2]. It is based on the fact that changing the value of a single random variable (i.e., moving the position of a single vertex) has only little effect on the function (i.e., on the sum of degrees). To make sure that this is actually true, we exclude certain bad events that happen only with low probability: First, the maximum degree in $S^R_{\rho_2}$ should not be too high such that moving a single vertex can increase its degree only slightly. Second, there should not be too many vertices in $S^R_{\rho_2}$ such that the sum of degrees actually changes only for few vertices (as we do not count vertices not in $S^R_{\rho_2}$). Overall we obtain the following lemma.

▶ **Lemma 14.** *Let G be a hyperbolic random graph. For every sector S of angular width φ, the degrees of the nodes in $S^R_{\rho_2}$ sum to $\mathcal{O}(\varphi n)$ with high probability if $\varphi = \Omega(n^{1-1/\alpha} \log n)$.*

The Neigborhood of a Vertex with Radius ρ. For the second phase, we showed in Section 3.2.2 that it remains to bound the sum of degrees in the neighborhood of the corner vertices. Recall that they both have radius $\rho = 1/\alpha(\log n - \log\log n)$. Let v be a vertex with radius ρ and let A be the disk with radius R around v. Note that we already know from Section 3.2 that the maximum angular distance of neighbors of v with radius at least ρ is $\tilde{\mathcal{O}}(n^{1-1/\alpha})$. Thus, A^R_ρ is contained within a sector of this width and we can use Theorem 8 to obtain the desired bound for this part. Moreover, as in Lemma 12, we can bound the number of vertices with small radius. For all radii in between, A contains a sector of angular width $\Omega(n^{1-1/\alpha})$. It is thus not surprising that for each degree occurring in this part, the number of vertices of this degree is concentrated around its expectation. Hence, similar arguments as for Lemma 13, lead to the following lemma.

▶ **Lemma 15.** *Let G be a hyperbolic random graph and let v be a hypothetical vertex with radius $\rho = 1/\alpha(\log n - \log\log n)$ and arbitrary angular coordinate. The degrees of neighbors of v sum to $\tilde{\mathcal{O}}(n^{2-1/\alpha} + n^{1/(2\alpha)} + \delta_{\max})$ with high probability.*

5 Conclusion

To conclude, we discuss why we think that the bound $\tilde{\mathcal{O}}(n^{2-1/\alpha} + n^{1/(2\alpha)} + \delta_{\max})$ is rather tight; see Figure 4 (left) for a plot of the exponents. Clearly, the maximum degree of the graph is a lower bound, i.e., we cannot improve the $\delta_{\max}$. As $\delta_{\max} = \tilde{\Theta}(n^{1/(2\alpha)})$ holds almost surely [12], we also cannot improve below $\tilde{\mathcal{O}}(n^{1/(2\alpha)})$. For the term $n^{2-1/\alpha}$ we do not have a lower bound. Thus, the gray region in Figure 4 (left) is the only part where our bound can potentially be improved. However, by only making a single step from a vertex with radius $\rho = 1/\alpha(\log n - \log\log n)$, we can already reach vertices with angular distance $\Theta(n^{1-1/\alpha})$. Thus, it seems likely, that there exists a start-destination pair such that all vertices within a sector of this angular width are actually explored. As such a sector contains $\Theta(n^{2-1/\alpha})$ vertices, our bound seems rather tight (at least asymptotically and up to poly-logarithmic factors). For a comparison of our theoretical bound with actual search-space sizes in hyperbolic random graphs, see Figure 4.

Abstract

Given a finite set of points $P \subseteq \mathbb{R}^d$, we would like to find a small subset $S \subseteq P$ such that the convex hull of S approximately contains P. More formally, every point in P is within distance ϵ from the convex hull of S. Such a subset S is called an ϵ-hull. Computing an ϵ-hull is an important problem in computational geometry, machine learning, and approximation algorithms.

In many applications, the set P is too large to fit in memory. We consider the streaming model where the algorithm receives the points of P sequentially and strives to use a minimal amount of memory. Existing streaming algorithms for computing an ϵ-hull require $O(\epsilon^{(1-d)/2})$ space, which is optimal for a worst-case input. However, this ignores the structure of the data. The minimal size of an ϵ-hull of P, which we denote by OPT, can be much smaller. A natural question is whether a streaming algorithm can compute an ϵ-hull using only $O(\mathsf{OPT})$ space.

We begin with lower bounds that show, under a reasonable streaming model, that it is not possible to have a single-pass streaming algorithm that computes an ϵ-hull with $O(\mathsf{OPT})$ space. We instead propose three relaxations of the problem for which we can compute ϵ-hulls using space near-linear to the optimal size. Our first algorithm for points in $\mathbb{R}^2$ that arrive in random-order uses $O(\log n \cdot \mathsf{OPT})$ space. Our second algorithm for points in $\mathbb{R}^2$ makes $O(\log(\epsilon^{-1}))$ passes before outputting the ϵ-hull and requires $O(\mathsf{OPT})$ space. Our third algorithm, for points in $\mathbb{R}^d$ for any fixed dimension d, outputs, with high probability, an ϵ-hull for all but δ-fraction of directions and requires $O(\mathsf{OPT} \cdot \log \mathsf{OPT})$ space.

1 Introduction

The question addressed by this paper is: *Can we compute approximate convex hulls of data streams using near-optimal space?* Approximate convex hulls are fundamental in computational geometry, computer vision, data mining, and many more (see e.g. [2]), and computing them in a streaming manner is important in the big data regime.

Our notion of approximate convex hulls is the commonly used ϵ-hull. Let P be a set of n points in $\mathbb{R}^d$. Let $\mathcal{C}(P)$ denote the convex hull of P, the smallest convex set containing P. We want a small subset S of P such that all points in P are inside $\mathcal{C}(S)$ or within distance ϵ from $\mathcal{C}(S)$. Since every point in P can be approximated by a sparse convex combination of points in S, S is also called a generating set [7]. For an example motivation of this particular definition, consider two far-away sensors rapidly collecting data: one of positive examples and the other of negative examples; if it is expected that these should be linearly separable with some margin ϵ, then an appropriate small summary of their data would be an ϵ-hull.

ϵ-hulls and their variants have been studied extensively in the literature. In the multiplicative error variant, ϵ-kernels, one requires that any directional width (the diameter of S in a particular direction) of S is a $(1 \pm \epsilon)$ approximation to that of P. ϵ-hulls and ϵ-kernels are intimately connected: algorithms for ϵ-kernels typically apply a transformation to the data, and then use algorithms for ϵ-hulls. For more details, we refer the reader to [2].

Existing work focuses on worst case bounds, which scale poorly with the dimension d. The worst case lower bound for the size of an ϵ-hull is $\Omega(\epsilon^{-(d-1)/2})$. Recently, it has been shown in [7] that one can do much better than the worst case bound if the size of the smallest ϵ-hull for P (which we denote as OPT) is small. In their paper, they show that one can efficiently obtain S of size nearly linear in OPT and at most linear in the dimension d.

One concern of the algorithms in [7] is that they require storing all points of P in memory. The huge size of real-world datasets limits the applicability of these algorithms. A natural question to ask is whether it is possible to efficiently maintain an ϵ-hull of P when P is presented as a data stream while using a small amount of memory.

We provide both negative and positive results, summarized below.

1.1 Our Contributions

Let OPT be the optimal size of an ϵ-hull. In Section 3, we show, under a reasonable streaming model, that no streaming algorithm can achieve space bounds comparable to OPT. In particular, no streaming algorithm can have space complexity competitive with $f(\mathsf{OPT}, d)$ in 3

dimensions or higher for any $f : \mathbb{N} \times \mathbb{N} \to \mathbb{N}$. This lower bound guides us to consider variants on this problem. Note that the lower bound applies specifically to streaming algorithms; for the batch setting, [7] gives a polynomial-time algorithm that computes an ϵ-hull with space $O(d\mathsf{OPT} \log \mathsf{OPT})$.

We devise and prove the correctness of streaming algorithms for three relaxations of the problem. In Section 4, we show the first relaxation, in which the points are from $\mathbb{R}^2$ and come in a random order. In Section 5, we relax the problem (again in $\mathbb{R}^2$) by allowing the algorithm to make multiple passes over the stream. In Section 6, we show the third relaxation, in which the points come in an arbitrary order and from d-dimensional space, but we only require to approximate the convex hull in a large fraction of all directions.

In the first relaxation, our algorithm maintains an initially empty point set S. When our algorithm sees a new point p, it adds p to S if p is at least distance ϵ away from the convex hull of S. Additionally, our algorithm keeps removing points $p' \in S$ when some p' is contained inside the convex hull of $S \setminus \{p'\}$, that is, removing p' does not change the convex hull of S. Surprisingly, for any point stream P, with high probability this algorithm keeps an ϵ-hull of size $O(\mathsf{OPT} \cdot \log n)$, where n is the size of P.

In the second relaxation, we permit the algorithm to make a small number of passes over the stream. Our algorithm begins the first pass by taking $O(1)$ directions and storing the point with maximal dot product with each direction. In each of $O(\log(\frac{1}{\epsilon}))$ subsequent passes, we refine the solution by adding a new direction in sectors that incurred too much error while potentially deleting old directions that become no longer necessary. The algorithm computes an ϵ-hull of size $O(\mathsf{OPT})$.

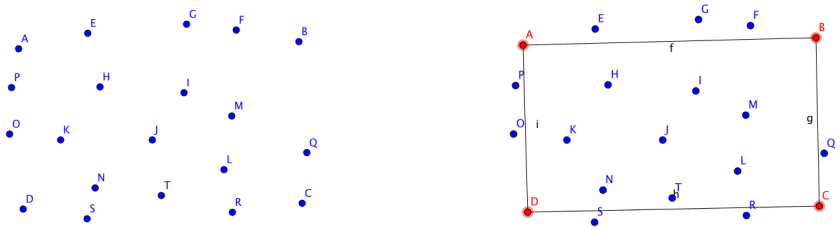
In the third relaxation, we only need to be correct in most directions (all but a δ fraction of directions). Our algorithm picks $O_d(\frac{\mathsf{OPT}}{\delta^2} \log \frac{\mathsf{OPT}}{\delta})$ random unit vectors. For each of these vectors v, we keep the point in the stream that has maximal dot product with v.

To the best of our knowledge, this is the first work that gives lower bounds and streaming algorithms for ϵ-hulls with space complexity comparable to the optimal approximation.

1.2 Related Work

Batch Algorithms. We use the term batch algorithm for an algorithm that stores the entire set of points in memory. In the batch setting, Bentley, Preparata, and Faust [5] give a $O_d(1/\epsilon^{(d-1)})$ space algorithm for computing an ϵ-hull of a set of points (assuming constant dimension d). Agarwal, Har-Peled, and Varadarajan [1] improve the result to give a $O_d(1/\epsilon^{(d-1)/2})$ space algorithm for ϵ-kernels, a multiplicative approximation of convex hulls. The running time bounds were further improved in [8, 10, 12]. Recently, Blum, Har-Peled, and Raichel [7] give the only known batch algorithms for an ϵ-hull that are competitive with the optimal ϵ-hull size of the given point set.

Streaming Algorithms with Worst Case Guarantees. Hershberger and Suri [11] and Agarwal & Yu [3] give 2D one-pass streaming algorithms for ϵ-hulls that uses $O(1/\sqrt{\epsilon})$ space. Agarwal, Har-Peled, and Varadarajan [1] give a one-pass streaming algorithm for ϵ-kernels that uses $O_d((1/\epsilon^{\frac{d-1}{2}}) \log^d n)$ space. Chan [8] removes the dependency on n and gives a streaming algorithm for ϵ-kernels that uses $O_d((1/\epsilon^{d-3/2}) \log^d 1/\epsilon)$ space. This was then improved to $O_d((1/\epsilon^{\frac{d-1}{2}}) \log \frac{1}{\epsilon})$ [13] and the time complexity was further improved by Arya and Chan [4]. Chan [9] also gives a dynamic streaming (allowing deletions in the stream) algorithm based on polynomial methods. All of these space bounds assume a constant dimension d, and focus on worst case guarantees.



(a) Set of points. **(b)** ϵ-hull in red (for suitable ϵ).

Figure 1 ϵ-hull of a set of points.

ϵ-kernels vs ϵ-hulls. Past work focuses on both ϵ-hulls and ϵ-kernels, a multiplicative error variant. ϵ-kernels can be trickier to compute, but are closely related to ϵ-hulls, and often use algorithms for ϵ-hulls as a core subroutine. We focus on ϵ-hulls, but extending this work to ϵ-kernels is an exciting (non-trivial) avenue for future research. In particular, typical reductions from ϵ-kernels to ϵ-hulls (e.g. see [2]) are not compatible with the notion of OPT.

Our Techniques. The proof of our 2D random order algorithm exposes an elegant connection between our 2D result, and a classic 1D result. Our multipass algorithm and (ϵ, δ)-hull algorithm are built on existing methods (e.g. [1, 3]) in that a core subroutine involves preserving the maximal point along certain directions.

2 Preliminaries

▶ **Definition 2.1.** For any bounded set $C \subseteq \mathbb{R}^d$, a point q is ϵ-*close* to C if $\inf_{x \in C} \|q - x\|_2 \leq \epsilon$.

▶ **Definition 2.2.** Given a set of points $P \subseteq \mathbb{R}^n$, $S \subseteq P$ is an ϵ-*hull* of P if for every $p \in P$, p is ϵ-close to $\mathcal{C}(S)$, the convex hull of S.

▶ **Definition 2.3.** Let $\mathsf{OPT}(P, \epsilon)$ denote the number of points in a (not necessarily unique) smallest ϵ-hull of P. We omit P and ϵ if it is clear from the context.

2.1 Streaming Model

Our streaming model, while simple, captures most streaming algorithms for ϵ-hulls in the literature. In our model, a streaming algorithm $\mathcal{A}$ is given ϵ in advance but not the size of the input point stream $P \in \mathbb{R}^d$. P is presented to an algorithm $\mathcal{A}$ sequentially:

$$P = (p_1, p_2, \ldots, p_t, \ldots),$$

where $p_t \in \mathbb{R}^d$ is the point coming at time t. Note that P may have duplicate points. For the ϵ-hull problem, we require Algorithm $\mathcal{A}$ to maintain a subset $S \subseteq P$. For each point $p \in P$, $\mathcal{A}$ can choose to add p to S (remembering p) or ignore p (therefore permanently forgetting p). $\mathcal{A}$ can also choose to delete points in S, in which case these points are permanently lost. After one-pass of the stream, we require S to be an ϵ-hull of the points set P. A trivial streaming algorithm could just keep all points it has seen. However, such an algorithm would not be feasible in the big data regime. Ideally, $\mathcal{A}$ should use space competitive with $\mathsf{OPT}(P, \epsilon)$.

3 Lower Bounds

An (f, r)-optimal algorithm in dimension d uses space competitive with $f(\mathsf{OPT}(P, \epsilon), d)$ and maintains an $(r\epsilon)$-hull where $r > 1$. Note that this definition is rather permissive, since it allows an arbitrary function of OPT and allows slack in ϵ as well.

▶ **Definition 3.1.** For $r \geq 1$, $f : \mathbb{N} \times \mathbb{N} \to \mathbb{N}$, we say a streaming algorithm $\mathcal{A}$ is (f, r)-optimal if given arbitrary $\epsilon > 0$ and point stream $P \subseteq \mathbb{R}^d$, $\mathcal{A}$ keeps an $(r\epsilon)$-hull of P of size at most $f(\mathsf{OPT}(P, \epsilon), d)$.

▶ **Theorem 3.2.** *For all $r \geq 1$, $d \geq 3$, $f : \mathbb{N} \times \mathbb{N} \to \mathbb{N}$, there does not exist an (f, r)-optimal streaming algorithm in $\mathbb{R}^d$.*

Proof. See Theorem A.5, Theorem A.6, and Corollary A.8 in the Appendix of the full version for the proof. Here we give high level intuition for the case $r = 1$, $d = 3$. In our proof, we assume for the sake of contradiction that there exists such a streaming algorithm A and function f. We construct 3 sequences of points P_1, P_2, P_3. Let $P_1 \circ P_2$ denote sequence P_1 followed by sequence P_2 (P_2 appended to P_1). We then show that if A keeps an ϵ-hull of size at most $f(\mathsf{OPT}(P_1 \circ P_2, \epsilon), 3)$ after receiving $P_1 \circ P_2$, then it cannot keep an ϵ-hull of size at most $f(\mathsf{OPT}(P_1 \circ P_2 \circ P_3, \epsilon), 3)$ after receiving $P_1 \circ P_2 \circ P_3$. This is a contradiction.

To do this, we ensure that $|P_2|$ is much larger than $|P_1|$ and that P_1 is an ϵ-hull of $P_1 \circ P_2$. This forces the algorithm to keep only a small proportion of points in $P_1 \circ P_2$. We then ensure that $|P_3|$ is much larger than $|P_2|$ and that P_2 is an ϵ-hull for $P_2 \circ P_3$. However, since the algorithm only kept a small number of points in P_2, it is forced to keep many points in P_3. See the appendix for precise details. The result extends easily for $d > 3$. For $r > 1$, we use a similar construction, but add more sets of points $P_4, P_5, \ldots$ ◀

We can also ask a slightly different question: what if an algorithm is given an additional parameter k in advance, and only needs to maintain an ϵ-hull at time t when OPT of the substream at time t falls below k. The algorithm we give for (ϵ, δ)-hulls in Section 6 is of this form. In the appendix of the full version (Definition A.9 and Theorem A.10), we formulate a lower bound for this case.

Our lower bounds guide future research by showing that we need to think beyond the current streaming models, add reasonable assumptions to the problem, or the space bounds of our algorithms must include some functions of ϵ or $|P|$ (along with OPT and d).

4 2D Random Order Algorithm (ROA)

In many cases, data points are generated i.i.d., for example in mixture models or topic models (e.g. [6]). In this section we assume a more general setup: that the points come in a random order. More precisely, for all sets of points P, every permutation of P must have equal probability density. The case where the data points are generated i.i.d. (*making no assumptions about the distribution*) is a special case. We assume the points are in 2D. To begin, we introduce the following definition.

▶ **Definition 4.1.** A point p is *interior* to P if p is in the convex hull of $P \setminus \{p\}$.

4.1 1D Algorithm

To motivate our 2D algorithm, we begin with a classic result in 1-dimension. Consider the algorithm **ROA-insertion**: Begin by keeping a set $S = \{\}$. For each point $p \in P$ that the algorithm sees, if the distance from p to the convex hull of S is at most ϵ, we discard p. Otherwise, we add p to S.

Algorithm 1 Pseudocode for ROA (2D random order algorithm).

```
S ← {}
when p ∈ P is received do:
    if dist(p, C(S)) ≤ ε then:
        // Discard p
    else:
        S ← S ∪ {p}
        for p′ ∈ S sequentially do:
            If p′ is an interior point of S then S ← S \ {p′}
        end for
end when
```

▶ **Lemma 4.2.** *There exists a constant $c > 0$ such that for any random order input stream P containing at most n points, ROA-insertion maintains a subset $S \subseteq P$ which is an ϵ-hull of P at all times. Moreover, if $P \subseteq \mathbb{R}^1$ then with probability at least $1 - 1/n^3$,*

$$|S| \leq c \cdot \log n \leq c \cdot \mathit{OPT}(P, \epsilon) \cdot \log n,$$

note that for any $\epsilon \geq 0$, if $P \subseteq \mathbb{R}^1$ then $1 \leq \mathit{OPT}(P, \epsilon) \leq 2$.

A natural question is whether the space bound for this algorithm generalizes to higher dimensions. Our experiments suggest that it does not even generalize to 2D. In our experiments, we set $\epsilon = 0$ and gave ROA-insertion n equally spaced points inside a square. OPT is 4, since all the points are contained inside a square. However, experimentally, the number of points kept by ROA-insertion increases much faster than $\log n$.

4.2 2D Algorithm

We extend algorithm ROA-Insertion to get algorithm **ROA**. Let the points kept by ROA at the i^{th} step of the algorithm be S_i. At each step i, we iteratively delete interior points from S_i until S_i has no interior points. We summarize algorithm ROA in Algorithm 1.

The proof of ROA gives an interesting connection between our 2D algorithm, and the 1D classical result in the previous section. We begin with a technical lemma (see Lemma B.1 in the appendix of the full version for the proof), and then proceed to the main theorem.

▶ **Lemma 4.3.** *(Similar Boundaries) Suppose A and B are ϵ-hulls of P. Let $\mathcal{H}$ denote the (two-way) Hausdorff distance and $\partial\mathcal{C}(A)$ denote the boundary of the convex hull of A. Then $\mathcal{H}(\partial\mathcal{C}(A), \partial\mathcal{C}(B)) \leq \epsilon$.*

▶ **Theorem 4.4.** *There exists a constant $c > 0$ such that for any random order input stream P containing at most n points, ROA maintains a subset $S \subseteq P$ which is an ϵ-hull of P at all times. Moreover, if $P \subseteq \mathbb{R}^2$ then with probability at least $1 - 1/n^2$,*

$$|S| \leq c \cdot \mathit{OPT}(P, \epsilon) \cdot \log n.$$

Since the algorithm is deterministic, the probability is over the arrival order of P.

Proof. An inductive argument shows that at each iteration i, S is an ϵ-hull of P. We focus on the proof of the space bound.

Step 1: Consider an optimal ϵ-hull T of P. We show that all points in S are near the boundary $\partial\mathcal{C}(T)$. Note that S does not contain any interior points, so for all $s \in S$, $s \in \partial\mathcal{C}(S)$. Then by Lemma 4.3, for every point $s \in S$, $\text{dist}(s, \partial\mathcal{C}(T)) \leq \epsilon$.

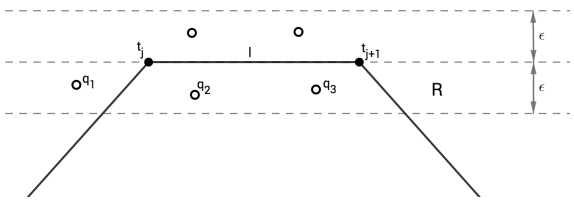


Figure 2 Figure for Theorem 4.4. Consider all points near segment $l = \overline{t_j t_{j+1}}$. Consider points $q_1, q_2, q_3 \in Q$ on one side of l. They are contained in a thin strip R of width ϵ.

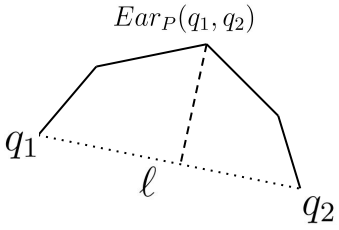

Figure 3 A diagram of $Ear_P(q_1, q_2)$. The dotted line is ℓ, and the length of the dashed line is $\mathsf{Error}_P(q_1, q_2)$.

Step 2: We split T into OPT sections, and show that with high probability our algorithm keeps $O(\log n)$ points for each section. Since T is optimal, it does not contain any interior points. Label the points in T: t_1, ..., t_k, clockwise along the boundary of the convex hull of T. For every $s \in S$, since $\text{dist}(s, \partial\mathcal{C}(T)) \leq \epsilon$, s is within distance ϵ from the line segment connecting some t_i and t_{i+1}. Now, referring to Figure 2, consider the line segment l connecting arbitrary t_j and t_{j+1}, and consider all points in P within distance ϵ from l. We group the points based on which side of the line segment they are on - consider the points Q on one side of the line segment.

The points Q are contained in some narrow strip R with width ϵ. Effectively, because Q is contained in a narrow strip, we can reduce to the 1D case and apply the proof from Lemma 4.2. To see this reduction, consider the projection of the points in Q onto the (infinite) line l' connecting t_j and t_{j+1}. Let $f(q_i)$ denote the projection of q_i onto line l'. If $f(q_k)$ is between $f(q_i)$ and $f(q_j)$, and q_k arrives after q_i and q_j, then our algorithm discards q_k because q_k is within distance ϵ from the line segment connecting q_i and q_j. Applying the 1D proof, we get that with high probability we keep $O(\log n)$ points for each segment.

Step 3: We take a union bound over the OPT sections to get the desired result, where we note that $\mathsf{OPT} \leq n$. ◀

5 2D Multipass Algorithm

In this section, we relax the problem by letting the algorithm pass over the stream P multiple times. Let $\text{diam}(P)$ refer to the diameter of the point-set P which is $\max_{x,y \in P} d(x, y)$. Our algorithm requires $\log(\frac{\text{diam}(P)}{\epsilon})$ passes and $O(\mathsf{OPT})$ memory. For convenience of exposition, we assume $\text{diam}(P) = 1$ and prove a bound of $\log(\frac{1}{\epsilon})$ passes. If $\text{diam}(P) \neq 1$, we can simply scale all the points, and ϵ, by $\frac{1}{\text{diam}(P)}$ and run the algorithm to get the desired bound.

By convention, we define the distance between a point p and a set A to be $d(p, A) = \min_{a \in A} d(p, a)$. In a slight abuse of notation, for a finite set P we define ∂P to be the subset of P that lies on the boundary of the convex hull of P. Formally:

▶ **Definition 5.1.** For a finite set $P \subset \mathbb{R}^2$, we define $\partial P = P \cap \partial\mathcal{C}(P)$. Here $\partial\mathcal{C}(P)$ means the boundary of the convex hull of P.

Given any two points $q_1, q_2 \in \partial P$, define $\ell = \mathcal{C}(\{q_1, q_2\})$ to be the line segment with endpoints q_1 and q_2. Observe that the set $\mathcal{C}(P) \setminus \ell$ has at most two connected components. Define $Ear_P(q_1, q_2)$ to be the component that lies to the left of the vector from q_1 to q_2. We define $\mathsf{Error}_P(q_1, q_2) = \max_{x \in Ear_P(q_1, q_2)} d(x, \ell)$ to be the maximum distance of a point in this

Algorithm 2 Input: a stream of points $P \subset \mathbb{R}^2$ and a value $\epsilon \in (0, 1]$. Output: an ϵ-approximate hull of P

1: $t_1 \leftarrow (1, 0)$, $t_2 \leftarrow (-1, 0)$
2: $T \leftarrow$ an ordered list (t_1, t_2)
3: For $i = \{1, 2\}$, associate $q_i \leftarrow \mathsf{GetMax}_P(t_i)$ with t_i
4: Initialize Flag to down position
5: **for all** $1 \leq i \leq |T|$ (in parallel) **do**
6: Compute $\mathsf{Error}_P(q_i, q_{i+1})$
7: Compute $\mathsf{Error}_P(q_{i-1}, q_{i+1})$
8: $t'_i \leftarrow$ direction bisecting t_i and t_{i+1}
9: $q'_i \leftarrow \mathsf{GetMax}(t'_i)$
10: **for all** $1 \leq i \leq |T|$ (in parallel) **do**
11: **if** $\mathsf{Error}_P(q_{i-1}, q_{i+1}) \leq \epsilon$ and neither t_{i+1} or t_{i-1} have been deleted **then**
12: Remove t_i from T
13: **if** $\mathsf{Error}_P(q_i, q_{i+1}) > \epsilon$ **then**
14: Add t'_i to T and associate q'_i with t'_i
15: Raise Flag
16: Recompute indices of T to preserve clockwise-order
17: Delete any points/vectors except $t_i \in T$ and their associated q_i
18: **if** Flag is up **then**
19: Go to Line 4
20: **else**
21: Output $\{q_1, \ldots, q_{|T|}\}$

component from ℓ. See Figure 3 for an example. Note that we can compute $\mathsf{Error}_P(q_1, q_2)$ in a single pass (see Algorithm 2 and Lemma C.1 in the Appendix of the full version).

Let t be a unit vector. Define $\mathsf{GetMax}_P(t)$ to be $\arg\max_{p \in P} p \cdot t$. It is clear that $\mathsf{GetMax}_P(t)$ can be computed in a single pass. Algorithm 2 is the main multipass algorithm, using Error and GetMax as blackboxes. We always maintain a set of directions T. On Lines 5-9 we run $3|T|$ single-pass algorithms completely in parallel, therefore requiring only a single pass. By the phrase "associating a point with a direction", we mean to keep this point as piece of satellite data.

Our main result for this section is the behavior of Algorithm 2. We define a word as the space required to store a single point in $\mathbb{R}^2$.

We begin with some preliminary statements. We defer the proofs of these lemmas to the Appendix of the full version (see Lemmas C.2, C.3, C.4, and C.6). Throughout this section, we use the convention of incrementing subscripts modulo n (for example $q_{n+1} = q_1$).

▶ **Lemma 5.2.** *If Algorithm 2 terminates, it outputs an ϵ-hull to P.*

▶ **Lemma 5.3.** *Algorithm 2 terminates in $3 + \lceil \log_2(1/\epsilon) \rceil$ passes.*

▶ **Lemma 5.4.** *Let $p, p', q', q \in \partial P$ be in clockwise order along $\partial \mathcal{C}(P)$. Then $\mathsf{Error}_P(p', q') \leq \mathsf{Error}_P(p, q)$.*

▶ **Lemma 5.5.** *There exists an ϵ-hull for P using only points from ∂P of cardinality at most $2\mathsf{OPT}(P, \epsilon)$.*

Note that Lemma 5.5 is not trivial. By definition, there exists an ϵ-hull for P of size $\mathsf{OPT}(P, \epsilon)$ using points from P. It may be that an ϵ-hull of optimal size must use a point from the interior of P. For example, consider a square of side length $r \in (\sqrt{2}\epsilon, 2\epsilon)$, where

∂P consists of the four corners. It is possible, due to interior points, that $\mathsf{OPT}(P,\epsilon) = 2$ and yet an ϵ-hull using only points from ∂P must use all four corners. Note that this example also shows that the bound in Lemma 5.5 is tight.

On Line 8, t_i' is defined as the direction that bisects t_i and t_{i+1}. We define the bisection of unit vectors a and b to be the unit vector obtained by rotating a clockwise through through half of the rotation required to point in the direction of b.

▶ **Theorem 5.6.** *Given a stream of points $P \subset \mathbb{R}^2$ and a value $\epsilon \in (0,1]$, Algorithm 2 terminates within $3 + \lceil \log_2(1/\epsilon) \rceil$ passes, stores at most $24\mathit{OPT}(P,\epsilon) + O(1)$ words, and returns an ϵ-hull of P of cardinality $6\mathit{OPT}(P,\epsilon)$.*

Proof. By Lemma 5.3, Algorithm 2 terminates after $3 + \lceil \log_2(1/\epsilon) \rceil$ passes. By Lemma 5.2, Algorithm 2 outputs an ϵ-hull to P. It only remains to bound the space usage and cardinality of the set returned

Let $W \subset \partial P$ be an ϵ-approximation of P such that $n = |W| \leq 2\mathsf{OPT}(P,\epsilon)$. Lemma 5.5 guarantees that such a W exists. Let $W = \{w_1, \ldots, w_n\}$ be an ordering of W that is clockwise in $\partial\mathcal{C}(P)$. By definition, $\mathsf{Error}_P(w_i, w_{i+1}) \leq \epsilon$ for every $i \in \mathbb{Z}$ (recall the convention of indexing modulo n). Consider the state of the algorithm at the beginning of a pass; for notation let T contain the directions $\{t_i\}_{i=1}^{|T|}$ associated respectively with $\{q_i\}_{i=1}^{|T|}$.

For $s \in \{1,2\}$, suppose that $w_i, q_j, q_{j+s}, w_{i+1}$ are in clockwise order of $\partial\mathcal{C}(P)$. By Lemma 5.4, $\mathsf{Error}_P(q_j, q_{j+s}) \leq \mathsf{Error}_P(w_i, w_{i+1}) \leq \epsilon$. We draw two conclusions. The first conclusion ($s = 1$) is that on Line 13, t_i' will not be added to T. The second conclusion ($s = 2$) is that on Line 11, t_{i+1} is a candidate for deletion (i.e. t_{i+1} will be deleted unless t_i or t_{i+2} have already been deleted).

Using the clockwise ordering of $\partial\mathcal{C}(P)$, we say that a point $q \in \partial P$ is on edge (w_i, w_{i+1}) if it lies between w_i and w_{i+1} in the ordering. Suppose that $\{q_j\}_{j=1}^{|T|}$ contains m points on edge (w_i, w_{i+1}). By the reasoning in the preceding paragraph, it is easy to verify that all but $\lceil \frac{m-1}{2} \rceil + 1$ will be deleted on Line 11. As for points added on Line 13, this can only occur at the boundary (between q_j and q_{j+1} where q_j is the last point on some edge) and therefore adds at most 1 point per edge.

Combining these facts, we see that an edge which enters a pass with m points finishes that pass with at most $\lceil \frac{m-1}{2} \rceil + 2$ points. Inductively we begin with $m = \{0,1,2\}$ for each edge. This implies that $m \leq 3$ after each pass. Therefore $|T| \leq 3n \leq 6\mathsf{OPT}(P,\epsilon)$ at all times.

Finally, observe that the storage of $4|T| + O(1)$ points are used in a pass. To compute Error without precision issues, storing a single point suffices. Therefore for each i we store one point for each of the two Error computations, one point for GetMax, and the original point q_i and vector t_i. The $O(1)$ is just a workspace to carry out the calculations. ◀

6 (ϵ, δ)-Hull

In this section we give an algorithm for a relaxation of ϵ-hulls, which we call (ϵ,δ)-hulls. Our results hold for arbitrary point sets $P \subseteq \mathbb{R}^d$. Intuitively, an (ϵ,δ)-hull of P is within distance ϵ from the boundary of the convex hull of P in at least a $1-\delta$ fraction of directions. We begin by building up the definition of an (ϵ,δ)-hull.

▶ **Definition 6.1.** Given a vector $v \in \mathbb{R}^d$ and a finite point set $P \subseteq \mathbb{R}^d$, we define the **directional extent** as

$$\omega_v(P) = \max_{p \in P} p \cdot v.$$

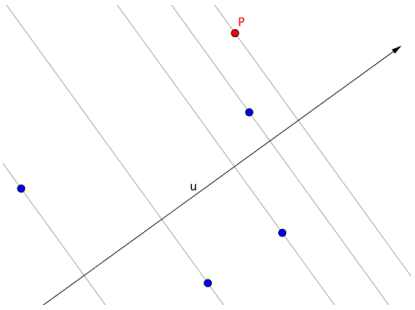

Figure 4 Point p maximizes the set of points in direction u because its projection onto u is the highest.

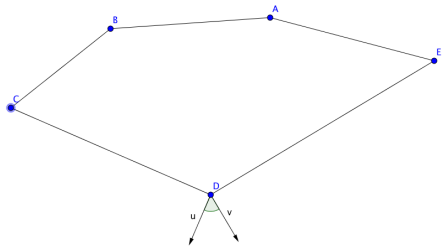

Figure 5 All vectors between u and v with Euclidean norm at most 1 are in E_D^T. See texts for details.

If $p \in \mathbb{R}^d$ is a point we define $\omega_v(p) = p \cdot v = \omega_v(\{p\})$. We say that S **maximizes** P in v if $\omega_v(P) = \omega_v(S)$ (see Figure 4). Note that S can be either a single vector or a set of vectors.

▶ **Definition 6.2.** Let $P \subset \mathbb{R}^d$ be a set of points and $S \subseteq P$. We say S **ϵ-maximizes** P in v if $v = 0$ or, letting $v' = v/\|v\|_2$, we have

$$|\omega_{v'}(P) - \omega_{v'}(S)| \leq \epsilon.$$

Note that as per definition 6.1, S can be either a single vector or a set of vectors.

▶ **Definition 6.3.** Given $P \subseteq \mathbb{R}^d$, an **(ϵ, δ)-hull** is a subset $S \subseteq P$ such that if we pick a vector v uniformly at random from the boundary of the unit sphere, $\mathcal{S}^{d-1}$, S ϵ-maximizes P in direction v with probability at least $1 - \delta$, that is,

$$\Pr_{v \sim \mathcal{S}^{d-1}}(|\omega_v(P) - \omega_v(S)| > \epsilon) \leq \delta.$$

Suppose we fix the dimension d. We give a randomized algorithm that uses m points and with probability at least $1 - \gamma$ gives us an (ϵ, δ)-hull of a point set P, where k is the optimal size for the ϵ-hull of P, and m satisfies:

$$m \in O_d\left(\frac{k}{\delta^2} \cdot \log \frac{k}{\gamma\delta}\right).$$

Note that m does not explicitly depend on ϵ. Our algorithm for d-dimensional space is as follows: Choose m uniformly random vectors in the unit ball B^d (or equivalently on the boundary of the unit ball, $\mathcal{S}^{d-1}$). For each chosen vector v we store a single point $p \in P$ that maximizes P in direction v, that is, $p \cdot v = \omega_v(P)$. This can easily be done in streaming. Note that the given complexity is for a fixed dimension d, the actual space complexity will be multiplied by some (exponential) function of d, but independent of ϵ.

6.1 Proof of (ϵ, δ)-hull Algorithm

Consider an arbitrary point set P, and suppose that our algorithm keeps a subset S of P. The core of our proof, leading up to lemma 6.11, shows that for each point that our algorithm picks, S gets closer to an (ϵ, δ)-hull. In particular, we define the set C of bad vectors in B^d, as vectors v s.t. S does not ϵ-maximize P in v. We want to bound the number of points we need to include in S so that C is small. Crucially, we show that C is a union of a small number of convex sets, and does not contain any vectors we selected (recall that our

algorithm selects uniformly random vectors in B^d, and uses these to select certain points in P). Then, we can approximate C with a union of ellipsoids, which has small VC-dimension. This finally allows us to apply the machinery of ϵ-nets to get the desired result.

We begin with some definitions and lemmas.

▶ **Definition 6.4.** Let B^d denote the unit ball in d dimensions. Let $\mathcal{S}^{d-1}$ denote the unit sphere in d dimensions, which is ∂B^d (the boundary of B^d).

▶ **Definition 6.5.** Let $V^d(S)$ denote the d-dimensional volume (Lebesgue measure) of a measurable set S in d-dimensional space.

▶ **Definition 6.6.** Given $T \subseteq \mathbb{R}^d$ and $t \in \mathbb{R}^d$, we define E_t^T to be the set of all vectors $v \in B^d$ such that t maximizes T in v, that is,

$$E_t^T = \{v \mid v \cdot t = \omega_v(T) \wedge |v|_2 \leq 1\}.$$

Figure 5 shows a set of points T. All vectors between u and v with Euclidean norm at most 1, in the range indicated by the angle, are in E_D^T. Note that u is perpendicular to line segment CD and v is perpendicular to line segment DE. Only points $t \in T$ that lie on the boundary of the convex closure of T have non-empty E_t^T.

▶ **Definition 6.7.** Given a point stream P, and a set S, we say *the set of bad vectors* C (with respect to P, S) is the set of vectors v in B^d such that S does not ϵ-maximize P in v. An equivalent definition of (ϵ, δ)-hulls is that $V^d(C)/V^d(B^d) \leq \delta$.

We are now ready to present the following lemmas about the properties of E_t^T.

▶ **Lemma 6.8** (ϵ-Maximization Lemma). *Suppose $P \subseteq \mathbb{R}^d$ is a finite set of points and $T \subseteq P$ is an ϵ-hull of P, and $t \in T$. Then t ϵ-maximizes P for all vectors $v \in E_t^T$ (see Definition 6.6).*

▶ **Lemma 6.9** (Covering Lemma). *For all finite point sets $T \subseteq \mathbb{R}^d$, $\bigcup_{t \in T} E_t^T = B^d$.*

▶ **Lemma 6.10** (Convex Lemma). *For any point $t \in \mathbb{R}^d$ and finite set $T \subseteq \mathbb{R}^d$, E_t^T is convex and has finite volume.*

We want to show that the set of points S our algorithm chooses is ϵ-maximal in most directions. One way is to show that for each point our algorithm picks, the set of *bad vectors* (vectors that our stored points do not ϵ-maximize) shrinks. We present a crucial lemma that formalizes this notion under some assumptions.

▶ **Lemma 6.11.** *Given a finite point set $P \subseteq \mathbb{R}^d$ and a finite-volume convex set $C \subseteq \mathbb{R}^d$. Assume that there exists some $p \in P$ s.t. for all unit vectors $v \in C$, p ϵ-maximizes P in v. Suppose that we pick arbitrary vectors $v_1, ..., v_k \in C$ and corresponding points $p_1, ..., p_k \in P$ s.t. for all i, p_i maximizes P in v_i. Then there exists a finite-volume convex subset $C' \subseteq C$ s.t.*

1. *For all $i \in [k]$, $v_i \notin C'$.*
2. *For all vectors $v \in C \setminus C'$, $S = \{p_1, ..., p_k\}$ ϵ-maximizes P in v.*

Proof. Consider a vector v_i that we picked, and corresponding point p_i. If $p_i = p$, then $C' = \{\}$ satisfies the required conditions. Otherwise, let $H_i = \{v \mid p_i \cdot v \geq p \cdot v\}$. H_i is a half-space that contains the vector v_i. Furthermore for all vectors $v \in H_i \cap C$, S ϵ-maximizes P in v. So the set of vectors in C that p_i does not maximize are contained in $H_i^c \cap C$, where H_i^c does not contain v_i. Applying this argument for each vector v_i and corresponding

point p_i, we can construct C' to be the intersection of C with the k (open) half-spaces H_i^c corresponding to each of the points p_i we selected. Our constructed C' is convex, because it is the intersection of convex sets, and it is bounded and measurable. ◀

For completeness, we include a standard lemma that is similar to the finite ϵ-net in computational geometry. Before we proceed, for a family of sets $\mathcal{H}$, we denote the simplified version of *VC-dimension* $d' = \widetilde{\text{VC}}(\mathcal{H})$ as the smallest positive integer d' such that for every finite set $A \subseteq \mathbb{R}^d$, $|\{h \cap A : h \in \mathcal{H}\}| \leq |A|^{d'}$ (that is, such that a simple variant of Sauer's Lemma holds). We then have the following lemma, which we prove in the appendix.

▶ **Lemma 6.12.** *Let $\tau, \gamma \in (0,1)$ be two parameters. Let $\mathcal{H}$ be a set of measurable sets in $\mathbb{R}^d$ such that $\widetilde{VC}(\mathcal{H}) \leq d'$ for some integer d'. Given a measuable convex set $C \subseteq \mathbb{R}^d$, let $\mathcal{H}_C = \{c \in \mathcal{H} : c \subseteq C\}$ be the sets of subsets of H contained in C. Suppose we choose $m = \Theta(\frac{d'}{\tau^2} \log \frac{d'}{\tau\gamma})$ points uniformly random in C. Then, except with probability γ, **all** sets $u \in \mathcal{H}_C$ with $V^d(u)/V^d(C) \geq \tau$ contains some selected point, where $V^d(u)$ denotes the volume of u.*

Before we present the main theorem, we note that the set of unions of k ellipsoids is of small VC-dimension. The formal proof is presented in the Appendix.

▶ **Lemma 6.13.** *Let $\mathcal{E}$ be the sets of all ellipsoids in $\mathbb{R}^d$. Let $\mathcal{E}^k = \{e_1 \cup e_2 \cup e_3 \ldots \cup e_k : e_i \in \mathcal{E}\}$. Then $\widetilde{VC}(\mathcal{H}) \leq 4kd^2$.*

Now we are ready to present the main theorem in this section.

▶ **Theorem 6.14.** *Let $\gamma, \delta \in (0,1), k \geq 1$ be parameters. Given a point stream P in $\mathbb{R}^d$ and $\epsilon \geq 0$. Suppose $\mathsf{OPT}(P, \epsilon) \leq k$. Then there exists a one-pass streaming algorithm, given P, γ, δ, k, stores a set $S \subseteq P$ of $m = \Theta_d\big(\frac{k}{\delta^2} \log \frac{k}{\gamma\delta}\big)$ points, such that, except with probability γ, S is an (ϵ, δ)-hull of P.*

Proof. To begin the proof, we recall the algorithm. We first pick uniformly at random $m = \Theta\big(\frac{d^{2d+2}k}{\delta^2} \log \frac{kd}{\gamma\delta}\big)$ directions from B^d, the d-dimensional unit ball. When the stream is coming, we maintain the extreme point from P in each direction. The output S is the set of extreme points in each direction.

Intuitively, S is an (ϵ, δ)-hull iff B^d only contains a small region of bad vectors (with respect to P, S). Let T be an optimal ϵ-hull of P, with $|T| = k$. Fix $t \in T$. Consider the set E_t^T. In our proof we will show that with high probability each set E_t^T only contains a small subset of bad vectors, C_t', such that, for all vectors $v \in E_t^T \setminus C_t'$, S ϵ-maximizes P in v. Then we show that $\sum_{t \in T} V^d(C_t') \leq \delta$, which completes the proof.

Suppose the selected random set of vectors is $A \subseteq B^d$. Fix $t \in T$. By Lemma 6.8, $t \in T$ ϵ-maximizes P for all vectors $v \in E_t^T$. Then by Lemma 6.11, there exists a finite-volume convex subset $C_t' \subseteq E_t^T$ such that $C_t' \cap A = \emptyset$ and for all $v \in E_t^T \setminus C_t'$, S ϵ-maximizes v. Next, for each $t \in T$, we select a large ellipsoid u_t contained in C_t' such that $V^d(C_t') \leq V^d(u_t)d^d$. Note that $\cup_{t \in T} C_t'$ is a member of the family $\mathcal{E}^{|T|} = \{h_1 \cup h_2 \cup \ldots \cup h_{|T|} : \forall i,\ h_i \text{ is an ellipsoid}\}$. By Lemma 6.13, $\widetilde{\text{VC}}(\mathcal{E}^{|T|}) \leq 4kd^2$. By Lemma 6.12, since all u_t do not contain any point from A, with probability at least $1 - \gamma$, it must be the case that $V^d(\cup_{t \in T} u_t)/V^d(B^d) \leq \delta/(d^d)$. Since the u_t are disjoint, this means that $V^d(\cup_{t \in T} C_t')/V^d(B^d) \leq \delta$. Furthermore, by Lemma 6.9, $\bigcup_{t \in T} E_t^T = B^d$. Therefore, with probability at least $1 - \gamma$, S ϵ-maximizes all vectors in B^d except for those in $\cup_{t \in T} C_t'$. Thus, S is an (ϵ, δ)-hull except with probability γ. ◀

Abstract

A small-biased function is a randomized function whose distribution of truth-tables is small-biased. We demonstrate that known explicit lower bounds on (1) the size of general Boolean formulas, (2) the size of De Morgan formulas, and (3) correlation against small De Morgan formulas apply to small-biased functions. As a consequence, any strongly explicit small-biased generator is subject to the best-known explicit formula lower bounds in all these models.

On the other hand, we give a construction of a small-biased function that is tight with respect to lower bound (1) for the relevant range of parameters. We interpret this construction as a natural-type barrier against substantially stronger lower bounds for general formulas.

1 Introduction

Formula size is one of the most thoroughly studied complexity measures of Boolean functions. A formula is a circuit in which every internal gate has fan-out one. The power of formulas depends on the types of gates allowed. In this work we consider two models: *General formulas* in which any gate of some pre-specified fan-in c is allowed, and *De Morgan formulas* that only use NOT gates and AND/OR gates of fan-in two.

Explicit size lower bounds for general formulas were first proved by Nečiporuk [18], who showed that the selector (addressing) function requires general constant fan-in formula size $\Omega(n^2/\log n \log\log n)$ over inputs of size n. Boppana and Sipser [8] applied a variant of this method to obtain an improved lower bound of $\Omega(n^2/\log n)$ for the element distinctness function by a related but different method.

The case of De Morgan formulas had been studied even earlier. Subbotovskaya [25] proved that computing parity on n bits requires formula size $\Omega(n^{3/2})$. Andreev [3] combined the ideas of Nečiporuk and Subbotovskaya to obtain a $n^{5/2-o(1)}$ De Morgan formula size lower bound for an explicit family of functions from $\{0,1\}^n$ to $\{0,1\}$. Following partial improvements (Impagliazzo and Nisan [11], Paterson and Zwick [19]), Håstad [10] showed

that Andreev's function requires formula size $n^{3-o(1)}$, which is optimal in the exponent.[2] The same lower bound was reproved by Dinur and Meir [9] using different methods.

More recently, Tal gave two lower-order improvements to Håstad's result. First, in [27] he showed that Andreev's function requires De Morgan formulas of size $\Omega(n^3/(\log n)^2 \log\log n)$, which is optimal for this function up to the doubly logarithmic term. Later, in [28] he showed that another function introduced by Komargodski and Raz [13] requires De Morgan formula size $\Omega(n^3/(\log n)(\log\log n)^2)$.

In a related line of works, Komargodski, Raz, and Tal [13, 14, 27] study correlation lower bounds against small formulas. For every $k \leq n^{1/3}$, they construct two variants of an explicit function that has correlation at most 2^{-k} with any De Morgan formula of size $n^3/(\log n)^{O(1)}k^2$. Their hard functions make use of error-correcting codes with good list-decodable properties and extractors for bit-fixing sources. Weaker correlation bounds for the parity function were proved by Santhanam [23] and, as observed in [14], also follow implicitly from bounds on the approximate degree of De Morgan formulas [6, 22].

Razborov and Rudich [21] observed that all formula size lower bounds (known at the time) are natural, meaning that the formulas to which the bounds apply cannot compute cryptographically pseudorandom functions. On the other hand, the class NC^1 of polynomial-size logarithmic-depth bounded fan-in circuit families, which are equivalent in power to polynomial-size formula families, is believed to contain pseudorandom functions. Naor and Reingold [16,17] and Banerjee, Peikert, and Rosen [5] proposed such candidate families based on the Decisional Diffie Hellman, hardness of factoring, and Learning With Errors hardness assumptions, respectively. These constructions suggest that explicit size n^C lower bounds for formulas is out of reach for current techniques for sufficiently large values of the exponent C. The values of C in these constructions (for the requisite levels of hardness) are apparently rather large, so they are unlikely to explain the perceived barriers of n^2 and n^3 for general and De Morgan formula size, respectively.

Our results

Our main conceptual contribution is the realization that all known formula size lower bound techniques also apply to small-biased functions. A randomized function is (K, ε)-biased if the induced distribution over truth-tables is a (K, ε)-biased distribution (it satisfies (1) below).

From the perspective of natural proofs, the known properties that distinguish small formulas from random functions are local in the sense that they only make a bounded number of non-adaptive queries to the function.[3] It is therefore reasonable to expect that the largeness condition of the relevant natural properties should continue to hold for random functions that only exhibit bounded independence. We show that these properties, in fact, merely require small bias [15], which is closely related to *approximate* bounded independence. As a direct consequence, we show that the best-known explicit formula lower bounds hold against any implicitly specified small-biased generator (the precise definition is given below).

▶ **Theorem 1.** *Any small-biased generator* $SB_{n,2^{-15n}} : \{0,1\}^{O(n)} \to \{0,1\}$

1. *requires fan-in c formulas of size* $\Omega(n^2/2^c \log n)$,
2. *requires De Morgan formulas of size* $\Omega(n^3/\log n\ (\log\log n)^2)$,
3. *has correlation at most* $2^{-\Omega(k)}$ *with De Morgan formulas of size at most* $n^3/(\log n)^{O(1)}k^2$ *for any* k *such that* $\omega(\log n) \leq k \leq n$.

[2] Our discussion of formula lower bounds is based on Chapter 6 of Jukna's book [12].
[3] The correlation lower bounds [13, 14] in fact apply adaptive queries of a restricted type.

Together with the existence of strongly explicit small-biased generators (see definition and discussion below), Theorem 1 reproves the best-known formula lower bounds in a unified manner and even gives a minor improvement in one case. Item 1 matches the explicit formula size lower bound of Nečiporuk. Item 2 matches the lower bound of Tal [28]. Item 3 is a minor improvement over the lower bound of Tal [27]. His proof requires the additional assumption $k \leq n^{1/3}$.

Like previous formula size lower bounds with the exception of [9], the proof of Theorem 1 relies on shrinkage. It is therefore not surprising that it merely matches but fails to improve the state of the art in explicit lower bounds. The value of Theorem 1 is in explaining hardness against formulas by a single natural property, namely small bias. In contrast, shrinkage proofs are tailored to the model in question. The proofs of [10, 18, 28] rely on shrinkage of a random restriction, the one of [8] on simultaneous shrinkage of multiple restrictions, while [13, 14, 27] use high probability shrinkage. While the role of small bias in the shrinkage arguments is more or less self-evident in certain proofs (Propositions 1 and 3), it is less obvious properties of small bias (Lemmas 2 and 3) that enables the others (Propositions 2, 4, and 5).

From a wider perspective, the utility of circuit lower bounds extends far beyond separating complexity classes, which is merely a motivating purpose. It is just as important to identify which natural (both in the common and technical sense) properties of functions make them intractable in specific computational models. In this sense Theorem 1 provides a new criterion for pseudorandomness of a cryptographic function against a restricted class of distinguishers.

On the other hand, in Theorem 6 we construct a (K, ε)-biased function F with fan-in two formula size $O(n(\log K)^2(\log 1/\varepsilon))$. For $\varepsilon = 2^{-2K}$, this is a $(K, 2^{-K})$-wise independent function of formula size $O(nK(\log K)^2)$, which matches our lower bounds for general formulas in Propositions 1 and 2 up to terms polylogarithmic in K.

In the parameter regimes that yield lower bounds 1 and 2 in Theorem 1, the function F has formula size $O((n \log n)^2)$ and De Morgan formula size $O(n^4(\log n)^3)$. We view this as a barrier to proving super-quadratic lower bounds for general formulas, and super-quartic ones for De Morgan formulas.

In the notation of Razborov and Rudich, our barriers are $\oplus$-natural, where $\oplus$ is the class of parity functions. However, they are not quasipolynomial-size-natural since our function F is not cryptographically pseudorandom: In addition to having small formula size, F is computable by polynomial-size, depth 3 circuit families with AND, OR, and PARITY gates (the class $\mathrm{AC}^0[\oplus]$), which is known not to contain cryptographic pseudorandom functions [20, 21, 24]. It remains open whether our bounds can be matched (or even improved in the case of De Morgan formulas) by a different construction that is plausibly secure with respect to all subexponential-size circuits, of which linear tests are a very special case.

Theorems 1 and 6 suggest that small-biased functions should be studied as suitable candidates for formula size lower bounds. In the extreme setting of parameters $K = 2^n$, $\varepsilon = 2^{-\Theta(n)}$, known constructions of small-biased functions have seed lengths linear in n and may be plausible candidates for improved formula size lower bounds. In this regime, the general and De Morgan formula sizes of F in Theorem 6 are as large as $\tilde{\Theta}(n^4)$. Do there exist, say, $(2^n, 2^{-100n})$-biased functions of smaller formula size?

Bounded independence and small bias

We will call a randomized function $F\colon \{0,1\}^n \to \{0,1\}$ (k, ε)-*wise independent* (in qualitative terms, *almost locally independent*) if for any k distinct inputs $x_1, \ldots, x_k$, the distribution

$(F(x_1), \ldots, F(x_k))$ is within statistical distance ε of the uniform distribution over $\{0,1\}^k$. A random function $F\colon \{0,1\}^n \to \{0,1\}$ is (K,ε)-*biased* (*locally small-biased*) if for any nonempty set X of at most K distinct inputs,

$$\left|\mathbb{E}\left[\prod_{x\in X}(-1)^{F(x)}\right]\right| \leq \varepsilon. \tag{1}$$

When $K = 2^n$ the family is called ε-*biased* (*small-biased*). Small bias implies bounded independence by the following claim [15, Corollary 2.1].

▶ **Claim 1.** *Every (K,ε)-biased function is $(K, 2^{K/2}\varepsilon)$-wise independent.*

Small-biased generators

A family of functions $SB_{n,\varepsilon}\colon \{0,1\}^{s(n,\varepsilon)} \times \{0,1\}^n \to \{0,1\}$ is a *small-biased generator* if the random function $F_r(x) = SB_{n,\varepsilon}(r,x)$ (with r uniformly random) is ε-biased for all n and ε. If we view $SB_{n,\varepsilon}$ as a function from $\{0,1\}^{s(n,\varepsilon)}$ to the set of truth-tables of functions $\{0,1\}^n \to \{0,1\}$, we recover the usual representation of a pseudorandom generator as a function of its seed.

The generator is *strongly explicit* if $s(n,\varepsilon) = O(n + \log 1/\varepsilon)$ and $SB_{n,\varepsilon}$ is uniformly polynomial-time computable. Known constructions of small-biased sets [1, 2, 7, 15, 26] are strongly explicit.

2 Small bias requires large formulas

We are aware of two techniques for proving general formula size lower bounds, the one of Nečiporuk [18] and the variant due to Boppana and Sipser [8]. We show that both imply lower bounds on the formula size of almost locally independent functions. While the second technique yields a stronger lower bound, we find the first one instructive as the role of almost-independence is more transparent.

In the case of De Morgan formulas, we study three proof techniques. The first one, based on average-case shrinkage, underlies the lower bound of Andreev including improvements by Impagliazzo and Nisan, Paterson and Zwick, Håstad, and Tal. We show that this method also bounds the formula size of almost independent functions.

The second method for De Morgan formula lower bounds is due to Tal, who applies a correlation-to-computation reduction in addition to bounds on average-case shrinkage. The third method, due to Komargodski and Raz and improvements by these authors and Tal, applies a high-probability shrinkage lemma to derive strong correlation lower bounds. We show that these two methods give lower bounds on the size of small-biased functions.

Arbitrary formulas

A *restriction* $f|_\rho$ of a function f under a partial assignment ρ of its inputs is the function on the unassigned inputs obtained by fixing all the assigned variables to their values. A random $\overline{k}$-restriction of f is the distribution of restrictions of f under a uniform random assignment that leaves exactly k inputs unassigned.

The *size* of a formula is the number of leaves in the formula tree, namely the number of variables occurring in the formula. The following shrinkage property of formulas follows immediately from linearity of expectation:

▶ **Claim 2.** *Assume $f\colon \{0,1\}^n \to \{0,1\}$ has formula size s. Then the expected formula size of a random $\overline{k}$-restriction of f is at most $(k/n)\cdot s$.*

We say a random function F has formula size at most s if every function in the support of F can be computed by a formula of size at most s.

▶ **Proposition 1.** *Assuming $c \leq \log\log k$, any $(2^k, 1/4)$-wise independent function $F\colon \{0,1\}^n \to \{0,1\}$ requires fan-in c formulas of size $\Omega(n \cdot 2^k/k \log k)$.*

Proof. Suppose F has formula size s. By Claim 2 and averaging, there exists a partial assignment ρ with k unassigned variables under which the expected formula size of $F|_\rho$ is at most ks/n. By Markov's inequality,

$$\Pr_F[\text{size}(F|_\rho) \leq 2ks/n] \geq \frac{1}{2} \tag{2}$$

for any distribution of functions F, where size denotes formula size.

A formula of size $\tilde{s}$ can be specified by listing its at most $2\tilde{s}$ gates in depth-first order. For a formula of fan-in c on k inputs, there are 2^{2^c} possible internal gates and k possible input gates, so the number of such formulas is at most $(2^{2^c} + k)^{2\tilde{s}} \leq (2k)^{2\tilde{s}}$. Therefore, setting $\tilde{s} = 2ks/n$, for a uniformly random function R it holds that

$$\Pr_R[\text{size}(R|_\rho) \leq 2ks/n] \leq \frac{(2k)^{4ks/n}}{2^{2^k}}. \tag{3}$$

The event "$\text{size}(F|_\rho) \leq 2ks/n$" depends on at most 2^k values of F, so if F is $(2^k, 1/4)$-wise independent, then

$$\Pr_F[\text{size}(F|_\rho) \leq 2ks/n] \leq \Pr_R[\text{size}(R|_\rho) \leq 2ks/n] + \frac{1}{4}. \tag{4}$$

Combining (2), (3), and (4), we obtain that $(2k)^{4ks/n}/2^{2^k} \geq 1/4$, from where the desired lower bound on s follows. ◀

An improved lower bound

We now discuss the other proof of Nečiporuk, which gives a slightly stronger lower bound in the regime of $k < \log n$ and for exponentially small error.

▶ **Proposition 2.** *For $k \leq \log n - 1$, any $(2 \cdot 2^k, 2^{-2^k})$-wise independent function $F\colon \{0,1\}^n \to \{0,1\}$ requires fan-in c formulas of size $\Omega(n \cdot 2^{k-c}/k)$.*

The proposition is proved by showing that the number of possible restrictions of a small formula that leave the least frequently occurring inputs unrestricted is small. On the other hand, the following lemma shows that the number of distinct restrictions of an almost locally independent function is large, even when the set of unrestricted variables is fixed. A $\overline{U}$-restriction is a restriction under any assignment in which U is the set of free variables.

▶ **Lemma 2.** *Assume F is $(2 \cdot 2^k, 2^{-2^k})$-wise independent. For any set U of k variables, the number of distinct $\overline{U}$-restrictions of F is at least $\min\{2^{n-k-2}, 2^{2^k-3}\}$ with probability more than half.*

In particular, when $k \leq \log n - 1$, a $(2 \cdot 2^k, 2^{-2^k})$-wise independent function family has at least $\frac{1}{8} \cdot 2^{2^k}$ distinct $\overline{U}$-restrictions with probability more than half.

Proof. Let ρ, ρ' be independent random partial assignments to the variables in $\overline{U}$. Then

$$\Pr_{F,\rho,\rho'}[F|_\rho = F|_{\rho'}] \leq \Pr[\rho = \rho'] + \Pr[F|_\rho = F|_{\rho'} \mid \rho \neq \rho']. \tag{5}$$

The first term equals 2^{-n+k}. To bound the second term, fix an arbitrary pair of distinct ρ, ρ'. The event that the restricted functions $F|_\rho$ and $F|_{\rho'}$ are identical depends on at most $2 \cdot 2^k$ values of F. By the almost local independence of F,

$$\Pr_F[F|_\rho = F|_{\rho'} \mid \rho \neq \rho'] \leq \Pr[R = R'] + 2^{-2^k},$$

where $R, R' \colon \{0,1\}^k \to \{0,1\}$ are independent uniformly random functions. Such functions are equal with probability at most 2^{-2^k}, and so the second term in (5) at most 2^{-2^k+1}. Therefore

$$\Pr_{F,\rho,\rho'}[F|_\rho = F|_{\rho'}] \leq 2^{-n+k} + 2^{-2^k+1}.$$

Now assume the support size of $F|_\rho$ over random ρ is less than S for at least half the functions F. Then the collision probability $\Pr_{\rho,\rho'}[F|_\rho = F|_{\rho'}]$ is at least $1/S$ for at least half the functions F and so

$$2^{-n+k} + 2^{-2^k+1} \geq \frac{1}{2S},$$

from where it follows that the larger of 2^{-n+k} and 2^{-2^k+1} is at least $1/4S$. It follows that $S \geq \min\{2^{n-k-2}, 2^{2^k-3}\}$. ◀

Proof of Proposition 2. Let s be the size of F. By Claim 2 and averaging, there is a set U of size k so that on average, F has at most $(k/n) \cdot s$ occurrences of variables from U. By Markov's inequality, at least half of the formulas in F have no more than $\tilde{s} = 2ks/n$ occurrences of variables from U.

We now upper bound the number of $\overline{U}$-restrictions of ϕ (for fixed ϕ and U). Under each partial assignment ρ to this inputs in $\overline{U}$, ϕ reduces to a formula $\phi|_\rho$ of size at most $\tilde{s}$. This formula can be simplified by propagating the restricted inputs and subsuming all gates of fan-in one into their parents or children in some canonical way. The simplified formula can then be described by specifying, say in depth first order, the truth-tables of its gates (of fan-in at least two). As there are at most $\tilde{s}$ such gates and each can compute one of at most 2^{2^c} possible functions, the desired number of restrictions can be at most $2^{2^c\tilde{s}}$.

By Lemma 2, there must then exist a formula in the support of F whose number of $\overline{U}$-restrictions is at most $2^{2^c\tilde{s}} = 2^{2^{c+1}ks/n}$ and at least $\frac{1}{8} \cdot 2^{2^k}$. It follows that $s = \Omega(n \cdot 2^{k-c}/k)$. ◀

Computation by De Morgan formulas

In this section we show that known proofs for De Morgan formula size also apply to small-biased functions. The following proof relies on expected shrinkage of De Morgan formulas under random restrictions [3, 10, 11, 19].

▶ **Proposition 3.** *Assuming $k \leq n/2$, any $(2^k, 1/4)$-wise independent function $F \colon \{0,1\}^n \to \{0,1\}$ requires De Morgan formula size $\Omega(n^2 \cdot 2^k/k^2 \log k)$.*

Proof. In a $\overline{p}$-random restriction, the unrestricted variables are sampled from the binomial distribution with parameter p. Tal [27] showed that if f has a De Morgan formula of size s then the expected formula size of a $\overline{p}$-random restriction of f is $\tilde{s} = O(p^2 s + \sqrt{p^2 s})$. Set $p = 2k/n$. By deviation bounds, for every f in the support of F, the event that ρ has fewer than $k = \frac{1}{2}pn$ unassigned inputs or $f|_\rho$ has formula size more than $4\tilde{s}$ has probability at most $\frac{1}{2}$.

By averaging, there exists a partial assignment ρ with k unassigned inputs under which $F|_\rho$ has formula size at most $4\tilde{s}$ for at least half the functions F. Since F is $(2^k, 1/4)$-wise

independent, the same is true for at least a quarter of truly random functions R. The number of size $4\tilde{s}$ De Morgan formulas on k inputs is at most $(2k)^{8\tilde{s}}$, and these must compute at least $\frac{1}{4} \cdot 2^{2^k}$ distinct functions. It follows that $\tilde{s} = \Omega(2^k/\log k)$. As $\tilde{s} = O(p^2 s + \sqrt{p^2 s})$ it follows that $p^2 s = \Omega(2^k/\log k)$. Using the constraint $k \geq \frac{1}{2}pn$ we obtain the desired bound. ◀

Tal [27] recently obtained a slight improvement to the aforementioned bounds. His method also applies to small-biased functions as demonstrated in the following proposition:

▶ **Proposition 4.** *Assume that $k \leq n/2$ and $2^{-\frac{7}{16}k2^{k/8}} < \varepsilon \leq 2^{-2k}$. Then every $(2^k, \varepsilon)$-biased F requires De Morgan formula size $\Omega(n^2 \log(1/\varepsilon)/k(\log k)^2)$.*

The proof relies on the large deviation bound for small-bias distributions of Naor and Naor [15, Section 5]. We rework it here in more convenient notation. We say a random variable X over $\{-1,1\}^K$ is ε-biased if $|\mathbb{E}[\prod_{i \in S} X_i]| \leq \varepsilon$ for every subset S of indices.

▶ **Lemma 3.** *Let t be even and X be a (t, ε)-biased random variable over $\{-1,1\}^K$. The probability that $|\sum X_i|$ exceeds δK is at most $\delta^{-t} \cdot (2(t/K)^{t/2} + \varepsilon)$.*

Proof. We apply a t-th moment calculation. By Markov's inequality,

$$\begin{aligned}\Pr\Big[\Big|\sum\nolimits_{i=1}^{K} X_i\Big| \geq \delta K\Big] &\leq \frac{1}{(\delta K)^t}\,\mathbb{E}\Big[\Big(\sum\nolimits_{i=1}^{K} X_i\Big)^t\Big] \\ &= \frac{1}{(\delta K)^t}\Big(\sum\nolimits_{S \in \mathcal{E}} \mathbb{E}\Big[\prod\nolimits_{i \in S} X_i\Big] + \sum\nolimits_{S \in \overline{\mathcal{E}}} \mathbb{E}\Big[\prod\nolimits_{i \in S} X_i\Big]\Big),\end{aligned}$$

where $\mathcal{E}$ is the set of ordered terms of size t in which every index appears an even number of times. The first expectation is upper bounded by the number of such terms, which is at most $K^{t/2} \cdot t!/(t/2)! \leq 2 \cdot (tK)^{t/2}$. The second expectation is upper bounded by the number of terms times the maximum bias of each term, namely $K^t \cdot \varepsilon$. The desired bound follows. ◀

The following consequence of the lemma is far from tight but will be of use in the proof of Proposition 4. The *correlation* of two functions $f, \phi\colon \{0,1\}^k \to \{0,1\}$ is $\langle f, \phi \rangle = \mathbb{E}_x[(-1)^{f(x)} \cdot (-1)^{g(x)}]$, where x is uniform in $\{0,1\}^n$.

▶ **Corollary 4.** *Assuming $2^{-\frac{7}{16}k2^{k/8}} < \varepsilon \leq 4 \cdot 2^{-2k}$ and $F\colon \{0,1\}^k \to \{0,1\}$ is $(2^k, \varepsilon)$-biased, for every $\phi\colon \{0,1\}^k \to \{0,1\}$, the probability that $|\langle F, \phi \rangle|$ is greater than $2^{-k/4}$ is at most $3 \cdot \varepsilon^{1/4}$.*

Proof. Assuming $4 \leq t \leq 2^{k/8}$, the expression $(t \cdot 2^{-k})^{t/2}$ is non-increasing as a function of t. By our assumption on ε, there must exist even value $4 \leq t < 2^{k/8}$ for which

$$\big((t+2)2^{-k}\big)^{(t+2)/2} < \varepsilon \leq (t2^{-k})^{t/2}. \tag{6}$$

Applying Lemma 3 with parameters $K = 2^k$, $\delta = 2^{-k/4}$ to the truth-table X of the (K, ε)-biased function $(-1)^{F(x) \oplus \phi(x)}$, we obtain that the desired probability is at most

$$(2^{-k/4})^t \cdot \big(2(t2^{-k})^{t/2} + \varepsilon\big) = 3 \cdot t^{t/2} \cdot 2^{-kt/4}.$$

To derive the corollary, it remains to show that $t^{t/2} \cdot 2^{-kt/4} \leq ((t+2)2^{-k})^{(t+2)/8}$. This follows from $k \geq (4t \log t)/(t-2)$, which is true in the regime $4 \leq t < 2^{k/8}$. ◀

Proof of Proposition 4. Initially we proceed as in the proof of Proposition 3 to obtain a partial assignment ρ with k unassigned inputs under which $F|_\rho$ has formula size $\tilde{s} = O((k/n)^2 s + \sqrt{(k/n)^2 s})$ for at least half the functions F. Let $\mathcal{S}$ (for shrinkage) denote this event so that $\Pr[\mathcal{S}] \geq \frac{1}{2}$.

Tal [28] showed that every formula of size $\tilde{s}$ has correlation at least $\delta = 2^{-k/4}$ (7) with some formula of size $\tilde{s}' = O(\sqrt{\tilde{s}} + \tilde{s}\log k/k)$. Let Φ be the set of all such formulas over inputs in U. Then we have

$$\mathbb{E}[|\langle F|_\rho, \Phi\rangle|] \geq \mathbb{E}[|\langle F|_\rho, \Phi\rangle| \mid \mathcal{S}] \cdot \Pr[\mathcal{S}] \geq \frac{\delta}{2},$$

where $|\langle f, \Phi\rangle|$ denotes the maximum value of $|\langle f, \phi\rangle|$ over all $\phi \in \Phi$. By Markov's inequality,

$$\Pr[|\langle F|_\rho, \Phi\rangle| \geq \delta/4] \geq \frac{\delta}{4}.$$

On the other hand, by a union bound and Corollary 4,

$$\Pr[|\langle F|_\rho, \Phi\rangle| \geq \delta/4] \leq 3|\Phi|\varepsilon^{1/4}.$$

From these two inequalities we obtain that

$$|\Phi| \geq \frac{1}{12} \cdot \varepsilon^{-1/4} \cdot \delta \geq \frac{\varepsilon^{-1/8}}{12}$$

by (7) and the assumption $\varepsilon \leq 2^{-2k}$. Since $|\Phi| \leq (9k)^{\tilde{s}'}$, it follows that $\tilde{s}' = \Omega(\log(1/\varepsilon)/\log k)$. A calculation shows that $s = \Omega(n^2 \log(1/\varepsilon)/k(\log k)^2)$ as desired. ◀

Correlation with De Morgan formulas

Komargodski, Raz, and Tal [13, 14, 27] proved a correlation lower bound for small De Morgan formulas. Their main technical ingredient is the following high-probability shrinkage lemma for De Morgan formulas [14, 27].

Lemma 5 and the proof of Proposition 5 use the following notation. Given a depth-$(n-k)$ decision tree Δ in n variables and a seed $\pi \in \{0,1\}^{n-k}$, the partial assignment $\Delta(\pi)$ is the one obtained by assigning values to the variables in Δ from root to leaf according to the sequence π (the first bit π_1 is assigned to the root variable, the second bit π_2 is assigned to its child, and so on).

▶ **Lemma 5** (High-probablity shrinkage). *For every constant $c > 0$ there exists a constant $c' > 0$ such that for every $c' \log n \leq k \leq n$ the following holds. For every formula f on n variables of size $s \leq n^c$ there exists a decision tree Δ over its variables of depth at most $n-k$ so that $f|_{\Delta(\pi)}$ has formula size $\tilde{s} = (\log n)^{O(1)} \cdot (k/n)^2 \cdot s$ except with probability $\delta = 2^{-\Omega(k)}$ over the choice of π.*

Without loss of generality we will assume that Δ is a complete decision tree of depth exactly $n-k$ so that $\Delta(\pi)$ has exactly k unrestricted variables for every π.

▶ **Proposition 5.** *Assuming $2^{-\frac{7}{16}k2^{k/8}} \leq \varepsilon \leq 3^{-8n} \cdot 2^{-2k}$ and $\omega(\log n) \leq k \leq n$, for every $(2^k, \varepsilon)$-biased F, at most a $2^{-\Omega(k)}$-fraction of F has correlation more than $2^{-\Omega(k)}$ with formulas of size at most $n^2 \log(1/\varepsilon)/(\log n)^{O(1)}k^2$.*

Proof of Proposition 5. Let $\mathcal{C}$ (for correlating) be the event that F has correlation at least 2δ in absolute value with some formula $\hat{F}$ of size at most s (which may depend on F) so that

$$\mathbb{E}_F[|\langle F, \hat{F}\rangle| \mid \mathcal{C}] \geq 2\delta.$$

We set $\delta = 2^{-\Omega(k)}$ and assume that $\delta \geq 2^{-k/8}$ (8). For every complete decision tree Δ (which may depend on $\hat{F}$) of depth $n-k$,

$$\mathbb{E}_{F,\pi}[|\langle F|_{\Delta(\pi)}, \hat{F}|_{\Delta(\pi)}\rangle| \mid \mathcal{C}] \geq \mathbb{E}_F\left[|\mathbb{E}_\rho[\langle F|_{\Delta(\pi)}, \hat{F}|_{\Delta(\pi)}\rangle]| \;\middle|\; \mathcal{C}\right] = \mathbb{E}_F[|\langle F, \hat{F}\rangle| \mid \mathcal{C}] \geq 2\delta, \quad (9)$$

where $\pi \sim \{0,1\}^{n-k}$ is a random seed. Let $\mathcal{S}$ be the event that $\hat{F}|_{\Delta(\pi)}$ has formula size at most $\tilde{s} = (\log n)^C \cdot (k/n)^2 \cdot s$ (10). By Lemma 5,

$$\Pr_{F,\pi}[\overline{\mathcal{S}} \mid \mathcal{C}] \leq \delta. \tag{11}$$

By the formula for conditional expectations,

$$\begin{aligned}\mathbb{E}[|\langle F|_{\Delta(\pi)}, \hat{F}|_{\Delta(\pi)}\rangle| \mid \mathcal{C}] &= \mathbb{E}[|\langle F|_{\Delta(\pi)}, \hat{F}|_{\Delta(\pi)}\rangle| \mid \mathcal{C}\mathcal{S}] \cdot \Pr[\mathcal{S} \mid \mathcal{C}] \\ &\quad + \mathbb{E}[|\langle F|_{\Delta(\pi)}, \hat{F}|_{\Delta(\pi)}\rangle| \mid \mathcal{C}\overline{\mathcal{S}}] \cdot \Pr[\overline{\mathcal{S}} \mid \mathcal{C}] \\ &\leq \mathbb{E}[|\langle F|_{\Delta(\pi)}, \hat{F}|_{\Delta(\pi)}\rangle| \mid \mathcal{C}\mathcal{S}] + \Pr[\overline{\mathcal{S}} \mid \mathcal{C}],\end{aligned}$$

so (9) and (11) imply that

$$\mathbb{E}_{F,\pi}[|\langle F|_{\Delta(\pi)}, \hat{F}|_{\Delta(\pi)}\rangle| \mid \mathcal{C}\mathcal{S}] \geq \delta.$$

Let Φ be the set of all size-$\tilde{s}$ formulas over k variables. Then $|\Phi| \leq (9k)^{\tilde{s}}$ (12). Since conditioned on $\mathcal{S}$ all formulas $\hat{F}|_{\Delta(\pi)}$ are in Φ, it must be the case that

$$\mathbb{E}_{F,\pi}[|\langle F|_{\Delta(\pi)}, \Phi\rangle| \mid \mathcal{C}\mathcal{S}] \geq \delta,$$

where $\langle f, \Phi\rangle$ denotes the maximum of $\langle f, \phi\rangle$ over all $\phi \in \Phi$. By the formula for conditional expectations, $\mathbb{E}_{F,\pi}[|\langle F|_{\Delta(\pi)}, \Phi\rangle|]$ must be at least $\delta \cdot \Pr[\mathcal{C}\mathcal{S}]$. We can then bound $\Pr[\mathcal{C}\mathcal{S}]$ by

$$\Pr[\mathcal{C}\mathcal{S}] \leq \frac{1}{\delta} \cdot \mathbb{E}_{F,\pi}[|\langle F|_{\Delta(\pi)}, \Phi\rangle|] \leq \frac{1}{\delta}\Big(\frac{\delta^2}{4} + \Pr_{F,\pi}[|\langle F|_{\Delta(\pi)}, \Phi\rangle| \geq \delta^2/4]\Big). \tag{13}$$

Let $\mathcal{P}_k^n$ denote the set of partial assignments that leave k inputs unassigned. As each input can take value 0, take value 1, or be unassigned, $\mathcal{P}_k^n$ has size at most 3^n. By Corollary 4, (8), and a union bound,

$$\begin{aligned}\Pr_{F,\pi}[|\langle F|_{\Delta(\pi)}, \Phi\rangle| \geq \delta^2/4] &\leq \Pr_F[|\langle F|_\rho, \phi\rangle| \geq \delta^2/4 \text{ for some } \rho \in \mathcal{P}_k^n \text{ and } \phi \in \Phi] \\ &\leq 3^n \cdot |\Phi| \cdot 3\varepsilon^{1/4}.\end{aligned}$$

Using (8) and the assumption $\varepsilon \leq 3^{-8n} \cdot 2^{-2k}$, the right hand side is at most $(\delta^2/4) \cdot 12|\Phi|\varepsilon^{1/8}$. By (12) and (10), this quantity is at most $\delta^2/4$ as long as $s \leq n^2 \log(1/\varepsilon)/(\log n)^C k^2$. Plugging into (13), we conclude that $\Pr[\mathcal{C}\mathcal{S}]$ is at most $\delta/2$ for formulas of the desired size.

Finally, applying (11) again, we have

$$\Pr[\mathcal{C}] = \frac{\Pr[\mathcal{C}\mathcal{S}]}{1 - \Pr[\overline{\mathcal{S}} \mid \mathcal{C}]} \leq \frac{\delta/2}{1-\delta} \leq \delta. \qquad \blacktriangleleft$$

3 Main results

Proof of Theorem 1

Let F be the random function $F(x) = SB_{n,2^{-15n}}(s,x)$ for uniformly random s. To obtain item 1, we apply Proposition 2 with $k = \log n - 1$ and Claim 1. (Proposition 1 gives the weaker bound $\Omega(n^2/\log n \log\log n)$ for fan-in up to $c = \log\log\log n$.)

For item 2, we apply Proposition 4 with $k = 3\log n$ and $\varepsilon = n^9 e^{-n}$. (Proposition 3 with $k = \log n$ gives the weaker bound $\Omega(n^3/(\log n)^2 \log\log n)$.)

For item 3, we apply Proposition 5 with $\varepsilon = 3^{-8n} \cdot 2^{-2n}$. The conclusion is that at most a $2^{-\Omega(k)}$-fraction of F can have correlation more than $2^{-\Omega(k)}$ with formulas of size s. Therefore the correlation between $SB_{n,2^{-15n}}$ and size s formulas can be at most $2^{-\Omega(k)}$. $\blacktriangleleft$

Moderate formulas for small bias

▶ **Theorem 6.** *For every n, k, and ε, there exists a $(2^k, \varepsilon)$-biased $F\colon \{0,1\}^n \to \{0,1\}$ of fan-in two formula size $O(nk^2 \cdot \log 1/\varepsilon)$.*

Applying Claim 1 and a suitable change of parameters we obtain the following corollary to Theorem 6:

▶ **Corollary 7.** *For every n, K, and ε there exist (K, ε)-wise independent functions with formula size $O(n \cdot (\log K)^2 \cdot (K + \log 1/\varepsilon))$.*

Proof of Theorem 6. Let $H_t\colon \{0,1\}^n \to \{0,1\}$ be the random function

$$H_t(x) = \begin{cases} \text{a random bit}, & \text{if } Ax = b, \\ 0, & \text{if not}, \end{cases}$$

where A and b are a uniformly random $t \times n$ matrix and t-dimensional boolean vector, respectively, and all algebra is over $\mathbb{F}_2$. We let

$$F = F_1 \oplus F_2 \oplus \cdots \oplus F_{k+2},$$

where the F_t are independent XORs of $6 \log 1/\varepsilon$ independent copies of H_t. Since H_t has formula size $O(tn)$, F has formula size $O(nk^2 \cdot \log 1/\varepsilon)$.

We now prove that F is $(2^k, \varepsilon)$-biased. Let X be any nonempty set of at most 2^k distinct inputs. Set $t = \lfloor \log |X| \rfloor + 2$ and let $\mathcal{U}$ (for unique) be the event that exactly one x in X satisfies $Ax = b$ for a random $t \times n$ matrix A and t-dimensional vector b. By the isolation lemma of Valiant and Vazirani [29], $\mathcal{U}$ has probability at least $1/8$ (see for example [4, Lemma 17.19]). By the rule of conditional expectations,

$$\begin{aligned} &\left|\mathbb{E}\Big[\prod\nolimits_{x\in X}(-1)^{H_t(x)}\Big]\right| \\ &\quad\le \left|\mathbb{E}\Big[\prod\nolimits_{x\in X}(-1)^{H_t(x)}\Big|\mathcal{U}\Big]\right| \cdot \Pr[\mathcal{U}] + \left|\mathbb{E}\Big[\prod\nolimits_{x\in X}(-1)^{H_t(x)}\Big|\overline{\mathcal{U}}\Big]\right| \cdot \Pr[\overline{\mathcal{U}}] \\ &\quad\le |\mathbb{E}[(-1)^{H_t(u)} \mid \mathcal{U}]| \cdot \Pr[\mathcal{U}] + 1 \cdot \Pr[\overline{\mathcal{U}}] \\ &\quad= 0 \cdot \Pr[\mathcal{U}] + 1 \cdot \Pr[\overline{\mathcal{U}}] \\ &\quad\le 7/8. \end{aligned}$$

By independence, it follows that

$$\left|\mathbb{E}\Big[\prod\nolimits_{x\in X}(-1)^{F_t(x)}\Big]\right| = \left|\mathbb{E}\Big[\prod\nolimits_{x\in X}(-1)^{H_t(x)}\Big]\right|^{6\log 1/\varepsilon} \le \left(\frac{7}{8}\right)^{6\log 1/\varepsilon} \le \varepsilon,$$

so $|\mathbb{E}[\prod_{x\in X}(-1)^{F(x)}]| = \prod_{t=1}^{k+2} |\mathbb{E}[\prod_{x\in X}(-1)^{F_t(x)}]|$ is also upper bounded by ε. ◀

Our small-biased function can be viewed as a simplified variant of a construction of Naor and Naor [15, Section 3.1.1]. The simplifications can be partly explained by a difference in objectives: Naor and Naor (and other constructions) aim to optimize the seed length, while we are interested in minimizing formula size.

By the standard simulation of fan-in two formulas by De Morgan formulas, F has De Morgan formula size at most $O((nk^2 \log 1/\varepsilon)^2)$. The De Morgan formula size analysis can be slightly improved to $O(n^2k^3(\log 1/\varepsilon)^2)$ by observing that the middle layer of AND gates does not suffer from the quadratic blow-up.

Specifically, in the parameter settings used in the proof of items 1 and 2 in Theorem 1, the function F has fan-in two formula size $O((n \log n)^2)$ and De Morgan formula size $O(n^4(\log n)^3)$.

For item 3, plugging in $\varepsilon = 2^{-k}$ gives the (De Morgan) formula size upper bound $O(n^4k^3)$. This can be improved to $O(n^4(\log(n/k))^3)$: In the proof of Corollary 4 (and Proposition 5) it is sufficient that F be (t, ε)-biased where t is the unique even integer satisfying (6). For our choice of parameters t is on the order of n/k.

Abstract

An *obstacle representation* of a graph is a mapping of the vertices onto points in the plane and a set of connected regions of the plane (called *obstacles*) such that the straight-line segment connecting the points corresponding to two vertices does not intersect any obstacles if and only if the vertices are adjacent in the graph. The obstacle representation and its *plane* variant (in which the resulting representation is a plane straight-line embedding of the graph) have been extensively studied with the main objective of minimizing the number of obstacles. Recently, Biedl and Mehrabi [5] studied *non-blocking grid obstacle representations* of graphs in which the vertices of the graph are mapped onto points in the plane while the straight-line segments representing the adjacency between the vertices is replaced by the L_1 (Manhattan) shortest paths in the plane that avoid obstacles.

In this paper, we introduce the notion of *geodesic obstacle representations* of graphs with the main goal of providing a generalized model, which comes naturally when viewing line segments as shortest paths in the Euclidean plane. To this end, we extend the definition of obstacle representation by allowing *some* obstacles-avoiding shortest path between the corresponding points in the underlying metric space whenever the vertices are adjacent in the graph. We consider both *general* and *plane* variants of geodesic obstacle representations (in a similar sense to obstacle representations) under any polyhedral distance function in $\mathbb{R}^d$ as well as shortest path distances in graphs. Our results generalize and unify the notions of obstacle representations, plane obstacle representations and grid obstacle representations, leading to a number of questions on such representations.

1 Introduction

An obstacle representation of an (undirected simple) graph G is pair (φ, S) where $\varphi : V(G) \to \mathbb{R}^2$ maps vertices of G to distinct points in $\mathbb{R}^2$ and S is a set of connected subsets of $\mathbb{R}^2$ with the property that, for every $u, w \in V(G)$, $uw \in E(G)$ if and only if the line segment with endpoints $\varphi(u)$ and $\varphi(w)$ is disjoint from $\cup S$. The elements of S are called *obstacles*. It is easy to see that every graph G has an obstacle representation: obtain a straight-line drawing of G by taking any φ that does not map three vertices of G onto a single line, and let S be the set of the open faces in the resulting arrangement of line segments.

Since every graph has an obstacle representation, this defines a natural graph parameter called the *obstacle number*, $\text{obs}(G) = \min\{|S| : (\varphi, S) \text{ is an obstacle representation of } G\}$. Since their introduction by Alpert et al. [2], obstacle numbers have been studied extensively with the main goal of bounding the obstacle numbers of various classes of graphs (see e.g. [3, 8, 11, 12, 14, 16] and the references therein).

For planar graphs, there is also a natural notion of a *plane obstacle representation* (φ, S) which is an obstacle representation in which φ defines a plane straight-line embedding of G. This leads to *plane obstacle number*: $\text{plane-obs}(G) = \min\{|S| : (\varphi, S) \text{ is a plane obstacle representation of } G\}$. Using Euler's formula, it is not hard to see that the plane obstacle number of any n-vertex planar graph is $O(n)$: let φ define any plane drawing of G with no three vertices collinear and take S to be the set of open faces in this drawing. Since an n-vertex planar graph has at most $2n - 4$ faces, this implies $\text{plane-obs}(G) \leq 2n - 4$.

Recently, Biedl and Mehrabi [5] studied *non-blocking grid obstacle representations* of graphs, consisting of the pair (φ, S) as before in which φ maps the vertices of the graph to points in the plane and S is a set of obstacles, but the adjacency in the graph is represented by replacing straight-line segments with L_1 shortest paths in the plane. That is, for every $u, w \in V(G)$, $uw \in E(G)$ if and only if some L_1 shortest path from $\varphi(u)$ to $\varphi(w)$ is disjoint from $\cup S$; see Figure 1 for an illustration of these obstacle representations.

Geodesic obstacle representation. In this paper, we generalize the notions of obstacle representations [2], plane obstacle representations, and grid obstacle representations [5] by introducing *geodesic obstacle representations* of graphs. This natural generalization of obstacle representations comes from viewing line segments as shortest paths in the Euclidean plane. An obstacle representation (φ, S) has the property that $uw \in E(G)$ if and only if the shortest path from $\varphi(u)$ to $\varphi(w)$ does not intersect $\cup S$. The Euclidean distance is a very special case because the shortest path between any two points p and q is unique. To

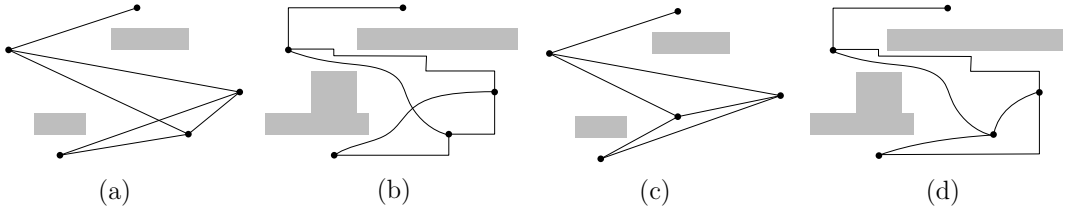

Figure 1 Four different obstacle representations of the same graph G: (a) an obstacle representation, (b) a geodesic obstacle representation under L_1 distance, (c) a plane obstacle representation, and (d) a non-crossing geodesic obstacle representation under L_1 distance.

accommodate other distance measures, we extend the definition of obstacle representation by saying that $uw \in E(G)$ if and only if *some* shortest path from $\varphi(u)$ to $\varphi(w)$ does not intersect $\cup S$. In this way, we can obtain many generalizations of obstacle representations by changing the underlying distance measure. For example, with the L_1 distance measure, every xy-monotone path is a shortest path. Therefore, if (φ, S) is an obstacle representation under L_1, then $uw \in E(G)$ if and only if there is some xy-monotone path from u to w that avoids $\cup S$. Analogous to plane obstacle representations, we can define *non-crossing* geodesic obstacle representations in which φ defines a plane embedding of graph G. Under the L_1 metric, this non-crossing version is equivalent to non-blocking grid obstacle representations as defined by Biedl and Mehrabi [5].

Considering the L_1 metric in the plane, one can view a geodesic obstacle representation of G as a partition of the neighbours of each vertex $u \in V(G)$ into four sets based on which of the four quadrants relative to u the neighbours of u are in the representation. Consequently, if $uv, vw \in E(G)$ in such a way that v is in the same quadrant of u as w is in the quadrant of v in a representation, then we must have $uw \in E(G)$ since there is an xy-monotone path from u to w in the representation. Notice that it is now not clear whether every graph has a geodesic obstacle representation. In fact, Pach [15] showed that there exists a bipartite graph that does not admit a grid obstacle representation. Indeed, the focus of this paper is to determine, for a class $\mathcal{G}$ of graphs, whether or not every member of $\mathcal{G}$ has a geodesic obstacle representation (under some metric space). Clearly, the existence of such representations is more likely if one extends the definition of monotonicity by considering $2k$ equal-angled *cones* around each vertex (instead of $2k = 4$ quadrants), where $k > 2$ is an integer. This leads us to the general question of, informally speaking, what is the minimum integer $k > 0$ for which every member of $\mathcal{G}$ has a geodesic obstacle representation when shortest paths are defined by monotone paths relative to such $2k$ equal-angled cones around each vertex. In this paper, with this "parameter k", we study geodesic obstacle representations and its non-crossing version under polyhedral distance functions in $\mathbb{R}^d$ as well as shortest path distances in graphs. See Section 2 for a formal definition of this generalized notion of obstacle representations.

Related work. It is known that every n-vertex graph has obstacle number $O(n \log n)$ [3] and some n-vertex graphs have obstacle number $\Omega(n/(\log \log n)^2)$ [8]. For planar graphs, there exist planar graphs with obstacle number 2 (the icosahedron is an example [4]), but the best upper bound on the obstacle number of an n-vertex planar graph is $O(n)$. Recall the $O(n)$ upper bound on the plane obstacle number of any n-vertex planar graph by Euler's formula. A lower bound of $\Omega(n)$ is also not difficult: any plane drawing of the $\sqrt{n} \times \sqrt{n}$ grid $G_{\sqrt{n}\times\sqrt{n}}$ has at least $n - 2\sqrt{n}$ bounded faces. Each of these faces has at least four vertices and therefore requires at least one obstacle, so plane-obs$(G_{\sqrt{n}\times\sqrt{n}}) \geq n - 2\sqrt{n}$. Gimbel et al. [11] have nailed the leading constant by showing that every planar graph has plane

obstacle number at most $n-3$, the maximum being attained by planar bipartite graphs. See [2, 3, 8, 11] and the references therein for more details of results on obstacle number and its plane version.

While the obstacle numbers have been extensively studied under the Euclidean distance as shortest path, not much is known about obstacle representations under other shortest path metrics. In fact, we are only aware of the works of Bishnu et al. [6], and Biedl and Mehrabi [5] both of which considered only a restricted version of obstacle representations. Bishnu et al. [6] showed that any n-vertex planar graph G has an obstacle representation on an $O(n^4) \times O(n^4)$ grid in the plane under L_1 metric, with the additional restriction that, for any $uw \in E(G)$, the shortest path from $\varphi(u)$ to $\varphi(w)$ also avoids $\varphi(v)$ for all $v \in V(G) \setminus \{u, w\}$ (in addition to avoiding $\cup S$). Biedl and Mehrabi [5] relaxed this "vertex blocking" constraint and were able to show that every n-vertex planar bipartite graph has a non-blocking grid obstacle representation on an $O(n) \times O(n)$ grid. They left open the problem of finding other classes of graphs for which such non-blocking grid obstacle representations exist and, in particular, whether every planar graph has such a representation.

Our results. In this paper, we prove the following results:

- For any integer $k > 1$, there is a graph with $O(k^2)$ vertices that does not have a geodesic obstacle representation with parameter k. On the other hand, every n-vertex graph has a geodesic obstacle representation with every $k \geq n$.
- For any integer $d > 1$ and any integer $k > 1$, there exists a graph that does not have a geodesic obstacle representation in $\mathbb{R}^d$ with parameter k. On the other hand, every n-vertex graph has a geodesic obstacle representation in $\mathbb{R}^3$ with $k = \lceil (1/2) \log_2 n + 2 \rceil$.
- Every planar graph of treewidth at most 2 (and hence every outerplanar graph) has a non-crossing geodesic obstacle representation with $k = 2$; i.e., a non-blocking obstacle representation.
- Not every planar 3-tree has a non-crossing geodesic obstacle representation with $k = 2$, answering the question asked by Biedl and Mehrabi [5] negatively. Moreover, not every planar 4-connected triangulation has a non-crossing geodesic obstacle representation with $k = 2$.
- Every planar 3-tree has a non-crossing geodesic obstacle representation with $k = 3$. Furthermore, every 3-connected cubic planar graph has a non-crossing geodesic obstacle representation with $k = 7$.
- Every n-vertex graph admits a non-crossing geodesic obstacle representation when taking the D-cube graph as the underlying distance metric, where $D = C \log n$ for some constant $C > 0$.

Organization. We first give some definitions and notation in Section 2. Then, we show our results for (general) geodesic obstacle representations in Section 3 and for its non-crossing version in Section 4. Finally, we give our result for graph metrics in Section 5, and conclude the paper with a discussion on open problems in Section 6.

Throughout this paper, the proofs of lemmas and theorems marked with $(*)$ are given in the full version of the paper [7] due to space constraints.

2 Notation and Preliminaries

Let (X, δ) be a metric space. A *curve* over X is a function $f : [0, 1] \to X$. We call $f(0)$ and $f(1)$ the *endpoints* of the curve f and define the *image* of f as $I(f) = \{f(t) : 0 \leq t \leq 1\}$. A curve f is a *geodesic* if, for every $0 \leq t \leq 1$, $\delta(f(0), f(t)) + \delta(f(t), f(1)) = \delta(f(0), f(1))$. A

path space is a triple $(X, \delta, \mathcal{C})$, where (X, δ) is a metric space and $\mathcal{C}$ is a set of curves over X that has the following closure property: if the curve f is in $\mathcal{C}$ then, for every $0 \leq t \leq 1$, $\mathcal{C}$ also contains the curves $g(x) = f(x \cdot t)$ and $h(x) = f(t + x \cdot (1 - t))$. A path space $(X, \delta, \mathcal{C})$ is *connected* if, for every distinct pair $u, w \in X$, there is some path in $\mathcal{C}$ with endpoints u and w. For a path space $P = (X, \delta, \mathcal{C})$ and a subset $R \subset X$, we denote the subspace induced by R as $P[R] = (R, \delta, \{f \in \mathcal{C} : I(f) \subseteq R\})$. The subspace that *avoids* R is defined as $P \setminus R = P[X \setminus R]$. Moreover, any curve in $P \setminus R$ is called an *R-avoiding curve*. With these definitions in hand, we are ready to define a generalization of obstacle representations.

▶ **Definition 1.** An *$(X, \delta, \mathcal{C})$-obstacle representation* of a graph G is a pair (φ, S) where $\varphi : V(G) \to X$ is a one-to-one mapping and S is a set of connected subspaces of $(X, \delta, \mathcal{C})$ with the property that, for every $u, w \in V(G)$, $uw \in E(G)$ if and only if $\mathcal{C}$ contains a $\cup S$-avoiding geodesic with endpoints $\varphi(u)$ and $\varphi(w)$.

Notice that it is now not clear whether every graph has an $(X, \delta, \mathcal{C})$-obstacle representation. Indeed, the focus of this paper is to determine, for a class $\mathcal{G}$ of graphs and a particular path space $(X, \delta, \mathcal{C})$, whether or not every member of $\mathcal{G}$ has an $(X, \delta, \mathcal{C})$-obstacle representation. This is closely related to certain types of embeddings of G into X. An *embedding* (φ, c) of a graph G into $(X, \delta, \mathcal{C})$ consists of a one-to-one mapping $\varphi : V(G) \to X$ and a function $c : E(G) \to \mathcal{C}$ such that, for each $uw \in E(G)$, the endpoints of $c(uw)$ correspond to $\varphi(u)$ and $\varphi(w)$. The embedding is *geodesic* if $c(uw)$ is a geodesic for every $uw \in E(G)$. Moreover, the embedding (φ, c) is *non-crossing* if $c(uw)$ is disjoint from $c(xz)$, for every $uw, xz \in E(G)$ with $\{u, w\} \cap \{x, z\} = \emptyset$. Observe that given an $(X, \delta, \mathcal{C})$-obstacle representation (φ, S) of G, for each $uw \in E(G)$, we can choose some $\cup S$-avoiding geodesic $c(uw) \in \mathcal{C}$ with endpoints $\varphi(u)$ and $\varphi(w)$. Then, the pair (φ, c) gives a geodesic embedding of G into X. If we can choose c such that (φ, c) is also non-crossing, then we say that the representation (φ, S) is *non-crossing*.

Distance functions. In this paper, we focus on the $(X, \delta, \mathcal{C})$-obstacle representation using polyhedral distance functions in $\mathbb{R}^d$. For a set $N = \{v_0, \ldots, v_{t-1}\}$ of vectors in $\mathbb{R}^d$, we define the *polyhedral distance function*

$$\delta_N(p, q) = \min \left\{ \sum_{i=0}^{t-1} |a_i| : q - p = \sum_{i=0}^{t-1} a_i v_i \right\}.$$

Every such distance function defines a centrally symmetric polyhedron $P_N = \{x \in \mathbb{R}^d : \delta_N(\mathbf{0}, x) \leq 1\}$. The facets of P_N determine the geodesics. For a (closed) facet F of P_N, we denote the *cone* C_F as the union of all rays originating at the origin and containing a point on F (this is the conical hull of F). For a point $x \in \mathbb{R}^d$, the *F-sector* of x is $Q_F^N(x) = C_F + x$. For a facet of F of P_N, we say that a curve f is *δ_N-monotone in direction F* if, for all $0 \leq a \leq b \leq 1$, $f(b) \in Q_F^N(f(a))$. We say that a curve is *δ_N-monotone* if it is δ_N-monotone in direction F for some facet F of P_N. Observe that a curve f is a geodesic for δ_N if and only if f is δ_N-monotone.

▶ **Observation 2.** *If uw and xz are curves that are each δ_N-monotone in direction F and $uw \cap xz$ contains at least one point p, then $\delta_k(u, z) = \delta_k(u, p) + \delta_k(p, z)$ and $\delta_k(x, w) = \delta_k(x, p) + \delta_k(p, w)$.*

When $X = \mathbb{R}^d$, we let $\mathcal{C}_d$ denote the set of curves over $\mathbb{R}^d$. For the sake of compactness, when $X = \mathbb{R}^d$, we denote the $(\mathbb{R}^d, \delta_N, \mathcal{C}_d)$-obstacle representation by *δ_N-obstacle representation*. For the plane case $d = 2$, we define, for each integer $k \geq 2 \in \mathbb{N}$, the *regular distance*

function $\delta_k = \delta_{N_k}$, where $N_k = \{(\cos(i\pi/k), \sin(i\pi/k)) : i \in \{0, \ldots, 2k-1\}\}$. In this case, the associated polygon P_N is a regular $2k$-gon. Moreover, we use δ_k*-obstacle representation* as shorthand for $(\mathbb{R}^2, \delta_k, \mathcal{C}_2)$-obstacle representation. Moreover, for a point in $\mathbb{R}^2$, we denote the i-sector of x by $Q_i^k(x)$, for $i \in \{0, \ldots, 2k-1\}$.

In addition to polyhedral distance functions, we consider obstacle representations under *graph distance*. For a graph H, we denote the set of neighbours of a vertex u in H by $N_H(u)$ and the degree of u by $\deg_H(u)$. Moreover, let δ_H denote the graph distance and let $\mathcal{C}_H$ be the set of curves that define paths in H. Then, we call a $(H, \delta_H, \mathcal{C}_H)$-obstacle representation an H-obstacle representation. If we consider the infinite square grid H_4 (resp., the infinite triangular grid H_6), for instance, then it is not difficult to argue that a graph G has a non-crossing δ_2-obstacle representation (resp., non-crossing δ_3-obstacle representation) if and only if G has a non-crossing H_4-obstacle representation (resp., non-crossing H_6-obstacle representation). In general, for any integer $D > 1$, define the D-cube graph Q_D to be the graph with vertex set $V(Q_D) = \{0,1\}^D$ and that contains the edge uw if and only if u and w differ in exactly one coordinate.

3 General Representations

In this section, we show our results for the general representations. We first consider the special case of $\mathbb{R}^2$ and will then discuss our results for higher dimensions. We start by the following result.

▶ **Theorem 3.** *For any $\epsilon > 0$, there exists a graph G with $n = n(\epsilon)$ vertices such that G has no δ_k-obstacle representation for any $k < n^{1-\epsilon}$.*

Proof. For some constant $c > 0$ and all sufficiently large n, there exists a graph G with n vertices and $cn^{2-2/r}$ edges and that contains no $K_{r,r}$ as subgraph [1]. Let (φ, S) be a δ_k-obstacle representation of G and let (φ, c) be an embedding of G obtained by taking, for each $uw \in E(G)$, $c(uw)$ to be some shortest $\cup S$-avoiding path from $\varphi(u)$ to $\varphi(w)$. From this point on we identify the vertices of G with the points they are embedded to and the edges of G with the curves they are embedded to.

By definition each edge $uw \in E(G)$ is k-monotone. Since P_N has at most $2k$ facets and each edge is monotone in at least two of these directions, this means that it has some facet F such that G contains $E(G)/k$ edges that are monotone in direction F. Consider the graph G' consisting of only these edges and the embedding φ of G'. Observe that if two edges uw and xy of G' intersect at some point p, then (after appropriate relabelling), this implies that there is a $\cup S$-avoiding geodesic from u to x as well as from w to y. Therefore, $ux, uw \in E(G')$.

Therefore, if G' contains an r-tuple of pairwise crossing edges, then G' contains a $K_{r,r}$ subgraph. Now, observe that the edges of G' are monotone in some direction and (after an appropriate rotation) we can assume that they are x-monotone. We call this an x*-monotone embedding*. Valtr [17] has shown that for every fixed r, there exists a constant $C = C(r)$ such that any x-monotone embedding of any n-vertex graph with more than $Cn \log n$ edges contains a set of r pairwise crossing edges. In our case, this means that G contains a $K_{r,r}$ subgraph if $(cn^{2-2/r})/k \geq Cn \log n$, which gives a contradiction when $k \leq cn^{1-2/r}/C \log n$. The result then follows by choosing any $r > 2/\epsilon$. ◀

As $k \to \infty$, δ_k becomes the usual Euclidean distance function and δ_k-obstacle representations are just the usual obstacle representations, which we know every graph has. Thus, for every $n \in \mathbb{N}$, there is a threshold value $k(n)$ such that every n-vertex graph has a $\delta_{k(n)}$-obstacle representation. Theorem 3 shows that $k(n) \in \Omega(n^{1-\epsilon})$ and the following theorem shows that $k(n) \in O(n)$.

▶ **Theorem 4** (∗). *Every n-vertex graph G has a δ_k-obstacle representation for $k = \lceil n/2 \rceil$.*

Higher dimensions. The proof of Theorem 3 makes critical use of the fact that obstacle representations live in the plane so that any sufficiently dense (sub)graph has a k-tuple of pairwise crossing edges. An obvious question, then, is whether every graph has a δ_N-obstacle representation in $\mathbb{R}^3$ (i.e., an $(\mathbb{R}^3, \delta_N, \mathcal{C}_3)$-obstacle representation), where δ_N is some polyhedral distance function. The following theorem shows that the answer to this question is no.

▶ **Theorem 5.** *Let δ_N be a polyhedral distance function over $\mathbb{R}^d$ whose corresponding polyhedron P_N has $2k$ facets, for $k \in o(\log n)$. Then, there exists an n-vertex graph G that has no δ_N-obstacle representation.*

Proof. Let G be an n-vertex graph with no clique and no independent set of size larger than $2 \log n$. The existence of such graphs was shown by Erdős and Renyi [10]. Suppose, for the sake of contradiction, that G has some δ_N-obstacle representation (φ, S). Let $\prec$ denote lexicographic order over points in $\mathbb{R}^d$.

We will k-colour the $\binom{n}{2}$ pairs of vertices of G where the colours are facets of P_N. A pair (u, w) with $u \prec w$ is coloured with a facet F of P_N such that $w \in Q_F^N(u)$. If more than one such facet exists, we choose one arbitrarily. For each $i \in \{1, \ldots, k\}$, let $\prec_i$ denote the partial order obtained by restricting the total order $\prec$ to the pairs of vertices in G with colour i. We claim that for at least one i, $\prec_i$ contains a chain $v_1 \prec_i \cdots \prec_i v_r$ of size $r \geq n^{1/k}$. To see why this is so, observe that, by Dilworth's Theorem, if $\prec_k$ does not contain a chain of length $n^{1/k}$, then it contains an antichain A_k of size $n^{1-1/k}$. Now, proceed inductively on $\prec_1, \ldots, \prec_{k-1}$ and A_k, observing that every pair in A_k is coloured with $\{1, \ldots, k-1\}$.

Next, consider the relation $\prec_i'$ over $v_1, \ldots, v_r$ in which $v_a \prec_i v_b$ if and only if $1 \leq a < b \leq r$ and $v_a v_b \in E(G)$. Observe that $\prec_i'$ is a partial order over $\{v_1, \ldots, v_r\}$. Therefore, by Dilworth's Theorem, it contains a chain of size at least $\sqrt{r}$ or it contains an antichain of size at least $\sqrt{r}$. A chain corresponds to a clique in G and an antichain corresponds to an independent set in G. This contradicts our choice of G when $\sqrt{r} > 2 \log n$, which is true for all $k \in o(\log n)$ and all sufficiently large n. ◀

Theorem 5 shows that, for some n-vertex graphs G, any δ_N-obstacle representation of G must use a distance function δ_N with $k = \Omega(\log n)$ facets. Our next result shows that, even in $\mathbb{R}^3$, a polyhedral distance function with $k = O(\log n)$ facets is indeed sufficient.

▶ **Theorem 6** (∗). *Let δ_N be any polyhedral distance function in $\mathbb{R}^d$, where $d \geq 3$, for which the polyhedron P_N has at least $2 \log_2 n$ facets. Then, every n-vertex graph G has a δ_N-obstacle representation.*

If we take t generic unit vectors in $\mathbb{R}^3$, then the polyhedral distance function determined by these vectors defines a polyhedron having $2t$ vertices and $4t-8$ triangular faces. Theorem 6 therefore implies that a polyhedral distance function determined by $t \geq (1/2) \log_2 n + 2$ unit vectors is sufficient to allow a obstacle representation of any n-vertex graph.

In constant dimensions $d > 3$, there exists sets of t vectors in $\mathbb{R}^d$ defining polytopes with $\Theta(t^{\lfloor d/2 \rfloor})$ facets. Therefore, in $\mathbb{R}^d$, every n-vertex graph has a δ_N-obstacle representation with $|N| \in O(\sqrt[\lfloor d/2 \rfloor]{\log n})$ vectors.

4 Non-Crossing Representations

In this section, we consider non-crossing δ_k-obstacle representations. The following lemma shows that these representations are equivalent to plane δ_k-obstacle embeddings.

▶ **Lemma 7** (∗). *A graph G has a non-crossing δ_k-obstacle representation if and only if G has a non-crossing δ_k-obstacle embedding.*

Lemma 7 allows us to focus our effort on studying the existence (or not) of plane δ_k-obstacle embeddings. We begin with non-crossing δ_k-obstacle embeddings of small treewidth graphs.

Treewidth. A *k-tree* is any graph that can be obtained in the following manner: we begin with a clique on $k+1$ vertices and then we repeatedly select a subset of the vertices that form a k-clique K and add a new vertex adjacent to every element in K. The class of k-trees is exactly the set of edge-maximal graphs of treewidth k. A graph G is called a *partial k-tree* if it is a subgraph of some k-tree. The class of partial k-trees is exactly the class of graphs of treewidth at most k. We will make use of the following lemma, due to Dujmović and Wood [9] in some recursive embeddings.

▶ **Lemma 8** (Dujmović and Wood [9]). *Every k-tree is either a clique on $k+1$ vertices or it contains a non-empty independent set S and a vertex $u \notin S$, such that (i) $G \setminus S$ is a k-tree, (ii) $\deg_{G\setminus S}(u) = k$, and (iii) every element in S is adjacent to u and $k-1$ elements of $N_{G\setminus S}(u)$.*

4.1 δ_2-Obstacle Representations

In this section, we focus on plane δ_2-obstacle embeddings. Recall that these are equivalent to the non-blocking planar grid obstacle representation studied by Biedl and Mehrabi [5]. We begin with the positive result that all graphs of treewidth at most 2 (i.e., partial 2-trees) have plane δ_2-obstacle embeddings.

▶ **Theorem 9.** *Every partial 2-tree has a plane straight-line δ_2-obstacle embedding.*

Proof. Let G be a partial 2-tree. We can, without loss of generality, assume that G is connected. If $|V(G)| < 4$, then the result is trivial, so we can assume $|V(G)| \geq 4$. We now proceed by induction on $|V(G)|$.

Let $T = T(G)$ be a 2-tree with vertex set $V(G)$ and that contains G. Apply Lemma 8 to find the vertex set S and the vertex u. Let x and y be the neighbours of u in $T \setminus S$. Now, apply induction to find a plane straight-line δ_2-obstacle embedding of the graph G' whose vertex set is $V(G') = V(G) \setminus S$ and whose edge set is $E(G') = E(G \setminus S) \cup \{ux, uy\}$. Denote by S_x (resp., S_y) the neighbours of x (resp., y) that belong to S.

Now, observe that, since u has degree 2 in G' and the edges ux and uy are in G', this embedding does not contain any monotone path of the form uxw or uyw for any $w \in V(G) \setminus \{u, x, y\}$. Therefore, if we place the vertices in S sufficiently close to u, we will not create any monotone path of the form ayw or axw for any $a \in S$ and any $w \in V(G) \setminus \{u, x, y\}$. What remains is to show how to place the elements of S in order to avoid unwanted monotone paths of the form uay, uax, or aub for any $a, b \in S$. There are three cases to consider:

1. $x \in Q_i^2(u)$ and $y \in Q_{i+2}^2(u)$ for some $i \in \{0, \ldots, 3\}$. W.l.o.g., assume that $Q_{i+3}^2(u)$ does not intersect the segment xy. Then, we can embed the elements of S in $Q_{i+3}^2(u)$ without creating any new monotone paths; see Figure 2(a).
2. $x, y \in Q_i^2(u)$ for some $i \in \{0, \ldots, 3\}$. There are two subcases:
   - **(i)** At least one of ux or uy is in $E(G)$. Suppose $ux \in E(G)$. Then we embed S_x in $Q_i^2(u)$ and embed S_y in $Q_{i+3}^2(u)$; see Figure 2(b). The only monotone paths this creates are of the form uax with $a \in S_x$, which is acceptable since $ux \in E(G)$.

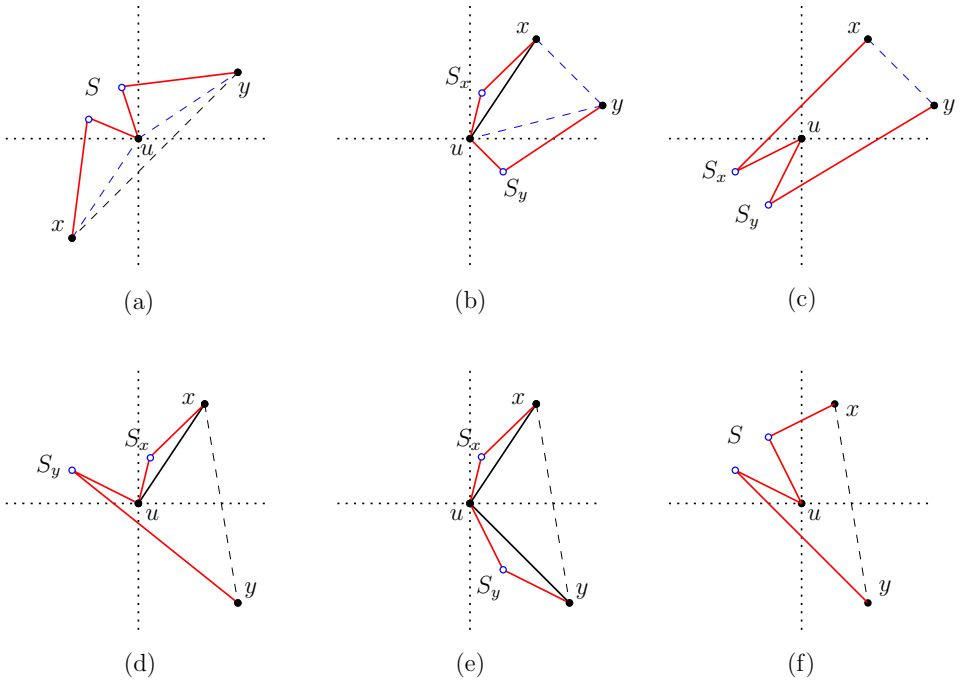

Figure 2 An illustration in supporting the proof of Theorem 9.

(ii) Neither ux nor uy is in $E(G)$. In this case, we embed all of S in $Q^2_{i+2}(u)$ (see Figure 2(c)). This does not create any new monotone paths.

3. $x \in Q^2_i(u)$ and $y \in Q^2_{i+3}(u)$ for some $i \in \{0, \ldots, 3\}$. We have three subcases to consider:

(i) $|\{ux, uy\} \cap E(G)| = 1$. In this case, assume $ux \in E(G)$. Then, we embed the vertices of S_x in $Q^2_i(u)$ and we embed the vertices of S_y in $Q^2_{i+1}(u)$. See Figure 2(d). The only monotone paths this creates are of the form uax with $a \in S_x$, which is acceptable since $ux \in E(G)$.

(ii) $|\{ux, uy\} \cap E(G)| = 2$. In this case, we embed the vertices of S_x in $Q^2_i(u)$ and we embed the vertices of S_y in $Q^2_{i+3}(u)$ (see Figure 2(e)). The only monotone paths this creates are of the form uax with $a \in S_x$ and uby with $b \in S_y$, which is acceptable since $ux, uy \in E(G)$.

(iii) $|\{ux, uy\} \cap E(G)| = 0$. In this case, we embed all of S into Q^2_{i+1} (see Figure 2(f)). This does not create any new monotone paths.

This completes the proof of the theorem. ◀

In the full version of the paper [7], we show that not every planar 3-tree admits a non-crossing δ_2-obstacle embedding.

▶ **Theorem 10** (∗). *There exists a planar 3-tree that does not have a non-crossing δ_2-obstacle embedding.*

We further prove that even 4-connectivity does not help to guarantee the existence of non-crossing δ_2-obstacle embeddings. To this end, we show that a 4-connected triangulation having a plane δ_2-obstacle representation must have a constrained 4-colouring in the sense that, for the neighbours of a vertex, which colours and in what order are they allowed to be assigned to them. The following theorem then follows by finding a 4-connected triangulation that does not admit such a constrained 4-colouring (see the full version of the paper [7]).

▶ **Theorem 11** (∗). *There exists a 4-connected triangulation G with maximum degree 7 that has no plane δ_2-obstacle embedding.*

4.2 Higher-k δ_k-Obstacle Representations

In this section, we consider the non-crossing embeddings for $k > 2$. We show that planar 3-trees have plane δ_3-obstacles embeddings and that all 3-connected cubic planar graphs have plane δ_7-obstacles embeddings. We start by planar 3-trees.

▶ **Theorem 12.** *Every planar 3-tree has a plane δ_3-obstacle embedding.*

Proof Sketch. Here, we sketch the proof; see the full version of the paper [7] for the complete proof. The proof is by induction on $n = |V(G)|$ in which our inductive hypothesis is that every n vertex planar 3-tree has a plane δ_3-obstacle embedding in which the neighbours of each vertex u occupy at least 3 of the sectors $Q_0^3(u), \ldots, Q_5^3(u)$. The key to our proof is the result of Dujmovic and Wood [9] when specialized to planar 3-trees, which says that every planar 3-tree is either K_4 or has a vertex u and an independent set S ($|S| \leq 3$) such that $G \setminus S$ is a 3-tree, u has degree 3 in $G \setminus S$ with neighbours x, y and z, and every vertex r in S forms a clique with exactly one of uxy, uyz or uzx.

By applying this result and recursing on $G \setminus S$ (when $n > 4$), we obtain a plane δ_3-obstacle embedding of $G \setminus S$. By our induction hypothesis, there are two cases depending on the locations of x, y and z with respect to u. In both cases, the elements of S are placed close enough to u that we do not create any new δ_3-monotone paths involving vertices other than those in $\{u, x, y, z\} \cup S$. Since $\{u, x, y, z\}$ form a clique, we only need to worry about (possibly) creating a new δ_3-monotone path involving at least one vertex of S. ◀

We next show that every 3-connected cubic planar graph has a plane δ_7-obstacle embedding. The algorithm contrustructs a δ_7-obstacle embedding by adding one vertex per time according to a canonical ordering of the graph [13], and at each step it maintains a set of geometric invariants which guarantee its correctness. The key ingredients are the fact that each new vertex v to be inserted has exactly two neighbors in the already constructed representation, together with the existence of a set of edges whose removal disconnects the representation in two parts, each containing one of the two neighbors of v. A sufficient stretching of these edges allows for a suitable placement for vertex v. See the full version of the paper for details [7].

▶ **Theorem 13** (∗). *Every 3-connected cubic plane graph has a plane δ_7-obstacle embedding.*

5 Graph Metrics

In this section, we consider the problem under graph distances. Recall the graph D-cube, Q_D whose vertex set is $V(Q_D) = \{0, 1\}^D$ and that contains the edge uw if and only u and w differ in exactly one coordinate. It is not hard to see that every n vertex graph has a Q_n-obstacle representation: Each vertex of G is assigned a coordinate with a single 1 bit. Then, for any two vertices u and w there are exactly two shortest paths in Q_n joining them and they each have length 2. One path goes through the intermediate vertex $\mathbf{0} = (0, \ldots, 0)$ and the other goes through $u + w$. Therefore, by placing an obstacle at $\mathbf{0}$ and at each $u + w$ for which $uw \notin E(G)$, we obtain a Q_D-obstacle representation of G. The following theorem shows we can do this with much fewer coordinates.

▶ **Theorem 14.** *There exists a constant $C > 0$ such that, for $D = C \log n$, every n-vertex graph has a non-crossing Q_D-obstacle representation.*

Proof. Consider the following embedding (φ, c) of G into Q_D: For each $u \in V(G)$, $\varphi(u)$ is a random element of $\{0,1\}^D$. We use the notation u_i to denote the ith coordinate of u. Let $\prec$ denote lexicographic order on D-tuples. For each edge $uw \in E(G)$ with $u \prec w$, we take $c(uw)$ to be the *greedy* path that visits, for $i = 0, \ldots, D$, the vertex $uw_i = (w_1, \ldots, w_i, u_{i+1}, \ldots, u_D)$. Thus $uw_0, \ldots, uw_D$ is a sequence of vertices that—after removing duplicates—is a shortest path, in Q_D, from u to w. Note that there is an asymmetry here that we should be careful of, so for $u \prec w$, we define $wu_i = (w_1, \ldots, w_{D-i}, u_{D-i+1}, \ldots, u_D) = uw_{D-i}$. Here are some observations about the embedding (φ, c):

1. All vertex distances are close to $D/2$: The distance between any two vertices is a binomial$(D, 1/2)$ random variable. Therefore, by Chernoff's bounds, for any constant $\epsilon > 0$ and for any vertex pair $u \neq w$, $\Pr\{|\delta_{Q_D}(u,w) - D/2| > \epsilon(D/2)\} \leq n^{-\Omega(C)}$. By the union bound, the probability that there exists any pair of vertices $u \neq w$ with $|\delta_{Q_D}(u,w) - D/2| > \epsilon(D/2)$ is also $n^{-\Omega(C)}$.
2. The embedding is non-crossing: For any four distinct vertices $u \prec w$ and $x \prec y$, and any $i, j \in \{0, \ldots, D\}$, the vertices uw_i and xy_j are independent random D-bit strings. Therefore, $\Pr\{\delta_{Q_D}(uw_i, xy_j) \leq 1\} = (D+1)/2^D$. By the union bound, the probability that there exists any four vertices u, w, x, y and any pair of indices i, j for which $\delta_{Q_D}(uw_i, xy_j) \leq 1$ is at most $n^4(D+1)^3/2^D = n^{-\Omega(C)}$.
3. No geodesic passes close to a vertex except its endpoints: Let u, w, and x be distinct vertices and $r \in \{0, \ldots, D\}$ be an integer. Then, the probability that there exists any geodesic with endpoints u and w that contains a vertex z with $\delta_{Q_D}(z, x) \leq r$ is at most $n^{-\Omega(C)}$. To see why this is so, suppose that such a geodesic, C, contains a vertex z such that $\delta_{Q_D}(z, x) \leq r$. Then, at least one of the following events occurs:
   (a) $\delta_{Q_D}(u, w) \geq (1+\epsilon)D/2$;
   (b) $\delta_{Q_d}(u, x) \leq (1+\epsilon)D/4 + r$; or
   (c) $\delta_{Q_d}(w, x) \leq (1+\epsilon)D/4 + r$.
   Point 1 above establishes that the probability of the first event is $n^{-\Omega(C)}$ and that, for $r \leq (1-3\epsilon)D/4$, the probability of each of the other two events is $n^{-\Omega(C)}$. Applying the union bound over all 3 events, and over all $\binom{n}{3}$ choices of u, w, and x then shows that the probability that there is any triple u, w, x such that any geodesic from u to w passes within distance $(1-3\epsilon)D/4$ of x is $n^{-\Omega(C)}$.
4. Paths diverge quickly: Let $xu, xw \in E(G)$, be two edges of G with the common endpoint x and let $r \in \{0, \ldots, D\}$. We want to show that the directed paths xu and xw diverge quickly. There are three cases to consider:
   a. $x \prec u$ and $x \prec w$. In this case $xu_r = xw_r$ if and only if $u_1, \ldots, u_r = w_1, \ldots, w_r$, so $\Pr\{xu_r = xw_r\} = 2^{-r}$.
   b. $x \prec u$ and $w \prec x$. In this case, we consider $xu_r = u_1, \ldots, u_r, x_{r+1}, \ldots, x_D$ and $xw_r = wx_{D-r} = x_1, \ldots, x_{D-r}, w_{D-r+1}, \ldots, w_D$. For any choice of i, these two strings have independent bits in at least r locations, so $\Pr\{xu_r = xw_r\} \leq 2^{-r}$.
   c. $u \prec x$ and $w \prec x$. In this case $xu_r = ux_{D-r} = x_1, \ldots, x_{D-r}, u_{D-r+1}, \ldots, u_D$ and $xw_r = wx_{D-r} = x_1, \ldots, x_{D-r}, w_{D-i+1}, \ldots, w_D$. So $\Pr\{xu_r = xw_r\} = 2^{-r}$.
   If we choose $r = \alpha \log n$, then this probability is at most $n^{-\Omega(\alpha)}$. Again, the union bound shows that the probability that there is any u, w, or x such that $xu_r = xw_r$ is at most $n^{-\Omega(\alpha)}$.

In the following, we choose C sufficiently large and $\alpha < (1/4 - \epsilon)C$ also sufficiently large so that with probability greater than 0, we obtain an embedding for which all four of preceding properties hold. Therefore, there exists some embedding (φ, c) such that 1. for all $u, w \in V(G)$, $|\delta_{Q_D}(u,w) - D/2| \leq \epsilon D/2$; 2. for all $uw, xy \in E(G)$ with $\{u, w\} \cap \{x, y\} = \emptyset$,

$\delta_{Q_D}(c(uw), c(xy)) > 1$; 3. for all $uw \in E(G)$ and $x \in V(G) \setminus \{u, w\}$, $\delta_{Q_D}(c(uw), x) \geq (1-\epsilon)D/4$; and 4. for all $xu, xw \in E(G)$ and all $r \geq \alpha \log n$, $xu_r \neq xw_r$.

To obtain a Q_D-obstacle representation (φ, S) we take S to contain all the vertices not used in any path of the embedding (φ, c). To verify that this is indeed a non-crossing Q_D-obstacle representation, we need only verify that, for any $u, w \in V(G)$ with $uw \notin E(G)$, $\delta_{Q_D \setminus S}(u, w) > \delta_{Q_D}(u, w)$. This is implied by the following inequality, which relates distances in G to those in $Q_D \setminus S$:

$$\delta_{Q_D \setminus S}(u, w) \geq \delta_G(u, w)(1-\epsilon)D/2 - (\delta_G(u, w) - 1)2\alpha \log n \ . \tag{1}$$

Note (1) is sufficient since, if $uw \notin E(G)$, then $\delta_G(u, w) \geq 2$ and (1) implies $\delta_{Q_D \setminus S}(u, w) \geq (1-\epsilon)D - 2\alpha \log n = ((1-\epsilon)C - 2\alpha) \log n > (1+\epsilon)D/2$, which contradicts Property 1. Thus, all that remains is to establish (1). To do this, consider any path P from u to w in $Q_D \setminus S$. Since the only vertices in $Q_D \setminus S$ are those that are used by some embedded edge of G, the path P consists of a sequence of subpaths $P_0, \ldots, P_k$ where each P_i is a subpath of $c(x_i y_i)$ for some edge $x_i y_i \in E(G)$. Note that Property 3 implies that $x_0 = u$ and that $x_k = w$. Furthermore, Properties 2 and 3 imply that $x_i = y_{i-1}$ for each $i \in \{1, \ldots, k\}$. Therefore, $x_0, \ldots, x_k$ is a path in G from u to w, so $k \geq \delta_G(u, w)$. Finally, Property 4 implies that, for each $i \in \{1, \ldots, k-1\}$, the portion of $c(x_i, x_{i+1})$ not used by P_i has length at most $2\alpha \log n$. Thus, the length of P is at least $k(1-\epsilon)D/2 - 2(k-1)\alpha \log n$, as required. ◀

It is worth noting that Theorem 14 is closely related to Theorem 6. Indeed, before perturbing it, the point set X used in the proof of Theorem 6 is a projection of the vertices of Q_D with $D = \lceil \log_2 n \rceil$ onto $\mathbb{R}^3$. In Theorem 6 we then perturb X to obtain a non-crossing embedding. In the proof of Theorem 14 we have to be more careful to avoid crossings.

6 Conclusion

In this paper, we introduced the geodesic obstacle representation of graphs, providing a unified generalization of obstacle representations and grid obstacle representations. Our work leaves several problems open. As perhaps the main question, does every planar graph admit a non-crossing δ_k-obstacle representation for some constant k? It would be also interesting to extend the classes of graphs for which non-crossing δ_k-obstacle representations exist for small values of k. For graph metrics, given two graphs G and H, is it NP-hard to decide if G has an H-obstacle representation?

Abstract

In this work, we initiate the study of *bottleneck* complexity as a new communication efficiency measure for secure multiparty computation (MPC). Roughly, the bottleneck complexity of an MPC protocol is defined as the maximum communication complexity required by any party within the protocol execution.

We observe that even without security, bottleneck communication complexity is an interesting measure of communication complexity for (distributed) functions and propose it as a fundamental area to explore. While achieving $O(n)$ bottleneck complexity (where n is the number of parties) is straightforward, we show that: (1) achieving *sublinear* bottleneck complexity is *not* always possible, even when no security is required. (2) On the other hand, several useful classes of functions do have $o(n)$ bottleneck complexity, when no security is required.

Our main positive result is a compiler that transforms any (possibly insecure) efficient protocol with fixed communication-pattern for computing any functionality into a secure MPC protocol while preserving the bottleneck complexity of the underlying protocol (up to security parameter overhead). Given our compiler, an efficient protocol for any function f with sublinear bottleneck complexity can be transformed into an MPC protocol for f with the same bottleneck complexity.

Along the way, we build cryptographic primitives – incremental fully-homomorphic encryption, succinct non-interactive arguments of knowledge with ID-based simulation-extractability property and verifiable protocol execution – that may be of independent interest.

1 Introduction

Secure multi-party computation (MPC) [32, 20] is a fundamental notion in cryptography, enabling a collection of mutually distrusting parties to jointly evaluate a function on their private inputs while revealing nothing beyond the function output. In the past decades, a great deal of research has been dedicated to the design and optimization of efficient MPC protocols.

In this work, we study one fundamental metric of MPC efficiency: the required *communication* between parties. In particular, we focus on the communication complexity of MPC in large-scale settings, where the number of participants is significant.

In nearly all existing works in MPC literature, the communication complexity goal has been to minimize the *total* communication of the protocol across all n parties. However, for many important applications, such as peer-to-peer computations between lightweight devices,[1] total costs (such as total communication) are only secondarily indicative of the feasibility of the computation, as opposed to the primary issue of *per-party* cost. Indeed, while a total communication bound L implies average per-party communication of the protocol is L/n, the computation may demand a subset of the parties to *each* communicate as much as $\Theta(L)$. When all parties contribute input to the computation, then $L \geq n$, meaning these parties must bear communication proportional to the *total number of parties*. In large-scale distributed settings, or when the protocol participants are lightweight devices, such a requirement could be prohibitive.

New efficiency measure: (MPC) Bottleneck Complexity

To address these concerns, we initiate the study of *bottleneck complexity* of MPC. The bottleneck complexity of a protocol Π is defined as the *maximum communication required by any party* within the protocol execution. One may further specialize this to incoming versus outgoing communication. The MPC bottleneck complexity of a (distributed) function is the minimum possible bottleneck complexity of a secure MPC protocol for the function. In this work, our goal is to explore this notion as a complexity measure for distributed computations, and to develop secure protocols with low bottleneck complexity.

Bottleneck complexity addresses certain (practically important) aspects ignored by standard communication complexity. For instance, if two messages are transmitted in two different parts of a network, say $A \to B$ and $C \to D$, they would be delivered faster than two messages sent to/from the same party, say $A \to B$ and $C \to B$. While both have same total communication, the latter has higher bottleneck communication.

Bottleneck Complexity without Security

Before studying bottleneck communication complexity for secure protocols, we first consider this measure for arbitrary protocols without any security considerations. Indeed, this already forms an interesting measure of complexity for (distributed) functions, and we propose it as a fundamental area to explore. As in the case of total communication complexity (which coincides with bottleneck complexity for the case of 2 parties), there is a trivial upper bound of $O(n)$ bottleneck complexity for any n-party functionality (with boolean inputs), where all parties simply send their input to a central party who computes the functionality. On

[1] For example, optimizing navigation routes based on traffic information contributed by the cell phones of drivers on the road, without revealing the locations of individual users.

the other hand, in many functions, bottleneck complexity brings out structures that total communication complexity overlooks. For instance, in computing say the XOR or AND of n bits, total communication complexity is $\Theta(n)$, but the bottleneck complexity is $O(1)$. These functions naturally allow for *incremental computation* along a chain, in which each party receives and sends a single bit. Indeed, there is a large class of useful functions which have protocols with low bottleneck complexity, as discussed below.

However, a priori it is not clear whether *all* functions can be computed in a similar manner. This brings us to the first question considered in this work:

Can all functions be computed (without security)
with *sublinear* bottleneck complexity?

For concreteness, we may consider n-party functions, with n inputs (one for each party) each k bits long, and a single-bit output. Because of the trivial $O(nk)$ upper bound on total communication complexity for any such function (as discussed above), each party *on average* needs only to communicate $O(k)$ bits. But in this protocol, the communication complexity of the central party—and thus bottleneck complexity of the protocol—is $(n-1)k$ bits. Surprisingly, we show that this is the best one can ask for, for general functions. That is, there exist n-party functionalities with k-bit inputs for which the bottleneck complexity is $\Omega(nk)$.

▶ **Theorem 1.** *(Informal.) There exist n-party functions with k-bit input for each party that have bottleneck complexity close to that in the trivial upperbound, namely $(n-1)k$.*

Our proof is based on a counting argument, and quantifies over possibly inefficient functions too. Interestingly, giving an explicit efficient function f with such a lower bound will require a breakthrough in complexity theory, as it would imply an $\Omega(n^2)$ lower bound on the circuit size of computing f. (We discuss this connection below.)

Functions with Low Bottleneck Complexity

Despite the above lower bound, there is a large class of interesting functions which do have sublinear bottleneck complexity. One simple but widely applicable example is addition in a finite group: the sum of n group elements distributed among n parties can be aggregated bottom-up (and then disseminated top-down) using a constant-degree tree, with every party communicating $O(d)$ group elements, where d is its degree in the tree. [2]

A wider class of functions are obtained from the literature on streaming algorithms [18, 26]. Indeed, any streaming algorithm with a small memory and a small number of passes corresponds to a low bottleneck complexity function. (Here, we refer to the actual function that the streaming algorithm computes, which may in fact be an approximation to some other desired function.) This is because we can design a protocol which passes around the state of the streaming algorithm from one party to the next, in the order in which their inputs are to be presented to the algorithm.

On the other hand, low bottleneck complexity protocols appear to be much more general than streaming algorithms. Indeed, observe that the low bottleneck complexity protocol described above has a very special communication structure of a chain (or multi-pass cycle). We leave it as an open problem to separate these two notions – i.e., find functions which have low bottleneck complexity protocols, but do not have low-memory streaming algorithms.

[2] If the group is not abelian, the tree used should be such that its in-order traversal should result in the parties to be ordered in the same way their inputs are ordered in the sum being computed.

Finally, we note that, any n-input function with a constant fan-in circuit of subquadratic size (i.e., $o(n^2)$ gates) has a sublinear bottleneck complexity protocol. To see this, first we note that such a circuit can be made to have constant fan-out as well, by increasing the circuit size by a constant factor. [3] Then, a sublinear bottleneck complexity protocol can be obtained from the circuit by partitioning all the $o(n^2)$ gates roughly equally among the n parties, and letting the parties evaluate the gates assigned to them, communicating with each other when wires cross party boundaries. The communication incurred by each party is bounded by the number of wires incident on all the gates it is assigned, which is $o(n)$.

MPC Bottleneck complexity

We next turn our attention to achieving low bottleneck complexity for *secure* computation of functionalities. We focus on the general setting where up to $n-1$ out of n parties can be corrupted. As a baseline, we observe that the MPC protocol of Dodis *et al.* [15] based on "additive-spooky encryption" can be easily adapted to obtain generic secure computation with $O(n)$ bottleneck complexity (where $O(n)$ hides factors of the security parameter). Therefore, as in the insecure setting, we focus on constructing MPC protocols with sublinear $o(n)$ bottleneck complexity.

Specifically, we ask the question:

> If a function f can be computed with bottleneck complexity L,
> can it be computed *securely* with the same bottleneck complexity,
> up to a multiplicative overhead of the security parameter?

We note that the goal of sublinear bottleneck complexity is strictly stronger than the recently studied problem of MPC with sublinear communication locality [5]. The locality of a protocol is the maximum number of other parties that any party must communicate with during the course of the protocol. It is easy to see that sublinear bottleneck complexity directly implies sublinear locality (since sending/receiving $o(n)$ bits means that a party can only communicate with $o(n)$ neighbors); however, as locality does not place any requirements on the number of bits communicated by a party, the converse is not true. Indeed, without security requirements, every function has an $O(1)$-local protocol, which is not the case for bottleneck complexity.

We show a general compiler which transforms any (possibly insecure) efficient multi-party protocol Π for computing a function f into a protocol Π' for *securely* computing f, preserving the per-party communication and computation requirements up to $O(\lambda^c)$ factors in the security parameter λ for small constant c. The original protocol Π can have an arbitrary communication pattern; however, we require that this pattern must be fixed a priori (independent of inputs) and known to all parties. Our compiler additionally preserves the topology of communication graph of Π (and in particular, preserves locality).

▶ **Theorem 2** (Informal). *There is a transformation which maps any (possibly insecure) efficient protocol with fixed-communication-pattern for an n-party distributed function f into a secure MPC protocol for f with asymptotically (as a function of n) the same communication and computational requirements per party, and using the same communication graph as the original protocol.*

[3] Given a gate with fan-out $d > 2$, consider the depth-1 tree T rooted that gate with d leaves being the gates to which its outputs are connected. T can be replaced by an equivalent *binary* tree T' with the same root and leaves, and $d-2$ new internal nodes. The new internal nodes of T' can be "charged" to the leaves of T. On doing this for all gates in the circuit, each gate gets charged at most as many times as its fan-in. Since each gate in the original circuit has constant fan-in, this transformation increases the circuit size by at most a constant factor.

The transformation to achieve security against passive corruption is based on a new tool that we develop, namely *Incremental Fully Homomorphic Encryption*, which we show can be instantiated from the Learning With Errors (LWE) assumption, à la [19]. For security against active corruption (possibly for restricted auxiliary information), we build zero-knowledge succinct non-interactive arguments of knowledge (ZK-SNARK [2]) with an"ID-based" simulation-extractability property (see Section 1.1 for details). We rely on a setup that includes a common random string and a (bare) public-key infrastructure, where all the n parties have deposited keys for themselves, and which all the parties can access for free. The setup can be reused for any number of executions.

Our Contributions

To summarize, our main contributions in this work are as follows:

- We introduce a new measure of per-party communication complexity for (distibuted) functions, called bottleneck complexity.
- We demonstrate the existence of n-party functions with k bits of input for each party, that have bottleneck complexity $\Theta(nk)$. Showing an explicit function with $\Omega(n)$ bottleneck complexity will require showing an explicit function with $\Omega(n^2)$ circuit size complexity. On the other hand, we observe that many useful classes of functions do have $o(n)$ bottleneck complexity.
- We show a general transformation from arbitrary efficient protocols to secure MPC protocols (in a model with public setup) that asymptotically (as a function of n) preserves the communication and computational requirements per party, and preserves the same communication graph.
- As part of our transformation, we introduce cryptographic primitives—Incremental FHE, Verifiable Protocol Execution—and give a construction of ZK-SNARKs with an ID-based simulation-extractability property. These may be of independent interest.

We expand on the transformation in the following section.

1.1 Our Techniques

We describe the main ideas underlying our positive result: the bottleneck-complexity-preserving transformation from arbitrary protocols to secure ones.

At a high-level, we follow an intuitive outline for our compiler: (1) We first compile an insecure protocol into a protocol that is secure against semi-honest (or honest-but-curious) adversaries using fully homomorphic encryption (FHE). (2) We then use zero-knowledge succinct arguments of knowledge (ZK-SNARKs) to compile it into a protocol that is (standalone) secure against malicious adversaries. However, we run into several technical challenges along the way, requiring us to develop stronger guarantees for FHE and SNARKs, as well as some other new ideas. We elaborate on these challenges and our solutions below.

Semi-honest Security

A natural starting idea to obtain semi-honest security is to execute an "encrypted" version of the underlying (insecure) protocol by using FHE. Once the parties have the encrypted output, they execute the FHE decryption process to learn the output. The immediate problem with implementing this idea in the multiparty setting is which key must we use for encryption and decryption. If a single party knows the (entire) decryption key, then we cannot guarantee security.

To address this problem, two approaches have been developed in the literature: threshold FHE [1], where the parties jointly generate a public key for an FHE scheme such that each party only knows a share of the decryption key, and multi-key FHE [25], where each party has its own public and secret key pair and FHE evaluation can be performed over ciphertexts computed w.r.t. different public keys.

While these approaches have been shown to suffice for constructing round-efficient MPC protocols, they are not directly applicable to our setting. This is for two reasons:

- Threshold FHE and multi-key FHE systems are defined in the broadcast model of communication where each party gets to see the messages sent by all the other parties. In contrast, our setting is inherently point-to-point, where a party only communicates with its neighbors in the communication graph of the underlying insecure protocol. Indeed, in order to maintain sublinear bottleneck complexity, we cannot afford each party to communicate with all the other parties.
- Further, in all known solutions for threshold FHE [1] and multi-key FHE [25, 9, 27, 6, 29], the size of one or more protocol messages of each party grows at least linearly with the number of parties. This directly violates our sublinear bottleneck complexity requirement.

To address these issues, we define and implement a new notion of *incremental* FHE (IFHE). Roughly, an IFHE scheme is defined similarly to threshold FHE, with the following key strengthened requirements: a "joint" public key can be computed by incrementally combining shares provided by different parties in an arbitrary order. Similarly, a ciphertext w.r.t. the joint public key can be decrypted by incrementally combining partial decryption shares provided by parties in an arbitrary order. Crucially, the intermediate keys and partial decryption values must be *succinct*.

We construct an IFHE scheme with appropriate security guarantees based on the Gentry-Sahai-Waters FHE scheme [19]. Using IFHE, we are able to directly compile an insecure protocol into a semi-honest secure protocol. In fact, this protocol can withstand a slightly stronger adversary – called a *semi-malicious* adversary [1] – which is allowed to maliciously choose its random tape. This will be crucially exploited in the next step, because without it, one will need to enforce honest random-tapes for all the parties (using n-way coin-tossing-in-the-well) which would incur $\Omega(n)$ communication already.

From Semi-Malicious to Malicious Security

A natural approach to achieve security against malicious adversaries is to use the GMW paradigm [20]. Roughly, in the GMW compiler, each party first commits to its input and random tape. Later, whenever a party sends a message of a semi-malicious protocol,[4] it also proves in ZK to *all* the other parties that it is behaving correctly w.r.t. the committed input and random tape.

The GMW commit-and-prove methodology is problematic in our setting since we cannot allow a party to talk to all other parties (directly or indirectly through the other nodes). Yet, in order to achieve security, each honest party must verify not just that its neighbors behave correctly, but that *all* corrupt parties (many of whom may not directly interact with any honest party) behaved honestly. A priori, these may seem to be contradictory goals.

We address all of these challenges by presenting a new generic compiler for *Verifiable Protocol Execution* (VPE), modeled as a functionality $\mathcal{F}_{\mathsf{vpe}}$. Our protocol Π_{vpe} for implementing

[4] The standard GMW compiler is defined for semi-honest protocols and also involves a coin-tossing step. Here, we consider a natural variant that works for semi-malicious protocols.

$\mathcal{F}_{\mathsf{vpe}}$ asymptotically preserves the per-party communication and computational complexity (up to a multiplicative factor polynomial in the security parameter) of the underlying semi-malicious protocol. We construct Π_{vpe} from two main ingredients: (1) a new commitment protocol that allows the parties to compute a succinct "aggregate" commitment over the inputs and randomness of all of the parties. (2) ZK-SNARKs with a strong extraction property as well as simulation-soundness to ensure that adversary cannot prove false statements even upon receiving simulated proofs. We refer the reader to the full version for details on our commitment protocol. Here, we discuss our use of ZK-SNARKs.

ID-Based Simulation-Extractable ZK-SNARKs

We rely on ZK-SNARKs to let parties provide not just proofs of correctly computing their own messages, but also of having verified previous proofs *recursively*. This use of SNARKs for recursive verification resembles prior work on proof-carrying data [8, 3]. The key difference is that proof-carrying data only addresses correctness of computation, whereas in our setting, we are also concerned with privacy. In particular, in order to argue security, we also require these proofs to be simulation-sound with extractability (or simply *simulation-extractable*) [30, 31], which presents a significant additional challenge.

The core challenge in constructing simulation-extractable ZK-SNARKs (SE-ZK-SNARKs) arises from the inherent limitation that extraction from the adversary must be non-black-box (since the size of the extracted witness is larger than the proof itself), but the adversary receives simulated proofs which he cannot directly produce on his own. Indeed, for this reason SE-ZK-SNARKs are impossible to achieve with strong universal composability (UC) security [23]. To reduce the security of an SE-ZK-SNARK construction to an underlying knowledge assumption (such as standard SNARKs), one must thus either (a) start with an assumption that guarantees non-black-box extraction even in the presence of an oracle (which can be problematic [16]), or (b) somehow in the reduction be able to provide *the code* to answer the adversary's simulated proof queries, without voiding the reduction by including the simulation trapdoor itself.

Two recent works have presented constructions of SE-ZK-SNARKs, each adopting a different approach. Groth and Maller [21] embody approach (a), constructing full SE-ZK-SNARKs from a new specific pairing-based knowledge assumption which assumes extraction in the presence of black-box access to an oracle with the trapdoor. Alternatively, Garman *et al.* [17] take approach (b), basing their construction on standard SNARKs; however, their construction is only applicable to a restricted security model where the statements on which the adversarial prover requests simulated proofs are fixed in advance (in which case these proofs can be hardcoded in the reduction). The case where the adversary's queries are chosen *adaptively* as a function of previously simulated proofs (which we need for our transformation) is not currently addressed in this setting.

We provide a new solution for handling adaptive queries, without relying upon oracle-based assumptions as in [21]. We consider an ID-based notion of SE-ZK-SNARKs, where each proof is generated with respect to an identity (chosen from a set of identities that are fixed in advance). In our definition, the adversary must fix a set ID^* of "honest" identities in advance and can then receive simulated proofs on adaptively chosen statements w.r.t. identities from this set. It must then come up with an accepting proof for a new statement w.r.t. an identity $\mathsf{id} \notin \mathsf{ID}^*$.

We show how to transform any SNARK argument system into an ID-based SE-ZK-SNARKs by relying on only standard cryptographic assumptions. Very roughly, in our construction, it is possible to "puncture" the trapdoor trap for the CRS w.r.t. an identity set

ID^*. A punctured trapdoor $\mathsf{trap}_{\mathsf{ID}^*}$ can only be used to simulate the proofs w.r.t. identities $\mathsf{id} \in \mathsf{ID}^*$, but cannot be used to simulate proofs w.r.t. identities $\mathsf{id} \notin \mathsf{ID}^*$. Using such a punctured trapdoor, we are able to successfully implement approach (b) in the adaptive setting. We implement this idea by using identity-based signatures, which can be readily constructed using certificate chains from a standard signature scheme.

Ultimately, we obtain recursively verifiable ID-based SE-ZK-SNARK generically from signatures and (standard) SNARKs with an "additive extraction overhead." While the latter is a relatively strong requirement [22], such primitives have been considered in prior work [10, 3] and appears to be as justified as the standard SNARK assumption.

Auxiliary Inputs

In order to achieve the standard MPC security, we require SE-ZK-SNARKs that allow extraction even w.r.t. adversaries with auxiliary inputs from arbitrary distribution, which in turn requires SNARKs with the same extraction property. However, even assuming SNARKs which are secure only with respect to specific auxiliary information distribution, our construction obtains MPC that is secure with respect to restricted auxiliary information (see the full version for details).

1.2 Related Work

Communication complexity models

The vast majority of study in communication complexity (c.f. [24]) focuses on the setting of only two parties, in which case the total and bottleneck complexities of protocols align (asymptotically). In the multi-party setting, several models are considered regarding how the input to f begins initially distributed among the players. The most common such models are the "number-on-forehead" model, in which parties begin holding all inputs except their own, and the model considered in this work (as is standard in MPC), frequently known as the "number in hand" model, where each party begins with his own input. In all cases, the "communication complexity" within the given model refers to the total communication of all parties.

Communication complexity of MPC

Communication complexity of secure multiparty computation (MPC) has been extensively studied over the years. Communication complexity preserving compilers from insecure to secure protocols were introduced in the 2-party setting by [28]. The setting of MPC with many parties was first predominantly considered in the line of work on scalable MPC [11, 12]. Here the focus was on optimizing the complexity as a function of the circuit size $|C|$, and the resulting n-party protocols have per-party communication $\tilde{O}(|C|/n) + \mathrm{poly}(n)$. Some of these works explicitly achieve load-balancing (e.g., [14, 4]), a goal similar in spirit to bottleneck complexity, where the complexity of the protocol is evenly distributed across the parties. To the best of our knowledge, however, the $\mathrm{poly}(n)$ term in the per-party communication complexity is $\Omega(n)$ in all works aside from [33], which achieves $\tilde{O}(|C|/n)$ *amortized* per-party communication but $\tilde{O}(|C|/n + n)$ *bottleneck* complexity (due to its dependence on [7]).

Communication Locality

A related notion to bottleneck complexity is communication locality [5]. The locality of a party is the number of total other parties it must communicate with throughout the protocol, and the locality of the protocol is the worst case locality of any party. In [5], Boyle et al.

studied locality in secure MPC and showed (based on various computational assumptions) that any efficiently computable function has a polylog(n)-locality secure MPC protocol.

Lower bounds on MPC communication complexity

As discussed, lower bounds on standard multi-party communication complexity cannot directly imply meaningful lower bounds on bottleneck complexity, as no such bound can exceed $\Omega(n)$ (attainable by all parties sending their input to a single party), but this implies only a bound of $\Omega(1)$ bottleneck complexity. For *secure* computation, in [13], Damgård et al. showed that securely evaluating a circuit of m multiplication gates requires $\Omega(n^2 m)$ total communication in the information-theoretic security setting. This implies a super-linear lower bound for bottleneck complexity in their setting. We note, however, that their lower bound does not apply to us, as we consider computational security, and further, their lower bound does not apply to the setting where the number of parties is larger than the security parameter.

2 Preliminaries and Definitions

By $x \in_R \mathbb{Z}_q^n$ we denote that x is uniformly sampled from $\mathbb{Z}_q^n$, and by $x \leftarrow D$ we denote that x is sampled from a distribution D. By $\overset{c}{\approx}$ we denote computational indistinguishability. We denote an N-party additive secret sharing of $x \in \mathbb{Z}_q$ by $[x]_q^N$. That is, each P_i owns $x_i \in \mathbb{Z}_q$ such that $x = \sum_{i \in [N]} x_i$. When it is clear, we write $[x]$ for brevity.

Communication Model

We consider a synchronous network among n parties, $P_1, \cdots, P_n$, that allows secure communication between (some) pairs of parties; the channels are authenticated and leak nothing except the number of bits in each message.

An n-party protocol π in this model is a "next-message function," that takes as input the round number t, two identities $i, j \in [n]$ and the view of P_i, and outputs the message from P_i to P_j in round t. The view of a party consists of its input, random-tape, and all the messages received in prior rounds of the protocol. If the next-message function is invoked with the keyword out instead of a receiver, π generates the output for the "sender" (for simplicity, we shall restrict ourselves to protocols that produce output only on termination).

We shall require that in a protocol, the message on any edge (i, j) at any round t is encoded using a *prefix-free code* that is agreed up on between the sender and the receiver. Adopting this model precludes communication by not sending any bits. [5]

Security for MPC

We use a standard simulation-based security definition for MPC protocols in the *standalone security* model. We consider two notions of corruptions: (1) active adversaries, who may arbitrarily deviate from the protocol strategy, and (2) semi-malicious adversaries, who follow the protocol instructions but may choose their random tapes arbitrarily. Both of these

[5] While one may argue that it is reasonable to allow zero-cost communication in this manner, it can be abused to communicate large amounts of information at the cost of a single bit, by using a large number of rounds. Further, such signalling cannot be used if multiple such protocols are executed concurrently. Also, practically, the prefix-free communication is more amenable to implementing a synchronous model over an asynchronous network, as delays will not be mistaken for shorter (or empty) messages.

adversaries can abort the execution whenever they choose. We shall also consider a notion of MPC security in which the auxiliary information given to the adversary at the beginning of the protocol is restricted to be from a class of distributions. We refer the reader to the full version for further details.

2.1 Bottleneck Complexity

We introduce a new *per-party* communication metric for distributed computations.

▶ **Definition 3** (Bottleneck Complexity of Protocol)**.** The *individual communication complexity* of a party P_i in an n-party protocol π, denoted as $\mathcal{CC}_i(\pi)$, is the expected number of bits sent or received by P_i in an execution of π, with worst-case inputs.

The *bottleneck complexity* ($\mathcal{BC}$) of an n-party protocol π is the worst-case communication complexity of any party. That is, $\mathcal{BC}(\pi) = \max_{i\in[n]} \mathcal{CC}_i(\pi)$.

▶ **Definition 4** (Bottleneck Complexity of Function)**.** The *bottleneck complexity of an n-input function f* is the minimum value of $\mathcal{BC}(\pi)$ when quantified over all n-party distributed protocols π which correctly evaluate f.

Analogously, we define the *MPC bottleneck complexity* of f as the minimum $\mathcal{BC}(\pi)$ quantified over all n-party protocols π which *securely* evaluate f.

Admissible Protocols

We will show techniques that transform general (insecure) protocols to secure ones. Here we define the required minimal assumption of the original protocols, which we refer to as admissibility. Roughly, a protocol is admissible if its next-message function is polynomial-time computable and it has a fixed communication pattern. Below $\mathbb{Z}_+$ denotes non-negative integers.

▶ **Definition 5** (Admissible Protocol)**.** Let f be a polynomial function, k be a security parameter, and let $\pi = \{\pi_1, ..., \pi_n\}$ be a possibly randomized n-party protocol, where π_i is a next message function of P_i. Let $x = \{x_1, ..., x_n\}$ and $r = \{r_1, ..., r_n\}$ be the input set and the random string set respectively. Denote $\left\{m^t_{i,j}(x,r)\right\}^{t\in[T]}_{i,j\in[n]}$ as the set of the messages generated by $\pi(x,r)$, and let $|m^t_{i,j}(x,r)| \in [0, f(k)]$ be the length of message from P_i to P_j at time t.[6] We say π is admissible if it satisfies the following two conditions:

- **Polynomial-Time Computable:** For each i, next-message function π_i is expressed by a circuit of fixed polynomial-size in $|x_i| + |r_i|$, with a universally bounded depth.
- **Fixed Communication Pattern:** A protocol π is said to have a *fixed communication pattern* if, irrespective of the input and random-tapes of the parties, the total number of rounds $t_{\max}$ is fixed and there is a function len : $[t_{\max}] \times [n] \times [n] \to \mathbb{Z}_+$ that maps (t, i, j) to the length of message (possibly 0) from P_i to P_j at round t as determined by π for any view of P_i.

Note that above we allow randomized protocols, as some interesting low bottleneck complexity protocols (e.g., those derived from streaming algorithms) tend to be randomized.

---

[6] Precisely, for each $i \in [n], t \in [T]$, $\{m_{i,j}(x,r)\}^t_{j\in[n]} \leftarrow \pi_i\left(x_i, r_i, \{m_{j,i}(x,r)\}^{t\in[t-1]}_{j\in[n]}\right)$

3 Lowerbound on Bottleneck Complexity of Distributed Functions

In this section we show that for most functions f on n inputs (each input could be as short as 1 bit, and the output a single bit delivered to a single party), for any distributed computation protocol π that implements f, the (incoming) bottleneck complexity $\mathcal{BC}(\pi)$ is at least $n - O(\log n)$ bits. In fact, this holds true even without any security requirement. This is tight in the sense that, even with a security requirement, there is a protocol in which only one party has individual communication complexity $\Omega(n)$, and all others have communication proportional to their inputs and outputs (with a multiplicative overhead independent of the number of parties).

This is somewhat surprising since many interesting functions do have protocols with constant communication complexity. As mentioned before, any (possibly randomized) function which has a streaming algorithm or a sub-quadratic sized circuit (with small fan-in gates) gives rise to low botteleneck complexity protocols.

To show our lower-bound, we need to therefore rely on functions with roughly a quadratic lower-bound on circuit size. Given the current lack of explicit examples of such functions, we present an *existential result*, and leave it as a conjecture that there are n-bit input boolean functions with polynomial sized circuits with bottleneck communication complexity of $\tilde{\Omega}(n)$. For simplicity, we discuss the case of perfectly correct protocols, but as we shall point out, a small constant probability of error does not change the result significantly. This result says that there is a function (in fact, most functions) such that the best bottleneck complexity is almost achieved by the trivial protocol, in which one party receives the inputs of all the other $n - 1$ parties and carries out the computation locally. We prove the following in the full version.

▶ **Theorem 6.** *$\exists f : \{0,1\}^{k \times n} \to \{0,1\}$ such that any n-party, each with k bits input, distributed computation protocol that computes f correctly will have at least one party receiving at least $(n-1)k - O(\log nk)$ bits in the worst-case.*

4 Incremental FHE

We define and implement a new notion of incremental FHE (IFHE), which is used within our main positive result. We start by providing syntax and security definitions for IFHE in Section 4.1. We describe our construction of IFHE in Section 4.2. Our construction builds upon the FHE scheme of Gentry, Sahai and Waters (GSW) [19]; we refer the reader to the full version for discussion on the specific properties of their scheme that we rely upon.

4.1 Definitions

(Leveled) Fully Homomorphic Encryption

A fully homomorphic encryption (FHE) scheme consists of algorithms (KEYGEN, ENCRYPT, EVAL, DECRYPT), where (KEYGEN, ENCRYPT, DECRYPT) constitute a semantically secure public-key encryption scheme, and EVAL refers to the homomorphic evaluation algorithm on ciphertexts. An ℓ-leveled FHE scheme supports homomorphic evaluation of circuits of depth at most ℓ.

Incremental FHE

An IFHE scheme is defined similarly to threshold FHE [1], with the following key modifications: a "joint" public key can be computed by incrementally combining shares provided by different parties in an arbitrary order. Similarly, a ciphertext w.r.t. the joint public key can be

decrypted by incrementally combining partial decryption shares provided by parties in an arbitrary order. Crucially, the intermediate keys and partial decryption values must be *succinct*.

For technical reasons, it is convenient to describe the joint decryption procedure via three sub-algorithms: A procedure PreDec which pre-processes a homomorphically evaluated ciphertext to be safe for joint decryption; PartDec run by each individual party on a ciphertext (with his share of the secret key) to generate his contribution toward the decryption; and CombineDec which combines the outputs of PartDec from each party for a given ciphertext to reconstruct the final decrypted output. In addition to standard semantic security, we also require the output of PartDec to hide information about the secret key share that was used; this is captured by the Simulatability of Partial Decryption property below.

▶ **Definition 7** (Incremental FHE)**.** An *incremental fully homomorphic encryption (IFHE)* scheme is an FHE scheme with an additional algorithm IFHE.CombineKeys and with Decrypt replaced by three algorithms IFHE.PreDec, IFHE.PartDec and IFHE.CombineDec. By PK_S we denote a combined public key of a subset $S \subseteq [n]$ of parties. Particularly, $\mathrm{PK}_{\{i\}} = \mathrm{PK}_i$ is generated by P_i using the algorithm Keygen, and $\mathrm{PK} = \mathrm{PK}_{[n]}$ is the final public key. Similarly, by v_S we denote a combined decryption, and by v_i when $S = \{i\}$. For the completeness of notations, let PK_S and v_S be empty strings when $S = \emptyset$. We describe the syntax of the four algorithms as follows:

- IFHE.CombineKeys$(\mathrm{PK}_S, \mathrm{PK}_T)$: On input 2 combined public keys $\mathrm{PK}_S, \mathrm{PK}_T$, where $S \cap T = \emptyset$, output a combined public key $\mathrm{PK}_{S\cup T}$.
- IFHE.PreDec$(\mathrm{PK}, \mathbf{C})$: On input a final public key PK and a ciphertext $\mathbf{C}$, sample a public random $\mathbf{R}$, and output a re-randomized ciphertext $\mathbf{C}'$ of the same plaintext.
- IFHE.PartDec$(\mathrm{PK}, \mathrm{SK}_i, \mathbf{C})$: On input a final public key PK, ith secret key SK_i, ciphertext $\mathbf{C}$, output a partial decryption v_i.
- IFHE.CombineDec(v_S, v_T): On input 2 partial decryptions v_S, v_T, where $S \cap T = \emptyset$, if $|S \cup T| < n$, output a partial decryption $v_{S\cup T}$; otherwise, output a plaintext y as the final decryption.

Also, we require the following additional properties:

Efficiency: There are polynomials $poly_1(\cdot), poly_2(\cdot)$ such that for any security parameter λ and any $S \subseteq [n], S \neq \emptyset$, $|\mathrm{PK}_S| = poly_1(\lambda)$ and $|v_S| = poly_2(\lambda)$.

Correctness: Given a set of plaintexts and a circuit to evaluate, the correctness of IFHE says that the FHE evaluation of the circuit over the ciphertexts can always be decrypted to the correct value, where the ciphertexts are encryption of plaintexts using a single combined public key.

Furthermore, by "Incremental" FHE, we mean that the final combined public key as well as the final combined decryption can be formed in an arbitrary incremental manner. We defer the formal definition of correctness to the full version.

Semantic security under Combined Keys (against Semi-Malicious Adversary): Given the parameters prepared in the initial setup, the (corrupted) parties $\{P_j\}_{j\neq i}$, instead of using random strings to compute $\{\mathrm{PK}_i, \mathrm{SK}_i\}_{j\neq i}$, can use an arbitrary string to generate $\{\mathrm{PK}_i, \mathrm{SK}_i\}_{j\neq i}$. Then as long as an honest party generates $(\mathrm{PK}_i, \mathrm{SK}_i)$ independently, the encryption using the final combined public key $(\mathrm{PK}_{[n]}, \mathrm{SK}_{[n]})$ is semantically secure. Formally, we say that the IFHE scheme has semantic security under combined keys if the advantage $\Pr[\beta' = \beta] - 1/2$ in the following experiment is negligible for all PPT Adv.

1. $(\mathsf{params}) \leftarrow \mathrm{Setup}(1^\lambda, 1^d)$

2. $\forall j \neq i$, Adv computes $(\text{PK}_j, \text{SK}_j)$ according to $\text{KEYGEN}(\mathsf{params})$ but replaces the randomly sampled string by a chosen one. Then Adv computes a combined key $\text{PK}_{[n]\setminus\{i\}}$ according to COMBINEKEYS, picks $x \in \{0,1\}$ and sends $(\text{PK}_{[n]\setminus\{i\}}, x)$ to the challenger.
3. The challenger computes $(\text{PK}_i, \text{SK}_i) \leftarrow \text{KEYGEN}(\mathsf{params})$, $\text{PK} \leftarrow \text{COMBINEKEYS}(\text{PK}_i, \text{PK}_{[n]\setminus\{i\}})$, and chooses a random bit $\beta \xleftarrow{\$} \{0,1\}$. If $\beta = 0$, it lets $\mathbf{C} := \text{ENCRYPT}(\text{PK}, 0)$, and else $\mathbf{C} := \text{ENCRYPT}(\text{PK}, x)$, and sends $\mathbf{C}$ to Adv.
4. Finally Adv outputs a bit β'.

Simulatability of Partial Decryption: There is a PPT simulator SIM, s.t. for every combined public key PK, ciphertext $\mathbf{C}'$ of a plaintext y, index $i \in [n]$:

$$\left\{\text{PK}, \mathbf{C}', \{\text{SK}_j\}_{j\in[n]\setminus\{i\}}, v_i\right\} \overset{c}{\approx} \left\{\text{PK}, \mathbf{C}', \{\text{SK}_j\}_{j\in[n]\setminus\{i\}}, v_i'\right\},$$

where $v_i \leftarrow \mathsf{IFHE}.\text{PARTDEC}(\text{PK}, \text{SK}_i, \mathbf{C}')$ and $v_i' \leftarrow \text{SIM}(\text{PK}, \{\text{SK}_j\}_{j\in[n]\setminus\{i\}}, y, \mathbf{C}')$.

4.2 Construction of IFHE

We present an IFHE scheme building on the FHE scheme of Gentry et al. [19]. The SETUP, KEYGEN, ENCRYPT, and EVAL parts are the same as those of [19], while COMBINEKEYS, PREDEC, PARTDEC and COMBINEDEC parts are new. The algorithms are described as follows:

An IFHE scheme.

- **Setup:** $(\mathsf{params}) \leftarrow \mathsf{IFHE}.\text{SETUP}(1^\lambda, 1^d)$. Same as GSW, where $\mathsf{params} = (q, n, m, \chi, B_\chi, \mathbf{B})$.
- **Key Generation:** $(\text{PK}_i, \text{SK}_i) \leftarrow \mathsf{IFHE}.\text{KEYGEN}(\mathsf{params})$. Same as GSW, where $\text{PK}_i = (\mathbf{B}, \mathbf{b}_i)$ and $\text{SK}_i = \mathbf{t}_i \equiv (-\mathbf{s}_i, 1)$.
- **Combining Keys:** $\text{PK}_{S\cup T} \leftarrow \mathsf{IFHE}.\text{COMBINEKEYS}(\text{PK}_S, \text{PK}_T)$
  On input $\text{PK}_S = (\mathbf{B}, \mathbf{b}_S)$ and $\text{PK}_S = (\mathbf{B}, \mathbf{b}_T)$, output $\text{PK}_{S\cup T} = (\mathbf{B}, \mathbf{b}_S + \mathbf{b}_T)$. Particularly $\text{PK}_{[n]}$ is abbreviated as PK or a matrix $\mathbf{A}$.
- **Encryption:** $\mathbf{C}_i \leftarrow \mathsf{IFHE}.\text{ENCRYPT}(\text{PK}, x_i)$. Same as GSW.
- **Evaluation:** $\mathbf{C} \leftarrow \mathsf{IFHE}.\text{EVAL}(\mathbf{C}_1, ..., \mathbf{C}_\tau; f)$. Same as GSW.
- **Preparing Decryption:** $\mathbf{C}' \leftarrow \mathsf{IFHE}.\text{PREDEC}(\text{PK}_i, \mathbf{C})$
  On input $\text{PK} = \mathbf{A}$ and $\mathbf{C} \in \mathbb{Z}_q^{n\times m}$, sample a public random matrix $\mathbf{R}$ in $\{0,1\}^{m\times m}$ and output $\mathbf{C}' = \mathbf{C} + \mathbf{AR}$.
- **Partial Decryption:** $v_i \leftarrow \mathsf{IFHE}.\text{PARTDEC}(\text{PK}_i, \text{SK}_i, \mathbf{C}')$
  On input $\text{PK} = \mathbf{A}$, $\text{SK}_i \equiv \mathbf{t}_i \equiv (-\mathbf{s}_i, 1)$, and $\mathbf{C}' \in \mathbb{Z}_q^{n\times m}$, sample $\mathbf{e}_i' \leftarrow \chi^m$, set $\mathbf{t}_i' = t_i$ if $i = 1$ and $\mathbf{t}_i' = (-\mathbf{s}_i, 0)$ if $i > 1$, and output $v_i = (\mathbf{t}_i'\mathbf{C}' - \mathbf{e}_i')\mathbf{G}^{-1}(\mathbf{w}^T)$, where $\mathbf{w} = (0, ..., 0, \lceil q/2 \rceil) \in \mathbb{Z}_q^n$.
- **Combining Decryption:** $\mathsf{IFHE}.\text{COMBINEDEC}(v_S, v_T)$
  On input two partial decryptions v_S, v_T with $S \cap T = \emptyset$, compute a partial decryption $v_{S\cup T} = v_S + v_T$. For $|S \cup T| < n$, output $v_{S\cup T}$; for $|S \cup T| = n$, output a plaintext $y = \left\lfloor \frac{v}{q/2} \right\rceil$.

---

5 Summary of Further Results

Due to space limitations we defer the remaining technical sections to the full version. We first demonstrate how to convert an arbitrary admissible multi-party distributed protocol Π (as per Definition 5) for computing a function f to a protocol Π_{sm} for computing f secure against

semi-malicious adversaries, while preserving *per-party* computation and communication. Note that as per Definition 5 the communication pattern of the starting protocol Π can be arbitrary, but we require that it be fixed (i.e., not data dependent).

▶ **Theorem 8.** *Let* IFHE *be an incremental FHE scheme, and* Π *be an* n*-party protocol for evaluating a function* f *with fixed communication pattern. Then there exists a protocol* Π_{sm} *that securely evaluates* f *against up to* $(n-1)$ semi-malicious *corruptions, preserving the per-party computation and communication requirements of* Π *up to* $\mathrm{poly}(\lambda)$ *multiplicative factors (independent of the number of parties* n*). Moreover, the communication pattern of* Π_{sm} *is identical to that of* Π *plus two additional traversals of a communication spanning tree of* Π*.*

At a very high level, the parties will run a one-pass protocol to (incrementally) construct a joint key for the incremental FHE scheme, then execute the original protocol Π underneath FHE encryption, and finally run one more pass to (incrementally) decrypt.

Next, we give a general compiler to transform the above protocol into a maliciously-secure MPC protocol, while preserving the bottleneck complexity. Our compiler relies upon multiple cryptographic ingredients, most notably, ID-based simulation-extractable succinct non-interactive arguments of knowledge (ZK-SNARKs) – a notion that we define and construct in this work (see the full version).

▶ **Theorem 9.** *Let* Π_{sm} *be an MPC protocol that securely evaluates a functionality* f *against* semi-malicious *corruptions, as in Theorem 8. Then, assuming the existence of an ID-based simulation-extractable succinct non-interactive arguments of knowledge, non-interactive commitment schemes and a family of collision-resistant hash functions, there exists a compiler that transforms* Π_{sm} *into another MPC protocol* Π *in the (bare) public-key and common reference string model such that* Π *computes the same functionality* f *and preserves the per-party computation and communication of* Π_{sm} *up to* $\mathrm{poly}(\lambda)$ *multiplicative factors (independent of the number of parties* n*).*

We remark that in the above theorem, the ID-based SE-ZK-SNARK is w.r.t. arbitrary auxiliary inputs. We stress, however, that in order to achieve a weaker MPC definition where the adversary only receives restricted auxiliary inputs, the requirement on the SE-ZK-SNARK can be similarly relaxed as well.

Abstract

We revisit one of the classic problems in the data stream literature, namely, that of estimating the frequency moments F_p for $0 < p < 2$ of an underlying n-dimensional vector presented as a sequence of additive updates in a stream. It is well-known that using p-stable distributions one can approximate any of these moments up to a multiplicative $(1+\epsilon)$-factor using $O(\epsilon^{-2}\log n)$ bits of space, and this space bound is optimal up to a constant factor in the turnstile streaming model. We show that surprisingly, if one instead considers the popular random-order model of insertion-only streams, in which the updates to the underlying vector arrive in a random order, then one can beat this space bound and achieve $\tilde{O}(\epsilon^{-2}+\log n)$ bits of space, where the $\tilde{O}$ hides $\mathrm{poly}(\log(1/\epsilon)+\log\log n)$ factors. If $\epsilon^{-2} \approx \log n$, this represents a roughly quadratic improvement in the space achievable in turnstile streams. Our algorithm is in fact deterministic, and we show our space bound is optimal up to $\mathrm{poly}(\log(1/\epsilon)+\log\log n)$ factors for deterministic algorithms in the random order model. We also obtain a similar improvement in space for $p = 2$ whenever $F_2 \gtrsim \log n \cdot F_1$.

1 Introduction

Analyzing massive datasets has become an increasingly challenging problem. Data sets, such as sensor networks, stock data, web/network traffic, and database transactions, are collected at a tremendous pace. Traditional algorithms that store an entire dataset in memory are impractical. The *streaming model* has emerged as an important model for coping with massive datasets. Streaming algorithms are typically randomized and approximate, making a single pass over the data and using only a small amount of memory.

A well-studied problem in the streaming model is that of estimating the frequency moments of an underlying vector. Formally, in an *insertion-only stream*, the algorithm is presented with a sequence of integers $\langle a_1, a_2, \ldots, a_m \rangle$ from a universe $[n]$. A *turnstile stream* is defined similarly except integers may also be removed from the stream. The p-th frequency moment of the stream is defined to be $F_p = \sum_{i \in [n]} f_i^p$, where f_i is number of times integer i occurs in the stream, i.e., its frequency. The quantity F_p is a basic, yet very important statistic of a dataset (e.g. [1]). For example, interpreting 0^0 as 0, F_0 is equal to the number of distinct items in the stream. F_2 measures the variance and can be used to estimate the size of a self-join in database applications. It also coincides with the (squared) Euclidean norm of a vector and has applications in geometric and linear algebraic problems on streams. For other non-integer $p > 0$, F_p can serve as a measure of the entropy or skewness of a dataset, which can be useful for query optimization.

In their seminal paper, Alon, Matias & Szegedy [2] introduced the study of frequency moments in the streaming model. Nearly two decades of research have been devoted to the space and time complexity of this problem. An incomplete list of papers on frequency moments includes [3, 8, 11, 18–20, 23], and [7]; please also see the references therein. In the turnstile model, $\Theta(\epsilon^{-2} \log(mn))$ bits of space is necessary and sufficient for a randomized one-pass streaming algorithm to obtain a $(1 \pm \epsilon)$-approximation to F_p for $0 < p \leq 2$ [21]. Here, by $(1 \pm \epsilon)$-approximation, we mean that the algorithm outputs a number $\tilde{F}_p$ for which $(1 - \epsilon)F_p \leq \tilde{F}_p \leq (1 + \epsilon)F_p$. For larger values of p, i.e., $p > 2$, the memory required becomes polynomial in n rather than logarithmic [5, 11, 19].

In this paper, we study the frequency moment estimation problem in the *random-order model*, which is a special case of insertion streams in which the elements in the stream occur in a uniformly random order and the algorithm sees the items in one pass over this random order. This model was initially studied by Munro and Paterson [22], which was one of the initial papers on data streams in the theory community. Random-order streams occur in many real-world applications and are studied in, e.g., [10, 13, 15] and the references therein. It has been shown that there is a considerable difference between random order streams and general arbitrary order insertion streams for problems such as quantile estimation [10, 16]. Notice that [12] studies the frequency moment problem for stochastic streams, in which data points are generated from some distribution. That model is different from ours, but when conditioning on the realizations of the values of each point, the stream is exactly in random order. Therefore, our upper bounds are applicable to that model as well.

However, there is a gap in our understanding for the important problem of F_p-estimation, $0 < p \leq 2$, in the random order model. On the one hand there is an $\Omega(\epsilon^{-2})$ bits of space lower bound [9]. On the other hand, the best upper bound we have is the same as the best upper bound in the turnstile model, namely $O(\epsilon^{-2} \log n)$ bits [2, 20, 21]. In practice it would be desirable to obtain $O(\epsilon^{-2} + \log n)$ bits rather than $O(\epsilon^{-2} \log n)$ bits, since if ϵ is very small this can lead to considerable savings. For example, if $\epsilon^{-2} \approx \log n$, it would represent a roughly quadratic improvement. The goal of this work is to close this gap in our understanding of the memory required for F_p-estimation, $0 < p \leq 2$, in the random order model. Note that in all our bounds, we apply the convention that $m = \text{poly}(n)$.

1.1 Our Contribution

In this paper, we make considerable progress on understanding the space complexity of F_p estimation with $0 < p \leq 2$, in random order streams. Specifically,

- for F_2, we show that there exists a simple, and in fact deterministic, one-pass algorithm using $\mathcal{O}(\epsilon^{-2}+\log n)$ bits of space to output a $(1\pm\epsilon)$ approximation, provided $F_2 \geq m\cdot\log n$,
- for F_p with $p \in (0,2)\backslash\{1\}$, we obtain a one-pass deterministic algorithm to obtain a $(1 \pm \epsilon)$ approximation using $\tilde{O}(\epsilon^{-2} + \log n)$ bits of space[3]. We also show that this space complexity is optimal for deterministic algorithms in the random order model, up to $\text{poly}(\log(1/\epsilon)) + \text{poly}(\log\log n)$ factors. Note that for the case $p = 1$, F_p is the length of the stream, which can be computed using $O(\log n)$ bits of memory.

1.2 Our Techniques

For F_2, we partition the stream updates into a sequence of small blocks for which each block can be stored using $\mathcal{O}(\epsilon^{-2})$ bits. We then construct an unbiased estimator by counting the number of "pairs" of updates that belong to the same universe item. The counting can be done exactly and with only $\mathcal{O}(\log n)$ bits of space in each small block. We further show that if $F_2 \geq \log n \cdot F_1$, we can obtain the desired concentration by averaging the counts over all blocks. The analysis of the concentration is by constructing a Doob martingale over the pairs and applying Bernstein's inequality.

For F_p with $0 < p < 2$ our algorithm is considerably more involved. We first develop a new reduction from estimating F_p to finding ℓ_p heavy hitters (an ℓ_p heavy hitter is an item with frequency comparable to $F_p^{1/p}$ of the stream) and then we establish the heavy hitter algorithm. Both our new reduction and the heavy hitter-finding algorithm are redesigned over the existing ones to allow us to obtain better space complexity. Our heavy hitter finding algorithm is similar to that of [6]. However, we need to be more careful so that the final space bound of the heavy hitter algorithm can be controlled (e.g., we cannot afford to store $\Omega(1/\epsilon^2)$ many coordinate IDs, which would cost $\Omega((\log n)/\epsilon^2)$ bits of space. We have to store only $O(1/\epsilon^2)$ many approximate values). The major contribution of our algorithm is the careful reduction from F_p estimation to ℓ_p heavy hitter-finding. Many reductions are known in the literature but are suffering from a $\text{poly}(\log n)$ space blow up. Our careful reduction allows us to pay only a $\text{poly}(\log\log n)$ space blow up.

In what follows, we illustrate the high level ideas of the heavy hitter reduction. Let $v = (f_1, f_2, \ldots, f_n)$ be the frequency vector of the items. We first apply a random scaling X_i to each f_i, where each X_i is pairwise independently drawn from some distribution. We argue that finding the leading ℓ_p heavy hitter of the scaled frequency vector (denoted as $X_{i^*} f_{i^*}$) gives a good estimation of the $F_p^{1/p}$ of the original stream. The distribution of X_i is a so-called p-inverse distribution (see Definition 2 for details). This distribution has a similar tail as that of the max-stable distributions used in [3] or the precision sampling distribution in [4]. However, it has different properties better suited to our setting, e.g., we can use pairwise independent variables to do the scaling. In contrast, for max-stable distributions, we have to use fully random hash functions and apply pseudo-random generators, which is problematic in our very low space regime (a related technique called tabulation-based hashing has similar problems). Note that [4] does not require pseudo-random generators, but their precision sampling technique aims to solve a more general family of problems and their

[3] We use $\tilde{O}$ to hide $\text{poly}(\log\log n + \log\epsilon^{-1})$ factors.

distribution has a slightly different form, e.g., the random variable is drawn from a continuous distribution. The p-inverse distribution is particularly suited for p-norm estimation, and allows for a concise algorithm and improved space complexity in our setting.

After choosing the random scalings, we group the coordinates of v into $\Theta(\log n)$ levels by their scalings, i.e., if $2^{-w}F_p < X_i^p \leq 2^{-w+1}F_p$, then i is in level w for some integer w. Since we do not know F_p before the stream arrives, the exact level ID is not known to the algorithm. But since each X_i is obtained pseudo-randomly, the algorithm is able to know whether two coordinates are in a same level or not (i.e., the relative level ID) before looking at the stream. Let $Z_w \subset [n]$ be the set of universe items in level w. We observe that if for some coordinate $i^* \in Z_w$, it satisfies $X_{i*}^p f_{i^*}^p \approx F_p$, then $f_{i^*}^p = \Omega(2^w)$. Fortunately, we can also show that in expectation, i^* is an ℓ_p-heavy hitter of the substream induced by Z_w (i.e., in expectation the F_p of the stream restricted to Z_w is approximately 2^w). Our algorithm simply *looks for* i^* *from* Z_w *for every* $w \in [\log n]$. One may notice that if we run the search instance in parallel, then there will be a $(\log n)$-factor blowup in the space of a heavy hitter algorithm. However, we can show that for random order streams, one can choose a $w_0 = \Theta(\log \log n)$ such that

1. for all $w > w_0$: the search for the heavy hitter i^* can be done in one pass and in sequence for each w. This is because f_{i^*} is large (i.e., $\Omega(2^w)$) and a small portion of the random order stream contains sufficient information about i^*.
2. 2. for all $w \leq w_0$: with high probability, $|Z_w| = \text{poly}(\log n)$. We thus do a brute force search for each level w below w_0 in parallel. Each search instance uses a small amount of memory because of the small universe size.

The final space overhead becomes a $\text{poly}(w_0)$ factor rather than a $\Theta(\log n)$ factor. This observation is critical to reduce space usage for approximating frequency moments in random order streams and is, to the best of our knowledge, new. For $p \geq 2$, the above claim is no longer true. We leave the exact space complexity for $p \geq 2$ as an open problem.

1.3 Roadmap

In Section 2, we introduce some definitions and the p-inverse distribution. In Section 3, we present our algorithm for F_2. In Section 4, we present our generic framework for approximating F_p as well as our main result. In Section A of the full version of this paper, we present the detailed construction of each subroutine used in Section 4, and the details of the main algorithm. In Section 6, we introduce our deterministic algorithm, which uses our randomized algorithm as a subroutine. We also show its optimality in the same section.

2 Preliminaries

▶ **Definition 1** (Aggregate Streaming). An *insertion-only stream* (or simply *stream*) $\mathcal{S} = \langle a_1, a_2, \ldots, a_m \rangle$ is a sequence of integers, where each $a_i \in [n]$. A *weighted stream* $\mathcal{S}' = \langle (a_1, w_1), (a_2, w_2), \ldots, (a_m, w_m) \rangle$ is a sequence of pairs, where each $a_i \in [n]$ and each $w_m \in \mathbb{R}$. The insertion-only stream $\mathcal{S}$ is a special case of a weighted stream with all the weights being 1. The frequency $f_i(\mathcal{S}')$ of a weighted stream is defined as the sum of all weights of the item i. Formally,

$$f_i(\mathcal{S}') := \sum_{j=1}^{m} \mathbb{I}(a_j = i) w_j.$$

The frequency vector $V(\mathcal{S}') \in \mathbb{R}^n$ is the vector with i-th coordinate equal to $f_i(\mathcal{S}')$, for each $i \in [n]$. The p-th frequency moment, for $p \geq 0$, is defined as

$$F_p(\mathcal{S}') := \|V(\mathcal{S}')\|_p^p := \sum_{i=1}^{n} f_i^p(\mathcal{S}').$$

For time $0 < t_1 \leq t_2 \leq m$, we let

$$\mathcal{S}'^{:t_1} := \langle (a_1, w_1), (a_2, w_2), \ldots, (a_{t_1}, w_{t_1}) \rangle \quad \text{and}$$
$$\mathcal{S}'^{t_1:t_2} := \langle (a_{t_1}, w_{t_1}), (a_{t_1+1}, w_{t_1+1}), \ldots, (a_{t_2}, w_{t_2}) \rangle$$

be sub-streams of $\mathcal{S}'$ from 1 to t_1 or from t_1 to t_2.

We introduce a discretized version of the α-Fréchet distribution: the α-Inverse distribution.

▶ **Definition 2.** Fixing an $\alpha > 0$, we say a random variable X on $\mathbb{N}$ is drawn from an α-*Inverse* distribution if

$$\mathbb{P}[X < x] = 1 - \tfrac{1}{x^\alpha} \quad \text{for} \quad x \in \mathbb{N}_+.$$

▶ **Definition 3** (α-Scaling Transformation)**.** Given an $\alpha > 0$, an *α-scaling transformation (ST)* $\mathcal{T}_{k,\alpha} : [n]^m \to ([k] \times [n] \times \mathbb{R})^m$ is a function acting on a stream of length m on the universe $[n]$. On input stream $\mathcal{S}$, it outputs a weighted stream $\mathcal{S}'$ of length km on universe $[k] \times [n]$ via the following operation: let $X_{i,j}$ be identically distributed and independent (or, actually, limited independence suffices) α-Inverse random variables, where $i = 1, 2, \ldots, k$ and $j = 1, 2, \ldots, n$. For each $a \in \mathcal{S}$, the transformation outputs

$$\mathcal{T}_{k,\alpha}(a) \to ((a, 1), X_{1,a}), ((a, 2), X_{2,a}), \ldots, ((a, k), X_{k,a}).$$

The next lemma shows that the $\frac{k}{2}$-th largest element of the transformed frequency vector gives a good approximation to the α-norm of the vector.

▶ **Lemma 4.** *Let $\mathcal{S}$ be a stream of items from the universe $[n]$. Let $\mathcal{T}_{k,\alpha}$ be a pairwise independent α-ST with $k \geq \frac{160}{\alpha^2\epsilon^2}$ being an even integer and $\alpha \geq 0$, where $\epsilon \in (0, \frac{1}{2\alpha})$. Let $\mathcal{S}' = T_{k,\alpha}(\mathcal{S})$. Define the two sets,*

$$U_+ := \{(a, r) \in [n] \times [k] : f_{(a,r)}(\mathcal{S}') \geq 2^{1/\alpha}(1 - \epsilon)\|V(\mathcal{S})\|_\alpha\}$$

and

$$U_- := \{(a, r) \in [n] \times [k] : f_{(a,r)}(\mathcal{S}') < 2^{1/\alpha}(1 + \epsilon)\|V(\mathcal{S})\|_\alpha\}.$$

Then with probability at least 0.9*,*

$$|U_+| \geq \tfrac{k}{2}, \quad |\overline{U_-}| < \tfrac{k}{2} \quad \textit{and} \quad |U_+ \cap U_-| > 0,$$

where $\overline{U}$ is the complement of the set U.

The proof of this lemma is provided in Section B of the full version.

3 A Simple F_2 Algorithm For Long Streams

We start with a very simple algorithm for approximating F_2 in a random order stream. We denote the algorithm by `RANDF2`. The algorithm has a parameter $b > 0$. It treats the stream updates as a series of length b blocks, i.e.,

$$\mathcal{S} = (B_1, B_2, \ldots, B_{m/b}).$$

Initialize a register $K = 0$. At any time, suppose the current block is B_i. The algorithm simply stores everything it sees until the end of B_i. After storing B_i entirely, the algorithm computes

$$K_i = \sum_{j=1} \binom{f_j(B_i)}{2}.$$

This can be done using $b \log n$ bits of space. Then, the counter K is updated as

$$K \leftarrow K + K_i.$$

At the end of the stream, the algorithm computes

$$Y = \frac{2K(m^2 - m)}{(b^2 - b)T} + m,$$

where T is the ID of the last complete block, and m is the length of the stream. The algorithm uses $O(b \log n)$ bits. By setting

$$b = \Theta[\max((\epsilon^2 \log n)^{-1}, 2) \cdot \log \tfrac{1}{\delta}],$$

we obtain the following theorem.

▶ **Theorem 5.** *Let $\mathcal{S}$ be a random order stream satisfying $F_2(\mathcal{S}) \geq m \cdot \log n$. After one pass over the stream $\mathcal{S}$, Y is a $(1 \pm \epsilon)$ approximation to $F_2(\mathcal{S})$ with probability at least $1 - \delta$. Moreover, to compute Y, `RANDF2` uses $\mathcal{O}(\epsilon^{-2} \log \delta^{-1} + \log n)$ bits of memory.*

Proof. For each $j \in [n]$, we let its stream updates be $u_1^{(j)}, u_2^{(j)}, \ldots, u_{f_j(\mathcal{S})}^{(j)}$. Then K_i is the number of pairs of the form $(u_{\ell_1}^{(j)}, u_{\ell_2}^{(j)})$ appearing in B_i. We denote $F_2 = F_2(\mathcal{S})$ and $F_1 = F_1(\mathcal{S})$ for simplicity. Thus,

$$\forall i \in [T] : \mathbb{E}(K_i) = \frac{\sum_{j=1}^{n} \binom{f_j(\mathcal{S})}{2}}{\binom{F_1}{2}} \binom{b}{2} = \frac{F_2 - m}{m^2 - m} \frac{(b^2 - b)}{2}.$$

Thus, by linearity of expectation,

$$\mathbb{E}[Y] = F_2.$$

We now prove that Y is concentrated around its mean. Notice that the algorithm can be viewed as sampling a number of "pairs". A pair is formed by two updates to the same universe element. There are $q = (F_2 - F_1)/2$ many pairs. Let $P = [q]$ denote the set of pairs. For each pair $z \in P$, we let X_z denote the indicator that X_z is sampled by some bucket. Let $K = \sum_{z \in P} X_z$. Note that this K is the same as the one denoted in the algorithm. Let $Q_z = \mathbb{E}[K | X_1, X_2, \ldots, X_z]$. The Q_z for $z = 1, 2, \ldots$ form a Doob martingale. Also notice that $|Q_z - Q_{z-1}| \leq 1$. Next, we proceed to bound the variance of

$$Q_z - Q_{z-1} = X_z | X_1, X_2, \ldots X_{z-1}.$$

For a pair $z \in P$, let a, b be the two nodes. Consider a fixed assignment of $X_1, X_2, \ldots X_{z-1}$. Also note that, knowing X_i, the two nodes of the i-th pair are assigned to some block.

Now, if from the $X_1, X_2, \ldots, X_{z-1}$, a, b are both assigned and to the same block, then $X_z = 1$ and otherwise $X_z = 0$. For both cases $\mathrm{Var}(Q_z - Q_{z-1}) = 0$. If a, b are assigned, but it cannot be determined if they are in the same block, then $\mathbb{P}[X_z = 1] \leq b/m$ and thus $\mathrm{Var}(X_z) \leq b/m$. If only one of a, b is assigned, then $\mathbb{P}[X_z = 1] \leq b/m$, and thus

$\mathrm{Var}(X_z) \le b/m$. Lastly, if both a, b are not assigned, then $\mathbb{P}[X_z = 1] \le b/m$. Thus $\mathrm{Var}(X_z) \le b/m$. Overall, we have that $v_z^2 := \mathrm{Var}(Q_z - Q_{z-1}) \le b/m$ for all possible $X_1, X_2, \ldots, X_{z-1}$. Let

$$V = \sum_z v_z^2 \le \tfrac{b(F_2-m)}{2m}.$$

Next, by Bernstein's inequality [14], we have that,

$$\mathbb{P}[|K - \mathbb{E}(K)| \ge t] \le 2\exp\left(-\tfrac{t^2}{2V(1+t/3V)}\right).$$

Since we need to have a $(1 \pm \epsilon)$ approximation to F_2, we can set

$$\frac{2t(m^2-m)b}{(b^2-b)m} \le \epsilon F_2 \quad \text{and} \quad t = \epsilon\frac{F_2 b}{2m}.$$

Since $F_2 \ge m \cdot \log n \cdot \log \frac{1}{\delta}$, and ϵ is sufficiently small, we can bound the error probability by:

$$\begin{aligned}\mathbb{P}[|K - \mathbb{E}(K)| \ge t] &\le 2\exp\left(-\frac{t^2}{2V(1+t/3V)}\right)\\ &\le 2\exp\left(-\frac{\epsilon^2 F_2^2 b}{8m(F_2-m)}\right) \le \delta, \end{aligned} \tag{1}$$

for $b = \Omega(\frac{\log \frac{1}{\delta}}{\epsilon^2 \cdot \log n})$. Finally, since $K \in \mathbb{E}(K) \pm \epsilon F_2 b/(2m)$, we have

$$Y \in F_2 \pm \epsilon\tfrac{F_2 b}{2m} \cdot \tfrac{2(m^2-m)b}{(b^2-b)m} \subset (1 \pm \epsilon)F_2$$

as desired. ◀

4 A Generic Framework for F_p Estimation

In this section, we first construct a generic framework for F_p estimation, and then we construct all the components in subsequent sections. For a random order stream $\mathcal{S}$, we will need the following three components to construct an F_p estimation algorithm.

- A counter that stores the time for the current update;
- An algorithm that gives a constant approximation to the current $F_p(\mathcal{S}^{:t})$;
- An algorithm that computes an accurate $(1 \pm \epsilon)$ approximation to $F_p(\mathcal{S})$ given $\mathrm{poly}(\log n, \epsilon^{-1})$ approximations to m and $F_p(\mathcal{S})$.

To begin, we denote by `C2Fp` a data structure that, once initialized with a $\mathrm{poly}(\log n, \epsilon^{-1})$-approximation of both the length and p-th frequency moments, $F_p(\mathcal{S})$, supports two operations: update and query. At the end of the stream, `C2Fp.query()` returns either `Fail` or a $(1 \pm \epsilon)$-approximation to F_p of the input stream $\mathcal{S}$. Component (1) will be used to guess the length of the stream, and component (2) will be used to guess an approximation to $F_p(\mathcal{S})$. We denote component (2) by `ConstFp`, which is a data structure that supports both update and query operations. `ConstFp.query()` returns a 2-approximation to $F_p(\mathcal{S}^{:t})$ at some fixed t. The full framework is described in Algorithm 1.

Our full algorithm is denoted by `RndF`$_p$, which uses `C2Fp` as a subroutine. From a high level, the algorithm constantly guesses the length of the stream. If at some point in time the algorithm finds that the current guess of the length is at least a factor $C = \mathrm{poly}(\epsilon^{-1}, \log n)$ smaller than the true value of the stream, then the algorithm initializes a new instance of `C2Fp` to estimate the F_p value of the stream. At the end, it is guaranteed that a stored

Algorithm 1: Full algorithm for F_p in random order: $\texttt{RndF}_p$.

Data:
$\mathcal{S} = \langle a_1, a_2, \ldots, a_m \rangle$ is a random order stream of length m from a universe $[n]$ (known in advance);
$p \in (0, 2]$ is a real number, which is a constant;

Initialize (p, n, ϵ, δ)**:**
  $m_0 \leftarrow 1$, $m_1 \leftarrow 1$ $G_0 \leftarrow 1$. Here m_0 is the approximate length, G_0 is a guess of F_p, ϵ is the target precision, and δ is the failure probability;
  $A_1 \leftarrow$new $\texttt{C2Fp}(p, \epsilon/3, n, m_0, G_0, \delta/3)$, $A_2 \leftarrow$new $\texttt{C2Fp}(p, \epsilon/3, n, m_0, G_0, \delta/3)$;
  $A_3 \leftarrow$new $\texttt{ConstFp}(p, n, \delta/3)$;
  $C \leftarrow \text{poly}(\frac{1}{\epsilon}, \log \frac{n}{\delta})$;

Update a**:**
  A_1.update(a), A_2.update(a), A_3.update(a);
  $m_1 \leftarrow m_1 + 1$;
  if $m_1 \geq C m_0$ **then**
    $A_1 \leftarrow A_2$;
    $G_0 \leftarrow A_3$.query();
    $m_0 \leftarrow m_1$;
    $A_2 \leftarrow$new $\texttt{C2Fp}(p, \epsilon/3, n, m_0, G_0, \delta/3)$;

Query():
  return A_1.query();

instance of C2Fp uses at least a $(1 - \text{poly}(\epsilon, 1/\log n))$ portion of the stream to approximate the frequency moments. It can be verified that an accurate estimation of F_p of this portion of the stream will serve as a good estimator for the overall stream. Therefore, if C2Fp is able to output the correct answer with high probability, then the algorithm RndF is guaranteed to be correct with high probability.

▶ **Theorem 6** (Main Theorem). *For fixed $p \in [0, 2)$, $\epsilon \in (0, 1)$,$\delta \in (\frac{1}{\text{poly}(n)}, \frac{1}{2})$, and $n \in \mathbb{N}_+$, algorithm $\texttt{RndF}_p$, makes a single pass over a random order stream $\mathcal{S}$ on universe $[n]$, and outputs a number $\hat{F}$ such that, with probability at least $1 - \delta$,*

$$(1 - \epsilon)F_p(\mathcal{S}) \leq \hat{F} \leq (1 + \epsilon)F_p(\mathcal{S}),$$

where the probability is over both the randomness of the algorithm and the randomness of the data stream. The algorithm uses

$$\mathcal{O}[(\frac{1}{\epsilon^2}(\log\log n + \log\frac{1}{\epsilon})^4 + \log n)\log\frac{1}{\delta}]$$

bits of memory in the worst case.

Proof. Without loss of generality, we assume $F_p(\mathcal{S}) = \Omega(\text{poly}\frac{1}{\epsilon}\text{poly}\log\frac{n}{\delta})$, since otherwise we can use a turnstile F_p algorithm with memory $\mathcal{O}\big(\frac{1}{\epsilon^2}\log\log\frac{n}{\delta} + \frac{1}{\epsilon^2}\log\frac{1}{\epsilon}\big)$ bits to solve the F_p estimation problem. Initialize $m_0 = 1$. Let $\mathcal{S}' = \mathcal{S}^{m_0:m}$. By definition of the algorithm, A_1 is an instance of C2Fp that runs on $\mathcal{S}'$. Let $\mathcal{S}'' = \mathcal{S}^{0:m_0}$ and $C = \text{poly}\epsilon^{-1}\text{polylog}\frac{n}{\delta}$. By definition of the algorithm, we always update m_0 so that

$$\frac{m}{C^2} \leq m_0 \leq \frac{m}{C},$$

at the end of the stream. By Lemma 24 and Lemma 25 of the full version of this paper, we have, with probability at least $1 - \delta/3$,

$$\frac{F_p(\mathcal{S})}{5^p C^{2p}} \leq F_p(\mathcal{S}'') \leq (17\log\frac{20n}{\delta})^p(C^{-1}F_p(\mathcal{S}) + 4\log\frac{20n}{\delta}) \leq \frac{(18\log\frac{20n}{\delta})^p}{C}F_p(\mathcal{S}),$$

where the last inequality holds for sufficiently large $F_p(\mathcal{S})$. Conditioned on this event, we obtain that

$$\|V(\mathcal{S}'')\|_p \leq \frac{(18 \log \frac{20n}{\delta})}{C^{1/p}} \|V(\mathcal{S})\|_p \leq \frac{\epsilon}{3p} \|V(\mathcal{S})\|_p,$$

for sufficiently large C. By the triangle inequality, we obtain

$$(1 - \epsilon/(3p))\|V(\mathcal{S})\|_p \leq \|V(\mathcal{S})\|_p - \|V(\mathcal{S}'')\|_p \leq \|V(\mathcal{S}')\|_p \leq \|V(\mathcal{S})\|_p.$$

Thus $F_p(\mathcal{S}')$ is a $(1 \pm \epsilon/3)$ approximation to $F_p(\mathcal{S})$.

In the algorithm, A_3 is an instance of `ConstFp`, i.e., by Theorem 7. Let G_0 be the output of A_3.query(). Since with probability at least $1 - \delta/3$, A_3 outputs a c_0 approximation to $F_p(\mathcal{S}'')$ for some constant c_0, we obtain that G_0 is a $5^p c_0 C^{2p} (\log \frac{20n}{\delta})^{p-1}$ approximation to $F_p(\mathcal{S}')$.

In the algorithm, A_1 is an instance of `C2Fp`, which runs on the stream $\mathcal{S}'$ at any time t with the required parameters, i.e., G_0. By Theorem 8, with probability at least $1 - \delta/3$, A_1.query() outputs a $(1 \pm \epsilon/3)$ approximation to $F_p(\mathcal{S}')$, and thus a $(1 \pm \epsilon)$ approximation to $F_p(\mathcal{S})$. By a union bound, the overall algorithm is correct with probability at least $1 - \delta$.

By Theorem 16 and Theorem 17, of the full version, the space needed for A_1 and A_2 is

$$\mathcal{O}[(\frac{1}{\epsilon^2}(\log \log n + \log \frac{1}{\epsilon})^4 + \log n) \log \frac{1}{\delta}].$$

The space needed for A_3 is $\mathcal{O}(\log n \log \frac{1}{\delta})$ (Theorem 7). Thus the total space is dominated by the total space used by A_1 and A_2 as desired. ◀

The following is a theorem required in the above proof.

▶ **Theorem 7** (Const. F_p approx., [21]).
For a fixed n, there exists a turnstile streaming algorithm, which on input a stream $\mathcal{S}$ of length m, outputs a number $F \in (1 \pm \epsilon)F_p(\mathcal{S})$ with probability at least $1 - \delta$. The algorithm uses $\mathcal{O}(\epsilon^{-2} \log m + \log \log(n)) \log \delta^{-1})$ bits of space in the worst case.

In subsequent sections, we will construct the `C2Fp` Algorithm.

5 A $(1 \pm \epsilon)$ Approximation to F_p With a Prior

In this section, we construct the algorithm `C2Fp`. We assume that the input is a random order stream and that the algorithm is given two parameters, $\hat{m}$ and G, which are $\text{poly}(\epsilon^{-1}, \log n)$ approximations to the length and the p-th frequency moments of the stream $\mathcal{S}$, respectively.

5.1 High Level Idea

Although the high level idea is introduced in the introduction, we repeat it here with more details for better understanding of the algorithm. To illustrate the intuition of the algorithm, we first consider a constant factor approximation algorithm. Estimating the frequency moments can be reduced to finding the *heavy hitters* of a scaled vector, as shown in Lemma 4. Suppose the frequency vector in a stream is $v = (f_1(\mathcal{S}), f_2(\mathcal{S}), \ldots, f_n(\mathcal{S}))$, and the scaling applied to it is $X = (X_1, X_2, \ldots, X_n)$, where the X_i are pairwise independent *p-Inverse* (see Definition 2) random variables. Let i^* be the maximum of the scaled vector. By Lemma 4, we expect $X_{i^*}^p f_{i^*}^p(\mathcal{S}) \approx F_p$. We group the coordinates of v into $\Theta(\log n)$ levels by their scalings, i.e., if $2^{-w} F_p < X_i^p \leq 2^{-w+1} F_p$, then i is in level w. Let $Z_w \subset [n]$ be the universe items in

level w. We observe that if $i^* \in Z_w$, then $f_{i^*}^p(\mathcal{S}) = \Omega(2^w)$. Luckily, we can also show that, in expectation, i^* is an F_p-heavy hitter of the substream induced by Z_w. Our algorithm is simply *looking for i^* from Z_w for every $w \in [\log n]$*. One may notice that if we run the search instances in parallel, then there will be a $\log n$ factor blowup in the space. However, we can show that in a random order stream, one can choose a $w_0 = \Theta(\log \log n)$ such that

1. for all $w > w_0$: the search for i^* can be done in one pass and in series for each w.
2. for all $w \le w_0$: with high probability, $|Z_w| = \operatorname{poly} \log n$. We thus do a brute force search for each level w below w_0 in parallel.

The final space overhead is a $\operatorname{poly}(w_0)$ factor rather than $\Theta(\log n)$.

To reduce the error from constant to $(1 \pm \epsilon)$, we repeat the above process $\Theta\left(\frac{1}{\epsilon^2}\right)$ times conceptually. Namely, we apply a p-ST $\mathcal{T}_{k,p}$ transformation to the stream, where $k = \Theta\left(\frac{1}{\epsilon^2}\right)$. For $r = 1, 2, \ldots, [k]$, $i = 1, 2, \ldots, n$, we denote the scaling p-Inverse random variable by $X_i^{(r)}$. We wish to find the heavy hitter for each r using the same procedure described above. By Lemma 4, the $k/2$-th largest of all the outputs serves as a good approximation to $F_p(\mathcal{S})$.

5.2 The Algorithm

The algorithm needs three components, `SmallApprox`, `SmallCont` and `LargeCont`. All these algorithms support "update" and "query" operations. `SmallApprox` returns fail if $F_p(\mathcal{S})$ is much larger than $\operatorname{poly}(\epsilon^{-1}, \log n)$, otherwise returns an approximation to $F_p(\mathcal{S})$. `SmallApprox` is a turnstile streaming F_p algorithm [21] but with restricted memory. Once the memory exceeds the memory quota, the algorithm simply returns `Fail`. `SmallCont` estimates the contribution from the small-valued frequencies and `LargeCont` estimates the contribution from the large-valued frequencies. The correctness of these algorithms is presented in Theorem 16 and 17 of the full version of this paper. The full algorithm is presented in Algorithm 2. The following theorem guarantees its correctness.

▶ **Theorem 8.** *Fix $p \in [0, 2]$, $\epsilon \in (0, 1/2)$ and $\delta = \Omega(1/\operatorname{poly}(n))$. Let $\mathcal{S}$ be a random order stream on universe $[n]$ and with length m. Given that $C_0^{-1} F_p(\mathcal{S}) \le G_0 \le F_p(\mathcal{S})$ and $C_0^{-1} m \le m_0 \le m$ for some $C_0 = \operatorname{poly}(\epsilon^{-1}, \log n)$, there exists an algorithm $\mathcal{A}$, which makes a single pass over $\mathcal{S}$ and outputs a number F such that $F \in (1 \pm \epsilon) F_p(\mathcal{S})$ with probability at least $1 - \delta$, where the probability is over both the randomness of the algorithm and of the order of the stream. The algorithm uses*

$$\mathcal{O}[(\tfrac{1}{\epsilon^2}(\log \log n + \log \tfrac{1}{\epsilon})^4 + \log n) \log \tfrac{1}{\delta}]$$

bits of memory in the worst case.

We postpone the full proof and detailed algorithmic constructions to the appendix.

6 Deterministic Algorithm for F_p Approximation

In this section we introduce our deterministic algorithm for F_p approximation, which follows from our randomized algorithm with an initial space-efficient randomness extraction procedure applied to a prefix of the stream.

6.1 Upper Bound

▶ **Theorem 9.** *Fix $p \ge 0, \epsilon \in (0, 1)$. There exists a deterministic algorithm that makes a single pass over a random order stream $\mathcal{S}$ on the universe $[n]$, and outputs a number*

Algorithm 2: F_p-Algorithm with Approximation: `C2Fp`$(p, \epsilon, n, m_0, G_0)$.

Data:
$p \in [0, 2]$, a real number;
$L \in [\frac{F_p(\mathcal{S})}{C_0}, F_p(\mathcal{S})]$ for some $C_0 = \Theta[\text{poly}(\epsilon^{-1}, \log n)]$;
$m_0 \in [\frac{m}{C_0}, m]$;
$\mathcal{S} = \langle a_1, a_2, \ldots, a_m \rangle$ is random order stream of length m;
Result: $F \in (1 \pm \epsilon)F_p(\mathcal{S})$;

Initialize(p, n, ϵ, δ)**:**
  $k \leftarrow \Theta\big(\frac{1}{\epsilon^2}\big)$;
  $X_i^{(r)} \sim p$-Inverse distribution for $i \in [n]$ and $r \in [k]$, pairwise independent;
  $w_0 \leftarrow d_0\big(\log\log n + \log\frac{1}{\epsilon}\big)$ for some large constant d_0;
  Let $K \in \mathbb{R}^{n \times k}$ have entries $K_{i,r} = X_i^{(r)} v_i$ (only for notational purposes);
  $B_1 \leftarrow$ new `SmallApprox`(p, n, ϵ);
  $B_2 \leftarrow$ new `SmallCont`$(p, n, k, \epsilon, w_0, L, \{X_i^r\})$;
  $B_3 \leftarrow$ new `LargeCont`$(p, n, k, \epsilon, w_0, L, \{X_i^r\})$;
Update(a)**:**
  B_1.update(a); B_2.update(a); B_3.update(a);
Query:
  if B_1.*query*$() \neq$`Fail` **then**
    return B_1.query()
  else if B_2.*query*$() =$`Fail` *or* B_3.*query*$() =$`Fail` **then**
    return `Fail`;
  else
    $R \leftarrow$ the $(k/2)$-th largest element of B_2.query() $\circ$ B_3.query();
    return $(R)^p/2$

$F \in (1 \pm \epsilon)F_p(\mathcal{S})$ with probability at least $1 - \delta$, where the randomness is over the order of the stream updates. The algorithm uses

$$\mathcal{O}\left[\frac{1}{\epsilon^2}\left(\log\log n + \log\frac{1}{\epsilon}\right)^4 \log\frac{1}{\delta} + \log n \cdot \left(\log\log n + \log\frac{1}{\delta}\right) \cdot \frac{1}{\delta} + \log n \log\frac{1}{\epsilon}\right]$$

bits of memory, provided $\delta \geq 1/\text{poly}(n)$.

Proof. W.l.o.g., we assume $\epsilon \geq 1/\sqrt{n}$, since otherwise we can simply store an approximate counter for each item in the stream. It is sufficient to show that we are able to derandomize the randomized algorithm using the random updates from the stream using a near-logarithmic number of bits of space. First we pick $s = \mathcal{O}(\log\log n + \log\delta^{-1})$ and store all the universe items, their frequencies and their first arrival times until we obtain s distinct items in the stream. Let z_1 denote when the this happens. We assume the stream is long enough that this step can be done, since otherwise we obtain an exact estimate of F_p. We show in Section 6.1.1 how to obtain a nearly uniformly random seed of s bits.

We thus obtain a nearly uniform sample from all the prime numbers with $\mathcal{O}(\log\log n + \log\frac{1}{\delta})$ bits (note that there are $\text{poly}(\log n/\delta)$ many such prime numbers). Let this sampled prime number be q. For the next $\mathcal{O}(\log n/\delta)$ distinct universe items, denoted by R, we argue that with probability at least $1 - \delta$, all of them are distinct modulo q. Indeed, consider any $r_1, r_2 \in R$ with $r_1 \neq r_2$. Then $r_1 - r_2$ can have at most $\log n$ prime factors ([17], p.355). For

all $\binom{|R|}{2}$ pairs, their differences can have at most $\mathcal{O}(\log^3 n/\delta^3)$ distinct prime factors in total. Thus with probability at least $1-\delta$, q does not divide any of the differences. Therefore the set R is mapped to distinct numbers modulo q. The value q can be stored using at $\mathcal{O}(\log\log n + \log\frac{1}{\delta})$ bits.

Next we approximately store the frequencies of each item in R using the random order stream. To do this, we first fix the following numbers $g_1 = 1, g_2 = 2, g_3 = 4, \ldots, g_i = 2^{i-1}$. For each $r \in R$, we store the largest number i such that $f_r(\mathcal{S}^{z_1:g_i}) = \text{poly}(\log n, \epsilon^{-1})$ and $f_r(\mathcal{S}^{z_1:g_i})$ as well. Therefore, such an operation only costs $\mathcal{O}(\frac{\log n}{\delta}(\log\log n + \log\frac{1}{\delta} + \log\epsilon^{-1}))$ bits. By Lemma 22 of the full version, the frequency of each item is preserved up to a $(1\pm\epsilon)$ factor with probability at least $1 - 1/\text{poly}(n)$. Note that if the stream ends before we observe all of R, we obtain a good approximation to $F_p(\mathcal{S})$ immediately. We also store the first occurrence in the stream of each item in R. We also store the parity of the first appearance of each item.

Repeating the extraction argument in Section 6.1.1 for the set R, we can now extract $\mathcal{O}(\log n)$ bits that is $(1\pm\delta)$ close to uniform. Given these bits, it now suffices to run our earlier randomized algorithm on the remaining part of the stream.

There is one last problem remaining, however. Namely, it may be the case that the stream used for extracting random bits contributes too much to $F_p(\mathcal{S})$, causing the estimation of the randomized algorithm to have too much error (since the prefix and the suffix of the stream share the same items, we need to take the p-th power of the sum of their frequencies). This problem can be solved as follows – we can continue the frequency estimation in parallel with the randomized algorithm until the F_p value becomes at least a $1/\epsilon$ factor larger than the time when we initialized our randomized algorithm. Therefore, if the stream ends before this happens, then we use the frequency estimates for calculating $F_p(\mathcal{S})$ from our deterministic algorithm. Otherwise we use the value of the randomized algorithm (which is seeded with the seed found by our deterministic algorithm). In either case, the overall error is at most ϵF_p. ◀

6.1.1 Derandomization

Let $s > 0$ be a parameter. Suppose we store $t = \mathcal{O}(s/\delta)$ distinct universe items with their approximate frequencies as well as the IDs and the parities of their first appearances in the stream. Denote the set of these items by H and the overall length of the stream as m'. First, we sort the items by their approximate counts and take the smallest $\delta t/100$ items as set L. We additionally sort the items in L by their IDs, and obtain a bit string b of length $|L|$, where each bit b_i is the parity of the first appearance of the i-th item in L. Since L contains the smallest $\delta t/100$ items of H, we have for each $w \in L$, $f_w(\mathcal{S}^{0:m'}) \le m'/t/(1-\delta/100)$. Thus for each bit b_i,

$$\mathbb{P}[b_i = 0], \mathbb{P}[b_i = 1] \in \frac{1}{2} \pm \frac{2}{m'}.$$

and

$$\forall x \in \{0,1\}^{|L|} : \mathbb{P}[b = x] \in (\frac{1}{2} \pm \frac{2}{m'})^{|L|} \subset \frac{1}{2^{|L|}}(1 \pm \frac{5|L|}{m'}) \subset \frac{1}{2^{|L|}}(1 \pm \frac{\delta}{20}).$$

As such, we obtain a bit stream of length $\Omega(s)$, that is close to uniform bits up to a $(1\pm\delta)$ factor.

Abstract

We study a generic framework that provides a unified view on two important classes of problems: (i) extensions of the k-median problem where clients are interested in having multiple facilities in their vicinity (e.g., due to the fact that, with some small probability, the closest facility might be malfunctioning and so might not be available for using), and (ii) finding winners according to some appealing multiwinner election rules, i.e., election system aimed for choosing representatives bodies, such as parliaments, based on preferences of a population of voters over individual candidates. Each problem in our framework is associated with a vector of weights: we show that the approximability of the problem depends on structural properties of these vectors. We specifically focus on the harmonic sequence of weights, since it results in particularly appealing properties of the considered problem. In particular, the objective function interpreted in a multiwinner election setup reflects to the well-known Proportional Approval Voting (PAV) rule.

Our main result is that, due to the specific (harmonic) structure of weights, the problem allows constant factor approximation. This is surprising since the problem can be interpreted as a variant of the k-median problem where we do not assume that the connection costs satisfy the triangle inequality. To the best of our knowledge this is the first constant factor approximation algorithm for a variant of k-median that does not require this assumption. The algorithm we propose is based on dependent rounding [Srinivasan, FOCS'01] applied to the solution of a natural LP-relaxation of the problem. The rounding process is well known to produce distributions over integral solutions satisfying *Negative Correlation* (NC), which is usually sufficient for the analysis of approximation guarantees offered by rounding procedures. In our analysis, however, we need to use the fact that the carefully implemented rounding process satisfies a stronger property, called *Negative Association* (NA), which allows us to apply standard concentration bounds for *conditional* random variables.

1 Introduction

This paper considers a general unified framework for two classes of problems: (i) extensions of the k-median problem where clients care about having multiple facilities in their vicinity, and (ii) finding winning committees according to a number of well-known, but hard-to-compute multiwinner election systems[1]. Let us first formalize our framework; we will discuss motivation and explain the relation to k-median and to multiwinner elections later on.

For a natural number $t \in \mathbb{N}$, by $[t]$ we denote the set $\{1, \ldots, t\}$. Let $\mathcal{F} = \{F_1, \ldots, F_m\}$ be the set of m facilities and let $\mathcal{D} = \{D_1, \ldots, D_n\}$ be the set of n clients (demands). The goal is to pick a set of k facilities that altogether are most satisfying for the clients. Different clients can have different preferences over individual facilities – by $c_{i,j}$ we denote the *cost* that client D_j suffers when using facility F_i (this can be, e.g., the communication cost of client D_j to facility F_i, or a value quantifying the level of personal dissatisfaction of D_j from F_i). Following Yager [34], we use ordered weighted average (OWA) operators to define the cost of a client for a bundle of k facilities C. Formally, let $w = \big(w_1, \ldots, w_k\big)$ be a non-increasing vector of k weights. We define the w-cost of a client D_j for a size-k set of facilities C as $w(C, j) = \sum_{i=1}^{k} w_i c_i^{\rightarrow}(C, j)$, where $c^{\rightarrow}(C, j) = (c_1^{\rightarrow}(C, j), \ldots, c_k^{\rightarrow}(C, j)) = \mathrm{sort}_{\mathrm{ASC}}\big(\{c_{i,j} \colon F_i \in C\}\big)$ is a non-decreasing permutation of the costs of client D_j for the facilities from C. Informally speaking, the highest weight is applied to the lowest cost, the second highest weight to the second lowest cost, etc. In this paper we study the following computational problem.

▶ **Definition 1** (OWA k-MEDIAN)**.** In OWA k-MEDIAN we are given a set $\mathcal{D} = \{D_1, \ldots, D_n\}$ of clients, a set $\mathcal{F} = \{F_1, \ldots, F_m\}$ of facilities, a collection of clients' costs $\big(c_{i,j}\big)_{i \in [m], j \in [n]}$, a positive integer k ($k \leq m$), and a vector of k non-increasing weights $w = \big(w_1, \ldots, w_k\big)$. The task is to compute a subset C of $\mathcal{F}$ that minimizes the value

$$w(C) = \sum_{j=1}^{n} w(C, j) = \sum_{j=1}^{n} \sum_{i=1}^{k} w_i c_i^{\rightarrow}(C, j).$$

Note that OWA k-MEDIAN with weights $(1, 0, 0, \ldots, 0)$ is the k-MEDIAN problem. Sometimes the costs represent distances between clients and facilities. Formally, this means that there exists a metric space $\mathcal{M}$ with a distance function $d \colon \mathcal{M} \times \mathcal{M} \to \mathbb{R}_{\geq 0}$, where each client and each facility can be associated with a point in $\mathcal{M}$ so that for each $F_i \in \mathcal{F}$ and each $D_j \in \mathcal{D}$ we have $d(i, j) = c_{i,j}$. When this is the case, we say that the *costs satisfy the triangle inequality*, and use the terms "costs" and "distance" interchangeably. Then, we use the prefix METRIC for the names of our problems. E.g., by METRIC OWA k-MEDIAN we denote the variant of OWA k-MEDIAN where the costs satisfy the triangle inequality.

We are specifically interested in the following two sequences of weights:

[1] We note that multiwinner election rules have many applications beyond the political domain – such applications include finding a set of results a search engine should display [12], recommending a set of products a company should offer to its customers [25, 26], allocating shared resources among agents [29, 28], solving variants of segmentation problems [23], or even improving genetic algorithms [15].

(1) **harmonic:** $w_{\text{har}} = \left(1, 1/2, 1/3, \ldots, 1/k\right)$. By Harmonic k-median we denote the OWA k-median problem with the harmonic vector of weights.
(2) ***p*-geometric:** $w_{\text{geom}} = \left(1, p, p^2, \ldots, p^{k-1}\right)$, for some $p < 1$.

The two aforementioned sequences of weights, w_{har} and w_{geom}, have their natural interpretations, which we discuss later on (for instance, see Examples 3 and 4).

1.1 Motivation

In this subsection we discuss the applicability of the studied model in two settings.

Multiwinner Elections

Different variants of the OWA k-median problem are very closely related to the preference aggregation methods and multiwinner election rules studied in the computational social choice, in particular, and in AI, in general – we summarize this relation in Table 1 and in Figure 1. In particular, one can observe that each "median" problem is associated with a corresponding "winner" problem. Specifically, the k-median problem is known in computational social choice as the Chamberlin–Courant rule. Let us now explain the differences between the winner ("election") and the median ("facility location") problems:

1. The election problems are usually formulated as maximization problems, where instead of (negative) costs we have (positive) utilities. The two variants, the minimization (with costs) and the maximization (with utilities) have the same optimal solutions. Yet, there is a substantial difference in their approximability.
   Approximating the minimization variant is usually much harder. For instance, consider the Chamberlin–Courant (CC) rule which is defined by using the sequence of weights $(1, 0, 0, \ldots, 0)$. In the maximization variant standard arguments can be used to prove that a greedy procedure yields the approximation ratio of $(1 - 1/e)$. This stands in a sharp contrast to the case when the same rule is expressed as the minimization one; in such a case we cannot hope for virtually any approximation [30] (we extend this result in Theorem 21 in [6]). Approximating the minimization variant is also more desired. E.g., a $1/2$-approximation algorithm for (maximization) CC can effectively ignore half of the population of clients, whereas it was argued [30] that a 2-approximation algorithm for the minimization (if existed) would be more powerful. In this paper we study the harder minimization variant, and give the first constant-factor approximation algorithm for the minimization OWA-Winner with the harmonic weights.
2. In facility location problems it is usually assumed that the costs satisfy the triangle inequality. This relates to the previous point: since the problem cannot be well approximated in the general setting, one needs to make additional assumptions. One of our main results is showing that there is a k-median problem (OWA k-median with harmonic weights) that admits a constant-factor approximation without assuming that the costs satisfy the triangle inequality; this is the first known result of this kind.

The special case of Harmonic k-median where each cost belongs to the binary set $\{0, 1\}$ is equivalent to finding winners according to Proportional Approval Voting. The harmonic sequence $w_{\text{har}} = (1, 1/2, 1/3, \ldots, 1/k)$ is in a way exceptional: indeed, PAV can be viewed as an extension of the well known D'Hondt method of apportionment (used for electing parliaments in many contemporary democracies) to the case where the voters can vote for individual candidates rather than for political parties [4]. Further, PAV satisfies several other appealing properties, such as extended justified representation [3]. This is one of the reasons why we are specifically interested in the harmonic weights. For more discussion on PAV and other approval-based rules, we refer the reader to the survey of Kilgour [22].

Table 1 The relation between the k-MEDIAN problems and the corresponding problems studied in AI, in particular in the computational social choice community.

k-median problem	election rule	comment
OWA k-MEDIAN	OWA-Winner [29]	Finding winners according to OWA-Winner rules is the maximization variant of OWA k-MEDIAN (utilities instead of costs).
	Thiele methods [33]	Thiele methods are OWA-Winner rules for 0/1 costs.
HARMONIC k-MEDIAN	PAV [33]	In PAV we assume the 0/1 costs. So far, only the maximization variant was considered in the literature.
k-MEDIAN	Chamberlin–Courant [9]	In CC, usually some specific form of utilities is assumed – different utilities have been considered, but always in the maximization variant (utilities instead of costs).

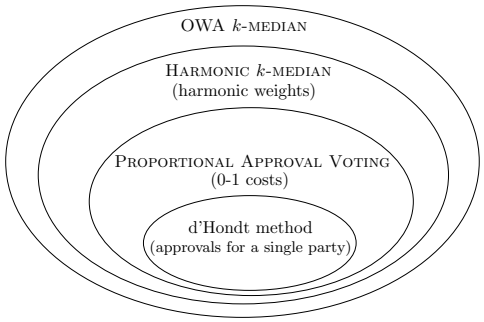

Figure 1 The relation between the considered models. OWA k-MEDIAN is the most general model. PROPORTIONAL APPROVAL VOTING and HARMONIC k-MEDIAN due to the use of harmonic weights can be viewed as natural extensions of the well known and commonly used D'Hondt method of apportionment [4].

OWA k-median as an Extension of k-median

Intuitively, our general formulation extends k-MEDIAN to scenarios where the clients not only use their most preferred facilities, but when there exists a more complex relation of "using the facilities" by the clients. Similar intuition is captured by the FAULT TOLERANT version of the k-MEDIAN problem introduced by Swamy and Shmoys [32] and recently studied by Hajiaghayi et al. [17]. There, the idea is that the facilities can be malfunctioning, and to increase the resilience to their failures each client needs to be connected to several of them.

▶ **Definition 2** (FAULT TOLERANT k-MEDIAN)**.** In FAULT TOLERANT k-MEDIAN problem we are given the same input as in k-MEDIAN, and additionally, for each client D_j we are given a natural number $r_j \geq 1$, called *the connectivity requirement*. The cost of a client D_j is the sum of its costs for the r_j closest open facilities. Similarly as in k-MEDIAN, we aim at choosing at most k facilities so that the sum of the costs is minimized.

When the values $\left(r_j\right)_{j\in[n]}$ are all the same, i.e., if $r_j = r$ for all j, then FAULT TOLERANT k-MEDIAN is called r-FAULT TOLERANT k-MEDIAN and it can be expressed as OWA k-MEDIAN for the weight vector w with r ones followed by $k - r$ zeros. Yet, in the typical

setting of k-MEDIAN problems one additionally assumes that the costs between clients and facilities behave like distances, i.e., that they satisfy the triangle inequality. Indeed, the $(2.675+\epsilon)$-approximation algorithm for k-MEDIAN [5], the 93-approximation algorithm for FAULT TOLERANT k-MEDIAN [17], the 2-approximation algorithm for k-CENTER [18], and the 6.357-approximation algorithm for k-MEANS [1], they all use triangle inequalities. Moreover it can be shown by straightforward reductions from the SET COVER problem that there are no constant factor approximation algorithms for all these settings with general (non-metric) connection costs unless $\mathsf{P}=\mathsf{NP}$.

Using harmonic or geometric OWA weights is also well-justified in case of facility location problems, as illustrated by the following examples.

▶ **Example 3** (Harmonic weights: proportionality)**.** Assume there are $\ell \leq k$ cities, and for $i \in [\ell]$ let N_i denote the set of clients who live in the i-th city. For the sake of simplicity, let us assume that $k \cdot |N_i|$ is divisible by n. Further, assume that the cost of traveling between any two points within a single city is negligible (equal to zero), and that the cost of traveling between different cities is equal to one. Our goal is to decide in which cities the k facilities should be opened; naturally, we set the cost of a client for a facility opened in the same city to zero, and – in another city – to one. Let us consider OWA k-MEDIAN with the harmonic sequence of weights w_{har}. Let n_i denote the number of facilities opened in the i-th city in the optimal solution. We will show that for each i we have $n_i = \frac{k|N_i|}{n}$, i.e., that the number of facilities opened in each city is proportional to its population. Towards a contradiction assume there are two cities, i and j, with $n_i \geq \frac{k|N_i|}{n} + 1$ and $n_j \leq \frac{k|N_j|}{n} - 1$. By closing one facility in the i-th city and opening one in the j-th city, we decrease the total cost by at least:

$$|N_j| \cdot w_{n_j+1} - |N_i| \cdot w_{n_i} = \frac{|N_i|}{n_j+1} - \frac{|N_i|}{n_i} > \frac{|N_j|n}{k|N_j|} - \frac{|N_i|n}{k|N_i|} = 0.$$

Since, we decreased the cost of the clients, this could not be an optimal solution. As a result we see that indeed for each i we have $n_i = \frac{k|N_i|}{n}$.

▶ **Example 4** (Geometric weights: probabilities of failures)**.** Assume that we want to select k facilities and that each client will be using his or her favorite facility only. Yet, when a client wants to use a facility, it can be malfunctioning with some probability p; in such a case the client goes to her second most preferred facility; if the second facility is not working properly, the client goes to the third one, etc. Thus, a client uses her most preferred facility with probability $1-p$, her second most preferred facility with probability $p(1-p)$, the third one with probability $p^2(1-p)$, etc. As a result, the expected cost of a client D_j for the bundle of k facilities C is equal to $w(C,j)$ for the weight vector $w = \big(1-p, (1-p)p, \ldots, (1-p)p^{k-1}\big)$. Finding a set of facilities, that minimize the expected cost of all clients is equivalent to solving OWA k-MEDIAN for the p-geometric sequence of weights (in fact, the sequence that we use is a p-geometric sequence multiplied by $(1-p)$, yet multiplication of the weight vector by a constant does not influence the structure of the optimal solutions).

1.2 Our Results and Techniques

Our main result is showing, that there exists a 2.3589-approximation algorithm for HARMONIC k-MEDIAN for general connection costs (not assuming triangle inequalities). This is in contrast to the innaproximability of most clustering settings with general connection costs.

Our algorithm is based on dependent rounding of a solution to a natural linear program (LP) relaxation of the problem. We use the *dependent rounding* (DR) studied by Srinivasan et al. [31, 16], which transforms in a randomized way a fractional vector into an integral one. The sum-preservation property of DR ensures that exactly k facilities are opened.

DR satisfies, what is well known as *negative correlation (NC)* – intuitively, this implies that the sums of subsets of random variables describing the outcome are more centered around their expected values than if the fractional variables were rounded independently. More precisely, negative correlation allows one to use standard concentration bounds such as the Chernoff-Hoeffding bound. Yet, interestingly, we find out that NC is not sufficient for our analysis in which we need a conditional variant of the concentration bound. The property that is sufficient for conditional bounds is *negative association* (NA) [20]. In fact its special case that we call *binary negative association* (BNA), is sufficient for our analysis. It captures the capability of reasoning about conditional probabilities. Thus, our work demonstrates how to apply the (B)NA property in the analysis of approximation algorithms based on DR. To the best of our knowledge, Harmonic k-median is the first natural computational problem, where it is essential to use BNA in the analysis of the algorithm.

We additionally show that the 93-approximation algorithm of Hajiaghayi et al. [17] can be extended to OWA k-median (our technique is summarized in Section 3) – this time we additionally need to assume that the costs satisfy the triangle inequality. Indeed, without this assumption the problem is hard to approximate for a large class of weight vectors; for instance, for p-geometric sequences with $p < 1/e$ or for sequences where there exists $\lambda \in (0, 1)$ such that clients care only about the λ-fraction of opened facilities. Due to space constraints the formulation and the discussion on these hardness results are redelegated to the full version of the paper [6, Appendix E].

For the paper to be self-contained in [6, Appendix A] we discuss in detail the process of dependent rounding (including a few illustrative examples); in particular, we provide an alternative proof that DR satisfies binary negative association. Our proof is more direct and shorter than the proofs known in the literature [24].

2 Harmonic k-median and Proportional Approval Voting: a 2.3589-approximation Algorithm

In this section we demonstrate how to use the Binary Negative Association (BNA) property of Dependent Rounding (DR) to derive our main result – a randomized constant-factor approximation algorithm for Harmonic k-median. In [6, Appendix A] we provide a detailed discussion on DR and BNA, including a proof that DR satisfies BNA, and several examples.

▶ **Theorem 5.** *There exists a polynomial time randomized algorithm for* Harmonic k-median *that gives* 2.3589*-approximation in expectation.*

▶ **Corollary 6.** *There exists a polynomial time randomized algorithm for the minimization* Proportional Approval Voting *that gives* 2.3589*-approximation in expectation.*

In the remainder of this section we will prove the statement of Theorem 5. Consider the following linear program (1–5) that is a relaxation of a natural ILP for Harmonic k-median.

$$\min \quad \sum_{j=1}^{n}\sum_{\ell=1}^{k}\sum_{i=1}^{m} w_\ell \cdot x_{ij}^{\ell} \cdot c_{ij} \qquad (1)$$

$$\sum_{i=1}^{m} y_i = k \qquad (2)$$

$$\sum_{\ell=1}^{k} x_{ij}^{\ell} \le y_i \qquad \forall i \in [m],\ j \in [n] \qquad (3)$$

$$\sum_{i=1}^{m} x_{ij}^{\ell} \ge 1 \qquad \forall j \in [n],\ \ell \in [k] \qquad (4)$$

$$y_i, x_{ij}^{\ell} \in [0,1] \qquad \forall i \in [m],\ j \in [n],\ \ell \in [k] \qquad (5)$$

The intuitive meaning of the variables and constraints of the above LP is as follows. Variable y_i denotes how much facility F_i is opened. Integral values 1 and 0 correspond

to, respectively, opening and not opening the i-th facility. Constraint (2) encodes opening exactly k facilities. Each client $D_j \in \mathcal{D}$ has to be assigned to each among k opened facilities with different weights. For that we copy each client k times: the ℓ-th copy of a client D_j is assigned to the ℓ-th closest to D_j open facility. Variable x_{ij}^{ℓ} denotes how much the ℓ-th copy of D_j is assigned to facility F_i. In an integral solution we have $x_{ij}^{\ell} \in \{0,1\}$, which means that the ℓ-th copy of a client can be either assigned or not to the respective facility. The objective function (1) encodes the cost of assigning all copies of all clients to the opened facilities, applying proper weights. Constraint (3) prevents an assignment of a copy of a client to a not-opened part of a facility. In an integer solution it also forces assigning different copies of a client to different facilities. Observe that, due to non-increasing weights w_ℓ, the objective (1) is smaller if an ℓ'-th copy of a client is assigned to a closer facility than an ℓ''-th copy, whenever $\ell' < \ell''$. Constraint (4) ensures that each copy of a client is served by some facility.

Just like in most facility location settings it is crucial to select the facilities to open, and the later assignment of clients to facilities can be done optimally by a simple greedy procedure. We propose to select the set of facilities in a randomized way by applying the DR procedure to the y vector from an optimal fractional solution to linear program (1–5). This turns out to be a surprisingly effective methodology for Harmonic k-median.

2.1 Analysis of the Algorithm

Let $\mathrm{OPT}^{\mathrm{LP}}$ be the value of an optimal solution (x^*, y^*) to the linear program (1–5). Let OPT be the value of an optimal solution $(x^{\mathrm{OPT}}, y^{\mathrm{OPT}})$ for Harmonic k-median. Easily we can see that $(x^{\mathrm{OPT}}, y^{\mathrm{OPT}})$ is a feasible solution to the linear program (1–5), so $\mathrm{OPT}^{\mathrm{LP}} \leq \mathrm{OPT}$. Let $Y = (Y_1, \ldots, Y_m)$ be the random solution obtained by applying the DR procedure described in [6, Appendix A] to the vector y^*. Recall that DR preserves the sum of entries (see [6, Appendix A]), hence we have exactly k facilities opened. It is straightforward to assign clients to the open facilities, so the variables $X = (X_{ij}^{\ell})_{j\in[n],i\in[m],\ell\in[k]}$ are easily determined.

We will show that $\mathbb{E}[\mathrm{cost}(Y)] \leq 2.3589 \cdot \mathrm{OPT}^{\mathrm{LP}}$. In fact, we will show that $\mathbb{E}[\mathrm{cost}_j(Y)] \leq 2.3589 \cdot \mathrm{OPT}_j^{\mathrm{LP}}$, where the subindex j extracts the cost of assigning client D_j to the facilities in the solution returned by the algorithm. In our analysis we focus on a single client $D_j \in \mathcal{D}$. Next, we reorder the facilities $\{F_1, F_2, \ldots, F_m\}$ in the non-decreasing order of their connection costs to D_j (i.e., in the non-decreasing order of c_{ij}). Thus, from now on, facility F_i is the i-th closest facility to client D_j; ties are resolved in an arbitrary but fixed way.

The ordering of the facilities is depicted in Figure 2, which also includes information about the fractional opening of facilities in y^*, i.e., facility F_i is represented by an interval of length y_i^*. The total length of all intervals equals k. Next, we subdivide each interval into a set of (small) ϵ-size pieces (called ϵ-subintervals); ϵ is selected so that $1/\epsilon$, and y_i^*/ϵ for each i, are integers. Note that the values y_i^*, which originate from the solution returned by an LP solver, are rational numbers. The subdivision of $[0, k]$ into ϵ-subintervals is shown in Figure 2 on the "$(Z_r)_{r\in\{1,2,\ldots,k/\epsilon\}}$" level.

The idea behind introducing the ϵ-subintervals is the following. Although computationally the algorithm applies DR to the y^* variables, for the sake of the analysis we may think that the DR process is actually rounding z variables corresponding to ϵ-subinterval under the additional assumption that rounding within individual facilities is done before rounding between facilities. Formally, we replace the vector $Y = (Y_1, Y_2, \ldots, Y_m)$ by an equivalent vector of random variables $Z = (Z_1, Z_2, \ldots, Z_{k/\epsilon})$. Random variable Z_r represents the r-th ϵ-subinterval. We will use the following notation to describe the bundles of ϵ-subintervals

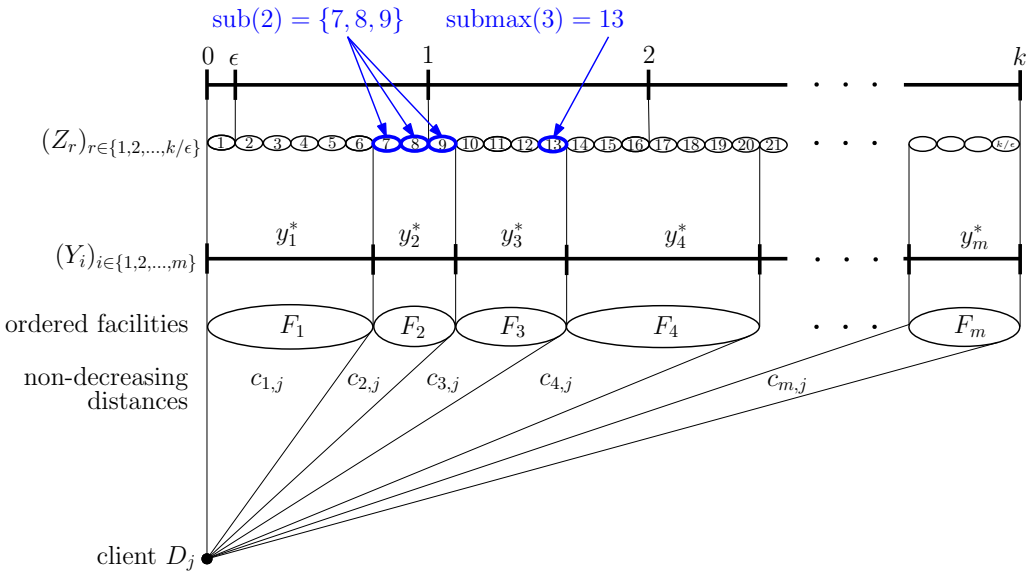

Figure 2 Ordering of the facilities by $c_{i,j}$ for the chosen client D_j. Definitions of the variables Y_i, Z_r and of the indices $\mathrm{sub}(i)$ and $\mathrm{submax}(i)$.

that correspond to particular facilities:

$$\mathrm{submax}(0) = 0 \qquad \text{and} \qquad \mathrm{submax}(i) = \mathrm{submax}(i-1) + \frac{y_i^*}{\epsilon}, \tag{6}$$

$$\mathrm{sub}(i) = \{\mathrm{submax}(i-1)+1, \ldots, \mathrm{submax}(i)\}. \tag{7}$$

Intuitively, $\mathrm{sub}(i)$ is the set of indexes r such that Z_r represents an interval belonging to the i-th facility. Examples for both definitions are shown in Figure 2 in the upper level. Formally, the random variables Z_r are defined so that:

$$Y_i = \sum_{r \in \mathrm{sub}(i)} Z_r \qquad \text{and} \qquad Y_i = 1 \implies \exists!\, r \in \mathrm{sub}(i) \quad Z_r = 1. \tag{8}$$

For each $r \in \{1, 2, \ldots, k/\epsilon\}$ we can write that:

$$\Pr[Z_r = 1] = \Pr[Z_r = 1 \big| Y_{\mathrm{sub}^{-1}(r)} = 1] \cdot \Pr[Y_{\mathrm{sub}^{-1}(r)} = 1] = \frac{\epsilon}{y^*_{\mathrm{sub}^{-1}(r)}} \cdot y^*_{\mathrm{sub}^{-1}(r)} = \epsilon \tag{9}$$

and $\Pr[Z_r = 0] = 1 - \epsilon$, hence $\mathbb{E}[Z_r] = \epsilon$. Also we have:

$$\Pr\left[Y_i = 1\right] = \Pr\left[\sum_{r \in \mathrm{sub}(i)} Z_r = 1\right] = \Pr\left[\bigvee_{r \in \mathrm{sub}(i)} Z_r = 1\right] = \sum_{r \in \mathrm{sub}(i)} \Pr\left[Z_r = 1\right]. \tag{10}$$

When $Y_i = 1$ its representative is chosen randomly among $(Z_r)_{r \in \mathrm{sub}(i)}$ independently of the choices of representatives of other facilities. Therefore

$$\forall_{i \in [m]} \quad \forall_{r \in \mathrm{sub}(i)} \quad \mathbb{E}\left[f(Y) \mid Y_i = 1\right] = \mathbb{E}\left[f(Y) \mid Y_i = 1 \ \wedge \ Z_r = 1\right], \tag{11}$$

for any function f on vector $Y = (Y_1, Y_2, \ldots, Y_m)$. Now we are ready to analyze the expected cost for any client $D_j \in \mathcal{D}$. Here we use the special assumption on the harmonic weights.

$$
\begin{aligned}
\mathbb{E}[\mathrm{cost}_j(Y)] \leq & \sum_{i=1}^{m}\left(\mathbb{E}\left[\frac{c_{ij}}{1+\sum_{i'=1}^{i-1}Y_{i'}}\middle| Y_i=1\right]\cdot\Pr\left[Y_i=1\right]\right)\\
\overset{(10)}{=} & \sum_{i=1}^{m}\left(c_{ij}\cdot\mathbb{E}\left[\frac{1}{1+\sum_{i'=1}^{i-1}Y_{i'}}\middle| Y_i=1\right]\cdot\sum_{r\in\mathrm{sub}(i)}\Pr\left[Z_r=1\right]\right)\\
= & \sum_{i=1}^{m}\left(c_{ij}\cdot\sum_{r\in\mathrm{sub}(i)}\mathbb{E}\left[\frac{1}{1+\sum_{i'=1}^{i-1}Y_{i'}}\middle| Y_i=1\right]\cdot\Pr\left[Z_r=1\right]\right)\\
\overset{(11)}{=} & \sum_{i=1}^{m}\left(c_{ij}\cdot\sum_{r\in\mathrm{sub}(i)}\mathbb{E}\left[\frac{1}{1+\sum_{i'=1}^{i-1}Y_{i'}}\middle| Y_i=1\wedge Z_r=1\right]\cdot\Pr\left[Z_r=1\right]\right)\\
\overset{(8),(9)}{=} & \sum_{i=1}^{m}\left(\epsilon\cdot c_{ij}\cdot\sum_{r\in\mathrm{sub}(i)}\mathbb{E}\left[\frac{1}{1+\sum_{r'=1}^{\mathrm{submax}(i-1)}Z_{r'}}\middle| Z_r=1\right]\right)\\
\overset{(8)}{=} & \sum_{i=1}^{m}\left(\epsilon\cdot c_{ij}\cdot\sum_{r\in\mathrm{sub}(i)}\mathbb{E}\left[\frac{1}{1+\sum_{r'=1}^{r-1}Z_{r'}}\middle| Z_r=1\right]\right) \qquad (12)
\end{aligned}
$$

W.l.o.g., assume that $\mathrm{OPT}_j^{\mathrm{LP}}>0$. Hence the approximation ratio for any client D_j is

$$
\frac{\mathbb{E}[\mathrm{cost}_j(Y)]}{\mathrm{OPT}_j^{\mathrm{LP}}}\overset{(7),(12)}{\leq}\frac{\sum_{r=1}^{k/\epsilon}\epsilon\cdot c_{\mathrm{sub}^{-1}(r),j}\cdot\mathbb{E}\left[\frac{1}{1+\sum_{r'=1}^{r-1}Z_{r'}}\middle| Z_r=1\right]}{\sum_{r=1}^{k/\epsilon}\epsilon\cdot c_{\mathrm{sub}^{-1}(r),j}\cdot\frac{1}{\lceil r\epsilon\rceil}}=
$$

note that $\mathrm{sub}^{-1}(r)$ is an index of a facility that contains Z_r. Now we convert the sum over facilities into a sum over unit intervals. A unit interval is represented as a sum of $1/\epsilon$ many ϵ-subintervals:

$$
=\frac{\sum_{\ell=1}^{k}\sum_{r=(\ell-1)/\epsilon+1}^{\ell/\epsilon}c_{\mathrm{sub}^{-1}(r),j}\cdot\mathbb{E}\left[\frac{1}{1+\sum_{r'=1}^{r-1}Z_{r'}}\middle| Z_r=1\right]}{\sum_{\ell=1}^{k}\sum_{r=(\ell-1)/\epsilon+1}^{\ell/\epsilon}c_{\mathrm{sub}^{-1}(r),j}\cdot\frac{1}{\ell}}\leq
$$

W.l.o.g., we can assume that first interval has non-zero costs: $\sum_{r=1}^{1/\epsilon}c_{\mathrm{sub}^{-1}(r),j}>0$, otherwise the LP pays 0 and our algorithm pays 0 in expectation on intervals from non-empty prefix of $(1,2,\ldots,k)$. With this assumption we can take maximum over intervals:

$$
\overset{\text{Lemma 17 in [6]}}{\leq}\max_{\ell\in[k]}\left(\frac{\sum_{r=(\ell-1)/\epsilon+1}^{\ell/\epsilon}c_{\mathrm{sub}^{-1}(r),j}\cdot\mathbb{E}\left[\frac{1}{1+\sum_{r'=1}^{r-1}Z_{r'}}\middle| Z_r=1\right]}{\sum_{r=(\ell-1)/\epsilon+1}^{\ell/\epsilon}c_{\mathrm{sub}^{-1}(r),j}\cdot\frac{1}{\ell}}\right)\leq
$$

Costs $c_{\mathrm{sub}^{-1}(r),j}$ can be general and they could be hard to analyze. Therefore we would like to remove costs from the analysis. We will use Lemma 18 from [6] for which the technique of

splitting variables Y_i into Z_r was needed. We are using the fact that the variables Z_r have the same expected values; otherwise the coefficient in front of the expected value would be $c_{ij} \cdot y_i^*$, i.e., not monotonic. Thus

$$\overset{\text{Lemma 18 in [6]}}{\leq} \max_{\ell \in [k]} \left(\epsilon \cdot \ell \cdot \sum_{r=(\ell-1)/\epsilon+1}^{\ell/\epsilon} \mathbb{E}\left[\frac{1}{1+\sum_{r'=1}^{r-1} Z_{r'}} \middle| Z_r = 1 \right] \right). \tag{13}$$

Consider the expected value in the above expression for a fixed $r \in \{(\ell-1)/\epsilon + 1, \ldots, \ell/\epsilon\}$:

$$\begin{aligned} E_r &= \mathbb{E}\left[\frac{1}{1+\sum_{r'=1}^{r-1} Z_{r'}} \middle| Z_r = 1 \right] = \sum_{t=1}^{k} \frac{1}{t} \Pr\left[\sum_{r'=1}^{r-1} Z_{r'} = t-1 \middle| Z_r = 1 \right] = \\ &= \sum_{t=1}^{\ell} \frac{1}{t} \Pr\left[\sum_{r'=1}^{r-1} Z_{r'} = t-1 \middle| Z_r = 1 \right] + \sum_{t=\ell+1}^{k} \frac{1}{t} \Pr\left[\sum_{r'=1}^{r-1} Z_{r'} = t-1 \middle| Z_r = 1 \right]. \end{aligned} \tag{14}$$

For $t \in \{1, 2, \ldots, \ell\}$ we consider the conditional probability in the above expression, denote it by $p_r(t-1)$, and analyze the corresponding cumulative distribution function $H_r(t-1)$:

$$p_r(t-1) = \Pr\left[\sum_{r'=1}^{r-1} Z_{r'} = t-1 \middle| Z_r = 1 \right], \tag{15}$$

$$H_r(t-1) = \Pr\left[\sum_{r'=1}^{r-1} Z_{r'} \leq t-1 \middle| Z_r = 1 \right] = \sum_{t'=0}^{t-1} p_r(t'), \tag{16}$$

We continue the analysis of E_r:

$$\begin{aligned} E_r &\overset{(14),(15)}{=} \sum_{t=1}^{\ell} \frac{1}{t} p_r(t-1) + \sum_{t=\ell+1}^{k} \frac{1}{t} p_r(t-1) \\ &\overset{(16)}{=} H_r(0) + \sum_{t=2}^{\ell} \frac{1}{t} \left(H_r(t-1) - H_r(t-2) \right) + \sum_{t=\ell+1}^{k} \frac{1}{t} p_r(t-1) \\ &= H_r(0) + \sum_{t=2}^{\ell} \frac{1}{t} H_r(t-1) - \sum_{t=2}^{\ell} \frac{1}{t} H_r(t-2) + \sum_{t=\ell+1}^{k} \frac{1}{t} p_r(t-1) \\ &= \sum_{t=1}^{\ell} \frac{1}{t} H_r(t-1) - \sum_{t=1}^{\ell-1} \frac{1}{t+1} H_r(t-1) + \sum_{t=\ell+1}^{k} \frac{1}{t} p_r(t-1) \\ &= \sum_{t=1}^{\ell-1} \frac{1}{t} H_r(t-1) - \sum_{t=1}^{\ell-1} \frac{1}{t+1} H_r(t-1) + \frac{1}{\ell} H_r(\ell-1) + \sum_{t=l+1}^{k} \frac{1}{t} p_r(t-1) \\ &\leq \sum_{t=1}^{\ell-1} \left(\frac{1}{t} - \frac{1}{t+1} \right) H_r(t-1) + \frac{1}{\ell} \left(H_r(\ell-1) + \sum_{t=\ell+1}^{k} p_r(t-1) \right) \\ &= \sum_{t=1}^{\ell-1} \frac{1}{t(t+1)} H_r(t-1) + \frac{1}{\ell} \left(H_r(\ell-1) + \sum_{t=\ell+1}^{k} p_r(t-1) \right) \\ &\leq \sum_{t=1}^{\ell-1} \frac{1}{t(t+1)} H_r(t-1) + \frac{1}{\ell}. \end{aligned} \tag{17}$$

▶ **Lemma 7.** *For any $\ell \in [k]$, $t \in [\ell-1]$ and $r \in \{(\ell-1)/\epsilon + 1, (\ell-1)/\epsilon + 2, \ldots, \ell/\epsilon\}$ we have*

$$H_r(t-1) \leq e^{-r \cdot \epsilon} \cdot \left(\frac{e \cdot r \cdot \epsilon}{t} \right)^t.$$

The proof of Lemma 7 combines the use of the BNA property of variables $\{Z_1, Z_2, \ldots, Z_{k/\epsilon}\}$ with applications of Chernoff-Hoeffding bounds. Due to the space constraints, the proof is moved to the full version of the paper [6, Appendix C]. In the end, we get the following bound on the approximation ratio.

▶ **Lemma 8.** *For any $j \in [n]$ we have*

$$\frac{\mathbb{E}[\text{cost}_j(Y)]}{\text{OPT}_j^{\text{LP}}} \leq 2.3589.$$

A proof uses inequalities (13), (17) as well as Lemma 7 with an upper bound derived by an integral of the function $f_t(x) = e^{-x}$. We made numerical calculation for $\ell \in \{1, 2, \ldots, 88\}$ and for other case we used Stirling formula and Taylor series for e^{ℓ} to derive analytical upper bound. Full proof, including a plot of numericaly obtained values, is presented in [6, Appendix C].

3 OWA k-median with Costs Satisfying the Triangle Inequality

In this section we construct an algorithm for OWA k-median with costs satisfying the triangle inequality. Thus, the problem we address in this section is more general than Harmonic k-median (i.e., the problem we have considered in the previous section) in a sense that we allow for arbitrary non-increasing sequences of weights. On the other hand, it is less general in a sense that we require the costs to form a specific structure (a metric).

In our approach we first adapt the algorithm of Hajiaghayi et al. [17] for Fault Tolerant k-median so that it applies to the following, slightly more general setting: for each client D_j we introduce its multiplicity $m_j \in \mathbb{N}$ – intuitively, this corresponds to cloning D_j and co-locating all such clones in the same location as D_j. However, this will require a modification of the original algorithm for Fault Tolerant k-median, since we want to allow the multiplicities $\{m_j\}_{D_j \in \mathcal{D}}$ to be exponential with respect to the size of the instance (otherwise, we could simply copy each client a sufficient number of times, and use the original algorithm of Hajiaghayi et al.).

Next, we provide a reduction from OWA k-median to such a generalization of Fault Tolerant k-median. The resulting Fault Tolerant k-median with Clients Multiplicities problem can be cast as the following integer program:

$$\begin{aligned}
\min \quad & \sum_{j=1}^{n}\sum_{i=1}^{m} m_j \cdot x_{ij} \cdot c_{ij} && \sum_{i=1}^{m} x_{ij} = r_j && \forall j \in [n] \\
& \sum_{i=1}^{m} y_i = k && x_{ij} \leq y_i && \forall i \in [m],\ j \in [n] \\
& && y_i, x_{ij} \in \{0,1\} && \forall i \in [m] \\
& && m_j \in \mathbb{N} && \forall j \in [n]
\end{aligned}$$

▶ **Theorem 9.** *There is a polynomial-time* 93*-approximation algorithm for* Metric Fault Tolerant k-median with Clients Multiplicities.

Proof can be found in [6, Appendix D]. Consider reduction from OWA k-median to Fault Tolerant k-median with Clients Multiplicities depicted on Figure 3.

▶ **Lemma 10.** *Let I be an instance of* OWA k-median*, and let I' be an instance of* Fault Tolerant k-median with Clients Multiplicities *constructed from I through reduction from Figure 3. An α-approximate solution to I' is also an α-approximate solution to I.*

Proof can be found in [6, Appendix D].

▶ Reduction. Let us take an instance I of OWA k-median $\left(\mathcal{D}, \mathcal{F}, k, w, \{c_{ij}\}_{F_i \in \mathcal{F}, D_j \in \mathcal{D}}\right)$ where $w_i = \frac{p_i}{q_i}, i \in [k]$ are rational numbers in the canonical form. We construct an instance I' of Fault Tolerant k-median with Clients Multiplicities with the same set of facilities and the same number of facilities to open, k. Each client $D_j \in \mathcal{D}$ is replaced with clients $D_{j,1}, D_{j,2}, \ldots, D_{j,k}$ with requirements $1, 2, \ldots, k$, respectively. For $Q = \prod_{r=1}^{k} q_r$, the multiples of the clients are defined as follows:

- $m_{j,\ell} = (w_\ell - w_{\ell+1}) \cdot Q$, for each $\ell \in [k-1]$, and
- $m_{j,k} = w_k \cdot Q$.

Figure 3 Reduction from OWA k-median to Fault Tolerant k-median with Clients Multiplicities.

▶ **Corollary 11.** *There exists a* 93*-approximation algorithm for* Metric OWA k-median *that runs in polynomial time.*

4 Concluding Remarks and Open Questions

We have introduced a new family of k-median problems, called OWA k-median, and we have shown that our problem with the harmonic sequence of weights allows for a constant factor approximation even for general (non-metric) costs. This algorithm applies to Proportional Approval Voting. In the analysis of our approximation algorithm for Harmonic k-median, we used the fact that the dependent rounding procedure satisfies Binary Negative Association.

We showed that any Metric OWA k-median can be approximated within a factor of 93 via a reduction to Fault Tolerant k-median with Clients Multiplicities. We also obtained that OWA k-median with p-geometric weights with $p < 1/e$ cannot be approximated without the assumption of the costs being metric. The status of the non-metric problem with p-geometric weights with $p > 1/e$ remains an intriguing open problem.

Using approximation and randomized algorithms for finding winners of elections requires some comment. First, the multiwinner election rules such as PAV have many applications in the voting theory, recommendation systems and in resource allocation. Using (randomized) approximation algorithms in such scenarios is clearly justified. However, even for other high-stake domains, such as political elections, the use of approximation algorithms is a promising direction. One approach is to view an approximation algorithm as a new, full-fledged voting rule (for more discussion on this, see the works of Caragiannis et al. [7, 8], Skowron et al. [30], and Elkind et al. [13]). In fact, the use of randomized algorithms in this context has been advocated in the literature as well – e.g., one can arrange an election where each participant is allowed to suggest a winning committee, and the best out of the suggested committees is selected; in such case the approximation guaranty of the algorithm corresponds to the quality of the outcome of elections (for a more detailed discussion see [30]) [2]. Nonetheless, we think that it would be beneficial to learn whether our algorithm can be efficiently derandomized.

[2] Indeed, approximation algorithms for many election rules have been extensively studied in the literature. In the world of single-winner rules, there are already very good approximation algorithms known for the Kemeny's rule [2, 10, 21] and for the Dodgson's rule [27, 19, 7, 14, 8]. A hardness of approximation has been proven for the Young's rule [7]. For the multiwinner case we know good (randomized) approximation algorithms for Minimax Approval Voting [11], Chamberlin–Courant rule [30], Monroe rule [30], or maximization variant of PAV [29].

Abstract

We show that popular hardness conjectures about problems from the field of fine-grained complexity theory imply structural results for resource-based complexity classes. Namely, we show that if either k-Orthogonal Vectors or k-CLIQUE requires $n^{\epsilon k}$ time, for some constant $\epsilon > 1/2$, to *count* (note that these conjectures are significantly weaker than the usual ones made on these problems) on randomized machines for all but finitely many input lengths, then we have the following derandomizations:

- BPP can be decided in polynomial time *using only* n^{α} *random bits* on average over *any* efficient input distribution, for any constant $\alpha > 0$
- BPP can be decided in polynomial time with *no randomness* on average *over the uniform distribution*

This answers an open question of Ball et al. (STOC '17) in the positive of whether derandomization can be achieved from conjectures from fine-grained complexity theory. More strongly, these derandomizations improve over all previous ones achieved from *worst-case uniform* assumptions by succeeding on all but finitely many input lengths. Previously, derandomizations from worst-case uniform assumptions were only know to succeed on infinitely many input lengths. It is specifically the structure and moderate hardness of the k-Orthogonal Vectors and k-CLIQUE problems that makes removing this restriction possible.

Via this uniform derandomization, we connect the problem-centric and resource-centric views of complexity theory by showing that exact hardness assumptions about specific problems like k-CLIQUE imply quantitative and qualitative relationships between randomized and deterministic time. This can be either viewed as a barrier to proving some of the main conjectures of fine-grained complexity theory lest we achieve a major breakthrough in unconditional derandomization or, optimistically, as route to attain such derandomizations by working on very concrete and weak conjectures about specific problems.

1 Introduction

Computational complexity can be viewed through two main perspectives: problem-centric or resource-centric. Problem-centric complexity theory asks what resources are required to solve *specific problems*, while resource-centric complexity deals with the relative power of different computational models given different resource budgets such as time, memory, non-determinism, randomness, etc. (see [17] for a discussion). Through complete problems, these two perspectives often coincide, so that a resource-centric view acts as a fine proxy for answering questions about the complexity of specific problems. The rapidly progressing field of fine-grained complexity theory, however, brings attention back to the problem-centric viewpoint, raising fine distinctions even between problems complete for the same complexity class, and making connections between problems at very different levels of complexity. To what extent are these two approaches linked, i.e., to what extent can inferences about the fine-grained complexities of specific problems be made from general assumptions about complexity classes, and vice versa?

Here, we examine such links between the fine-grained complexity of specific problems such as the k-Orthogonal Vectors and k-CLIQUE problems and general results about derandomization of algorithms. Derandomization has been a very fruitful study in complexity theory, with many fascinating connections between lower bounds, showing that problems require large amounts of resources to solve, and upper bounds, showing that classes of probabilistic algorithms can be 'derandomized' by simulating them deterministically in a non-trivial fashion. In particular, the hardness-to-randomness framework shows that in many cases, the existence of any "hard" problem can be used to derandomize classes of algorithms. We reconsider this framework from the fine-grained, problem-centric perspective. We show that replacing a generic hard problem with specific hardness conjectures from fine-grained complexity leads to quantitatively and qualitatively stronger derandomization results than one gets from the analogous assumption about a generic problem. In particular, we show that starting from these assumptions, we can simulate any polynomial-time probabilistic algorithm (on any samplable distribution on inputs with a very small fraction of errors) by a polynomial time probabilistc algorithm that uses only n^α random coins, for any $\alpha > 0$. This type of derandomization previously either assumed the existence of cryptographic One-Way Functions or *exponential non-uniform* hardness of Boolean functions.

Thus, the problem-centric conjectures of fine-grained complexity cannot live in isolation from classical resource-centric consequences about the power of randomness. Viewed another way, our results can be seen as a barrier to proving some of the key hardness assumptions used by fine-grained complexity theory. That is, despite recent progress towards proving hardness for k-Orthogonal Vectors, one of fine-grained complexity's key problems, in restricted models of computation [29], doing so for general randomized algorithms would immediately prove *all* problems in BPP are easy on average (over, say, uniformly chosen inputs).

1.1 Our Results

We obtain two main theorems about the power of BPP from uniform worst-case assumptions about well-studied problems from fine-grained complexity theory. We consider the k-Orthogonal Vectors (k-OV) and the k-CLIQUE problems, defined and motivated in Section 2.1, and show that (even weaker versions of) popular conjectures about their hardness give two flavors of average-case derandomization that improve over the classical *uniform* derandomizations.

All previous derandomizations from *uniform* assumptions on worst-case hardness only succeed on *infinitely many input lengths*. Our work is the first to use worst-case uniform assumptions to derandomize BPP *for all but finitely many input lengths*, giving a standard inclusion. The only other worst-case uniform assumptions known to imply such results are those so strong as to imply cryptographic assumptions or circuit lower bounds, fitting closer to the cryptographic or non-uniform derandomization literature. In contrast, our *uniform derandomizations* are from extremely weak worst-case uniform conjectures on simple, natural, combinatorial problems. Informally, we prove the following:

▶ **Informal Theorem 1.** *If k-OV or k-CLIQUE requires $n^{\epsilon k}$ time, for some constant $\epsilon > 1/2$, to **count** on randomized machines in the worst-case for all but finitely many input lengths, then BPP can be decided in polynomial time **using only** n^{α} **random bits** on average over **any** efficient input distribution, for any constant $\alpha > 0$.*

Randomness can be removed entirely by simply brute-forcing all random bits and taking the majority of the outputs to give the following more standard full derandomization.

▶ **Corollary.** *If k-OV or k-CLIQUE requires $n^{\epsilon k}$ time, for some constant $\epsilon > 1/2$, to **count** on randomized machines in the worst-case for all but finitely many input lengths, then BPP can be decided with **no randomness** in sub-exponential time on average over **any** efficient input distribution.*

This conclusion is strictly stronger than the classic uniform derandomizations of [25, 38]. The weakest uniform assumption previously known to imply such a conclusion was from those already strong enough to imply the cryptographic assumption of the existence of One-Way Functions that are hard to invert for polynomial time adversaries [9, 19, 20, 23, 42] or those implying *non-uniform* circuit lower bounds [4].

Our second main theorem, using techniques from [31], shows how to remove all randomness *within polynomial time* if the distribution over inputs is uniform. The only stronger derandomization from uniform assumptions were, again, from those already strong enough to imply circuit lower bounds or the cryptographic assumption of the existence of One-Way Permutations that require *exponential* time to invert [9, 20, 42].

▶ **Informal Theorem 2.** *If k-OV or k-CLIQUE require $n^{\epsilon k}$ time, for some constant $\epsilon > 1/2$, to **count** on randomized machines in the worst-case for all but finitely many input lengths, then BPP can be decided in polynomial time with **no randomness** on average over **the uniform distribution**.*

1.2 Related Work

Connections Between Problem-Centric and Resource-Centric Complexity. Most connections from problem-centric to resource-centric complexity show that faster algorithms for OV or related problems give circuit lower bounds. For instance, improvements in EDIT-DISTANCE algorithms imply circuit lower bounds [2] and solving OV faster (and thus

CNF-SAT [40]) implies circuit lower bounds [26]. These are all non-uniform results, however, whereas in this paper we are concerned with *machines* and their resource-bounds as opposed to circuits. On the uniform side, [18] recently showed that the exact complexity of k-Orthogonal Vectors is closely related to the complexity of uniform AC^0, although a connection between more powerful machine models and fine-grained assumptions was still not known until now. Further, most of these results follow from OV being *easy*. Our work shows instead that there are interesting resource-centric consequences if our fine-grained problems are *hard*.

Uniform Derandomization Framework. The uniform derandomization framework was introduced in [25], a breakthrough paper that showed the first derandomization from a uniform assumption ($\mathsf{EXP} \neq \mathsf{BPP}$) in the *low-end* setting: a weak assumption gives a *slow* (subexponential-time) deterministic simulation of BPP. This is in contrast to our simulation which retains small amounts of randomness but is *fast* (this is a strictly stronger result as it recovers the [25] derandomization as a corollary).

We build on [38], which simplifies the proof of [25] to prove that $\mathsf{PSPACE} \neq \mathsf{BPP}$ implies a non-trivial deterministic simulation of BPP. The technique of [38] carefully arithmetizes the PSPACE-complete problem TQBF and uses this as a hard function in the generator of [25]. Our proof substitutes a carefully-arithmetized k-OV problem from [8]. Numerous other works study derandomization from uniform assumptions ([27, 33, 24, 22, 37]), but these all focus on assumptions and consequences about *nondeterministic* classes.

All worst-case uniform derandomizations, including [38] and [25], seem to only be able to achieve simulations of BPP that succeed for infinitely many input lengths because of how their proofs use downward self-reductions. Our is the first work to achieve simulations on *all but finitely many input lengths*, because the k-OV and k-CLIQUE-inspired problems have very parallelizable downward self reductions so that we can reduce to a *single* much smaller input length rather than recurse through a chain of incrementally smaller input lengths in our downward self-reduction.

Heuristics by Extracting Randomness From the Input. A separate line of work began when [21] introduced the idea of using the *input itself* as a source of randomness to heuristically simulate randomized algorithms over uniformly-distributed inputs. While their assumptions contain oracles and are mostly non-uniform and average-case, they construct an algebraic problem inside P whose worst-case uniform hardness can be used in the framework of [25] to get an *infinitely-often* simulation of BPP in polynomial time. Our work differs in that we achieve an *almost-everywhere* simulation, that our assumptions are based on canonical fine-grained problems, and that our assumptions aren't against machines with SAT-oracles. Further, the downward self-reduction of their problem requires an expansion by minors of the determinant and so they cannot also obtain an *almost-everywhere* heuristic using our techniques without placing the determinant in NC^1 (as our modification to [25] exploits *embarrassingly parallel* downward self reductions).

The work of [31], generalizing [36], removes the SAT-oracles needed in the assumptions of [21] by showing that the Nisan-Wigderson generator (see [35]) remains secure against *non-uniform* adversaries even if the seed is revealed to potential distinguishers. In Section 3.2.2 we will show their arguments can be made *uniform* so we can derandomize from uniform assumptions. Seed-revealing Nisan-Wigderson generators are used in [31] to obtain polynomial-time heuristics for randomized algorithms, where the uniformly distributed input is used as a seed to the generator. The derandomizations in [31] are achieved from *non-uniform* assumptions of polynomial *average-case* hardness. From *worst-case uniform* assumptions we achieve the same derandomizations.

2 Preliminaries

All complexity measures of fine-grained problems will refer to time on a randomized word RAM with $O(\log(n))$-bit word length, as is standard for the fine-grained literature [41, 8]. Specifically, we will consider two-sided bounded error as in [8].

2.1 Fine-Grained Hardness

The problem-centric field of fine-grained complexity theory has had impressive success in showing the fixed polynomial time ("fine-grained") hardness of many practical problems by assuming the fine-grained hardness of four "key" well-studied problems, as discussed in [8]. We obtain our results under hardness conjectures about two of these four key problems: the k-Orthogonal Vectors (k-OV) problem and the k-CLIQUE problem.

***k*-CLIQUE.** Denote the matrix multiplication constant by ω. The fastest known algorithm for deciding if a graph has a k-CLIQUE (given its adjacency matrix) runs in time $O(n^{\omega k/3})$, and was discovered in 1985 [34] for k a multiple of three (for other k different ideas are needed [14]). It is conjectured that no algorithm can improve the exponent to a better constant. The parameterized version of the famous NP-hard MAX-CLIQUE problem [30], k-CLIQUE is one of the most heavily studied problems in theoretical computer science and is the canonical intractable (W[1]-complete) problem in parameterized complexity (see [1] for a review of the copious evidence of k-CLIQUE's hardness and consequences of its algorithm's exponent being improved). Recent work has shown that conjecturing k-CLIQUE to require $n^{\omega k/3-o(1)}$ time, for k a multiple of three, leads to interesting hardness results for other important problems such as parsing languages and RNA folding [1, 12, 5, 7], and it is known that refuting this conjecture deterministically would give a faster exact algorithm for MAX-CUT [40]. Our results hold under a *much weaker version of the conjecture*:

▶ **Definition 1** (Weak k-CLIQUE Conjecture)**.** There exists an absolute constant $\epsilon_0 > 1/2$ such that, for all $k \in \mathbb{N}$ a multiple of three, any randomized algorithm that *counts* the number of k-CLIQUE's in an n node graph requires $n^{\epsilon_0 k}$ time.

Note that this conjecture gives leeway for the exponent of the k-CLIQUE algorithm to be improved so long as it doesn't get down to $k/2$; even finding a linear time algorithm for Boolean matrix multipliaction ($\omega = 2$) would not contradict this conjecture! Further, even if it is possible to *decide* the k-CLIQUE problem that quickly, this conjecture still holds unless it is possible to *count all of the k-CLIQUE's in that time.*

***k*-Orthogonal Vectors.** Although the k-CLIQUE problem is certainly *at least* as important as the k-OV problem, for concreteness we will use the k-OV problem to demonstrate our techniques throughout the paper. Proofs based on hardness of k-CLIQUE follow identically.

▶ **Definition 2** (k-Orthogonal Vectors Problem, k-OV$_{n,d}$)**.** For an integer $k \geq 2$, the k-OV$_{n,d}$ problem on vectors of dimension d is to determine, given k sets $(U_1, \ldots, U_k)$ of n vectors from $\{0,1\}^d$ each, whether there exist $u_i \in U_i$ for each i such that over $\mathbb{Z}$,

$$\sum_{\ell \in [d]} u_{1\ell} \cdots u_{k\ell} = 0$$

If left unspecified, d is to be taken to be $d(n) = \lceil \log^2 n \rceil$.

▶ **Definition 3** (k-Orthogonal Vectors Conjecture, k-OVC)**.** For any $d = \omega(\log n)$, for all $k \geq 2$, any randomized algorithm for the k-$\mathsf{OV}_{n,d}$ problem requires $n^{k-o(1)}$ time.

For $k = 2$ the Orthogonal Vectors conjecture for deterministic algorithms has been extensively studied and is supported by the *Strong Exponential Time Hypothesis* (SETH) [40], which states that there is no $\epsilon > 0$ such that t-SAT can be solved in time $\widetilde{O}(2^{n(1-\epsilon)})$ for all values of t. The natural generalization to k-OV is studied in [8, 18] and its deterministic hardness is also supported by SETH. While SETH has been controversial , the deterministic k-OV conjecture seems to be a much weaker assumption and is independently believable and supported: it has been shown that it holds unless *all* first-order graph properties become easy to decide [18] and the 2-OV conjecture has recently been proven unconditionally when the model of computation is restricted to branching programs [29]. This conjecture has also been used to support the hardness of many practical and well-studied fine-grained problems [3, 6, 13]. As with k-CLIQUE, our main results will hold *using a much weaker version of the randomized k-OV conjecture* introduced below.

▶ **Definition 4** (Weak k-Orthogonal Vectors Conjecture)**.** For any $d = \omega(\log n)$, there exists an absolute constant $\epsilon_0 > 1/2$ such that, for all $k \geq 2$, any randomized algorithm *counting* the number of k-$\mathsf{OV}_{n,d}$ solutions requires $n^{\epsilon_0 k}$ time.

▶ Remark. For all of these conjectures we will also consider the strengthened versions that assume that all algorithms running in time less than what is required will fail *on all but finitely many input lengths*, as opposed to only on infinitely many input lengths. For natural problems we expect that hardness grows, instead of oscillates, asymptotically.

For the purposes of derandomization, for a given k, we will use a family of polynomials introduced in [8], $\left\{f^k_{n,d,p} : \mathbb{F}_p^{knd} \to \mathbb{F}_p\right\}_{n,d,p\in\mathbb{N}}$, such that the variables are grouped into sets of size nd in the form of a matrix $U_i \in \mathbb{F}_p^{n\times d}$ where the n rows $u_i \in U_i$ are each collections of d variables:

$$f^k_{n,d,p}(U_1, \ldots, U_k) = \sum_{u_1\in U_1,\ldots,u_k\in U_k} \prod_{\ell\in[d]} (1 - u_{1\ell} \cdots u_{k\ell})$$

The worst-case hardness of evaluating these polynomials was related to the worst-case hardness of k-OV_n in [8].

▶ **Lemma 5.** *Let p be the smallest prime number larger than n^k and $d = \lceil \log^2(n) \rceil$. If $f^k_{n,d,p}$ can be computed in $O(n^{k/2+c})$ time for some $c > 0$, then k-OV_n can be **counted** in time $\widetilde{O}(n^{k/2+c})$*

Derandomization from uniform assumptions typically requires two other properties of the assumed hard problem: random self-reducibility and downward self-reducibility. We recall from [8] that $f^k_{n,d,p}$ satisfies both of these properties. We give a polynomial for k-CLIQUE and show that it also has the necessary properties in the full version.

Random Self-Reducible. $f^k_{n,d,p}$ is *random self-reducible* by the following classical lemma [32, 15] (see [8] for a proof). Note that degree $\log^2 n$ adds negligibly to the random self-reduction time.

▶ **Lemma 6** (Random Self-Reducibility of Polynomials)**.** *If $f : \mathbb{F}_P^N \to \mathbb{F}_P$ is a degree $9 < D < P/12$ polynomial, then there exists a randomized algorithm that takes a circuit $\widehat{C}$ 3/4-approximating f and produces a circuit C exactly computing f, such that the algorithm succeeds with high probability and runs in time $poly(N, D, \log P, |\widehat{C}|)$.*

Downward Self-Reducible. We will show that $f^k_{n,d,p}$ is downward self-reducible in the sense that, if we we have a way to produce an oracle for $f^k_{\sqrt{n},d,p}$, we can quickly compute $f^k_{n,d,p}$ with it. Compare this to downward self reducibility going from input size n to $n-1$ in previous uniform derandomizations. We exploit our more dramatic shrinkage and parallelism to later give an almost-everywhere derandomization, instead of an infinitely-often one. The proof of the following lemma is in the full version.

▶ **Lemma 7.** *If there exists an algorithm A that, on input 1^n, outputs a circuit C computing $f^k_{\sqrt{n},d,p}$, then there exists an algorithm that computes $f^k_{n,d,p}$ in time $O(n^{k/2}|C| + \mathsf{TIME}(A))$.*

2.2 Derandomization

We now define pseudorandom generators (PRGs) in terms of their distinguishers.

▶ **Definition 8** (Distinguishers)**.** A test $T : \{0,1\}^{m^\ell} \to \{0,1\}$ is an ϵ-*distinguisher* against $G : \{0,1\}^m \to \{0,1\}^{m^\ell}$, denoted $T \in \mathsf{DIS}(G, \epsilon)$, if:

$$\left| \Pr_{r \sim \mathcal{U}_{m^\ell}} [T(r)] - \Pr_{z \sim \mathcal{U}_m} [T(G(z))] \right| > \epsilon$$

We also will consider the seemingly weaker object of distinguishers that succeed if they are also given the seed to the PRG. These were studied in [38] to relate uniform derandomization to average-case hardness and in [31] to derandomize over the uniform distribution by *using the random input itself as the seed* to the PRG.

▶ **Definition 9** (Seed-Aware Distinguishers)**.** A test $T : \{0,1\}^m \times \{0,1\}^{m^\ell} \to \{0,1\}$ is an ϵ-*seed-aware distinguisher* against G, denoted $T \in \mathsf{DIS}(G, \epsilon)$, if:

$$\left| \Pr_{x \sim \mathcal{U}_m, r \sim \mathcal{U}_{m^\ell}} [T(x, r)] - \Pr_{x \sim \mathcal{U}_m} [T(x, G(x))] \right| > \epsilon$$

Standard hardness-to-randomness arguments typically derandomize using generators that are based on some 'hard' function by contrapositive: if derandomization fails, then a distinguisher for the generator can be produced. Further, from a distinguisher, we can create a small circuit for the supposedly hard function that the generator was based on. For our purposes, we require an algorithmic version of this argument for derandomization from *uniform* hardness assumptions. More specifically, we will use the following lemma which was originally proved for distinguishers [38, 25] but Lemma 2.9 of [31] proves that it also holds for seed-aware distinguishers (while the proof of [31] is non-uniform, it is easy to see that it can be made constructive, in the same way that [25] gave a constructive version of [35]). Thus, $\mathsf{DIS}(G, \epsilon)$ in the lemma below can be thought to refer to either regular or seed-aware distinguishers (which justifies overloading this notation).

▶ **Lemma 10** (Algorithmic Distinguishers to Predictors ([38, 25]))**.** *For every random self-reducible f, there exists a function G with stretch m bits to m^ℓ bits and a constant c such that*

- *$G(z)$ is in time $(|z|^\ell)^c$ with oracle access to f on inputs of length at most $|z|$*
- *There exists a polynomial-time randomized algorithm A that, with high probability, given as input circuit $D \in \mathsf{DIS}(G, \epsilon)$ for ϵ at least inverse polynomial and an oracle for f, prints a circuit computing f exactly.*

2.3 Uniform Derandomization

Average-Case Tractability. We give standard definitions of average-case tractability (for an extensive survey of these notions, see [10]).

▶ **Definition 11** ($t(n)$-Samplable Ensemble)**.** An ensemble $\mu = \{\mu_n\}$ is $t(n)$-samplable if there is a randomized algorithm A that, on input a number n, outputs a string in $\{0,1\}^*$ and:

- A runs in time at most $t(n)$ on input n, regardless of its internal coin tosses
- for every n and for every $x \in \{0,1\}^*$, $\Pr[A(n) = x] = \mu_n(x)$

With this notion of samplable ensemble we can now consider *heuristic algorithms* that perform well on some language $\mathcal{L} : \{0,1\}^* \to \{0,1\}$ over some μ. The pair $(\mathcal{L}, \mu)$ is a *distributional problem.*

▶ **Definition 12** (Heuristics for Distributional Problems)**.** For $t : \mathbb{N} \to \mathbb{N}$, $\delta : \mathbb{N} \to \mathbb{R}^+$, we say $(\mathcal{L}, \mu) \in \text{Heur}_{\delta(n)}\mathsf{DTIME}[t(n)]$ if there is a time $t(n)$ deterministic algorithm A such that, for all but finitely many n: $\Pr_{x\sim\mu_n}[A(x) \neq \mathcal{L}(x)] \leq \delta(n)$.

For a class of languages $\mathcal{C}$ we say $(\mathcal{C}, \mu) \in \text{Heur}_{\delta(n)}\mathsf{DTIME}[t(n)]$ if $(\mathcal{L}, \mu) \in \text{Heur}_{\delta(n)}\mathsf{DTIME}[t(n)]$ for all $\mathcal{L} \in \mathcal{C}$. As in [10], $\text{Heur}_\delta\mathsf{P}$ is defined as the union over all polynomials p of $\text{Heur}_\delta\mathsf{DTIME}(p(n))$ and HeurP is the intersection over all inverse polynomial $\delta(n)$ of $\text{Heur}_\delta\mathsf{P}$. $\mathsf{HeurSUBEXP}$ is defined similarly where $\mathsf{SUBEXP} = \cap_{\epsilon>0}\mathsf{DTIME}\left[2^{n^\epsilon}\right]$. Finally, to discuss the *randomness-reduced* simulations we construct, we define BPTIME with a limited number of random coins in the natural way.

▶ **Definition 13** (Randomized Heuristics with Bounded Coins)**.** For $t : \mathbb{N} \to \mathbb{N}$, $\delta : \mathbb{N} \to \mathbb{R}^+$, and coin bound $r : \mathbb{N} \to \mathbb{N}$ we say $(\mathcal{L}, \mu) \in \text{Heur}_{\delta(n)}\mathsf{BPTIME}_{[r(n)]}[t(n)]$ if there is randomized algorithm A running in time $t(n)$ and flipping $r(n)$ coins such that, for all but finitely many n: $\Pr_{x\sim\mu_n}\left[\Pr_{r\sim\mathcal{U}_{r(n)}}[A(x,r) \neq \mathcal{L}(x)] > 1/3\right] \leq \delta(n)$

For example, $\text{Heur}\mathsf{BPP}_{[r(n)]}$ denotes the class of distributional problems that, for every inverse polynomial error, have a polynomial time randomized algorithm using only $r(n)$ random coins.

Infinitely-Often Simulation. As opposed to an algorithm that decides a language (possibly on average) "for all but finitely many n" as in Definition 12, an infinitely-often (io-) qualifier can be added to any complexity class to specify that an algorithm need only succeed on infinitely many input lengths within the time and error bounds. Thus, to derandomize BPP into $\mathsf{io\text{-}HeurP}$ over the uniform distribution is to say that every language in BPP can be simulated on average in polynomial time by an algorithm that is only guaranteed to succeed for infinitely many input lengths. *There is no guarantee on what those input lengths are or how large the gaps could be between them.* This is obviously a very undesirable notion of 'tractability'.

Non-uniform hardness to randomness trade-offs can derandomize almost-everywhere (the desired notion of tractability for asymptotics) by assuming almost-everywhere hardness: that no algorithm works *for all sufficiently large input lengths.* That is, the 'infinitely-often' qualifier on the consequent can be *flipped* across the implication to be an 'almost-everywhere' qualifier on the assumption and vice-versa. Thus, the unrealistic 'infinitely-often' notion of tractability can be dropped by slightly strengthening the assumption to the (as argued in Section 2.1's remark) realistic 'almost-everywhere' hardness. For *non-uniform* derandomizations this is possible.

Starting with [25] and the techniques it introduced, all *uniform* derandomizations have been infinitely-often derandomizations *without* being able to flip the io- qualifier to an 'almost-everywhere' assumption. Our work is the first that is able to do this in the uniform derandomization framework, thus removing the 'infinitely-often' qualifier from our derandomizations.

3 Fine-Grained Derandomization

We will prove our main derandomization results (Theorems 17 and 20) here. Under either the (weak) k-OV or k-CLIQUE conjectures, we derandomize BPP on average, where 'on average' will have two different flavors. Although all techniques apply to k-CLIQUE, for concreteness we will use k-OV throughout this section.

We show in Section 3.1 that if we base pseudorandom generators on $f^k_{n,d,p}$, then an algorithm printing distinguishers for this PRG can be used to count k-OV solutions quickly. We will then show in Section 3.2 how to attain these distinguisher-printing algorithms if derandomization *doesn't* work on average (for both flavors of on average). Thus, a failed derandomization using these PRGs refutes the k-OV conjecture (similarly for k-CLIQUE).

3.1 Counting k-OV from Distinguishers

In this section we show that any algorithm producing a distinguisher for $G^{f^k_{m,d,p}}$ (the generator guaranteed to exist from Lemma 14, using the hard function $f^k_{m,d,p}$) can be used to quickly count k-OV solutions. First, Lemma 14 follows immediately by combining the distinguisher to predictor algorithm of Lemma 10 with the fact that $f^k_{m,d,p}$ is random self-reducible as in Lemma 6.

▶ **Lemma 14.** *There is a randomized algorithm $A^{f^k_{m,d,p}}$ that takes any circuit D that is a distinguisher for $G^{f^k_{m,d,p}}$ and produces a circuit C exactly computing $f^k_{m,d,p}$, such that A succeeds with high probability and runs in time* $\mathsf{poly}(m, d, \log p, |D|)$

As $f^k_{m,d,p}$ is efficiently computable (unlike the hard problems of [25]) in time $O(m^k \mathsf{poly}(d, \log p))$, we get the following theorem *without* an oracle by running the algorithm guaranteed in Lemma 14 with each oracle call answered by naïve brute force computation of $f^k_{m,d,p}$.

▶ **Lemma 15.** *There is a randomized algorithm B that takes any circuit D that is a distinguisher for $G^{f^k_{m,d,p}}$ and produces a circuit C of size* $\mathsf{poly}(m, d, \log p, |D|)$ *exactly computing $f^k_{m,d,p}$. B succeeds with high probability and runs in time $O(m^k \mathsf{poly}(m, d, \log p, |D|))$.*

Now we show that, if we have an algorithm producing a distinguisher, then we have an algorithm counting k-OV.

▶ **Theorem 16.** *Let p be the smallest prime number larger than n^k and $d = \lceil \log^2(n) \rceil$. If there is an algorithm A that, on input 1^n, outputs a distinguisher D of* $\mathsf{poly}(n)$ *size for $G^{f^k_{\sqrt{n},d,p}}$, then there exists a randomized algorithm counting k-OV_n that runs in time $O(n^{k/2+c} + \mathsf{TIME}(A))$, where c only depends on $|D|$.*

Proof. Using A, we print a distinguisher circuit D for $G^{f^k_{\sqrt{n},d,p}}$. Then, by Lemma 15, we know there exists a randomized algorithm running in time $O(n^{k/2}\mathsf{poly}(\sqrt{n}, d, \log p, |D|)) = O(n^{k/2+c_1})$ that yields a circuit exactly computing $f^k_{\sqrt{n},d,p}$ of size only $\mathsf{poly}(\sqrt{n}, d, \log p, |D|) = O(n^{c_2})$, where c_1 and c_2 only depend on $|D|$. Thus, by Lemma 7, there exists an algorithm

computing $f^k_{n,d,p}$ in time $O(n^{k/2+c_2} + (n^{k/2+c_1} + \mathsf{TIME}(A))) = O(n^{k/2+c} + \mathsf{TIME}(A))$ for $c = \max\{c_1, c_2\}$. Finally, this gives us an algorithm running in time $\widetilde{O}(n^{k/2+c} + \mathsf{TIME}(A))$ to count k-OV_n by Lemma 5. ◀

3.2 Printing Distinguishers from Failed Derandomization

3.2.1 Randomness-Reduced Heuristics Over Any Efficient Distribution

Our first main result in derandomizing BPP is to reduce the amount of randomness required to arbitrarily small quantities, over any efficient distribution of inputs. This simulation trades time for reduced randomness under fine-grained hardness assumptions.

▶ **Theorem 17.** *If the weak k-OV conjecture holds almost everywhere, then, for all polynomially samplable ensembles μ and for all constants $\alpha > 0$, $(\mathsf{BPP}, \mu) \in \mathrm{Heur}\mathsf{BPP}_{[n^\alpha]}$.*

Thus, for any efficient distribution over inputs that nature might be drawing from and for any inverse polynomial error rate we specify, we can simulate BPP using only n^α random bits for any constant $\alpha > 0$ we want. In contrast to typical full derandomizations which brute-force all seeds to a pseudorandom generator and take majority answer (which we can also do with our randomness-reduced derandomization to get a subexponential-time full derandomization), we show that choosing a *single random seed* and using the generator's output as our randomness yields randomness-reduced simulations so long as the generator is efficient enough (which it typically is not; 'quick' complexity-theoretic PRGs are usually given exponential time in their seed length).

▶ **Definition 18** (Randomness-Reduced Simulations)**.** Let $A : \{0,1\}^N \times \{0,1\}^{N^\ell} \to \{0,1\}$ be a randomized algorithm that uses N^ℓ random bits and let $G : \{0,1\}^{N^\alpha} \to \{0,1\}^{N^\ell}$ be a function. Then for constant $\alpha > 0$, define the randomness-reduced simulation to be a randomized algorithm $B : \{0,1\}^N \times \{0,1\}^{N^\alpha} \to \{0,1\}$ using only N^α random bits as $B(x,r) = A(x, G(r))$.

Lemma 19 states that if this simulation fails, we can uniformly print a distinguisher for the function G. This proof is identical to that of Lemma 18 in [25] and is recalled in the full version.

▶ **Lemma 19** (Failed Randomness-Reduction to Distinguishers)**.** *Let A, B, and G be as in Definition 18 such that for language $\mathcal{L} : \{0,1\}^N \to \{0,1\}$, $\Pr_{r \sim \mathcal{U}_{N^\ell}}[A(x,r) \neq \mathcal{L}(x)] \leq 1/10$. That is, that A as a good randomized algorithm deciding $\mathcal{L}$ for all $x \in \{0,1\}^N$. Yet, also assume that, for μ samplable in time N^{a_1} and $\delta(n) = 1/N^{a_2}$, it holds that*

$$\Pr_{x \sim \mu_N}\left[\Pr_{r \sim \mathcal{U}_{N^\alpha}}[B(x,r) \neq \mathcal{L}(x)] > 1/3\right] \geq \delta(N)$$

So B is a (randomness-reduced) randomized algorithm that does not decide $\mathcal{L}$ on average over μ. Then $1^N \mapsto \mathsf{DIS}(G, 1/5)$ is in randomized time N^c $\mathsf{TIME}(G)$ for c depending on a_1 and a_2.

Randomness-Reduced Simulation from k-OV. To finish defining a randomness-reduced simulation, we need to use a specific pseudorandom generator G that, for input length N, stretches N^α coins to N^ℓ. Thus, consider the family of simulations B_k using the standard generators $G^{f^k_{\sqrt{n},d,p}}$ of Lemma 10 that map $\sqrt{n}^s$ bits to $\sqrt{n}^b$ bits, for some fixed s and any b we choose, using $f^k_{\sqrt{n},d,p}$ as our hard function, for $d = \log^2 n$ and p the smallest

prime number larger than n^k. Set $b = s\ell/\alpha$ and $\sqrt{n} = N^{\alpha/s}$. Note that $\mathsf{TIME}(G^{f^k_{\sqrt{n},d,p}}) = \mathsf{poly}(N)\ n^{k/2} = \mathsf{poly}(N)$ by naïvely evaluating $f^k_{\sqrt{n},d,p}$ at each oracle call, giving an efficient randomness-reduced simulation. Further, since $N = \mathsf{poly}(n)$, $\mathsf{TIME}(G^{f^k_{\sqrt{n},d,p}})$ also equals $n^{k/2+c}$ for some constant c not depending on k (this will be useful in quickly counting k-OV_n using downward self-reducibility in the following proof). Thus, given an N^ℓ-coin machine A, we have the N^α-coin machine $B_k(x,r) = A\left(x, G^{f^k_{\sqrt{n},d,p}}(r)\right)$. We now prove our main Theorem 17 using this simulation and the above lemma.

Proof of Theorem 17. We proceed by contradiction. Assume that the weak k-OV_n conjecture holds for all but finitely many input lengths, where $\epsilon_0 = 1/2 + \gamma$ for some constant $\gamma > 0$, but that there exists $\mathcal{L} \in \mathsf{BPP}$, a polynomially samplable distribution μ, constant α, and an inverse polynomial function $\delta(N)$ such that *any* polynomial-time randomness-reduced algorithm with coin bound N^α fails in deciding $\mathcal{L}$ on average over μ within $\delta(N)$ error for infinitely many input lengths N.

Since $\mathcal{L} \in \mathsf{BPP}$ there is a randomized algorithm A deciding $\mathcal{L}$ with probability of error at most $1/10$ over its randomness yet, since *any* polynomial-time randomness-reduced algorithm fails to decide $\mathcal{L}$ on average, B_k, the randomness-reduced simulation of A described above, fails on average infinitely often, for *any* constant k. Thus, the antecedents of Lemma 19 are satisfied and we can uniformly print $D \in \mathsf{DIS}(G^{f^k_{\sqrt{n},d,p}}, 1/5)$ in time $n^{c_1}\ \mathsf{TIME}\left(G^{f^k_{\sqrt{n},d,p}}\right) = n^{c_1}\ n^{c_2} n^{k/2}$.

This uniform printing of D allows us to apply Theorem 16 to count k-OV_n in time $O(n^{k/2+c_3} + n^{k/2+c_1+c_2}) = O(n^{k/2+c}) = O(n^{(\frac{1}{2}+\frac{c}{k})k})$ for *any* k, where $c = \max\{c_1 + c_2, c_3\}$. Setting k such that $\frac{c}{k} < \gamma$ yields our contradictions: on the infinitely many input lengths where B_k fails to derandomize $\mathcal{L}$, the algorithm counts k-OV faster than $n^{\epsilon_0 k}$ time. ◀

3.2.2 Fast Heuristics for BPP Over the Uniform Distribution

Here we present our second flavor of derandomization: a fully deterministic heuristic for BPP when inputs are sampled according to the uniform distribution.

▶ **Theorem 20.** *If the weak k-OV conjecture holds almost everywhere, then $(\mathsf{BPP}, \mathcal{U}) \in \mathrm{HeurP}$.*

This strictly improves previous uniform derandomizations over the uniform distribution. Specifically, [21] can be seen to achieve our derandomization identically from a worst-case uniform assumption if combined with techniques from [31] *except only on infinitely many input lengths.*

We proceed by showing that if a PRG fails to give a good heuristic for BPP over the uniform distribution, a seed-aware distinguisher for the PRG can be produced uniformly and efficiently, which can then be used to count k-OV solutions quickly using Theorem 16.

▶ **Definition 21** (Input-As-Seed Heuristics)**.** Let $A : \{0,1\}^N \times \{0,1\}^{N^\ell} \to \{0,1\}$ be a polynomial-time randomized algorithm using N^ℓ random bits. Let $G : \{0,1\}^N \to \{0,1\}^{N^\ell}$ be a deterministic function. Define the heuristic $B : \{0,1\}^N \to \{0,1\}$ that uses its input as G's seed as $B(x) = A(x, G(x))$.

We prove a uniform analog of the Main Lemma of [31], which gave the consequences of failed heuristics in the *non-uniform* setting. Namely, we prove:

▶ **Lemma 22** (Failed Heuristics to Distinguishers). *Let* $A : \{0,1\}^N \times \{0,1\}^{N^\ell} \to \{0,1\}$ *and* $\mathcal{L} : \{0,1\}^N \to \{0,1\}$ *be functions such that* $\Pr_{x\sim\mathcal{U}_N, r\sim\mathcal{U}_{N^\ell}}[A(x,r) \neq \mathcal{L}(x)] \leq \rho$. *Let* B *be the input-as-seed heuristic for* A *using function* G. *Then, if* B *does* ***not*** *succeed on a* $(5\rho+\epsilon)$ *fraction of the inputs of a given length, the map* $1^N \mapsto \mathsf{DIS}(G,\epsilon)$ *is uniform and in randomized polynomial time, for infinitely many* N.

We sketch the proof here (see the full version for a proof). If B is a *bad* heuristic for $\mathcal{L}$, then we could use $B(x) = A(x, G(x))$ as a seed-aware distinguisher for G by comparing $B(x)$ to $\mathcal{L}(x)$. Unfortunately we cannot afford to print distinguishers with $\mathcal{L}$-oracles. But since we are guaranteed that A is a *good* heuristic for $\mathcal{L}$, we can obtain a deterministic circuit close to $\mathcal{L}$ from A, by fixing a string of good random bits r'. The proof of the analogous lemma in [31] uses non-uniformity to obtain a good r' for distinguishing, but we can instead obtain good strings r' by showing that there are *many* good random strings. We find a good r' by a sample-and-test procedure. If we compare $B(x)$ and the fixed-coin algorithm $A(x,r')$, they will also tend to disagree, giving the necessary distinguishing gap.

Fully Deterministic Heuristics from k-OV. Here we specify a family of heuristics B_k, by specifying the generator G, that stretches a seed of length N to N^ℓ, as the generators $G^{f^k_{\sqrt{n},d,p}}$ of Lemma 10. These map $\sqrt{n}^s$ bits to $\sqrt{n}^b$ bits, for some fixed s and any b we choose, using $f^k_{\sqrt{n},d,p}$, for $d = \log^2 n$ and p the smallest prime number larger than n^k. Set $b = s\ell$ and $\sqrt{n} = N^{1/s}$. All comments about the runtime of the randomness-reduced heuristic in Section 3.2.1 also apply to this fully deterministic heuristic. Thus, given an N^ℓ-coin machine A, we have the *deterministic* machine $B_k(x) = A\left(x, G^{f^k_{\sqrt{n},d,p}}(x)\right)$.

This can now be used to prove Theorem 20, although we defer this proof to the full version as it is very similar to the proof of Theorem 17 in Section 3.2.1.

4 Open Questions

- We derandomize under hardness conjectures about two of four 'key' problems in fine-grained complexity: k-OV and k-CLIQUE. What about k-SUM and APSP? APSP doesn't seem to have a natural hierarchy and so doesn't fit our framework (although it does reduce to ZERO-TRIANGLE which generalizes to ZERO-k-CLIQUE and should easily work in our framework using polynomials similar to those in [8]). k-SUM however is actually computable in $O(n^{\lceil k/2\rceil})$ time and so our downward self-reducibility techniques are not fast enough to break this conjecture in the contrapositive. The clearest path we see to getting derandomization without reintroducing the io- qualifier is to find a polynomial for k-SUM that is also computable in $\widetilde{O}(n^{\lceil k/2\rceil})$ time (unlike the one found in [8]).
- Our derandomizations hold under (randomized) SETH, since SETH implies the k-OV conjecture. Can a better derandomization be obtained directly from SETH, the stronger assumption? A stumbling block here is the random self-reduction, an ingredient in all known uniform derandomization techniques: If t-SAT has a straightforward and efficient random-self-reduction, PH collapses [16, 11]. So derandomizing from SETH directly could require new ideas, or a strange random self-reduction. An *inefficient* random self-reduction for t-SAT shouldn't collapse PH except to say that t-SAT has a mildly exponential MA proof which is already known to be true [39], although most random self-reductions we know are through arithmetization which seems to always have 'low' degree to the point that such a polynomial would still collapse PH.
- Is a strong "derandomization to hardness" converse possible for these heuristic simulations of BPP? In the full version of this paper, we show a weak converse: our simulation

is impossible without separting DTIME[$n^{\omega(1)}$] from BPP. But this is a very different statement from the k-OV or k-CLIQUE conjectures. In [31], they show that herusitic simulations of BPP with inverse-subexponential error rates imply circuit lower bounds, by generalizing techniques of [28]. Do the efficient inverse-polynomial error heuristics we obtain imply any circuit lower bounds?

Abstract

Ranking algorithms are deployed widely to order a set of items in applications such as search engines, news feeds, and recommendation systems. Recent studies, however, have shown that, left unchecked, the output of ranking algorithms can result in decreased diversity in the type of content presented, promote stereotypes, and polarize opinions. In order to address such issues, we study the following variant of the traditional ranking problem when, in addition, there are *fairness* or *diversity* constraints. Given a collection of items along with 1) the value of placing an item in a particular position in the ranking, 2) the collection of *sensitive* attributes (such as gender, race, political opinion) of each item and 3) a collection of fairness constraints that, for each k, bound the number of items with each attribute that are allowed to appear in the top k positions of the ranking, the goal is to output a ranking that maximizes the value with respect to the original rank quality metric while respecting the constraints. This problem encapsulates various well-studied problems related to bipartite and hypergraph matching as special cases and turns out to be hard to approximate even with simple constraints. Our main technical contributions are fast exact and approximation algorithms along with complementary hardness results that, together, come close to settling the approximability of this constrained ranking maximization problem. Unlike prior work on the approximability of constrained matching problems, our algorithm runs in linear time, even when the number of constraints is (polynomially) large, its approximation ratio does not depend on the number of constraints, and it produces solutions with small constraint violations. Our results rely on insights about the constrained matching problem when the objective function satisfies certain properties that appear in common ranking metrics such as discounted cumulative gain (DCG), Spearman's rho or Bradley-Terry, along with the nested structure of fairness constraints.

1 Introduction

Selecting and ranking a subset of data is a fundamental problem in information retrieval and at the core of ubiquitous applications including ordering search results such (e.g., Google), personalized social media feeds (e.g., Facebook, Twitter or Instagram), ecommerce websites (e.g., Amazon or eBay), and online media sites (e.g., Netflix or YouTube). The basic

algorithmic problem that arises is as follows: There are m *items* (e.g., webpages, images, or documents), and the goal is to output a list of $n \ll m$ items in the order that is most *valuable* to a given user or company. For each item $i \in [m]$ and a position $j \in [n]$ one is given a number W_{ij} that captures the *value* that item i contributes to the ranking if placed at position j. These values can be tailored to a particular query or user and a significant effort has gone into developing models and mechanisms to learn these parameters [31]. In practice there are many ways one could arrive at W_{ij}, each of which results in a slightly different metric for the value of a ranking – prevalent examples include versions of discounted cumulative gain (DCG) [26], Bradley-Terry [6] and Spearman's rho [41]. Note that for many of these metrics, one does not necessarily need nm parameters to specify W and typically m "degrees of freedom" is enough (just specifying the "quality of each item"). Still, we choose to work with this general setting, and only abstract out the most important properties such a weight matrix W satisfies. Generally, for such metrics, W_{ij} is non-increasing in both i and j, and if we interpret $i_1 < i_2$ to mean that i_1 has better *quality* than i_2, then the value of the ranking can only increase by placing i_1 above i_2 in the ranking. Formally, such values satisfy the following property (known as monotonicity and the Monge condition)

$$W_{i_1 j_1} \geq W_{i_2 j_1} \quad \text{and} \quad W_{i_1 j_1} \geq W_{i_1 j_2} \quad \text{and} \quad W_{i_1 j_1} + W_{i_2 j_2} \geq W_{i_1 j_2} + W_{j_1 i_2} \tag{1}$$

for all $1 \leq i_1 < i_2 \leq m$ and $1 \leq j_1 < j_2 \leq n$. The *ranking maximization* problem is to find an assignment of the items to each of the n positions such that the total value obtained is maximized. In this form, the problem is equivalent to finding the maximum weight matching in a complete $m \times n$ bipartite graph and has a well known solution – the Hungarian algorithm.

However, recent studies have shown that producing rankings in this manner can result in one type of content being overrepresented at the expense of another. This is a form of *algorithmic bias* and can lead to grave societal consequences – from search results that inadvertently promote stereotypes by over/under-representing sensitive attributes such as race and gender [28, 5], to news feeds that can promote extremist ideology [18] and possibly even influence the results of elections [2, 3]. For example, [21] demonstrated that by varying the ranking of a set of news articles the voting preferences of undecided voters can be manipulated. Towards ensuring that no type of content is overrepresented in the context of the ranking problem as defined above, we introduce the *constrained ranking maximization* problem that restricts allowable rankings to those in which no type of content dominates – i.e., *to ensure the rankings are fair*.

Since fairness (and bias) could mean different things in different contexts, rather than fixing one specific notion of fairness, we allow the *user* to specify a set of *fairness constraints*; in other words, we take the constraints as input. As a motivating example, consider the setting in which the set of items consists of m images of computer scientists, each image is associated with several (possibly non-disjoint) sensitive attributes or *properties* such as gender, ethnicity and age, and a subset of size n needs to be selected and ranked. The user can specify an upper-bound $U_{k\ell} \in \mathbb{Z}_{\geq 0}$ on the number of items with property ℓ that are allowed to appear in the top k positions of the ranking, and similarly a lower-bound $L_{k\ell}$. Formally, let $\{1, 2, \ldots, p\}$ be a set of properties and let $P_\ell \subseteq [m]$ be the set of items that have the property ℓ (note that these sets need not be disjoint). Let x be an $m \times n$ binary assignment matrix whose j-th column contains a one in the i-th position if item i is assigned to position j (each position must be assigned to exactly one item and each item can be assigned to at most one position). We say that x satisfies the fairness constraints if for all

$\ell \in [p]$ and $k \in [n]$, we have

$$L_{k\ell} \leq \sum_{1 \leq j \leq k} \sum_{i \in P_\ell} x_{ij} \leq U_{k\ell},$$

If we let $\mathcal{B}$ be the family of all assignment matrices x that satisfy the fairness constraints, the constrained ranking optimization problem is: Given the sets of items with each property $\{P_1, \ldots, P_p\}$, the fairness constraints, $\{L_{k\ell}\}$, $\{U_{k\ell}\}$, and the values $\{W_{ij}\}$, find

$$\arg\max_{x \in \mathcal{B}} \sum_{i \in [m], j \in [n]} W_{ij} x_{ij}.$$

This problem is equivalent to finding a maximum weight matching of size n *that satisfies the given fairness constraints* in a weighted complete $m \times n$ bipartite graph, and now becomes non-trivial – its complexity is the central object of study in this paper.

Beyond the fairness and ethical considerations, traditional *diversification* concerns in information retrieval such as query ambiguity (does "jaguar" refer to the car or the animal?) or user context (does the user want to see webpages, news articles, academic papers or images?) can also be cast in this framework. Towards this, a rich literature on diversifying rankings has emerged in information retrieval. On a high-level, several approaches redefine the objective function to incorporate a notion of diversity and leave the ranking maximization problem unconstrained. E.g., a common approach is to re-weight the w_{ij}s to attempt to capture the amount of diversity item i would introduce at position k conditioned on the items that were placed at positions $1, \ldots, k-1$ (see [7, 47, 17, 46, 48]), or casting it directly as an (unconstrained) multi-objective optimization problem [43]. Alternate approaches mix together or aggregate different rankings, e.g., as generated by different interpretations of a query [36, 20]. Diversity has also been found to be desirable by users [14], and has been observed to arise inherently when the ranking is determined by user upvotes [12]. Despite these efforts and the fact that all major search engines now diversify their results, highly uniform content is often still displayed – e.g., certain image searches can display results that have almost entirely the same attributes [28]. Further, [23] showed that no single diversification function can satisfy a set of natural axioms that one would want any fair ranking to have. In essence, there is a tension between relevance and fairness – if the w_{ij}s for items that have a given property are much higher than the rest, the above approaches cannot correct for overrepresentation. Hence the reason to cast the problem as a constrained optimization problem: The objective is still determined by the values but the solution space is restricted by fairness constraints.

Theoretically, the fairness constraints come with a computational price: The constrained ranking maximization problem can be seen to generalize various **NP**-hard problems such as independent set, hypergraph matching and set packing. Unlike the unconstrained case, even checking if there is a complete feasible ranking (i.e., $\mathcal{B} \neq \emptyset$) is **NP**-hard. As a consequence, in general, we cannot hope to produce a solution that does not violate any constraints. Some variants and generalizations of our problem have been studied in the TCS and optimization literature; here we mention the three most relevant. Note that some may leave empty positions in the ranking as opposed to selecting n elements to rank as we desire. [1] considered the bipartite perfect matching problem with poly(m) constraints. They present a polynomial time randomized algorithm that finds a near-perfect matching which violates each constraint additively by at most $O(\sqrt{m})$. [24] improved the above result to a $(1+\varepsilon)$-approximation algorithm; however, the running time of their algorithm is roughly $m^{K^{2.5}/\varepsilon^2}$ where K is the number of hard constraints and the output is a matching. [42] studied the approximability of

the packing integer program problem which, when applied to our setting and gives an $O(\sqrt{m})$ approximation algorithm. In the constrained ranking maximization problem presented above, all of these results seem inadequate; the number of fairness constraints is $2np$ which would make the running time of [24] too large and an additive violation of $O(\sqrt{m})$ would render the upper-bound constraints impotent.

The main technical contributions of this paper are fast, exact and approximation algorithms for this constrained ranking maximization problem along with complementary hardness results which, together, give a solid understanding of the computational complexity of this problem. To overcome the limitations of the past work on constrained matching problems, our results often make use of two structural properties of such a formulation: A) The set of constraints can be broken into p groups; for each property $\ell \in [p]$ we have n (nested) upper-bound constraints, one for each $k \in [n]$, and B) The objective function satisfies the property stated in (1). Using properties A) and B) we obtain efficient – polynomial, or even linear time algorithms for this problem in various interesting regimes. Both these properties are natural in the information retrieval setting and could be useful in other algorithmic contexts involving rankings.

2 Our model

We study the following *constrained ranking maximization problem*

$$\arg\max_{x \in R_{m,n}} \sum_{i \in [m], j \in [n]} W_{ij} x_{ij} \qquad \text{s.t.} \quad L_{k\ell} \leq \sum_{1 \leq j \leq k} \sum_{i \in P_\ell} x_{ij} \leq U_{k\ell} \qquad \forall\, \ell \in [p], k \in [n], \tag{2}$$

where $R_{m,n}$ is the set of all matrices $\{0,1\}^{m \times n}$ which represent ranking m items into n positions. Recall that W_{ij} represents the profit of placing item i at position j and for every property $\ell \in [p]$ and every position k in the ranking, $L_{k\ell}$ and $U_{k\ell}$ are the lower and upper bound on the number of items having property ℓ that are allowed to be in the top k positions in the ranking. For an example, we refer to Figure 1.

We distinguish two important special cases of the problem: when only the upper-bound constraints are present, and when only the lower-bound constraints are present. These variants are referred to as the *constrained ranking maximization problem (U)* and the *constrained ranking maximization problem (L)* respectively, and to avoid confusion we sometimes add (LU) when talking about the general problem with both types of constraints present. Furthermore, most our results hold under the assumption that the weight function W is monotone and satisfies the Monge property (1), whenever these assumptions are not necessary, we emphasize this fact by saying that *general weights* are allowed.

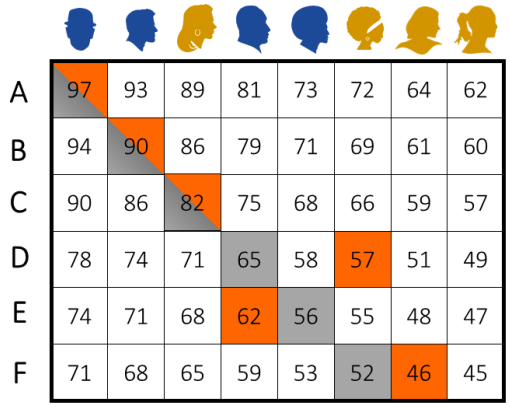
3 Our results

In this section, we present an overview of our results. The statements of theorems here are informal for the ease of readability and for the formal statements our results, we refer the reader to the full version of the paper [13].

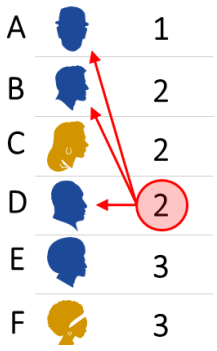
Let the *type*

$$T_i := \{\ell \in [p] : i \in P_\ell\}$$

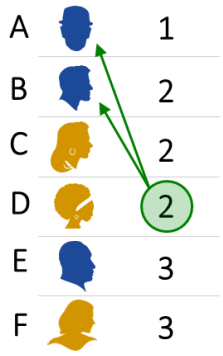
of item i be the set of properties that the item i has. Our first result is an exact algorithm for solving the constrained ranking maximization problem whose running time is polynomial if the number of distinct T_is, denoted by q, is constant.



(a) An example of a value matrix W. The values corresponding to the optimal (unconstrained) ranking in (b) and the optimal constrained ranking in (c) are depicted by gray and orange respectively. (Note that, for clarity of the rank order, the above is the transpose of the matrix referred to as W in the text.)



(b) The optimal unconstrained ranking. The upper-bound constraint at position D is violated as there are 3 men, but only 2 are allowed.



(c) The optimal constrained ranking. The upper-bound constraint at position D is no longer violated; in fact all constraints are satisfied.

Figure 1 A simple example of our framework: In (a) a matrix of W_{ij}s is presented. Here, the options are people who are either male (blue) or female (yellow), and 6 of them must be ranked. We assume that there is a single upper-bound constraint for each position in the ranking which is applied to both genders as depicted in figures (b) and (c). The constraints are satisfied in the latter, but not the former. The weights of these two rankings are depicted in figure (a).

▶ **Theorem 3.1** (Exact dynamic programming-based algorithm). *There is an algorithm that solves the constrained ranking maximization problem (LU) in $O(pqn^q + pm)$ time when the values W satisfy property* (1).

This algorithm combines a geometric interpretation of our problem along with dynamic programming and proceeds by solving a sequence of $q-$dimensional sub-problems. When q is allowed to be large, the problem is **NP**-hard; see Theorem 3.5.

Generally, we may not be able to assume that q is a constant and, even then, it would be desirable to have algorithms whose running time is close to $(m+n)p$, the size of the input. Towards this we consider a natural parameter of the set of properties: The size of the largest T_i, namely

$$\Delta := \max_{i \in [m]} |T_i|.$$

The complexity of the constrained ranking maximization problem turns out to show interesting behavior with respect to Δ (note that $\Delta \leq p$ and typically $p \ll q$). The case when $\Delta = 1$ corresponds to the simplest practical setting where there are p disjoint properties, i.e., the properties partition the set of items. For instance, a set of images of humans could be partitioned based on the ethnicity or age of the individual. Note that even though $q = p$ for $\Delta = 1$, this q could still be large and the previous theorem may have a prohibitively large running time.

When $\Delta = 1$ we prove that the constrained ranking maximization problem (LU) is polynomial time solvable even when the matrix W does not satisfy the property (1).

▶ **Theorem 3.2** (Polynomial time algorithm for $\Delta = 1$). *The constrained ranking maximization problem (LU) for general weights and $\Delta = 1$ can be solved in $\widetilde{O}(n^2 m)$ time.*

The above is obtained by reducing this variant of the ranking maximization problem to the minimum cost flow problem, that can be solved efficiently (the network is acyclic). We note that even though the running time is polynomial in m, it might be still not satisfactory for practical purposes. With the aim of designing faster – linear time algorithms, we focus on the case when only upper-bound constraints are present. For this case, we analyze a natural linear programming (LP) relaxation for the constrained ranking maximization problem (U). It reveals interesting structure of the problem and motivates a fast greedy algorithm. Formally, the relaxation considers the set $\Omega_{m,n}$ defined as

$$\Omega_{m,n} := \left\{ x \in [0,1]^{m \times n} : \sum_{j=1}^{n} x_{ij} \leq 1 \text{ for all } i \in [m], \quad \sum_{i=1}^{m} x_{ij} = 1, \text{ for all } j \in [n] \right\}$$

and the following linear program

$$\max_{x \in \Omega_{m,n}} \sum_{i=1}^{m} \sum_{j=1}^{n} W_{ij} x_{ij} \qquad \text{s.t.} \qquad \sum_{i \in P_\ell} \sum_{j=1}^{k} x_{ij} \leq U_{k\ell}, \ \forall\ \ell \in [p],\ k \in [n]. \tag{3}$$

Observe that in the absence of fairness constraints, (3) represents the maximum weight bipartite matching problem – it is well known that the feasible region of its fractional relaxation has integral vertices and hence the optimal values of these two coincide. However, in the constrained setting, even for $\Delta = 1$, it can be shown that the feasible region is no longer integral – it can have fractional vertices. For this reason, it is not true that maximizing any linear objective results in an integral solution. Surprisingly, we prove that for $\Delta = 1$ the cost functions we consider are special and never yield optimal fractional (vertex) solutions.

▶ **Theorem 3.3** (Exact LP-based algorithm for $\Delta = 1$)**.** *Consider the linear programming relaxation* (3) *for the constrained ranking maximization problem (U) when* $\Delta = 1$ *and the objective function satisfies* (1)*. Then there exists an optimal solution with integral entries and hence the relaxation is exact. Further, there exists a greedy algorithm to find an optimal integral solution in* $O(np + m)$ *time.*

The proof relies on a combinatorial argument on the structure of tight constraints that crucially uses the assumption that $\Delta = 1$ and the property (1) of the objective function. Note that the result of Theorem 3.3 implies in particular that whenever the linear program (3) is feasible then there is also an integer solution – a feasible ranking. This can be also argued for the general (LU) variant of the problem and its corresponding LP relaxation. However, extending Theorem 3.3 to this case seems more challenging and is left as an open problem.

When trying to design algorithms for larger Δ, the difficulty is that the constrained ranking *feasibility* problem remains **NP**-hard (in fact, even hard to approximate when feasibility is guaranteed) for $\Delta \geq 3$; see Theorem 3.5. Together, these results imply that unless we restrict to feasible instances of the constrained ranking problem, it is impossible to obtain any reasonable approximation algorithm for this problem. In order to bypass this barrier, we focus on the (U) variant of the problem and present an *algorithmically verifiable* condition for feasibility and argue that it is natural in the context of information retrieval. For each $1 \leq k \leq n$, we consider the set

$$S_k := \{l \in [p] : U_{(k-1)\ell} + 1 \leq U_{k\ell}\}$$

of all properties whose constraints increase by at least 1 when going from the $(k-1)$st to the kth position. We observe that the following *abundance of items* condition is sufficient for

feasibility:

$$\forall k \text{ there are at least } n \text{ items } i \text{ s.t. } T_i \subseteq S_k. \tag{4}$$

Intuitively, this says that there should be always at least a few ways to extend a feasible ranking of $(k-1)$ items to a ranking of k items. Simple examples show that this condition can be necessary for certain constraints $\{U_{k\ell}\}$. In practice, this assumption is almost never a problem – the available items m (e.g., webpages) far outnumber the size of the ranking n (e.g., number of results displayed in the first page) and the number of properties p (i.e., there are only so many "types" of webpages).

We show that assuming condition (4), there is a linear-time algorithm that achieves an $(\Delta+2)$-approximation, while only slightly violating the upper-bound constraints. This result does not need assumption (1), rather only that the W_{ij}s are non-negative. This result is near-optimal; we provide an $\Omega\left(\frac{\Delta}{\log \Delta}\right)$ hardness of approximation result (see Theorem 3.5 and the full version of the paper [13] for more details).

▶ **Theorem 3.4** ($(\Delta+2)$-approximation algorithm)**.** *For the constrained ranking maximization problem (U), under the assumption* (4)*, there is an algorithm that in linear time outputs a ranking x with value at least $\frac{1}{\Delta+2}$ times the optimal one, such that x satisfies the upper-bound constraints with at most a twice multiplicative violation, i.e.,*

$$\sum_{i \in P_\ell} \sum_{j=1}^{k} x_{ij} \leq 2U_{k\ell}, \quad \textit{for all } \ell \in [p] \textit{ and } k \in [n].$$

One can construct artificial instances of the ranking problem, where the output of the algorithm indeed violates upper-bound constraints with a 2-multiplicative factor. However, these violations are caused by the presence of high-utility items with a large number of properties. Such items are unlikely to appear in real-life instances and thus we expect the practical performance of the algorithm to be better than the worst-case bound given in Theorem 3.4 suggests. Lastly we summarize our hardness results for the constrained ranking problem.

▶ **Theorem 3.5** (Hardness Results – Informal)**.** *The following variants of the constrained ranking feasibility (U) and constrained ranking maximization (U) problem are* **NP***-hard.*

1. *Deciding feasibility for the case of $\Delta \geq 3$.*
2. *Under the feasibility condition* (4)*, approximating the optimal value of a ranking within a factor $O\left(\Delta/\log \Delta\right)$, for any $\Delta \geq 3$.*
3. *Deciding feasibility when only the number of items m, number of positions n, and upper-bounds u are given as input; the properties are fixed for every m.*
4. *For every constant c, deciding between whether there exists a feasible solution or every solution violates some constraint by a factor of c.*

Organization of the rest of the paper

In Section 4 we discuss other related work. Section 5 contains an overview of the proofs of our main results. For complete proofs, we refer the reader to the full version of the paper [13]. In Section 6 we provide a discussion of possible directions for future work and open problems.

4 Other related work

Information retrieval, which focuses on selecting and ranking subsets of data, has a rich history in computer science, and is a well-established subfield in and of itself; see, e.g., the foundational work by [39]. The probability ranking principle (PRP) forms the foundation of information retrieval research [32, 38]; in our context it states that *a system's ranking should order items by decreasing value.* Our problem formulation and solutions are in line with this – *subject to satisfying the diversity constraints.*

A related problem is diverse data summarization in which a subset of items with varied properties must be selected from a large set [35, 9], or similarly, voting with diversity constraints in which a subset of items of people with varied properties or attributes must be selected via a voting procedure [34, 10]. However, the formulation of these problem is considerably different as there is no need to produce a ranking of the selected items, and hence the analogous notion of constraints is more relaxed. Extending work on fairness in classification problems [45], the fair ranking problem has also been studied as an (unconstrained) multi-objective optimization problem, and various fairness metrics of a ranking have been proposed [43].

Combining the learning of values along with the ranking of items has also been studied [37, 40]; in each round an algorithm chooses an ordered list of k documents as a function of the estimated values W_{ij} and can receive a click on one of them. These clicks are used to update the estimate of the W_{ij}s, and bounds on the regret (i.e., learning rate) can be given using a bandit framework. In this problem, while there are different types of items that can affect the click probabilities, there are no constraints on how they should be displayed.

Recent work has shown that, in many settings, there are impossibility results that prevent us from attaining both *property* and *item* fairness [30]. Indeed, our work focuses on ensuring property fairness (i.e., no property is overrepresented), however this comes at an expense of item fairness (i.e., depending on which properties an item has, it may have much higher / lower probability of being displayed than another item with the same value). In our motivating application we deal with the ranking of documents or webpages, and hence are satisfied with this trade-off. However, further consideration may be required if, e.g., we wish to rank people as this would give individuals different likelihoods of being near the top of the list based on their properties rather than solely on their value.

5 Proof overviews

Overview of the proof of Theorem 3.1. We first observe that the constrained ranking maximization problem has a simple geometric interpretation. Every item $i \in [m]$ can be assigned a *property vector* $t_i \in \{0,1\}^p$ whose ℓ-th entry is 1 if item i has property ℓ and 0 otherwise. We can then think of the constrained ranking maximization problem as finding a sequence of n distinct items $i_1, i_2, \ldots, i_n$ such that $L_k \leq \sum_{j=1}^{k} t_{i_j} \leq U_k$ for all $k \in [n]$, where U_k is the vector whose ℓ-th entry is $U_{\ell k}$. In other words, we require that the partial sums of the vectors corresponding to the top k items in the ranking stay within the region $[L_{k1}, U_{k1}] \times [L_{k2}, U_{k2}] \times \cdots \times [L_{kn}, U_{kn}]$ defined by the fairness constraints.

Let $Q := \{t_i : i \in [m]\}$ be the set of all the different property vectors t_i that appear for items $i \in [m]$, and let us denote its elements by $v_1, v_2, \ldots, v_q$. A simple but important observation is that whenever two items $i_1, i_2 \in [m]$ (with say $i_1 < i_2$) have the same property vector: $t_{i_1} = t_{i_2}$, then in every optimal solution either i_1 will be ranked above i_2, only i_1 is ranked, or neither is used. This follows from the assumption that the weight matrix is monotone in i and j and satisfies the property as stated in (1).

Let us now define the following sub-problem that asks for the *property vectors* of a feasible solution: Given a tuple $(s_1, s_2, \ldots, s_q) \in \mathbb{N}^q$ such that $k = s_1 + s_2 + \cdots + s_q \leq n$, what is the optimal way to obtain a feasible ranking on k items such that s_j of them have property vector equal to v_j for all $j = 1, 2, \ldots, q$? Given a solution to this sub-problem, using the observation above, it is easy to determine which items should be used for a given property vector, and in what order. Further, one can easily solve such a sub-problem given the solutions to smaller sub-problems (with a smaller sum of s_js), resulting in a dynamic programming algorithm with $O(n^q)$ states and, hence, roughly the same running time.

Overview of the proof of Theorem 3.2. The main idea is to reduce ranking maximization to the minimum cost flow problem and then observe several structural properties of the resulting instance which allow one to solve it efficiently (in $\widetilde{O}(n^2 m)$ time).

Given an instance of the constrained ranking maximization problem (U), we construct a weighted flow network $G = (V, E)$ such that every feasible ranking corresponds to a feasible flow of value n in G. Roughly, for every item i and every property ℓ a chain of n vertices is constructed so that placing item i (such that $i \in P_\ell$) at position k corresponds to sending one unit of flow through the chain corresponding to item i up to its kth vertex and then switching to the chain corresponding to property ℓ. Edge weights in these gadgets (chains) are chosen in such a way that the cost of sending a unit through this path is $-W_{i,k}$. The capacities in chains corresponding to properties implement upper-bound constraints. The lower-bound constraints can be also enforced by putting appropriate weights on edges of these chains.

The instance of the minimum cost flow problem we construct has $O(nm)$ vertices and $O(nm)$ edges and is acyclic, which allows to replace the application of the Bellman-Ford algorithm in the first phase of the Successive Shortest Path algorithm by a linear-time procedure. This then easily leads to an implementation in $O(n^2 m \log m)$ time.

Overview of the proof of Theorem 3.3. Unlike the $\Delta = 0$ case where the LP-relaxation (3) has no non-integral vertex (it is the assignment polytope) , even when $p = 1$, fractional vertices can arise (see the full version of the paper [13]). Theorem 3.3 implies that for $\Delta = 1$, although the feasible region of (3) is not integral in all directions, it is along the directions of interest. In the proof we first reduce the problem to the case when $m = n$ (i.e., when one has to rank all of the items) and w has the *strict* form of property (1) (i.e., when the inequalities in assumption (1) are strict). Our strategy then is to prove that for every fractional feasible solution $x \in \Omega_{m,m}$ there is a direction $y \in \mathbb{R}^{m \times m}$ such that the solution $x' := x + \varepsilon y$ is still feasible (for some $\varepsilon > 0$) and its weight is larger than the weight of x. This implies that every optimal solution is necessarily integral.

Combinatorially, the directions we consider correspond to 4-cycles in the underlying complete bipartite graph, such that the weight of the matching can be improved by swapping edges along the cycle. The argument that shows the existence of such a cycle makes use of the special structure of the constraints in this family of instances.

To illustrate the approach, suppose that there exist two items $i_1 < i_2$ that have the same property $\ell \in [p]$, and for some ranking positions $j_1 < j_2$ we have

$$x_{i_1 j_2} > 0 \quad \text{and} \quad x_{i_2 j_1} > 0. \tag{5}$$

Following the strategy outlined above, consider $x' = x + \varepsilon y$ with $y \in \mathbb{R}^{m \times m}$ to be zero everywhere except $y_{i_1 j_1} = y_{i_2 j_2} = 1$ and $y_{i_1 j_2} = y_{i_2 j_1} = -1$. We would like to prove that the weight of x' is larger than the weight of x and that x' is feasible for some (possibly small)

$\varepsilon > 0$. The reason why we gain by moving in the direction of y follows from property (1). Feasibility in turn follows because y is orthogonal to every constraint defining the feasible region. Indeed, the only constraints involving items i_1, i_2 are those corresponding to the property ℓ. Further, every such constraint is of the form[1] $\langle 1_{R_k}, x\rangle \leq U_{k\ell}$ where 1_{R_k} is the indicator vector of a rectangle $R_k := P_\ell \times [k]$. Such a rectangle contains either all non-zero entries of y, two non-zero entries (with opposite signs), or none. In any of these cases, $\langle 1_{R_k}, y\rangle = 0$.

Using a reasoning as above, one can show that no configuration of the form (5) can appear in any optimal solution for i_1, i_2 that share a property ℓ. This implies that the support of every optimal solution has a certain structure when restricted to items that have any given property $\ell \in [p]$; this structure allows us to find an improvement direction in case the solution is not integral. To prove integrality we show that for every fractional solution $x \in \mathbb{R}^{m\times m}$ there exists a fractional entry $x_{ij} \in (0, 1)$ that can be slightly increased without violating the fairness constraints. Moreover since the i-th row and the j-th column must contain at least one more fractional entry each (since the row- and column-sums are 1), we can construct (as above) a direction y, along which the weight can be increased. The choice of the corresponding entries that should be altered requires some care, as otherwise we might end up violating fairness constraints.

The second part of Theorem 3.3 is an algorithm for solving the constrained ranking maximization problem for $\Delta = 1$ in optimal (in the input size) running time of $O(np + m)$. We show that a natural greedy algorithm can be used. More precisely, one iteratively fills in ranking positions by always selecting the *highest value* item that is still available and does not lead to a constraint violation. An inductive argument based that relies on property 1 and the $\Delta = 1$ assumption gives the correctness of such a procedure.

Overview of the proof of Theorem 3.4. Let $\Delta > 1$ be arbitrary. The most important part of our algorithm is a greedy procedure that finds a large weight solution to a slightly relaxed problem in which not all positions in the ranking have to be occupied. It processes pairs $(i, j) \in [m] \times [n]$ in non-increasing order of weights W_{ij} and puts item i in position j whenever this does not lead to constraint violation.

To analyze the approximation guarantee of this algorithm let us first inspect the combinatorial structure of the feasible set. In total there are $p \cdot n$ fairness constraints in the problem and additionally $m + n$ "matching" constraints, saying that no "column" or "row" can have more than a single one in the solution matrix $x \in \{0, 1\}^{m\times n}$. However, after relaxing the problem to the one where not all ranking positions have to be filled, one can observe that the feasible set is just an intersection of $p + 2$ matroids on the common ground set $[m] \times [n]$. Indeed, two of them correspond to the matching constraints, and are partition matroids. The remaining p matroids correspond to properties: for every property ℓ there is a chain of subsets $S_1 \subseteq S_2 \subseteq \cdots \subseteq S_n$ of $[m] \times [n]$ such that

$$\mathcal{I}_\ell = \{S \subseteq [m] \times [n] : |S \cap S_k| \leq U_{k\ell} \text{ for all } k = 1, 2, \ldots, n\}$$

is the set of independent sets in this (laminar) matroid. In the work [27] it is shown that the greedy algorithm run on an intersection of K matroids yields K-approximation, hence $(p + 2)$-approximation of our algorithm follows.

[1] By $\langle \cdot, \cdot \rangle$ we denote the inner product between two matrices, i.e., if $x, y \in \mathbb{R}^{m\times n}$ then $\langle x, y\rangle := \sum_{j=1}^{m} \sum_{i=1}^{n} x_{ij} y_{ij}$.

To obtain a better – $(\Delta + 2)$-approximation bound, a more careful analysis is required. The proof is based on the fact that, roughly, if a new element is added to a feasible solution S, then at most $\Delta + 2$ elements need to be removed from S to make it again feasible. Thus adding greedily one element can cost us absence of $\Delta + 2$ other elements of weight at most the one we have added. This idea can be formalized and used to prove the $(\Delta + 2)$-approximation of the greedy algorithm. This is akin to the framework of K-extendible systems by [33] in which this greedy procedure can be alternatively analyzed. Finally, we observe that since the problem solved was a relaxation of the original ranking maximization problem, the approximation ratio we obtain with respect to the original problem is still $(\Delta + 2)$.

It remains to complete the ranking by filling in any gaps that may have been left by the above procedure. This can be achieved in a greedy manner that only increases the value of the solution, and violates the constraints by at most a multiplicative factor of 2.

Overview of the proof of Theorem 3.5. Our hardness results are based on a general observation that one can encode various types of packing constraints using instances of the constrained ranking maximization (U) and feasibility (U) problem. The first result (part 1. in Theorem 3.5) – **NP**-hardness of the feasibility problem (for $\Delta \geq 3$) is established by a reduction from the hypergraph matching problem. Given an instance of the hypergraph matching problem one can think of its hyperedges as items and its vertices as properties. Degree constraints on vertices can then be encoded by upper-bound constraints on the number of items that have a certain property in the ranking. The inapproximability result (part 2. in Theorem 3.5) is also established by a reduction from the hypergraph matching problem, however in this case one needs to be more careful as the reduction is required to output instances that are feasible.

Our next hardness result (part 3. in Theorem 3.5) illustrates that the difficulty of the constrained ranking optimization problem (U) could be entirely due to the upper-bound numbers $U_{k\ell}$s. In particular, even when the part of the input corresponding to which item has which property is fixed, and only depends on m (and, hence, can be *pre-processed* as in [22]), the problem remains hard. This is proven via a reduction from the independent set problem. The properties consists of all pairs of items $\{i_1, i_2\}$ for $i_1, i_2 \in [m]$. Given any graph $G = (V, E)$ on m vertices, we can set up a constrained ranking problem whose solutions are independent sets in G of a certain size. Since every edge $e = \{i_1, i_2\} \in E$ is a property, we can set a constraint that allows at most one item (vertex) from this property (edge) in the ranking.

Finally, part 4. in Theorem 3.5 states that it is not only hard to decide feasibility but even to find a solution that does not violate any constraint by more than a constant multiplicative factor $c \in \mathbb{N}$. The obstacle in proving such a hardness result is that, typically, even if a given instance is infeasible, it is easy to find a solution that violates *many* constraints by a small amount. To overcome this problem we employ an inapproximability result for the maximum independent set problem by [25] and an idea by [16]. Our reduction (roughly) puts a constraint on every $(c+1)-$clique in the input graph $G = (V, E)$, so that at most one vertex (item) is picked from it. Then a solution that does not violate any constraint by a multiplicative factor more than c corresponds to a set of vertices S such that the induced subgraph $G[S]$ has no c-clique. Such a property allows us to prove (using elementary bounds on Ramsey numbers) that G has a large independent set. Hence, given an algorithm that is able to find a feasible ranking with no more than a c-factor violation of the constraints, we can approximate the maximum size of an independent set in a graph $G = (V, E)$ up to a factor of roughly $|V|^{1-1/c}$; which is hard by [25].

6 Discussion and future work

In this paper, motivated by controlling and alleviating algorithmic bias in information retrieval, we initiate the study of the complexity of a natural constrained optimization problem concerning rankings. Our results indicate that the constrained ranking maximization problem, which is a generalization of the classic bipartite matching problem, shows fine-grained complexity. Both the structure of the constraints and the numbers appearing in upper-bounds play a role in determining its complexity. Moreover, this problem generalizes several hypergraph matching/packing problems. Our algorithmic results bypass the obstacles implicit in the past theory work by leveraging on the structural properties of the constraints and common objective functions from information retrieval. More generally, our results not only contribute to the growing set of algorithms to counter algorithmic bias for fundamental problems [19, 4, 44, 9, 11, 8, 29, 15], the structural insights obtained may find use in other algorithmic settings related to the rather broad scope of ranking problems.

Our work also suggests some open problems and directions. The first question concerns the $\Delta = 1$ case and its (LU) variant; Theorem 3.2 implies that it can be solved in $\widetilde{O}(n^2m)$ time, can this be improved to nearly-linear time, as we do for the (U) variant (Theorem 3.3)? Another question is the complexity of the constrained ranking maximization problem (in all different variants) when $\Delta = 2$ – is it in $\mathbf{P}$? The various constants appearing in our approximation algorithms are unlikely to be optimal and improving them remains important. In particular, our approximation algorithm for the case of large Δ in Theorem 3.4 may incur a 2-multiplicative violation of constraints. This could be significant when dealing with instances where the upper bound constraints are rather large (i.e., $U_{k\ell} \gtrsim \frac{k}{2}$) in which case, such a violation effectively erases all the constraints. It is an interesting open problem to understand whether this 2-violation can be avoided, either by providing a different algorithm or by making different assumptions on the instance.

In this work we consider linear objective functions for the the ranking optimization problem, i.e., the objective is an independent sum of profits for individual item placements. While this model might be appropriate in certain settings, there may be cases where one would prefer to measure the quality of a ranking as a whole, and in particular the utility of placing a given item at the kth position should also depend on what items were placed above it [46]. Thus defining and studying a suitable variant of the problem for a class of objectives on rankings that satisfy some version of the diminishing returns principle (submodularity), is of practical interest.

A related question that deserves independent exploration is to study the complexity of sampling a constrained ranking from the probability distribution induced by the objective (rather than outputting the ranking that maximizes its value, output a ranking with probability proportional to its value). Finally, extending our results to the online setting seems like an important technical challenge which is also likely to have practical consequences.

Abstract

We consider a generalization of k-median and k-center, called the *ordered k-median* problem. In this problem, we are given a metric space $(\mathcal{D}, \{c_{ij}\})$ with $n = |\mathcal{D}|$ points, and a non-increasing weight vector $w \in \mathbb{R}^n_+$, and the goal is to open k centers and assign each point $j \in \mathcal{D}$ to a center so as to minimize $w_1 \cdot$ (largest assignment cost) $+ w_2 \cdot$ (second-largest assignment cost) $+ \ldots + w_n \cdot$ (n-th largest assignment cost). We give an $(18 + \epsilon)$-approximation algorithm for this problem. Our algorithms utilize Lagrangian relaxation and the primal-dual schema, combined with an enumeration procedure of Aouad and Segev. For the special case of $\{0, 1\}$-weights, which models the problem of minimizing the ℓ largest assignment costs that is interesting in and of by itself, we provide a novel reduction to the (standard) k-median problem, showing that LP-relative guarantees for k-median translate to guarantees for the ordered k-median problem; this yields a nice and clean $(8.5 + \epsilon)$-approximation algorithm for $\{0, 1\}$ weights.

1 Introduction

Clustering is an ubiquitous problem that finds applications in various fields including data mining, machine learning, image processing, and bioinformatics. Many clustering problems involve finding a set F of at most k "centers" from an underlying set $\mathcal{D}$ of data points located in some metric space $\{c_{ij}\}_{i,j \in \mathcal{D}}$, and an assignment of data points to centers, so as to minimize some objective function of the assignment costs, i.e., the distances between data points and their assigned centers. These problems can typically also be stated as *facility-location* problems, wherein we seek a cost-effective way of opening facilities ($\equiv$ centers) and assigning clients ($\equiv$ data points) to open facilities. Given their widespread applicability, clustering and facility-location problems have been extensively studied in the Computer Science and Operations Research literature; see, e.g., [16, 22], as also the literature on the classical *k-median* (minimize *sum* of the assignment costs) [6, 13, 15, 4]), and *k-center* (minimize *maximum* assignment cost [10, 11]) problems.

We consider a common generalization of k-median and k-center, called the *ordered k-median problem* [17, 9]. As before, we are given a metric space $(\mathcal{D}, \{c_{ij}\}_{i,j\in\mathcal{D}})$, and an integer $k \geq 0$. We will often refer to points in $\mathcal{D}$ as clients. We are also given non-increasing, nonnegative weights $w_1 \geq w_2 \geq \ldots \geq w_n \geq 0$, where $n = |\mathcal{D}|$. For a vector $v \in \mathbb{R}^{\mathcal{D}}$, we use $v^{\downarrow}$ to denote the vector v with coordinates sorted in non-increasing order. That is, we have $v_i^{\downarrow} = v_{\sigma(i)}$, where σ is a permutation of $\mathcal{D}$ such that $v_{\sigma(1)} \geq v_{\sigma(2)} \geq \ldots v_{\sigma(n)}$. The goal in the ordered k-median problem is to choose a set F of k points from $\mathcal{D}$ as centers (or "facilities"), and assign each client $j \in \mathcal{D}$ to a center $i(j) \in F$, so as to minimize

$$cost\big(w; \vec{c} := \{c_{i(j)j}\}_{j\in\mathcal{D}}\big) := w^T \vec{c}^{\downarrow} = \sum_{j=1}^{n} w_j \vec{c}_j^{\downarrow}.$$

Observe that when all the w_is are 1, we obtain the k-median problem; on the other hand, setting $w_1 = 1$, $w_2 = \ldots = w_n = 0$, yields the k-center problem. Indeed the special case with $\{0, 1\}$ weights is already interesting: that is, for some $\ell \in [n]$, we have $w_1 = \ldots = w_\ell = 1$ and all the remaining w_is are 0; this captures the problem of minimizing the ℓ largest assignment costs, which Tamir [23] calls the *ℓ-centrum problem*.

The ordered k-median problem can be motivated from various perspectives. The problem was proposed in network location theory as a convenient way of unifying the k-median and k-center objectives, as also some other objective functions considered in location theory (see, e.g., [17]). Such a versatile model is also useful in the context of clustering applications, wherein the clustering objective (e.g., k-median or k-center) is often a means to an end, namely, producing a "good" clustering. The ordered k-median problem yields a suite of clustering objectives, including those that interpolate between the k-median and k-center objectives, and thereby offers a useful means of obtaining a variety of clustering solutions (which motivates the question of developing efficient algorithms for (approximately) solving this problem). Another motivation for studying ordered k-median comes from a fairness perspective: if the weights decrease geometrically (at a sufficiently large rate), then an optimal ordered-k-median solution yields a *min-max fair* assignment-cost vector: that is, a solution that minimizes the maximum assignment cost, subject to which, it minimizes the second largest assignment cost, and so on. Finally, the ℓ-centrum problem can also be interpreted as the following *robust-optimization* version of k-median. Suppose there is some uncertainty in the client-set that needs to be clustered: in every scenario, some (at most) ℓ clients need to be clustered, and we need to determine the k centers and the assignment of clients to centers before knowing the scenario realization. Robust optimization seeks to minimize the maximum scenario cost, which leads to precisely the ℓ-centrum problem.

While the special cases of k-median and k-center have been considered extensively from the viewpoint of developing approximation algorithms, much less is known about the approximability of the ordered k-median problem, especially in general metrics. Aouad and Segev [2] obtained a logarithmic-approximation ratio for general metrics, and Alamdari and Shmoys [1] obtain a bicriteria approximation for the special case, where w is a convex combination of $(1, 0, \ldots, 0)$ and $\left(\frac{1}{n}, \frac{1}{n}, \ldots, \frac{1}{n}\right)$, which is called the *centridian* problem [12].

Our results. We obtain constant-factor approximation algorithms for the ordered k-median problem. Together with the concurrent work of [3], these constitute the first constant-factor approximation guarantees for ordered k-median. Our main result is an (deterministic) $(18+\epsilon)$-approximation algorithm for the ordered k-median problem (Theorem 7). Our algorithm utilizes the *primal-dual schema and Lagrangian relaxation*, and, hence, is *combinatorial*.

En route, in Section 2, we first develop constant-factor approximation algorithms for the case of $\{0, 1\}$-weights. This introduces many of the ideas needed to handle the general

setting. We design two algorithms for this setting. Both algorithms are derived using a novel LP-relaxation that we propose for the problem, which leverages a key insight to circumvent the issue that the natural LP-relaxation has a large (non-constant) integrality gap.

Our first algorithm is a clean, combinatorial $(12+\epsilon)$-approximation algorithm that is based on the Jain-Vazirani primal-dual schema coupled with Lagrangian relaxation (Theorem 4). Both the algorithm and its analysis are versatile, and we show in Section 3 that the underlying ideas extend easily and, in combination with an enumeration procedure of [2], yield an $(18+\epsilon)$-approximation for the general setting. Our second algorithm for $\{0,1\}$-weights is based on LP-rounding, and yields an improved approximation factor via a novel *black-box reduction* to LP-relative algorithms for (standard) k-median. We show that an LP-relative α-approximation for k-median yields (essentially) a $2(\alpha+1)$-approximation; taking $\alpha = 3.25$ [7], we obtain an $(8.5+\epsilon)$-approximation for ordered k-median with $\{0,1\}$-weights (Theorem 5); we believe that this reduction is of independent interest.

Relationship with the work of [3]. Recently, we learnt that Byrka et al. [3] have also obtained a (randomized) $O(1)$-approximation guarantee (equal to $38+\epsilon$) for the ordered k-median problem. Our work was done independently and concurrently; a manuscript with the same approximation guarantees was posted on the arXiv in November 2017 [5]. In particular, our results for $\{0,1\}$ weights were obtained without knowledge of the work of [3]. But it was after we learnt of the results in [3] that we realized that our results can be extended to the general weighted setting.

While we use similar LP relaxations, our techniques are different. Whereas [3] crucially exploit properties of the Charikar-Li [7] LP-rounding algorithm, we leverage the (primal-dual + Lagrangian relaxation) methodology for k-median due to Jain and Vazirani [13]. Our algorithms are thus combinatorial. Our approximation factors improve upon those obtained in [3], *both* for $\{0,1\}$ weights and general weights; we believe that our algorithms and analyses are also simpler. Finally, our reduction to LP-relative algorithms for k-median shows that we do not need to rely on a *specific* k-median LP-rounding algorithm in order to tackle ordered k-median with $\{0,1\}$ weights, and suggests that the same might be true for general weights.

Our techniques. It is instructive to first discuss the $\{0,1\}$-weighted case. One of the main challenges is in coming up with a good LP-relaxation for this ℓ-centrum problem. The natural LP-relaxation augments the natural LP for k-median by imposing constraints encoding that the total assignment cost of any set of ℓ clients is at most B, where B is a new variable that we seek to minimize. It is well known that, even for (standard) k-median, one cannot hope to round an LP solution while approximately preserving the assignment cost of *each* client [6].[2] More significantly, whereas we can round and approximately preserve the sum of *all* assignment costs (as shown by k-median rounding), it turns out that we cannot preserve the sum of the ℓ largest assignment costs: the natural LP has a large (non-constant) integrality gap. This integrality gap is robust and cannot be alleviated by guessing the maximum assignment cost and incorporating this in the LP and the lower bound.[3] In essence, the cause for this disparity (between k-median and ℓ-centrum) is that the k-median objective crucially also includes the contribution from clients with small assignment costs.

[2] This is possible if we open $O(k)$ centers, using, e.g., the filtering-based algorithm of [21] for facility location.

[3] This is in contrast with k-center, where such preprocessing does mitigate the bad integrality gap of the natural LP and reduces it to a constant.

The key insight that allows us to circumvent this difficulty is the following. Suppose we aim to find a solution of objective value $O(B)$. Then, it suffices to find a solution where the total assignment cost of clients having assignment cost at least B/ℓ is $O(B)$: the remaining clients can contribute at most additional B towards the ℓ-centrum objective, since we consider at most ℓ clients in the ℓ-centrum objective value. Moreover, if there is a solution of ℓ-centrum objective value at most B, then the total assignment cost of clients with assignment cost at least B/ℓ is at most B. Thus, given a "guess" B of the optimal value, *our new LP* (P_B) *seeks to minimize the total assignment cost of clients having assignment cost larger than* B/ℓ.

The LP (P_B) corresponds to the LP-relaxation for k-median with *non-metric distances* given by $\{f_B(c_{ij})\}_{i,j\in\mathcal{D}}$, where $f_B(d) = d$ if $d \geq B/\ell$, and is 0 otherwise. Despite this complication, we devise two ways of leveraging (P_B) to obtain a solution of ℓ-centrum cost $O(OPT_B + B)$ (which yields an $O(1)$-approximation for the correct choice of B), both of which involve simple procedures with a clean analysis; here, OPT_B denotes the optimal value of (P_B). Our first algorithm is based on the Jain-Vazirani (JV) template [13]. This is our main result for $\{0,1\}$ weights (see Section 2.1), and this algorithm extends easily to the setting with general weights. We Lagrangify the cardinality constraint and move to the facility-location (FL) version where we may choose any number of centers but incur a fixed cost of (say) λ for each center we choose. We adapt the JV primal-dual algorithm and its analysis to obtain a so-called Lagrangian-multiplier-preserving guarantee for this FL version. By fine-tuning λ, we can then find two solutions, one with less than k centers and the other with more than k centers, whose convex combination has low cost; rounding this *bipoint solution* yields the final solution. This yields our 12-approximation algorithm.

The second algorithm utilizes LP-rounding. We show that after a clustering step, where we merge clients that are distance at most $\frac{B}{\ell}$-apart, the problem of rounding a solution to (P_B) reduces to that of rounding a fractional k-median solution on the cluster centers. Thus, any LP-relative α-approximation algorithm for k-median can be used to obtain a solution of cost at most $2(\alpha+1)\overline{B}$.

For general weights, the key again is to consider k-median with suitable (non-metric) proxy distances analogous to the $f_B(c_{ij})$s. We utilize a clever enumeration idea due to [2] to obtain these proxy distances. Whereas with $\{0,1\}$ weights, we created two distance buckets ($c_{ij} \geq B/\ell$ and $c_{ij} < B/\ell$) with weight multipliers 1 and 0, we now create $O\big(\log_{1+\epsilon}(\frac{n}{\epsilon})\big)$ buckets by grouping distances in powers of $(1+\epsilon)$. We guess the average weight (roughly speaking) incurred for a bucket by an optimal solution, and use this as the weight multiplier for the bucket. As argued in [2]: (a) if we enumerate average weights in powers of $(1+\epsilon)$ then there are only polynomially many choices; and (b) the resulting proxy distances provide a good approximation for the actual $cost(w;.)$-cost. Finally, we show that the primal-dual algorithm and its analysis developed in Section 2.1 extends to solve the k-median problem with these new proxy distances. Combining these ingredients, we obtain an $(18+\epsilon)$-approximation.

Other related work. While the ordered k-median problem, and its special cases, have been well studied in the Operations Research literature (see, e.g., [18, 14]), much of this work has focused either on modeling issues and formulations, or on solving the problem exactly in special cases, or via (non-polynomial time) heuristics. There is little prior work (i.e., discounting [3]) on the design of approximation algorithms for this problem, in general metrics. As mentioned earlier, for general metrics, we are only aware of the work of [2], who obtain a logarithmic-approximation ratio, and [1], who obtain a bicriteria approximation for the special case of the centridian problem.

A significant amount of research has taken place for special cases of the problem, e.g., the $k = 1$ setting [17], and the "continuous" version of the problem where centers can also be opened "in the middle of an edge" [19]. For these settings, fast exact algorithms have been developed in many interesting cases; see, e.g., [8, 23, 20] and the references therein. There is also a large body of work looking at compact integer-programming formulations, branch and bound methods etc.; for a detailed account of this and other work related to location theory and ordered-median models, we refer the reader to the books [18, 14].

2 The setting with $\{0,1\}$-weights

We first consider the setting with $\{0,1\}$ weights. Let $\ell \in [n]$ be such $w_1 = \ldots = w_\ell = 1$, $w_{\ell+1} = 0 = \ldots = w_n$. We abbreviate $cost(w;\vec{c})$ to $cost(\ell;\vec{c})$, or simply $cost(\vec{c})$. The $\{0,1\}$-weight setting serves as a natural starting point for two reasons. First, the problem of minimizing the ℓ most expensive assignment costs is a natural, well-motivated problem that is interesting in its own right. Second, the study of the $\{0,1\}$-case serves to introduce some of the key underlying ideas that are also used to handle the general setting. Notice also that a non-decreasing weight vector w can be written as a nonnegative linear-combination of such $\{0,1\}$ weight vectors.

The natural LP-relaxation for this ℓ-centrum problem has an $\Omega(\ell)$ integrality gap, and, as noted earlier, the integrality gap does not decrease even if we guess the maximum assignment cost and incorporate this in our LP and lower bound. Our constant-factor approximation algorithms are based on an alternate novel LP-relaxation, where, given a "guess" B of the optimal value, we seek to minimize the total assignment cost of clients having assignment cost at least B/ℓ. The rationale is that assignment costs that are smaller than B/ℓ can contribute at most B to the ℓ-centrum cost, and can hence be ignored when searching for a solution of ℓ-centrum cost $O(B)$. For $d \geq 0$, define $f_B(d) = d$ if $d \geq B/\ell$, and 0 otherwise. Throughout, i and j index points of $\mathcal{D}$. We consider the following LP.

$$\min \quad \sum_j \sum_i f_B(c_{ij}) x_{ij} \tag{P_B}$$

$$\text{s.t.} \quad \sum_i x_{ij} \geq 1 \qquad \text{for all } j \tag{1}$$

$$0 \leq x_{ij} \leq y_i \qquad \text{for all } i,j \tag{2}$$

$$\sum_i y_i \leq k. \tag{3}$$

Variable y_i indicates if facility i is open (i.e., i is chosen as a center), and x_{ij} indicates if client j is assigned to facility i. The first two constraints say that each client must be assigned to an open facility, and the third constraint encodes that at most k centers may be chosen.

An atypical aspect of our relaxation is that, while an integer solution corresponds to a solution to our problem, its objective value under (P_B) may *underestimate* the actual objective value; however, as alluded to above, the objective value of (P_B) is within an additive B of the actual objective value. Let OPT_B denote the optimal value of (P_B), and *opt* denote the optimal value of the ℓ-centrum problem.

▶ **Claim 1.** *If $B \geq opt$, then $OPT_B \leq opt \leq B$.*

Proof. Let $(\tilde{x}, \tilde{y})$ be the integer point corresponding to an optimal solution. Clearly, $(\tilde{x}, \tilde{y})$ is feasible to (P_B). There are at most ℓ assignment costs that are at least opt/ℓ (and hence at least B/ℓ). Therefore, the objective value of $(\tilde{x}, \tilde{y})$ is at most *opt*. ◀

▶ **Claim 2.** *Let $\vec{c}$ be an assignment-cost vector (where $\vec{c}_j$ is the assignment cost of j). Then, $cost(\ell;\vec{c}) \leq \sum_j f_B(\vec{c}_j) + B$.*

▶ **Claim 3.** *For any $B \geq 0$, we have: (i) $f_B(x) \leq f_B(y)$ if $x \leq y$; (ii) $\max\{f_B(x), f_B(y), f_B(z)\} \geq f_B\big(\frac{x+y+z}{3}\big)$ for any $x, y, z \geq 0$; and (iii) $3f_B(x/3) = f_{3B}(x)$ for any $x \geq 0$.*

We may assume that we have $\overline{B} \leq (1+\epsilon)opt$ (e.g., by enumerating all possible choices for opt in powers of $(1+\epsilon)$, or using binary search to find, within a $(1+\epsilon)$-factor, the smallest B such that $OPT_B \leq B$). While (P_B) closely resembles the LP-relaxation for k-median, notice that the assignment costs $\{f_B(c_{ij})\}$ used in the objective of (P_B) *do not form a metric*. Despite this complication, we show that ($\mathrm{P}_{\overline{B}}$) can be leveraged to obtain a solution of $cost(\ell;.)$-cost $O(\overline{B})$. We devise two algorithms for obtaining such a guarantee. The first algorithm is based on the primal-dual method and the Jain-Vazirani (JV) template [13]; this yields a 12-approximation algorithm. The second algorithm is based on LP-rounding, and shows that any LP-relative α-approximation algorithm for k-median can be used to obtain a solution of $cost(\ell.)$-cost at most $2(\alpha+1)\overline{B}$.

▶ **Theorem 4.** *We can obtain a solution to the ℓ-centrum problem of cost at most $\big(12 + O(\epsilon)\big) \cdot \overline{B} \leq \big(12 + O(\epsilon)\big) opt$.*

▶ **Theorem 5.** *Let (kmed-P) denote the k-median LP: $\min\big\{\sum_{j,i} c_{ij}x_{ij} : (1)\text{–}(3)\big\}$. Let $\mathcal{A}$ be an α-approximation algorithm for k-median whose approximation guarantee is proved relative to (kmed-P). We can obtain a solution to the ℓ-centrum problem of cost at most $2(\alpha+1)\overline{B}$. Thus, taking $\mathcal{A}$ to be the 3.25-approximation algorithm in [7], we obtain an $(8.5+\epsilon)$-approximation algorithm for the ℓ-centrum problem.*

Although Theorem 4 yields a worse approximation factor, the underlying primal-dual algorithm and analysis are quite versatile and extend easily to the setting with general weights. We prove Theorem 4 in this extended abstract. The proof of Theorem 5 can be found in Appendix A of the arXiv version [5] of this paper.

2.1 Proof of Theorem 4

As noted earlier, the proof relies on the primal-dual method. The dual of ($\mathrm{P}_{\overline{B}}$) is as follows.

$$\max \quad \sum_j \alpha_j - k \cdot \lambda \tag{$\mathrm{D}_{\overline{B}}$}$$

$$\text{s.t.} \quad \alpha_j \leq f_{\overline{B}}(c_{ij}) + \beta_{ij} \qquad \forall i,j \tag{4}$$

$$\sum_j \beta_{ij} \leq \lambda \qquad \forall i \tag{5}$$

$$\alpha, \lambda \geq 0.$$

Let $OPT := OPT_{\overline{B}}$ denote the optimal value of ($\mathrm{P}_{\overline{B}}$). We first fix λ and construct a solution that may open more than k centers but will have some near-optimality properties (see Theorem 6).

P1. Dual-ascent. Initialize $\mathcal{D}' = \mathcal{D}$, $\alpha_j = \beta_{ij} = 0$ for all $i, j \in \mathcal{D}$, $F = \emptyset$. The clients in $\mathcal{D}'$ are called *active clients*. If $\alpha_j \geq f_{\overline{B}}(c_{ij})$, we say that j reaches i. (So if $c_{ij} \leq \overline{B}/\ell$, then j reaches i from the very beginning.)

We repeat the following until all clients become inactive. Uniformly raise the α_js of all active clients, and the β_{ij}s for (i,j) such that $i \notin F$, j is active, and can reach i until one of the following events happen.

- Some client $j \in \mathcal{D}$ reaches some i (and previously could not reach i): if $i \in F$, we *freeze* j, and remove j from $\mathcal{D}'$.
- Constraint (5) becomes tight for some $i \notin F$: we add i to F; for every $j \in \mathcal{D}'$ that can reach i, we freeze j and remove j from $\mathcal{D}'$.

P2. **Pruning.** Pick a maximal subset T of F with the following property: for every $j \in \mathcal{D}$, there is at most one $i \in T$ such that $\beta_{ij} > 0$. Let $P = \{j : \exists i \in T \text{ s.t. } \beta_{ij} > 0\}$.

P3. Return T as the set of centers, and assign every j to the nearest point (in terms of c_{ij}) in T, which we denote by $i(j)$.

▶ **Theorem 6.** *The solution satisfies* $3\lambda|T| + \sum_{j\in P} f_{\overline{B}}(c_{i(j)j}) + \sum_{j\notin P} f_{3\overline{B}}(c_{i(j)j}) \le 3\sum_j \alpha_j$.

Proof. The proof resembles the analysis of the JV primal-dual algorithm for facility location, but the subtlety is that we need to deal with the complication that the $\{f_{\overline{B}}(c_{ij})\}_{i,j\in\mathcal{D}}$ "distances" do not form a metric.

Observe that for every $i \in T$, every client $j \in P$ for which $\beta_{ij} > 0$ satisfies $i(j) = i$. So

$$\sum_{j\in P} 3\alpha_j \ge \sum_{j\in P}\Big(3\beta_{i(j)j} + f_{\overline{B}}(c_{i(j)j})\Big) = 3\lambda|T| + \sum_{j\in P} f_{\overline{B}}(c_{i(j)j}).$$

We show that for each client $j \notin P$, there is some $i'' \in T$ such that $f_{3\overline{B}}(c_{i''j}) \le 3\alpha_j$, which will complete the proof. Let $i \in F$ be the facility that caused j to freeze, so $f_{\overline{B}}(c_{ij}) \le \alpha_j$. If $i \in T$, then we are done. Otherwise, since T is maximal, there is some $i' \in T$ and some client $k \in P$ such that $\beta_{i'k}, \beta_{ik} > 0$. Notice that $\alpha_j \ge \alpha_k$, since α_j grows at least until the time point when i joins F, and α_k grows until at most this time point. Therefore, $f_{\overline{B}}(c_{ik}), f_{\overline{B}}(c_{i'k}) \le \alpha_k \le \alpha_j$. We have $c_{i'j} \le c_{i'k} + c_{ik} + c_{ij}$. Now, by Claim 3, we have $f_{3\overline{B}}(c_{i'j}) \le f_{3\overline{B}}(c_{i'k} + c_{ik} + c_{ij}) = 3f_{\overline{B}}((c_{i'k} + c_{ik} + c_{ij})/3) \le 3\max(f_{\overline{B}}(c_{ik}), f_{\overline{B}}(c_{i'k}), f_{\overline{B}}(c_{ij})) \le 3\alpha_j$. ◀

Using standard arguments, by performing binary search on λ, we can achieve one of the following two outcomes.

(a) Obtain some λ such that the above algorithm returns a solution T with $|T| = k$: in this case, Theorem 6 implies that $\sum_j f_{3\overline{B}}(c_{i(j)j}) \le 3OPT$, and Claim 2 then implies that the $cost(\ell;.)$-cost of our solution is at most $3OPT + 3\overline{B} \le 6\overline{B}$.

(b) Obtain $\lambda_1 < \lambda_2$ with $\lambda_2 - \lambda_1 < \frac{\epsilon\overline{B}}{n}$ such that letting T_1 and T_2 be the solutions returned for λ_1 and λ_2, we have $k_1 := |T_1| > k > k_2 := |T_2|$. We describe below the procedure for extracting a low-cost feasible solution from T_1 and T_2, and analyze it, which will complete the proof of Theorem 4.

Extracting a feasible solution from T_1 and T_2 in outcome (b). Let $a, b \ge 0$ be such that $ak_1 + bk_2 = k$, $a + b = 1$. Thus, a convex combination of T_1 and T_2, called a *bipoint solution*, yields a feasible fractional solution and our task is to round this into a feasible solution. Let (α_1, β_1), (α_2, β_2) denote the dual solutions obtained for λ_1 and λ_2 respectively. Let $i_1(j)$ and $i_2(j)$ denote the centers to which j is assigned in T_1 and T_2 respectively. Let $d_{1,j} = f_{3\overline{B}}(c_{i_1(j)j})$ and $d_{2,j} = f_{3\overline{B}}(c_{i_2(j)j})$. Let $C_1 := \sum_j d_{1,j}$ and $C_2 := \sum_j d_{2,j}$. Then,

$$\begin{aligned} aC_1 + bC_2 &\le 3a\Big(\sum_j \alpha_{1,j} - k_1\lambda_1\Big) + 3b\Big(\sum_j \alpha_{2,j} - k_2\lambda_2\Big) \\ &\le 3a\Big(\sum_j \alpha_{1,j} - k\lambda_2\Big) + 3b\Big(\sum_j \alpha_{2,j} - k\lambda_2\Big) + 3ak_1(\lambda_2 - \lambda_1) \le 3OPT + 3\epsilon\overline{B} \end{aligned}$$

where the last inequality follows since $(\alpha_1, \beta_1, \lambda_2)$, $(\alpha_2, \beta_2, \lambda_2)$ are feasible solutions to $(D_{\overline{B}})$. If $b \ge 0.5$, then T_2 yields a feasible solution of $cost(\ell;.)$-cost at most $C_2 + 3\overline{B} \le 6OPT + (3+\epsilon)\overline{B}$. So suppose $a \ge 0.5$. The procedure for rounding the bipoint solution is as follows.

B1. Clustering. We first match facilities in T_2 with a subset of facilities in T_1 as follows. Initialize $\mathcal{D}' \leftarrow \mathcal{D}$, $A \leftarrow \emptyset$, and $M \leftarrow \emptyset$. While $\mathcal{D}' \neq \emptyset$, we repeatedly pick the client $j \in \mathcal{D}'$ with minimum $d_{1,j}+d_{2,j}$ value, and add j to A. We add the tuple $(i_1(j), i_2(j))$ to M, remove from $\mathcal{D}'$ all clients k (including j) such that $i_1(k) = i_1(j)$ or $i_2(k) = i_2(j)$, and set $\sigma(k) = j$ for all such clients. Let $M_1 = M$ denote the matching when $\mathcal{D}' = \emptyset$. Next, for each unmatched $i \in T_2$, we pick an arbitrary unmatched facility $i' \in T_1$, and add (i', i) to M. Let F_1 be the set of T_1-facilities that are matched, and $S := \{j \in \mathcal{D} : i_1(j) \in F_1\}$. Note that $|F_1| = |M| = k_2$.

B2. Opening facilities. We will open k_2 facilities at locations in $A \cup M$, and $k - k_2$ facilities from $T_1 \setminus F_1$. We solve the following LP to determine how to do this. Variables z_i for every $i \in T_1 \setminus F_1$ indicate if we open facility i; variable θ indicates if we give preference to F_1 (i.e., the T_1-facilities in M), or the facilities in T_2 (which are always matched).

$$\min \quad \sum_{j\in S}\big(\theta d_{1,j}+(1-\theta)d_{2,j}\big)+\sum_{k\notin S}\big(z_{i_1(k)}d_{1,k}+(1-z_{i_1(k)})(d_{2,k}+d_{1,\sigma(k)}+d_{2,\sigma(k)})\big) \quad \text{(R-P)}$$

$$\text{s.t.} \quad \sum_{i\in T_1\setminus F_1} z_i \le k-k_2, \qquad \theta \in [0,1], \quad z_i \in [0,1] \ \ \forall i \in T_1 \setminus F_1.$$

The above LP is integral. Given an integral optimal solution $(\tilde{\theta}, \tilde{z})$ to (R-P), we open facilities as follows. We open the facilities in $T_1 \setminus F_1$ specified by the $\tilde{z}_i$ variables that are 1. If $\tilde{\theta} = 1$, we open all the T_1-facilities in $M \setminus M_1$, and if $\tilde{\theta} = 0$, we open all the T_2-facilities in $M \setminus M_1$. For some clients $j \in A$, we may open a facility at j (instead of at $i_1(j)$ or $i_2(j)$). For every $j \in A$, if $\tilde{\theta}d_{1,j} + (1-\tilde{\theta})d_{2,j} = 0$, then we open a facility at j; otherwise, we open a facility at $i_1(j)$ if $\tilde{\theta} = 1$ and at $i_2(j)$ if $\tilde{\theta} = 0$.

Analysis. It suffices to show that (R-P) has a fractional solution of small objective value, and that the integral optimal solution $(\tilde{\theta}, \tilde{z})$ yields a feasible solution to our problem whose $cost(\ell; .)$-cost is comparable to the objective value of $(\tilde{\theta}, \tilde{z})$ in (R-P).

For the former, we argue that setting $\theta = a$, $z_i = a$ for all $i \in T_1 \setminus F_1$ yields a feasible solution of objective value at most $2(aC_1 + bC_2)$. We have $\sum_{i\in T_1\setminus F_1} z_i = a(k_1 - k_2) = k - k_2$. Every $j \in S$ contributes $ad_{1,j} + bd_{2,j}$ to the objective value of (R-P), which is also its contribution to $aC_1 + bC_2$. Consider $k \notin S$ with $\sigma(k) = j$, so $d_{1,j} + d_{2,j} \le d_{1,k} + d_{2,k}$. Its contribution to the objective value of (R-P) is $ad_{1,k}+b(d_{2,k}+d_{1,j}+d_{2,j}) \le (a+b)d_{1,k}+2bd_{2,k}$, which is at most twice its contribution to $aC_1 + bC_2$.

For the latter, we first show that every $k \in S$ has assignment cost at most $\tilde{\theta}d_{1,k} + (1 - \tilde{\theta})d_{2,k} + 6\overline{B}/\ell$. If a facility is opened in $\{k, i_1(k), i_2(k)\}$, then this clearly holds. Otherwise, it must be that $k \notin A$. Let $i = i_1(k)$ if $\tilde{\theta} = 1$, and $i_2(k)$ if $\tilde{\theta} = 0$. Since i is not open, it must be that i belongs to a tuple $(i_1(j), i_2(j))$ of M. Then, $j \in A$, and a facility is opened at j. we have that $c_{i,k} \le \tilde{\theta}d_{1,k} + (1 - \tilde{\theta})d_{2,k} + 3\overline{B}/\ell$ and $c_{i,j} \le 3\overline{B}/\ell$. The last inequality follows since the fact that none of $i_1(j)$, $i_2(j)$ is open implies that $\tilde{\theta}d_{1,j} + (1 - \tilde{\theta})d_{2,j} = 0$.

Now consider $k \notin S$ with $\sigma(k) = j$. If $\tilde{z}_{i_1(k)} = 1$, it's assignment cost is at most $d_{1,k} + 3\overline{B}/\ell$. Otherwise, a facility is opened in $\{j, i_1(j), i_2(j)\}$. If a facility is opened in $\{j, i_2(j)\}$, then k's assignment cost is at most $c_{i_2(k)k} + c_{i_2(j)j} \le d_{2,k} + d_{1,j} + d_{2,j} + 6\overline{B}/\ell$. Otherwise, it must be that $\tilde{\theta} = 1$ and $d_{1,j} = c_{i_1(j)j} > 3\overline{B}/\ell$; in this case, k' assignment cost is at most $c_{i_2(k)k} + c_{i_2(j)j} + c_{i_1(j)j} \le (d_{2,k} + 3\overline{B}/\ell) + (d_{2,j} + 3\overline{B}/\ell) + d_{1,j}$. Thus, the $cost(\ell; .)$-cost of our solution is at most the objective value of $(\tilde{\theta}, \tilde{z}) + 6\overline{B}$, which is at most $2(aC_1 + bC_2) + 6\overline{B} \le 6\,OPT + (6 + 3\epsilon)\overline{B} \le \big(12 + O(\epsilon)\big)\overline{B}$. This completes the proof.

3 The general weighted case

We now consider the general setting, where we have $n = |\mathcal{D}|$ non-increasing nonnegative weights $w_1 \geq \ldots \geq w_n \geq 0$, and the goal is to open k centers from $\mathcal{D}$ and assign each client $j \in \mathcal{D}$ to a center $i(j) \in F$, so as to minimize $cost\big(w; \vec{c} := \{c_{i(j)j}\}_{j\in\mathcal{D}}\big) := w^T\vec{c}^{\downarrow} = \sum_{j=1}^{n} w_j\vec{c}_j^{\downarrow}$.

By combining the ideas in Section 2 with an enumeration procedure due to Aouad and Segev in [2], we obtain the following result.

▶ **Theorem 7.** *We can obtain an $\big(18 + O(\epsilon)\big)$-approximation algorithm for ordered k-median that runs in time $\text{poly}\big((\frac{n}{\epsilon})^{1/\epsilon}\big)$.*

As before, we define suitable proxy costs analogous to the $f_B(c_{ij})$s for the setting with general weights. By defining these appropriately, it will be easy to argue that the primal-dual algorithm and its analysis extend to the setting with general weights, since essentially the only property that we use about $\{f_B(c_{ij})\}$ costs in Section 2 is that they satisfy Claim 3. Instead of creating two distance buckets in the $\{0, 1\}$ weighted case ($c_{ij} \geq B/\ell$ and $c_{ij} < B/\ell$), with weight multipliers 1 and 0, we now create $O\big(\log_{1+\epsilon}(\frac{n}{\epsilon})\big)$ buckets and utilize an enumeration idea due to Aouad and Segev [2]. In Section 3.1, we describe this enumeration procedure using our notation, and restate the main claims in [2] in a simplified form. Next, in Section 3.2, we discuss how to adapt the ideas in Section 2 to the k-median problem for the proxy costs (given by (7)) that we obtain from Section 3.1. At the end of this section, we combine this ingredients to prove Theorem 7.

3.1 Proxy costs and the enumeration idea of [2]

Throughout, let $\vec{o}^{\downarrow}$ denote the assignment-cost vector corresponding to an optimal solution, whose coordinates are sorted in non-increasing order. So the optimal cost opt is $\sum_{i=1}^{n} w_i\vec{o}_i^{\downarrow}$. By a standard argument, we can perturb w to eliminate very small weights w_i: for $i \in [n]$, set $\widetilde{w}_i = w_i$ if $w_i \geq \frac{\epsilon w_1}{n}$, and $\widetilde{w}_i = 0$ otherwise.

▶ **Claim 8.** *For any vector $v \in \mathbb{R}^n_+$, we have $(1-\epsilon)cost(w; v) \leq cost(\widetilde{w}; v) \leq cost(w; v)$.*

Proof. Since $\widetilde{w}_i \leq w_i$ for all $i \in [n]$, the upper bound on $cost(\widetilde{w}; v)$ is immediate. We have

$$cost(\widetilde{w}; v) = \sum_{i=1}^{n} \widetilde{w}_i v_i^{\downarrow} = cost(w; v) - \sum_{i\in[n]:w_i<\epsilon w_1/n} w_i v_i^{\downarrow} \geq cost(w; v) - \tfrac{\epsilon w_1}{n} \cdot n v_1^{\downarrow}. \qquad \blacktriangleleft$$

In the sequel, we always work with the $\widetilde{w}$-weights. We guess an estimate M of $\vec{o}_1^{\downarrow}$, and group distances in the range $\big[\frac{\epsilon M}{n}, M\big]$ (roughly speaking) by powers of $(1+\epsilon)$. Let T be the largest integer such that $\frac{\epsilon M}{n}(1+\epsilon)^T \leq M$. For $r = 0, \ldots, T$, we define the distance interval $I_r := \big[\frac{\epsilon M}{n}(1+\epsilon)^{T-r}, \frac{\epsilon M}{n}(1+\epsilon)^{T-r+1}\big)$. There are at most $1 + \log_{1+\epsilon}\big(\frac{n}{\epsilon}\big) = O\big(\frac{1}{\epsilon}\log\frac{n}{\epsilon}\big)$ intervals.

Finally, we guess a non-increasing vector $w_0^{\mathsf{est}} \geq w_1^{\mathsf{est}} \geq \ldots \geq w_T^{\mathsf{est}}$, where the w_r^{est}s are powers of $(1+\epsilon)$ in the range $[\frac{\widetilde{\epsilon w_1}}{n}, \widetilde{w}_1(1+\epsilon))$. As argued in [2], there are only $\exp\big(O(\frac{1}{\epsilon}\log(\frac{n}{\epsilon}))\big) = O\big((\frac{n}{\epsilon})^{1/\epsilon}\big)$ choices for $w^{\mathsf{est}} := (w_0^{\mathsf{est}}, \ldots, w_T^{\mathsf{est}})$. The intention is for w_r^{est} to represent (within a $(1+\epsilon)$-factor) the average $\widetilde{w}$-weight of the set $\{i \in [n] : \vec{o}_i^{\downarrow} \in I_r\}$. More precisely, we would like w_r^{est} to estimate the following quantity, for all $r \in \{0, \ldots, T\}$.

$$w_r^{\mathsf{avg}} := \begin{cases} \big(\sum_{i\in[n]:\vec{o}_i^{\downarrow}\in I_r} \widetilde{w}_i\big)/|\{i \in [n] : \vec{o}_i^{\downarrow} \in I_r\}| & \text{if } \{i \in [n] : \vec{o}_i^{\downarrow} \in I_r\} \neq \emptyset; \\ \min\{\widetilde{w}_i : \vec{o}_i^{\downarrow} \in \bigcup_{s<r} I_s\} & \text{if } \bigcup_{s<r} I_s \neq \emptyset; \\ \widetilde{w}_1 & \text{otherwise.} \end{cases} \tag{6}$$

The following claim will be useful.

▶ **Claim 9.** *For any $r \in \{0,\ldots,T\}$, we have $w_r^{\mathsf{avg}} \geq \max\{\widetilde{w}_i : \vec{o}_i^{\downarrow} \notin \bigcup_{s\leq r} I_s\}$.*

Proof. If w_r^{avg} is defined by cases 1 or 2 of (6), then the inequality follows since for every $i' \in \bigcup_{s\leq r} I_r$ and $i \notin \bigcup_{s\leq r} I_s$, we have $\widetilde{w}_{i'} \geq \widetilde{w}_i$ (since $\vec{o}_{i'}^{\downarrow} \geq \vec{o}_i^{\downarrow}$). If w_r^{avg} is defined by case 3 of (6), then $w_r^{\mathsf{avg}} = \widetilde{w}_1$, and again, the inequality holds. ◀

Given M and the corresponding intervals $I_0,\ldots,I_T$, and the vector w^{est}, we can now finally define our proxy costs as follows. For $d \geq 0$ and $\gamma \geq 1$, define

$$g_{M,w^{\mathsf{est}}}(\gamma;d) = \begin{cases} \widetilde{w}_1(1+\epsilon)d & \text{if } d/\gamma \geq \frac{\epsilon M}{n}(1+\epsilon)^{T+1}; \\ w_r^{\mathsf{est}} d & \text{if } d/\gamma \in I_r \text{ (where } r \in \{0,\ldots,T\}) \\ 0 & \text{if } d/\gamma < \frac{\epsilon M}{n}. \end{cases} \tag{7}$$

The above definition is essentially the scaled surrogate function in [2]. We abbreviate $g_{M,w^{\mathsf{est}}}(1;d)$ to $g_{M,w^{\mathsf{est}}}(d)$. The following two key lemmas are analogous to Claims 1 and 2, and show that for the right choice of M and w^{est}, evaluating the above proxy costs on an assignment-cost vector $\vec{c}$ yields a good estimate of the actual $cost(\widetilde{w};.)$-cost of $\vec{c}$. Similar statements, albeit stated somewhat differently, are proved in [2].

▶ **Lemma 10** (adapted from [2]). *Suppose $M \geq \vec{o}_1^{\downarrow}$ and the w^{est} satisfies $w_r^{\mathsf{est}} \leq (1+\epsilon)w_r^{\mathsf{avg}}$ for all $r \in \{0,\ldots,T\}$. Then, $\sum_{i=1}^n g_{M,w^{\mathsf{est}}}(\vec{o}_i^{\downarrow}) \leq (1+\epsilon)^2 cost(\widetilde{w};\vec{o}^{\downarrow})$.*

Proof. Since $\frac{\epsilon M}{n}(1+\epsilon)^{T+1} > M \geq \vec{o}_1^{\downarrow}$, there is no i such that $\vec{o}_i^{\downarrow} \geq \frac{\epsilon M}{n}(1+\epsilon)^{T+1}$. Fix $r \in \{0,\ldots,T\}$, and consider all $i \in [n]$ such that $\vec{o}_i^{\downarrow} \in I_r$. We have

$$\begin{aligned} \sum_{i\in[n]:\vec{o}_i^{\downarrow}\in I_r} g_{M,w^{\mathsf{est}}}(\vec{o}_i^{\downarrow}) = w_r^{\mathsf{est}} \sum_{i\in[n]:\vec{o}_i^{\downarrow}\in I_r} \vec{o}_i^{\downarrow} &\leq \frac{\epsilon M}{n}(1+\epsilon)^{T-r+1} \cdot w_r^{\mathsf{est}} \cdot \left|\{i\in[n] : \vec{o}_i^{\downarrow} \in I_r\}\right| \\ &\leq (1+\epsilon)\cdot\frac{\epsilon M}{n}(1+\epsilon)^{T-r+1} \cdot w_r^{\mathsf{avg}} \cdot \left|\{i\in[n] : \vec{o}_i^{\downarrow} \in I_r\}\right| \\ &= (1+\epsilon)\cdot\frac{\epsilon M}{n}(1+\epsilon)^{T-r+1} \cdot \sum_{i\in[n]:\vec{o}_i^{\downarrow}\in I_r} \widetilde{w}_i \leq (1+\epsilon)^2 \sum_{i\in[n]:\vec{o}_i^{\downarrow}\in I_r} \widetilde{w}_i\vec{o}_i^{\downarrow}. \end{aligned}$$

It follows that $\sum_{i=1}^n g_{M,w^{\mathsf{est}}}(\vec{o}_i^{\downarrow}) \leq (1+\epsilon)^2 cost(\widetilde{w};\vec{o}^{\downarrow})$. ◀

▶ **Lemma 11** (adapted from [2]). *Let $\gamma \geq 1$. Let $M \geq 0$, and suppose w^{est} satisfies $w_r^{\mathsf{avg}} \leq w_r^{\mathsf{est}}$ for all $r \in \{0,\ldots,T\}$. Let $\vec{c}$ be an assignment-cost vector. Then, we have the upper bound $cost(\widetilde{w};\vec{c}) \leq \sum_{i=1}^n g_{M,w^{\mathsf{est}}}(\gamma;\vec{c}_i) + \gamma(1+\epsilon)cost(\widetilde{w};\vec{o}^{\downarrow}) + \gamma\epsilon\widetilde{w}_1 M$.*

Proof. We have $cost(\widetilde{w};\vec{c}) = \sum_{i=1}^n \widetilde{w}_i\vec{c}_i^{\downarrow} \leq \sum_{i=1}^n g_{M,w^{\mathsf{est}}}(\gamma;\vec{c}_i) + \sum_{i:\ \widetilde{w}_i\vec{c}_i^{\downarrow} > g_{M,w^{\mathsf{est}}}(\gamma;\vec{c}_i^{\downarrow})} \widetilde{w}_i\vec{c}_i^{\downarrow}$. Consider some $i \in [n]$ for which $\widetilde{w}_i\vec{c}_i^{\downarrow} > g_{M,w^{\mathsf{est}}}(\gamma;\vec{c}_i^{\downarrow})$. It must be that $\vec{c}_i^{\downarrow}/\gamma < \frac{\epsilon M}{n}(1+\epsilon)^{T+1}$ as otherwise (see (7)), we have $g_{M,w^{\mathsf{est}}}(\gamma;\vec{c}_i^{\downarrow}) = (1+\epsilon)\widetilde{w}_1\vec{c}_i^{\downarrow} > \widetilde{w}_i\vec{c}_i^{\downarrow}$. If $g_{M,w^{\mathsf{est}}}(\gamma;\vec{c}_i^{\downarrow}) = 0$, then we have $\widetilde{w}_i\vec{c}_i^{\downarrow}/\gamma < \widetilde{w}_i \cdot \frac{\epsilon M}{n} \leq \widetilde{w}_1 \cdot \frac{\epsilon M}{n}$.

Otherwise, we claim that $\vec{c}_i^{\downarrow}/\gamma \leq (1+\epsilon)\vec{o}_i^{\downarrow}$. Suppose not. Suppose $\vec{c}_i^{\downarrow}/\gamma \in I_r$, where $r \in \{0,\ldots,T\}$. Since $\frac{\vec{c}_i^{\downarrow}/\gamma}{\vec{o}_i^{\downarrow}} > (1+\epsilon)$, we have that $\vec{o}_i^{\downarrow} \notin \bigcup_{s\leq r} I_s$. So by Claim 9, we have $w_r^{\mathsf{avg}} \geq \widetilde{w}_i$. Hence, $g_{M,w^{\mathsf{est}}}(\gamma;\vec{c}_i^{\downarrow}) = w_r^{\mathsf{est}}\vec{c}_i^{\downarrow} \geq w_r^{\mathsf{avg}}\vec{c}_i^{\downarrow} \geq \widetilde{w}_i\vec{c}_i^{\downarrow}$, which contradicts our assumption that $\widetilde{w}_i\vec{c}_i^{\downarrow} > g_{M,w^{\mathsf{est}}}(\gamma;\vec{c}_i^{\downarrow})$.

Putting everything together, we have that $\sum_{i:\widetilde{w}_i\vec{c}_i^{\downarrow} > g_{M,w^{\mathsf{est}}}(\gamma;\vec{c}_i^{\downarrow})} \widetilde{w}_i\vec{c}_i^{\downarrow} \leq n\gamma\widetilde{w}_1 \cdot \frac{\epsilon M}{n} + \gamma(1+\epsilon)\sum_{i\in[n]} \widetilde{w}_i\vec{o}_i^{\downarrow}$, which proves the lemma. ◀

Finally, we show that $g_{M,w^{\text{est}}}$ satisfies the analogue of Claim 3, which will be crucial in arguing that our algorithms and analysis from Section 4 carry over and allow us to solve, in an approximate sense, the k-median problem with the $\{g_{M,w^{\text{est}}}(c_{ij})\}$ proxy costs.

▶ **Lemma 12.** *For any $\gamma \geq 1$, $M \geq 0$, and w^{est}, we have: (i) $g_{M,w^{\text{est}}}(\gamma; x) \leq g_{M,w^{\text{est}}}(\gamma; y)$ if $x \leq y$; and (ii) $3\max\{g_{M,w^{\text{est}}}(\gamma; x), g_{M,w^{\text{est}}}(\gamma; y), g_{M,w^{\text{est}}}(\gamma; z)\} \geq g_{M,w^{\text{est}}}(3\gamma; x+y+z)$ for any $x, y, z \geq 0$.*

3.2 Solving the k-median problem with the $\left\{g_{M,w^{\text{est}}}(c_{ij})\right\}$ proxy costs

We now work with a fixed guess M, w^{est}, and give an algorithm for finding a near-optimal k-median solution with the $\{g_{M,w^{\text{est}}}(c_{ij})\}$ proxy costs. Our algorithm and analysis will be quite similar to the one in Section 4. The primal and dual LPs we consider are the same as (P$_B$) and (D$_{\overline{B}}$), except that we replace all occurrences of $f_B(c_{ij})$ and $f_{\overline{B}}(c_{ij})$ with $g_{M,w^{\text{est}}}(c_{ij})$. Let $OPT_{M,w^{\text{est}}}$ denote the optimal value of this LP.

The primal-dual algorithm for a given center-cost λ (steps P1–P3 in Section 4) is unchanged. The analysis also is essentially identical, since, previously, we only relied on the fact that the proxy costs satisfy an approximate triangle inequality, which is also true here (Lemma 12). We state below the guarantee from the primal-dual algorithm slightly differently, in the form suggested by part (ii) of Lemma 12; the proof mimics the proof of Theorem 6.

▶ **Theorem 13.** *For any $\lambda \geq 0$, the primal-dual algorithm (P1)–(P3) returns a set T of centers, an assignment $i(j) \in T$ for every $j \in \mathcal{D}$, and a dual feasible solution (α, β, λ) such that $3\lambda|T| + \sum_j g_{M,w^{\text{est}}}(3; c_{i(j)j}) \leq 3\sum_j \alpha_j$.*

Given Theorem 13, we can use binary search on λ, to either obtain: (a) some λ such for which we return a solution T with $|T| = k$; or (b) $\lambda_1 < \lambda_2$ with $\lambda_2 - \lambda_1 < \frac{\epsilon \widetilde{w}_1 M}{n}$ such that letting T_1 and T_2 be the solutions returned for λ_1 and λ_2, we have $k_1 := |T_1| > k > k_2 := |T_2|$. In case (a), Theorem 13 implies that $\sum_j g_{M,w^{\text{est}}}(3; c_{i(j)j}) \leq 3OPT_{M,w^{\text{est}}}$. In case (b), we again extract a low-cost feasible solution from T_1 and T_2 by rounding the bipoint solution given by their convex combination. As before, $a, b \geq 0$ be such that $ak_1 + bk_2 = k$, $a + b = 1$. Let (α_1, β_1), (α_2, β_2) denote the dual solutions obtained for λ_1 and λ_2 respectively. Let $i_1(j)$ and $i_2(j)$ denote the centers to which j is assigned in T_1 and T_2 respectively. Let $d_{1,j} = g_{M,w^{\text{est}}}(3; c_{i_1(j)j})$ and $d_{2,j} = g_{M,w^{\text{est}}}(3; c_{i_2(j)j})$. Let $C_1 := \sum_j d_{1,j}$ and $C_2 := \sum_j d_{2,j}$. Similar to before, we have $aC_1 + bC_2 \leq 3OPT_{M,w^{\text{est}}} + 3\epsilon\widetilde{w}_1 M$. The procedure for rounding this bipoint solution requires only minor changes to steps B1, B2 in Section 4.

Rounding the bipoint solution. If $b \geq 1/3$, then T_2 yields a feasible solution with $\sum_j g_{M,w^{\text{est}}}(3; c_{i_2(j)j}) = C_2 \leq 9OPT_{M,w^{\text{est}}} + 9\epsilon\widetilde{w}_1 M$. So suppose $a \geq 2/3$.

G1. Clustering. We match facilities in T_2 with a subset of facilities in T_1 as follows. Initialize $\mathcal{D}' \leftarrow \mathcal{D}$, $A \leftarrow \emptyset$, and $M \leftarrow \emptyset$. We repeatedly pick the client $j \in \mathcal{D}'$ with minimum $\max\{d_{1,j}, d_{2,j}\}$ value, and add j to A. (***This is the only change, compared to step B1.***) We add the tuple $(i_1(j), i_2(j))$ to M, remove from $\mathcal{D}'$ all clients k (including j) such that $i_1(k) = i_1(j)$ or $i_2(k) = i_2(j)$, and set $\sigma(k) = j$ for all such clients. Let $M_1 = M$ denote the matching when $\mathcal{D}' = \emptyset$. Next, for each unmatched $i \in T_2$, we pick an arbitrary unmatched facility $i' \in T_1$, and add (i', i) to M. Let F_1 be the set of T_1-facilities that are matched, and $S := \{j \in \mathcal{D} : i_1(j) \in F_1\}$. Note that $|F_1| = |M| = k_2$.

G2. Opening facilities. This is almost identical to step B2, except that we decide which facilities to open by now solving the following LP.

$$\min \quad \sum_{j\in S}\big(\theta d_{1,j}+(1-\theta)d_{2,j}\big)+\sum_{k\notin S}\big(z_{i_1(k)}d_{1,k}+(1-z_{i_1(k)})\cdot 3\max\{d_{1,k},d_{2,k}\}\big) \quad \text{(GR-P)}$$
$$\text{s.t.} \quad \sum_{i\in T_1\setminus F} z_i \le k-k_2, \qquad \theta\in[0,1], \quad z_i\in[0,1] \ \ \forall i\in T_1\setminus F.$$

Let $(\tilde\theta,\tilde z)$ be an optimal integral solution to (GR-P). If $\tilde\theta=1$, we open all facilities in F_1, and otherwise, all facilities in T_2. We also open the facilities from $T_1\setminus F_1$ for which $\tilde z_i=1$.

To analyze this, we first show that setting $\theta=a$, $z_i=a$ for all $i\in T_1\setminus F_1$ yields a feasible solution to (GR-P) of objective value at most $3(aC_1+bC_2)$. We have $\sum_{i\in T_1\setminus F_1} z_i = a(k_1-k_2)=k-k_2$. Every $j\in S$ contributes $ad_{1,j}+bd_{2,j}$ to the objective value of (GR-P). Consider $k\notin S$. Its contribution to the objective value of (GR-P) is

$$ad_{1,k}+3b\max\{d_{1,k},d_{2,k}\}=\max\{(a+3b)d_{1,k},ad_{1,k}+3bd_{2,k}\}\le 3(ad_{1,k}+bd_{2,k})$$

where the inequality follows since $a+3b\le 3a$ when $a\ge 2/3$. Thus, for every $j\in\mathcal{D}$, its contribution to the objective value of (GR-P) is at most thrice its contribution to aC_1+bC_2.

Suppose $\vec c$ is the assignment-cost vector resulting from $(\tilde\theta,\tilde z)$. We show that $\sum_j g_{M,w^{\mathsf{est}}}(9;\vec c_j)$ is at most the objective value of $(\tilde\theta,\tilde z)$ under (GR-P). For every $k\in S$, we have $g_{M,w^{\mathsf{est}}}(9;\vec c_k)\le g_{M,w^{\mathsf{est}}}(3;\vec c_k)\le \tilde\theta d_{1,k}+(1-\tilde\theta)d_{2,k}$. Now consider $k\notin S$ with $\sigma(k)=j$, so $\max\{d_{1,j},d_{2,j}\}\le\max\{d_{1,k},d_{2,k}\}$. If $\tilde z_{i_1(k)}=1$, then $g_{M,w^{\mathsf{est}}}(9;\vec c_k)\le g_{M,w^{\mathsf{est}}}(3;\vec c_k)\le d_{1,k}$. Otherwise, $\vec c_k\le c_{i_2(k)k}+c_{i_1(j)j}+c_{i_2(j)j}$, and so by Lemma 12, we have

$$\begin{aligned} g_{M,w^{\mathsf{est}}}(9;\vec c_k) &\le g_{M,w^{\mathsf{est}}}(9;c_{i_2(k)k}+c_{i_1(j)j}+c_{i_2(j)j})\\ &\le 3\max\{g_{M,w^{\mathsf{est}}}(3;c_{i_2(k)}),g_{M,w^{\mathsf{est}}}(3;c_{i_1(j)j}),g_{M,w^{\mathsf{est}}}(3;c_{i_2(j)j})\}\le 3\max\{d_{1,k},d_{2,k}\}.\end{aligned}$$

So in every case, $g_{M,w^{\mathsf{est}}}(9;\vec c_k)$ is bounded by the contribution of k to the objective value of $(\tilde\theta,\tilde z)$. Thus, we have proved the following theorem.

▶ **Theorem 14.** *For any $M\ge 0$, w^{est}, we can obtain a solution opening k centers whose assignment-cost vector $\vec c$ satisfies $\sum_j g_{M,w^{\mathsf{est}}}(9;\vec c_j)\le 9OPT_{M,w^{\mathsf{est}}}+9\epsilon\widetilde{w}_1 M$.*

Proof of Theorem 7. The proof follows by combining Theorem 14, Lemmas 10 and 11, and Claim 8. Recall that $\vec o^{\downarrow}$ is the assignment-cost vector corresponding to an optimal solution with coordinates sorted in non-increasing order, and $opt=\sum_{i=1}^n w_i\vec o_i^{\downarrow}$ is the optimal cost.

There are only n^2 choices for M, and $O\big((\frac{n}{\epsilon})^{1/\epsilon}\big)$ choices for w^{est}, so we may assume that in polynomial time, we have obtained $M=\vec o_1^{\downarrow}$, and w_r^{est}s satisfying $w_r^{\mathsf{avg}}\le w_r^{\mathsf{est}}\le(1+\epsilon)w_r^{\mathsf{avg}}$ for all $r\in\{0,\dots,T\}$. By Lemma 10, we know that $OPT_{M,w^{\mathsf{est}}}\le(1+\epsilon)^2 cost(\widetilde w;\vec o^{\downarrow})\le(1+\epsilon)^2 opt$. Let $\vec c$ be the assignment-cost vector of the solution returned by Theorem 14 for this M, w^{est}. Combining Theorem 14, Lemma 11, and Claim 8, we obtain that

$$\begin{aligned}(1-\epsilon)cost(w;\vec c)\le cost(\widetilde w;\vec c)&\le\big(9OPT_{M,w^{\mathsf{est}}}+9\epsilon\widetilde w_1 M\big)+9(1+\epsilon)cost(\widetilde w;\vec o^{\downarrow})+9\epsilon\widetilde w_1 M\\ &\le 9(1+\epsilon)^2 opt+9opt+O(\epsilon)opt=\big(18+O(\epsilon)\big)opt.\end{aligned}$$

4 Conclusions and discussion

We have described algorithms achieving approximation guarantees of $12+\epsilon$ and $18+\epsilon$ for the ℓ-centrum and ordered k-median problems. Our algorithms are combinatorial, utilizing

the primal-dual schema and Lagrangian relaxation, and improve upon the algorithms in [3], both in terms of approximation factors and simplicity of analysis.

One interesting research direction suggested by our work is to investigate the ordered-median and ℓ-centrum (i.e., ordered median with $\{0,1\}$-weights) versions of other optimization problems. In further work, we have been able to develop a general framework for devising algorithms for ordered-median problems. Our framework also yields improved guarantees for the ℓ-centrum and ordered k-median problems studied here. We obtain analogous improvements for ordered k-median. We defer details to a forthcoming manuscript.

Abstract

We study the $\mathcal{F}$-center problem with outliers: given a metric space (X, d), a general down-closed family $\mathcal{F}$ of subsets of X, and a parameter m, we need to locate a subset $S \in \mathcal{F}$ of centers such that the maximum distance among the closest m points in X to S is minimized.

Our main result is a *dichotomy theorem*. Colloquially, we prove that there is an efficient 3-approximation for the $\mathcal{F}$-center problem with outliers if and only if we can efficiently optimize a *poly-bounded* linear function over $\mathcal{F}$ subject to a partition constraint. One concrete upshot of our result is a polynomial time 3-approximation for the knapsack center problem with outliers for which no (true) approximation algorithm was known.

1 Introduction

The k-center problem is a classic discrete optimization problem with numerous applications. Given a metric space (X, d) and a positive integer k, the objective is to choose a subset $S \subseteq X$ of at most k points such that $\max_{v \in X} d(v, S)$ is minimized, where $d(v, S) = \min_{u \in S} d(v, u)$. Informally, the problem is to open k centers to serve all points, minimizing the maximum distance to service. This problem has been studied for at least 50 years [13, 14], is NP-hard to approximate to a factor better than 2 [18], and has a simple 2-approximation algorithm [11, 16].

In many applications one is interested in a nuanced version of the problem where instead of serving all points in X, the objective is to serve at least a certain number of points. This is the so-called k-center with outliers version, or the *robust k-center* problem. This problem was first studied by Charikar *et al.* in [8] which gives a 3-approximation for the problem. A best possible 2-approximation algorithm was recently given by Chakrabarty *et al.* in [6] (see also the paper [15] by Harris *et al.*).

Another generalization of the k-center problem arises when the location of centers has more restrictions. For instance, if each point in X has a different weight and the constraint is that the total weight of centers opened is at most k. This problem, now called the *knapsack center* problem, was studied by Hochbaum and Shmoys in [17] which gives a 3-approximation for the problem. To take another instance, X could be vectors in high dimension and the

centers picked need to be linearly independent vectors. This motivates the *matroid center* problem where the set of centers must be an independent set in a matroid. Chen *et al.* give a 3-approximation for this problem in [10].

Naturally, the two aforementioned generalizations can be taken together. Indeed, for the *robust matroid center* problem, that is, the problem of picking centers which are an independent set and only m points need to be served, there is a 7-approximation algorithm in [10]. This was recently improved to a 3-approximation in [15]. The *robust knapsack center* problem, however, has had no non-trivial approximation algorithm till this work. Both [10] and [15] give *bi-criteria* 3-approximation algorithms which violate the knapsack constraint by $(1+\varepsilon)$ (the running time of their algorithm is exponential in $1/\varepsilon$).

Our Contributions

Motivated by the state-of-affairs of the robust knapsack center problem, we study a broad generalization of the problems mentioned above. Let $\mathcal{F}$ be a general down-closed[1] family of subsets over X. In the *robust $\mathcal{F}$-center* problem we are given a metric space (X, d), a parameter m, and the objective is to select a subset $S \in \mathcal{F}$ such that $\min_{T \subseteq X, |T|=m} \max_{v \in T} d(v, S)$ is minimized. That is, the maximum distance of service of the closest m points is minimized.

Observe that if $\mathcal{F} := \{A : w(A) \leq k\}$ then we get the robust knapsack center problem, and if $\mathcal{F}$ is the collection of independent sets of a matroid, then we get the robust matroid center problem. But this generalization captures a host of other problems. For instance, one can consider multiple (but constant) knapsack constraints. Indeed, this was studied in both [17] and [10]. The former[2] only looks at the version *without* outliers and gives a polynomial time 3-approximation in the case when the weights are all polynomially bounded. The latter proves that when the weights are not polynomially bounded, there can be no approximation algorithm via a reduction to the Subset Sum problem, and gives a 3-approximation violating each knapsack constraint by at most $(1+\varepsilon)$ multiplicative factor.

Another instance is a single knapsack constraint along with a single matroid constraint. To our knowledge, this problem has not been studied earlier even in the case when outliers are not allowed. This problem seems natural: for instance, when the points are high dimensional vectors with weights and the collection of centers needs to be a linearly independent set with total weight at most k.

The complexity of the robust $\mathcal{F}$-center problem naturally depends on the complexity of $\mathcal{F}$. To understand this, we define the following optimization problem which depends only on the set-system $(X, \mathcal{F})$. We call it the *$\mathcal{F}$-maximization under partition constraints* or simply $\mathcal{F}$-PCM. In this problem, one is given an arbitrary partition $\mathcal{P}$ of X along with $\mathcal{F}$, and a *poly-bounded* (the range is at most a polynomial in $|X|$) value $\mathsf{val}(x)$ on each $x \in X$. The objective is to find a set $S \in \mathcal{F}$ maximizing $\mathsf{val}(S)$ such that S contains at most one element from each part of $\mathcal{P}$. Our main result stated colloquially (and formally stated as Theorem 4 and Theorem 5 in Section 2) is the following dichotomy theorem[3].

---

[1] if $A \in \mathcal{F}$ and $B \subseteq A$, then $B \in \mathcal{F}$.

[2] The complete proofs can be found in the STOC 1984 version of [17]

[3] We are deliberately being inaccurate here. We should state the theorem for the more general *supplier* version where the set X is partitioned into $F \cup C$ and only the points in C need to be covered and only the centers in F can be opened. Being more general, the algorithmic results are therefore stronger. On the other hand, we weren't able (and didn't try too hard) to make our hardness go through for the center version. In the Introduction we stick with the center version and switch to the supplier in the more formal subsequent sections.

▶ **Informal Theorem.** For any down-closed family $(X, \mathcal{F})$, the robust $\mathcal{F}$-center problem has an efficient 3-approximation algorithm if the $\mathcal{F}$-PCM problem can be solved in polynomial time. Otherwise, there is no efficient *non-trivial* approximation algorithm for the robust $\mathcal{F}$-center problem.

Note that in general, we are not concerned about how $\mathcal{F}$ is represented, because the only place the algorithm checks if a set S is in $\mathcal{F}$ is perhaps for solving the $\mathcal{F}$-PCM problem. So one can choose a representation that works best for the $\mathcal{F}$-PCM solver.

A series of corollaries follow from the above theorem. These are summarized in Table 1.

- When $\mathcal{F} = \{A : w(A) \leq k\}$, the $\mathcal{F}$-PCM problem can be solved in polynomial time via dynamic programming. This crucially uses that the val is poly-bounded. Therefore we get a 3-approximation for the robust knapsack center problem. (Theorem 17)
- When $\mathcal{F}$ is the independent set of a matroid, then the $\mathcal{F}$-PCM problem is a matroid intersection problem. Therefore we get a 3-approximation for the robust matroid center problem recovering the result from [15]. (Theorem 19)
- When $\mathcal{F} = \{A : w_1(A) \leq k_1, w_2(A) \leq k_2, \ldots, w_d(A) \leq k_d\}$ is defined by d weight functions *and* each weight function w_i is *poly-bounded*, then $\mathcal{F}$-PCM can be solved efficiently using dynamic programming. Therefore we get a 3-approximation algorithm for the robust multi-knapsack center problem, extending the result in [17] to the case with outliers. (Theorem 18)
- When $\mathcal{F}$ is given by the intersection of a single knapsack and a single matroid constraint, then we don't know the complexity. However, when the weight function $w(\cdot)$ is poly-bounded and the matroid is representable, then we can give a *randomized* algorithm for the $\mathcal{F}$-PCM problem via a reduction to the exact matroid intersection problem. Therefore, we get a randomized 3-approximation for this special case of robust knapsack-and-matroid center problem (Theorem 21).

Remark 1: The Zero Outlier Case. At this juncture, the reader may wonder about the complexity of the $\mathcal{F}$-center problem which doesn't allow any outliers. This is related to the following decision problem. Given $(X, \mathcal{F})$ and an arbitrary sub-partition $\mathcal{P}$ of X, the problem asks whether there is a set $S \in \mathcal{F}$ such that S contains *exactly* one element from each part of $\mathcal{P}$. We call this the *$\mathcal{F}$-feasibility under partition constraints* or simply the $\mathcal{F}$-PCF problem. Analogous to the informal theorem from earlier, the $\mathcal{F}$-center problem (without outliers) has an efficient 3-approximation algorithm if the $\mathcal{F}$-PCF problem can be solved efficiently; otherwise the $\mathcal{F}$-center problem has no non-trivial approximation algorithm. Indeed, this theorem is much simpler to prove and arguably the roots of this lie in [17].

This raises the main open question from our paper: *what is the relation between the $\mathcal{F}$-PCF and the $\mathcal{F}$-PCM problem?* Clearly, the $\mathcal{F}$-PCF problem is as easy as the $\mathcal{F}$-PCM problem (set all values equal to one in the latter). But is there an $\mathcal{F}$ such that $\mathcal{F}$-PCM is "hard" while $\mathcal{F}$-PCF is "easy"? One concrete example is the corollary discussed in the last bullet point above. When $\mathcal{F}$ is a single knapsack constraint and a single matroid constraint, then the $\mathcal{F}$-PCF problem is solvable in polynomial time by minimizing a linear function over a matroid polytope and another partition matroid *base* polytope. As noted above, we don't know the complexity of the $\mathcal{F}$-PCM problem in this case.

Remark 2: Handling Approximations. If the $\mathcal{F}$-PCM problem is NP-hard, then the robust $\mathcal{F}$-center has no non-trivial approximation algorithm. However approximation algorithms for $\mathcal{F}$-PCM translate to bi-criteria approximation algorithms for the robust $\mathcal{F}$-center problem. More precisely, if we have a ρ-approximation for the $\mathcal{F}$-PCM problem ($\rho \leq 1$), then we get

Table 1 All the above results can be obtained as corollary or simple extensions to our main result. The numbers in bold indicate new results.

The constraint system $\mathcal{F}$	Without Outliers	Robust (With Outliers)
Knapsack Constraint	3 [17]	**3** (Theorem 17)
Matroid Constraint	3 [10]	3 [15]
Multiple Knapsack (poly-bounded weights)	3 [17]	**3** (Theorem 18)
Knapsack and Matroid	**3** (Theorem 24)	Open **3** in special case (Theorem 21)
Multiple Knapsacks and Matroid Constraint	No uni-criteria approximation	**3**, $(1+\varepsilon)$ violating (Theorem 27)

a $(3, \rho)$-*bi-criteria* approximation algorithm for the robust $\mathcal{F}$-center problem. That is, we return a solution $S \in \mathcal{F}$ such that the maximum distance among the closest $\rho \cdot m$ points is at most 3 times the optimum value.

There could be a different notion of approximation possible for the $\mathcal{F}$-PCM problem. Given an instance, there may be an algorithm which returns a set S whose value is at least the optimum value but $S \in \mathcal{F}^R$ for some $\mathcal{F}^R \supseteq \mathcal{F}$ which is a 'relaxation' of $\mathcal{F}$. For instance, if $\mathcal{F}$ is the intersection of multiple (constant) knapsack constraints which are not poly-bounded, then for any constant $\varepsilon > 0$ the $\mathcal{F}$-PCM problem can be solved [9, 12] returning a set with value at least the optimum but violating each constraint by multiplicative $(1+\varepsilon)$. We can use the same to get a polynomial time 3-approximation for the robust multiple knapsack-center problem if we are allowed to violate the knapsack constraints by $(1+\varepsilon)$.

Our Technique

Although our theorem statement is quite general, the proof is quite easy. Let us begin with the $\mathcal{F}$-center problem without outliers. For this, we follow the algorithmic 'partitioning' idea outlined in paper [17] by Hochbaum and Shmoys. As is standard, we guess the optimum distance which we assume to be 1 by scaling. Initially, all points are marked uncovered. Subsequently, we pick *any* uncovered point x and consider a subset B_x of points within distance 1 from it. Note that the optimum solution *must* pick at least one point from each B_x to serve x. Next, we call x "responsible" for all uncovered points within a distance 2 from it, and mark all these points covered. Observe that all the newly covered points are within distance 3 from *any* point in B_x. We continue the above procedure till all points are marked covered. Also observe that the B_x's form a sub-partition $\mathcal{P}$ of the universe where each part has a responsible point. By the above two observations, we see that the $\mathcal{F}$-PCF problem must have a feasible solution with respect to $\mathcal{P}$, and any solution to the $\mathcal{F}$-PCF problem gives a 3-approximation to the $\mathcal{F}$-center problem.

Handling outliers is a bit trickier. The above argument doesn't work since the 'responsible' point may be an outlier in the optimal solution and we can no longer assert that the optimal solution must contain a point from each part. Indeed, the nub of the problem seems to be figuring out which points should be outliers. The 3-approximation algorithm in [8] by Charikar *et al.* (see also paper [1]) cleverly chooses the partitioning via a greedy procedure, but their argument seems hard to generalize to other constraints.

A different attack used in the algorithm in [6] by Chakrabarty *et al.* and that in [15] by Harris *et al.* is by writing an LP relaxation and using the solution of the LP to recognize

the outliers. At a high level, the LP assigns each point x a variable (in this paper we call it $\mathsf{cov}(x)$) that indicates the extent to which x is served. Subsequently, the partitioning procedure described in the first paragraph is run, except the responsible points are considered in decreasing order of $\mathsf{cov}(x)$. The hope is that points assigned higher $\mathsf{cov}(x)$ in the LP solution are less likely to be outliers, and therefore the partition returned by the procedure can be used to recover a 3-approximate solution. This idea does work for the natural LP relaxation of the robust matroid center problem but fails for the natural LP relaxation of the robust knapsack center problem. Indeed, the latter has unbounded integrality gap.

Our solution is to use the round-or-cut framework that has recently been a powerful tool in designing many approximation algorithms (see [7, 20, 19, 2, 5]). We consider the following "coverage polytope" for the robust $\mathcal{F}$-center problem: the variables are $\mathsf{cov}(x)$ denoting the extent to which x is covered by a convex combination of sets $S \in \mathcal{F}$. Of course, we cannot hope to efficiently check whether a particular cov lies in this polytope. Nevertheless, we show that for any cov in the coverage polytope, the partitioning procedure when run in the decreasing order of cov, has the property that there *exists* a solution $S \in \mathcal{F}$ intersecting each part at most once which covers at least m points. We can then use the algorithm for $\mathcal{F}$-PCM to find this set. Furthermore, and more crucially, if the partitioning procedure does not have this property, then we can efficiently find a *hyperplane separating* cov from the the coverage polytope. Therefore, we can run the ellipsoid algorithm on the coverage polytope each time either obtaining a separating hyperplane, or obtaining a cov that leads to a desired partition, and therefore a 3-approximation.

2 Preliminaries

In this section we give formal definitions and statements of our results. As mentioned in a footnote in the Introduction, we focus on the supplier version of the problem.

▶ **Definition 1** ($\mathcal{F}$-Supplier Problem)**.** The input is a metric space (X, d) on a set of points $X = F \cup C$ with distance function $d : X \times X \longrightarrow \mathbb{R}_{\geq 0}$ and $\mathcal{F} \subseteq 2^F$ a down-closed family of subsets of F. The objective is to find $S \in \mathcal{F}$ such that $\max_{v \in C} d(v, S)$ is minimized.

▶ **Definition 2** (Robust $\mathcal{F}$-Supplier Problem)**.** The input is an instance of the $\mathcal{F}$-supplier problem along with an integer parameter $m \in \{0, 1, \ldots, |C|\}$. The objective is to find $S \in \mathcal{F}$ and $T \subseteq C$ for which $|T| \geq m$, and $\max_{u \in T} d(u, S)$ is minimized.

Thus an instance $\mathcal{I}$ of the robust $\mathcal{F}$-supplier problem is defined by the tuple $(F, C, d, m, \mathcal{F})$. In the definitions above, F and C are often called the set of *facilities* and *customers* respectively.

Given the set system $\mathcal{F}$ defined over F, we define the following optimization problem.

▶ **Definition 3** ($\mathcal{F}$-PCM problem)**.** The input is $\mathcal{J} = (F, \mathcal{F}, \mathcal{P}, \mathsf{val})$ where F is a finite set and $\mathcal{F} \subseteq 2^F$ is a down-closed family, $\mathcal{P} \subseteq 2^F$ is a sub-partition of F, and $\mathsf{val} : F \longrightarrow \{0, 1, 2, \cdots\}$ is an integer-valued function with maximum range $|\mathsf{val}|$ satisfying: $\forall f_1, f_2 \in A \in \mathcal{P}$, $\mathsf{val}(f_1) = \mathsf{val}(f_2)$. The objective is to find:

$$\mathsf{opt}(\mathcal{J}) = \max_{S \in \mathcal{F}} \quad \mathsf{val}(S) : \quad |S \cap A| \leq 1, \quad \forall A \in \mathcal{P}$$

The next theorem is the main result of the paper.

▶ **Theorem 4.** *Given a Robust $\mathcal{F}$-Supplier instance $\mathcal{I} = (F, C, d, m, \mathcal{F})$, Let $\mathcal{A}$ be an algorithm that solves any $\mathcal{F}$-PCM instance $\mathcal{J} = (F, \mathcal{F}, \mathcal{P}, \mathsf{val})$, with $|\mathsf{val}| \leq |C|$, in time bounded by $T_{\mathcal{A}}(\mathcal{J})$. Then, there is a 3-approximation algorithm for the Robust $\mathcal{F}$-Supplier instance that runs in time* $\mathrm{poly}(|\mathcal{I}|)T_{\mathcal{A}}(\mathcal{J})$.

The next theorem is the (easier) second part of the dichotomy theorem. We show that if $\mathcal{F}$-PCM cannot be solved, then the corresponding Robust $\mathcal{F}$-Supplier cannot be approximated.

▶ **Theorem 5.** *Given any non-trivial approximation algorithm $\mathcal{B}$ for the Robust $\mathcal{F}$-Supplier problem that runs in time $T_{\mathcal{B}}(|\mathcal{I}|)$ on instance $\mathcal{I}$, any $\mathcal{F}$-PCM instance $\mathcal{J} = (F, \mathcal{F}, \mathcal{P}, \mathsf{val})$ can be solved in time* $\mathrm{poly}(|\mathcal{J}|)\, T_{\mathcal{B}}(|\mathcal{I}|)$*, where* $|\mathcal{I}| = \mathrm{poly}(|\mathcal{J}|)$.

The proof can be found in the full version of the paper.

We end this section by setting a few notations used in the remainder of the paper. For any $u \in F \cup C$ we let $B_C(u, r)$ be the customers in a ball of radius r around u i.e. $B_C(u, r) = \{v \in C : d(u, v) \leq r\}$. Similarly, define $B_F(u, r)$ as the facilities in a ball of radius r around u i.e. for $u \in F \cup C$, $B_F(u, r) = \{f \in F : d(u, f) \leq r\}$.

3 Algorithm and Analysis : Proof of Theorem 4

We fix $\mathcal{I} = (F, C, d, \mathcal{F}, m)$ the instance of the Robust $\mathcal{F}$-Supplier problem. We use $\widehat{\mathsf{opt}}$ to denote *our guess* of the value of the optimal solution. Without loss of generality, we can always assume $\widehat{\mathsf{opt}} = 1$ because if not, we could scale d to meet this criteria. Our objective henceforth is to either find a set $S \in \mathcal{F}$ such that $|\{v \in C : d(v, S) \leq 1\}| \geq m$, or prove that $\mathsf{opt}(\mathcal{I}) > 1$.

There are two parts to our proof. The first part is a partitioning procedure which given an assignment $\mathsf{cov}(v) \in \mathbb{R}_{\geq 0}$ for every customer $v \in C$, constructs an instance $\mathcal{J}$ of $\mathcal{F}$-PCM. We call cov *valuable* if $\mathcal{J}$ has optimum value $\geq m$. Our procedure ensures that if cov is valuable, then we get a 3-approximate solution for $\mathcal{I}$. This is described in Section 3.1. The second part contains the proof of Theorem 4. In particular we show how using the round-and-cut methodology using polynomially many calls to $\mathcal{A}$ (recall this is the algorithm for $\mathcal{F}$-PCM) we can either prove $\mathsf{opt}(\mathcal{I}) > 1$, or find a valuable cov. This is described in Section 3.2.

3.1 Reduction to $\mathcal{F}$-PCM

Algorithm 1 inputs an assignment $\{\mathsf{cov}(v) \in \mathbb{R}_{\geq 0} : v \in C\}$. It returns a sub-partition $\mathcal{P}$ of F and assigns $\mathsf{val} : F \to \{0, 1, \cdots, |C|\}$ such that all the facilities in the same part of $\mathcal{P}$ get the same val. That is, it returns an $\mathcal{F}$-PCM instance $\mathcal{J} = (F, \mathcal{F}, \mathcal{P}, \mathsf{val})$ with $|\mathsf{val}| \leq |C|$.

The algorithm maintains a set of *uncovered* customers $U \subseteq C$ initialized to C (Line 1). In each iteration, it picks the customer $v \in U$ with maximum cov (Line 5) and adds it to set $\mathsf{Reps}_{\mathsf{cov}}$ (Line 6). We add the set of facilities $B_F(v, 1)$ at distance 1 from v to $\mathcal{P}$ (Line 7, 8). For each such v, we eke out the subset $\mathsf{Chld}(v) = B_C(v, 2) \cap U$ of currently uncovered clients "represented" by v (Line 9). For every facility $f \in B_F(v, 1)$ we define its *value* to be: $\mathsf{val}(f) = |\mathsf{Chld}(v)|$ (Line 10). At the end of the iteration, $\mathsf{Chld}(v)$ is removed from U (Line 11) and the loop continues till U becomes $\emptyset$. This way, the algorithm partitions C into $\{\mathsf{Chld}(v) : v \in \mathsf{Reps}_{\mathsf{cov}}\}$ (see fact(6)). Claim 8 shows that $\mathcal{P}$ is a sub-partition of F.

▶ **Fact 6.** $\{\mathsf{Chld}(v) : v \in \mathsf{Reps}_{\mathsf{cov}}\}$ *is a partition of* C.

▶ **Fact 7.** *For a* $v \in \mathsf{Reps}_{\mathsf{cov}}$ *and any* $u \in \mathsf{Chld}(v)$ *line 6 of the algorithm implies* $\mathsf{cov}(v) \geq \mathsf{cov}(u)$.

▶ **Claim 8.** *$\mathcal{P}$ constructed by Algorithm 1 is a sub-partition of F.*

Proof. By Line 11 of the algorithm, for each $u, v \in \mathsf{Reps}_{\mathsf{cov}}$ we have $d(u, v) > 2$ hence $B_F(u, 1) \cap B_F(v, 1) = \emptyset$ implying $\mathcal{P}$ is a sub-partition of F. ◀

Algorithm 1 $\mathcal{F}$-PCM instance construction.

Input: Robust $\mathcal{F}$-Supplier instance $(F, C, d, m, \mathcal{F})$ and assignment $\{\mathsf{cov}(v) \in \mathbb{R}_{\geq 0} : v \in C\}$
Output: $\mathcal{F}$-PCM instance $(F, \mathcal{F}, \mathcal{P}, \mathsf{val})$

1: $U \leftarrow C$ ▷ The set of uncovered customers
2: $\mathsf{Reps}_{\mathsf{cov}} \leftarrow \emptyset$ ▷ The set of representatives
3: $\mathcal{P} \leftarrow \emptyset$ ▷ The sub-partition of F that will be returned
4: **while** $U \neq \emptyset$ **do**
5: $v \leftarrow \arg\max_{v \in U} \mathsf{cov}(v)$ ▷ The first customer in U in non-increasing cov order
6: $\mathsf{Reps}_{\mathsf{cov}} \leftarrow \mathsf{Reps}_{\mathsf{cov}} \cup v$
7: $B_F(v, 1) \leftarrow \{f \in F : d(f, v) \leq 1\}$ ▷ Facilities that can cover v with a ball of radius 1
8: $\mathcal{P} \leftarrow \mathcal{P} \cup B_F(v, 1)$
9: $\mathsf{Chld}(v) \leftarrow \{u \in U : d(u, v) \leq 2\}$ ▷ Equals to $B_C(v, 2) \cap U$
10: $\mathsf{val}(f) \leftarrow |\mathsf{Chld}(v)| \quad \forall f \in B_F(v, 1)$
11: $U \leftarrow U \backslash \mathsf{Chld}(v)$
12: **end while**

▶ **Claim 9.** *For each $v \in \mathsf{Reps}_{\mathsf{cov}}$ and $f \in B_F(v, 1)$, $\mathsf{Chld}(v) \subseteq B_C(f, 3)$.*

Proof. For any $u \in \mathsf{Chld}(v)$, we have $d(u, v) \leq 2$ and since $d(f, v) \leq 1$, the fact that d is metric implies $d(f, u) \leq 3$. ◀

▶ **Definition 10.** For $S \subseteq F$ let $R(S) = \{v \in \mathsf{Reps}_{\mathsf{cov}} : B_F(v, 1) \cap S \neq \emptyset\}$, be the set of representative customers in $\mathsf{Reps}_{\mathsf{cov}}$ that are covered by balls of radius 1 around the facilities in S.

▶ **Claim 11.** *Let $S \in \mathcal{F}$ be any feasible solution of the $\mathcal{F}$-PCM instance constructed by Algorithm 1. Then, $\sum_{f \in S} \mathsf{val}(f) = \sum_{v \in R(S)} |\mathsf{Chld}(v)|$.*

Proof. For an $f \in S$, according to Line 10 of the algorithm, $\mathsf{val}(f) > 0$ only if $f \in B_F(v, 1)$ for some $v \in \mathsf{Reps}_{\mathsf{cov}}$. Also, by definition of the $\mathcal{F}$-PCM problem, $|B_F(v, 1) \cap S| \leq 1$ for any $v \in \mathsf{Reps}_{\mathsf{cov}}$. That is, there is exactly one $f \in B_F(v, 1) \cap S$ for each $v \in R(S)$ and again by line 10, $\mathsf{val}(f) = |\mathsf{Chld}(v)|$. Summing this equality over all $v \in R(S)$ and the corresponding $f \in B_F(v, 1) \cap S$ proves the claim. ◀

▶ **Claim 12.** *Let $\mathcal{I} = (F, C, d, m, \mathcal{F})$ be a Robust $\mathcal{F}$-Supplier instance and let $\mathsf{cov} : C \to \mathbb{R}_{\geq 0}$ be a coverage function. Let $\mathcal{J} = (F, \mathcal{F}, \mathcal{P}, \mathsf{val})$ be the $\mathcal{F}$-PCM instance returned by Algorithm 1 on input $\mathcal{I}$ and cov. Given any feasible solution S to $\mathcal{J}$, we can cover at least $\mathsf{val}(S)$ customers of C by opening radius 3-balls around each facility in S.*

Proof. By considering $R(S)$ from Definition 10, Claim 11 gives: $\sum_{v \in R(S)} |\mathsf{Chld}(v)| = \sum_{f \in S} \mathsf{val}(f)$. From Fact 6, we get that for all $u, v \in \mathsf{Reps}_{\mathsf{cov}}$, $\mathsf{Chld}(u) \cap \mathsf{Chld}(v) = \emptyset$. Thus, $|\bigcup_{v \in R(S)} \mathsf{Chld}(v)| = \sum_{v \in R(S)} |\mathsf{Chld}(v)| = \mathsf{val}(S)$. Furthermore, by Claim 9, $\{v \in C : d(v, S) \leq 3\} \supseteq \bigcup_{u \in R(S)} \mathsf{Chld}(u)$ implying the size of the former is at least $\mathsf{val}(S)$, thus proving the lemma. ◀

The above claim motivates the following definition of *valuable* cov assignments, and the subsequent lemma.

▶ **Definition 13.** An assignment $\{\mathsf{cov}(v) \in \mathbb{R}_{\geq 0} : v \in C\}$ is *valuable* with respect to a Robust $\mathcal{F}$-Supplier instance $\mathcal{I} = (F, C, d, m, \mathcal{F})$, iff $\mathsf{opt}(\mathcal{J}) \geq m$, where $\mathcal{J}$ is the $\mathcal{F}$-PCM instance returned by Algorithm 1 from $\mathcal{I}$ and cov.

▶ **Lemma 14.** *Given an instance $\mathcal{I}$ of the Robust $\mathcal{F}$-Supplier problem with $\mathsf{opt}(\mathcal{I}) = 1$, and a valuable assignment cov with respect to it, we can obtain a 3-approximate solution in time $\mathrm{poly}(|\mathcal{I}|) + T_{\mathcal{A}}(\mathcal{J})$ where $\mathcal{J}$ is the instance constructed by Algorithm 1 from $\mathcal{I}$ and cov.*

Proof. Since cov is valuable, $\mathsf{opt}(\mathcal{J}) \geq m$. We use solver $\mathcal{A}$ to return an optimal solution $S \in \mathcal{F}$ with $\mathsf{val}(S) \geq m$. Claim 12 implies that S is a 3-approximate solution to $\mathcal{I}$. ◀

3.2 The Round and Cut Approach

If the guess $\widehat{\mathsf{opt}} = 1$ for $\mathcal{I} = (F, C, d, m, \mathcal{F})$ is at least $\mathsf{opt}(\mathcal{I})$, then the following polytope must be non-empty. To see this, if $S^* \in \mathcal{F}$ is the optimal solution to $\mathcal{I}$ then set $z_{S^*} := 1$ and $z_S := 0$ for $S \in \mathcal{F} \backslash S^*$.

$$\mathcal{P}^{\mathcal{I}}_{\mathsf{cov}} = \{(\mathsf{cov}(v) : v \in C) : \quad \sum_{v \in C} \mathsf{cov}(v) \geq m \tag{$\mathcal{P}^{\mathcal{I}}_{\mathsf{cov}}$.1}$$

$$\forall v \in C, \ \mathsf{cov}(v) - \sum_{S \in \mathcal{F}: d(v,S) \leq 1} z_S = 0 \tag{$\mathcal{P}^{\mathcal{I}}_{\mathsf{cov}}$.2}$$

$$\sum_{S \in \mathcal{F}} z_S = 1 \tag{$\mathcal{P}^{\mathcal{I}}_{\mathsf{cov}}$.3}$$

$$\forall S \in \mathcal{F}, \quad z_S \geq 0\} \tag{$\mathcal{P}^{\mathcal{I}}_{\mathsf{cov}}$.4}$$

Even though $\mathcal{P}^{\mathcal{I}}_{\mathsf{cov}}$ has exponentially many auxiliary variables (z_S for all $S \in \mathcal{F}$), its dimension is still $|C|$. The following gives a family of valid inequalities for $\mathcal{P}^{\mathcal{I}}_{\mathsf{cov}}$ via Farkas lemma.

▶ **Lemma 15.** *Let $\lambda(v) \in \mathbb{R}$ for every $v \in C$ be such that*

$$\sum_{\substack{v \in C: \\ d(v,S) \leq 1}} \lambda(v) \leq m \quad \forall S \in \mathcal{F} \tag{V1}$$

Then any $\mathsf{cov} \in \mathcal{P}^{\mathcal{I}}_{\mathsf{cov}}$ satisfies

$$\sum_{v \in C} \lambda(v)\mathsf{cov}(v) \leq m \tag{V2}$$

Proof. Given $\mathsf{cov} \in \mathcal{P}^{\mathcal{I}}_{\mathsf{cov}}$, there exists $\{z_S : S \in \mathcal{F}\}$ such that together they satisfy ($\mathcal{P}^{\mathcal{I}}_{\mathsf{cov}}$.1)-($\mathcal{P}^{\mathcal{I}}_{\mathsf{cov}}$.4).

$$\begin{aligned}\sum_{v \in C} \lambda(v)\mathsf{cov}(v) &=_{(\mathcal{P}^{\mathcal{I}}_{\mathsf{cov}}.2)} \sum_{v \in C} \lambda(v) \sum_{\substack{S \in \mathcal{F}: \\ d(v,S) \leq 1}} z_S = \sum_{S \in \mathcal{F}} z_S \sum_{\substack{v \in C: \\ d(v,S) \leq 1}} \lambda(v) \\ &\leq_{(\mathrm{V1}),(\mathcal{P}^{\mathcal{I}}_{\mathsf{cov}}.4)} m \sum_{S \in \mathcal{F}} z_S =_{(\mathcal{P}^{\mathcal{I}}_{\mathsf{cov}}.3)} m\end{aligned}$$

◀

The next lemma shows that all cov's in $\mathcal{P}^{\mathcal{I}}_{\mathsf{cov}}$ are valuable.

▶ **Lemma 16.** *Suppose an assignment $\{\mathsf{cov}(v) \in \mathbb{R}_{\geq 0} : v \in C\}$ is not valuable with respect to $\mathcal{I} = (F, C, d, m, \mathcal{F})$. Then there is a hyper-plane separating it from $\mathcal{P}^{\mathcal{I}}_{\mathsf{cov}}$ that can be constructed in polynomial time.*

Proof. If $\sum_{v\in C} \mathsf{cov}(v) < m$, this inequality itself is a separating hyper-plane and we are done. So we may assume $\sum_{v\in C} \mathsf{cov}(v) \geq m$.

Let $\mathcal{J} = (F, \mathcal{F}, \mathcal{P}, \mathsf{val})$ be the $\mathcal{F}$-PCM instance constructed by Algorithm 1 from $\mathcal{I}$ and cov. Fix $S \in \mathcal{F}$ and recall from Definition 10 that $R(S) = \{v \in \mathsf{Reps}_{\mathsf{cov}} : B_F(v,1) \cap S \neq \emptyset\}$. Pick an arbitrary $T \subseteq S$ for which $|B_F(v,1) \cap T| = 1$, for all $v \in R(S)$. Observe that by down-closedness of $\mathcal{F}$, we have $T \in \mathcal{F}$ which implies T is a feasible solution for $\mathcal{J}$, and since cov is not valuable $\mathsf{val}(T) < m$. Furthermore, Claim 11 applied to T gives $\mathsf{val}(T) = \sum_{v\in R(T)} |\mathsf{Chld}(v)|$. Since $R(S) = R(T)$ and $|\mathsf{Chld}(v)|$ is integer-valued, we get:

$$\sum_{v\in R(S)} |\mathsf{Chld}(v)| \leq m - 1 \tag{1}$$

Let $\alpha = \frac{m}{m-0.5} > 1$. Define $\lambda(v)$ for $v \in C$ as:

$$\lambda(v) = \begin{cases} \alpha|\mathsf{Chld}(v)| & v \in \mathsf{Reps}_{\mathsf{cov}} \\ 0 & \text{for all other } v \in C \end{cases}$$

Now observe that for any $S \in \mathcal{F}$:

$$\sum_{v\in C: d(v,S)\leq 1} \lambda(v) = \sum_{v\in \mathsf{Reps}_{\mathsf{cov}}: d(v,S)\leq 1} \alpha|\mathsf{Chld}(v)| = \alpha \sum_{v\in R(S)} |\mathsf{Chld}(v)| \leq \alpha(m-1) < m$$

That is, $\lambda(v)$'s satisfy (V1). Now we prove (V2) is not satisfied thus it can be used to separate cov from $\mathcal{P}^{\mathcal{J}}_{\mathsf{cov}}$.

$$\begin{aligned} \sum_{v\in C} \lambda(v)\mathsf{cov}(v) = \quad & \alpha \sum_{v\in \mathsf{Reps}_{\mathsf{cov}}} |\mathsf{Chld}(v)|\mathsf{cov}(v) \quad = \quad \alpha \sum_{v\in \mathsf{Reps}_{\mathsf{cov}}} \sum_{u\in \mathsf{Chld}(v)} \mathsf{cov}(v) \\ \geq_{\text{Fact 7}} \quad & \alpha \sum_{v\in \mathsf{Reps}_{\mathsf{cov}}} \sum_{u\in \mathsf{Chld}(v)} \mathsf{cov}(u) \quad =_{\text{Fact 6}} \quad \alpha \sum_{v\in C} \mathsf{cov}(v) \geq \alpha m > m \end{aligned}$$

◀

Proof of Theorem 4. Given the guess $\widehat{\mathsf{opt}}$ which is scaled to 1, we use the ellipsoid algorithm to check if $\mathcal{P}^{\mathcal{J}}_{\mathsf{cov}}$ is empty or not. Whenever ellipsoid asks if a given cov is in $\mathcal{P}^{\mathcal{J}}_{\mathsf{cov}}$ or not, run Algorithm 1 for this given cov to construct the corresponding $\mathcal{F}$-PCM instance $\mathcal{J}$ and use algorithm $\mathcal{A}$, promised in the statement of Theorem 4, to solve it. If $\mathsf{opt}(\mathcal{J}) \geq m$, then Lemma 14 implies that we have a 3-approximate solution. Otherwise, cov is not valuable, and we can use Lemma 16 to find a separating hyperplane. In polynomial time, either we get a $\mathsf{cov} \in \mathcal{P}^{\mathcal{J}}_{\mathsf{cov}}$ which by Lemma 16 has to be valuable, or we prove $\mathcal{P}^{\mathcal{J}}_{\mathsf{cov}}$ is empty and we modify our $\widehat{\mathsf{opt}}$ guess. For the correct guess, the latter case won't occur and we get a 3-approximate solution. ◀

4 Applications and Extensions

In this section we elaborate on the applications and extensions stated in the Introduction. We begin with looking at specific instances of $\mathcal{F}$ which have been studied in the literature, and some which have not.

Single and Multiple Knapsack Constraints. We look at

$$\mathcal{F}_{\mathsf{KN}} := \{S \subseteq F : \text{ for } i = 1, \ldots, d, \sum_{v\in S} w_i(v) \leq k_i\}$$

where there are d weight functions over F and k_i's are upper bounds on these weights. Of special interest is the case $d = 1$ in which we get the robust knapsack supplier problem also called the weighted k-supplier problem with outliers.

The $\mathcal{F}$-PCM problem for the above $\mathcal{F}_{\mathsf{KN}}$ has the following complexity: When $d = 1$, the problem can be solved in polynomial time. Indeed, given a partition $\mathcal{P}$, since $\mathsf{val}(u) = \mathsf{val}(v)$ for all v in the same part, any solution which picks a facility from a part $A \in \mathcal{P}$ may as well pick the one with the smallest weight in that part. Thus, the problem boils down to the usual knapsack problem in which we have $|\mathcal{P}|$ items where the item corresponding to part $A \in \mathcal{P}$ has weight $\min_{v \in A} w(v)$ and value $\mathsf{val}(v)$. Since the values are poly-bounded, this problem is solvable in polynomial time. Thus, we get the following corollary to Theorem 4 resolving the open question raised in [10] and [15].

▶ **Theorem 17.** *There is a polynomial time* 3*-approximation to the robust knapsack center problem.*

When $d > 1$, then the $\mathcal{F}$-PCM problem is NP-hard even when val is poly-bounded. However, if the w_i's are also poly-bounded (actually one of them can be general), then the $\mathcal{F}$-PCM problem can be solved in polynomial time using dynamic programming. This problem was in fact studied in [17] (the conference version) and is called the *suitcase* problem there. Thus, we get the following corollary to Theorem 4 extending the result in [17].

▶ **Theorem 18.** *There is a polynomial time* 3*-approximation to the robust multiple-knapsack center problem if the number of weights is a constant and all but possibly one weight function are poly-bounded.*

Single and Multiple Matroid Constraints. We look at

$$\mathcal{F}_{\mathsf{Mat}} := \{S \subseteq F : S \in \mathcal{I}_{M_i},\ \forall i = 1, \ldots, d\}$$

When $d = 1$, we get the robust matroid center problem. The $\mathcal{F}$-PCM paper reduces to finding a maximum value set in $\mathcal{I}_M$ and a partition matroid induced by $\mathcal{P}$. This is solvable in polynomial time even when val is general and not poly-bounded, and even when $\mathcal{I}_M$ is given as an independent set oracle. Thus, we get the following corollary to Theorem 4 obtaining the result in [15].

▶ **Theorem 19.** *[Theorem 1.1 in [15]] There is a polynomial time* 3*-approximation to the robust matroid center problem even when the matroid is described as an independent set oracle.*

When there are $d > 1$ matroids, then the $\mathcal{F}$-PCM problem is NP-hard. Therefore, Theorem 5 implies that for instance, we can have *no* unicriteria approximation for the robust matroid-intersection center problem.

Single Knapsack and Single Matroid Constraint. We look at

$$\mathcal{F}_{\mathsf{KN} \cap \mathsf{Mat}} := \{S \subseteq F : \sum_{v \in S} w(v) \leq k, \quad S \in \mathcal{I}_M\}$$

which is the intersection of a single matroid and a single knapsack constraint. To the best of our knowledge, the resulting Robust $\mathcal{F}$-Supplier problem has not been studied before. One natural instantiation is when F is a collection of high-dimensional vectors with weights and the constraint on the centers is to pick a linearly independent set with total weight at most k.

The corresponding $\mathcal{F}$-PCM problem asks us, given a partition $\mathcal{P}$ and poly-bounded values val, to find a set $S \in \mathcal{I}_{\mathcal{M}} \cap \mathcal{I}_{\mathcal{P}}$ of maximum value such that $w(S) \leq k$, where $\mathcal{I}_{\mathcal{P}}$ is the partition matroid induced by $\mathcal{P}$. We don't know if this problem can be solved in polynomial time, even in the case when M is another partition matroid.

However, the above problem is related to the *exact matroid intersection* problem. In this problem, we are given two matroids $\mathcal{M}$ and $\mathcal{P}$, and a weight function $\mathbf{w}$ on each ground element and a budget $\mathbf{W}$. The objective is to decide whether or not there is a set $S \in \mathcal{I}_{\mathcal{M}} \cap \mathcal{I}_P$ such that $\mathbf{w}(S) = \mathbf{W}$. Understanding the complexity of this problem is a long standing challenge [4, 21, 22]. When the matroids are representable over the same field, then [4] gives a randomized pseudopolynomial time algorithm for the problem. The following claim shows the relation between $\mathcal{F}$-PCM and the exact matroid intersection problem; this claim is essentially present in [3] and the reader can refer to the full version of our paper for the proof.

▶ **Claim 20.** *Given an algorithm for the exact matroid intersection problem, one can solve the $\mathcal{F}$-PCM problem in polynomial time when the weights w are poly-bounded.*

Armed with the non-trivial result about exact matroid intersection from [4], we get the following.

▶ **Theorem 21.** *Given a linear matroid $\mathcal{M}$ and a poly-bounded weight function, there is a randomized polynomial time 3-approximation to the robust knapsack-and-matroid center problem.*

4.1 The Case of No Outliers

The $\mathcal{F}$-supplier problem, that is the case of $m = |C|$, may be of special interest. In this case the problem is easier and the complexity is defined by the complexity of the following decision problem.

▶ **Definition 22** ($\mathcal{F}$-PCF problem)**.** The input is $\mathcal{J} = (F, \mathcal{F}, \mathcal{P})$ where F is a finite set, $\mathcal{F} \subseteq 2^F$ is a down-closed family and $\mathcal{P} \subseteq 2^F$ is an arbitrary sub-partition of F. The objective is to decide whether there *exists* a set $S \in \mathcal{F}$ such that $|S \cap A| = 1, \quad \forall A \in \mathcal{P}$.

▶ **Theorem 23.** *If the $\mathcal{F}$-PCF problem can be solved efficiently for any partition $\mathcal{P}$, then the $\mathcal{F}$-supplier problem has a polynomial time 3-approximation. Otherwise, there is no non-trivial approximation possible for the $\mathcal{F}$-supplier problem.*

Sketch. Run Algorithm 1 with an arbitrary assignment cov (and ignore the val's). Let $\mathcal{J} = (F, \mathcal{F}, \mathcal{P})$ be the resulting $\mathcal{F}$-PCF instance. If the guess $\widehat{\mathsf{opt}} = 1$ is correct, then note that the optimum solution S^* must satisfy $S^* \cap A \neq \emptyset$ for all $A \in \mathcal{P}$; if not, then the corresponding $v \in \mathsf{Reps}_{\mathsf{cov}}$ can't be served. Conversely, any S satisfying $S \cap A \neq \emptyset$ for all $A \in \mathcal{P}$ implies a 3-approximate solution. Therefore, an algorithm for $\mathcal{F}$-PCF can either give a 3-approximate solution or prove the guess $\widehat{\mathsf{opt}}$ is too low. ◀

Theorem 4 and Theorem 23 raise the question: is there any set of constraints for which the problem without outliers is significantly easier than the problem with outliers? We don't know the answer to this question, although we guess the answer is yes. For this, it suffices to design a set system for which $\mathcal{F}$-PCF is easy but $\mathcal{F}$-PCM is hard (perhaps NP-hard). To see the difference between these problems consider the $\mathcal{F}_{\mathsf{KN} \cap \mathsf{Mat}}$ family described in the previous subsection. We don't know if $\mathcal{F}$-PCM is easy or hard, but $\mathcal{F}$-PCF is easy: this amounts to minimizing $w(S)$ over $S \in \mathcal{I}_{\mathcal{M}} \cap \mathcal{B}_{\mathcal{P}}$ where $\mathcal{B}_{\mathcal{P}}$ is the base polytope induced by $\mathcal{P}$. This can be done in polynomial time, and therefore we get the following corollary.

▶ **Theorem 24.** *There is a polynomial time* 3*-approximation to the knapsack-and-matroid center problem.*

4.2 Handling Approximation

The technique used to prove Theorem 4 is robust enough to translate approximation algorithms for the $\mathcal{F}$-PCM problem to *bi-criteria* approximation algorithms for the Robust $\mathcal{F}$-Supplier problem. There are two notions of approximation algorithms for the $\mathcal{F}$-PCM problem and they lead to two notions of bi-criteria approximation.

The first is the standard notion: a ρ-approximation (for $\rho \leq 1$) algorithm that takes instance $\mathcal{J}$ of $\mathcal{F}$-PCM, returns a solution $S \in \mathcal{F}$ of value $\mathsf{val}(S) \geq \rho \cdot \mathsf{opt}(\mathcal{J})$. The corresponding bi-criteria approximation notion for the Robust $\mathcal{F}$-Supplier problem is the following: an (α, β)-approximation algorithm for instance $\mathcal{I}$ of Robust $\mathcal{F}$-Supplier returns a solution which opens centers at $S \in \mathcal{F}$ and the distance of at least βm customers to S is $\leq \alpha \cdot \mathsf{opt}(\mathcal{I})$. The proof of Theorem 4 in fact implies the following.

▶ **Theorem 25.** *Let $\mathcal{A}$ be a polynomial time ρ-approximate algorithm for the $\mathcal{F}$-PCM problem. Then there is a polynomial time $(3, \rho)$-bi-criteria approximation algorithm for the Robust $\mathcal{F}$-Supplier problem.*

The second notion of approximation for the $\mathcal{F}$-PCM problem is one which satisfies the constraints approximately. This notion is more problem dependent and makes sense only if there is a notion of an approximate relaxation $\mathcal{F}^R$ for the set $\mathcal{F}$. For example, an $(1+\varepsilon)$-relaxation for $\mathcal{F}_{\mathsf{KN}}$ could be the subsets S with $w_i(S) \leq (1+\varepsilon) \cdot k_i$ for all i. A ρ-violating algorithm for an instance $\mathcal{J}$ of $\mathcal{F}$-PCM would then return a set S with $\mathsf{val}(S) \geq \mathsf{opt}(\mathcal{J})$ but $S \in \mathcal{F}^R$ which is an ρ-relaxation for $\mathcal{F}$. This defines a different bi-criteria approximation notion for the Robust $\mathcal{F}$-Supplier problem. An α-approximate β-violating algorithm for the Robust $\mathcal{F}$-Supplier problem takes an instance $\mathcal{I}$ and returns a solution $S \in \mathcal{F}^R$ which is a β-relaxation for $\mathcal{F}$ such that at least m customers in C are at distance at most $\alpha \cdot \mathsf{opt}(\mathcal{I})$ to S.

▶ **Theorem 26.** *Let $\mathcal{A}$ be a polynomial time ρ-violating algorithm for the $\mathcal{F}$-PCM problem. Then there is a polynomial time* 3*-approximate-ρ-violating algorithm for the Robust $\mathcal{F}$-Supplier problem.*

When $\mathcal{F}$ is described by constant d knapsack constraints (with general weights) and a single matroid constraint, for any constant $\varepsilon > 0$ Chekuri *et al.* give an $(1+\varepsilon)$-approximation algorithm for the $\mathcal{F}$-PCM in [9]. Without the matroid constraint, Grandoni *et al.* give an $(1+\varepsilon)$-violating algorithm in [12]. Together, we get the following corollary. The latter recovers a result from [10].

▶ **Theorem 27.** *Fix any constant $\varepsilon > 0$. There is a polynomial time $(3, (1+\varepsilon))$-bi-criteria approximation algorithm for the robust supplier problem with constant many knapsack constraints and one matroid constraint. There is a polynomial time* 3*-approximate $(1+\varepsilon)$-violating algorithm for the robust supplier problem with constant many knapsack constraints.*

Abstract

In this work, we present a collection of new results on two fundamental problems in geometric data structures: *orthogonal point location* and *rectangle stabbing*.

- **Orthogonal point location.** We give the first linear-space data structure that supports 3-d point location queries on n disjoint axis-aligned boxes with *optimal* $O(\log n)$ query time in the (arithmetic) pointer machine model. This improves the previous $O\left(\log^{3/2} n\right)$ bound of Rahul [SODA 2015]. We similarly obtain the first linear-space data structure in the I/O model with optimal query cost, and also the first linear-space data structure in the word RAM model with sub-logarithmic query time.
- **Rectangle stabbing.** We give the first linear-space data structure that supports 3-d 4-sided and 5-sided rectangle stabbing queries in *optimal* $O(\log_w n + k)$ time in the word RAM model. We similarly obtain the first optimal data structure for the closely related problem of 2-d top-k rectangle stabbing in the word RAM model, and also improved results for 3-d 6-sided rectangle stabbing.

For point location, our solution is simpler than previous methods, and is based on an interesting variant of the van Emde Boas recursion, applied in a round-robin fashion over the dimensions, combined with bit-packing techniques. For rectangle stabbing, our solution is a variant of Alstrup, Brodal, and Rauhe's grid-based recursive technique (FOCS 2000), combined with a number of new ideas.

1 Introduction

In this work we present a plethora of new results on two fundamental problems in geometric data structures: (a) *orthogonal point location* (where the input rectangle or boxes are non-overlapping), and (b) *rectangle stabbing* (where the input rectangles or boxes are overlapping).

1.1 Orthogonal point location

Point location is among the most central problems in the field of computational geometry, which is covered in textbooks and has countless applications. In this paper we study the *orthogonal point location* problem. Formally, we want to preprocess a set of n *disjoint* axis-aligned boxes (hyperrectangles) in $\mathbb{R}^d$ into a data structure, so that the box in the set containing a given query point (if any) can be reported efficiently. There are two natural versions of this problem, for (a) *arbitrary disjoint boxes* where the input boxes need not fill the entire space, and (b) a *subdivision* where the input boxes fill the entire space.

Arbitrary disjoint boxes. Historically, the point location problem has been studied in the pointer machine model and the main question has been the following:

"Is there a linear-space structure with $O(\log n)$ query time?"

In 2-d this question has been successfully resolved: there exists a linear-space structure with $O(\log n)$ query time [19, 18, 14, 27, 30] (actually this result holds for nonorthogonal point location). In 3-d there has been work on this problem [15, 17, 2, 23], but the question has not yet been resolved. The currently best known result on the pointer machine model is a linear-space structure with $O(\log^{3/2} n)$ query time by Rahul [23]. In this paper,

- we obtain the first linear-space structure with $O(\log n)$ query time for 3-d orthogonal point location for arbitrary disjoint boxes. The structure works in the (arithmetic) pointer machine model and is *optimal* in this model.

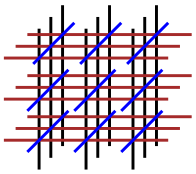
The orthogonal point location problem has been studied in the I/O-model and the word RAM as well (please see the full version for a brief description of these models). In the I/O model, an optimal solution is known in 2-d [16, 6]: a linear-space structure with $O(\log_B n)$ query time, where B is the block size (this result holds for nonorthogonal point location). However, in 3-d the best known result is a linear-space structure with a query cost of $O(\log_B^2 n)$ I/Os by Nekrich [20] (for orthogonal point location for disjoint boxes).

- In the I/O model, we obtain the first linear-space structure with $O(\log_B n)$ query cost for 3-d orthogonal point location for arbitrary disjoint boxes. This result is *optimal*.

In the word RAM model, an optimal solution in 2-d was given by Chan [10] with a query time of $O(\log\log U)$, assuming that input coordinates are in $[U] = \{0, 1, \ldots, U-1\}$. However, in 3-d the best known result for arbitrary disjoint boxes is a linear-space structure with $O(\log n \log\log n)$ query time: this result was not stated explicitly before but can obtained by an interval tree augmented with Chan's 2-d orthogonal point location structure [10] at each node. Our above new result with logarithmic query time is already an improvement even in the word RAM, but we can do slightly better still:

- In the w-bit word RAM model, we obtain the first linear-space structure with *sub-logarithmic* query time for 3-d orthogonal point location for arbitrary disjoint boxes. The time bound is $O(\log_w n)$. (We do not know whether this result is optimal, however.)

Subdivisions. In the plane, the two versions of the problem are equivalent in the sense that any arbitrary set of n disjoint rectangles can be converted into a subdivision of $\Theta(n)$ rectangles via the vertical decomposition. In 3-d, the two versions are no longer equivalent, since there exist sets of n disjoint boxes that need $\Omega\left(n^{3/2}\right)$ boxes to fill the entire space. See figure on the right.



In 3-d the special case of a subdivision is potentially easier than the arbitrary disjoint boxes setting, as the former allows for a fast $O(\log^2 \log U)$ query time in the word RAM model with $O(n \log \log U)$ space, as shown by de Berg, van Kreveld, and Snoeyink [13] (with an improvement by Chan [10]).

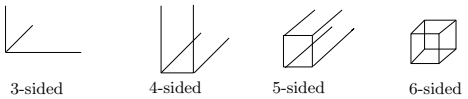
- In the word RAM model, we further improve de Berg, van Kreveld, and Snoeyink's method to achieve a *linear*-space structure with $O(\log^2 \log U)$ query time for 3-d orthogonal point location on subdivisions.

1.2 Rectangle stabbing

Rectangle stabbing is a classical problem in geometric data structures [1, 3, 7, 12, 23], which is as old, and as equally natural, as orthogonal range searching—in fact, it can be viewed as an "inverse" of orthogonal range searching, where the input objects are boxes and query objects are points, instead of vice versa. Formally, we want to preprocess a set S of n axis-aligned boxes (possibly overlapping) in $\mathbb{R}^d$ into a data structure, so that the boxes in S containing a given query point q can be reported efficiently. (As one of many possible applications, imagine a dating website, where each lady is interested in gentlemen whose salary is in a range $[S_1,S_2]$ and age is in a range $[A_1,A_2]$; suppose that a gentleman with salary x_q and age y_q wants to identify all ladies who might be potentially interested in him.)

Throughout this paper, we will assume that the endpoints of the rectangles lie on the grid $[2n]^3$ (this can be achieved via a simple rank-space reduction). In the word RAM model, Pătraşcu [21] gave a lower bound of $\Omega(\log_w n)$ query time for any data structure which occupies at most $n \log^{O(1)} n$ space to answer the 2-d rectangle stabbing query. Shi and Jaja [29] presented an optimal solution in 2-d which occupies linear space with $O(\log_w n + k)$ query time, where k is the number of rectangles reported.

We introduce some notation to define various types of rectangles in 3-d. (We will use the terms "rectangle" and "box" interchangably throughout the paper.) A rectangle in 3-d is called $(3+t)$-*sided* if it is bounded in t out of the 3 dimensions and unbounded (on one side) in the remaining $3-t$ dimensions.



In the word RAM model, an optimal solution in 3-d is known *only* for the 3-sided rectangle stabbing query: a linear-space structure with $O(\log \log_w n + k)$ query time (by combining the work of Afshani [1] and Chan [10]; this is optimal due to the lower bound of Pătraşcu and Thorup [22]). Finding an optimal solution for 4-, 5-, and 6-sided rectangle stabbing has remained open.

3-d 4- and 5-sided rectangle stabbing. Currently, the best-known result for 4-sided and 5-sided rectangle stabbing queries by Rahul [23] occupies $O(n \log^* n)$ space with $O(\log n + k)$ and $O(\log n \log \log n + k)$ query time, respectively. This result holds in the pointer machine model. For 4-sided rectangle stabbing, adapting Rahul's solution to the word RAM model does not lead to any improvement in the query time (the bottleneck is in answering $\log n$

3-d dominance reporting queries). For 5-sided rectangle stabbing, even if we assume the existence of an optimal 4-sided rectangle stabbing structure, plugging it into Rahul's solution can improve the query time to only $O(\log n + k)$, which is still suboptimal. In this paper,

- we obtain the first *optimal* solution for 3-d 4-sided and 5-sided rectangle stabbing in the word RAM model: a linear-space structure with $O(\log_w n + k)$ query time.

2-d top-k rectangle stabbing. Recently, there has been a lot of interest in top-k range searching [4, 8, 9, 24, 25, 26, 28, 31]. Specifically, in the 2-d top-k rectangle stabbing problem, we want to preprocess a set of *weighted* axis-aligned rectangles in 2-d, so that given a query point q and an integer k, the goal is to report the k largest-weight rectangles containing (or stabbed by) q. This problem is closely related to the 5-sided rectangle stabbing problem (by treating the weight as a third dimension, a rectangle r with weight $w(r)$ can be mapped to a 5-sided rectangle $r \times (-\infty, w(r)]$).

- By extending the solution for 3-d 5-sided rectangle stabbing problem, we obtain the first *optimal* solution for the 2-d top-k rectangle stabbing problem: a linear-space structure with $O(\log_w n + k)$ query time.

3-d 6-sided rectangle stabbing. Our new solution to 3-d 5-sided rectangle stabbing, combined with standard interval trees, immediately implies a solution to 3-d 6-sided rectangle stabbing with a query time of $O(\log_w n \cdot \log n + k)$, which is already new. But we can do slightly better still:

- We obtain a linear-space structure with $O(\log_w^2 n + k)$ query time for 3-d 6-sided rectangle stabbing problem in the word RAM model. We conjecture this to be optimal (the analogy is the lower bound of $\Omega(\log^2 n + k)$ query time for linear-space pointer machine structures [3]).

Back to orthogonal point location. Our solution for orthogonal point location uses rectangle stabbing as a subroutine: if there is an $S(n)$-space data structure with $Q(n) + O(k)$ query time to answer the rectangle stabbing problem in $\Re^d$, then one can obtain a data structure for orthogonal point location in $\Re^{d+1}$ with $O(S(n))$-space and $O(Q(n))$ time. By plugging in our new results for 3-d 6-sided rectangle stabbing, we obtain a linear-space word RAM structure which can answer any orthogonal point location query in 4-d in $O(\log_w^2 n)$ time, improving the previously known $O(\log^2 n \log\log n)$ bound [10].

1.3 Our techniques

Our results are obtained using a number of new ideas (in addition to existing data structuring techniques), which we feel are as interesting as the results themselves.

3-d orthogonal point location. To better appreciate our new 3-d orthogonal point location method, we first recall that the current best word-RAM method had $O(\log n \log\log n)$ query time, and was obtained by building an interval tree over the x-coordinates, and at each node of the tree, storing Chan's 2-d point location data structure on the yz-projection of the rectangles. Interval trees caused the query time to increase by a logarithmic factor, while Chan's 2-d structures achieved $O(\log\log n)$ query time via a complicated van-Emde-Boas-like

recursion. We can thus summarize this approach loosely by the following recurrence for the query time (superscripts refer to the dimension):

$$Q^{(3)}(n) = O(Q^{(2)}(n)\log n) \text{ and } Q^{(2)}(n) = Q^{(2)}(\sqrt{n}) + O(1)$$
$$\implies Q^{(3)}(n) = O(\log n \log\log n).$$

(Note that naively increasing the fan-out of the interval tree could reduce the query time but would blow up the space usage.)

In the pointer machine model, the current best data structure by Rahul [23], with $O(\log^{3/2} n)$ query time, required an even more complicated combination of interval trees, Clarkson and Shor's random sampling technique, 3-d rectangle stabbing, and 2-d orthogonal point location.

To avoid the extra $\log\log n$ factor, we cannot afford to use Chan's 2-d orthogonal point location structure as a subroutine; and we cannot work with just yz-projections, which intuitively cause loss of efficiency. Instead, we propose a more direct solution based on a new van-Emde-Boas-like recursion, aiming for a new recurrence of the form

$$Q^{(3)}(n) = Q^{(3)}(\sqrt{n}) + O(\log n).$$

The $O(\log n)$ term arises from the need to solve 2-d rectangle stabbing subproblems, on projections along all three directions (the yz-, xz-, and xy-plane), applied in a *round-robin* fashion. The new recurrence then solves to $O(\log n)$—notice how $\log\log$ disappears, unlike the usual van Emde Boas recursion! In the word RAM model, we can even use known sub-logarithmic solutions to 2-d rectangle stabbing to get $O(\log_w n)$ query time.

We emphasize that our new method is much *simpler* than the previous, slower methods, and is essentially self-contained except for the use of a known data structure for 2-d rectangle stabbing emptiness (which reduces to standard 2-d orthogonal range counting).

One remaining issue is space. In our new method, a rectangle is stored $O(\log\log n)$ times, due to the depth of the recursion. To achieve linear space, we need another idea, namely, *bit-packing* tricks, to compress the data structure. Because of the rapid reduction of the universe size in the round-robin van-Emde-Boas recursion, the amortized space in words per input box satisfies a recurrence of the form

$$s(n) = s(\sqrt{n}) + O\left(\frac{\log n}{w}\right) \implies s(n) = O\left(\frac{\log n}{w}\right) = O(1).$$

Our new result on the subdivision case is obtained by a similar space-reduction trick.

3-d 5-sided rectangle stabbing. For 3-d rectangle stabbing, the previous solution by Rahul [23] was based on a grid-based, $\sqrt{n}$-way recursive approach of Alstrup, Brodal, and Rauhe [5], originally designed for 2-d orthogonal range searching. The fact that the approach can be adapted here is nontrivial and interesting, since our input objects are now more complicated (rectangles instead of points) and the target query time is quite different (near logarithmic rather than $\log\log$). More specifically, Rahul first solved the 4-sided case via a complicated data structure, and then applied Alstrup et al.'s technique to reduce 5-sided rectangles to 4-sided rectangles, which led to a query-time recurrence similar to the following (subscripts denote the number of sides, and output cost related to k is ignored):

$$Q_4(n) = O(\log n) \text{ and } Q_5(n) = 2Q_5(\sqrt{n}) + O(Q_4(n)) \implies Q_5(n) = O(\log n \log\log n).$$

Intuitively, the reduction from the 5-sided to the 4-sided case causes loss of efficiency. To avoid the extra $\log\log n$ factor, we propose a new method that is also based on Alstrup *et*

al.'s recursive technique, but reduces 5-sided rectangles directly to 3-sided rectangles, aiming for a new recurrence of the form

$$Q_3(n) = O(\log\log_w n) \text{ and } Q_5(n) = 2Q_5(\sqrt{n}) + O(Q_3(n)).$$

During recursion, we do not put 4-sided rectangles in separate structures (which would slow down querying), but instead use a common tree for both 4-sided and 5-sided rectangles. The new recurrence then solves to $Q_5(n) = O(\log_w n)$ with an appropriate base case—notice how $\log\log$ again disappears, and notice how this gives a new result even for the 4-sided case!

One remaining issue is space. Again, we can compress the data structure by incorporating bit-packing tricks (which was also used in Alstrup *et al.*'s original method). For 4- and 5-sided rectangle stabbing, the space recurrence then solves to linear.

However, with space compression, a new issue arises. The cost of reporting each output rectangle in a query increases to $O(\log\log n)$ (the depth of the recursion), because of the need to *decode* the coordinates of a compressed rectangle. In other words, the query cost becomes $O(\log_w n + k\log\log n)$ instead of $O(\log_w n + k)$. This extra decoding overhead also occurred in previous work on 2-d orthogonal range searching by Alstrup *et al.* [5] and Chan *et al.* [11], and it is open how to avoid the overhead for that problem without sacrificing space (this is related to the so-called *ball inheritance problem* [11]).

We observe that for the 4- and 5-sided rectangle stabbing problem, a surprisingly simple idea suffices to avoid the overhead: instead of keeping pointers between consecutive levels of the recursion tree, we just keep pointers directly from each level to the *leaf* level.

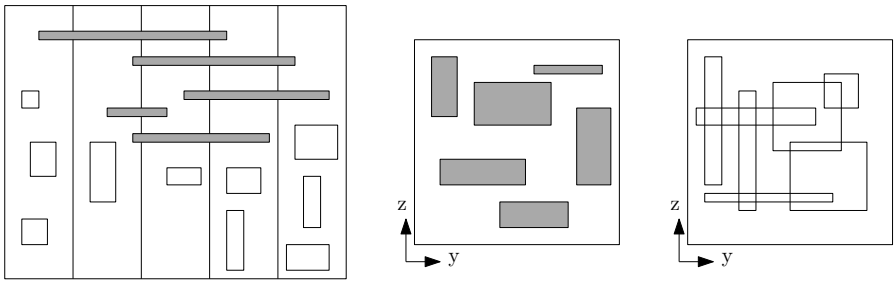
3-d 6-sided rectangle stabbing. We can solve 6-sided rectangle stabbing by using our result for 5-sided rectangle stabbing as a subroutine. However, the naive reduction via interval trees increases the query time by a $\log n$ factor instead of $\log_w n$. To speed up querying, the standard idea is to use a tree with a larger fan-out w^ε. This leads to various colored generalizations of 2-d rectangle stabbing with a small number w^ε of colors. Much of our ideas can be extended to solve these colored subproblems in a straightforward way, but a key subproblem, of answering colored 2-d dominance searching queries in $O(\log\log_w n + k)$ time with linear space, is nontrivial. We solve this key subproblem via a clever use of 2-d shallow cuttings, combined with a grouping trick, which may be of independent interest.

2 Orthogonal Point Location in 3-d

Preliminaries. Our solution to 3-d orthogonal point location will require known data structures for *2-d orthogonal point location* and *2-d rectangle stabbing emptiness*. The proofs are presented in the full version.

▶ **Lemma 1.** *Given n disjoint axis-aligned rectangles in $[U]^2$ ($n \le U \le 2^w$), there are data structures for point location with $O\left(\frac{n\log U}{w}\right)$ words of space and $O(\log n)$ query time in the pointer machine model, $O(\log_B n)$ query cost in the I/O model, and $O(\min\{\log\log U, \log_w n\})$ query time in the word RAM model.*

▶ **Lemma 2.** *Given n (possibly overlapping) axis-aligned rectangles in $[U]^2$ ($n \le U \le 2^w$), there are data structures for rectangle stabbing emptiness with $O\left(\frac{n\log U}{w}\right)$ words of space and $O(\log n)$ query time in the pointer machine model, $O(\log_B n)$ query cost in the I/O model, and $O(\log_w n)$ query time in the word RAM model.*



$\sqrt{U}$ slabs along x-axis (a) Left/right boxes of a slab (b) Short boxes of a slab (c)

Figure 1 Boxes obtained after partitioning along the x-direction.

Data structure. We are now ready to describe our data structure for 3-d orthogonal point location. We focus on the pointer machine model first. At the beginning, we apply a rank space reduction (replacing input coordinates by their ranks) so that all coordinates are in $[2n]^3$, where n is the global number of input boxes. Given a query point, we can initially find the ranks of its coordinates by three predecessor searches (costing $O(\log n)$ time in the pointer machine model).

We describe our preprocessing algorithm recursively. The input to the preprocessing algorithm is a set of n disjoint boxes that are assumed to be aligned to the $[U_x] \times [U_y] \times [U_z]$ grid. (At the beginning, $U_x = U_y = U_z = 2n$.)

Without loss of generality, assume that $U_x \geq U_y, U_z$. We partition the $[U_x] \times [U_y] \times [U_z]$ grid into $\sqrt{U_x}$ equal-sized vertical slabs perpendicular to the x-direction. See Figure 1. (In the symmetric case $U_y \geq U_x, U_z$ or $U_z \geq U_x, U_y$, we partition along the y- or z-direction instead.) We classify the boxes into two categories:

- *Short boxes.* For each slab, define its short boxes to be those that lie completely inside the slab.
- *Long boxes.* Long boxes intersect the boundary (vertical plane) of at least one slab. Each long box $\mathcal{B}$ is broken into three disjoint boxes:
  - *Left box.* Let s_L be the slab containing the left endpoint (with respect to the x-axis) of $\mathcal{B}$. The left box is defined as $\mathcal{B} \cap s_L$.
  - *Right box.* Let s_R be the slab containing the right endpoint of $\mathcal{B}$. The right box is defined as $\mathcal{B} \cap s_R$.
  - *Middle box.* The remaining portion of box $\mathcal{B}$ after removing its left and right box, i.e. $\mathcal{B} \setminus ((\mathcal{B} \cap s_L) \cup (\mathcal{B} \cap s_R))$.

We build our data structure as follows:

1. *Planar point location structure.* For each slab, we project its left boxes onto the yz-plane. The projected boxes remain disjoint, since they intersect a common boundary. We store them in a data structure for 2-d orthogonal point location by Lemma 1. We do this for the slab's right boxes as well.
2. *Rectangle stabbing structure.* For each slab, we project its short boxes onto the yz-plane. The short boxes are not necessarily disjoint. We store them in a data structure for 2-d rectangle stabbing emptiness by Lemma 2.
3. *Recursive middle structure.* We recursively build a *middle structure* on all the middle boxes.
4. *Recursive short structures.* For each slab, we recursively build a *short structure* on all the short boxes inside the slab.

By translation or scaling, these recursive short structures or middle structure can be made aligned to the $\left[\sqrt{U_x}\right] \times [U_y] \times [U_z]$ grid. In addition, we store the mapping from left/right/middle boxes to their original boxes, as a list of pairs (sorted lexicographically) packed in $O\left(\frac{n \log(U_x U_y U_z)}{w}\right)$ words.

Query algorithm. The following lemma is crucial for deciding whether to query recursively the middle or the short structure.

▶ **Lemma 3.** *Given a query point (q_x, q_y, q_z), if the query with (q_y, q_z) on the rectangle stabbing emptiness structure of the slab that contains q_x returns*

- NON-EMPTY*, then the query point cannot lie inside a box stored in the middle structure, or*
- EMPTY*, then the query point cannot lie inside a box stored in the slab's short structure.*

Proof. If NON-EMPTY is returned, then the query point is stabbed by the extension (along the x-direction) of a box in the slab's short structure and cannot be stabbed by any box stored in the middle structure, because of disjointness of the input boxes. If EMPTY is returned, then obviously the query point cannot lie inside a box stored in the short structure. ◀

To answer a query for a given point (q_x, q_y, q_z), we proceed as follows:

1. Find the slab that contains q_x by predecessor search over the slab boundaries.
2. Query with (q_y, q_z) the planar point location structures at this slab. If a left or a right box returned by the query contains the query point, then we are done.
3. Query with (q_y, q_z) the rectangle stabbing emptiness structure at this slab. If it returns NON-EMPTY, query recursively the slab's short structure, else query recursively the middle structure (after appropriate translation/scaling of the query point).

In step 3, to decode the coordinates of the output box, we need to map from a left/right/middle box to its original box; this can be done naively by another predecessor search in the list of pairs we have stored.

Query time analysis. Let $Q(U_x, U_y, U_z)$ denote the query time for our data structure in the $[U_x] \times [U_y] \times [U_z]$ grid. Observe that the number of boxes n is trivially upper-bounded by $U_x U_y U_z$ because of disjointness. The predecessor search in step 1, the 2-d point location query in step 2, and the 2-d rectangle stabbing query in step 3 all take $O(\log n) = O(\log(U_x U_y U_z))$ time by Lemmata 1 and 2. We thus obtain the following recurrence, assuming that $U_x \geq U_y, U_z$:

$$Q(U_x, U_y, U_z) = Q\left(\sqrt{U_x}, U_y, U_z\right) + O\left(\log\left(U_x U_y U_z\right)\right).$$

If $U_x = U_y = U_z = U$, then three rounds of recursion will partition along the x-, y-, and z-directions and decrease U_x, U_y, and U_z in a round-robin fashion, yielding

$$Q(U, U, U) = Q\left(\sqrt{U}, \sqrt{U}, \sqrt{U}\right) + O(\log U),$$

which solves to $Q(U, U, U) = O(\log U)$. As $U = 2n$ initially, we get $O(\log n)$ query time.

Space analysis. Let $s(U_x, U_y, U_z)$ denote the *amortized* number of words of space needed per input box for our data structure in the $[U_x] \times [U_y] \times [U_z]$ grid. The amortized number of words per input box for the 2-d point location and rectangle stabbing structures is $O\left(\frac{\log(U_x U_y U_z)}{w}\right)$ by Lemmata 1 and 2. We thus obtain the following recurrence, assuming that $U_x \geq U_y, U_z$:

$$s(U_x, U_y, U_z) = s\left(\sqrt{U_x}, U_y, U_z\right) + O\left(\frac{\log(U_x U_y U_z)}{w}\right).$$

Three rounds of recursion yield

$$s(U, U, U) = s\left(\sqrt{U}, \sqrt{U}, \sqrt{U}\right) + O\left(\frac{\log U}{w}\right),$$

which solves to $s(U, U, U) = O\left(\frac{\log U}{w}\right)$. As $U = 2n$ initially, the total space in words is $O\left(n\frac{\log n}{w}\right) \leq O(n)$. Note that the above analysis ignores an overhead of $O(1)$ words of space per node of the recursion tree, but by shortcutting degree-1 nodes, we can bound the number of nodes in the recursion tree by $O(n)$. To summarize, we claim the following results:

▶ **Theorem 4.** *Given n disjoint axis-aligned boxes in 3-d, there are data structures for point location with $O(n)$ words of space and $O(\log n)$ query time in the pointer machine model, $O(\log_B n)$ query cost in the I/O model, and $O(\log_w n)$ query time in the word RAM model.*

Proof. The proof for the I/O model and the word RAM model can be found in the full version. ◀

Further applications of this framework to subdivisions, 4-d and higher dimensions can be found in the full version.

3 Rectangle Stabbing

3.1 Preliminaries

▶ **Lemma 5.** *(Rahul [23]) There is a data structure of size $O(n)$ words which can answer a 5-sided 3-d rectangle stabbing query in $O(\log^2 n \cdot \log\log n + k)$ time.*

▶ **Lemma 6.** *(Leaf structure.) For a set of size $O(w^{1/4})$, there is a data structure of size $O(w^{1/4})$ words which can answer a 5-sided 3-d rectangle stabbing query in $O(1 + k)$ time.*

3.2 3-d 5-sided rectangle stabbing

Skeleton of the structure. Consider the projection of the rectangles of S on to the xy-plane and impose an orthogonal $\left[\!\left[2\sqrt{\frac{n}{\log^4 n}}\right]\!\right] \times \left[\!\left[2\sqrt{\frac{n}{\log^4 n}}\right]\!\right]$ grid such that each horizontal and vertical slab contains the projections of $\sqrt{n \log^4 n}$ sides of S. This grid is the root node of our tree $\mathcal{T}$. For each vertical and horizontal slab, we recurse on the rectangles of S which are *sent* to that slab. At each node of the recursion tree, if we have m rectangles in the subproblem, the grid size changes to $\left[\!\left[2\sqrt{\frac{m}{\log^4 m}}\right]\!\right] \times \left[\!\left[2\sqrt{\frac{m}{\log^4 m}}\right]\!\right]$. We stop the recursion when a node has less than $w^{1/4}$ rectangles.

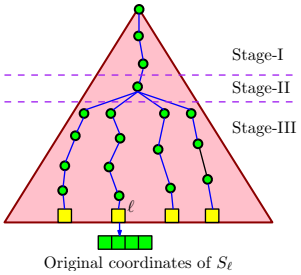


Figure 2

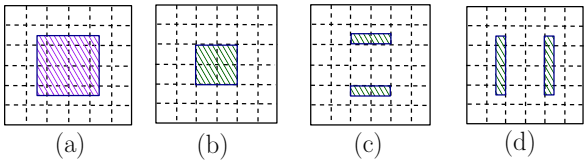

Figure 3

Breaking the rectangles. The solution of Rahul [23] *breaks* only one side to reduce 5-sided rectangles to 4-sided rectangles, and then uses the solution for 4-sided rectangle stabbing as a black box. Unlike the approach of Rahul [23], we will break two sides of each 5-sided rectangle to obtain $O(\log \log n)$ 3-sided rectangles.

For a node in the tree, the intersection of every pair of horizontal and vertical grid line defines a *grid point*. A rectangle $r \in S$ is associated with four root-to-leaf paths (as shown in Figure 2). Any node (say, v) on these four paths is classified w.r.t. r into one of the three stages as follows:

Stage-I. The xy-projection of r intersects none of the grid points. Then r is not stored at v, and sent to the child corresponding to the row or column r lies in.

Stage-II. The xy-projection of r intersects at least one of the grid points. Then r is broken into at most five disjoint pieces. The first piece is a *grid rectangle*, which is the bounding box of all the grid points lying inside r, as shown in Figure 3(b). The remaining four pieces are two *column rectangles* and two *row rectangles* as shown in Figure 3(c) and (d), respectively. The grid rectangle is stored at v. Note that each column rectangle (resp., row rectangle) is now a 4-sided rectangle in $\mathbb{R}^3$ w.r.t. its column (resp., row), and is sent to its corresponding child node.

Stage-III. The xy-projection of a 4-sided piece of r intersects at least one of the grid points. Without loss of generality, assume that the 4-sided rectangle r is unbounded along the negative x-axis. Then the rectangle is broken into at most four disjoint pieces: a *grid rectangle*, two *row rectangles*, and a *column rectangle*, as shown in Figure 4(b), (c) and (d), respectively. The grid rectangle and the two row rectangles are stored at v, and the column rectangle is sent to its corresponding child node. Note that the two row rectangles are now 3-sided rectangles in $\mathbb{R}^3$ w.r.t. their corresponding rows (unbounded in one direction along x-, y- and z-axis).

Encoding structures. Let S_v be the set of rectangles stored at a node v in the tree. We apply a rank space reduction (replacing input coordinates by their ranks) so that the coordinates of all the endpoints are in $[2|S_v|]^3$. If v is a leaf node, then we build an instance of Lemma 6. Otherwise, the following three structures will be built using S_v:

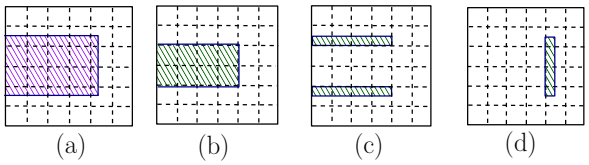

Figure 4

(A) Slow structure. An instance of Lemma 5 is built on S_v to answer the 3-d 5-sided rectangle stabbing query when the output size is "large".
(B) Grid structure. For each cell c of the grid, among the rectangles which completely cover c, pick the $\log^3 |S_v|$ rectangles with the largest span along the z-direction. Store them in a list $Top(c)$ in decreasing order of their span.
(C) 3-d dominance structure. For a given row or column in the grid, based on the 3-sided rectangles stored in it, a linear-space 3-d dominance reporting structure [1, 10] is built. This structure is built for each row and column slab.

Where are the original coordinates stored? Unlike the previous approaches for indexing points [5, 11], we use a somewhat unusual approach for storing the original coordinates of each rectangle. In the process of breaking each 5-sided rectangle described above, there will be four leaf nodes where portions of the rectangle will get stored. We will choose these leaf nodes to store the original coordinates of the rectangle (see Figure 2). The benefit is that each 3-sided rectangle (stored at a node v) has to maintain a decoding pointer of length merely $O(\log |S_v|)$ to point to its original coordinates stored in its subtree.

Query algorithm and analysis. Given a query point q, we start at the root node and perform the following steps: First, query the dominance structure corresponding to the horizontal and the vertical slab containing q. Next, for the grid structure, locate the cell c on the grid containing q. Scan the list $Top(c)$ to keep reporting till (a) all the rectangles have been exhausted, or (b) a rectangle not containing q is found. If case (a) happens and $|Top(c)| = \log^3 |S_v|$, then we discard the rectangles reported till now, and query the slow structure. The decoding pointers will be used to report the original coordinates of the rectangles. Finally, we recurse on the horizontal and the vertical slab containing q. If we visit a leaf node, then we query the leaf structure (Lemma 6).

First, we analyze the space. Let $s(|S_v|)$ be the *amortized* number of bits needed per input 5-sided rectangle in the subtree of a node v. The amortized number of bits needed per rectangle for the encoding structures and the pointers to the original coordinates is $O(\log |S_v|)$. This leads to the following recurrence:

$$s(n) = s(\sqrt{n \log^4 n}) + O(\log n)$$

which solves to $s(n) = O(\log n)$ bits. Therefore, the overall space is bounded by $O(n)$ words.

Next, we analyze the query time. To simplify the analysis, we will exclude the output size term while mentioning the query time. At the root, the time taken to query the grid and the dominance structure is $O(\log \log_w n)$. This leads to the following recurrence:

$$Q(n) = 2Q(\sqrt{n \log^4 n}) + O(\log \log_w n)$$

with a base case of $Q(w^{1/4}) = O(1)$. This solves to $Q(n) = O(\log_w n - \log \log_w n) = O(\log_w n)$. For each reported rectangle it takes constant time to recover its original coordinates. The

time taken to query the slow structure is dominated by the output size. Therefore, the overall query time is $O(\log_w n + k)$.

▶ **Theorem 7.** *There is a data structure of size $O(n)$ words which can answer any 3-d 5-sided rectangle stabbing query in $O(\log_w n + k)$ time. This is optimal in the word RAM model.*

Our solution for 2-d top-k rectangle stabbing can be found in the full version.

3.3 3-d 6-sided rectangle stabbing

The complete discussion on 6-sided rectangle stabbing can be found in the full version. Here we will only highlight the key result.

▶ **Lemma 8.** *There exists an optimal linear-space data structure that answers z-restricted 3-d 4-sided rectangle stabbing queries in $O(\log \log_w n + k)$ time. A z-restricted 4-sided rectangle is of the form $(-\infty, x] \times (-\infty, y] \times [i, j]$, where integers $i, j \in [w^\varepsilon]$ and $\varepsilon = 0.1$.*

Proof. We can safely assume that $n > w^{2\varepsilon} \cdot \log w \log\log n$, because the case of $n < w^{2\varepsilon} \cdot \log w \log\log n = O(w^{1/4})$ can be handled in $O(1+k)$ time by using the structure of Lemma 6. To keep the discussion short, we will assume that $k < \log w \cdot \log\log n$ (handling small values of k is typically more challenging).

Shallow cuttings. A point p_1 is said to *dominate* point p_2 if it has a larger x-coordinate and a larger y-coordinate value. Our main tool to handle this case are *shallow cuttings* which have the following three properties: (a) A t-shallow cutting for a set P of 2-d points is a union of $O(n/t)$ cells where every cell is of the form $[a, +\infty) \times [b, +\infty)$, (b) every point that is dominated by at most t points from P will lie within some cell(s), and (c) each cell contains at most $O(t)$ points of P. A cell $[a, +\infty) \times [b, +\infty)$ can be identified by its corner (a, b). We denote by $Dom(c)$ the set of points that dominate the corner c.

Data structure. We classify rectangles according to their z-projections. The set S_{ij} contains all rectangles of the form $r = (-\infty, x_f] \times (-\infty, y_f] \times [i, j]$. Since $1 \le i \le j \le w^\varepsilon$, there are $O(w^{2\varepsilon})$ sets S_{ij}. Every rectangle r in S_{ij} is associated with a point $p(r) = (x_f, y_f)$. We construct a t-shallow cutting L_{ij} with $t = \log w \cdot \log\log n$ for the set of points $p(r)$, such that $r \in S_{ij}$. A rectangle $r = (-\infty, x_f] \times (-\infty, y_f] \times [i, j]$ is stabbed by a query point $q = (q_x, q_y, q_z)$ if and only if $p(r) \in S_{ij}$ and the point $p(r)$ dominates the 2-d point (q_x, q_y). We can find points of a set S_{ij} that dominate q using the shallow cutting L_{ij}. However, to answer the stabbing query we must simultaneously answer a dominance query on $O(w^{2\varepsilon})$ different sets of points.

We address this problem by *grouping* corners of different shallow cuttings into one structure. Let $\mathcal{C}_{ij}$ denote the set of corners in a shallow cutting L_{ij} and let $\mathcal{C} = \bigcup_{\forall i,j \in [w^\varepsilon]} \mathcal{C}_{ij}$. The set $\mathcal{C}$ is divided into disjoint groups, so that every group G_α consists of $w^{2\varepsilon}$ consecutive corners (with respect to their x-coordinates): for any $c \in G_\alpha$ and $c' \in G_{\alpha+1}$, $c.x < c'.x$. We say that a corner $c \in \mathcal{C}_{ij}$ is immediately to the left of G_α if it is the rightmost corner in $\mathcal{C}_{ij}$ such that $c_x \le c'_x$ for any corner $c' = (c'_x, c'_y)$ in G_α. The set of corners $\overline{G}_\alpha$ contains (1) all corners from G_α, and (2) for every pair i, j such that $1 \le i \le j \le w^\varepsilon$, the corner $c \in \mathcal{C}_{ij}$ immediately to the left of G_α. The set R_α contains all rectangles r such that $p(r) \in Dom(c)$ for each corner $c \in \overline{G}_\alpha$. Since R_α contains $O(w^{2\varepsilon} \log w \cdot \log\log n) = O(w^{1/6})$ rectangles, we can perform a rank-space reduction and answer queries on R_α in $O(k+1)$ time by using Lemma 6.

Next, we will show that the space occupied by this structure is $O(n)$. The crucial observation is that the number of corners in G_α is $w^{2\varepsilon}$ and the number of "immediately left" corners added to each $\overline{G}_\alpha$ is also bounded by $w^{2\varepsilon}$. The number of corners in set $\mathcal{C}$ is bounded by $\sum_{\forall L_{i,j}} O\left(1 + \frac{|S_{ij}|}{t}\right) = O(n/t)$, since $n/t > w^{2\varepsilon}$. Therefore, the number of groups will be $O\left(\frac{n}{tw^{2\varepsilon}}\right)$. Each set R_α contains $O(w^{2\varepsilon}t)$ rectangles. Therefore, the total space occupied by this structure is $\sum_{\forall\alpha} |R_\alpha| = O(\frac{n}{tw^{2\varepsilon}} \cdot w^{2\varepsilon}t) = O(n)$.

Query algorithm. Given a query point $q = (q_x, q_y, q_z)$, we find the set G_α that "contains" q_x. Then we report all the rectangles in R_α that are stabbed by q by using Lemma 6. We need $O(\log\log_w n)$ time to find the group G_α [22] and, then $O(1 + k)$ time to report $R_\alpha \cap q$. ◀

Abstract

We study a natural problem in graph sparsification, the Spanning Tree Congestion (STC) problem. Informally, it seeks a spanning tree with no tree-edge *routing* too many of the original edges.

For any general connected graph with n vertices and m edges, we show that its STC is at most $\mathcal{O}(\sqrt{mn})$, which is asymptotically optimal since we also demonstrate graphs with STC at least $\Omega(\sqrt{mn})$. We present a polynomial-time algorithm which computes a spanning tree with congestion $\mathcal{O}(\sqrt{mn} \cdot \log n)$. We also present another algorithm for computing a spanning tree with congestion $\mathcal{O}(\sqrt{mn})$; this algorithm runs in sub-exponential time when $m = \omega(n \log^2 n)$.

For achieving the above results, an important intermediate theorem is *generalized Győri-Lovász theorem*. Chen et al. [8] gave a non-constructive proof. We give the first elementary and constructive proof with a local search algorithm of running time $\mathcal{O}^*(4^n)$. We discuss some consequences of the theorem concerning graph partitioning, which might be of independent interest.

We also show that for any graph which satisfies certain *expanding properties*, its STC is at most $\mathcal{O}(n)$, and a corresponding spanning tree can be computed in polynomial time. We then use this to show that a random graph has STC $\Theta(n)$ with high probability.

1 Introduction

Graph Sparsification/Compression generally describes a transformation of a *large* input graph into a *smaller/sparser* graph that preserves certain feature (e.g., distance, cut, congestion, flow) either exactly or approximately. The algorithmic value is clear, since the smaller graph might be used as a preprocessed input to an algorithm, so as to reduce subsequent running time and memory requirement. In this paper, we study a natural problem in graph sparsification, the Spanning Tree Congestion (STC) problem. Informally, the STC problem seeks a spanning tree with no tree-edge *routing* too many of the original edges. The problem is well-motivated by network design applications, where designers aim to build sparse networks that meet traffic demands, while ensuring no connection (edge) is too congested. Indeed, the root of this problem dates back to at least 30 years ago under the name of "load factor" [5, 25], with natural motivations from parallel computing and circuit design applications. The STC problem was formally defined by Ostrovskii [21] in 2004, and since then a number of results have been presented.

Two canonical goals for graph sparsification problems are to understand the trade-off between the sparsity of the output graph(s) and how well the feature is preserved, and to devise (efficient) algorithms for computing the sparser graph(s). These are also our goals for the STC problem. We focus on two scenarios: (A) general connected graphs with n vertices and m edges, and (B) graphs which exhibit certain *expanding properties*.

For (A), we show that the spanning tree congestion (STC) is at most $\mathcal{O}(\sqrt{mn})$, which is a factor of $\Omega(\sqrt{m/n})$ better than the trivial bound of m. We present a polynomial-time algorithm which computes a spanning tree with congestion $\mathcal{O}(\sqrt{mn} \cdot \log n)$. We also present another algorithm for computing a spanning tree with congestion $\mathcal{O}(\sqrt{mn})$; this algorithm runs in sub-exponential time when $m = \omega(n \log^2 n)$. For almost all ranges of average degree $2m/n$, we also demonstrate graphs with STC at least $\Omega(\sqrt{mn})$. For (B), we show that the expanding properties permit us to devise polynomial-time algorithm which computes a spanning tree with congestion $\mathcal{O}(n)$. Using this result, together with a separate lower-bound argument, we show that a random graph has $\Theta(n)$ STC with high probability.

For achieving the results for (A), an important intermediate theorem is *generalized Győri-Lovász theorem*, which was first proved by Chen et al. [8]. Their proof uses advanced techniques in topology and homology theory, and is non-constructive. For brevity, we will say "k-connected" for "k-vertex-connected" henceforth.

▶ **Definition 1.** In a graph $G = (V, E)$, a k-connected-partition is a k-partition of V into $\cup_{j=1}^{k} V_j$, such that for each $j \in [k]$, $G[V_j]$ is connected.

▶ **Theorem 2** ([8, Theorems 25, 26])**.** *Let $G = (V, E)$ be a k-connected graph. Let w be a weight function $w : V \to \mathbb{R}^+$. For any $U \subset V$, let $w(U) := \sum_{v \in U} w(v)$. Given any k distinct terminal vertices $t_1, \cdots, t_k$, and k positive integers $T_1, \cdots, T_k$ such that for each $j \in [k]$, $T_j \geq w(t_j)$ and $\sum_{i=1}^{k} T_i = w(V)$, there exists a k-connected-partition of V into $\cup_{j=1}^{k} V_j$, such that for each $j \in [k]$, $t_j \in V_j$ and $w(V_j) \leq T_j + \max_{v \in V} w(v) - 1$.*

One of our main contributions is to give the first elementary and constructive proof by providing a *local search* algorithm with running time $\mathcal{O}^*(4^n)$.

▶ **Theorem 3.** *(a) There is an algorithm which given a k-connected graph, computes a k-connected-partition satisfying the conditions stated in Theorem 2 in time $\mathcal{O}^*(4^n)$.*
(b) If we need a $(\lfloor k/2 \rfloor + 1)$-partition instead of k-partition (the input graph remains assumed to be k-connected), the algorithm's running time improves to $\mathcal{O}^*(2^{\mathcal{O}((n/k)\log k)})$.

We make three remarks. First, the $\mathcal{O}^*(2^{\mathcal{O}((n/k)\log k)})$-time algorithm is a key ingredient of our algorithm for computing a spanning tree with congestion $\mathcal{O}(\sqrt{mn})$. Second, since Theorem 2 guarantees the existence of such a partition, the problem of computing such a partition is not a *decision problem* but a *search problem*. Our algorithm shows that this problem is in the complexity class PLS [12]; we raise its completeness in PLS as an open problem. Third, the running times do not depend on the weights.

The STC Problem, Related Problems and Our Results. Given a connected graph $G = (V, E)$, let T be a spanning tree. For an edge $e = (u, v) \in E$, its detour with respect to T is the unique path from u to v in T; let $\mathsf{DT}(e, T)$ denote the set of edges in this detour. The stretch of e with respect to T is $|\mathsf{DT}(e, T)|$, the length of its detour. The dilation of T is $\max_{e\in E} |\mathsf{DT}(e, T)|$. The edge-congestion of an edge $e \in T$ is $\mathsf{ec}(e, T) := |\{f \in E : e \in \mathsf{DT}(f, T)\}|$, i.e., the number of edges in E whose detours contain e. The congestion of T is $\mathsf{cong}(T) := \max_{e\in T} \mathsf{ec}(e, T)$. The spanning tree congestion (STC) of the graph G is $\mathsf{STC}(G) := \min_T \mathsf{cong}(T)$, where T runs over all spanning trees of G.

We note that there is an equivalent cut-based definition for edge-congestion, which we will use in our proofs. Given a connected graph $G = (V, E)$, an edge set $F \subseteq E$ and two disjoint vertex subsets $V_1, V_2 \subset V$, we let $F(V_1, V_2) := \{ e = \{v_1, v_2\} \in F \mid v_1 \in V_1 \text{ and } v_2 \in V_2 \}$. For each tree-edge $e \in T$, removing e from T results in two connected components; let U_e denote one of the components. Then $\mathsf{ec}(e, T) := |E(U_e, V \setminus U_e)|$.

Various types of congestion, stretch and dilation problems are studied in computer science and discrete mathematics; see the survey [24] for more details. In these problems, one typically seeks a spanning tree (or some other structure) with minimum congestion, stretch or dilation. Among them, the most famous one is the Low Stretch Spanning Tree (LSST) problem, which seeks a spanning tree which minimizes the total stretch of all the edges of G [3]. It is easy to see that minimizing the total stretch is equivalent to minimizing the total edge-congestion of the selected spanning tree. Several strong results were published about the LSST problem. Alon et al. [3] had shown a lower bound of $\Omega(\max\{n \log n, m\})$. Upper bounds have been derived and many efficient algorithms have been devised; the current best upper bound is $\tilde{\mathcal{O}}(m \log n)$. [3, 9, 1, 14, 2] Since total stretch is identical to total edge-congestion, the best upper bound for the LSST problem automatically implies an $\tilde{\mathcal{O}}(\frac{m}{n} \log n)$ upper bound on the *average* edge-congestion. But in the STC problem, we concern the *maximum* edge-congestion.

In comparison, there were not many strong and general results for the STC Problem, though it was studied extensively in the past 13 years. The problem was formally proposed by Ostrovskii [21] in 2004. Prior to this, Simonson [25] had studied the same parameter under a different name to approximate the cut width of outer-planar graph. A number of graph-theoretic results were presented on this topic [22, 17, 16, 15, 7]. Some complexity results were also presented recently [20, 6], but most of these results concern special classes of graphs. The most general result regarding STC of general graphs is an $\mathcal{O}(n\sqrt{n})$ upper bound by Löwenstein, Rautenbach and Regen in 2009 [19], and a matching lower bound by Ostrovskii in 2004 [21]. Note that the above upper bound is not interesting when the graph is sparse, since there is also a trivial upper bound of m. In this paper we come up with a strong improvement to these bounds after 8 years:

Theorem (informal): *For a connected graph G with n vertices and m edges, its spanning tree congestion is at most $\mathcal{O}(\sqrt{mn})$. In terms of average degree $d_{avg} = 2m/n$, we can state this upper bound as $\mathcal{O}(n\sqrt{d_{avg}})$. There is a matching lower bound.*

Our proof for achieving the $\mathcal{O}(\sqrt{mn})$ upper bound is constructive. It runs in exponential time in general; for graphs with $m = \omega(n \log^2 n)$ edges, it runs in sub-exponential time. By using an algorithm of Chen et al. [8] for computing *single-commodity confluent flow* from single-commodity splittable flow, we improve the running time to polynomial, but with a slightly worse upper bound guarantee of $\mathcal{O}(\sqrt{mn} \cdot \log n)$.

Motivated by an open problem raised by Ostrovskii [23] concerning STC of random graphs, we formulate a set of *expanding properties*, and prove that for any graph satisfying these properties, its STC is at most $\mathcal{O}(n)$. We devise a polynomial time algorithm for computing a spanning tree with congestion $\mathcal{O}(n)$ for such graphs. This result, together with a separate lower-bound argument, permit us to show that for random graph $\mathcal{G}(n,p)$ with $1 \geq p \geq \frac{c \log n}{n}$ for some small constant $c > 1$, its STC is $\Theta(n)$ with high probability, thus resolving the open problem raised by Ostrovskii completely.

Min-Max Graph Partitioning and the Generalized Győri-Lovász Theorem. It looks clear that the powerful Theorem 2 can make an impact on graph partitioning. We discuss a number of its consequences which might be of wider interest.

Graph partitioning/clustering is a prominent topic in graph theory/algorithms, and has a wide range of applications. A popular goal is to partition the vertices into sets such that the number of edges across different sets is *small*. While the *min-sum* objective, i.e., minimizing the total number of edges across different sets, is more widely studied, in various applications, the more natural objective is the *min-max* objective, i.e., minimizing the maximum number of edges leaving each set. The min-max objective is our focus here.

Depending on applications, there are additional constraints on the sets in the partition. Two natural constraints are (i) balancedness: the sets are (approximately) balanced in sizes, and (ii) induced-connectivity: each set induces a connected subgraph. The balancedness constraint appears in the application of *domain decomposition* in parallel computing, while the induced-connectivity constraint is motivated by divide-and-conquer algorithms for spanning tree construction. Imposing both constraints simultaneously is not feasible for every graph; for instance, consider the star graph with more than 6 vertices and one wants a 3-partition. Thus, it is natural to ask, for which graphs do partitions satisfying both constraints exist. Theorem 2 implies a simple sufficient condition for existence of such partitions.

By setting the weight of each vertex in G to be its degree, and using the fact that (the maximum degree) $\leq n \leq \frac{2m}{k}$ for any k-connected graph on n vertices and m edges, we have

▶ **Proposition 4.** *If G is a k-connected graph with m edges, then there exists a k-connected-partition, such that the total degree of vertices in each part is at most $4m/k$. Consequently, the min-max objective is also at most $4m/k$.*

Due to expander graphs, this bound is optimal up to a small constant factor. This proposition (together with Lemma 9) implies the following crucial lemma for achieving some of our results.

▶ **Lemma 5.** *Let G be a k-connected graph with m edges. Then $\mathsf{STC}(G) \leq 4m/k$.*

Proposition 4 can be generalized to include approximate balancedness in terms of number of vertices. By setting the weight of each vertex to be cm/n plus its degree in G, we have

▶ **Proposition 6.** *Given any fixed $c > 0$, if G is a k-connected graph with m edges and n vertices, then there exists a k-connected-partition such that the total degree of vertices in each part is at most $(2c+4)m/k$, and the number of vertices in each part is at most $\frac{2c+4}{c} \cdot \frac{n}{k}$.*

Further Related Work. Concerning STC problem, Okamoto et al. [20] gave an $\mathcal{O}^*(2^n)$ algorithm for computing the exact STC of a graph. For graph partitioning, Kiwi, Spielman and Teng [13] formulated the min-max k-partitioning problem and gave bounds for classes of graphs with *small separators*, which were then improved by Steurer [26]. On the algorithmic side, the min-sum objective has been extensively studied; the min-max objective, while striking as the more natural objective in some applications, has received much less attention. The only algorithmic work on this objective (and its variants) are Svitkina and Tardos [28] and Bansal et al. [4]. None of the above work addresses the induced-connectivity constraint.

The classical version of Győri-Lovász Theorem (i.e., the vertex weights are uniform) was proved independently by Győri [10] and Lovász [18]. Lovász used homology theory and is non-constructive. Győri's proof is elementary and is constructive implicitly, but he did not analyze the running time. Polynomial time algorithms for constructing the k-partition were devised for $k = 2, 3$ [27, 29], but no non-trivial finite-time algorithm was known for general graphs with $k \geq 4$. Recently, Hoyer and Thomas [11] provided a clean presentation of Győri's proof by introducing their own terminology, which we use for our constructive proof.

In the full version, we discuss some other related work and some interesting open problems.

2 Technical Overview

To prove the generalized Győri-Lovász theorem, we follow the same framework of Győri's proof [10], and we borrow terminology from the recent presentation by Hoyer and Thomas [11]. But it should be emphasized that proving our generalized theorem is not straight-forward, since in Győri's proof, at each stage a single vertex is moved from one set to other to make progress, while making sure that the former set remains connected. In our setting, in addition to this we also have to ensure that the weights in the partitions do not exceed the specified limit; and hence any vertex that can be moved from one set to another need *not* be candidate for being transferred. The proof of the theorem is presented in Section 3.

As discussed, a crucial ingredient for our upper bound results is Lemma 5, which is a direct corollary of the generalized Győri-Lovász theorem. The lemma takes care of the highly-connected cases; for other cases we provide a recursive way to construct a low congestion spanning tree. See Section 4 for details. For showing our lower bound for general graphs, the challenge is to maintain high congestion while keeping density small. To achieve this, we combine three expander graphs with *little* overlapping between them, and we further make those overlapped vertices of very high degree. This will force a tree-edge adjacent to the centroid of the tree to have high congestion. See Section 5 for details.

We formulate a set of expanding properties which permit constructing a spanning tree of better congestion guarantee in polynomial time. The basic idea is simple: start with a vertex v of high degree as the root, then try to grow the tree by keep attaching new vertices to it, while keeping the invariant that the subtrees rooted at each of the neighbours of v are roughly balanced in size; each such subtree is called a *branch*. But when trying to grow the tree in a balanced way, we will soon realize that as the tree grows, all the remaining vertices might be adjacent only to a few "heavy" branches. To help the balanced growth, our algorithm identifies a *transferable* vertex in a "heavy" branch, and it and its descendants in the tree can be transferred to a "lighter" branch. Another technique is to use multiple rounds of matching between vertices in the tree and the remaining vertices to attach new vertices to the tree. This will tend to make sure that all subtrees do not grow uncontrolled. By showing that random graph satisfies the expanding properties with appropriate parameters, we show that its STC is $\Theta(n)$ with high probability. These results are formally presented in Section 6; see the full version for the complete algorithm and its analysis.

3 Generalized Győri-Lovász Theorem

Let $G(V, E)$ be a k-connected graph on n vertices and m edges, and $w : V \to \mathbb{R}^+$ be a weight function. For any subset $U \subseteq V$, we write $w(U) := \sum_{u \in U} w(u)$. Let $w_{max} := \max_{v \in V} w(v)$. We prove Theorem 3 in this section. Observe that the classical Győri-Lovász Theorem follows from Theorem 3 by taking $w(v) = 1$ for all $v \in V$ and $T_j = n_j$ for all $j \in [k]$. We note that a perfect generalization where one requires that $w(V_j) = T_j$ is not possible – think when all vertex weights are even integers, while some T_j is odd.

3.1 Key Combinatorial Notions

We first highlight the key combinatorial notions used for proving Theorem 3.

Fitted Partial Partition. First, we introduce the notion of *fitted partial partition* (FPP). An FPP A is a tuple of k subsets of V, $(A_1, \ldots, A_k)$, such that the k subsets are pairwise disjoint, and for each $j \in [k]$:

1. $t_j \in A_j$ and $G[A_j]$ is connected, and
2. $w(A_j) \leq T_j + w_{max} - 1$ (we say the set is *fitted* for satisfying this inequality).

We say an FPP is a *Strict Fitted Partial Partition* (SFPP) if $A_1 \cup \cdots \cup A_k$ is a proper subset of V. We say the set A_j is *light* if $w(A_j) < T_j$, and we say it is *heavy* otherwise. Note that there exists at least one light set in any SFPP, for otherwise $w(A_1 \cup \cdots \cup A_k) \geq \sum_{j=1}^{k} T_j = w(V)$, which means $A_1 \cup \cdots \cup A_k = V$. Also note that by taking $A_j = \{t_j\}$, we have an FPP, and hence at least one FPP exists.

Configuration. For a set A_j in an FPP A and a vertex $v \in A_j \setminus \{t_j\}$, we define the reservoir of v with respect to A, denoted by $R_A(v)$, as the vertices in the same connected component as t_j in $G[A_j] \setminus \{v\}$. Note that $v \notin R_A(v)$.

For a *heavy* set A_j, a sequence of vertices $(z_1, \ldots, z_p)$ for some $p \geq 0$ is called a cascade of A_j if $z_1 \in A_j \setminus \{t_j\}$ and $z_{i+1} \in A_j \setminus R_A(z_i)$ for all $1 \leq i < p$. The cascade is called a null cascade if $p = 0$, i.e., if the cascade is empty. Note that for light set, we do *not* need to define its cascade since we do not use it in the proof.

A configuration $\mathcal{C}_A$ is defined as a pair (A, D), where $A = (A_1, \cdots, A_k)$ is an FPP, and D is a set of cascades, which consists of exactly one cascade (possibly, a null cascade) for each heavy set in A. A vertex in some cascade of the configuration is called a cascade vertex.

Given a configuration, we define rank and level inductively as follows. Any vertex in a light set is said to have level 0. For $i \geq 0$, a cascade vertex is said to have rank $i + 1$ if it has an edge to a level-i vertex but does not have an edge to any level-i' vertex for $i' < i$. A vertex u is said to have level i, for $i \geq 1$, if $u \in R_A(v)$ for some rank-i cascade vertex v, but $u \notin R_A(w)$ for any cascade vertex w such that rank of w is less than i. A vertex that is not in $R_A(v)$ for any cascade vertex v is said to have level ∞.

A configuration is called a valid configuration if for each heavy set A_j, rank is defined for each of its cascade vertices and the rank is strictly increasing in the cascade, i.e., if $\{z_1, \ldots, z_p\}$ is the cascade, then $\mathsf{rank}(z_1) < \cdots < \mathsf{rank}(z_p)$. Note that by taking $A_j = \{t_j\}$ and taking the null cascade for each heavy set (in this case A_j is heavy if $w(t_j) = T_j$), we get a valid configuration.

Configuration Vectors and Their Total Ordering. For any vertex, we define its neighborhood level as the smallest level of any vertex adjacent to it. A vertex v of level ℓ is said to satisfy maximality property if each vertex adjacent on it is either a rank-$(\ell+1)$ cascade vertex, has a level of at most $\ell+1$, or is one of the terminals t_j for some j. For any $\ell \geq 0$, a valid configuration is called an ℓ-maximal configuration if all vertices having level at most $\ell-1$ satisfy the maximality property. Note that by definition, any valid configuration is a 0-maximal configuration.

For a configuration $\mathcal{C}_A = ((A_1, \ldots, A_k), D)$, we define $S_A := V \setminus (A_1 \cup \cdots \cup A_k)$. An edge uv is said to be a bridge in $\mathcal{C}_A$ if $u \in S_A$, $v \in A_j$ for some $j \in [k]$, and $level(v) \neq \infty$.

A valid configuration $\mathcal{C}_A$ is said to be ℓ-good if the highest rank of a cascade vertex in $\mathcal{C}_A$ is exactly ℓ (if there are no cascade vertices, then we take the highest rank as 0), $\mathcal{C}_A$ is ℓ-maximal, and all bridges uv in $\mathcal{C}_A$ (if any) are such that $u \in S_A$ and $level(v) = \ell$. Note that taking $A_j = \{t_j\}$ and taking the null cascade for each heavy set gives a 0-good configuration.

For each configuration $\mathcal{C}_A = (A, D)$, we define a configuration vector as below:

$$(L_A \ , \ N_A^0 \ , \ N_A^1 \ , \ N_A^2 \ , \ \ldots \ , \ N_A^n \ ),$$

where L_A is the number of light sets in A, and N_A^ℓ is the number of all level-ℓ vertices in $\mathcal{C}_A$.

Next, we define ordering on configuration vectors. Let $\mathcal{C}_A$ and $\mathcal{C}_B$ be configurations. We say $\mathcal{C}_A >_0 \mathcal{C}_B$ if

- $L_A < L_B$, or
- $L_A = L_B$, and $N_A^0 > N_B^0$.

We say $\mathcal{C}_A =_0 \mathcal{C}_B$ if $L_A = L_B$ and $N_A^0 = N_B^0$. We say $\mathcal{C}_A \geq_0 \mathcal{C}_B$ if $\mathcal{C}_A =_0 \mathcal{C}_B$ or $\mathcal{C}_A >_0 \mathcal{C}_B$. We say $\mathcal{C}_A =_\ell \mathcal{C}_B$ if $L_A = L_B$, and $N_A^{\ell'} = N_B^{\ell'}$ for all $\ell' \leq \ell$.

For $1 \leq \ell \leq n$, we say $\mathcal{C}_A >_\ell \mathcal{C}_B$ if

- $\mathcal{C}_A >_{\ell-1} \mathcal{C}_B$, or
- $\mathcal{C}_A =_{\ell-1} \mathcal{C}_B$, and $N_A^\ell > N_B^\ell$.

We say $\mathcal{C}_A \geq_\ell \mathcal{C}_B$ if $\mathcal{C}_A =_\ell \mathcal{C}_B$ or $\mathcal{C}_A >_\ell \mathcal{C}_B$. We say $\mathcal{C}_A > \mathcal{C}_B$ ($\mathcal{C}_A$ is *strictly better* than $\mathcal{C}_B$) if $\mathcal{C}_A >_n \mathcal{C}_B$.

3.2 Proof of Theorem 3(a)

We use two technical lemmas about configuration vectors and their orderings to prove Theorem 3(a). The proof of Theorem 3(b) follows closely with the proof of Theorem 3(a), but makes use of an observation to give an improved bound on the number of configuration vectors navigated by the local search algorithm.

▶ **Lemma 7.** *Given any ℓ-good configuration $\mathcal{C}_A = (A = (A_1, \ldots, A_k), D_A))$ that does not have a bridge, we can find an $(\ell+1)$-good configuration $\mathcal{C}_B = (B = (B_1, B_2, \ldots, B_k), D_B)$ in polynomial time such that $\mathcal{C}_B > \mathcal{C}_A$.*

▶ **Lemma 8.** *Given an ℓ-good configuration $\mathcal{C}_A = (A = (A_1, \ldots, A_k), D_A)$ having a bridge, we can find in polynomial time a valid configuration $\mathcal{C}_B = (B = (B_1, \ldots, B_k), D_B)$ such that one of the following holds:*

- *$\mathcal{C}_B >_\ell \mathcal{C}_A$, and $\mathcal{C}_B$ is an ℓ-good configuration, or*
- *$\mathcal{C}_B \geq_{\ell-1} \mathcal{C}_A$, there is a bridge $u'v'$ in $\mathcal{C}_B$ such that $u' \in S_B$ and $level(v') \leq \ell - 1$, and $\mathcal{C}_B$ is an $(\ell-1)$-good configuration.*

Proof of Theorem 3(a): We always maintain a configuration $\mathcal{C}_A = (A, D_A)$ that is ℓ-good for some $\ell \geq 0$. If the FPP A is not an SFPP at any point, then we are done. So assume A is an SFPP.

We start with the 0-good configuration where $A_j = \{t_j\}$ and the cascades of all heavy sets are null cascades. If our current configuration $\mathcal{C}_A$ is an ℓ-good configuration that has no bridge, then we use Lemma 7 to get a configuration $\mathcal{C}_B$ such that $\mathcal{C}_B > \mathcal{C}_A$ and B is $(\ell+1)$-good. We take $\mathcal{C}_B$ as the new current configuration $\mathcal{C}_A$. If our current configuration $\mathcal{C}_A$ is an ℓ-good configuration with a bridge, then we get an ℓ'-good configuration $\mathcal{C}_B$ for some $\ell' \geq 0$ such that $\mathcal{C}_B > \mathcal{C}_A$ by repeatedly applying Lemma 8 at most ℓ times. So in either case, we get a strictly better configuration that is ℓ'-good for some $\ell' \geq 0$ in polynomial time. We call this an iteration of our algorithm.

Notice that the number of iterations possible is at most the number of distinct configuration vectors possible. It is easy to see that the number of distinct configuration vectors with highest rank at most r is at most $\binom{n+r-1}{n}$. Since rank of any point is at most n, the number of iterations of our algorithm is at most $(k+1) \cdot \binom{2n}{n} \leq n \cdot 4^n$. Since each iteration runs in polynomial time as guaranteed by the two lemmas, the required running time is $\mathcal{O}^*(4^n)$.

When the algorithm terminates, the FPP given by the current configuration is not an SFPP and this gives the required partition.

Proof of Lemma 7: Since $\mathcal{C}_A$ is ℓ-maximal, any vertex that is at level $\ell' < \ell$ satisfies maximality property. So, for satisfying $(\ell+1)$-maximality, we only need to worry about the vertices that are at level ℓ. Let X_j be the set of all vertices $x \in A_j$ such that x is adjacent to a level-ℓ vertex, $level(x) \geq \ell + 1$ (i.e., $level(x) = \infty$ as the highest rank of any cascade vertex is ℓ), $x \neq t_j$, and x is not a cascade vertex of rank ℓ.

We claim that there exists at least one j for which X_j is not empty. If that is not the case, then we exhibit a cut set of size at most $k-1$. For each j such that A_j is a heavy set with a non-null cascade, let y_j be the highest ranked cascade vertex in A_j. For each j such that A_j is a heavy set with a null cascade, let y_j be t_j. Let Y be the set of all y_j such that A_j is a heavy set. Note that $|Y| \leq k-1$ as A is an SFPP and hence has at least one light set. Let Z_∞ be the set of all vertices in $V \setminus Y$ that have level ∞ and Z be the remaining vertices in $V \setminus Y$. Since A is an SFPP, $S_A \neq \emptyset$, and since all vertices in S_A have level ∞, we have that $Z_\infty \neq \emptyset$. Z is not empty because there exists at least one light set in A and the vertices in a light set have level 0. We show that there is no edge between Z_∞ and Z in G. Suppose there exists an edge uv such that $u \in Z_\infty$ and $v \in Z$. If $u \in S_A$, then uv is a bridge which is a contradiction by our assumption that $\mathcal{C}_A$ does not have a bridge. Hence $u \in A_j$ for some $j \in [k]$. Note that A_j has to be a heavy set, otherwise u has level 0. We have that u is not a cascade vertex (as all cascade vertices with level ∞ are in Y) and $u \neq t_j$ (as all t_j such that $level(t_j) = \infty$ are in Y). Also, v is not of level ℓ as otherwise, $u \in X_j$ but we assumed X_j is empty. But then, v has level at most $\ell - 1$, u has level ∞, and there is an edge uv. This means that $\mathcal{C}_A$ was not ℓ-maximal, which is a contradiction. Thus, there exists at least one j for which X_j is not empty.

For any j such that $X_j \neq \emptyset$, there is at least one vertex x_j such that $X_j \setminus \{x_j\} \subseteq R_A(x_j)$. Now we give the configuration $\mathcal{C}_B$ as follows. We set $B_j = A_j$ for all $j \in [k]$. For each heavy set A_j such that $X_j \neq \emptyset$, we take the cascade of B_j as the cascade of A_j appended with x_j. For each heavy set A_j such that $X_j = \emptyset$, we take the cascade of B_j as the cascade of A_j. It is easy to see that $\mathcal{C}_B$ is $(\ell+1)$-maximal as each vertex that had an edge to level-ℓ vertices in $\mathcal{C}_A$ is now either a rank $\ell+1$ cascade vertex or a level-$(\ell+1)$ vertex or is t_j for some j.

Also, notice that all the new cascade vertices that we introduce (i.e., the x_j's) have their rank as $\ell+1$ and there is at least one rank $\ell+1$ cascade vertex as X_j is not empty for some j. Since there were no bridges in $\mathcal{C}_A$, all bridges in $\mathcal{C}_B$ has to be from S_B to a vertex having level $\ell+1$. Hence, $\mathcal{C}_B$ is $(\ell+1)$-good. All vertices that had level at most ℓ in $\mathcal{C}_A$ retained their levels in $\mathcal{C}_B$. And, at least one level-∞ vertex of $\mathcal{C}_A$ became a level-$(\ell+1)$ vertex in $\mathcal{C}_B$ because the cascade vertex that was at rank ℓ becomes level-$(\ell+1)$ vertex now in at least one set. Since $\mathcal{C}_A$ had no level-$(\ell+1)$ vertices, this means that $\mathcal{C}_B > \mathcal{C}_A$.

Proof of Lemma 8: Let uv be a bridge where $u \in S_A$. Let A_{j^*} be the set containing v. Note that $level(v) = \ell$ because $\mathcal{C}_A$ is ℓ-good. We keep $B_j = A_j$ for all $j \neq j^*$. But we modify A_{j^*} to get B_{j^*} as described below. We maintain that if A_j is a heavy set then B_j is also a heavy set for all j, and hence maintain that $L_B \leq L_A$.

Case 1: A_{j^*} is a light set (i.e., when $\ell = 0$). We take $B_{j^*} = A_{j^*} \cup \{u\}$. For all j such that B_j is a heavy set, cascade of B_j is taken as the null cascade. We have $w(A_{j^*}) \leq T_j - 1$ because A_{j^*} is a light set. So, $w(B_{j^*}) = w(A_{j^*}) + w(u) \leq (T_j - 1) + w_{max}$, and hence B_{j^*} is fitted. Also, $G[B_{j^*}]$ is connected and hence $(B_1, \ldots, B_k)$ is an FPP. We have $\mathcal{C}_B >_0 \mathcal{C}_A$ because either B_{j^*} became a heavy set in which case $L_B < L_A$, or it is a light set in which case $L_B = L_A$ and $N^0_B > N^0_A$. It is easy to see that $\mathcal{C}_B$ is 0-good.

Case 2: A_{j^*} is a heavy set i.e., when $\ell \geq 1$.

Case 2.1: $w(A_{j^*} \cup \{u\}) \leq T_j + w_{max} - 1$. We take $B_{j^*} = A_{j^*} \cup \{u\}$. For each j such that B_j is a heavy set (A_j is also heavy set for such j), the cascade of B_j is taken as the cascade of A_j. $G[B_{j^*}]$ is clearly connected and B_{j^*} is fitted by assumption of the case that we are in. Hence B is indeed an FPP. Observe that all vertices that had level $\ell' \leq \ell$ in $\mathcal{C}_A$ still has level ℓ' in $\mathcal{C}_B$. Since $level(v)$ was ℓ in $\mathcal{C}_A$ by ℓ-goodness of $\mathcal{C}_A$, u also has level ℓ in $\mathcal{C}_B$; and u had level ∞ in $\mathcal{C}_A$. Hence, $\mathcal{C}_B >_\ell \mathcal{C}_A$. It is also easy to see that $\mathcal{C}_B$ remains ℓ-good.

Case 2.2: $w(A_{j^*} \cup \{u\}) \geq T_j + w_{max}$. Let z be the cascade vertex of rank ℓ in A_{j^*}. Note that A_{j^*} should have such a cascade vertex as $v \in A_{j^*}$ has level ℓ. Let $\bar{R}$ be $A_{j^*} \setminus (R_A(z) \cup z)$, i.e., $\bar{R}$ is the set of all vertices in $A_{j^*} \setminus \{z\}$ with level ∞. We initialize $B_{j^*} := A_{j^*} \cup \{u\}$. Now, we delete vertices one by one from B_{j^*} in a specific order until B_{j^*} becomes fitted. We choose the order of deleting vertices such that $G[B_{j^*}]$ remains connected. Consider a spanning tree τ of $G[\bar{R} \cup \{z\}]$. τ has at least one leaf, which is not z. We delete this leaf from B_{j^*} and τ. We repeat this process until τ is just the single vertex z or B_{j^*} becomes fitted. If B_{j^*} is not fitted even when τ is the single vertex z, then delete z from B_{j^*}. If B_{j^*} is still not fitted then delete u from B_{j^*}. Note that at this point $B_{j^*} \subset A_{j^*}$ and hence is fitted. Also, note that $G[B_{j^*}]$ remains connected. Hence $(B_1, \ldots, B_k)$ is an FPP. B_{j^*} does not become a light set because B_j became fitted when the last vertex was deleted from it. Before this vertex was deleted, it was not fitted and hence had weight at least $T_{j^*} + w_{max}$ before this deletion. Since the last vertex deleted has weight at most w_{max}, B_{j^*} has weight at least T_{j^*} and hence is a heavy set. Now we branch into two subcases for defining the cascades.

Case 2.2.1: $z \in B_{j*}$ (i.e, z was not deleted from B_{j^*} in the process above). For each j such that B_j is a heavy set, the cascade of B_j is taken as the cascade of A_j. Since a new ℓ level vertex u is added and all vertices that had level at most ℓ retain their level, we have that $\mathcal{C}_B >_\ell \mathcal{C}_A$. It is also easy to see that $\mathcal{C}_B$ remains ℓ-good.

Case 2.2.2: $z \notin B_{j^*}$ (i.e, z was deleted from B_{j^*}). For each j such that B_j is a heavy set, the cascade of B_j is taken as the cascade of A_j but with the rank ℓ cascade vertex (if it has any) deleted from it. $\mathcal{C}_B \geq_{\ell-1} \mathcal{C}_A$ because all vertices that were at a level of $\ell' = \ell - 1$ or

smaller, retain their levels. Observe that there are no bridges in $\mathcal{C}_B$ to vertices that are at a level at most $\ell-2$, all vertices at a level at most $\ell-2$ still maintain the maximality property, and we did not introduce any cascade vertices. Hence, $\mathcal{C}_B$ is $(\ell-1)$-good. It only remains to prove that there is a bridge $u'v'$ in $\mathcal{C}_B$ such that $level(v') \leq \ell-1$. We know $z \in S_B$. Since z was a rank ℓ cascade vertex in $\mathcal{C}_A$, z had an edge to z' such that z' had level $\ell-1$ in $\mathcal{C}_A$. Observe that level of z' is at most $\ell-1$ in $\mathcal{C}_B$ as well. Hence, taking $u'v' = zz'$ completes the proof.

4 Upper Bounds for Spanning Tree Congestion

We first state the following easy lemma, which together with Proposition 4, implies Lemma 5.

▶ **Lemma 9.** *In a graph $G=(V,E)$, let t_1 be a vertex, and let $t_2,\cdots,t_\ell$ be any $(\ell-1)$ neighbours of t_1. Suppose that there exists a ℓ-connected-partition $\cup_{j=1}^{\ell} V_\ell$ such that for all $j \in \ell$, $t_j \in V_j$, and the sum of degree of vertices in each V_j is at most D. Let τ_j be an arbitrary spanning tree of $G[V_j]$. Let e_j denote the edge $\{t_1,t_j\}$. Let τ be the spanning tree of G defined as $\tau := \left(\cup_{j=1}^{\ell}\ \tau_j\right) \bigcup \left(\cup_{j=2}^{\ell}\ e_j\right)$. Then τ has congestion at most D.*

▶ **Theorem 10.** *For any connected graph $G=(V,E)$, there is an algorithm which computes a spanning tree with congestion at most $8\sqrt{mn}$ in time $\mathcal{O}^*\left(2^{\mathcal{O}\left(n\log n/\sqrt{m/n}\right)}\right)$.*

▶ **Theorem 11.** *For any connected graph $G=(V,E)$, there is a polynomial time algorithm which computes a spanning tree with congestion at most $16\sqrt{mn}\log n$.*

The two algorithms follows the same framework, depicted in Algorithm 1. It is a recursive algorithm; the parameter $\hat{m}$ is a global parameter, which is the number of edges in the input graph G in the first level of the recursion; let $\hat{n}$ denote the number of vertices in this graph.

The only difference between the two algorithms is in Line 15 on how this step is executed, with trade-off between the running time of the step $T(\hat{m}, n_{_H}, m_{_H})$, and the guarantee $D(\hat{m}, n_{_H}, m_{_H})$. For proving Theorem 10, we use Theorem 3(b), Proposition 4 and Lemma 9, yielding $D(\hat{m}, n_{_H}, m_{_H}) \leq 8m_{_H}\sqrt{n_{_H}/\hat{m}}$ and $T(\hat{m}, n_{_H}, m_{_H}) = \mathcal{O}^*\left(2^{\mathcal{O}(n_{_H}\log n_{_H}/\sqrt{\hat{m}/n_{_H}})}\right)$. For proving Theorem 11, we make use of an algorithm in Chen et al. [8], which yields $D(\hat{m}, n_{_H}, m_{_H}) \leq 16m_{_H}\sqrt{n_{_H}/\hat{m}}\log n_{_H}$ and $T(\hat{m}, n_{_H}, m_{_H}) = \mathsf{poly}(n_{_H}, m_{_H})$. Next, we discuss the algorithm in Chen et al., then we prove Theorem 11.

Single-Commodity Confluent Flow. In a *single-commodity confluent flow* problem, the input includes a graph $G=(V,E)$, a *demand* function $w: V \to \mathbb{R}^+$ and ℓ sinks $t_1,\cdots,t_\ell \in V$. For each $v \in V$, a flow of amount $w(v)$ is routed from v to one of the sinks. But there is a restriction: at every vertex $u \in V$, the outgoing flow must leave u on at most 1 edge, i.e., the outgoing flow from u is unsplittable. The problem is to seek a flow satisfying the demands which minimizes the *node congestion*, i.e., the maximum incoming flow among all vertices. Since the incoming flow is maximum at one of the sinks, it is equivalent to minimize the maximum flow received among all sinks. (We assume that no flow entering a sink will leave.) *Single-commodity splittable flow* problem is almost identical to single-commodity confluent flow problem, except that the above restriction is dropped, i.e., now the outgoing flow at u can split along multiple edges. Note that here, the maximum incoming flow might not be at a sink. It is known that single-commodity splittable flow can be solved in polynomial time. For brevity, we drop the phrase "single-commodity" from now on. Corollary 13 below follows from Theorem 12 and Proposition 4.

Algorithm 1: `FindLCST`$(H, \hat{m})$

Input : A connected graph $H = (V_H, E_H)$ on n_H vertices and m_H edges
Output : A spanning tree τ of H

1 **if** $m_H \leq 8\sqrt{\hat{m} n_H}$ **then**
2 | **return** an arbitrary spanning tree of H
3 **end**
4 $k \leftarrow \left\lceil \sqrt{\hat{m}/n_H} \right\rceil$
5 $Y \leftarrow$ a global minimum vertex cut of H
6 **if** $|Y| < k$ **then**
7 | $X \leftarrow$ the smallest connected component in $H[V_H \setminus Y]$
8 | $Z \leftarrow V_H \setminus (X \cup Y)$
9 | $\tau_1 \leftarrow$ `FindLCST`$(H[X], \hat{m})$
10 | $\tau_2 \leftarrow$ `FindLCST`$(H[Y \cup Z], \hat{m})$; ($H[Y \cup Z]$ is connected as Y is a global min cut)
11 | **return** $\tau_1 \cup \tau_2 \cup$ (an arbitrary edge between X and Y)
12 **else**
13 | $t_1 \leftarrow$ an arbitrary vertex in V_H
14 | Pick $\lfloor k/2 \rfloor$ neighbors of t_1 in the graph H; denote them by $t_2, t_3, \cdots, t_{\lfloor k/2 \rfloor + 1}$. Let e_j denote edge $t_1 t_j$ for $2 \leq j \leq \lfloor k/2 \rfloor + 1$.
15 | Compute a $(\lfloor k/2 \rfloor + 1)$-connected-partition of H, denoted by $\cup_{j=1}^{\lfloor k/2 \rfloor + 1} V_j$, such that for each $j \in [\lfloor k/2 \rfloor + 1]$, $t_j \in V_j$, and the total degree (w.r.t. graph H) of vertices in each V_j is at most $D(\hat{m}, n_H, m_H)$. Let the time needed be $T(\hat{m}, n_H, m_H)$.
16 | For each $j \in [\lfloor k/2 \rfloor + 1]$, $\tau_j \leftarrow$ an arbitrary spanning tree of $G[V_j]$
17 | **return** $\left(\cup_{j=1}^{\lfloor k/2 \rfloor + 1} \tau_j\right) \bigcup \left(\cup_{j=2}^{\lfloor k/2 \rfloor + 1} e_j\right)$
18 **end**

▶ **Theorem 12** ([8, Section 4]). *Suppose that given graph G, demand w and ℓ sinks, there is a splittable flow with node congestion q. Then there exists a polynomial time algorithm which computes a confluent flow with node congestion at most $(1 + \ln \ell)q$ for the same input.*

▶ **Corollary 13.** *Let G be a k-connected graph with m edges. Then for any $\ell \leq k$ and for any ℓ vertices $t_1, \cdots, t_\ell \in V$, there exists a polynomial time algorithm which computes an ℓ-connected-partition $\cup_{j=1}^{\ell} V_\ell$ such that for all $j \in \ell$, $t_j \in V_j$, and the total degrees of vertices in each V_j is at most $4(1 + \ln \ell)m/\ell$.*

Congestion Analysis. We view the whole recursion process as a recursion tree. There is no endless loop, since down every path in the recursion tree, the number of vertices in the input graphs are *strictly* decreasing. On the other hand, note that the leaf of the recursion tree is resulted by either (i) when the input graph H to that call satisfies $m_H \leq 8\sqrt{\hat{m} n_H}$, or (ii) when Lines 13–17 are executed. An internal node appears only when the vertex-connectivity of the input graph H is *low*, and it makes two recursion calls.

We prove the following statement by induction from bottom-up: for each graph which is the input to some call in the recursion tree, the returned spanning tree of that call has congestion at most $16\sqrt{\hat{m} n_H} \log n_H$.

We first handle the two basis cases (i) and (ii). In case (i), `FindLCST` returns an arbitrary spanning tree, and the congestion is bounded by $m_H \leq 8\sqrt{\hat{m}n_H}$. In case (ii), by Corollary 13 and Lemma 9, `FindLCST` returns a tree with congestion at most $16m_H\sqrt{n_H/\hat{m}}\log n_H \leq 16\sqrt{\hat{m}n_H}\log n_H$.

Next, let H be the input graph to a call which is represented by an internal node of the recursion tree. Recall the definitions of X, Y, Z, τ_1, τ_2 in the algorithm.

Let $|X| = x$. Note that $1 \leq x \leq n_H/2$. Then by induction hypothesis, the congestion of the returned spanning tree is at most

$$\begin{aligned}&\max\{\text{ congestion of } \tau_1 \text{ in } H[X]\ ,\ \text{congestion of } \tau_2 \text{ in } H[Y \cup Z]\ \} \ +\ |X|\cdot|Y| \\ &\leq 16\sqrt{\hat{m}(n_H - x)}\log(n_H - x) \ +\ \left(\sqrt{\hat{m}/n_H} + 1\right)\cdot x.\end{aligned}$$

Viewing x as a real variable, by taking derivative, it is easy to see that the above expression is maximized at $x = 1$. Thus the congestion is at most $16\sqrt{\hat{m}(n_H - 1)}\log(n_H - 1) + \sqrt{\hat{m}/n_H} + 1 \ \leq\ 16\sqrt{\hat{m}n_H}\log n_H$. In the full version, we do the running time analysis.

5 Lower Bound for Spanning Tree Congestion

Here, we give a lower bound on spanning tree congestion which matches our upper bound.

▶ **Theorem 14.** *For any sufficiently large n, and for any m satisfying $n^2/2 \geq m \geq \max\{16n\log n, 100n\}$, there exists a connected graph with $N = (3 - o(1))n$ vertices and $M \in [m, 7m]$ edges, for which the spanning tree congestion is at least $\Omega(\sqrt{mn})$.*

By some standard random graph arguments, we show that when $n^2/2 \geq m \geq 16n\log n$, there exists a connected graph $H(n, m)$ with n vertices and $[m/2, 2m]$ edges, such that for each subset of vertices S with $|S| \leq n/2$, the number of edges leaving S is $\Omega((m/n)\cdot|S|)$.

We discuss our construction for Theorem 14. The full proof is in the full version. The vertex set V is the union of three vertex subsets V_1, V_2, V_3, such that $|V_1| = |V_2| = |V_3| = n$, $|V_1 \cap V_2| = |V_2 \cap V_3| = \sqrt{m/n}$, and V_1, V_3 are disjoint. In each of V_1, V_2 and V_3, we embed $H(n, m)$. Up to this point, the construction is similar to that of Ostrovskii [21], except that we use $H(n, m)$ instead of a complete graph. The new component in our construction is adding the following edges. For each vertex $v \in V_1 \cap V_2$, add an edge between v and every vertex in $(V_1 \cup V_2) \setminus \{v\}$. Similarly, for each vertex $v \in V_3 \cap V_2$, add an edge between v and every vertex in $(V_3 \cup V_2) \setminus \{v\}$. This new component is crucial: without it, we could only prove a lower bound of $\Omega(m/\sqrt{n}) = \Omega(\sqrt{mn}\cdot\frac{\sqrt{m}}{n})$.

6 Graphs with Expanding Properties

For any vertex subset $U, W \subset V$, let $N_W(U)$ denote the set of vertices in W which are adjacent to a vertex in U. Let $N(U) := N_{V\setminus U}(U)$.

▶ **Definition 15.** A graph $G = (V, E)$ on n vertices is an (n, s, d_1, d_2, d_3, t)-expanding graph if the following four conditions are satisfied:

(1) for each vertex subset S with $|S| = s$, $|N(S)| \geq d_1 n$;
(2) for each vertex subset S with $|S| \leq s$, $|N(S)| \geq d_2|S|$;
(3) for each vertex subset S with $|S| \leq n/2$ and for any subset $S' \subset S$, $|N_{V\setminus S}(S')| \ \geq\ |S'| - t$.
(4) For each vertex subset S, $|E(S, V \setminus S)| \leq d_3|S|$.

▶ **Theorem 16.** *For any connected graph G which is an (n, s, d_1, d_2, d_3, t)-expanding graph, there is a polynomial time algorithm which computes a spanning tree with congestion at most*

$$d_3 \cdot \left[4 \cdot \max \left\{ s+1 \ , \ \left\lceil \frac{3d_1 n}{d_2} \right\rceil \right\} \cdot \left(\frac{1}{2d_1} \right)^{\log_{(2-\delta)} 2} + t \right], \quad \textit{where } \delta = \frac{t}{d_1 n}.$$

In the full version, we show that for random graph $\mathcal{G}(n,p)$ with $p \geq 64 \log n/n$. with high probability the graph is an (n, s, d_1, d_2, d_3, t)-expanding graph with $s = \Theta(1/p)$, $d_1 = \Theta(1)$, $d_2 = \Theta(np)$, $d_3 = \Theta(np)$, $t = \Theta(1/p)$ (and hence $\delta = o(1)$). Applying the above theorem, together with a separate lower bound argument, we show:

▶ **Theorem 17.** *If $G \in \mathcal{G}(n,p)$ where $p \geq 64 \log n/n$, then with probability at least $1 - \mathcal{O}(1/n)$, its STC is $\Theta(n)$.*

Fully Dynamic Almost-Maximal Matching: Breaking the Polynomial Worst-Case Time Barrier

Moses Charikar[1]

Shay Solomon[2]
IBM Research, T. J. Watson Research Center, Yorktown Heights, New York, USA

Abstract

The state-of-the-art algorithm for maintaining an approximate maximum matching in fully dynamic graphs has a polynomial *worst-case* update time, even for poor approximation guarantees. Bhattacharya, Henzinger and Nanongkai showed how to maintain a constant approximation to the minimum vertex cover, and thus also a constant-factor estimate of the maximum matching size, with polylogarithmic worst-case update time. Later (in SODA'17 Proc.) they improved the approximation to $2+\epsilon$. Nevertheless, the fundamental problem of *maintaining* an approximate matching with sub-polynomial worst-case time bounds remained open.

We present a randomized algorithm for maintaining an *almost-maximal* matching in fully dynamic graphs with polylogarithmic worst-case update time. Such a matching provides $(2+\epsilon)$-approximations for both maximum matching and minimum vertex cover, for any $\epsilon > 0$. The worst-case update time of our algorithm, $O(\mathsf{poly}(\log n, \epsilon^{-1}))$, holds deterministically, while the almost-maximality guarantee holds with high probability. Our result was done independently of the $(2+\epsilon)$-approximation result of Bhattacharya et al., thus settling the aforementioned problem on dynamic matchings and providing essentially the best possible approximation guarantee for dynamic vertex cover (assuming the unique games conjecture).

To prove this result, we exploit a connection between the standard oblivious adversarial model, which can be viewed as inherently "online", and an "offline" model where some (limited) information on the future can be revealed efficiently upon demand. Our randomized algorithm is derived from a deterministic algorithm in this offline model. This approach gives an elegant way to analyze randomized dynamic algorithms, and is of independent interest.

1 Introduction

Consider a *fully dynamic* setting where we start from an initially empty graph on n fixed vertices G_0, and at each time step i a single edge (u, v) is either inserted in the graph G_{i-1} or deleted from it, resulting in graph G_i. The problem of maintaining a large matching or a small vertex cover in such graphs has attracted a lot of research attention in recent years. In general, one would like to devise an algorithm for maintaining a "good" matching and/or vertex cover with $\mathsf{polylog}(n)$ *update time* (via a data structure that answers queries of whether an edge is matched or not in constant time), where "good" means a good approximation to the maximum matching and/or the minimum vertex cover, and the update time is the time required by the algorithm to update the matching/vertex cover at each step.

One may try to optimize the *amortized* (i.e., average) update time of the algorithm or its *worst-case* (i.e., maximum) update time, over a worst-case sequence of graphs. There is a strong separation between the state-of-the-art amortized bounds and the worst-case bounds. A similar separation exists for various other dynamic graph problems, such as spanning tree, minimum spanning tree and two-edge connectivity. Next, we provide a brief literature survey on dynamic matchings. (See [17, 2, 18, 19] for a detailed survey.)

In FOCS'11, [2] devised an algorithm for maintaining a *maximal matching* with an expected amortized update time of $O(\log n)$ under the oblivious adversarial model.[3] Building on [2], [19] devised a different randomized algorithm with constant amortized update time. Note that a maximal matching provides a 2-approximation for both the maximum matching and the minimum vertex cover, while a better-than-2 approximate vertex cover cannot be efficiently computed under the unique games conjecture (UGC) [14]. In SODA'15 [5] (respectively, STOC'16 [6]) devised a deterministic algorithm for maintaining $(2+\epsilon)$-approximate vertex cover (resp., matching) with amortized update time $O(\log n/\epsilon^2)$ (resp., $O(\mathsf{poly}(\log n, \epsilon^{-1}))$). All these time bounds are amortized.

All the known algorithms for maintaining a better-than-2 approximate matching (for general graphs) require polynomial update time. In FOCS'13 [12] devised a deterministic algorithm for maintaining $(1+\epsilon)$-approximate matching with a worst-case update time $O(\sqrt{m}/\epsilon^2)$, improving over the 3/2-approximation result of [16]. [4] maintained $(3/2+\epsilon)$-approximate matching with an *amortized* update time $O(m^{1/4}/\epsilon^{2.5})$, generalizing their earlier work [3] for bipartite graphs, but the time bound in [3] is worst-case not amortized.

There are two main open questions in this area. The 1st is if one can maintain a *better-than-2* approximate matching in *amortized* polylogarithmic update time. The 2nd is:

▶ **Question 1.** *Can one maintain a "good" (close to 2) approximate matching and/or vertex cover with* worst-case *polylogarithmic update time?*

In a recent breakthrough, Bhattacharya, Henzinger and Nanongkai devised a deterministic algorithm that maintains a *constant* approximation to the minimum vertex cover, and thus also a constant-factor estimate of the maximum matching size, with polylogarithmic worst-case update time. While this result makes significant progress towards Question 1, this fundamental question remained open.[4] In particular, no algorithm for maintaining a matching with sub-polynomial worst-case update time was known, even if a polylogarithmic approximation guarantee on the matching size is allowed!

[3] In the standard *oblivious adversarial model* (cf. [8], [13]), the adversary knows all the edges in the graph and their arrival order, but is not aware of the random bits used by the algorithm.

[4] Later (in SODA'17 Proc. [7]) Bhattacharya et al. significantly improved the approximation to $2+\epsilon$. However, our result was done independently to [7]. Moreover, [7] solves Question 1 only for vertex cover. Independently of us, Arar et al. [1] solves Question 1 for matching by building on [7].

In this paper we devise a *randomized* algorithm that maintains an *almost-maximal matching (AMM)* with a polylogarithmic update time. We say that a matching for G is *almost-maximal* w.r.t. some slack parameter ϵ, or $(1-\epsilon)$-*maximal* in short, if it is maximal w.r.t. any graph obtained from G after removing $\epsilon \cdot |\mathcal{M}^*|$ arbitrary vertices, where $\mathcal{M}^*$ is a maximum matching for G. Just as a maximal matching provides a 2-approximation for matching and vertex cover, an AMM provides a $(2+\epsilon)$-approximation. We show:

▶ **Theorem 2.** *For any $\epsilon > 0$, one can maintain an AMM with worst-case update time $O(\mathsf{poly}(\log n, \epsilon^{-1}))$, where the $(1-\epsilon)$-maximality guarantee holds with high probability.*

Our update time is $O(\max\{\log^7 n/\epsilon, \log^5 n/\epsilon^4\})$; reducing this bound towards constant lies outside the scope of this paper; see Sec. 9 in the full version [9] (shortly, "i.t.f.v.").

The algorithm's worst-case guarantee can be strengthened, using [20], to bound the number of changes (replacements) to the matching. Optimizing this measure is important in various practical applications; refer to [20] for a motivation of this measure.

Our result resolves Question 1 in the affirmative, up to the ϵ dependency. In particular, it is essentially the best result possible under the UGC for the dynamic vertex cover problem; it started to circulate in Nov. 2016, and is independent of the $(2+\epsilon)$-vertex cover result of [7].

On the way to this result, we devise a *deterministic* algorithm that maintains an AMM with a polylogarithmic update time in a natural *offline model* that is described next. This deterministic algorithm may be of independent interest, as the offline setting seems important in its own right; see p. 3 i.t.f.v. for further details.

1.1 A Technical Overview

The offline model. Suppose the entire update sequence is known in advance, and is stored in some data structure. Suppose further that for any i, accessing the ith edge update via the data structure is efficient, taking $\mathsf{polylog}(n)$ or even $O(1)$ time. A natural question is whether one can exploit this knowledge of the future to obtain better algorithms for maintaining a good matching and/or vertex cover. Consider in particular the *maximal matching* problem, and a deletion of a matched edge (u, v) from the graph (which is the problematic part). If u has a free neighbor, we need to match them, and similarly for v. The algorithm may naively scan the neighbors of u and v, which may require $O(n)$ time. Surprisingly, this naive $O(n)$ bound is the state-of-the-art for general (dense) graphs, unless one allows both randomization and amortization [2, 19]. Can one do better in the offline setting?

We argue that a dynamic maximal matching can be maintained in the offline setting *deterministically* with constant *amortized* update time. To this end, we make the following observation: The machinery of [2, 19] extends *seamlessly* to the offline setting. More specifically, in contrast to the algorithms [2, 19], which choose the matched edge of v *uniformly at random* among a subset of its adjacent edges E_v that is computed carefully by those algorithms (details below), in the offline setting we choose the matched edge to be the one that will be deleted last among E_v. (We do not choose the edge that will be deleted last among all adjacent edges of v, as this is doomed; see the technical overview i.t.f.v). It is readily verified that the analysis of [2, 19] carries over to the offline setting directly.

The resulting deterministic algorithm for the offline setting is inherently *amortized*, whereas our focus is on *worst-case* bounds. To obtain good worst-case bounds, we build on the machinery of [2, 19]. The price of translating the amortized bounds of [2, 19] into a similar worst-case bound is that the maintained matching is no longer maximal, but rather

almost-maximal.[5] This translation is highly non-trivial, and is carried out in two stages. First, we consider the offline setting, and devise a deterministic algorithm there. Coping with the offline setting is easier than with the standard setting, as it allows us to ignore intricate probabilistic considerations, and to handle them separately. Second, we convert the results for the offline setting to the standard setting. The algorithm itself remains essentially the same. (Instead of choosing the edge that will be deleted last, choose a random edge.) On the other hand, showing that the maintained matching remains almost-maximal requires more work. This two-stage approach thus provides an elegant way to analyze randomized dynamic algorithms, and we believe it would be useful in other dynamic graph problems as well.

The framework of [2, 19]. We next provide a rough description of the *amortized* framework of [2, 19]. (The approach of [19] builds on the framework of [2] and extends it; for clarity, we won't distinguish between [2] and [19].)

Matched edges will be chosen randomly. If an edge $e = (u, v)$ is chosen to the matching uniformly at random among k adjacent edges of either u or v, w.l.o.g. u, we say that its *potential* is k. Under the oblivious adversarial model, the expected number of edges incident on u that are deleted from the graph before deleting edge (u, v) is $k/2$. Thus, following a deletion of a matched edge (u, v) with potential k from the graph, we have time $\tilde{O}(k)$ to handle u and v in the amortized sense.

Each vertex v dynamically maintains a *level* ℓ_v; informally, v's level will be logarithmic in the potential value of the matched edge adjacent to v. Free vertices are at level -1; matched vertices are at levels between 0 and $O(\log n)$. Based on vertices' levels, a dynamic edge orientation is maintained, where each edge is oriented towards the lower level endpoint.

When a vertex u becomes free, the algorithm (usually) chooses a mate for it randomly. If this mate w is already matched, say to w', the algorithm has to delete edge (w, w') from the matching in order to match u with w. However, we will be able to compensate for the loss in potential value (caused by deleting edge (w, w') from the matching) if it is significantly smaller than the potential of the newly created matched edge. Since vertices' levels are logarithmic in their potential, all neighbors of u with lower level should have potential value at most half the potential value of the new matched edge on u. In other words, for each of those neighbors, we can afford to break their old matched edge. Hence, the mate w of u will be chosen uniformly at random among u's neighbors with lower level.

A central obstacle is to distinguish between neighbors of u with level ℓ_u and those with lower level. Indeed, it is possible that most of u's neighbors have level ℓ_u, and none of them can be chosen as a mate for u. Roughly speaking, the execution of the algorithm splits into two cases. If the current out-degree of u is not (much) larger than its out-degree at the time its old matched edge got created, then we should be able to afford to scan all of them, due to sufficiently many adversarial edge deletions that are expected to occur. Notice that in this case the charging argument is based on *past* edge deletions.

The second case is when the out-degree of u is (much) larger than what it was when the old matched edge got created. The time needed for distinguishing u's neighbors at level ℓ_u from those at lower levels could be significantly larger than the "money" we got from

[5] The amortized update time analysis of the algorithm from [2] (both the FOCS'11 and subsequent journal SICOMP'15 versions) was erroneous, but was corrected in a subsequent erratum by the same authors. (The amortized update time analysis of the algorithm from [19] is different than the one used in [2], and does not have that mistake.) Although our algorithm builds on the machinery of [2, 19], the mistake in [2] does not affect the current paper, as we provide an independent analysis for a different algorithm, which bounds the worst-case update time of our algorithm rather than the amortized update time.

past edge deletions. In this case the algorithm *raises* u to a possibly much higher level ℓ^*, where there are not too many neighbors for u at that level as compared to the number of neighbors at lower levels. Having raised u to that level, we can perform the random sampling of its mate among all neighbors of level lower than ℓ^*. Notice that in this case the charging argument is not based on the past, but rather on *future* edge deletions.

Our approach. Note that the framework of [2, 19] is inherently *amortized*: Every once in a while there are "expensive" operations, which are charged to "cheap" operations that occurred in the past or will occur in the future. To obtain a low worst-case update time, we should be *cheap in any time interval*, thus we can rely neither on the past nor the future. Consider a matched edge (u, v) deleted by the adversary. We expect the adversary to make many edge deletions on at least one of these endpoints before deleting this edge. Alas, it is possible that all these edge deletions occurred a long time ago, which is useless for a worst-case algorithm. Consider the offline setting, and let $e_1, \ldots, e_\eta$ be η arbitrary matched edges with potential value k. For each such edge e_i, let $S(e_i)$ be its *sample*, i.e., the set of edges from which e_i was sampled to the matching. In the offline setting e_i will be deleted only after all $k-1$ other edges from its sample have been deleted. However, it is possible that the adversary first deletes the first $k-1$ edges from the samples of each of the matched edges, and only then turn to deleting the matched edges. Assuming k is large, it takes a long time for the adversary to delete the first $\eta(k-1)$ edges from all η samples, but the amortized algorithms of [2, 19] remain *idle* during all this time. An algorithm with a low worst-case update time must be active in this time interval, as immediately afterwards the adversary can remove the η matched edges from the graph, much faster than the algorithm can add edges to the matching in their place, leading to a poor approximation guarantee. Hence, at any point in time, the algorithm needs to be proactive and protect itself from such a situation happening in the future.

Generally, while in an amortized algorithm invariants may sometimes be violated and then restored via expensive operations, an algorithm with a low worst-case update time should persistently "clean" the graph, making sure that it is never close to violating any invariant. Naturally, we will need to maintain additional invariants to those maintained by the amortized algorithms [2, 19]. To this end we employ four different data structures that we call *schedulers*, each for a different purpose. Each of those schedulers consists of $O(\log n)$ sub-schedulers, a single sub-scheduler per level. Next we fix some level $\ell \approx \log k$, where k is the potential of the matched edges on that level, and focus on it.

The scheduler `unmatch-schedule` periodically removes edges from the matching, one after another, by always picking a matched edge whose *remaining sample* (i.e., the set of edges from the sample that have not been deleted yet from the graph) is smallest. As strange as it might seem, this strategy enables us to guarantee that only few matched edges will ever be deleted by the adversary. Note that removing a matched edge from the matching is not a cheap operation, as we need to find new mates for the two endpoints of the edge. Thus, the execution of the scheduler must be *simulated* over sufficiently many adversarial updates, which may include more deletions. But, as we control the rate at which the scheduler is working, we can make sure that it works sufficiently faster than the adversary. Therefore, in this "game" between the scheduler and the adversary, the scheduler will always win.

The role of `unmatch-schedule` is to make sure that all the samples are pretty full. Intuitively, this provides the counter-measure of relying on past adversarial edge deletions, as done in the amortized argument. The next scheduler `rise-schedule` provides the counter-measure of relying on future adversarial edge deletions. Recall that future edge deletions

are used in the amortized argument only in the case that a vertex had to rise to a higher level, which occurs only if its out-degree became too large for its current level. The role of `rise-schedule` is to make sure that vertices' out-degrees are always commensurate with their level. This scheduler periodically raises vertices to the level ℓ of which it is in charge, one after another, by always choosing to raise a vertex with the largest number of neighbors at level lower than ℓ. Although the two schedulers are based on the same principle, the game that we play here is not between the scheduler and the adversary, because here the algorithm itself may change the level of vertices and their out-degree, so `rise-schedule` has to compete against both the adversary and the algorithm. In contrast to the other scheduler, speeding up the rate at which `rise-schedule` works will not help winning the game. Instead, we manage to bound the speed of this scheduler with respect to that of the (adversary + algorithm), which enables us to show that the out-degree of all vertices is always in check.

For the offline model, these two schedulers suffice. However, in the oblivious adversarial model, the adversary will manage to delete some matched edges from time to time. The scheduler `free-schedule` periodically handles all the vertices that become free due to the adversary, one after another. Using the property that all samples are always pretty full, we manage to prove that only an ϵ-fraction of the matched edges get destroyed by the adversary at any time interval. Note that this bound is probabilistic – to make sure that it indeed occurs with high probability, we also use another scheduler `shuffle-schedule`, which periodically removes a random edge from the matching. For technical reasons, it is vital that `shuffle-schedule` would work sufficiently faster than some of the other schedulers.

2 The Update Algorithm

2.1 Invariants and schedulers. Our algorithm builds on the amortized algorithms by [2, 19], which maintain for each vertex v a *level* ℓ_v, with $-1 \leq \ell_v \leq \log_\gamma(n-1)$, where $\gamma = \Theta(\log n)$. (We use logarithms in base $\gamma = \Theta(\log n)$, whereas [2] and [19] use base 2 and 5, respectively.) Based on the levels of vertices, an edge orientation is maintained, with the vertex out-degree serving as an important parameter. The amortized algorithms of [2, 19] maintain the following invariants (Invariants 3(a)-3(d)) *at all times*. i.e., these invariants hold at the *end of the execution* of the update algorithms (and before the next update operation occurs). These invariants may become violated *throughout the execution* of the update algorithms. Also, the runtime of the update algorithms of [2, 19] may be $\Omega(n)$ in the worst case, thus it may take them a lot of time to restore the validity of these invariants, once violated. We added a comment to the right of each of these invariants, either /* maintained */ or /* partially maintained */, to indicate jf the respective invariant is maintained fully or only partially by our new algorithm. Our algorithm will maintain Invariants 3(a) and 3(b) at all times, as in the amortized algorithms [2, 19], where Invariants 3(c) and 3(d) are maintained only partially. Next, we make this statement precise.

▶ **Invariant 3.**

(a) *Any matched vertex has level at least 0. /* maintained */*

(b) *The endpoints of any matched edge are of the same level, and this level remains unchanged until the edge is deleted from the matching. (We henceforth define the level of a matched edge, which is at least 0 by item (a), as the level of its endpoints.) /* maintained */*

(c) *Any free vertex has level -1 and out-degree 0. (The matching is maximal.) /* partially maintained */*

(d) *An edge (u, v) with $\ell_u > \ell_v$ is* oriented *by the algorithm as $u \to v$. (If $\ell_u = \ell_v$, the orientation of (u, v) is determined suitably by the algorithm.) /* partially maintained */*

Once a matched vertex becomes free, its level will exceed -1 until the update algorithm handles it. We say that such a vertex is *temporarily free* (shortly, *TF*), meaning that it is not matched to any vertex yet, but its level and out-degree remain temporarily as before. From now on, we distinguish between *free* and *TF* vertices: Free vertices are unmatched and their level is -1, while TF vertices are unmatched and their level exceeds -1. By making this distinction, Invariant 3(c) holds true as stated. Combining it with Invariant 3(a), we obtain:

▶ **Invariant 4.** *Any vertex of level -1 is unmatched and has out-degree 0.*

Invariants 3(c) and 4 do not apply to TF vertices; thus there may be edges between TF (thus unmatched) vertices, hence the matching is not maximal. The challenge is to guarantee that the number of TF vertices is small w.r.t. the number of matched vertices, yielding an AMM.

TF vertices are handled via data structures that we call *schedulers*. We distinguish between vertices that become TF due to the adversary and those due to the update algorithm itself. For each level ℓ, we maintain a queue Q_ℓ of level-ℓ vertices that become TF due to the adversary, and the vertices in Q_ℓ will be handled, one after another, via appropriate schedulers. We will need to make sure that the total number of vertices over the queues of all levels is in check at all times. The various schedulers need to work together, without conflicting each other; the exact way in which they work is described soon.

A TF vertex that is being handled by some scheduler is called *active*, and the process of handling it may be simulated over multiple update operations. Hence, there might be *inconsistencies* in the data structures throughout this process concerning the active vertices. To account for those inconsistencies, we hold a list of active vertices, denoted *Active*, and we will make sure that this list is of size $O(\log_\gamma n) = O(\log n)$ at any point in time. By bounding the number of active vertices, we can *authenticate* the up-to-date information concerning active vertices efficiently; this *authentication process* is described i.t.f.v in Section 2.3. Our algorithm maintains the following relaxation of Invariant 3(d).

▶ **Invariant 5.** *Any edge (u, v), with $\ell_u > \ell_v$ and $u, v \notin$ Active, is* oriented *as $u \to v$.*

For each vertex v, we maintain its neighbors and outgoing neighbors in linked lists $\mathcal{N}_v$ and $\mathcal{O}_v$, and its incoming neighbors via a more detailed structure $\mathcal{I}_v$; see p. 8 i.t.f.v.

Our algorithm employs four different schedulers, each of which consists of $O(\log_\gamma n) = O(\log n)$ sub-schedulers, a single sub-scheduler per level $\ell = 0, 1, \ldots, \log_\gamma(n-1)$. It is instructive to think of each sub-scheduler as running threads of execution, and of its scheduler as synchronizing $O(\log n)$ threads, one per level. Each thread executed by a level-ℓ sub-scheduler, hereafter *level-ℓ thread*, will run in the same amount of time $T_\ell = \gamma^\ell \cdot \Theta(\log^4 n)$, by "sleeping" if finishing the execution prematurely. To achieve a low worst-case update time, the execution of any such thread is not carried out at once, but is rather carried out (or *simulated*) over multiple update operations, simulating a fixed number of computation steps per update operation; we refer to that number as a *simulation parameter*, and we'll use two of them, $\Delta := \Theta(\log^5 n/\epsilon)$ and $\Delta' = \Delta \cdot \gamma = \Delta \cdot \Theta(\log n)$. The schedulers `free-schedule`, `rise-schedule` and `shuffle-schedule` use a simulation parameter of Δ', whereas `unmatch-schedule` uses a simulation parameter of Δ, and is thus "slower" than the others by a factor of $\gamma = \Theta(\log n)$. The simulation parameters, Δ or Δ', determine the number of update operations required to finish the execution of the thread, T_ℓ/Δ or T_ℓ/Δ', respectively. We refer to this number as the *(level ℓ) simulation time*; unlike the simulation parameters, which do not change with the level, the simulation times grow with each level by a factor of γ.

1st scheduler. The first scheduler `free-schedule` handles all vertices that become TF due to the adversary; for each level $\ell = 0, 1, \ldots, \log_\gamma(n-1)$, the corresponding sub-scheduler `free-schedule`$_\ell$ handles all vertices of Q_ℓ, one after another. The exact procedure for handling a TF vertex v, `handle-free`(v), is described in Section 2.4. Procedure `handle-free`(v) will be executed by a single level-ℓ thread corresponding to v that runs in an overall time of T_ℓ, simulating Δ' steps of this procedure following each update operation. The $\log_\gamma(n-1)+1$ execution threads (over all levels) executed by `free-schedule` following every update operation are handled *sequentially*, by decreasing order of simulation times, and thus by decreasing order of levels, i.e., the $\log_\gamma(n-1)$-level thread is handled first, then the $\log_\gamma(n-1)-1$-level thread, etc., until the 0-level thread. Note that these threads execute different calls of Procedure `handle-free`, which handle vertices at different levels. [[S: moved this sentence]] Following each update operation, the $\log_\gamma(n-1)$-level thread simulates Δ' steps of its own call of Procedure `handle-free`, the $\log_\gamma(n-1)-1$-level thread simulates Δ' steps of its own call, and so on, hence the total time spent by `free-schedule` following a single update operation is $\Delta' \cdot (\log_\gamma(n-1)+1) = O(\log^7 n/\epsilon)$.

By the same principle, the total time spent by `rise-schedule` and `shuffle-schedule` following a single update operation will be bounded by $\Delta' \cdot (\log_\gamma(n-1)+1) = O(\log^7 n/\epsilon)$. On the other hand, `unmatch-schedule` has a simulation parameter of Δ rather than Δ', so the total time spent by this scheduler following a single update will be bounded by $\Delta \cdot (\log_\gamma(n-1)+1) = O(\log^6 n/\epsilon)$. This scheme gives rise to a worst-case update time of $O(\log^7 n/\epsilon)$, and this bound holds *deterministically*.

2nd scheduler. The second scheduler `unmatch-schedule` removes matched edges from the matching; for each ℓ, the corresponding sub-scheduler `unmatch-schedule`$_\ell$ removes level-ℓ edges from the matching, one after another, as follows. Each level-ℓ matched edge $e = (u, v)$ is sampled uniformly at random from between $(1-\epsilon)\cdot\gamma^\ell$ and γ^ℓ edges. (In the offline setting, we choose the edge that will be deleted last among those.) We refer to this edge set, denoted by $S(e)$, as the *sample space* (or *sample*) of e. As time progresses, some edges of $S(e)$ may be deleted from the graph; denote by $S^*(e)$ the *original* sample of e, with $(1-\epsilon)\cdot\gamma^\ell \le |S^*(e)| \le \gamma^\ell$, and by $S_t(e) = S(e)$ its sample *remaining* at time t. The goal of `unmatch-schedule`$_\ell$ is to guarantee that the samples of all level-ℓ matched edges never reach $(1-2\epsilon)\cdot\gamma^\ell$; more accurately, `unmatch-schedule`$_\ell$ maintains the following invariant:

▶ **Invariant 6.** *For any level-ℓ matched edges e with $T_\ell/\Delta \ge 1$ and any t, $|S_t(e)| > (1-2\epsilon)\cdot\gamma^\ell$.*

To maintain this invariant, `unmatch-schedule`$_\ell$ will always remove a matched edge of smallest remaining sample (can be easily carried out in $O(1)$ time). For each level-ℓ matched edge $e = (u, v)$ that is removed by `unmatch-schedule`$_\ell$, its two endpoints u and v become TF, and they are handled by appropriate calls to Procedure `handle-free`. More specifically, we execute Procedure `handle-free`(u) and then `handle-free`(v) by running a level-ℓ thread, which runs in an overall time of T_ℓ, simulating Δ steps of execution following each update operation. The intuition as to why `unmatch-schedule`$_\ell$ can maintain Invariant 6 is the following. (See Section 4.2 i.t.f.v. for the formal argument.) Since $T_\ell = \gamma^\ell \cdot \Theta(\log^4 n)$ and $\Delta = \Theta(\log^5 n/\epsilon)$, the simulation time T_ℓ/Δ of a thread run by `unmatch-schedule`$_\ell$ (which designates the number of update operations needed for simulating its entire execution) is $\Theta(\epsilon(\gamma^\ell/\log n))$. In other words, `unmatch-schedule`$_\ell$ can remove a level-ℓ matched edge within $T_\ell/\Delta = \Theta(\epsilon(\gamma^\ell/\log n))$ adversarial update operations. On the other hand, the expected number of adversarial edge deletions needed to turn a "full" level-ℓ matched edge e (with sample $|S^*(e)| \ge (1-\epsilon)\cdot\gamma^\ell$) into an "under full" edge (with sample $\le (1-2\epsilon)\cdot\gamma^\ell$) is

$\Omega(\epsilon \cdot \gamma^\ell)$. Thus `unmatch-schedule`$_\ell$ is "faster" than the adversary by at least a logarithmic factor, assuming $T_\ell/\Delta \geq 1$ (which holds when $\gamma^\ell = \Omega(\log n/\epsilon)$), a property that suffices for showing that no edge is ever under full, i.e., the samples of all level-ℓ matched edges are always in check. This is the idea behind maintaining the validity of Invariant 6 in levels ℓ for which the simulation time satisfies $T_\ell/\Delta \geq 1$. This invariant, in turn, guarantees that the adversary is unlikely to delete any particular edge from the matching, using which we show (in Section 6 i.t.f.v.) that the maintained matching is always almost-maximal with high probability. The complementary regime of levels, namely, levels ℓ for which $T_\ell/\Delta < 1$, is trivial and does not rely on Invariant 6, as then the adversary does not make any edge deletion within the time required by a level-ℓ thread to complete its entire execution.

3rd scheduler. Let $N_v(\ell)$ denote the set of neighbors of v with level strictly lower than ℓ, and write $\phi_v(\ell) = |N_v(\ell)|$. For each vertex v, we will maintain the $\phi_v(\ell)$ values for all levels ℓ greater than the current level ℓ_v of v. For any level $\ell \leq \ell_v$, the corresponding value $\phi_v(\ell)$ will not be maintained, and the algorithm will have to compute it "on the fly", if needed. The algorithm of [2] maintains the invariant that $\phi_v(\ell) < \gamma^\ell$, for any v and $\ell > \ell_v$. (Recall that γ is taken to be constant in [2], whereas here we take γ to be $\Theta(\log n)$.) The scheduler `rise-schedule` maintains the following relaxation of the invariant from [2], and it does so by raising vertices to higher levels in a specific order, as described next.

▶ **Invariant 7.** *For any vertex v and any level $\ell > \ell_v$, $\phi_v(\ell) \leq \gamma^\ell \cdot O(\log^2 n)$.*

For each level ℓ, the corresponding sub-scheduler `rise-schedule`$_\ell$ is responsible for maintaining the invariant w.r.t. that level. Whenever a new level-ℓ thread is initiated by `rise-schedule`$_\ell$, it starts by *authenticating* the $\phi_v(\ell)$ values over all vertices v using the *Active* list. (The authentication process takes time $O(\log^2 n)$ to guarantee that all $\phi_v(\ell)$ values are up to date, and is described in Section 2.3 i.t.f.v.) Then the thread picks a vertex v whose $\phi_v(\ell)$ value is highest among all vertices with level lower than ℓ (can be easily carried out in $O(1)$ time). These steps take time $O(\log^2 n)$, and are thus carried out by the thread "instantly", i.e., without simulating their execution over subsequent update operations. The same execution thread continues to removing v's old matched edge (v, w) (if exists) from the matching, and raises v to level ℓ by executing Procedure `set-level`(v, ℓ), whose description is in Section 2.2. The runtime of this procedure is high, so its execution is simulated over multiple update operations, simulating Δ' execution steps following each update operation. Then the same execution thread handles the two TF vertices v and w using Procedure `handle-free`, i.e., it continues to executing the call to `handle-free`(v) and then to `handle-free`(w), simulating Δ' execution steps following each update operation.

4th scheduler. The fourth scheduler `shuffle-schedule` removes matched edges from the matching uniformly at random. By working faster than some other schedulers (`unmatch-schedule` in particular), it forms a dominant part of the algorithm, using which we show (Section 6.2 i.t.f.v.) that it provides a near-uniform random shuffling of the matched edges. This random shuffling facilitates the proof of the assertion that the adversary is unlikely to delete any particular edge from the matching. For each ℓ, the sub-scheduler `shuffle-schedule`$_\ell$ always picks a matched edge uniformly at random among all remaining level-ℓ edges, and then removes it from the matching. As with `unmatch-schedule`$_\ell$, for each level-ℓ matched edge $e = (u, v)$ that is removed by `shuffle-schedule`$_\ell$, its two endpoints u and v become TF, and they are handled by calls to Procedure `handle-free`. We execute these calls (to `handle-free`(u) and `handle-free`(v)) by running a level-ℓ thread, which runs

in an overall time of T_ℓ, and we simulate Δ' (rather than Δ as with `unmatch-schedule`$_\ell$) execution steps following each update operation, which ensures that `shuffle-schedule` is faster than `unmatch-schedule` by a logarithmic factor. We only need to apply the shuffling in levels ℓ for which the simulation time satisfies $T_\ell/\Delta \geq 1$, as in the complementary regime ($T_\ell/\Delta < 1$) the adversary does not make any edge deletion within the time required by a level-ℓ thread to complete its entire execution, and then a random shuffling is redundant.

2.2 Procedure `set-level`(v, ℓ). (This procedure is described in detail in Section 3.1 i.t.f.v.) Whenever the update algorithm examines a vertex v, it may need to re-evaluate its level. After the new level ℓ is determined (outside this procedure, details below), the algorithm calls Procedure `set-level`(v, ℓ). Although setting the level of v to ℓ can be done instantly, the task of Procedure `set-level`(v, ℓ) is to update the relevant data structures as a result of this level change. This process involves updating the sets of outgoing and incoming neighbors of v and some of its neighbors (or "flipping" the respective edges) so as to maintain Invariant 5, and also updating the ϕ values of v and its relevant neighbors. We refer to this (possibly long) process as the *falling* (if $\ell < \ell_v$) or *rising* of v (if $\ell > \ell_v$); the thread executing this procedure simulates multiple execution steps following each update operation. We will need to make sure that any call to `set-level`(v, ℓ) is executed by a level-$\hat{\ell}$ thread, where $\hat{\ell} \geq \tilde{\ell} := \max\{\ell_v, \ell\}$. We show (see Lemma 3.2 i.t.f.v.) that the runtime of this procedure is bounded by $O((\phi_v(\tilde{\ell}+1) + \log n) \cdot \log n)$, where $\phi_v(\tilde{\ell}+1)$ is the number of v's neighbors of level $< \tilde{\ell}+1$ at the beginning of this procedure's execution.

2.3 Procedures `handle-insertion`(u, v) and `handle-deletion`(u, v). (These procedures are described in detail in Section 3.2 i.t.f.v.) An edge insertion (u, v) is handled (via `handle-insertion`(u, v)) in the obvious way in time $O(\log^4 n)$, which is within the time reserved for a single update operation. An edge deletion (u, v) is handled (via `handle-deletion`(u, v)) similarly, unless (u, v) is matched, in which case both u and v become TF, and they are inserted to the queue Q_{ℓ_u} (by Invariant 3(b) $\ell_u = \ell_v$). As described above, `free-schedule`$_{\ell_u}$ will handle u and v (by making the calls to `handle-free`(u) and `handle-free`(v)), one after another, after handling all preceding vertices in Q_{ℓ_u}.

2.4 Procedure `handle-free`(v). (This procedure is described in detail in Section 3.3 i.t.f.v.) This procedure handles a TF vertex v, and is first invoked by the schedulers as described above, but then also recursively. It starts by computing the highest level $\ell, 0 \leq \ell \leq \ell_v$, where $\phi_v(\ell) \geq \gamma^\ell$, and the corresponding vertex set $N_\ell(v)$ of v, in order to sample a neighbor w of level $< \ell$ as v's new mate. The sampling is done from the set $N'_\ell(v)$ of non-active vertices in $N_\ell(v)$. To match v with w, we first delete the old matched edge (w, w') on w (if exists), thus rendering w' TF. Second, we let v and w fall and rise to the same level ℓ, respectively, by calling to `set-level`(v, ℓ) and `set-level`(w, ℓ). We then match v with w, thus creating a new level-ℓ matched edge (satisfying Invariant 3(b)). Finally, assuming w was previously matched to w', we handle w' recursively by calling to `handle-free`(w'). (In the degenerate case that no level ℓ as above exists, we have $\phi_v(0) = 0$, i.e., v does not have any neighbor at level -1, thus we call `set-level`$(v, -1)$ and v becomes free.)

Our update algorithm guarantees that this procedure is executed by a level-ℓ_v thread, where ℓ_v is v's level at the outset of the procedure's execution. The same thread is used also for all subsequent recursive calls. We show (Lemma 3.1 i.t.f.v.) that the runtime of Procedure `handle-free`(v) is bounded by $O(\gamma^{\ell_v} \cdot \log^4 n)$.

3 Analysis

3.1 Schedulers. The principle that governs the operation of `unmatch-schedule` and `rise-schedule` can be described via a balls and bins game by [11, 15, 10] between two players. Initially there are N empty bins. In each round Player I removes a bin of largest size, then Player II may add up to $b \geq 1$ balls to bins. The game ends when no bin is left or when the size of any bin reaches some parameter k. Player I wins (respectively, loses) in the former (resp., latter) case. As follows from [11, 15, 10], Player I wins if $b < \frac{k}{(\ln N+1)}$.

To prove that `unmatch-schedule` and `rise-schedule` maintain Invariants 4 and 5, respectively, we carefully build on this principle in several steps; see Sections 4.2 and 4.3 i.t.f.v. The analysis of `rise-schedule` is more intricate than that of `unmatch-schedule`, as our update algorithm affects both players in the underlying balls and bins game; we henceforth focus on `rise-schedule`, highlighting some insights behind our analysis. Consider the variant of the game where the bins are not empty initially, but rather contain at most $k' \ll k$ balls each. Using the same argument, Player 1 wins if $b < \frac{k-k'}{(\ln N+1)}$. We show that Invariant 7 is maintained by translating this variant of the game appropriately.

Fix any level $\ell \geq 0$. Invariant 7 requires that the $\phi_v(\ell)$ values are always $< \gamma^\ell \cdot O(\log^2 n)$, for all v with $\ell_v < \ell$. In the balls and bins game, the bins represent the respective vertex sets $N_v(\ell)$ (of v's neighbors of level $\leq \ell - 1$), for $\ell_v < \ell$. (Our algorithm does not maintain these sets, only the ϕ values.) The sub-scheduler $\texttt{rise-schedule}_\ell$ is Player I in the game; it always picks a vertex v whose $\phi_v(\ell)$ value is highest, and raises it to level ℓ. Following this rise, $\ell_v = \ell$, hence the invariant for v and level ℓ holds vacuously. Thus, the analog of removing a bin by Player I is to raise a vertex to level ℓ.

At the beginning the graph is empty, so all vertex levels are -1 and all vertex sets $N_v(\ell)$ are empty. Thus initially we have an empty bin for every vertex. As time progresses some of these bins are being removed due to vertex rising. When a vertex rises to level ℓ, all its bins up to level ℓ are removed instantly. Bins are also created due to vertices falling, by Procedure `handle-free`. When a vertex v starts falling from level ℓ_v to level ℓ, it is as if the corresponding vertex sets $N_v(j)$ in all levels $j \in \{\ell + 1, \ldots, \ell_v\}$ are created instantly; the level of v is viewed as its destination level ℓ from the moment its falling to level ℓ starts. Although the same vertex set $N_v(j)$ may be removed and created multiple times, we view any such newly created set as a different bin that was there from the game's outset. To comply with the initial bound of $\leq k'$ balls in any bins, we set $k' = k'_\ell$ as γ^ℓ, and prove (Lemma 4.1 i.t.f.v.) that any newly created level-ℓ bin contains $\leq k' = \gamma^\ell$ balls.

The level-ℓ vertex sets $N_v(\ell)$ and values $\phi_v(\ell)$ may grow either due to edge insertions (by adversary) or due to falling vertices (by update algorithm). In other words, Player II in the game is (adversary + update algorithm). Letting Player I ($\texttt{rise-schedule}_\ell$) work faster than the other sub-schedulers is problematic: While this would lead to more vertices rising, which helps Player I win, each vertex rising may trigger the fall of another vertex, which has the opposite effect. Instead, we prove (Lemma 4.2 i.t.f.v.) that the number of balls $b = b_\ell$ added to the bins by Player II while Player I removes a bin is $O(\gamma^\ell \cdot \log n)$. It is easy to verify that the number N of level-ℓ bins is polynomially bounded, so $\ln N = \Theta(\log n)$. Taking $k = O(\gamma^\ell \cdot \log^2 n)$ completes the translation of the balls and bins game. By setting the constant appropriately, we obtain $b < \frac{k-k'}{\ln N}$, hence Player I wins the game. Consequently, we showed that Invariant 7 is maintained.

3.2 Proof of (Almost-)Maximality. To prove almost-maximality, we show that the number of TF vertices is always an ϵ-fraction of the number of matched edges. We only consider here TF vertices due to the adversary of levels ℓ with $T_\ell/\Delta \geq 1$, as the complementary case

is easy. Any matched edge is created by the algorithm by first determining its level, and only then performing the sampling. If the edge is matched at level ℓ, it is chosen uniformly at random from between $(1-\epsilon)\cdot\gamma^\ell$ and γ^ℓ edges. We thus fix some level ℓ with $T_\ell/\Delta \geq 1$, and focus on the matched edges at that level. Invariant 6 holds for level ℓ, thus the samples of all level-ℓ edges always contain with probability (w.p.) 1 at least $(1-2\epsilon)\cdot\gamma^\ell$ edges.

Consider any time step t, and let V_t be the set of vertices of level ℓ at time t. Let $A_t = A'_t \cap A''_t$, where A'_t is the event that $|V_t| = \Omega(\log^4 n/\epsilon^3)$ and A''_t is the event that an $\Omega(\epsilon)$-fraction of the vertices of V_t are TF due to the adversary at time t. We argue that $\mathbb{P}(A_t) = O(n^{-c+2})$, for some (big enough) constant c. This assertion, which is given as Lemma 6.1 i.t.f.v., is central in our proof of the almost-maxiamlity guarantee, and the almost-maximality guarantee is derived as a simple corollary (Theorems 6.5 and 6.6 i.t.f.v.). Next, we give some insights behind the proof.

Any matched edge is sampled uniformly at random from between $(1-\epsilon)\cdot\gamma^\ell$ and γ^ℓ edges. Consider the edges of the sample $S^*(e)$ of e in the order they are deleted by the adversary, *even after the edge is removed from the matching*, either by the adversary or by the algorithm. A matched edge is called *bad* if it is one of the first (at most) $2\epsilon\cdot\gamma^\ell$ edges in this ordering; otherwise it is good. Invariant 6 guarantees that the samples of all level-ℓ edges always contain $\geq (1-2\epsilon)\cdot\gamma^\ell$ edges, so at most $2\epsilon\cdot\gamma^\ell$ edges are deleted from the sample of any matched edge (while it is matched). It follows that a good edge cannot get deleted by the adversary while it is matched (hereafter, get *hit*); a bad edge may get hit.

The probability of an edge to be bad is $\leq \frac{2\epsilon\cdot\gamma^\ell}{(1-\epsilon)\cdot\gamma^\ell}$, which is at most 4ϵ for all $\epsilon < 1/2$. Our argument, alas, is not applied on all matched edges created since the algorithm's outset, but rather on a subset of edges that are matched at a certain time step t', and there are dependencies on previous coin flips of our algorithm, which are the result of edges being removed from the matching by the update algorithm itself (not the adversary). Indeed, given that some edge e is matched at time t', the sample of e may be significantly reduced, which could increase the probability of e being bad. To overcome this hurdle, we use `shuffle-schedule` to show that the fraction of bad edges at any time is $O(\epsilon)$ w.h.p. To this end, we apply a game, hereafter the *shuffling game*, where in each step a single edge is either added or deleted (starting with no edges) by the following players: (1) `Adder`: adds an edge, which is bad w.p. $\leq 4\epsilon$, (2) `Shuffler`: deletes an edge uniformly at random among the existing edges, (3) `Malicious`: deletes a good edge. A newly created matched edge is bad w.p. $\leq 4\epsilon$, thus `Adder` assumes the role of creating matched edges by the algorithm, and so only an $O(\epsilon)$-fraction of the matched edges created by `Adder` are bad w.h.p. `Shuffler` assumes the role of `shuffle-schedule` in the algorithm, deleting matched edges uniformly at random. If the fraction of bad edges during some time interval is $\Theta(\epsilon)$, the fraction of bad edges deleted by `Shuffler` in this interval is $\Theta(\epsilon)$ w.h.p., hence `Shuffler` does not change the fraction of bad edges by too much. The role of `Malicious` is not to model the exact behavior of the other (non-shuffled) parts of the algorithm that remove matched edges, but rather to capture the worst-case scenario that might happen. We show that the affect of `Malicious` to the game is negligible, which implies that even if the other (non-shuffled) parts were to delete only good edges, the fraction of bad edges would be $O(\epsilon)$; formally, we prove that the fraction of bad edges at any step t' is w.h.p. $O(\epsilon)$. This proof, provided in Section 6.2 i.t.f.v, is nontrivial and makes critical use of the property that `Shuffler` is faster than `Malicious` by a logarithmic factor; we then show that the parties corresponding to `Shuffler` and `Malicious` in the algorithm indeed satisfy this property (Lemma 6.2 i.t.f.v.).

Equipped with this bound on the fraction of bad edges at any time step, we consider the last time t' prior to t in which the queue Q_ℓ of TF level-ℓ vertices is empty, i.e., Q_ℓ is non-empty in the entire time interval $[t'+1, t]$, thus `free-schedule`$_\ell$ is never idle during that

time. We need to bound the fraction of bad edges not only among the ones matched at time t', but also among those that get matched between times t' and t. The fraction of bad edges among those matched at time t' is $O(\epsilon)$ w.h.p. by the shuffling game; as for those that get created later on, there is no dependency on coin flips that the algorithm made prior to time t', and so the probability of any of those edges to be bad is $\leq 4\epsilon$, independently of whether previously created matched edges are bad, and by Chernoff we get that the fraction of bad edges among them is $O(\epsilon)$ too. The formal proof for this bound on the fraction of bad edges among those is provided in Section 6.3 i.t.f.v., and it implies that only an $O(\epsilon)$-fraction of all those edges may get hit w.h.p., and thus get into the queue. This bound, however, does not suffice to argue that the number of vertices in Q_ℓ at time t is an $O(\epsilon)$-fraction of the matching size, due to edges that get deleted from the matching by the algorithm itself. Nonetheless, since `free-schedule`$_\ell$ is no slower than the other sub-schedulers (as its simulation parameter is Δ'), we show in Section 6.3 i.t.f.v. that it removes vertices from Q_ℓ in the interval $[t'+1, t]$ at least at the same rate as matched edges get deleted by the algorithm. By formalizing these assertions and carefully combining them, we conclude with the required result, and with the almost-maximality guarantee as a corollary. The deterministic worst-case update time follows from the description of the algorithm (refer to the first paragraph of page 8).

Abstract

Edit distance is a fundamental measure of distance between strings and has been widely studied in computer science. While the problem of estimating edit distance has been studied extensively, the equally important question of actually producing an alignment (i.e., the sequence of edits) has received far less attention. Somewhat surprisingly, we show that any algorithm to estimate edit distance can be used in a black-box fashion to produce an approximate alignment of strings, with modest loss in approximation factor and small loss in run time. Plugging in the result of Andoni, Krauthgamer, and Onak, we obtain an alignment that is a $(\log n)^{O(1/\varepsilon^2)}$ approximation in time $\tilde{O}(n^{1+\varepsilon})$.

Closely related to the study of approximation algorithms is the study of metric embeddings for edit distance. We show that min-hash techniques can be useful in designing edit distance embeddings through three results: (1) An embedding from Ulam distance (edit distance over permutations) to Hamming space that matches the best known distortion of $O(\log n)$ and also implicitly encodes a sequence of edits between the strings; (2) In the case where the edit distance between the input strings is known to have an upper bound K, we show that embeddings of edit distance into Hamming space with distortion $f(n)$ can be modified in a black-box fashion to give distortion $O(f(\text{poly}(K)))$ for a class of periodic-free strings; (3) A randomized dimension-reduction map with contraction c and asymptotically optimal expected distortion $O(c)$, improving on the previous $\tilde{O}(c^{1+2/\log\log\log n})$ distortion result of Batu, Ergun, and Sahinalp.

1 Introduction

The *edit distance* $\Delta_{\text{ed}}(x, y)$ between two strings x and y is the minimum number of character insertions, deletions, and substitutions needed to transform x into y. This is a fundamental distance measure on strings, extensively studied in computer science [2–5, 9, 11, 17, 21, 24]. Edit distance has applications in areas including computational biology, signal processing, handwriting recognition, and image compression [19]. One of its oldest and most important uses is as a tool for comparing differences between genetic sequences [1, 19, 20].

The textbook dynamic-programming algorithm for edit distance runs in time $O(n^2)$ [20, 23, 24], and can be leveraged to recover a sequence of edits, also known as an *alignment*. The quadratic run time is prohibitively large for massive datasets (e.g., genomic data), and conditional lower bounds suggest that no strongly subquadratic time algorithm exists [5].

The difficulty of computing edit distance has motivated the development of fast heuristics [1, 10, 14, 19]. On the theoretical side, the tradeoff between run time and approximation factor (or distortion) is an important question (see [15, Section 6], and [16, Section 8.3.2]). Andoni and Onak [4] (building on beautiful work of Ostrovsky and Rabani [21]) gave an algorithm that estimates edit distance within a factor of $2^{\tilde{O}(\sqrt{\log n})}$ in time $n^{1+o(1)}$. The current best known tradeoff was obtained by Andoni, Krauthgamer and Onak [3], who gave an algorithm that estimates edit distance to within factor $(\log n)^{O(1/\varepsilon)}$ with run time $O(n^{1+\varepsilon})$.

Alignment Recovery

While these algorithms produce estimates of edit distance, they do not produce an alignment between strings (i.e., a sequence of edits). By decoupling the problem of numerical estimation from the problem of alignment recovery, the authors of [4] and [3] are able to exploit techniques such as metric space embeddings[4] and random sampling in order to obtain better approximations. The algorithm of [3] runs in phases, with the i-th phase distinguishing between whether $\Delta_{\text{ed}}(x, y)$ is greater than or significantly smaller than $\frac{n}{2^i}$. At the beginning of each phase, a nuanced random process is used to select a small fraction of the positions in x, and then the entire phase is performed while examining only those positions. In total, the full algorithm samples an $\tilde{O}\left(\frac{n^{\varepsilon}}{\Delta_{\text{ed}}(x,y)}\right)$-fraction of the letters in x. Note that this is a polynomially small fraction as we are interested in the case where $\Delta_{\text{ed}}(x, y) > n^{1/2}$ (if the edit distance is small, we can run the algorithm of Landau et al. [18] in linear time). Given that the algorithm only views a small portion of the positions in x, it is not clear how to recover a global alignment between the two strings.

We show, somewhat surprisingly, that any edit distance estimator can be turned into an approximate aligner in a black box fashion with modest loss in approximation factor and small loss in run time. For example, plugging the result of [3] into our framework, we get an algorithm with distortion $(\log n)^{O(1/\varepsilon^2)}$ and run time $\tilde{O}(n^{1+\varepsilon})$. To the best of our knowledge, the best previous result that gave an approximate alignment was the work of Batu, Ergun, and Sahinalp [7], which has distortion that is polynomial in n.

[4] The algorithm of [4] has a recursive structure in which at each level of recursion, every substring α of some length l is assigned a vector v_α such that the ℓ_1 distance between vectors closely approximates edit distance between substrings. The vectors at each level of recursion are constructed from the vectors in lower levels through a series of procedures culminating in an application of Bourgain's embedding to a sparse graph metric. As a result, although the distances between vectors in the top level of recursion allow for a numerical estimation of edit distance, it is not immediately clear how one might attempt to extract additional information from the vectors in order to recover an alignment.

Embeddings of Edit Distance Using Min-Hash Techniques

The study of approximation algorithms for edit distance closely relates to the study of embeddings [4, 7, 21]. An *embedding* from a metric space M_1 to a metric space M_2 is a map of points in M_1 to M_2 such that distances are preserved up to some factor D, known as the *distortion*. Loosely speaking, low-distortion embeddings from a complex metric space M_1 to a simpler metric space M_2 allow algorithm designers to focus on the simpler metric space, rather than directly handling the more complex one. Embeddings from edit distance to Hamming space have been widely studied [8, 9, 11, 21] and have played pivotal roles in the development of approximation algorithms [4] and streaming algorithms [8, 9].

The second contribution of this paper is to introduce new algorithms for three problems related to embeddings for edit distance. The algorithms are unified by the use of min-hash techniques to select pivots in strings. We find this technique to be particularly useful for edit distance because hashing the content of strings allows us to split strings in places where their content is aligned, thereby getting around the problem of insertions and deletions misaligning the strings. In several of our results, this allows us to obtain algorithms which are either more intuitive or simpler than their predecessors. The three results are summarized below.

Efficiently Embedding the Ulam Metric into Hamming Space: For the special case of the Ulam metric (edit distance on permutations), we present a randomized embedding ϕ of permutations of size n to poly(n)-dimensional Hamming space with distortion $O(\log n)$. Given strings x and y, the Hamming differences between $\phi(x)$ and $\phi(y)$ not only approximate the edit distance between x and y, but also implicitly encode a sequence of edits from x to y. If the output string of our embedding is stored using a sparse vector representation, then the embedding can be computed in linear time, and its output can be stored in linear space. The logarithmic distortion matches that of Charikar and Krauthgamer's embedding into ℓ_1-space [11], which did not encode the actual edits and needed quadratic time and number of dimensions. Our embedding also supports efficient updates, and can be modified to reflect an edit in expected time $O(\log n)$ (as opposed to the deterministic linear time of [11]).

Embedding Edit Distance in the Low-Distance Regime: Recently, there has been considerable attention devoted to edit distance in the low-distance regime [8, 9]. In this regime, we are interested in finding algorithms that run faster or perform better given the promise that the edit distance between the input strings is small. This regime is of considerable interest from the practical point of view. Landau, Myers and Schmidt [18] gave an exact algorithm for strings with edit distance K that runs in time $O(n+K^2)$. Recently, Chakraborty, Goldenberg and Koucký [9] gave a randomized embedding of edit distance into Hamming space that has distortion linear in the edit distance with probability at least $2/3$.

Given an embedding with distortion $\gamma(n)$ (a function of the input size), could one obtain an embedding whose distortion is a function of K, the edit distance, instead of n? We answer this question in the affirmative for the class of (D, R)-periodic free strings. We say that a string is (D, R)-periodic free if none of its substrings of length D are periodic with period of at most R. For $D \in$ poly(K) and $R = O(K^3)$, we show that the embedding of Ostrovksy and Rabani [21] can be used in a black-box fashion to obtain an embedding with distortion $2^{O\left(\sqrt{\log K \log\log K}\right)}$ for (D, R)-periodic free strings with edit distance of at most K. Our result can be seen as building on the min-hash techniques of [11, Section 3.5] (which in turn extends ideas from [6]). The authors of [11] give an embedding for $(t, 180tK)$-non-repetitive strings with distortion $O(t \log(tK))$ [11]. The key difference is that our notion of (D, R)-periodic free is much less restrictive than the notion of non-repetitive strings studied in [11].

Optimal Dimension Reduction for Edit Distance: The aforementioned work of Batu et al. [7] introduced and studied an interesting notion of dimension reduction for edit distance: An embedding of edit distance on length-n strings to edit distance on length-n/c strings (with larger alphabet size) is called a *dimension-reduction map* with *contraction* c. By first performing dimension reduction, one can then apply inefficient algorithms to the contracted strings at a relatively small overall cost. This idea was used in [7] to design an approximation algorithm with approximation factor $O(n^{1/3+o(1)})$. We provide a dimension-reduction map with contraction c and asymptotically optimal expected distortion $O(c)$, improving on the distortion of $\tilde{O}(c^{1+2/\log\log\log n})$ obtained by the deterministic map of [7].[5]

2 Preliminaries

Throughout the paper, we will use Σ to denote an alphabet,[6] and Σ^n to denote the set of words of length n over that alphabet. Additionally, we use $\mathcal{P}_n$ to denote the set of permutations of length n over Σ, or equivalently, the subset of Σ^n containing words whose letters are distinct. Given a string w of length n, we denote its letters by $w_1, w_2, \ldots, w_n$, and we use $w[i:j]$ to denote the substring $w_i w_{i+1} \cdots w_j$ (which is empty if $j < i$).

An *edit operation* is either an insertion, a deletion, or a substitution of a letter with another letter in a word. Given words x and y, an *alignment* from x to y is a sequence of edits transforming x to y. The *edit distance* $\Delta_{\text{ed}}(x, y)$ is the minimum number of edits needed to transform x to y. Alternatively, it is the length of an optimal alignment.

For convenience, we make the Simple Uniform Hashing Assumption [12], which assumes access to a fully independent family $\mathcal{H}$ of hash functions mapping $\Theta(\log n)$ bits to $\Theta(\log n)$ bits with constant time evaluation. For our applications, this can be simulated using the family of Pagh and Pagh [22], which is independent on any given set of size n with high probability. The family can be constructed in linear time and uses $O(n \log n)$ random bits.

3 Alignment Recovery Using a Black-Box Approximation Algorithm

In this section, we show how to transform a black-box edit distance approximation algorithm $\mathcal{A}$ into an approximate alignment algorithm $\mathcal{B}$. The algorithm $\mathcal{B}$ appears here as Algorithm 1. In the description of the algorithm, we rely on the following definition of a partition.

▶ **Definition 3.1.** A *partition* of a string u into m parts is a tuple $P = (p_0, p_1, p_2, \ldots, p_m)$ such that $p_0 = 0$, $p_m = |u|$, and $p_0 \le p_1 \le \cdots \le p_m$. For $i \in \{1, \ldots, m\}$, the *i-th part of P* is the subword $P_i := u[p_{i-1} + 1 : p_i]$, which is empty if $p_i = p_{i-1}$. A partition of a string u into m parts is an *equipartition* if each of the parts is of size either $\lfloor |u|/m \rfloor$ or $\lceil |u|/m \rceil$.

Formally, we assume that the approximation algorithm $\mathcal{A}$ has the following properties:

1. There is some non-decreasing function γ such that for all $n > 0$, and for any two strings u, v with $|u| + |v| \le n$, $\Delta_{\text{ed}}(u, v) \le \mathcal{A}(u, v) \le \gamma(n) \cdot \Delta_{\text{ed}}(u, v)$.
2. $\mathcal{A}(u, v)$ runs in time at most $T(n)$ for some non-decreasing function T which is super-additive in the sense that $T(j) + T(k) \le T(j + k)$ for $j, k \ge 0$.

We are now ready to state the main theorem of this section.

[5] When comparing these distortions, one should note that $2/\log\log\log n$ goes to zero very slowly; in particular, $c^{1+2/\log\log\log n} \ge c^{1.66}$ for all $n \le 10^{82}$, the number of atoms in the universe.

[6] We assume that characters in Σ can be represented in $\Theta(\log n)$ bits, where n is the size of input strings.

Algorithm 1 Black-Box Approximate Alignment Algorithm.

Input: Strings u, v with $|u| + |v| \leq n$.
Parameters: $m \in \mathbb{N}$ satisfying $m \geq 2$ and an approximation algorithm $\mathcal{A}$ for edit distance.

1. If $|u| \leq 1$, then find an optimal alignment in time $O(|v|)$ naively.
2. Let $P = (p_0, p_1, \ldots, p_m)$ be an equipartition of u.
3. Let S consist of the positions in v which can be reached by adding or subtracting a power of $(1 + \frac{1}{m})$ to some p_i. Formally, define

$$S = \left(\{p_0, \ldots, p_m\} \cup \{|v|\} \cup \left\{ \left\lceil p_i \pm \left(1 + \frac{1}{m}\right)^j \right\rceil \mid i, j \geq 0 \right\} \right) \cap \{0, \ldots, |v|\}.$$

4. Using dynamic programming, find a partition $Q = (q_0, \ldots, q_m)$ of v such that each q_i is in S, and such that the cost $\sum_{i=1}^{m} \mathcal{A}(P_i, Q_i)$ is minimized:
   a. For $l \in S$, let $f(l, j)$ be the subproblem of returning a choice of $q_0, q_1, \ldots, q_j$ with $q_j = l$ which minimizes $\sum_{i=1}^{j} \mathcal{A}(P_i, Q_i)$.
   b. Solve $f(l, j)$ by examining precomputed answers for subproblems of the form $f(l', j-1)$ with $l' \leq l \in S$: if $f(l', j-1)$ gives a choice of $q_0, q_1, \ldots, q_{j-1}$ with $\sum_{i=1}^{j-1} \mathcal{A}(P_i, Q_i) = t$, then we can set $q_j = l$ to get $\sum_{i=1}^{j} \mathcal{A}(P_i, Q_i) = t + \mathcal{A}(P_j, v[l' + 1 : l])$.
   (Here, $\mathcal{A}(P_j, v[l' + 1 : l])$ is computed using $\mathcal{A}$.)
5. Recurse on each pair (P_i, Q_i). Combine the resulting alignments between each P_i and Q_i to obtain an alignment between u and v.

▶ **Theorem 3.2.** *For all u, v with $|u| + |v| \leq n$ and $m \geq 2$, Algorithm 1 outputs an alignment from u to v of size at most $(3\gamma(n))^{O(\log_m n)} \cdot \Delta_{ed}(u, v)$. Moreover, the run time is $\tilde{O}(m^5 \cdot T(n))$.*

Before continuing, we provide a brief discussion of Algorithm 1. The algorithm first breaks u into a partition P of m equal parts. It then uses the black-box algorithm $\mathcal{A}$ to search for a partition Q of v such that $\sum_i \Delta_{\text{ed}}(P_i, Q_i)$ is near minimal; after finding such a Q, the algorithm recurses to find approximate alignments between P_i and Q_i for each i. Rather than considering every option for the partition $Q = (q_0, \ldots, q_m)$, the algorithm limits itself to those for which each q_i comes from a relatively small set S.

The set S is carefully designed so that although it is small, any optimal partition Q^{opt} of v can be in some sense well approximated by some partition Q using only q_i values from S. This limits the multiplicative error introduced at each level of recursion to be bounded by $3\gamma(n)$; across the $O(\log_m n)$ level of recursion, the total multiplicative error becomes $3\gamma(n)^{O(\log_m n)}$. The fact that the recursion depth appears in the exponent of the multiplicative error is why we partition u and v into many parts at each level.

Next we discuss several implications of Theorem 3.2. The parameter m allows us to trade off the approximation factor and the run time of the algorithm. When taken to the extreme, this gives two particularly interesting results.

▶ **Corollary 3.3.** *Let $0 < \varepsilon < 1$ (not necessarily constant). Then m can be chosen so that Algorithm 1 has approximation ratio $(3\gamma(n))^{O(\frac{1}{\varepsilon})}$ and run time $\tilde{O}\left(T(n) \cdot n^{\varepsilon}\right)$.*

▶ **Corollary 3.4.** *Let $0 < \varepsilon < 1$ (not necessarily constant). Then m can be chosen so that Algorithm 1 has approximation ratio $n^{O(\varepsilon)}$ and run time $\tilde{O}(T(n)) \cdot (3\gamma(n))^{O(1/\varepsilon)}$.*

We can apply Corollary 3.3 to the algorithm of Andoni et al. [3] with approximation ratio $(\log n)^{O(1/\varepsilon)}$ and run time $O(n^{1+\varepsilon})$ as follows. (Note that ε may be $o(1)$.)

▶ **Corollary 3.5.** *There exists an approximate-alignment algorithm which runs in time* $\tilde{O}(n^{1+\varepsilon})$*, and has approximation factor* $(\log n)^{O(1/\varepsilon^2)}$ *with probability* $1 - \frac{1}{\text{poly}(n)}$.

3.1 Proof of Theorem 3.2

The proof of the theorem will follow from Proposition 3.6, which bounds the run time of Algorithm 1, and Proposition 3.11, which bounds the approximation ratio.

Throughout this section, let u, v and m be the values given to Algorithm 1. Let $P = (p_0, \ldots, p_m)$ be the equipartition of u, and let S be the set defined by Algorithm 1.

▶ **Proposition 3.6.** *Algorithm 1 runs in time* $\tilde{O}(T(|u| + |v|) \cdot m^5)$.

Proof. If $|u| \leq 1$, then we can find an optimal alignment in time $O(|v|)$ naively. Suppose $|u| > 1$. Notice that $|S| \leq O(m^2 \log n)$. In particular, because $(1 + \frac{1}{m})^{(m+1)\ln n} \geq n$,

$$S \subseteq \{p_0, \ldots, p_m\} \cup \{|v|\} \cup \left\{ \left\lceil p_i \pm \left(1 + \frac{1}{m}\right)^j \right\rceil \mid i \in [0:m], j \in [0:(m+1)\ln n] \right\},$$

which has size at most $O(m^2 \log n)$.

Finding an equipartition of u can be done in linear time, and constructing S takes time $O(|S|) = \tilde{O}(m^2)$. In order to perform the fourth step which selects Q, we must compute $f(l, j)$ for each $l \in S$ and $j \in [0:m]$. To evaluate $f(l, j)$, we must consider each $l' \in S$ satisfying $l' \leq l$, and then compute the cost of $f(l', j-1)$ plus $\mathcal{A}(P_j, v[l'+1:l])$ (which takes time at most $T(|u| + |v|)$ to compute). Therefore, each $f(l, j)$ is computed in time $O(|S| \cdot T(|u|+|v|)) \leq \tilde{O}(T(|u|+|v|) \cdot m^2)$. Because there are $O(m \cdot |S|) = \tilde{O}(m^3)$ subproblems of the form $f(l, j)$, the total run time of the dynamic program is $\tilde{O}(T(|u| + |v|) \cdot m^5)$.

So far we have shown that the first level of recursion takes time $\tilde{O}(T(|u| + |v|)m^5)$. The sum of the lengths of the inputs to Algorithm 1 at a particular level of the recursion is at most $|u| + |v|$. It follows by the super-additivity of $T(n)$ that the time spent in any given level of recursion is at most $\tilde{O}(T(|u| + |v|)m^5)$. Because each level of recursion reduces the sizes of the parts of u by a factor of $\Omega(m)$, the number of levels is at most $O(\log_m n) \leq O(\log n)$. Therefore, the run time is $\tilde{O}(T(|u| + |v|) \cdot m^5)$. ◀

When discussing the approximation ratio of Algorithm 1, it will be useful to have a notion of edit distance between partitions of strings.

▶ **Definition 3.7.** Given two partitions $C = (c_0, \ldots, c_m)$ and $D = (d_0, \ldots, d_m)$ of strings a and b respectively, we define $\Delta_{\text{ed}}(C, D) := \sum_i \Delta_{\text{ed}}(C_i, D_i)$.

In order to bound the approximation ratio of Algorithm 1, we will introduce, for the sake of analysis, a partition $Q^{\text{opt}} = (q_0^{\text{opt}}, \ldots, q_m^{\text{opt}})$ of v satisfying $\Delta_{\text{ed}}(P, Q^{\text{opt}}) = \Delta_{\text{ed}}(u, v)$. Recall that P is fixed, which allows us to use it in the definition of Q^{opt}.

We claim that some partition Q^{opt} satisfying $\Delta_{\text{ed}}(P, Q^{\text{opt}}) = \Delta_{\text{ed}}(u, v)$ must exist. If u and v differed by only a single edit, one could start from P and explicitly define Q^{opt} so that $\Delta_{\text{ed}}(P, Q^{\text{opt}}) = 1$ (by a case analysis of which type of edit was performed). It can then be shown by induction on the number of edits that, in general, we can obtain a partition Q^{opt} satisfying $\Delta_{\text{ed}}(P, Q^{\text{opt}}) = \Delta_{\text{ed}}(u, v)$.

Our strategy for bounding the approximation ratio will be to compare $\Delta_{\text{ed}}(P, Q)$ for the partition Q selected by our algorithm to $\Delta_{\text{ed}}(P, Q^{\text{opt}})$. We do this through three observations.

The first observation upper bounds $\Delta_{\text{ed}}(P, Q)$. Informally, it shows that the cost in edit distance which Algorithm 1 pays for selecting Q instead of Q^{opt} is at most $2\sum_{i=0}^{m} |q_i - q_i^{\text{opt}}|$.

▶ **Lemma 3.8.** *Let $Q = (q_0, \ldots, q_m)$ be a partition of v. Then*

$$\Delta_{ed}(P, Q) \leq \Delta_{ed}(u, v) + 2\sum_{i=1}^{m} |q_i - q_i^{opt}|.$$

Proof. Observe that

$$\Delta_{\text{ed}}(P, Q) \leq \Delta_{\text{ed}}(P, Q^{\text{opt}}) + \Delta_{\text{ed}}(Q^{\text{opt}}, Q) = \Delta_{\text{ed}}(u, v) + \sum_{i=1}^{m} \Delta_{\text{ed}}(Q_i^{\text{opt}}, Q_i).$$

Because Q and Q^{opt} are both partitions of v, $\Delta_{\text{ed}}(Q_i, Q_i^{\text{opt}}) \leq |q_{i-1} - q_{i-1}^{\text{opt}}| + |q_i - q_i^{\text{opt}}|$. In particular, $|q_{i-1} - q_{i-1}^{\text{opt}}|$ insertions to the left side of one of Q_i or Q_i^{opt} (whichever has its start point further to the right) will result in the two substrings having the same start-point; and then $|q_i - q_i^{\text{opt}}|$ insertions to the right side of one of Q_i or Q_i^{opt} (whichever has its end point further to the left) will result in the two substrings having the same end-point. Thus

$$\begin{aligned}\Delta_{\text{ed}}(u, v) + \sum_{i=1}^{m} \Delta_{\text{ed}}(Q_i^{\text{opt}}, Q_i) &\leq \Delta_{\text{ed}}(u, v) + \sum_{i=1}^{m} |q_{i-1} - q_{i-1}^{\text{opt}}| + |q_i - q_i^{\text{opt}}| \\ &\leq \Delta_{\text{ed}}(u, v) + 2\sum_{i=1}^{m} |q_i - q_i^{\text{opt}}|,\end{aligned}$$

where we are able to disregard the case of $i = 0$ because $q_0 = q_0^{\text{opt}} = 0$. ◀

The next observation establishes a lower bound for $\Delta_{\text{ed}}(u, v)$.

▶ **Lemma 3.9.** $\Delta_{ed}(u, v) \geq \frac{1}{m}\sum_{i=1}^{m} |p_i - q_i^{opt}|$.

Proof. Because $\Delta_{\text{ed}}(P, Q^{\text{opt}}) = \Delta_{\text{ed}}(u, v)$, we must have that for each $i \in [m]$,

$$\Delta_{\text{ed}}(u, v) = \Delta_{\text{ed}}(u[1 : p_i], v[1 : q_i^{\text{opt}}]) + \Delta_{\text{ed}}(u[p_i + 1 : |u|], v[q_i^{\text{opt}} + 1 : |v|]).$$

Notice, however, that the strings $u[1 : p_i]$ and $v[1 : q_i^{\text{opt}}]$ differ in length by at least $|q_i^{\text{opt}} - p_i|$. Therefore, their edit distance must be at least $|q_i^{\text{opt}} - p_i|$, implying that $\Delta_{\text{ed}}(u, v) \geq |q_i^{\text{opt}} - p_i|$.

Thus $\frac{1}{m}\Delta_{\text{ed}}(u, v) \geq \frac{1}{m}|q_i^{\text{opt}} - p_i|$. Summing over $i \in [m]$ gives the desired equation. ◀

So far we have shown that the cost in edit distance which Algorithm 1 pays for selecting Q instead of Q^{opt} is at most $2\sum_{i=0}^{m} |q_i - q_i^{\text{opt}}|$ (Lemma 3.8), and that the edit distance from u to v is at least $\frac{1}{m}\sum_{i=1}^{m} |p_i - q_i^{\text{opt}}|$ (Lemma 3.9). Next we compare these two quantities. In particular, we show that if Q is chosen to mimic Q^{opt} as closely as possible, then each of the $|q_i - q_i^{\text{opt}}|$ will become small relative to each of the $|p_i - q_i^{\text{opt}}|$.

▶ **Lemma 3.10.** *There exists a partition $Q = (q_0, \ldots, q_m)$ of v such that each q_i is in S, and such that for each $i \in [0 : m]$, $|q_i - q_i^{opt}| \leq \frac{1}{m}|p_i - q_i^{opt}|$.*

Proof Sketch. Consider the partition Q in which q_i is chosen to be the largest $s \in S$ satisfying $s \leq q_i^{\text{opt}}$. Observe that: (i) because $0 \in S$, each q_i always exists; (ii) because $|v| \in S$, we will have $q_m = |v|$; and (iii) because $q_0^{\text{opt}} \leq q_1^{\text{opt}} \leq \cdots \leq q_m^{\text{opt}}$, we will have that $q_0 \leq q_1 \leq \cdots \leq q_m$. Therefore, Q is a well-defined partition of v.

It remains to prove $|q_i - q_i^{\text{opt}}| \leq \frac{1}{m}|p_i - q_i^{\text{opt}}|$. For brevity, we focus on the case of $p_i < q_i^{\text{opt}}$. The other cases are conceptually similar and appear in the full version of this paper.

Assume $p_i < q_i^{\text{opt}}$. Consider the largest non-negative integer j such that $p_i + (1+\frac{1}{m})^j \leq q_i^{\text{opt}}$. One can verify that by definition of j, we must have

$$\left(1+\frac{1}{m}\right)^j \leq q_i^{\text{opt}} - p_i \leq \left(1+\frac{1}{m}\right)^{j+1}. \tag{3.1}$$

It follows that

$$q_i^{\text{opt}} - \left(p_i + \left(1+\frac{1}{m}\right)^j\right) \leq \left(1+\frac{1}{m}\right)^{j+1} - \left(1+\frac{1}{m}\right)^j = \frac{1}{m}\left(1+\frac{1}{m}\right)^j. \tag{3.2}$$

Since $\lceil p_i + (1+\frac{1}{m})^j \rceil \in S$, the definition of q_i ensures that q_i is between $p_i + (1+\frac{1}{m})^j$ and q_i^{opt} inclusive. Therefore, (3.2) implies $q_i^{\text{opt}} - q_i \leq \frac{1}{m}\left(1+\frac{1}{m}\right)^j$. Combining this with (3.1), it follows that $q_i^{\text{opt}} - q_i \leq \frac{1}{m}(q_i^{\text{opt}} - p_i)$, as desired. ◀

We are now equipped to bound the approximation ratio of Algorithm 1, thereby completing the proof of Theorem 3.2. We will use the preceeding lemmas to bound the approximation ratio at each level of recursion to $O(\gamma(n))$. The approximation ratio will then multiply across the $O(\log_m n)$ levels of recursion, giving total approximation ratio $O(\gamma(n))^{O(\log_m n)}$.

▶ **Proposition 3.11.** *Let $E(u,v)$ be the number of edits returned by Algorithm 1. Then*

$$\Delta_{ed}(u,v) \leq E(u,v) \leq \Delta_{ed}(u,v) \cdot (3\gamma(n))^{O(\log_m n)}.$$

Proof. Because Algorithm 1 finds a sequence of edits from u to v, clearly $\Delta_{\text{ed}}(u,v) \leq E(u,v)$. By Lemma 3.10 there is some partition $Q = (q_0, \ldots, q_m)$ of v such that each q_i is in S, and such that for each $i \in [0:m]$, $|q_i - q_i^{\text{opt}}| \leq \frac{1}{m}|p_i - q_i^{\text{opt}}|$. By Lemma 3.9, it follows that

$$\sum_{i=1}^{m} |q_i - q_i^{\text{opt}}| \leq \frac{1}{m}\sum_{i=1}^{m} |p_i - q_i^{\text{opt}}| \leq \Delta_{\text{ed}}(u,v).$$

Applying Lemma 3.8, we then get that

$$\Delta_{\text{ed}}(P,Q) \leq \Delta_{\text{ed}}(u,v) + 2\sum_{i=1}^{m} |q_i - q_i^{\text{opt}}| \leq 3\Delta_{\text{ed}}(u,v).$$

Thus there is some Q which Algorithm 1 is allowed to select such that $\Delta_{\text{ed}}(P,Q) \leq 3\Delta_{\text{ed}}(u,v)$. Since the approximation ratio of $\mathcal{A}$ is $\gamma(n)$, the true partition Q selected at the first level of recursion must satisfy $\Delta_{\text{ed}}(P,Q) \leq 3\gamma(n)\Delta_{\text{ed}}(u,v)$.

After the i-th level of recursion, u has implicitly been split into a large partition P^i, v has implicitly been split into a large partition Q^i, and the recursive subproblems are searching for edits between pairs of parts of P^i and Q^i. Since there is $3\gamma(n)$ distortion at each level, we can get by induction that $\Delta_{\text{ed}}(P^i, Q^i) \leq (3\gamma(n))^i \Delta_{\text{ed}}(u,v)$. Since there are $O(\log_m n)$ levels of recursion, the number of edits returned by the algorithm is at most $\Delta_{\text{ed}}(u,v) \cdot (3\gamma(n))^{O(\log_m n)}$. ◀

4 Embeddings and Dimension Reduction Using Min-Hash Techniques

4.1 Alignment Embeddings for Permutations

Here we present a randomized embedding from $\mathcal{P}_n$, the set of permutations of length n, into Hamming space with expected distortion $O(\log n)$. The embedding has the surprising

Algorithm 2 Alignment Embedding for Permutations.

Input: A string $w = w_1 \cdots w_n \in \mathcal{P}_n$.
Parameters: ε and $m \geq \log_{1/2+\varepsilon} \frac{1}{n} + 1$.

1. At the first level of recursion only:
   a. Initialize an array A of size $2^m - 1$ (indexed starting at one) with zeros. The array A will contain the output embedding.
   b. Select a hash function h mapping Σ to $r \log n$ bits for a sufficiently large constant r.
2. Let i minimize $h(w_i)$ out of the $i \in [n/2 - \varepsilon n : n/2 + \varepsilon n]$.[8] We call w_i the *pivot* in w.
3. Set $A[2^{m-1}] = w_i$.
4. Recursively embed $w_1 \cdots w_{i-1}$ into $A[1 : 2^{m-1} - 1]$.
5. Recursively embed $w_{i+1} \cdots w_n$ into $A[2^{m-1} + 1 : 2^m - 1]$.

property that it implicitly encodes alignments between strings. If the output is stored using run-length encoding,[7] then the size of the output and the run time are both $O(n)$.

The description of the embedding appears as Algorithm 2. For simplicity, we assume $0 \notin \Sigma$, which allows us to use 0 as a null character. The algorithm takes two parameters: ε and m. The parameter ε controls a trade-off between the distortion and the output dimension. The parameter m dictates the maximum depth of recursion that can be performed within the array A. In particular, m needs to be chosen such that the algorithm does not run out of space for the embedding in the recursive calls.

Since each recursive step takes as input words of size in the range $[(1/2-\varepsilon)n : (1/2+\varepsilon)n]$, the input size at the i-th level of the recursion is at most $(1/2+\varepsilon)^{i-1}n$. We need to choose m such that at the m-th level of recursion, the input size will be at most 1. Therefore, it suffices to pick m satisfying $m \geq \log_{1/2+\varepsilon} \frac{1}{n} + 1$.

We denote the resulting embedding of the input string w into the output array A by $\phi_{\varepsilon,m}(w)$. Moreover, for $m = \lceil \log_{1/2+\varepsilon} \frac{1}{n} + 1 \rceil$, we define $\phi_\varepsilon(w)$ to be $\phi_{\varepsilon,m}(w)$. Note that ϕ_ε embeds w into an array A of size $O\left(2^{\log_{1/2+\varepsilon} 1/n}\right) = O\left(n^{-1/\log(1/2+\varepsilon)}\right)$, which one can verify for $\varepsilon \leq \frac{1}{4}$ is $O(n^{1+6\varepsilon})$.

We call ϕ_ε an *alignment embedding* because ϕ_ε maps a string x to a copy of x spread out across an array of zeros. When we compare $\phi_\varepsilon(x)$ with $\phi_\varepsilon(y)$ by Hamming differences, ϕ_ε encodes an alignment between x and y; it pays for every letter which it fails to match up with another copy of the same letter. In particular, every pairing of a letter with a null corresponds to an insertion or deletion, and every pairing of a letter with a different letter corresponds to a substitution. Thus $\mathrm{Ham}(\phi_\varepsilon(x), \phi_\varepsilon(y))$ will always be at least $\Delta_{\mathrm{ed}}(x, y)$.

In the rest of this subsection we will prove the following theorem.

▶ **Theorem 4.1.** *For $\varepsilon \leq \frac{1}{4}$, there exists a randomized embedding ϕ_ε from $\mathcal{P}_n$ to $O(n^{1+6\varepsilon})$-dimensional Hamming space with the following properties.*

- *For $x, y \in \mathcal{P}_n$, $\phi_\varepsilon(x)$ and $\phi_{\varepsilon(y)}$ encode a sequence of $\mathrm{Ham}(\phi_\varepsilon(x), \phi_\varepsilon(y))$ edits from x to y. In particular, $\mathrm{Ham}(\phi_\varepsilon(x), \phi_\varepsilon(y)) \geq \Delta_{ed}(x, y)$.*
- *For $x, y \in \mathcal{P}_n$, $\mathbb{E}[\mathrm{Ham}(\phi_\varepsilon(x), \phi_\varepsilon(y))] \leq O\left(\frac{1}{\varepsilon} \log n\right) \cdot \Delta_{ed}(x, y)$.*
- *For $x \in \mathcal{P}_n$, $\phi_\varepsilon(x)$ is sparse in the sense that it only contains n non-zero entries. Moreover, if $\phi_\varepsilon(x)$ is stored with run-length encoding, it can be computed in time $O(n)$.*

[7] In run-length encoding, runs of identical characters are stored as a pair whose first entry is the character and the second entry is the length of the run.
[8] With high probability, there are no hash collisions.

The first property in the theorem follows from the discussion above. In order to prove $\mathbb{E}[\mathrm{Ham}(\phi_\varepsilon(x), \phi_\varepsilon(y))] \leq \Delta_{\mathrm{ed}}(x,y) O\left(\frac{1}{\varepsilon}\log n\right)$, we will consider a series of at most $2\Delta_{\mathrm{ed}}(x,y)$ insertions or deletions that are used to transform x into y. Each substitution operation can be emulated by an insertion and a deletion. Moreover, note that by ordering deletions before insertions, each of the intermediate strings will still be a permutation. In the following lemma, we bound the expected Hamming distance for just a single insertion (or equivalently, a deletion). By the triangle inequality, we get the bound on $\mathbb{E}[\mathrm{Ham}(\phi_\varepsilon(x), \phi_\varepsilon(y))]$.

▶ **Lemma 4.2.** *Let $x \in \mathcal{P}_n$ be a permutation, and let y be a permutation derived from x by a single insertion. Let $0 < \varepsilon \leq \frac{1}{4}$ and let m be large enough so that $\phi_{\varepsilon,m}$ is well-defined on x and y. Then $\mathbb{E}[\mathrm{Ham}(\phi_{\varepsilon,m}(x), \phi_{\varepsilon,m}(y))] \leq O\left(\frac{1}{\varepsilon}\log n\right)$.*

Proof. Observe that the set of letters in position-range $[(1/2-\varepsilon)|x| : (1/2+\varepsilon)|x|]$ in x differs by at most $O(1)$ elements from the set of letters in position-range $[(1/2-\varepsilon)|y| : (1/2+\varepsilon)|y|]$ in y. Thus with probability $1 - O(1/(\varepsilon n))$, there will be a letter l in the overlap between the two ranges whose hash is smaller than that of any other letter in either of the two ranges. In other words, the pivot in x (i.e., the letter in the position range with minimum hash) will differ from the pivot in y with probability $O(1/(\varepsilon n))$. Therefore,

$$\begin{aligned}
\mathbb{E}[\mathrm{Ham}(\phi_{\varepsilon,m}(x), \phi_{\varepsilon,m}(y))] &= \Pr[\text{pivots differ}] \cdot \mathbb{E}[\mathrm{Ham}(\phi_{\varepsilon,m}(x), \phi_{\varepsilon,m}(y)) \mid \text{ pivots differ}] \\
&\quad + \Pr[\text{pivots same}] \cdot \mathbb{E}[\mathrm{Ham}(\phi_{\varepsilon,m}(x), \phi_{\varepsilon,m}(y)) \mid \text{ pivots same}] \\
&\leq O\left(\frac{1}{\varepsilon n}\right) \cdot \mathbb{E}[\mathrm{Ham}(\phi_{\varepsilon,m}(x), \phi_{\varepsilon,m}(y)) \mid \text{ pivots differ}] \\
&\quad + \mathbb{E}[\mathrm{Ham}(\phi_{\varepsilon,m}(x), \phi_{\varepsilon,m}(y)) \mid \text{ pivots same}].
\end{aligned}$$

In general, $\mathrm{Ham}(\phi_{\varepsilon,m}(x), \phi_{\varepsilon,m}(y))$ cannot exceed $O(n)$. Thus

$$\begin{aligned}
\mathbb{E}[\mathrm{Ham}(\phi_{\varepsilon,m}(x), \phi_{\varepsilon,m}(y))] &\leq O\left(\frac{1}{\varepsilon n}\right) \cdot O(n) + \mathbb{E}[\mathrm{Ham}(\phi_{\varepsilon,m}(x), \phi_{\varepsilon,m}(y)) \mid \text{ pivots same}] \\
&\leq O\left(\frac{1}{\varepsilon}\right) + \mathbb{E}[\mathrm{Ham}(\phi_{\varepsilon,m}(x), \phi_{\varepsilon,m}(y)) \mid \text{ pivots same}].
\end{aligned}$$

If the pivot in x is the same as in y, then the insertion must take place to either the left or the right of the pivot. Clearly $\phi_{\varepsilon,m}(x)$ and $\phi_{\varepsilon,m}(y)$ will agree on the side of the pivot in which the edit does not occur. Inductively applying our argument to the side on which the edit occurs, we incur a cost of $O(1/\varepsilon)$ once for each level in the recursion. The maximum depth of the recursion is $O\left(\log_{1/2+\varepsilon}\frac{1}{n}\right) = O(\log n)$. This gives us $\mathbb{E}[\mathrm{Ham}(\phi_{\varepsilon,m}(x), \phi_{\varepsilon,m}(y))] \leq O\left(\frac{1}{\varepsilon}\right) \cdot \log n$. ◀

It remains only to analyze the run time. Notice that $\phi_\varepsilon(x)$ can be stored in space $\Theta(n)$ using run-length encoding. We can compute $\phi_\varepsilon(x)$ in time $O(n)$, as follows. Using Range Minimum Query [13] we can build a data structure which supports constant-time queries returning minimum hashes in contiguous substrings of x. This allows each recursive step in the embedding to be performed in constant time. Since each recursive step writes one of the n letters to the output, the total run time is bounded by $O(n)$.

4.2 Embedding into Hamming Space in the Low-Distance Regime

Assume we are given an embedding from edit distance in Σ^n into Hamming space with subpolynomial distortion $\gamma(n)$. We wish to use such an embedding as a black box in order to obtain a new embedding for the low edit distance regime: the new embedding, which would

Algorithm 3 Choose Next Block (Informal).

Input: A string x, the index i where the current block begins.
Output: The index where the next block begins.
Parameters: $W'' \ll W' \ll W$ set as needed.

1. Consider the window $x_i \cdots x_{i+W-1}$ of size W. Divide the second half of the window into non-overlapping sub-windows of size W', and pick one such sub-window at random.
2. Each substring of length W'' inside the sub-window is called a sub-sub-window (sub-sub-windows may overlap). Compute a hash of each of the sub-sub-windows.[9]
3. Return the start position of the sub-sub-window with the smallest hash.

be parameterized by a value K, would take any two strings $x, y \in \Sigma^n$ with $\Delta_{\text{ed}}(x, y) \leq K$ and map x and y into Hamming space with distortion $\gamma'(K)$, a function of K rather than n.

We make progress toward such an embedding with the added constraint that our strings x and y are (D, R)-periodic free for $D \in \text{poly}(K)$ of our choice and $R \in O(K^3)$. A string is (D, R)-*periodic free* if it contains no contiguous substrings of length D that are periodic with period at most R. Our embedding takes two such strings with $\Delta_{\text{ed}}(x, y) \leq K$ and maps them into Hamming space with distortion $\gamma(\text{poly}(K))$. If we select the black-box embedding to be embedding of Ostrovsky and Rabani [21], then this gives distortion $2^{O\left(\sqrt{\log K \log\log K}\right)}$.

Our main result in this section is stated as the following theorem.

▶ **Theorem 4.3.** *Suppose we have an embedding from edit distance in Σ^n to Hamming space with subpolynomial distortion $\gamma(n) \geq 2$. Let $K \in \mathbb{N}$ and pick some $D \in \text{poly}(K)$. Then there exists $R \in O(K^3)$ and an embedding α from edit distance into scaled Hamming space with the following property. For strings x and y that are (D, R)-periodic free and of edit distance at most K apart, α distorts the distance between x and y by at most $O(\gamma(K^3 D)) \leq O(\gamma(\text{poly}(K)))$ in expectation.*

The complete proof of Theorem 4.3 appears in the full version of the paper. Below we discuss the key ideas, which once again make use of min-hash techniques.

The main step in our embedding is to partition the strings x and y into parts of length $\text{poly}(K)$ in a way so that the sum of the edit distances between the parts equals $\Delta_{\text{ed}}(x, y)$ (with some probability), and then to apply the black-box embedding to each individual part.

We select the partition of x by going from left to right, and at each step choosing the next index at which the current block ends and the next one begins. The algorithm for selecting each successive block appears as Algorithm 3.

The goal of the algorithm is to find partitions of x and y that are aligned despite the edits. By picking a sub-window uniformly at random, we guarantee that with high probability (as a function of W, W') no edits occur directly within that sub-window. However, if x and y differ by an insertion or deletion prior to that sub-window, the sub-window within x may be misaligned with the sub-window within y. Nonetheless, the set of W''-letter sub-sub-windows of the sub-window of x will be almost the same as the set of W''-letter sub-sub-windows of the sub-window of y. By selecting the sub-sub-window with minimum hash as the start position for the next block, we are then able to guarantee that with high probability (as a function of W') we pick positions in x and y which are aligned with each other.

[9] By selecting W'', W', W appropriately, we can use the (D, R)-periodic free property to guarantee that these sub-sub-windows are distinct.

4.3 Dimension Reduction

A mapping of edit distance on length-n strings to edit distance on length-at-most-n/c strings (with larger alphabet size) is called a *dimension-reduction* map with *contraction* c [7]. The *distortion* of the map measures the multiplicative factor to which edit distance is preserved.

▶ **Theorem 4.4.** *There is a randomized dimension-reduction map ϕ with contraction c and expected distortion $O(c)$. In particular, for $x, y \in \Sigma^n$,*

$$\frac{1}{2c} \cdot \Delta_{ed}(x, y) \leq \Delta_{ed}(\phi(x), \phi(y)),$$

and

$$\mathbb{E}[\Delta_{ed}(\phi(x), \phi(y))] \leq O(1) \cdot \Delta_{ed}(x, y).$$

Moreover, for this definition of distortion, ϕ is within a constant factor of optimal. Additionally, ϕ can be evaluated in time $O(n \log c)$.

Note that the output of a dimension-reduction map may be over a much larger alphabet than the input. One should not be too alarmed by this, however, because alphabet reduction can be performed after the dimension reduction (by simply hashing to $\Theta(\log n)$ bits).

Below we summarize our approach to proving Theorem 4.4. The complete proof appears in the full version of the paper. When computing our dimension-reduction map $\phi(w)$ on a word w, one approach would be to split w into blocks of size c and to then define $\phi(w)$'s letters to correspond to blocks. This would achieve the desired reduction in dimension, and would have the effect that a single edit to $\phi(w)$ would correspond to at most c edits in w. However, a single insertion to w could change the content of linearly many blocks, corresponding to a large number of edits to $\phi(w)$. Thus the challenge is to instead break w into blocks in a way so that an edit to w affects only a small number of blocks.

In order to accomplish this, our actual ϕ breaks w into long periodic substrings and non-periodic substrings. The two types of substrings are then handled as follows:

Handling Long Periodic Substrings: Within the periodic substrings, we break the substring into blocks based on the periodic behavior. The key insight is that the embedding of the periodic substring will consist of the same block repeating many times. If an edit occurs in the middle of a long periodic substring, the embedding will still include the same block repeated many times, but $O(1)$ blocks around the edit will be modified. Since the blocks correspond to letters in $\phi(w)$, the edit to w results in $O(1)$ edits to $\phi(w)$.

Handling Non-Periodic Substrings: Within the non-periodic substrings, we select markers in a randomized fashion to determine block boundaries. The definition of non-periodic substrings guarantees that for every c adjacent letters, the $8c$-letter substrings $w_i w_{i+1} \cdots w_{i+8c-1}$ beginning at each of those c letters w_i are distinct. We utilize this property to select markers based on the minimum hash of $8c$-letter substrings. A letter is selected as a marker if the hash of the $8c$-letter string beginning at that letter is smaller than the hashes of any of the $8c$-letter strings beginning in the $c/2$ letters to its left or right. This localizes the selection so that edits to the string will only affect nearby markers.

When two markers are more than c apart, we additionally break the space between them into sub-blocks of size at most c. By preventing blocks in $\phi(w)$ from exceeding $O(c)$ in size, we can take a sequence of edits in $\phi(w)$ and generate a corresponding sequence of edits in w with distortion $O(c)$. When bounding the distortion in the other direction, we risk edits in

w taking place between two far-apart markers, which in turn could affect all of the blocks between those markers in $\phi(w)$. The main technical challenge is bounding the effect this has on the distortion. We do so by showing probabilistically that wherever there is an edit, there will be markers nearby which mitigate the impact of that edit on the block structure of $\phi(w)$.

Abstract

The classic Stable Roommates problem (the non-bipartite generalization of the well-known Stable Marriage problem) asks whether there is a *stable matching* for a given set of agents, *i.e.* a partitioning of the agents into disjoint pairs such that *no* two agents induce a *blocking pair*. Herein, each agent has a *preference list* denoting who it prefers to have as a partner, and two agents are blocking if they prefer to be with each other rather than with their assigned partners.

Since stable matchings may not be unique, we study an NP-hard optimization variant of Stable Roommates, called Egal Stable Roommates, which seeks to find a stable matching with a minimum egalitarian cost γ, *i.e.* the sum of the dissatisfaction of the agents is minimum. The *dissatisfaction* of an agent is the number of agents that this agent prefers over its partner if it is matched; otherwise it is the length of its preference list. We also study almost stable matchings, called Min-Block-Pair Stable Roommates, which seeks to find a matching with a minimum number β of blocking pairs. Our main result is that Egal Stable Roommates parameterized by γ is fixed-parameter tractable, while Min-Block-Pair Stable Roommates parameterized by β is W[1]-hard, even if the length of each preference list is at most five.

1 Introduction

This paper presents algorithms and hardness results for two variants of the Stable Roommates problem, a well-studied generalization of the classic Stable Marriage problem. Before describing our results, we give a brief background that will help motivate our work.

Stable Marriage and Stable Roommates. An instance of the Stable Marriage problem consists of two disjoint sets of n men and n women (collectively called *agents*), who are each equipped with his or her own personal *strict* preference list that ranks *every* member of the opposite sex. The goal is to find a bijection, or *matching*, between the men and the women that does not contain any blocking pairs. A *blocking pair* is a pair of man and woman who are not matched together but both prefer each other over their own matched partner. A matching with no blocking pairs is called a *stable matching*, and *perfect* if it is a bijection between *all* men and women.

Stable Marriage is a classic and fundamental problem in computer science and applied mathematics, and as such, entire books were devoted to it [24, 32, 50, 37]. The problem emerged from the economic field of matching theory, and it can be thought of as a generalization of the Maximum Matching problem when restricted to complete bipartite graphs. The most important result in this context is the celebrated Gale-Shapley algorithm [22]: This algorithm computes in polynomial time a perfect stable matching in *any* given instance, showing that regardless of their preference lists, there always exists a perfect stable matching between any equal number of men and women.

The Stable Marriage problem has several interesting variants. First, the preference lists of the agents may be *incomplete*, meaning that not every agent is an acceptable partner to every agent of the opposite sex. In graph theoretic terms, this corresponds to the bipartite incomplete case. The preference lists could also have *ties*, meaning that two or more agents may be considered equally good as partners. Finally, the agents may not be partitioned into two disjoint sets, but rather each agent may be allowed to be matched to any other agent. This corresponds to the non-bipartite case in graph theoretic terms, and is referred to in the literature as the Stable Roommates problem.

While Stable Marriage and Stable Roommates seem very similar, there is quite a big difference between them in terms of their structure and complexity. For one, any instance of Stable Marriage always contains a stable matching (albeit perhaps not perfect), even if the preference lists are incomplete and with ties. Moreover, computing some stable matching in any Stable Marriage instance with $2n$ agents can be done in $O(n^2)$ time [22]. However, an instance of Stable Roommates may have no stable matchings at all, even in the case of complete preference lists without ties (see the third example in Figure 1). Furthermore, when ties are present, deciding whether an instance of Stable Roommates contains a stable matching is NP-complete [47], even in the case of complete preference lists.

All variants of Stable Marriage and Stable Roommates mentioned here have several applications in a wide range of application domains. These include partnership issues in the real-world [22], resource allocation [5, 16, 27], centralized automated mechanisms that assign children to schools [3, 4], assigning school graduates to universities [7, 8], assigning medical students to hospitals [1, 2], and several others [6, 21, 29, 30, 33, 34, 35, 37, 38, 48, 49].

Optimization variants. As noted above, some Stable Roommates instances do not admit any stable matching at all, and in fact, empirical study suggests that a constant fraction of all sufficiently large instances will have no solution [46]. Moreover, even if a given Stable

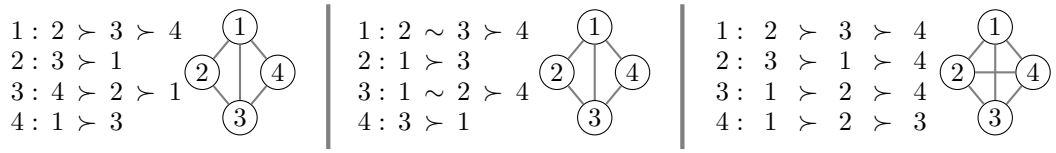

Figure 1 An example of three Stable Roommates instances, where $x \succ y$ means that x is strictly preferred to y, and $x \sim y$ means that they are equally good and tied as a partner. The instance on the left is incomplete without ties and has exactly two stable matchings $\{\{1,2\},\{3,4\}\}$ and $\{\{1,4\},\{2,3\}\}$, both of which are perfect. The instance in the middle is incomplete with ties and has two stable matchings $\{\{1,3\}\}$ and $\{\{1,2\},\{3,4\}\}$, the latter being perfect while the former not. The right instance is complete without ties and has no stable matchings at all.

Roommates instance admits a solution, this solution may not be unique, and there might be other stable matchings with which the agents are more satisfied overall. Given these two facts, it makes sense to consider two types of optimization variants for Stable Roommates: In one type, one would want to compute a stable matching that optimizes a certain social criterion in order to maximize the overall satisfaction of the agents. In the other, one would want to compute matchings which are as close as possible to being stable, where closeness can be measured by various metrics. In this paper, we focus on one prominent example of each of these two types – minimizing the egalitarian cost of a stable matching, and minimizing the number of blocking pairs in a matching which is close to being stable.

Egalitarian optimal stable matchings. Over the years, several social optimality criteria have been considered, yet arguably one of the most popular of these is the egalitarian cost metric [41, 32, 31, 36, 39]. The *egalitarian cost* of a given matching is the sum of the *rank*s of the partners of all agents, where the *rank* of the partner y of an agent x is the number of agents that are strictly preferred over y by x. The corresponding Egal Stable Marriage and Egal Stable Roommates problems ask whether there is a stable matching with egalitarian cost at most γ, for some given bound $\gamma \in \mathbb{N}$ (Section 2 contains the formal definition).

When the input preferences do not have ties (but could be incomplete), Egal Stable Marriage is solvable in $O(n^4)$ time [31]. For preferences with ties, Egal Stable Marriage becomes NP-hard [36]. Thus, already in the bipartite case, it becomes apparent that allowing ties in preference lists makes the task of computing an optimal egalitarian matching much more challenging. Marx and Schlotter [39] showed that Egal Stable Marriage is fixed-parameter tractable when parameterized by the parameter "sum of the lengths of all ties".

For Egal Stable Roommates, Feder [20] showed that the problem is NP-hard even if the preferences are complete and have no ties, and gave a 2-approximation algorithm for this case. Halldórsson et al. [25] showed inapproximability results for Egal Stable Roommates, and Teo and Sethuraman [51] proposed a specific LP formulation for Egal Stable Roommates and other variants. Cseh et al. [17] studied Egal Stable Roommates for preferences with bounded length ℓ and without ties. They showed that the problem is polynomial-time solvable if $\ell = 2$, and is NP-hard for $\ell \geq 3$.

Matchings with minimum number of blocking pairs. For the case where no stable matchings exist, the agents may still be satisfied with a matching that is close to being stable. One very natural way to measure how close a matching is to being stable is to count the number of blocking pairs [45, 19]. Accordingly, the Min-Block-Pair Stable Roommates problem asks to find a matching with a minimum number of blocking pairs.

Abraham et al. [6] showed that Min-Block-Pair Stable Roommates is NP-hard, and cannot be approximated within a factor of $n^{0.5-\varepsilon}$ unless P = NP, even if the given preferences

are complete. They also showed that the problem can be solved in $n^{O(\beta)}$ time, where n and β denote the number of agents and the number of blocking pairs, respectively. This implies that the problem is in the XP class (for parameter β) of parameterized complexity. Biró et al. [9] showed that the problem is NP-hard and APX-hard even if each agent has a preference list of length at most 3, and presented a $(2\ell - 3)$-approximation algorithm for bounded list length ℓ. Biró et al. [10] and Hamada et al. [26] showed that the related variant of Stable Marriage, where the goal is to find a matching with minimum blocking pairs among all maximum-cardinality matchings, cannot be approximated within $n^{1-\varepsilon}$ unless P = NP.

Our contributions. We analyze both Egal Stable Roommates and Min-Block-Pair Stable Roommates from the perspective of parameterized complexity, under the natural parameterization of each problem (*i.e.* the egalitarian cost and number of blocking pairs, respectively). We show that while the former is fixed-parameter tractable, the latter is W[1]-hard even when each preference list has length at most five and has no ties. This shows a sharp contrast between the two problems: Computing an optimal egalitarian stable matching is a much easier task than computing a matching with minimum blocking pairs.

When no ties are present, an instance of the Egal Stable Roommates problem has a lot of structure, and so we can apply a simple branching strategy for finding a stable matching with egalitarian cost of at most γ in $2^{O(\gamma)}n^2$ time. Moreover, we derive a kernelization algorithm, obtaining a polynomial problem kernel (Theorems 3 and 4). Note that the original reduction of Feder [20] already shows that Egal Stable Roommates cannot be solved in $2^{o(\gamma)}n^{O(1)}$ time unless the Exponential Time Hypothesis [18] fails.

When ties are present, the problem becomes much more challenging because several agents may be tied as a first ranked partner and it is not clear how to match them to obtain an optimal egalitarian stable matching. Moreover, we have to handle unmatched agents. When preferences are complete or without ties, all stable matchings match the same (sub)set of agents and this subset can be found in polynomial time [24, Chapter 4.5.2]. Thus, unmatched agents do not cause any real difficulties. However, in the case of ties and with incomplete preferences, stable matchings may involve different sets of unmatched agents. Aiming at a socially optimal egalitarian stable matching, we consider the cost of an unmatched agent to be the length of its preference list [39]. (For the sake of completeness, we also consider two other variants where the cost of an unmatched agent is either zero or a constant value, and show that both these variants are unlikely to be fixed-parameter tractable.) Our first main result is given in the following theorem:

▶ **Theorem 1.** Egal Stable Roommates *can be solved in* $\gamma^{O(\gamma)} \cdot (n \log n)^3$ *time, even for incomplete preferences with ties, where* n *is the number of agents and* γ *the egalitarian cost.*

The general idea behind our algorithm is to apply random separation [13] to "separate" irrelevant pairs from the pairs that belong to the solution matching, and from some other pairs that would not block our solution. This is done in two phases, each involving some technicalities, but in total the whole separation can be computed in $\gamma^{O(\gamma)} \cdot n^{O(1)}$ time. After the separation step, the problem reduces to Minimum-Weight Perfect Matching, and we can apply known techniques. Recall that for the case where the preferences have no ties, a simple depth-bounded search tree algorithm suffices (Theorem 4).

In Section 4, we show that Min-Block-Pair Stable Roommates is W[1]-hard with respect to the parameter β (the number of the blocking pairs) even if each input preference list has length at most five and does not have ties. This implies that assuming bounded

length of the preferences does not help in designing an $f(\beta) \cdot n^{O(1)}$-time algorithm for Min-Block-Pair Stable Roommates, unless FPT = W[1]. Our W[1]-hardness result also implies as a corollary a lower-bound on the running time of any algorithm. By adapting our reduction, we also answer in the negative an open question regarding the number of blocking agents proposed by Manlove [37, Chapter 4.6.5] (Corollary 14).

▶ **Theorem 2.** *Let n denote the number of agents and β denote the number of blocking pairs. Even when each input preference list has length at most five and has no ties,* Min-Block-Pair Stable Roommates *is W[1]-hard with respect to β and admits* no $f(\beta) \cdot n^{o(\beta)}$*-time algorithms unless the Exponential Time Hypothesis is false.*

Besides the relevant work mentioned above there is a growing body of research regarding the parameterized complexity of preference-based stable matching problems [39, 40, 43, 42, 23, 15]. Due to space constraints we deferred the proofs for results marked by $\star$ to a full version [14].

2 Definitions and notation

Let $V = \{1, 2, \ldots, n\}$ be a set of even number n agents. Each agent $i \in V$ has a subset of agents $V_i \subseteq V$ which it finds *acceptable* as a partner and has a *preference list* $\succeq_i$ on V_i (*i.e.* a transitive and complete binary relation on V_i). Here, $x \succeq_i y$ means that i weakly prefers x over y (*i.e.* x is better or as good as y). We use $\succ_i$ to denote the asymmetric part (*i.e.* $x \succeq_i y$ and $\neg(y \succeq_i x)$) and $\sim_i$ to denote the symmetric part of $\succeq_i$ (*i.e.* $x \succeq_i y$ and $y \succeq_i x$). For two agents x and y, we call x *most acceptable* to y if x is a maximal element in the preference list of y. Note that an agent can have more than one most acceptable agent. We extend $\succeq$ to $X \succeq Y$ for pairs of disjoint subsets $X, Y \subseteq V$ in the natural way.

A preference profile $\mathcal{P}$ for V is a collection $(\succeq_i)_{i \in V}$ of preference lists for each agent $i \in V$. A profile $\mathcal{P}$ may have the following properties: It is *complete* if for each agent $i \in V$ it holds that $V_i \cup \{i\} = V$; otherwise it is *incomplete*. If there are three agents $i \in V$, $x, y \in V_i$ such that $x \sim_i y$, then we say that x and y are *tied* by i and that the profile $\mathcal{P}$ has *ties*. To an instance $(V, \mathcal{P})$ we assign an *acceptability graph*, which has V as its vertex set and two agents are connected by an edge if each finds the other acceptable. Without loss of generality, G does not contain isolated vertices. The *rank* of an agent i in the preference list of some agent j is the number of agents x that j strictly prefers over i: $\mathsf{rank}_j(i) \coloneqq |\{x \mid x \succ_j i\}|$.

For a preference profile with acceptability graph G and edge set $E(G)$, a *matching* $M \subseteq E(G)$ is a subset of disjoint pairs $\{x, y\}$ of agents with $x \neq y$. If $\{x, y\} \in M$, then we denote the partner y of x by $M(x)$; otherwise we call the pair $\{x, y\}$ *unmatched*. We write $M(x) = \perp$ if agent x has *no partner*; *i.e.* if agent x is not involved in any pair in M. If *no* agent x has $M(x) = \perp$ then M is *perfect*. Given a matching M of $\mathcal{P}$, an unmatched pair $\{x, y\} \in E(G) \setminus M$ *is blocking* M if both x and y prefer each other to being unmatched or to their assigned partners, *i.e.* it holds that $\big(M(x) = \perp \vee y \succ_x M(x)\big) \wedge \big(M(y) = \perp \vee x \succ_y M(y)\big)$. We call a matching M *stable* if no unmatched pair is blocking M. The Stable Roommates problem has as input a preference profile $\mathcal{P}$ for a set V of (even number) n agents and asks whether $\mathcal{P}$ admits a stable matching. When preferences are complete, each stable matching is perfect.

The two problems we consider in the paper are Egal Stable Roommates and Min-Block-Pair Stable Roommates. The latter asks to determine whether a given preference profile $\mathcal{P}$ for a set of agents V has a stable matching with at most β blocking pairs. The former problem asks to find a stable matching with minimum egalitarian cost; the egalitarian cost of a given matching M is as follows: $\gamma(M) \coloneqq \sum_{i \in V} \mathsf{rank}_i(M(i))$, where we augment the definition rank with $\mathsf{rank}_i(\perp) \coloneqq |V_i|$. For example, the second profile in Figure 1 has two stable matchings $M_1 = \{\{1, 3\}\}$ and $M_2 = \{\{1, 2\}, \{3, 4\}\}$ with $\gamma(M_1) = 4$ and $\gamma(M_2) = 2$.

Algorithm 1: A modified version of the phase-1 algorithm of Irving [28].

```
repeat
    foreach agent u ∈ U whose preference list contains at least one unmarked agent do
        w ← the first agent in the preference list of u such that {u, w} is not yet marked
        foreach u′ with u ≻_w u′ do mark {u′, w}
until no new pair was marked in the last iteration
```

The egalitarian cost, as originally introduced for the Stable Marriage problem, does not include the cost of an unmatched agent because the preference lists are complete. For complete preferences, a stable matching must assign a partner to each agent, meaning that our notion of egalitarian cost equals the one used in the literature. For preferences without ties, all stable matchings match the same subset of agents [24, Chapter 4.5.2]. Thus, the two concepts differ only by a fixed value which can be pre-determined in polynomial time [24, Chapter 4.5.2]. For incomplete preferences with ties, there seems to be no consensus on whether to "penalize" stable matchings by the cost of unmatched agents [17]. Our concept of egalitarian cost complies with Marx and Schlotter [39], but we tackle other concepts as well (Section 3.3).

3 Minimizing the egalitarian cost

In this section we give our algorithmic and hardness results for Egal Stable Roommates. Section 3.1 treats the case when no ties are present, where we can use a straightforward branching strategy. In Section 3.2 we solve the case where ties are present. Herein, we need a more sophisticated approach based on random separation. Finally, in Section 3.3, we study variants of the egalitarian cost, differing in the cost assigned to unmatched agents.

3.1 Warm-up: Preferences without ties

By the stability concept, if the preferences have no ties and two agents x and y that are each other's most acceptable agents, then any stable matching must contain $\{x, y\}$, which has cost zero. Hence, we can safely add such pairs to a solution matching. After we have matched all pairs of agents with zero cost, all remaining, unmatched agents induce cost at least one when they are matched. This leads to a simple depth-bounded branching algorithm. In terms of kernelization, we can delete any two agents that induce zero cost and delete agents from some preference list that are ranked higher than γ. This gives us a polynomial kernel.

First, we recall a part of the polynomial-time algorithm by Irving [28] which finds an *arbitrary* stable matching for preferences without ties. The whole algorithm works in two phases. We present here a modified version of the first phase to determine "relevant" agents by sorting out *fixed* pairs – pairs of agents that occur in every stable matching [24, Chapter 4.4.2] – and *marked pairs* – pairs of agents that cannot occur in any stable matching. The modified phase-1 algorithm is given in Algorithm 1. Herein, by *marking a pair* $\{u, w\}$ we mean marking the agents u and w in the preference lists of w and u, respectively.

Let $\mathcal{P}_0$ be the preference profile produced by Algorithm 1. We introduce some more notions. For each agent x, let $\mathsf{first}(\mathcal{P}_0, x)$ and $\mathsf{last}(\mathcal{P}_0, x)$ denote the first and the last agent in the preference list of x that are not marked, respectively. We call a pair $\{x, y\}$ a *fixed pair* if $\mathsf{first}(\mathcal{P}_0, x) = y$ and $\mathsf{first}(\mathcal{P}_0, y) = x$. Let $\mathsf{marked}(\mathcal{P}_0)$ denote the set of all agents whose preference lists consist of only marked agents, and let $\mathsf{unmarked}(\mathcal{P}_0)$ denote the set of all agents whose preference lists have at least one unmarked agent. By [24, Chapters 4.4.2 and

4.5.2], we can neglect all agents that are in the fixed pairs and ignore all "irrelevant" agents from $\mathsf{marked}(\mathcal{P}_0)$. We can now shrink our instance to obtain a polynomial size problem kernel.

▶ **Theorem 3.** Egal Stable Roommates *for preferences without ties but with possibly incomplete preferences admits a size-$O(\gamma^2)$ problem kernel with at most $3\gamma+1$ agents and at most $\gamma+1$ agents in each of the preference lists.*

Proof sketch. Let $I=(\mathcal{P},V,\gamma)$ be an instance of Egal Stable Roommates and let $\mathcal{P}_0$ be the profile that Algorithm 1 produces for $\mathcal{P}$. We use F to denote the set of agents of all fixed pairs, and we use O to denote the set of ordered pairs (x,y) of agents such that x ranks y higher than γ. Briefly put, our kernelization algorithm will delete all agents in $F\cup\mathsf{marked}(\mathcal{P}_0)$, and introduce $O(\gamma)$ dummy agents to replace the deleted agents and some more that are identified by O. Initially, F and O are set to empty sets.

1. If $|\mathsf{marked}(\mathcal{P}_0)|>\gamma$ or if there is an agent x in $\mathsf{unmarked}(\mathcal{P}_0)$ with $\mathsf{rank}_x(\mathsf{first}(\mathcal{P}_0,x))>\gamma$, then return a trivial no-instance.
2. For each two agents $x,y\in\mathsf{unmarked}(\mathcal{P}_0)$ with $\mathsf{first}(\mathcal{P}_0,x)=y$ and $\mathsf{first}(\mathcal{P}_0,y)=x$, add to F the agents x and y. Let $\hat{\gamma}=\gamma-\sum_{x\in F}\mathsf{rank}_x(\mathsf{first}(\mathcal{P}_0,x))-\sum_{x\in\mathsf{marked}(\mathcal{P}_0)}|V_x|$.
3. If $2\hat{\gamma}<|\mathsf{unmarked}(\mathcal{P}_0)\setminus F|$, then return a trivial no-instance.
4. Add to the original agent set a set D of $2k$ *dummy agents* $d_1,d_2,\ldots,d_{2k}$, where $k=2\lceil\hat{\gamma}/2\rceil$, such that for each $i\in\{1,2,\ldots,k\}$, the preference list of d_i consists of only d_{k+i}, and the preference list of d_{k+i} consists of only d_i.
5. For each two $x,y\in\mathsf{unmarked}(\mathcal{P}_0)$ with $\mathsf{rank}_x(y)>\hat{\gamma}$, add to O the ordered pair (x,y).
6. For each agent $a\in\mathsf{unmarked}(\mathcal{P}_0)\setminus F$ do the following.
   (1) For each $i\in\{0,1,2,\ldots,\hat{\gamma}\}$, let x be the agent with $\mathsf{rank}_a(x)=i$. If $x\in F\cup\mathsf{marked}(\mathcal{P}_0)$ or if $(x,a)\in O$, then replace in a's preference list agent x with a dummy agent d, using a different dummy for each i, and append a to the preference list of d.
   (2) Delete all agents y in the preference list of a with $\mathsf{rank}_a(y)>\hat{\gamma}$.
7. Delete $F\cup\mathsf{marked}(\mathcal{P}_0)$ from $\mathcal{P}_0$.

The proof that the above algorithm produces a problem kernel with the desired size in the desired running time is deferred to a full version [14]. ◀

Using a simple branching algorithm, we obtain the following.

▶ **Theorem 4** ($\star$). *Let n denote the number of agents and γ denote the egalitarian cost.* Egal Stable Roommates *without ties can be solved in $O(2^\gamma\cdot n^2)$ time.*

3.2 Preferences with ties

When the preferences may contain ties, we can no longer assume that if two agents are each other's most acceptable agents, denoted as a *good pair*, then a minimum egalitarian cost stable matching would match them together; note that good pairs do not induce any egalitarian cost. This is because their match could force other pairs to be matched together that have large cost. Nevertheless, a good pair will never block any other pair, *i.e.* no agent in a good pair will form with an agent in some other pair a blocking pair. However, a stable matching may still contain some other pairs which have non-zero cost. We call such pairs *costly pairs*. Aiming to find a stable matching M with egalitarian cost at most γ, it turns out that we can also identify in $\gamma^{O(\gamma)}\cdot n^{O(1)}$ time a subset S of pairs of agents, which contains all costly pairs of M and contains no two pairs that may *induce a blocking pair*. It hence suffices to find a minimum-cost maximal matching in the graph induced by S and the good pairs.

The crucial idea is to use the random separation technique [13] to highlight the difference between the matched costly pairs in M and the unmatched costly pairs. This enables us to ignore the costly pairs which pairwisely block each other or are blocked by some pair in M so as to obtain the desired subset S. Before describing the algorithm, we show that we can focus on the case of perfect matchings, even for incomplete preferences. (Note that the case with complete preferences is covered because stable matchings for such case are always perfect.) We show this by introducing dummy agents to extend each non-perfect stable matching to a perfect one, without altering the egalitarian cost.

▶ **Lemma 5** (⋆). Egal Stable Roommates *for n agents and egalitarian cost γ is $O(\gamma \cdot n^2)$-time reducible to* Egal Stable Roommates *for at most $n+\gamma$ agents and egalitarian cost γ with an additional requirement that the stable matching should be perfect.*

Lemma 5 allows, in a subprocedure of our main algorithm, to compute a min-cost *perfect* matching in polynomial time instead of a min-cost *maximal* matching (which is NP-hard).

The algorithm. As mentioned, we use random separation [13]. We apply it already in derandomized form using Bshouty's construction of cover-free families [11], a notion related to universal sets [44]. Let $\hat{n}, p, q \in \mathbb{N}$ such that $p + q \leq \hat{n}$. A family $\mathcal{F}$ of subsets of some $\hat{n}$-element universe U is called $(\hat{n}, p, q)$-*cover-free family* if for each subset $S \subseteq U$ of cardinality $p+q$ and each subset $S' \subseteq S$ of cardinality p, there is a member $A \in \mathcal{F}$ with $S \cap A = S'$.[1] The result by Bshouty [11, Theorem 4] implies that if $p \in o(q)$, then there is an $(\hat{n}, p, q)$-cover-free family of cardinality $q^{O(p)} \cdot \log \hat{n}$ which can be computed in time linear of this cardinality.

In the remainder of this section, we prove Theorem 1. Let $\mathcal{P}$ be a preference profile for a set V of agents, possibly incomplete and with ties. For brevity we denote by a *solution* (of $\mathcal{P}$) a stable matching M with egalitarian cost at most γ. By Lemma 5, we assume that each solution is perfect. Our goal is to construct a graph with vertex set V which contains all matched "edges", representing the pairs, of some solution and some other edges for which no two edges in this graph are blocking each other. Herein, we say that two edges $e, e' \in \binom{V}{2}$ are *blocking each other* if, assuming both edges (which are two disjoint pairs of agents) are in the matching, they would *induce a blocking pair*, *i.e.* $u' \succ_u v$ and $u \succ_{u'} v'$, where $e \coloneqq \{u, v\}$ and $e' \coloneqq \{u', v'\}$. Pricing the edges with their corresponding cost, by Lemma 5, it is then enough to find a minimum-cost perfect matching. The graph is constructed in three phases (see Algorithm 2). In the first phase, we start with the acceptability graph of our profile $\mathcal{P}$ and remove all edges whose "costs" each exceed γ. In the second and the third phases, we remove all edges that block each other while keeping a stable matching with minimum egalitarian cost intact.

We introduce some more necessary concepts. Let G be the acceptability graph corresponding to $\mathcal{P}$ with vertex set V, which also denotes the agent set, and with edge set E. The *cost* of an edge $\{x, y\}$ is the sum of the ranks of each endpoint in the preference list of the other: $\mathsf{rank}_x(y) + \mathsf{rank}_y(x)$. We call an edge $e \coloneqq \{x, y\}$ a *zero edge* if it has *cost* zero, *i.e.* $\mathsf{rank}_x(y) + \mathsf{rank}_y(x) = 0$, otherwise it is a *costly edge* if the cost does not exceed γ. We ignore all edges with cost exceeding γ. Note that no such edge belongs to or is blocking any stable matching with egalitarian cost at most γ. To distinguish between zero edges and costly edges, we construct two subsets E^{zero} and E^{exp} such that E^{zero} consists of all zero edges, *i.e.* $E^{\mathsf{zero}} \coloneqq \{\{x, y\} \in E \mid \mathsf{rank}_x(y) + \mathsf{rank}_y(x) = 0\}$, and E^{exp} consists of all costly edges, *i.e.* $E^{\mathsf{exp}} \coloneqq \{\{x, y\} \in E \mid 0 < \mathsf{rank}_x(y) + \mathsf{rank}_y(x) \leq \gamma\}$.

[1] The standard definition of cover-free families [11] is stated differently from but equivalent [12] to ours.

Algorithm 2: Constructing a perfect stable matching of egalitarian cost at most γ.

Input: A set V of agents, a preference profile $\mathcal{P}$ over V, and a budget $\gamma \in \mathbb{N}$.
Output: A stable matching of egalitarian cost at most γ if it exists.

/* Phase 1 */
1 $(V, E) \leftarrow$ The acceptability graph of $\mathcal{P}$
2 $E^{\mathsf{zero}} \leftarrow \{\{x, y\} \in E \mid \mathsf{rank}_x(y) + \mathsf{rank}_y(x) = 0\}$ // The set of zero edges in E
3 $E^{\mathsf{exp}} \leftarrow \{\{x, y\} \in E \mid 1 \leq \mathsf{rank}_x(y) + \mathsf{rank}_y(x) \leq \gamma\}$ // The set of costly edges in E
4 $E_1 \leftarrow E^{\mathsf{zero}} \cup E^{\mathsf{exp}}$
/* Phase 2 */
5 $\mathcal{F}^{\mathsf{exp}} \leftarrow (|E^{\mathsf{exp}}|, \gamma, \gamma^3)$-cover-free family over the universe E^{exp}
6 **foreach** $E' \in \mathcal{F}^{\mathsf{exp}}$ **do**
7 Apply Rule 1 to E_1 to obtain E_2
/* Phase 3 */
8 $\mathcal{C} \leftarrow (|V|, \gamma^2 + 2 \cdot \gamma, 2 \cdot \gamma)$-cover-free family over the universe V
9 **foreach** $V' \in \mathcal{C}$ **do**
10 Apply Rules 2 and 3 to E_2 to obtain E_3
11 $M \leftarrow$ Minimum-cost perfect matching in the graph (V, E_3) or $\perp$ if none exists
12 **if** $M \neq \perp$ and M has cost at most γ **then return** M

Phase 1. We construct a graph $G_1 = (V, E_1)$ from G with vertex set V and with edge set $E_1 := E^{\mathsf{zero}} \cup E^{\mathsf{exp}}$. The following is easy to see.

▶ **Lemma 6.** *If $\mathcal{P}$ has a stable matching M with egalitarian cost at most γ, then $M \subseteq E_1$.*

Observe also that a zero edge cannot block any other edge because the agents in a zero edge already obtain their most acceptable agents. Thus, we have the following.

▶ **Lemma 7.** *If two edges in E_1 block each other, then they are both costly edges.*

Phase 2. In this phase, comprising Lines 5–7 in Algorithm 2, we remove from G_1 some of the costly edges that block each other (by Lemma 7, no zero edges are blocking any other edge). For technical reasons, we distinguish two types of costly edges: We say that a costly edge e with $e := \{u, v\}$ is *critical for its endpoint* u if the largest possible rank of v over all linearizations of the preference list of u exceeds γ, *i.e.* $|\{x \in V_u \setminus \{v\} \mid x \succeq_u v\}| > \gamma$. Otherwise, e is *harmless for* u. If an edge is critical for at least one endpoint, then we call it *critical* and otherwise *harmless*. Observe that a critical edge could still belong to a solution. If two edges e and e' block each other due to the blocking pair $\{u, u'\}$ with $u \in e, u' \in e'$ such that e' is harmless for u', then we say that e is *harmlessly blocking* e' (at the endpoint u'). Note that blocking is symmetric while harmlessly blocking is not.

Intuitively, we want to distinguish the solution edges from all edges blocked by the solution. There is a "small" number of harmless edges blocked by the solution, so we can easily distinguish between them. For the critical edges, we do not have such a bound; we deal with the critical edges blocked by the solution in Phase 3 in some other way.

▶ **Lemma 8** ($\star$). *Let M be a stable matching with egalitarian cost at most γ. In G_1, at most γ^2 edges are harmlessly blocked by some edge in M.*

Let $M' := M \cap E^{\mathsf{exp}}$ be the set of all costly edges in some solution M and let B_M be the set of all edges harmlessly blocked by some edge in M. By the definition of costly edges and by Lemma 8, it follows that $|M'| \leq \gamma$ and $|B_M| \leq \gamma^2$. In order to identify and delete all edges in B_M we apply random separation. Compute a $(|E^{\mathsf{exp}}|, \gamma, \gamma^2)$-cover-free family $\mathcal{F}^{\mathsf{exp}}$ over the universe E^{exp}. For each member of $\mathcal{F}^{\mathsf{exp}}$, perform all the computations below (in this phase and in Phase 3). By the properties of cover-free families, $\mathcal{F}^{\mathsf{exp}}$ contains a *good*

member E' that "separates" M' from B_M, *i.e.* $M' \subseteq E'$ and $B_M \subseteq E^{\mathsf{exp}} \setminus E'$. Formally, we call a member $E' \in \mathcal{F}^{\mathsf{exp}}$ *good* if there is a solution M such that each costly edge in M belongs to E', and each edge that is harmlessly blocked by M belongs to $E^{\mathsf{exp}} \setminus E'$. We also call E' *good for* M. By the property of cover-free families, if there is a solution M, then $\mathcal{F}^{\mathsf{exp}}$ contains a member E' which is good for M. In the following we present two data reduction rules that delete edges and show their correctness. By *correctness* we mean that, if some member $E' \in \mathcal{F}^{\mathsf{exp}}$ is good, then the corresponding solution is still present after the edge deletion.

Recall that the goal was to compute a graph that contains all edges from a solution and some other edges such that no two edges in the graph block each other. Observe that we can ignore the edges in $E^{\mathsf{exp}} \setminus E'$, because, if E' is good, then it contains all costly edges in the corresponding solution. This implies the correctness of the first part of the following reduction rule. The correctness for the second part follows from the definition of being good.

▶ **Rule 1.** Remove all edges in $E^{\mathsf{exp}} \setminus E'$ from E_1. If there are two edges $e, e' \in E'$ that are harmlessly blocking each other, then remove both e and e' from E_1.

Let $G_2 = (V, E_2)$ be the graph obtained from G_1 by exhaustively applying Rule 1. By the goodness of E' and by the correctness of Rule 1, we have the following.

▶ **Lemma 9.** *If there is a stable matching M with egalitarian cost at most γ, then $\mathcal{F}^{exp}$ contains a member E' such that the edge set E_2 of G_2 defined for E' contains all edges of M.*

By Lemma 7 and since all pairs of edges that are harmlessly blocking each other are deleted by Rule 1, we have the following.

▶ **Lemma 10.** *If two edges in G_2 block each other due to a blocking pair $\{u, u'\}$, then one of the edges is critical for u or u'.*

Phase 3. In Line 10 of Algorithm 2 we remove from G_2 the remaining (critical) edges that do not belong to M but are blocked by some other edges. This includes the edges that are blocked by M. While the number of edges blocked by M could still be unbounded, we show that there are only $O(\gamma^2)$ agents due to which an edge could be blocked by M. The idea here is to identify such agents, helping to find and delete edges blocked by M or blocking some other edges. We introduce one more notion. Consider an arbitrary matching N (*i.e.* a set of disjoint pairs of agents) of G_2. Let $e \in N$ and $e' \in E_2 \setminus N$ be two edges. If they induce a blocking pair $\{u, u'\}$ with $u \in e$ and $u' \in e'$, then we say that u' is a *culprit* of N. We obtain the following upper bound on the number of culprits with respect to a solution.

▶ **Lemma 11 ($\star$).** *Let M be a stable matching. Then, each culprit of M is incident with some edge in M. If M has egalitarian cost at most γ, then it admits at most γ culprits.*

Consider a solution M and let $\mathsf{CI}(M) = \{v \in V \mid v$ is a culprit of or incident with some costly edge of $M\}$. By Lemma 11 and since M has at most γ costly edges, it follows that $|\mathsf{CI}(M)| \leq 3\gamma$. We aim to identify in $\mathsf{CI}(M)$ a subset $\mathsf{R}(M)$ of agents incident with a critical edge in M, *i.e.* $\mathsf{R}(M) = \{v \in \mathsf{CI}(M) \mid \{v, w\} \in M$ with $\{v, w\}$ being critical for $v\}$. Since M has at most γ costly edges, it follows that $|\mathsf{R}(M)| \leq 2\gamma$. To "separate" $\mathsf{R}(M)$ from $\mathsf{CI}(M)$, we compute a $(|V|, 2\gamma, 3\gamma)$-cover-free family $\mathcal{C}$ on the set V. We call a member $V' \in \mathcal{C}$ *good* if there is a solution $M \subseteq E_2$ such that $\mathsf{R}(M) \subseteq V'$ and $(\mathsf{CI}(M) \setminus \mathsf{R}(M)) \subseteq V \setminus V'$. By a similar reasoning as given for Phase 2 and by the properties of cover-free families, if there is a solution $M \subseteq E_2$, then $\mathcal{C}$ contains a good member V'. For this member, the following two reduction rules will not destroy the solution.

▶ **Rule 2** (⋆). For each agent $y \in V \setminus V'$, delete all incident edges that are critical for y.

After having exhaustively applied Rule 2, we use the following reduction rule.

▶ **Rule 3** (⋆). If E_2 contains two edges e and e' that induce a blocking pair $\{u, u'\}$ with $u \in e$ and $u' \in e'$ such that e is critical for u, then remove e' from E_2.

Let $G_3 = (V, E_3)$ be the graph obtained after having exhaustively applied Rules 2 and 3 to G_2. By the correctness of Rules 2 and 3 we have the following.

▶ **Lemma 12.** *If there is a stable matching $M \subseteq E_2$ with egalitarian cost at most γ, then the constructed cover-free family $\mathcal{C}$ contains a good member $V' \in \mathcal{C}$ such that the edge set E_3 of G_3 resulting from the application of Rules 2 and 3 contains all edges of M.*

Since for each member $V' \in \mathcal{C}$, we delete all edges that pairwisely block each other, each perfect matching in G_3 induces a stable matching. We thus have the following.

▶ **Lemma 13** (⋆). *If G_3 admits a perfect matching M with edge cost at most γ, then M corresponds to a stable matching with egalitarian cost at most γ.*

Thus, to complete Algorithm 2, in Line 11 we compute a minimum-cost perfect matching for G_3 and output yes, if it has egalitarian cost at most γ. Summarizing, by Lemma 5 if there is a stable matching of egalitarian cost at most γ, then it is perfect and thus, by Lemmas 6, 9 and 12, there is a perfect matching in G_3 of cost at most γ. Hence, if our input is a yes-instance, then Algorithm 2 accepts by returning a desired solution. Ifi it accepts, then by Lemma 13 the input is a yes-instance. The running time is proved in a full version [14].

3.3 Variants of the egalitarian cost for unmatched agents

As discussed in Sections 1 and 2, when the input preferences are incomplete, a stable matching may leave some agents unmatched. In the absence of ties, all stable matchings leave the same set of agents unmatched [24, Chapter 4.5.2]. Hence, whether an unmatched agent should infer any cost is not relevant in terms of complexity. However, when preferences are incomplete and with ties, stable matchings may involve different sets of matched agents. The cost of unmatched agents changes the parameterized complexity dramatically. In particular, as soon as the cost of an unmatched agent is bounded by a fixed constant, seeking for an optimal egalitarian stable matching is parameterized intractable. See the full version [14].

4 Minimizing the number of blocking pairs

In this section, we strengthen the known result [6] by showing that Min-Block-Pair Stable Roommates is W[1]-hard with respect to "the number β blocking pairs", even when each preference list has length at most five. The main building block of our reduction, which is from the W[1]-hard Multi-Colored Independent Set problem (see our full version [14] for the definition), is a selector gadget (Construction 1) that always induces at least one blocking pair and allows for many different configurations. To keep the lengths of the preference lists short we use "duplicating" agents (Construction 2).

First, we discuss a vertex-selection gadget which we later use to select a vertex of the input graph into the independent set. The selected vertex is indicated by an agent which is matched to someone *outside* of the vertex-selection gadget. The gadget always induces at least one blocking pair. An illustration is shown in a full version [14]. In the following, let n' be a positive integer, and all additions and subtractions in the superscript are taken modulo $2n' + 1$:

▶ **Construction 1.** Consider the following four disjoint sets U, A, C, D of $2n'+1$ agents each, where $A \coloneqq \{a^i \mid 0 \le i \le 2n'\}$, $U \coloneqq \{u^i \mid 0 \le i \le 2n'\}$, $C \coloneqq \{c^i \mid 0 \le i \le 2n'\}$, and $D \coloneqq \{d^i \mid 0 \le i \le 2n'\}$. The preferences of the agents in $A \cup C \cup D$ are: $\forall i \in \{0, 1, \ldots, 2n'\}$: agent a^i: $a^{i+1} \succ a^{i-1} \succ u^i \succ c^i \succ d^i$, agent c^i: $d^i \succ a^i$, agent d^i: $a^i \succ c^i$.

The preferences of the agents in U are intentionally left unspecified and we define them later when we use the gadget. Regardless of the preferences of the agents in U, we can verify that if no a^i obtains an agent u^i as a partner, then it induces at least two blocking pairs.

Next, we construct verification gadgets that ensure that no two adjacent vertices are chosen into the independent set solution. See the full version for an illustration [14]. Herein, let δ be a positive integer, and all additions and subtractions in the superscript are taken modulo $2\delta + 2$.

▶ **Construction 2.** Consider two disjoint sets $X \uplus Y$ where $X = \{x^i \mid 0 \le i \le 2\delta+1\}$ is a set of $2\delta+2$ agents and $Y = \{y^i \mid 1 \le i \le \delta\}$ is a set of δ agents. Let a, b be two agents distinct from the agents in $X \cup Y$. The preference lists of the agents from X are as follows.

	Agent x^0:	$x^1 \succ a \succ x^{2\delta+1}$,	Agent $x^{2\delta+1}$:	$x^0 \succ b \succ x^{2\delta}$.
$\forall i \in \{1, \ldots, \delta\}$:	Agent x^{2i-1}:	$x^{2i} \succ x^{2i-2}$,	Agent x^{2i}:	$x^{2i+1} \succ y^i \succ x^{2i-1}$.

The preferences of the agents a, b and those in Y are intentionally left unspecified and will be defined when we use the gadget later. Regardless of the concrete preferences of agents in $Y \cup \{a, b\}$, we claim that the above gadget has two possible matchings such that no blocking pair involves any agent from X. The first one is straightforward from the definition of the preference lists: $\{\{x^{2i}, x^{2i+1}\} \mid i \in \{0, 1, \ldots, \delta\}\}$. The second one matches x^0 to a, $x^{2\delta+1}$ to b, while keeping the remaining agents matched in some stable way.

Proof sketch of Theorem 2. Let $(G = (V_1, V_2, \ldots, V_k, E))$ be a Multi-Colored Independent Set instance (see our full version [14] for the definition). Without loss of generality, assume that each vertex subset V_j has exactly $2n'+1$ vertices with the form $V_j = \{v_j^0, v_j^1, \ldots, v_j^{2n'}\}$. Construct a Min-Block-Pair Stable Roommates instance with the following groups of agents: $U_j, A_j, B_j, C_j, D_j, F_j, W_j$, $j \in \{1, 2, \ldots, k\}$, where U_j corresponds to the vertex subset V_j. Let δ_j^i be the degree of vertex v_j^i. For each vertex $v_j^i \in V_j$, construct $2\delta_j^i + 2$ agents $u_j^{i,0}, u_j^{i,1}, \ldots, u_j^{i,2\delta_j^i+1}$ and let $U_j^i = \{u_j^{i,z} \mid 0 \le z \le 2\delta_j^i + 1\}$. Define $U_j = \cup_{0 \le i \le 2n'} U_j^i$. For each $(Q, q) \in \{(A, a), (B, b), (C, c), (D, d), (F, f), (W, w)\}$ and for each $i \in \{1, 2, \ldots, k\}$, the set $Q_j \coloneqq \{q_j^i \mid 0 \le i \le 2n'\}$ consists of $2n'+1$ agents. The preference lists of the agents in U_j^i obey the verification gadget constructed in Construction 2. Formally, for each $j \in \{1, \ldots, k\}$ and each $i \in \{0, 1, \ldots, 2n'\}$ we introduce a *verification gadget for* v_j^i as in Construction 2 where we set $\delta = \delta_j^i$, $x^z = u_j^{i,z}$, $0 \le z \le 2\delta_j^i + 1$, $a = a_j^i$, and $b = b_j^i$. The agents from Y correspond to the neighbors of v_j^i: For each neighbor $v_{j'}^{i'}$ of v_j^i we pick a not-yet-set agent y^z in the verification gadget for v_j^i and a not-yet-set agent $y^{z'}$ in the verification gadget for $v_{j'}^{i'}$, and define $y^z = u_{j'}^{i',2z'}$ and $y^{z'} = u_j^{i,2z}$.

For each $j \in \{1, \ldots, k\}$, the preference lists of $A_j \cup C_j \cup D_j \cup \{u_j^{i,0} \mid 0 \le i \le 2n'\}$ obey Construction 1. Formally, for each $j \in \{1, \ldots, k\}$ we introduce a vertex-selection gadget as in Construction 1 and for each $i \in \{0, 1, \ldots, 2n'\}$ we set $a^i = a_j^i$, $c^i = c_j^i$, $d^i = d_j^i$, and $u^i = u_j^{i,0}$. Analogously, for each $j \in \{1, \ldots, k\}$ we introduce a vertex-selection gadget for $B_j \cup F_j \cup W_j \cup \{u_j^{i,2\delta_j^i+1} \mid 0 \le i \le 2n'\}$: For each $i \in \{0, 1, \ldots, 2n'\}$ we set $a^i = b_j^i$, $c^i = f_j^i$, $d^i = w_j^i$, and $u^i = u_j^{i,2\delta_i^j+1}$. To complete the construction, we set the upper bound on the number of blocking pairs as $\beta = 2k$. The correctness proof is deferred to a full version [14]. ◀

The reduction given in the proof of Theorem 2 shows that the lower-bound on β in [6, Lemma 4] is tight. The reduction also answers an open question by Manlove [37, Chapter 4.6.5] about the complexity of the following problem. Given a preference profile and an integer η, Min-Block-Agents Stable Roommates asks whether there is a matching with at most η *blocking agents*. Herein, an agent is a *blocking agent* if it is involved in a blocking pair.

▶ **Corollary 14** ($\star$). *Let n be the number of agents and η be the number of blocking agents. Even when each input preference list has length at most five and has no ties,* Min-Block-Agents Stable Roommates *is NP-hard and W[1]-hard with respect to η.* Min-Block-Agents Stable Roommates *for preferences without ties is solvable in $O(2^{\eta^2} \cdot n^{\eta+2})$ time.*

Abstract

We show explicit separations between the expressive powers of multilinear formulas of small-depth and all polynomial sizes.

Formally, for any $s = s(n) = n^{O(1)}$ and any $\delta > 0$, we construct explicit families of multilinear polynomials $P_n \in \mathbb{F}[x_1, \ldots, x_n]$ that have multilinear formulas of size s and depth three but no multilinear formulas of size $s^{1/2-\delta}$ and depth $o(\log n / \log\log n)$.

As far as we know, this is the first such result for an algebraic model of computation.

Our proof can be viewed as a derandomization of a lower bound technique of Raz (JACM 2009) using ε-biased spaces.

1 Introduction

The main aim of Computational Complexity is to understand as precisely as possible the amounts of computational resources required to perform interesting computational tasks. These resources could be of various kinds depending on the computational model under consideration, e.g., time and space for traditional algorithms, size and depth for Boolean and Algebraic circuits, the number of random bits for randomized algorithms, total communication for communication protocols and so on.

A fundamental question regarding any given resource is if access to more of that resource strictly increases the power of the underlying computational model. Classical theorems in Computational Complexity theory such as the *Time Hierarchy theorem* [13] and *Space Hierarchy Theorem* [18] answer this question (in the affirmative) for the resources of time and space on multitape Turing Machines.

In this paper, we consider an analogous question for *Algebraic formulas*. Algebraic formulas (and their variants such as Algebraic circuits, Algebraic Branching Programs etc.) are the natural computational model for computing multivariate polynomials over some underlying domain, usually a field $\mathbb{F}$. Many natural problems, such as the Determinant, Permanent, Matrix Multiplication, the Fast Fourier Transform etc. fit into this general framework. Algebraic formulas compute multivariate polynomials from the ring $\mathbb{F}[x_1, \ldots, x_n]$ using the natural algebraic operations of sum and product.

The *size* of an algebraic formula is the number of algebraic operations it uses and is a measure of the efficiency of the formula (it roughly corresponds to the time in the case of traditional algorithms). One can also consider the *depth* of the formula, which measures how nested the algebraic operations in the formula are, and corresponds to how parallelizable the underlying procedure is. In this paper, we consider the question of proving a *Size-hierarchy theorem* for Algebraic formulas. Somewhat informally, we ask the following.

▶ **Question 1** (The Size-Hierarchy Question). *For any $\delta > 0$, are there explicit families of polynomials $P_n \in \mathbb{F}[x_1, \ldots, x_n]$ that can be computed by formulas of size $s(n)$ but not by formulas of size less than $s(n)^{1-\delta}$?*

(See Section 2 for the definition of "explicit". We note that requiring explicit polynomial families is necessary since counting arguments easily yield the existence of polynomials that have formulas of size $s(n)$ but not size $s(n)^{1-\delta}$ for most reasonable functions $s(n)$. However, as is standard in Circuit Complexity, the interesting question is finding an explicit function that witnesses this separation.)

As of now, the size-hierarchy question is far beyond the range of our techniques for most non-trivial parameters. Indeed, we do not have techniques to prove *any* explicit strong lower bounds for general algebraic formulas, let alone lower bounds for explicit polynomials that further have algebraic formulas of some prescribed size $s(n)$.

So, we restrict ourselves to the setting of *multilinear formulas*, which are algebraic formulas that are required to compute a multilinear polynomial[1] at each intermediate stage of computation. Note that the most efficient formula for computing some multilinear polynomial need not be multilinear (this is known to be true for small-depth multilinear formulas [8]) and so this is indeed a restriction. Nevertheless, it is a reasonable restriction for formulas that compute multilinear polynomials and has been the focus of a large body of work [20, 22, 21, 24, 23, 25, 15, 11, 17, 8, 3, 7] with interesting upper as well as lower bound results.

Therefore, it is natural to consider the size-hierarchy question in the setting of multilinear formulas. It follows from the work of Raz [21] and Raz and Yehudayoff [24] that for $s(n) \leq n^{O(1)}$, there are explicit polynomial families that can be computed by multilinear formulas of size s but not by multilinear formulas of size less than s^{δ_0} for some positive, but small, δ_0. (One needs to mine the proofs for the exact value of δ_0. The best value that we could obtain for δ_0 was less than $1/30$.)

In this paper, we prove a near-tight multilinear size-hierarchy theorem for *small-depth* multilinear formulas. It is known [6, 5] that any multilinear formula of polynomial size s can be converted to another of size at most $s^{1+\delta}$ and depth $O(\log n)$ (for any fixed $\delta > 0$). Below, we consider multilinear formulas of smaller depth $O(\log n / \log\log n)$. The main result is the following.

▶ **Theorem 2.** *For any fixed $c \in \mathbb{N}$ and $\delta \in (0, 1/2)$, there exists an explicit polynomial family $P_n \in \mathbb{F}[x_1, \ldots, x_n]$ that has a multilinear formula of depth 3 and size at most $s = O(n^c)$ but no multilinear formulas of size less than $s^{(1/2)-\delta}$ and depth $\Delta < \log n / 100 \log\log n$.*

As such, our result is incomparable with the separation implied by [21, 24] since we further assume that our formulas have small depth. However, in the setting of small-depth multilinear formulas, our result improves on the separation of [21, 24] in two ways. The first is that we obtain a separation of s versus $s^{(1/2)-\delta}$ as opposed to the s versus s^{δ_0} separation

[1] Recall that a *multilinear* polynomial $P \in \mathbb{F}[x_1, \ldots, x_n]$ is one in which each variable has degree at most 1.

obtained by [21, 24]. The second is that the polynomials P_n that we consider have *depth-three* formulas of size s. This is in contrast to the polynomials constructed in [21, 24], that have formulas of size s but also depth $\Omega(\sqrt{\log s})$, which is considerably larger.[2] Finally, our proof technique is based on a derandomization of a special case of a lower bound technique of Raz [22]. This derandomization leaves some scope for improvement: an optimal result along these lines would resolve the size-hierarchy question optimally yielding a separation between sizes s and $s^{1-\delta}$ for any $\delta > 0$. An optimal derandomization of the more general lower bound technique of Raz would yield the same result for general multilinear formulas (without the depth restriction).

1.1 Related Work

Our work is partially motivated by hierarchy theorems for *Boolean circuits*, which compute functions $f : \{0,1\}^n \to \{0,1\}$ using simple Boolean operations such as AND and OR. Superpolynomial lower bounds have been known for constant-depth Boolean circuits since the early 1980s [12, 1, 14]. However, a size hierarchy theorem in this setting was obtained relatively recently by Rossman [26], who proved that for any constant $k \in \mathbb{N}$, there are explicit functions that have depth-two Boolean circuits of size $O(n^k)$ but not of size less than $n^{k/4}$. This was then improved by Amano [4] who showed that for any fixed k and δ there are explicit functions that have depth two Boolean circuits of size $O(n^k)$ but no circuits of size less than $n^{k-\delta}$.

Our proofs build on standard techniques for proving lower bounds for multilinear formulas. While these ideas are essentially due to Raz [22], we use a high-level reformulation of this argument that appears in the survey of Shpilka and Yehudayoff [28].

1.2 Proof Outline

Our proof can be seen as a derandomization of (a special case of a) technique of Raz [22] for proving lower bounds for multilinear formulas. Here, we follow a well-known reformulation of this proof that appears in [15, 28, 11].

Say we want to show that a multilinear polynomial $P \in \mathbb{F}[X]$ does not have a small-depth multilinear formula of size s'. The proof strategy consists of two steps. The first step is a decomposition lemma that says that any multilinear polynomial P that is computed by a small-depth multilinear formula of size s' can be written as a sum of s' polynomials, each of which is of the form $f = f_1 \cdot f_2 \cdot \ldots \cdot f_t$ where the f_i's are multilinear polynomials over pairwise disjoint *non-empty* sets of variables $X_1, \ldots, X_t$ that partition the variable set X. Following [28], we call such a polynomial a *t-product polynomial.* Here, t is some growing function of the number of variables n and the depth of the formula.

Thus, to show that P does not have a small-depth multilinear formula of size s', it suffices to show that it cannot be written as a sum of s' many t-product polynomials for a large t. This is the second step. To argue this, Raz used a rank-based argument. Specifically, we partition the variables X into any two sets[3] Y and Z and consider any polynomial $P(X)$ as a polynomial in the variables in Y, with coefficients from $\mathbb{F}[Z]$. The dimension of the space of coefficients (as vectors over the base field $\mathbb{F}$) is considered to be a measure of the complexity of P. The idea is that polynomials with small formulas will have low complexity and hence, by choosing a P of high complexity we obtain a lower bound.

[2] In fact, the polynomial families from [21, 24] do not have formulas of constant-depth and comparable size. This follows from a later lower bound result of Raz and Yehudayoff [25].

[3] Actually, the sets Y and Z also need to be of equal size. We ignore this for now for the sake of exposition.

Unfortunately, this idea by itself is not enough to prove a strong lower bound. This is because of the fact that given any partition (Y, Z), there is a small depth-2 multilinear formula $F_{(Y,Z)}$ (which is also a t-product polynomial for large t) that has maximum dimension w.r.t. this partition. To overcome this, we consider a *random* partition (Y, Z) and show that any t-product polynomial will have low-rank w.r.t. this random partition with high probability. Using a union bound, we then show that any sum of s' many t-product polynomials must be of low-rank w.r.t. some partition. If, on the other hand, our choice of polynomial P has high rank w.r.t. *every* partition, we obtain a lower bound.

The crux of the matter therefore is to argue that given any t-product polynomial $f = f_1 \cdots f_t$ as above, and a random partition (Y, Z), the polynomial f is low-rank w.h.p., w.r.t. this partition. Formally, for the union bound over s' many such polynomials to go through, we need the following criterion to hold.

$$\Pr_{(Y,Z)}[f \text{ does not have small rank w.r.t. } (Y, Z)] < \frac{1}{s'}.$$

Raz [22] showed that this reduces to a combinatorial discrepancy question. Note that any choice of partition (Y, Z) of X induces a partition (Y_i, Z_i) of each X_i ($i \in [t]$). To prove the above bound, it actually suffices to show[4] that

$$\Pr_{(Y,Z)}[|\{i \in [t] \mid |Y_i| - \lfloor |X_i|/2 \rfloor \text{ odd}\}| \text{ is small}] < \frac{1}{s'}.$$

But this is quite easy to argue. Since (Y, Z) is a random partition, each $|Y_i| - \lfloor |X_i|/2 \rfloor$ is odd with probability $1/2$. Since the X_i ($i \in [t]$) are pairwise disjoint, these events are mutually independent and hence by a Chernoff bound, it is easy to show that the probability of the above event is $1/2^{\Omega(t)} < 1/s'$ for the specific t that we obtain in the decomposition lemma (this is where the small-depth assumption comes in). This completes the proof.

The derandomization. Our idea is to simulate the purely random partition argument of Raz, but using instead a random partition from a small predefined set $\mathcal{S} = \{(Y^{(1)}, Z^{(1)}), \ldots, (Y^{(s)}, Z^{(s)})\}$ of partitions. We would like to show that for a random $j \in [s]$ and any product polynomial $f = f_1 \cdots f_t$ as above, we similarly obtain

$$\Pr_j[|\{i \in [t] \mid |Y_i^{(j)}| - \lfloor |X_i|/2 \rfloor \text{ is odd}\}| \text{ is small}] < \frac{1}{s'} \tag{1}$$

where $Y_i^{(j)}$ denotes the set $X_i \cap Y^{(j)}$.

If we have a set $\mathcal{S}$ as above, we obtain a size-hierarchy theorem as follows. First, we construct a multilinear formula $F_{\mathcal{S}}$ of size roughly s that is full-rank w.r.t. each of the partitions in $\mathcal{S}$: this is done by simply taking a suitable linear combination of the formulas $F_{(Y^{(j)},Z^{(j)})}$ ($j \in [s]$) mentioned above. On the other hand, we know that given any small-depth multilinear formula F' of size s', (1) implies that F' cannot compute a polynomial that is full-rank w.r.t. all the partitions in $\mathcal{S}$, and in particular cannot compute the same polynomial as F. This proves a separation between small-depth multilinear formulas of size s and size s'. The question now is – how do we construct such a set $\mathcal{S}$ as described above while keeping s as close to s' as possible?

[4] Raz in fact shows that it suffices to bound the probability that $\sum_{i \in [t]} ||Y_i| - |X_i|/2|$ is small. Here, we only use the fact that for each i such that $|Y_i| - \lfloor |X_i|/2 \rfloor$ is odd, we must have $||Y_i| - |X_i|/2| \geq 1/2$. This harks back to an earlier result of Nisan and Wigderson [20] who use a simpler parity argument to prove a lower bound for *set-multilinear* formulas.

Our construction of the set $\mathcal{S}$ follows two steps. We first show that it suffices to construct a set that satisfies the following somewhat weaker condition.

$$\Pr_j[|\{i \in [t] \mid |Y_i^{(j)}| - \lfloor |X_i|/2 \rfloor \text{ is odd}\}| \ = 0] < \frac{1}{2s'} \tag{2}$$

We deduce (1) from (2) by adapting a combinatorial proof of the Chernoff bound that appears in a result of Impagliazzo and Kabanets [16].

Finally, we show that for (2) it suffices to use *Small-Bias* spaces, which are a standard tool in the derandomization literature [19]. Known explicit constructions of small-bias spaces [2] yield sets $\mathcal{S}$ satisfying (2) of size roughly $s = (s')^2$. This yields a separation between size s and size roughly $\sqrt{s}$ as stated in Theorem 2.

We remark that non-constructively, we can show that there exist sets $\mathcal{S}$ satisfying (2) of size roughly s'. Constructing such sets explicitly would improve our result to a near-tight size-hierarchy theorem.

2 Preliminaries

Recall that a polynomial $P \in \mathbb{F}[x_1, \ldots, x_n]$ is *multilinear* if each variable has degree at most 1 in P.

A family $\{P_n \in \mathbb{F}[x_1, \ldots, x_n] \mid n \geq 1\}$ of multilinear polynomials is said to be *explicit* if there is a deterministic algorithm that given as input n and a monomial m over the variables $x_1, \ldots, x_n$, computes in time poly(n) the coefficient of the monomial m in P_n.

2.1 Multilinear formulas

For the detailed introduction to algebraic formulas, we refer the reader to standard resources such as [28, 27]. Having said that, we do make a few remarks.

- All the gates in our formulas may have *unbounded* fan-in.
- The size of a formula refers to the number of gates (including input gates) in it, and depth of the formula refers to the number of gates on the longest path from an input gate to output gate.

An algebraic formula F computing a polynomial from $\mathbb{F}[X]$ is said to be *multilinear* if each gate in the formula computes a multilinear polynomial.

We state below a decomposition lemma for small-depth multilinear formulas.

Define a polynomial $f \in \mathbb{F}[X]$ to be a *t-product polynomial* if we can write f as $f_1 \cdots f_t$, where we can find a partition of X into pairwise disjoint non-empty sets $X_1^f, \ldots, X_t^f$ such that f_i is a multilinear polynomial from $\mathbb{F}[X_i^f]$.[5] We say that X_i^f is the set *ascribed* to f_i in the t-product polynomial f. We use Vars(f_i) (with a slight abuse of notation)[6] to denote X_i^f.

The following is easily implied by Lemma 3.8 in [28].

▶ **Lemma 3.** *Assume that $f \in \mathbb{F}[X]$ can be computed by a multilinear circuit over n variables of size at most s and depth at most Δ. Then, f is the sum of at most $s \cdot n$ many t-product polynomials for $t = \Omega(n^{1/2\Delta})$.*

[5] Note that we do not need f_i ($i \in [t]$) to depend non-trivially on all (or any) of the variables in X_i^f.
[6] Vars$(\cdot)$ is used to describe variables ascribed to gates in a circuit as well as to denote variables ascribed to polynomials.

2.2 Partial derivative matrices and relative rank

From here on, for the sake of simplicity, we will assume that n is even[7].

Let X, W be disjoint sets of variables with $X = \{x_1, \ldots, x_n\}$. Let $\mathbb{F}$ be any field. Let $\mathbb{G} = \mathbb{F}(W)$ be the field of rational functions over $\mathbb{F}$ generated by set of variables W. Let Y and Z be disjoint variable sets $\{y_1, \ldots, y_n\}$ and $\{z_1, \ldots, z_n\}$. We consider *injective* maps $\rho : X \to Y \cup Z$ which we call *partitioning functions*.

We can index partitioning functions by elements of $\{0,1\}^n$ as follows. Fix $\mathbf{a} \in \{0,1\}^n$ be any vector. Let $1_\mathbf{a} = \{i \mid \mathbf{a}(i) = 1\}$ and $0_\mathbf{a} = \{i \mid \mathbf{a}(i) = 0\}$, and thus, $|1_\mathbf{a}| + |0_\mathbf{a}| = n$. For a vector $\mathbf{a} \in \{0,1\}^n$, define the partitioning function $\rho_\mathbf{a}$ by $\rho_\mathbf{a}(x_i) = y_i$ if $i \in 1_\mathbf{a}$ and $\rho_\mathbf{a}(x_i) = z_i$ otherwise, i.e. if $i \in 0_\mathbf{a}$. Let $\mathrm{Img}(\rho_\mathbf{a})$ denote the subset of $Y \cup Z$ that $\rho_\mathbf{a}$ maps the set X to. Let $Y_\mathbf{a} = Y \cap \mathrm{Img}(\rho_\mathbf{a})$ and let $Z_\mathbf{a} = Z \cap \mathrm{Img}(\rho_\mathbf{a})$. If the vector $\mathbf{a}$ is balanced[8] then we also get that $|Y_\mathbf{a}| = |Z_\mathbf{a}| = n/2$. For a balanced vector $\mathbf{a}$, we call $\rho_\mathbf{a}$ a *balanced partition*.

Note that given any $\mathbf{a} \in \{0,1\}^n$ and any multilinear polynomial $f \in \mathbb{F}[X, W]$, the partitioning function $\rho_\mathbf{a}$ defines by substitution a *multilinear*[9] polynomial in $\mathbb{F}[Y_\mathbf{a} \cup Z_\mathbf{a} \cup W]$, which we denote $f|_{\rho_\mathbf{a}}$. We will consider $f|_{\rho_\mathbf{a}}$ as a polynomial in $\mathbb{G}[Y_\mathbf{a} \cup Z_\mathbf{a}]$.

For any disjoint sets of variables Y' and Z', let $g \in \mathbb{G}[Y' \cup Z']$ be a multilinear polynomial. Define the $2^{|Y'|} \times 2^{|Z'|}$ matrix $M_{(Y',Z')}(g)$ whose rows and columns are labelled by distinct multilinear monomials in Y' and Z' respectively and the (m_1, m_2)th entry of $M_{(Y',Z')}(g)$ is the coefficient of the monomial $m_1 \cdot m_2$ in g. We will use the rank of this matrix as a measure of the complexity of g.

We define the *relative-rank* of g w.r.t. (Y', Z'), denoted $\mathrm{relrk}_{(Y',Z')}(g)$, by

$$\mathrm{relrk}_{(Y',Z')}(g) = \frac{\mathrm{rank}(M_{(Y',Z')}(g))}{2^{(|Y'|+|Z'|)/2}}.$$

The above notion is implicit in the work of Nisan and Wigderson [20] and Raz [22].

We note the following properties of relative rank.

▶ **Proposition 4.** *Let $g, g_1, g_2 \in \mathbb{G}[Y' \cup Z']$ be multilinear polynomials.*

1. $\mathrm{relrk}_{(Y',Z')}(g) \leq 1$. *Further if $|Y'| \neq |Z'|$, then* $\mathrm{relrk}_{(Y',Z')}(g) \leq 1/\sqrt{2}$.
2. $\mathrm{relrk}_{(Y',Z')}(g_1 + g_2) \leq \mathrm{relrk}_{(Y',Z')}(g_1) + \mathrm{relrk}_{(Y',Z')}(g_2)$.
3. *If Y' is partitioned into Y'_1, Y'_2 and Z' into Z'_1, Z'_2 with $g_i \in \mathbb{G}[Y'_i \cup Z'_i]$ ($i \in [2]$), then* $\mathrm{rank}(M_{(Y',Z')}(g)) = \mathrm{rank}(M_{(Y'_1,Z'_1)}(g_1)) \cdot \mathrm{rank}(M_{(Y'_2,Z'_2)}(g_2))$. *In particular,* $\mathrm{relrk}_{(Y',Z')}(g_1 \cdot g_2) = \mathrm{relrk}_{(Y'_1,Z'_1)}(g_1) \cdot \mathrm{relrk}_{(Y'_2,Z'_2)}(g_2)$.

2.3 Explicit ε-biased spaces

The following notions are borrowed from [2]. For any $\mathbf{a}, \mathbf{b} \in \{0,1\}^n$, let $(\mathbf{a}, \mathbf{b})_2$ denote the inner product of the binary vectors $\mathbf{a}$ and $\mathbf{b}$ modulo 2, that is, $(\mathbf{a}, \mathbf{b})_2 = \sum_{i=1}^n \mathbf{a}(i) \cdot \mathbf{b}(i) \pmod 2$.

▶ **Definition 5.** Let $\mathcal{S}$ be a multiset in $\{0,1\}^n$. Let $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ be chosen uniformly from $\mathcal{S}$. The multiset $\mathcal{S}$ is said to be an ε-biased space if for every $\mathbf{b} = (b_1, b_2, \ldots, b_n) \in$

[7] If n is odd, everything will work as is with n replaced by $n - 1$.
[8] A vector $\mathbf{a} \in \{0,1\}^n$ is said to be balanced if $|1_\mathbf{a}| = |0_\mathbf{a}|$.
[9] The polynomial is multilinear by the injectivity of $\rho_\mathbf{a}$.

$\{0,1\}^n \setminus \{0\}^n$, the random variable $(\mathbf{x}, \mathbf{b})_2$ is ε-biased. That is, for all $\mathbf{b} \in \{0,1\}^n \setminus \{0\}^n$,

$$\left| \mathop{\mathbf{E}}_{\mathbf{x} \in \mathcal{S}} [(-1)^{(\mathbf{x},\mathbf{b})_2}] \right| \leq \varepsilon.$$

A standard probabilistic argument implies the existence of ε-biased spaces of size $O(n/\varepsilon^2)$. Explicit constructions of size $\mathrm{poly}(n/\varepsilon)$ were first presented by Naor and Naor in [19]. We use the following construction of Alon, Goldreich, Håstad and Peralta [2].

▶ **Theorem 6** ([2], Proposition 3). *There is a deterministic algorithm, which given as input $n \in \mathbb{N}$ and $\varepsilon > 0$, produces an ε-biased set $\mathcal{S}$ of size $O(n^2/\varepsilon^2)$ in time $\mathrm{poly}(|\mathcal{S}|)$.*

3 The hard polynomial and restrictions

3.1 Subspace-avoiding sets

▶ **Definition 7.** We say that a multiset $\mathcal{S} \subseteq \{0,1\}^n$ is (ε, k)-*subspace avoiding* if for any affine subspace V of $\{0,1\}^n$ (here identified with $\mathbb{F}_2^n$) with co-dimension k,

$$\Pr_{\mathbf{x} \in \mathcal{S}}[\mathbf{x} \in V] \leq \frac{1}{2^k} + \varepsilon.$$

The above definition is quite similar to the notion of *subspace evasive sets* that have been studied in the literature (see, e.g. [10]). However, there also seems to be a crucial difference between the two settings, since in [10] the interest is in evading subspaces of small *dimension* whereas we are trying to avoid subspaces of somewhat large but still relative small *co-dimension*. In particular, it is not clear to us if [10] can be used to give better constructions of subspace avoiding sets than the ones we obtain here.

The following fact is immediate from the definition above.

▶ **Fact 8.** *If $k = 10 \log \frac{1}{\varepsilon}$ and $\mathcal{S}$ is an (ε, k)-subspace avoiding set, then $\Pr_{\mathbf{x} \in \mathcal{S}}[\mathbf{x} \in V] \leq 2\varepsilon$.*

It is a standard fact [19, 9] that ε-biased spaces are in particular (ε, k)-subspace avoiding. We state this claim below. The proof is omitted for lack of space.

▶ **Claim 9.** *Any ε-biased space $\mathcal{S}$ is also an (ε, k)-subspace avoiding set.*

We will use the vectors from an (ε, k)-subspace avoiding set to define our hard polynomial. For reasons that will become apparent, it is helpful to have the vectors in the subspace avoiding set to be *balanced*, i.e. have an equal number of 0s and 1s. However, a priori, there is no reason to assume that the vectors we obtain via some construction of such a set will be balanced. In order to make them balanced, we will use the following trick.

For $i \in [n]$, let $\boldsymbol{\alpha}_i \in \{0,1\}^n$ denote the vector defined by $\boldsymbol{\alpha}_i(j) = 0$ if $j > i$ and $\boldsymbol{\alpha}_i(j) = 1$ otherwise. Let $\mathbf{0}$ denote the all zero vector, i.e. $\mathbf{0} = 0^n$. Let $\mathcal{V} = \{\boldsymbol{\alpha}_1, \boldsymbol{\alpha}_2, \ldots, \boldsymbol{\alpha}_n, \mathbf{0}\}$. Note that, for any $\mathbf{a} \in \{0,1\}^n$, there exists an $\mathbf{x} \in \mathcal{V}$ such that $\mathbf{a} \oplus \mathbf{x}$ is balanced. In particular for $\mathbf{x} \in \mathcal{V}$ chosen *at random*, the probability that $\mathbf{a} \oplus \mathbf{x}$ is balanced is at least $1/(n+1)$.

Now, let $\mathcal{S}$ be an (ε, k)-subspace avoiding set. Let $\mathcal{S} \oplus \mathbf{x}$ denote the set of all vectors obtained by shifting all the vectors in $\mathcal{S}$ by $\mathbf{x}$, i.e. $\mathcal{S} \oplus \mathbf{x} = \{\mathbf{a} \oplus \mathbf{x} \mid \mathbf{a} \in \mathcal{S}\}$. We have the following easily verifiable fact.

▶ **Fact 10.** *Let $\mathcal{S}$ be an (ε, k)-subspace avoiding set. Then for each $\mathbf{x} \in \{0,1\}^n$, $\mathcal{S} \oplus \mathbf{x}$ is also an (ε, k)-subspace avoiding set.*

For any $\mathbf{x}$, let $\mathcal{B}_{\mathbf{x}}$ be the balanced vectors in $\mathcal{S} \oplus \mathbf{x}$. From our reasoning above, we get that $\mathbf{E}_{\mathbf{x}\in\mathcal{V}}[|\mathcal{B}_{\mathbf{x}}|] \geq |\mathcal{S}|/(n+1)$. By averaging, we see that there exists an $\mathbf{x} \in \mathcal{V}$ such that $|\mathcal{B}_{\mathbf{x}}| \geq |\mathcal{S}|/(n+1)$. We will now fix such an $\mathbf{x}$. We will denote it by $\mathbf{x}_0$ and work with some $\mathcal{B} \subseteq \mathcal{B}_{\mathbf{x}_0}$ of size exactly $\lceil |\mathcal{S}|/(n+1) \rceil$. Clearly, given $\mathcal{S}$, such an $\mathbf{x}_0$ and $\mathcal{B}$ can be found in time $\text{poly}(|\mathcal{S}|, n)$ by simply computing all the sets $\mathcal{S} \oplus \mathbf{x}$ ($\mathbf{x} \in \mathcal{V}$) and counting the number of balanced vectors in them.

We have shown the following claim.

▶ **Claim 11.** *Let $\mathcal{S} \subseteq \{0,1\}^n$ be any (ε, k)-subspace avoiding set. Then, there is an $\mathbf{x}_0 \in \{0,1\}^n$ and a set $\mathcal{B}$ of balanced vectors from $\mathcal{S} \oplus \mathbf{x}_0$ such that $|\mathcal{B}| = \Theta(|\mathcal{S}|/n)$. Further, given $\mathcal{S}$, such an $\mathbf{x}_0$ and $\mathcal{B}$ can be found deterministically in time* $\text{poly}(|\mathcal{S}|, n)$.

3.2 The hard polynomial

We now define the explicit polynomial family that we will use to prove our size hierarchy theorem.

Let $n \in \mathbb{N}$ be any positive even integer and let $\varepsilon > 0$ be any positive real parameter. Let $\mathcal{S}_{n,\varepsilon}$ be the explicit ε-biased space from Theorem 6. We further fix an $\mathbf{x}_0 \in \{0,1\}^n$ and a set $\mathcal{B}$ of balanced vectors from $\mathcal{S}_{n,\varepsilon} \oplus \mathbf{x}_0$ such that $|\mathcal{B}| = \Theta(|\mathcal{S}_{n,\varepsilon}|/n)$ as guaranteed to exist by Claim 11. Note that by Theorem 6 and Claim 11, $|\mathcal{B}|$ can be computed in time $\text{poly}(n/\varepsilon)$. We denote $|\mathcal{B}|$ by τ.

Fix any $\mathbf{a} \in \mathcal{B}$. Let $1_{\mathbf{a}} = \{i_1, \ldots, i_{n/2}\}$ and $0_{\mathbf{a}} = \{j_1, \ldots, j_{n/2}\}$, where $i_1 < i_2 < \ldots < i_{n/2}$ and $j_1 < j_2 \ldots < j_{n/2}$. Define $\Gamma_{\mathbf{a}}(X) = \prod_{t=1}^{n/2}(x_{i_t} + x_{j_t})$.

We will use $\Gamma_{\mathbf{a}}(X)$ for $\mathbf{a} \in \mathcal{B}$ to define our hard polynomial. As in [22, 24] we define such a polynomial using a set W of auxiliary variables. Intuitively, the variables W help us in *tagging* a certain polynomial $\Gamma_{\mathbf{a}}(X)$ with the appropriate vector $\mathbf{a}$ from the set $\mathcal{B}$. We will now formally describe this idea.

Since $|\mathcal{B}| = \tau$, we can fix a one-one map $\mathcal{C} : \mathcal{B} \to \{0,1\}^{\log \tau}$. Let the vectors in $\mathcal{B}$ be enumerated in some arbitrary order, say $\mathbf{a}_1, \ldots, \mathbf{a}_\tau$. For an index $i \in [\tau]$, let $\mathcal{C}(\mathbf{a}_i) = (u_{i,1} \ldots, u_{i,T})$. We will denote this vector by $\mathbf{u}_i$, we will call $\mathbf{u}_i$ the *encoding* of $\mathbf{a}_i$.

Let $T = \log \tau$. Let $W = \{w_1, \ldots, w_T\}$ be a new set of auxiliary variables. For a vector $\mathbf{u} \in \{0,1\}^T$, let $\phi_{\mathbf{u}}(j) = w_j$ if $u_j = 1$ and $\phi_{\mathbf{u}}(j) = 1 - w_j$ otherwise. Then let $W_{\mathbf{u}} = \prod_{j\in[T]} \phi_{\mathbf{u}}(j)$. We will say that a polynomial $W_{\mathbf{u}}$ is the *label* of the vector $\mathbf{u}$. We will say that the tagging of the polynomial $\Gamma_{\mathbf{a}}(X)$ is obtained by multiplying $\Gamma_{\mathbf{a}}(X)$ with the label of the encoding of $\mathbf{a}$, i.e. with $W_{\mathcal{C}(\mathbf{a})}$. Note that, given $\mathbf{a} \in \mathcal{B}$, the polynomial $W_{\mathcal{C}(a)} \cdot \Gamma_{\mathbf{a}}(X)$ can be computed by a depth-2 multilinear formula, which itself can be constructed in time $\text{poly}(n, \tau) = \text{poly}(n/\varepsilon)$.

We are now ready to define our hard polynomial.

$$P_{n,\varepsilon}(X, W) = \sum_{\mathbf{a}\in\mathcal{B}} W_{\mathcal{C}(\mathbf{a})} \cdot \Gamma_{\mathbf{a}}(X).$$

We have the following.

▶ **Lemma 12.** *The polynomial $P_{n,\varepsilon}(X, W)$ can be computed by a depth 3 multilinear formula $F_{n,\varepsilon}$ of size $s = O(\tau(n+2\log\tau)) = O(n^2/\varepsilon^2 + (n/\varepsilon^2)\log(n/\varepsilon))$ that can be constructed in time* $\text{poly}(s)$. *Further, there is a deterministic* $\text{poly}(s)$*-time algorithm that, given a multilinear monomial m over the variables $X \cup W$, computes the coefficient of m in $P_{n,\varepsilon}(X, W)$.*

Proof. Everything but the last statement is immediate from the preceding discussion. To prove the final statement, it suffices to note that the coefficient of m can be found in each constituent depth-2 formula in time $\text{poly}(n) = \text{poly}(s)$. Summing these coefficients yields the coefficient of m in $P_{n,\varepsilon}(X, W)$. ◀

Another property of our hard polynomial that is true by construction is the following.

▶ **Lemma 13.** *For any $n \in \mathbb{N}$ and $\varepsilon > 0$, let $P_{n,\varepsilon}(X,W) \in \mathbb{F}[X,W]$ be the polynomial defined above, which we will consider as a polynomial from $\mathbb{G}[X]$ where $\mathbb{G} = \mathbb{F}(W)$. For any $\mathbf{a} \in \mathcal{B}$, let restriction $\rho_{\mathbf{a}} : X \to Y \cup Z$ be the restriction as defined in Section 2.2. Then* $\operatorname{relrk}_{(Y_{\mathbf{a}},Z_{\mathbf{a}})}(P_{n,\varepsilon}(X,W)|_{\rho_{\mathbf{a}}}) = 1$.

Proof. Fix any $\mathbf{a} \in \mathcal{B}$ and consider the balanced partition $\rho_{\mathbf{a}} : X \to Y_{\mathbf{a}} \cup Z_{\mathbf{a}}$. We analyze the partial derivative matrix $M_{(Y_{\mathbf{a}},Z_{\mathbf{a}})}(P_{n,\varepsilon}(X,W)|_{\rho_{\mathbf{a}}})$ whose entries are polynomials over the variables in W. To show that $\operatorname{relrk}_{(Y_{\mathbf{a}},Z_{\mathbf{a}})}(P_{n,\varepsilon}(X,W)|_{\rho_{\mathbf{a}}}) = 1$, we need to show that $M_{(Y_{\mathbf{a}},Z_{\mathbf{a}})}(P_{n,\varepsilon}(X,W)|_{\rho_{\mathbf{a}}})$ is a full rank matrix over $\mathbb{G}$. Towards that, it is sufficient to show that $\det(M_{(Y_{\mathbf{a}},Z_{\mathbf{a}})}(P_{n,\varepsilon}(X,W)|_{\rho_{\mathbf{a}}}))$ is a non-zero polynomial over the variables in W. Further, it is enough to show that there is an assignment $A : W \to \{0,1\}$ to the W-variables such that $\det(M_{(Y_{\mathbf{a}},Z_{\mathbf{a}})}(P_{n,\varepsilon}(X,A(W))|_{\rho_{\mathbf{a}}}))$ evaluates to a non-zero value. This is what we will do. (A similar proof strategy is used in the proof of Claim 4.6 in [3].)

Let the vector $\mathbf{u} = \mathcal{C}(\mathbf{a})$. For all $i \in [\log \tau]$, A sets the variable w_i to 1 if $u_i = 1$ and 0 otherwise. Now, it is easy to see that $P_{n,\varepsilon}(X, A(W)) = \Gamma_{\mathbf{a}}(X)$. This also implies that

$$\det(M_{(Y_{\mathbf{a}},Z_{\mathbf{a}})}(P_{n,\varepsilon}(X,A(W))|_{\rho_{\mathbf{a}}})) = \det(M_{(Y_{\mathbf{a}},Z_{\mathbf{a}})}(\Gamma_{\mathbf{a}}(X)|_{\rho_{\mathbf{a}}}))$$

Now it is easy to check that $M_{(Y_{\mathbf{a}},Z_{\mathbf{a}})}(\Gamma_{\mathbf{a}}(X)|_{\rho_{\mathbf{a}}})$ is a permutation matrix and hence $\det(M_{(Y_{\mathbf{a}},Z_{\mathbf{a}})}(\Gamma_{\mathbf{a}}(X)|_{\rho_{\mathbf{a}}}))$ is non-zero. This implies that $\det(M_{(Y_{\mathbf{a}},Z_{\mathbf{a}})}(P_{n,\varepsilon}(X,A(W))|_{\rho_{\mathbf{a}}}))$ is non-zero as well. Thus, $\det(M_{(Y_{\mathbf{a}},Z_{\mathbf{a}})}(P_{n,\varepsilon}(X,W)|_{\rho_{\mathbf{a}}}))$ is a non-zero polynomial over the variables in W and we get that $M_{(Y_{\mathbf{a}},Z_{\mathbf{a}})}(P_{n,\varepsilon}(X,W)|_{\rho_{\mathbf{a}}})$ is a full rank matrix. ◀

4 The lower bound

In this section, we show that for f, a t-product polynomial, and $\mathbf{a}$ chosen randomly from an $(\varepsilon, 10\log(1/\varepsilon))$-subspace avoiding set, the polynomial $f|_{\rho_{\mathbf{a}}}$ has low relative-rank with high probability. We then use this to prove the main theorem.

▶ **Lemma 14.** *Let $s \in \mathbb{N}$ and $\varepsilon > 0$ be parameters such that $s \geq 1/\varepsilon$. Let $f \in \mathbb{G}[X]$ be a t-product polynomial with $t \geq (\log s)^3$. Let $\mathcal{S}_0$ be any $(\varepsilon, 10\log\frac{1}{\varepsilon})$-subspace avoiding set defined in Section 3.2. For any $\mathbf{a} \in \{0,1\}^n$, let $\rho_{\mathbf{a}}$ denote the partitioning function defined in Section 2.2. Then,*

$$\Pr_{\mathbf{a}\in\mathcal{S}_0}[\operatorname{relrk}_{(Y_{\mathbf{a}},Z_{\mathbf{a}})}(f|_{\rho_{\mathbf{a}}}) \geq \frac{1}{s}] \leq 5 \cdot \varepsilon.$$

Proof of Lemma 14. For all $k \in [t]$, let $\mathbf{r}^{(k)} = (r_1^{(k)}, r_2^{(k)}, \ldots, r_n^{(k)})$ be a vector in $\{0,1\}^n$ such that

$$r_i^{(k)} = \begin{cases} 1 & \text{if } x_i \in \operatorname{Vars}(f_k), \\ 0 & \text{otherwise.} \end{cases}$$

Let $\mathcal{E}_k(\mathbf{a})$ be a 0-1 random variable defined as follows. If $|\operatorname{Vars}(f_k)|$ is odd, $\mathcal{E}_k(\mathbf{a})$ is always 0. Otherwise, define $\beta_k = |\operatorname{Vars}(f_k)|/2 \pmod 2$ and

$$\mathcal{E}_k(\mathbf{a}) = \begin{cases} 1 & \text{if } (\mathbf{r}^{(k)}, \mathbf{a})_2 = \beta_k, \\ 0 & \text{otherwise.} \end{cases}$$

The main step in the proof of Lemma 14, is the following claim.

▶ **Claim 15.** *If $\mathcal{S}_0$ is a $(\varepsilon, 10\log\frac{1}{\varepsilon})$-subspace avoiding set, then* $\Pr_{\mathbf{a}\in\mathcal{S}_0}[\sum_{k\in[t]}\mathcal{E}_k(\mathbf{a}) \geq t - 2\log s] \leq 5\cdot\varepsilon$.

First, we will prove Lemma 14 using this claim. In order to do that, we will show that for all $\mathbf{a}\in\mathcal{S}_0$ the condition that $(\sum_{k\in[t]}\mathcal{E}_k(\mathbf{a}) < t - 2\log s$ implies $\mathrm{relrk}_{(Y_\mathbf{a},Z_\mathbf{a})}(f|_{\rho_\mathbf{a}}) \leq \frac{1}{s}$.

For any vector $\mathbf{a}\in\mathcal{S}_0$ and for $k\in[t]$, let $Y_{k,\mathbf{a}} = \rho_\mathbf{a}(\mathrm{Vars}(f_k))\cap Y_\mathbf{a}$ and let $Z_{k,\mathbf{a}} = \rho_\mathbf{a}(\mathrm{Vars}(f_k))\cap Z_\mathbf{a}$. By Item 3 in Proposition 4 we know that

$$\mathrm{relrk}_{(Y_\mathbf{a},Z_\mathbf{a})}(f|_{\rho_\mathbf{a}}) = \prod_{k\in[t]}\mathrm{relrk}_{(Y_{k,\mathbf{a}},Z_{k,\mathbf{a}})}(f_k|_{\rho_\mathbf{a}}).$$

We claim that for any $k\in[t]$, if $\mathcal{E}_k(\mathbf{a})=0$, then $\mathrm{relrk}_{(Y_{k,\mathbf{a}},Z_{k,\mathbf{a}})}(f_k|_{\rho_\mathbf{a}}) \leq 1/\sqrt{2}$. To see this, note that, for any $k\in[t]$, $\mathcal{E}_k(\mathbf{a})=1$ if and only if $|\mathrm{Vars}(f_k)|$ is even and $(\mathbf{r}^{(k)},\mathbf{a})_2 = \beta_k$. Now, if $|\mathrm{Vars}(f_k)|$ is odd then we can never have $|Y_{k,\mathbf{a}}| = |Z_{k,\mathbf{a}}|$ and hence by Item 1 of Proposition 4, $\mathrm{relrk}_{(Y_{k,\mathbf{a}},Z_{k,\mathbf{a}})}(f_k|_{\rho_\mathbf{a}}) \leq 1/\sqrt{2}$. Further, if $|\mathrm{Vars}(f_k)|$ is even and $|Y_{k,\mathbf{a}}| - |\mathrm{Vars}(f_k)|/2 \neq 0 \pmod 2$, then again we must have $|Y_{k,\mathbf{a}}| \neq |Z_{k,\mathbf{a}}|$ and hence $\mathrm{relrk}_{(Y_{k,\mathbf{a}},Z_{k,\mathbf{a}})}(f_k|_{\rho_\mathbf{a}}) \leq 1/\sqrt{2}$.

Now if $\sum_{k\in[t]}\mathcal{E}_k(\mathbf{a}) \leq t - 2\log s$ then there exist at least $(2\log s)$ elements $k\in[t]$ such that $\mathcal{E}_k(\mathbf{a})=0$. Hence, $\mathrm{relrk}_{(Y_\mathbf{a},Z_\mathbf{a})}(f|_{\rho_\mathbf{a}}) \leq (1/\sqrt{2})^{2\log s} \leq 1/s$.

Thus, in order to upper bound the probability of the event that $\mathrm{relrk}_{(Y_\mathbf{a},Z_\mathbf{a})}(f|_{\rho_\mathbf{a}}) \geq 1/s$, it suffices to upper bound the probability of $\sum_{k\in[t]}\mathcal{E}_k(\mathbf{a}) \geq t - 2\log s$, which by Claim 15 is at most 5ε. This concludes the proof of Lemma 14.

It remains to prove Claim 15, which we do now. The proof follows a combinatorial proof of the Chernoff bound due to Impagliazzo and Kabanets [16].

Proof of Claim 15. Let $\ell = t - 2\log s$ and $\mathcal{E}(\mathbf{a}) = \sum_{k\in[t]}\mathcal{E}_k(\mathbf{a})$. Let $R(\mathbf{a})$ be a Boolean random variable such that

$$R(\mathbf{a}) = \begin{cases} 1 & \text{if } \sum_{k\in[t]}\mathcal{E}_k(\mathbf{a}) \geq \ell, \\ 0 & \text{otherwise.}\end{cases}$$

Thus, $\Pr_{\mathbf{a}\in\mathcal{S}}[\mathcal{E}(\mathbf{a}) \geq \ell] = \mathbf{E}_{\mathbf{a}\in\mathcal{S}}[R(\mathbf{a})]$. Fix a vector $\mathbf{a}$. Let $\tilde{R}(\mathbf{a})\in[0,1]$ be the random variable defined by $\tilde{R}(\mathbf{a}) = \mathbf{E}_A[\prod_{i\in A}\mathcal{E}_i(\mathbf{a})]$, where $A\subseteq[t]$ is an independently and uniformly randomly chosen subset of size $2\log s$.

We claim that for every $\mathbf{a}\in\mathcal{S}_0$, $R(\mathbf{a}) \leq 2\cdot\tilde{R}(\mathbf{a})$. Assuming this, we get the following.

$$\begin{aligned}\Pr_{\mathbf{a}}[\sum_{k\in[t]}\mathcal{E}_k(\mathbf{a}) \geq \ell] = \mathop{\mathbf{E}}_{\mathbf{a}}[R(\mathbf{a})] &\leq 2\mathop{\mathbf{E}}_{\mathbf{a}}[\mathop{\mathbf{E}}_{A}[\prod_{i\in A}\mathcal{E}_i(\mathbf{a})]] \\ &= 2\mathop{\mathbf{E}}_{A}[\mathop{\mathbf{E}}_{\mathbf{a}}[\prod_{i\in A}\mathcal{E}_i(\mathbf{a})]] = 2\mathop{\mathbf{E}}_{A}[\Pr_{\mathbf{a}}[\prod_{i\in A}\mathcal{E}_i(\mathbf{a})=1]]. \end{aligned} \tag{3}$$

Consider an individual term $\mathcal{E}_A(\mathbf{a}) := \prod_{i\in A}\mathcal{E}_i(\mathbf{a})$ in the above expression. We claim that $\mathbf{E}_\mathbf{a}[\mathcal{E}_A(\mathbf{a})] \leq 2\varepsilon$. To see this, note that we have one of the following two scenarios. Either A contains an i such that $|\mathrm{Vars}(f_i)|$ is odd, in which case $\mathcal{E}_A(\mathbf{a}) = \mathcal{E}_i(\mathbf{a}) = 0$ with probability 1. Otherwise, $|\mathrm{Vars}(f_i)|$ is even for each $i\in A$ and then $\mathbf{a}$ satisfies $\mathcal{E}_A(\mathbf{a})=1$ if and only if $\mathbf{a}$ satisfies the system of linear equations $\{(\mathbf{a},\mathbf{r}^{(i)})_2 = \beta_i \mid i\in A\}$. Since the $\mathbf{r}^{(i)}$'s are non-zero and linearly independent, this system of equations defines an affine subspace of codimension $|A| = 2\log s$. Now, by invoking Claim 9, we get that $\Pr_\mathbf{a}[\prod_{i\in A}\mathcal{E}_i(\mathbf{a})=1] \leq 1/s^2 + \varepsilon \leq 2\varepsilon$, where the final inequality uses $s\geq 1/\varepsilon$. Substituting this back in (3), we get that $\Pr_\mathbf{a}[\mathcal{E}(\mathbf{a}) \geq \ell] \leq 4\varepsilon$.

To complete the proof, we need to show that for every $\mathbf{a} \in \mathcal{S}_0$, $R(\mathbf{a}) \leq 2\tilde{R}(\mathbf{a})$. If $R(\mathbf{a}) = 0$, then this statement is trivial. If not, $R(\mathbf{a}) = 1$. That is, there exist at least ℓ many $k \in [t]$ such that $\mathcal{E}_k(\mathbf{a}) = 1$. Then,

$$\tilde{R}(\mathbf{a}) = \mathop{\mathbf{E}}_{A}[\prod_{i \in A} \mathcal{E}_i(\mathbf{a})] = \Pr_{A}[\text{for all } i \in A,\ \mathcal{E}_i(\mathbf{a}) = 1] \geq \frac{\binom{\ell}{2\log s}}{\binom{t}{2\log s}} = \frac{\binom{t-2\log s}{2\log s}}{\binom{t}{2\log s}} \geq 1/2,$$

where the final inequality follows from the fact that $t \geq (\log s)^3$. This completes the proof of Lemma 14. ◀

The main theorem

We now prove our main theorem. It is restated here for the sake of convenience.

▶ **Theorem 16.** *For any fixed positive $c \in \mathbb{N}$ and $\delta \in (0, 1/2)$, there exists an explicit polynomial family $P_n \in \mathbb{F}[x_1, \ldots, x_n]$ that has multilinear formulas of depth 3 and size at most $O(s)$ where $s = n^c$, but no multilinear formulas of size less than $s^{(1/2)-\delta}$ and depth $\Delta < \log n/100 \log\log n$.*

Proof. We first show that we can assume without loss of generality that $c \geq 10/\delta$. Say this is not the case: we then have $s = n^c < n^{10/\delta}$. Now, let $m = s^{\delta/10} \leq n$. We will then define a polynomial over only the variables $\{x_1, \ldots, x_m\}$. So the number of variables reduces to m and $s = m^{10/\delta}$ (in particular, the new value of c is now $10/\delta$). Thus, we can always reduce the problem to the case when $c \geq 10/\delta$.

So we assume without loss of generality that $s \geq n^{10/\delta}$. We will fix our polynomial P_n to be $P_{n/2,\varepsilon}(X, W)$ as defined in Section 3.2 for $\varepsilon = n/\sqrt{s}$, where the variable set $X = \{x_1, \cdots, x_{n/2}\}$ and $W \subseteq \{x_{n/2+1}, \ldots, x_n\}$ is some fixed set of size $\log \tau \leq \log s$ (since $s \leq n^c$, it is clear that $\log s \leq n/2$). From Lemma 12, we know that $\{P_n \mid n \in \mathbb{N}\}$ is an explicit family of multilinear polynomials such that each P_n is computed by a depth three multilinear formula of size $O(s)$. Further, from Lemma 13, we get that $\text{relrk}_{(Y_\mathbf{a}, Z_\mathbf{a})}(P_n(X, W)|_{\rho_\mathbf{a}}) = 1$ for every choice of $\mathbf{a} \in \mathcal{B}$, where $\mathcal{B}$ is as defined in Section 3.2.

Let us assume that P_n can be computed by a depth Δ multilinear formula Φ of size $s' < s^{1/2-\delta}$. We consider $P_n(X, W)$ as a polynomial from the ring $\mathbb{G}[X]$ where $\mathbb{G} = \mathbb{F}(W)$. We also consider Φ as a multilinear formula computing a polynomial from $\mathbb{G}[X]$ (i.e. we consider the variables from W in Φ as constants from the underlying field $\mathbb{G}$.)

From Lemma 3, we know that P_n can be written as a sum of at most $s'' = s' \cdot n$ many t-product polynomials where $t = \Omega(n^{1/2\Delta})$. Note that as $\Delta < \log n/100 \log\log n$, we have $t = \Omega((\log n)^{50}) \geq (\log s)^{40}$, the latter inequality following from the fact that $\log s = O(\log n)$.

Assume that the t-product polynomials in the above decomposition are $f_1, \ldots, f_{s''} \in \mathbb{G}[X]$. So, we have $P_n = \sum_{i \in [s'']} f_i$. We would like to show that

$$\Pr_{\mathbf{a} \in \mathcal{B}}[\text{relrk}_{(Y_\mathbf{a}, Z_\mathbf{a})}(P_n|_{\rho_\mathbf{a}}) < 1] > 0 \tag{4}$$

which would contradict Lemma 13 and hence prove the theorem.

In order to prove inequality (4), by the sub-additivity property (Proposition 4 Item 2) of the relative-rank, it suffices to show the following.

$$\Pr_{\mathbf{a} \in \mathcal{B}}[\forall i \in [s'], \text{relrk}_{(Y_\mathbf{a}, Z_\mathbf{a})}(f_i|_{\rho_\mathbf{a}}) < 1/s''] > 0.$$

Equivalently, it suffices to prove that

$$\Pr_{\mathbf{a} \in \mathcal{B}}[\exists i \in [s''], \text{relrk}_{(Y_\mathbf{a}, Z_\mathbf{a})}(f_i|_{\rho_\mathbf{a}}) \geq 1/s''] < 1. \tag{5}$$

Recall from Section 3.2 that the set $\mathcal{B}$ is defined to be a subset of the set $\mathcal{S}_0 = \mathcal{S}_{n,\varepsilon} \oplus \mathbf{x}_0$ of size $\tau = \Theta(|\mathcal{S}_0|/n)$. Also, by Claim 9 and Fact 10, it follows that $\mathcal{S}_0$ is an $(\varepsilon, 10\log(1/\varepsilon))$-biased set. By using Lemma 14, we get that for each t-product polynomial f_i, we have that

$$\Pr_{\mathbf{a}\in\mathcal{S}_0}[\mathrm{relrk}_{(Y_\mathbf{a},Z_\mathbf{a})}(f_i|_{\rho_\mathbf{a}}) \geq \frac{1}{s}] \leq 5\varepsilon.$$

Therefore, by a simple union bound, we get that

$$\Pr_{\mathbf{a}\in\mathcal{S}_0}[\exists i : \mathrm{relrk}_{(Y_\mathbf{a},Z_\mathbf{a})}(f_i|_{\rho_\mathbf{a}}) \geq \frac{1}{s}] \leq 5s'' \cdot \varepsilon. \tag{6}$$

As $\mathcal{B}$ is a subset of $\mathcal{S}_0$, we get that

$$\frac{|\mathcal{B}|}{|\mathcal{S}_0|} \cdot \Pr_{\mathbf{a}\in\mathcal{B}}[\exists i : \mathrm{relrk}_{(Y_\mathbf{a},Z_\mathbf{a})}(f_i|_{\rho_\mathbf{a}}) \geq \frac{1}{s}] \leq \Pr_{\mathbf{a}\in\mathcal{S}_0}[\exists i : \mathrm{relrk}_{(Y_\mathbf{a},Z_\mathbf{a})}(f_i|_{\rho_\mathbf{a}}) \geq \frac{1}{s}]. \tag{7}$$

Hence, using the inequalities (6), (7) and the fact that $|\mathcal{B}|/|\mathcal{S}_0| = \Theta(1/n)$, we get

$$\Pr_{\mathbf{a}\in\mathcal{B}}[\exists i : \mathrm{relrk}_{(Y_\mathbf{a},Z_\mathbf{a})}(f_i|_{\rho_\mathbf{a}}) \geq \frac{1}{s}] \leq O\left(\frac{s''n^2}{\sqrt{s}}\right) \leq \frac{s'n^4}{\sqrt{s}}. \tag{8}$$

As $s \geq n^{10/\delta}$ we get $n^4 \leq s^{\delta/2}$. Therefore, as long as $s' \leq O(s^{1/2-\delta})$, inequality (5) is satisfied, which then implies that inequality (4) is also satisfied.

If inequality (4) is satisfied, then there exists a partitioning function $\rho_\mathbf{a}$ for $\mathbf{a} \in \mathcal{B}$ such that $\mathrm{relrk}_{(Y_\mathbf{a},Z_\mathbf{a})}(P_n|_{\rho_\mathbf{a}}) < 1$. This contradicts Lemma 13 which tells us $\mathrm{relrk}_{(Y_\mathbf{a},Z_\mathbf{a})}(P_n|_{\rho_\mathbf{a}}) = 1$ with respect to every partitioning function $\rho_\mathbf{a}$ ($\mathbf{a} \in \mathcal{B}$). ◀

Abstract

The restricted max-min fair allocation problem seeks an allocation of resources to players that maximizes the minimum total value obtained by any player. It is NP-hard to approximate the problem to a ratio less than 2. Comparing the current best algorithm for estimating the optimal value with the current best for constructing an allocation, there is quite a gap between the ratios that can be achieved in polynomial time: $4+\delta$ for estimation and $6+2\sqrt{10}+\delta \approx 12.325+\delta$ for construction, where δ is an arbitrarily small constant greater than 0. We propose an algorithm that constructs an allocation with value within a factor $6+\delta$ from the optimum for any constant $\delta > 0$. The running time is polynomial in the input size for any constant δ chosen.

1 Introduction

Background. Let P be a set of m players. Let R be a set of n indivisible resources. Resource $r \in R$ is worth a non-negative integer value v_{pr} for player $p \in P$. An allocation is a partition of R into disjoint subsets $\{C_p : p \in P\}$ so that player p is assigned the resources in C_p. The *max-min fair allocation* problem is to distribute resources to players so that the minimum total value of resources received by any player is maximized. The *value of an allocation* is $\min_{p\in P} \sum_{r\in C_p} v_{pr}$. So we want to find an allocation with maximum value.

No algorithm can achieve an approximation ratio less than 2 unless P = NP [5]. Bansal and Sviridenko [4] proposed the configuration LP and showed that it can be solve to any desired accuracy in polynomial time. The configuration LP turns out to be a useful tool for this problem. Using it, approximation ratios of $O(\sqrt{m \log m})$ and $O(n^{\delta} \log n)$ for any $\delta \geqslant \frac{9 \log\log n}{\log n}$ have been attained [3, 4, 6, 12]. In this paper, we focus on the *restricted case* in which each resource r is desired by some subset of players, and has the same value v_r for those who desire it and value 0 for the rest. Even in this case, no approximation ratio better than 2 can be obtained unless P = NP [5]. Bansal and Sviridenko [4] designed a $O\big(\frac{\log\log m}{\log\log\log m}\big)$-approximation algorithm which is based on rounding the configuration LP. Feige [8] proved that the integrality gap of the configuration LP is bounded by a constant

(large and unspecified). His proof was made constructive by Haeupler et al. [10], and hence, results in a constant-approximation algorithm. Asadpour et al. [2] proved that the integrality gap of the configuration LP is at most 4. As a consequence, by solving the configuration LP approximately, one can estimate the optimal solution value within a factor of $4 + \delta$ for any constant $\delta > 0$. However, it is not known how to construct a $(4 + \delta)$-approximate allocation in polynomial time. Annamalai et al. [1] developed a $(6+2\sqrt{10}+\delta)$-approximation algorithm. Their algorithm is purely combinatorial, but the analysis still relies on the configuration LP. There is quite a gap between the current best estimation ratio $4 + \delta$ and the current best approximation ratio $6 + 2\sqrt{10} + \delta \approx 12.325 + \delta$.

If one constrains the *restricted case* further by requiring $v_r \in \{1, \varepsilon\}$ for some fixed constant $\varepsilon \in (0, 1)$, then it becomes the $(1, \varepsilon)$-*restricted case*. Golovin proposed an $O(\sqrt{n})$-approximation algorithm [9]. Chan et al. [7] showed that it is still NP-hard to obtain an approximation ratio less than 2 and that the algorithm in [1] achieves an approximation ratio of 9 in this case. The analysis in [7] does not rely on the configuration LP.

Our contributions. We propose an algorithm for the restricted max-min fair allocation problem that achieves an approximation ratio of $6 + \delta$ for any constant $\delta > 0$. It runs in polynomial time for any constant δ chosen. Our algorithm uses the same framework as [1]: we maintain a stack of layers to record the relation between players and resources, and use lazy update and a greedy strategy to achieve a polynomial running time.

Our first contribution is a greedy strategy that is much more aggressive than that in [1]. Let τ^* be the optimal solution value. Let $\lambda > 2$ be the target approximation ratio. To obtain a λ-approximate solution, the value of resources a player need is τ^*/λ. The greedy strategy in [1] considers a player greedy if that player claims at least $\tau^*/2$ worth of resources, which is more than needed. In contrast, we consider a player greedy if it claims (nearly) the largest total value among all the candidates. When building the stack, both [1] and we add greedy players and the resources claimed by them to the stack. Intuitively, our more aggressive definition of greedy leads to faster growth of the stack, and hence a significantly smaller approximation ratio can be achieved.

Our aggressive strategy brings challenge to the analysis that approaches in [1, 7] cannot cope with. Our second contribution is a new analysis tool: an injection that maps a lot of players in the stack to their *competing players* who can access resources of large total value. Since players added to the stack must be greedy, they claim more than their competing players. Therefore, such an injection allows us to conclude that players in the stack claim large worth of resources. By incorporating competing players into the analysis framework in [7], we improve the approximation ratio to $6 + \delta$. Our analysis does not rely on the configuration LP, and is purely combinatorial.

2 Preliminaries

Let τ^* be the optimal solution value. Let λ denote our target approximation ratio. Given any value $\tau \leqslant \tau^*$, our algorithm returns an allocation of value τ/λ in polynomial time. We will show how to combine this algorithm with binary search to obtain an allocation of value at least τ^*/λ in the end. We assume that τ is no more than τ^* in the rest of this section.

Bipartite graph and thin edges. A resource r is *fat* if $v_r \geqslant \tau/\lambda$; otherwise, r is *thin*. Let G be the bipartite graph formed by representing the players in P and the fat resources in R as vertices, and connecting a player p and a fat resource r by an edge if p desires r. Similarly,

players and thin resources form a hypergraph, namely, there are vertices representing players in P and thin resources in R, and a player p and a subset B of thin resources form an edge (p, B) if p desires all resources in B. (Note that $(p, \emptyset)$ is included.) We call the edges of this hypergraph *thin edges*. For a subset B of thin resources, we define the value of B as $value(B) = \sum_{r \in B} v_r$. For a thin edge $e = (p, B)$, its value $value(e)$ is defined to be the total value of thin resources covered by it, i.e., $value(e) = value(B)$. We use uppercase calligraphic letters to denote subsets of thin edges. Given a set $\mathcal{S}$ of thin edges, define $value(\mathcal{S})$ to be the total value of the thin resources covered by $\mathcal{S}$.

Partial allocation. Since our target approximation ratio is λ, it suffices to assign each player p either a single fat resource r such that $\{p, r\}$ is an edge of G, or a subset B of thin resources such that (p, B) is a thin edge and $value(B) \geqslant \tau/\lambda$. Hence, it suffices to consider allocations that consist of two parts, one being a maximum matching M of G and the other being a subset $\mathcal{E}$ of thin edges such that every player is covered by either M or $\mathcal{E}$, no two edges in $\mathcal{E}$ share any resource, and every edge in $\mathcal{E}$ has value at least τ/λ.

Our algorithm will start with an arbitrary maximum matching of G alone, grow and update the set $\mathcal{E}$ of thin edges, and whenever necessary, update the maximum matching as well. We call the intermediate solutions *partial allocations*. A **partial allocation** consists of a maximum matching M of G and a set $\mathcal{E}$ of thin edges such that: (i) no player is covered by both M and $\mathcal{E}$; (ii) no two edges in $\mathcal{E}$ share any resource; (iii) every edge $(p, B) \in \mathcal{E}$ is minimal in the sense that $value(B) \geqslant \tau/\lambda$ and every proper subset $B' \subset B$ has value less than τ/λ. We say a player p is *satisfied* by a partial allocation if p is covered by M or $\mathcal{E}$. A partial allocation is an allocation if it satisfies every player.

Node-disjoint paths. We define a family of networks which are heavily used in both our algorithm and its analysis. With respect to any arbitrary maximum matching M of G, define G_M to be a directed bipartite graph such that G_M has the same vertex set as G (i.e., players and fat resources), there is a directed edge from player p to resource r if $\{p, r\}$ is an edge of G that is not used in M, and there is a directed edge from resource r to player p if $\{p, r\}$ is an edge of G that is used in M.

We use P_M and $\overline{P}_M$ to denote the subsets of players matched and unmatched in M, respectively. Given $S \subseteq \overline{P}_M$ and $T \subseteq P$, we use $G_M(S, T)$ to denote the problem of finding the maximum number of node-disjoint paths from S to T in G_M. This problem will arise in this paper for different choices of S and T. A feasible solution of $G_M(S, T)$ is just any set of node-disjoint paths from S to T in G_M. An optimal solution maximizes the number of paths. Let $f_M(S, T)$ denote the size of an optimal solution of $G_M(S, T)$. In case that $S \cap T \neq \emptyset$, a feasible solution may allow a path from a player $p \in S \cap T$ to itself, i.e., a path with no edge. We call such a path a *trivial path*. Other paths are *non-trivial*.

Let Π be any feasible solution of $G_M(S, T)$. The paths in Π originate from a subset of S, which we call the *sources*, and terminate at a subset of T, which we call the *sinks*. We denote the sets of sources and sinks by $source(\Pi)$ and $sink(\Pi)$, respectively. A trivial path has only one node which is both its source and sink. We use Π^0 and Π^+ to denote the sets of the trivial paths and the non-trivial paths in Π, respectively.

An optimal solution of $G_M(S, T)$ can be found by solving a maximum s-t flow problem as follows. Add a super source s and directed edges from s to all vertices in S. Add a super sink t and directed edges from all vertices in T to t. Set the capacities of all edges to 1. Find an integral maximum flow in the resulting network. The paths in G_M used by this maximum flow is an optimal solution of $G_M(S, T)$. Node-disjointness is ensured because, in the s-t flow network, each player has in-degree at most one and each resource has out-degree at most one.

Let π be a non-trivial path from $\bar{P}_M$ to P in G_M. If we ignore the directions of edges in π, then π is called an *alternating path* in the matching literature [11]. We use $M \oplus \pi$ to denote the result of flipping π, i.e., removing the edges in $\pi \cap M$ from the matching and adding the edges in $\pi \setminus M$ to the matching. $M \oplus \pi$ is also a maximum matching of G. We can extend the above operation and form $M \oplus \Pi^+$ for any feasible solution Π of $G_M(S,T)$ for any $S \subseteq \bar{P}_M$ and any $T \subseteq P$. $M \oplus \Pi^+$ is a maximum matching of G. The following results follow from basic theories of matching and network flow.

▶ **Claim 2.1.** *For any maximum matchings M and M' of G, (i) $f_M(\bar{P}_M, \bar{P}_{M'}) = |\bar{P}_M|$, and (ii) for every subset T of players, $f_M(\bar{P}_M, T) = f_{M'}(\bar{P}_{M'}, T)$.*

If one treats Π like a flow in the network G_M, then $G_{M \oplus \Pi^+}$ behaves like the residual graph with respect to Π. Claims 2.2 and 2.3 below concerns with augmentation using $G_{M \oplus \Pi^+}$.

▶ **Claim 2.2.** *Let Π be a feasible solution of $G_M(S,T)$. Then, $M \oplus \Pi^+$ is a maximum matching of G, so the directed bipartite graph $G_{M \oplus \Pi^+}$ is well defined. Also, Π is an optimal solution of $G_M(S,T)$ if and only if $G_{M \oplus \Pi^+}$ contains no path from $S \setminus source(\Pi)$ to $T \setminus sink(\Pi)$.*

▶ **Claim 2.3.** *Let Π be a feasible solution of $G_M(S,T)$. Suppose that $G_{M \oplus \Pi^+}$ contains a path π from $S \setminus source(\Pi)$ to $T \setminus sink(\Pi)$. We can use π to augment Π to a feasible solution Π' of $G_M(S,T)$ such that $|\Pi'| = |\Pi| + 1$, the vertex set of Π' is a subset of the vertices in $\Pi \cup \{\pi\}$, $source(\Pi') = source(\Pi) \cup \{source(\pi)\}$, and $sink(\Pi') = sink(\Pi) \cup \{sink(\pi)\}$.*

We can also push flow along a path in $G_{M \oplus \Pi^+}$ from $sink(\Pi)$ to T. This reroutes the flow in G_M without changing its flow value. Claim 2.4 below gives a precise statement.

▶ **Claim 2.4.** *Let Π be a feasible solution of $G_M(S,T)$. Suppose that there is a non-trivial path π in $G_{M \oplus \Pi^+}$ from $sink(\Pi)$ to T. Clearly, $sink(\pi) \notin sink(\Pi)$ because every node in $sink(\Pi)$ has zero in-degree in $G_{M \oplus \Pi^+}$. We can use π to convert Π to a feasible solution Π' of $G_M(S,T)$ such that $|\Pi'| = |\Pi|$, the vertex set of Π' is a subset of the vertices in $\Pi \cup \{\pi\}$, $source(\Pi') = source(\Pi)$, and $sink(\Pi') = (sink(\Pi) \setminus \{source(\pi)\}) \cup \{sink(\pi)\}$.*

3 The Algorithm

3.1 Overview

We give an overview of the common framework that our algorithm shares with that in [1]. Let M and $\mathcal{E}$ denote the maximum matching of G and the set of thin edges in the current partial allocation, respectively. Let p_0 be an arbitrary player who is not yet satisfied.

To satisfy p_0, the simplest case is that we can find a minimal thin edge (p_0, B) such that $value(B)$ is at least τ/λ and B excludes the resources covered by edges in $\mathcal{E}$, i.e., not blocked by any thin edge in $\mathcal{E}$. We can extend the partial allocation by adding (p_0, B) to $\mathcal{E}$.

More generally, we can use any thin edge (q, B) such that B meets the above requirements even if $q \neq p_0$, provided that there is a path from p_0 to q in G_M. If $q \neq p_0$, such a path is an alternating path in G with respect to M, and q is matched by M. We can flip this path to match p_0 with a fat resource and then include (q, B) in $\mathcal{E}$ to satisfy q.

We may have the situation that the thin edge (q, B) mentioned above is blocked by some thin edges in $\mathcal{E}$. Pick such a (q, B) arbitrarily, and call it (q_0, B_0). Let $\{(p_1, B'_1), \ldots, (p_k, B'_k)\}$ be the thin edges in $\mathcal{E}$ that block (q_0, B_0), i.e., $B_0 \cap B'_i \neq \emptyset$ for $i \in [1, k]$. To make (q_0, B_0) unblocked, we need to satisfy each player p_i, $i \in [1, k]$, with a fat resource or another thin edge. Afterwards, we can satisfy p_0 as before. To record the different states of the algorithm, we initialize a stack to contain $(p_0, \emptyset)$ as the first layer and then create another layer on top

that stores the sets $\mathcal{X}_2 = \{(q_0, B_0)\}$ and $\mathcal{Y}_2 = \{(p_1, B'_1), \ldots, (p_k, B'_k)\}$ among other things for bookkeeping. We change our focus to satisfy the set of players $Y_2 = \{p_1, \ldots, p_k\}$.

To satisfy a player in Y_2 (by a new edge), we need to identify a minimal thin edge (q_1, B_1) such that $value(B_1)$ is at least τ/λ and G_M contains two node-disjoint paths from $\{p_0\} \cup Y_2$ to $\{q_0, q_1\}$, and we also require B_1 to exclude the resources already covered by thin edges in the current stack (i.e., $\mathcal{X}_2$ and $\mathcal{Y}_2$) because the current plan to satisfy q_0 in the future involves some of these thin resources. If (q_1, B_1) is blocked by thin edges in $\mathcal{E}$, we initialize a set $\mathcal{X}_3 = \{(q_1, B_1)\}$; otherwise, we initialize a set $\mathcal{I} = \{(q_1, B_1)\}$. Ideally, if (q_1, B_1) is unblocked, we could immediately make some progress. Since there are two node-disjoint paths from $\{p_0\} \cup Y_2$ to $\{q_0, q_1\}$, q_1 is either reachable from p_0 or a player in Y_2. In the former case, we can satisfy p_0; in the latter case, the path from Y_2 to q_1 must be node-disjoint from the path from p_0 to q_0. We can remove a blocking edge from $\mathcal{Y}_2$ without affecting the alternating path from p_0 to q_0. But we would not do so because, as argued in [1], in order to achieve a polynomial running time, we should let $\mathcal{I}$ grow bigger so that a large progress can be made.

Since there are multiple players in Y_2 to be satisfied, we continue to look for another minimal thin edge (q_2, B_2) such that G_M contains three node-disjoint paths from $\{p_0\} \cup Y_2$ to $\{q_0, q_1, q_2\}$, $value(B_2) \geqslant \tau/\lambda$, and B_2 excludes the resources covered by thin edges in the current stack (i.e.,$\mathcal{X}_2 \cup \mathcal{Y}_2 \cup \mathcal{X}_3$) and $\mathcal{I}$. If (q_2, B_2) is blocked by thin edges in $\mathcal{E}$, we add (q_2, B_2) to $\mathcal{X}_3$; otherwise, we add it to $\mathcal{I}$. After collecting all such thin edges in $\mathcal{X}_3$ and $\mathcal{I}$, we construct the set $\mathcal{Y}_3$ of thin edges in the current partial allocation that block $\mathcal{X}_3$. Then, we add a new top layer to the stack that stores $\mathcal{X}_3$ and $\mathcal{Y}_3$ among other things for bookkeeping. Then, we turn our attention to satisfying the players in $\mathcal{Y}_3$ with new edges and so on. These repeated additions of layers to the stack constitute the build phase of the algorithm.

The build phase stops when we have enough thin edges in $\mathcal{I}$ to satisfy a predetermined fraction of players in $\mathcal{Y}_l$ for some l, and then we shrink this layer and delete all layers above it. The above is repeated until $\mathcal{I}$ is not large enough to satisfy the predetermined fraction of players in any $\mathcal{Y}_l$ in the stack. These repeated removal of layers constitute the collapse phase of the algorithm. At the end of the collapse phase, we switch back to the build phase.

The alternation of build and collapse phases continues until we succeed in satisfying player p_0, our original goal, that is stored in the bottommost layer in the stack.

A greedy strategy is also used for achieving a polynomial running time. In [1], when a blocked thin edge (q, B) is picked and added to $\mathcal{X}_l$ for some l, B is required to be a minimal set of value at least $\tau/2$, which is more than τ/λ. Intuitively, if such an edge is blocked, it must be blocked by many edges. Hence, the strategy leads to fast growth of stack. We use a more aggressive strategy: we allow the value of B to be as large as $\tau + \tau/\lambda$, and among all candidates, we pick the (q, B) with (nearly) the largest value. Our strategy leads to faster growth of the stack, and hence, a polynomial running time can be achieved for smaller λ.

3.2 Notation and definitions

A *state of the algorithm* consists of several components, namely, M, $\mathcal{E}$, a stack of layers, and a global variable $\mathcal{I}$ that stores a set of thin edge. The layers in the stack are indexed starting from 1 at the bottom. For $i \geqslant 1$, the i-th layer is a 4-tuple $(\mathcal{X}_i, \mathcal{Y}_i, d_i, z_i)$, where $\mathcal{X}_i$ and $\mathcal{Y}_i$ are sets of thin edges, and d_i and z_i are two numeric values that we will explain later. We use I, X_i and Y_i to denote the set of players covered by edges in $\mathcal{I}$, $\mathcal{X}_i$ and $\mathcal{Y}_i$, respectively. For any $k \geqslant 1$, let $\mathcal{X}_{\leqslant k}$ denote $\bigcup_{i=1}^{k} \mathcal{X}_i$, and $\mathcal{Y}_{\leqslant k}$, $X_{\leqslant k}$, and $Y_{\leqslant k}$ are similarly defined.

The sets $\mathcal{X}_i$ and $\mathcal{Y}_i$ are defined inductively. At the beginning of the algorithm, $\mathcal{X}_1 = \emptyset$, $\mathcal{Y}_1 = \{(p_0, \emptyset)\}$, $d_1 = z_1 = 0$, and $\mathcal{I} = \emptyset$. The first layer in the stack is thus $(\emptyset, \{(p_0, \emptyset)\}, 0, 0)$.

Consider the construction of the $(k+1)$-th layer in an execution of the build phase. When it first starts, $\mathcal{X}_{k+1}$ is initialized to be empty. We say that p is **addable** if $f_M(Y_{\leqslant k}, X_{\leqslant k+1} \cup I \cup \{p\}) > f_M(Y_{\leqslant k}, X_{\leqslant k+1} \cup I)$. Note that this definition depends on $X_{\leqslant k+1} \cup I$, so adding edges to $\mathcal{X}_{k+1}$ and $\mathcal{I}$ may affect the addability of players. Given an addable player p, we say that a thin edge (p, B) is **addable** if $value(B) \in [\tau/\lambda, \tau + \tau/\lambda]$ and B excludes resources currently in $\mathcal{X}_{\leqslant k+1} \cup \mathcal{Y}_{\leqslant k} \cup \mathcal{I}$. An addable thin edge (p, B) is **unblocked** if there exists a subset $B' \subseteq B$ such that $value(B') \geqslant \tau/\lambda$ and B' excludes resources used in $\mathcal{E}$. Otherwise, (p, B) is **blocked**. During the construction of the $(k+1)$th layer, the algorithm adds some blocked addable thin edges to $\mathcal{X}_{k+1}$ and some unblocked addable thin edges to $\mathcal{I}$. When the growth of $\mathcal{X}_{k+1}$ stops, the algorithm constructs $\mathcal{Y}_{k+1}$ as the set of the thin edges in $\mathcal{E}$ that share resource(s) with some edge(s) in $\mathcal{X}_{k+1}$. Edges in $\mathcal{Y}_{k+1}$ are called **blocking** edges.

After constructing $\mathcal{X}_{k+1}$ and $\mathcal{Y}_{k+1}$ and growing $\mathcal{I}$, we define $d_{k+1} := f_M(Y_{\leqslant k}, X_{\leqslant k+1} \cup I)$ and $z_{k+1} := |X_{k+1}|$. The values d_{k+1} and z_{k+1} do not change once computed unless the layer L_{k+1} is destructed in the collapse phase, although $f_M(Y_{\leqslant k}, X_{\leqslant k+1} \cup I)$ and $|X_{k+1}|$ may change subsequently. The values d_{k+1} and z_{k+1} are introduced only for the analysis.

Whenever we complete the construction of a new layer in the stack, we check whether any existing layer is collapsible. If so, we leave the build phase and enter the collapse phase, during which the stack is shrunk and the current partial allocation is updated. We stay in the collapse phase until no layer is collapsible. If the stack has become empty, we are done as the player p_0 has been satisfied. Otherwise, we reenter the build phase. We give the detailed specification of the build and collapse phases in the following.

3.3 Build phase

Assume that the stack currently contains layers $L_1, \ldots, L_k$ with L_k at the top. Let M and $\mathcal{E}$ denote the maximum matching in G and the set of thin edges in the current partial allocation, respectively. The following routine Build constructs the next layer L_{k+1}.

Build$(M, \mathcal{E}, \mathcal{I}, (L_1, \cdots, L_k))$

1. Initialize $\mathcal{X}_{k+1}$ to be the empty set.
2. If there is an addable player p and an unblocked addable edge (p, B), then:
   a. take a minimal subset $B' \subseteq B$ such that $value(B') \geqslant \tau/\lambda$ and B' excludes the resources used in $\mathcal{E}$ (we call (p, B') a *minimal unblocked addable edge*),
   b. add (p, B') to $\mathcal{I}$,
   c. go back to step 2.
3. When we come to step 3, no unblocked addable edge is left. If there are no (blocked) addable edges, go to step 4. For each addable player p who is incident to at least one addable edge, identify one *maximal blocked addable edge* (p, B) such that $B \not\subset B'$ for any blocked addable edge (p, B'). Pick the edge with the largest value among those identified, add it to $\mathcal{X}_{k+1}$, and repeat step 3.
4. At this point, the construction of $\mathcal{X}_{k+1}$ is complete. Let $\mathcal{Y}_{k+1}$ be the set of the thin edges in $\mathcal{E}$ that share resource(s) with some thin edge(s) in $\mathcal{X}_{k+1}$.
5. Compute $d_{k+1} := f_M(Y_{\leqslant k}, X_{\leqslant k+1} \cup I)$ and $z_{k+1} := \left|X_{k+1}\right|$.
6. Push the new layer $L_{k+1} = (\mathcal{X}_{k+1}, \mathcal{Y}_{k+1}, d_{k+1}, z_{k+1})$ onto the stack.

Build differs from its counterpart in [1] in several places, particularly in step 3. First, we requires blocked addable edges to be maximal while [1] only considers minimal addable edges of value at least $\tau/2$. Second, when adding addable edges to $\mathcal{X}_{k+1}$, we pick the one with (nearly) the largest value. In contrast, [1] arbitrarily picks one addable edge.

Table 1 Let ℓ denote the highest layer index in the current stack. Let M and $\mathcal{E}$ be the maximum matching and the set of thin edges in the current partial allocation.

Invariant 1	Every edge in $\mathcal{I}$ has value in $[\tau/\lambda, 2\tau/\lambda]$. Every edge in $\mathcal{X}_{\leqslant \ell}$ has value in $[\tau/\lambda, \tau+\tau/\lambda]$. No two edges from $\mathcal{X}_{\leqslant \ell}$ and $\mathcal{I}$ (both edges from either set or one edge from each set) cover the same player or share any resource.
Invariant 2	No edge in $\mathcal{E}$ shares any resource with any edge in $\mathcal{I}$.
Invariant 3	For all $i \in [1, \ell]$, every edge in $\mathcal{X}_i$ shares some resource(s) with some edge(s) in $\mathcal{Y}_i$ but not with any edge in $\mathcal{E} \setminus \mathcal{Y}_i$.
Invariant 4	$\mathcal{Y}_2, \ldots, \mathcal{Y}_\ell$ are disjoint subsets of $\mathcal{E}$. ($\mathcal{Y}_1 = \{(p_0, \emptyset)\}$ is not.)
Invariant 5	For all $i \in [1, \ell]$, no edge in $\mathcal{Y}_i$ shares any resource with any edge in $\mathcal{X}_j$ for any $j \neq i$.
Invariant 6	$f_M(Y_{\leqslant \ell-1}, I) = \lvert I \rvert$.
Invariant 7	For all $i \in [1, \ell-1]$, $f_M(Y_{\leqslant i}, X_{\leqslant i+1} \cup I) \geqslant d_{i+1}$.

Is it possible that $\mathcal{X}_{k+1} = \emptyset$ and $\mathcal{Y}_{k+1} = \emptyset$? We will establish Lemma 4.1 in Section 5.2, which implies that if $\mathcal{Y}_{k+1}$ is empty, then some layer below L_{k+1} is collapsible. As a result, the algorithm will enter the collapse phase next and L_{k+1} will be removed.

▶ **Lemma 3.1.** BUILD *runs in poly*(m, n) *time.*

▶ **Lemma 3.2.** BUILD *maintains invariants 1–7 in Table 1.*

3.4 Collapse phase

Let M be the maximum matching in the current partial allocation. Let $(L_1, L_2, \ldots, L_\ell)$ be the current stack. Deciding whether a layer can be collapsed requires a decomposition of $\mathcal{I}$.

Collapsibility. Let $\mathcal{I}_1 \cup \mathcal{I}_2 \cup \cdots \mathcal{I}_\ell$ be some partition of $\mathcal{I}$. Let I_i denote the set of players covered by $\mathcal{I}_i$. We use $\mathcal{I}_{\leqslant j}$ and $I_{\leqslant j}$ to denote $\bigcup_{i=1}^{j} \mathcal{I}_i$ and $\bigcup_{i=1}^{j} I_i$, respectively. Note that $\lvert I_i \rvert = \lvert \mathcal{I}_i \rvert$ by invariant 1. The partition $\mathcal{I}_1 \cup \mathcal{I}_2 \cup \cdots \mathcal{I}_\ell$ is a **canonical decomposition** of $\mathcal{I}$ if for all $i \in [1, \ell]$, $f_M(Y_{\leqslant i}, I_{\leqslant i}) = f_M(Y_{\leqslant i}, I) = \lvert I_{\leqslant i} \rvert = \lvert \mathcal{I}_{\leqslant i} \rvert$. [1]

▶ **Lemma 3.3** ([1]). *In poly*(ℓ, m, n) *time, one can compute a canonical decomposition* $\mathcal{I}_1 \cup \mathcal{I}_2 \cup \ldots \mathcal{I}_\ell$ *of* $\mathcal{I}$ *and a canonical solution of* $G_M(Y_{\leqslant \ell}, I)$ *which can be partitioned into a disjoint union* $\Gamma_1 \cup \Gamma_2 \cup \cdots \Gamma_\ell$ *such that for every* $i \in [1, \ell]$, Γ_i *is a set of* $\lvert I_i \rvert$ *paths from* Y_i *to* I_i.

The canonical decomposition and solution can be obtained by starting with an optimal solution of $G_M(Y_1, I)$ and successively augment it (using Claim 2.3) to optimal solutions of $G_M(Y_{\leqslant 2}, I), \ldots, G_M(Y_{\leqslant \ell}, I)$. The resulting optimal solution of $G_M(Y_{\leqslant \ell}, I)$ is an canonical solution, and also induces a canonical decomposition of $\mathcal{I}$.

Consider Γ_i. The sources (which are also sinks) of the trivial paths in Γ_i can be satisfied by a new thin edge from $\mathcal{I}_i$. Recall that the non-trivial paths in Γ_i are alternating paths of M. Their sources can be satisfied by fat resources if we flip these alternating paths and satisfy the sinks with thin edges from $\mathcal{I}_i$. If we do so, then edges in $\mathcal{Y}_i$ that cover $\mathit{source}(\Gamma_i)$ can be safely removed from $\mathcal{E}$ as the players in $\mathit{source}(\Gamma_i)$ are satisfied by new edges, and from $\mathcal{Y}_i$ since they no longer block edges in $\mathcal{X}_i$. A layer is collapsible if a certain portion of its blocking edges can be removed. More precisely, for any $i \in [0, \ell]$, L_i is **collapsible** if there is a canonical decomposition $\mathcal{I}_0 \cup \mathcal{I}_1 \cup \ldots \mathcal{I}_\ell$ of $\mathcal{I}$ such that $\lvert I_i \rvert \geqslant \mu \lvert Y_i \rvert$, where μ is a constant that will be determined later.

Collapse layers. When we find that some layer is collapsible, we run the routine Collapse below, which collapses layers in the stack until no layer is collapsible. Collapse works in the same manner as its counterpart in [1], but there are small differences in the presentation.

Collapse$(M, \mathcal{E}, \mathcal{I}, (L_1, \cdots, L_\ell))$

1. Compute a canonical decomposition $\mathcal{I}_1 \cup \mathcal{I}_2 \cup \cdots \mathcal{I}_\ell$ and a canonical solution $\Gamma_1 \cup \Gamma_2 \cup \cdots \Gamma_\ell$ of $G_M(Y_{\leqslant \ell}, I)$. If no layer is collapsible, go to build phase. Otherwise, let L_t be the collapsible layer with the smallest index t.
2. Remove all layers above L_t from the stack. Set $\mathcal{I} := \mathcal{I}_{\leqslant t-1}$.
3. Recall that $source(\Gamma_t) \subseteq Y_t$ by Lemma 3.3. Let $\mathcal{V}$ denote the set of the thin edges in $\mathcal{Y}_t$ that cover $source(\Gamma_t)$. Recall that $\mathcal{Y}_t \subseteq \mathcal{E}$.
   a. Update the maximum matching M by flipping the non-trivial paths in Γ_t, i.e., set $M := M \oplus \Gamma_t^+$. This matches the sources of non-trivial paths in Γ_t while leave their sinks unmatched.
   b. Add to $\mathcal{E}$ edges in I_t, i.e., set $\mathcal{E} := \mathcal{E} \cup \mathcal{I}_t$. Now the sinks of non-trivial paths are satisfied. Also the sources of trivial paths are satisfied by new thin edges.
   c. Now each player in $source(\Gamma_t)$ is satisfied either by a fat resource or a thin edge from $\mathcal{I}_t$. Edges in $\mathcal{V}$ can be safely removed from $\mathcal{E}$. Set $\mathcal{E} := \mathcal{E} \setminus \mathcal{V}$. Consequently, edges in $\mathcal{V}$ no longer block edges in $\mathcal{X}_t$. Set $\mathcal{Y}_t := \mathcal{Y}_t \setminus \mathcal{V}$.
4. If $t \geqslant 2$, we need to update $\mathcal{X}_t$ because the removal of $\mathcal{V}$ from $\mathcal{E}$ (and hence $\mathcal{Y}_t$) may make some edges in $\mathcal{X}_t$ unblocked. For each edge $(p, B) \in \mathcal{X}_t$ that becomes unblocked, perform the following:
   a. Remove (p, B) from $\mathcal{X}_t$.
   b. If $f_M(Y_{\leqslant t-1}, I \cup \{p\}) > f_M(Y_{\leqslant t-1}, I)$, then add (p, B') to $\mathcal{I}$, where B' is an arbitrary minimal subset of B such that $value(B') \geqslant \tau/\lambda$ and B' excludes the resources covered by $\mathcal{E}$.
5. If $t = 1$, step 3 already satisfied the player p_0 in the bottommost layer in the stack, so the algorithm terminates. Otherwise, update $\ell := t$ and go back to step 1.

▶ **Lemma 3.4.** Collapse *maintains invariants 1–7 in Table 1.*

4 Polynomial running time and binary search

Each call of Build and Collapse runs in time polynomial in ℓ, m and n. Lemma 4.1 below is the key to obtaining a bound on ℓ and the total number of calls of Build and Collapse. The proof of Lemma 4.1 is deferred to Section 5.

▶ **Lemma 4.1.** *Assume that the values τ and λ used by the algorithm satisfy the relations $\tau \leqslant \tau^*$ and $\lambda = 6 + \delta$ for an arbitrary constant $\delta \in (0, 1)$. There exists a constant $\mu \in (0, 1)$ dependent on δ such that for any state $(M, \mathcal{E}, \mathcal{I}, (L_1, \ldots, L_\ell))$ of the algorithm, if $|Y_{i+1}| < \sqrt{\mu}|Y_{\leqslant i}|$ for some $i \in [1, \ell - 1]$, then some layer below L_{i+1} must be collapsible.*

Lemma 4.1, immediately implies a logarithmic bound on the maximum number ℓ of layers. Using argument similar to that in [1, Lemmas 4.10 and 4.11], we can show that given a partial allocation, our algorithm can extend it to satisfy one more player in polynomial time. By repeating the algorithm at most n times, we can extend a maximum matching of G to an allocation of value at least τ/λ.

The remaining task is to binary search for τ^*. If we use a value τ that is at most τ^*, the algorithm terminates in polynomial time with an allocation. If we use a value $\tau > \tau^*$, there are two possible outcomes. We may be lucky and always have some collapsible layer below

L_{i+1} whenever $|Y_{i+1}| < \sqrt{\mu}|Y_{\leqslant i}|$ for some $i \in [1, \ell-1]$. In this case, the algorithm returns in polynomial time an allocation of value at least $\tau/\lambda \geqslant \tau^*/\lambda$. The second outcome is that no layer is collapsible at some point, but $|Y_{i+1}| < \sqrt{\mu}|Y_{\leqslant i}|$ for some $i \in [1, \ell-1]$. This can be detected in $O(1)$ time by maintaining $|Y_{i+1}|$ and $|Y_{\leqslant i}|$, which allows us to detect that $\tau > \tau^*$ and halt the algorithm. Since this is the first violation of this property, the running time before halting is polynomial in m and n. The last allocation returned by the algorithm during the binary search has value at least $\tau^*/\lambda = \tau^*/(6+\delta)$. We will see in Section 5.2 that a smaller δ requires a smaller μ and hence a higher running time.

▶ **Theorem 4.2.** *For any fixed constant $\delta \in (0,1)$, there is an algorithm for the restricted max-min fair allocation problem that returns a $(6+\delta)$-approximation in time polynomial in the number of players and the number of resources.*

5 Analysis

We will derive lower and upper bounds for the total value of the thin resources in the stack and show that if Lemma 4.1 does not hold, the lower bound would exceed the upper bound.

5.1 Competing players

To analyze our aggressive greedy strategy for selecting blocked addable thin edges, we need an injective map φ from the players covered by them to players who can access thin resources of high total value. The next result shows that these target players exist.

▶ **Lemma 5.1.** *Let* OPT *be an arbitrary optimal allocation. There exists a maximum matching M^* of G induced by* OPT *such that M^* matches every player who is assigned at least one fat resource in* OPT*. Hence, every player in $\bar{P}_{M^*}$ is assigned only thin resources in* OPT *that are worth a total value of τ or more, assuming that $\tau \leqslant \tau^*$.*

The domain of the injection φ is a subset of $X_{\leqslant \ell}$ and its image is a subset of $\bar{P}_{M^*}$. We call the image of φ the competing players. For any player $q \in X_{\leqslant \ell}$, $\varphi(q)$ has access to thin resources that are worth a total value of τ or more. Our goal is to prove that $\varphi(q)$ is also an addable player when q is added to $\mathcal{X}_{\leqslant \ell}$. Since the algorithm prefers q to $\varphi(q)$, either no addable edge is incident to $\varphi(q)$ or the maximal addable edge identified for $\varphi(q)$ has less value than the edge $e_q \in \mathcal{X}_{\leqslant \ell}$ that covers q. In both cases, more than $\tau - \mathit{value}(e_q)$ worth of thin resources assigned to $\varphi(q)$ in OPT are already in the stack. This will allow us to prove a good lower bound for the total value of the thin resources in the stack.

Lemma 5.2 below states the properties of competing players. We already discussed the usage of Lemma 5.2(i) and (ii). It would be ideal if the domain of φ could cover the entire $X_{\leqslant \ell}$. However, for technical reasons, when Collapse removes a player from $X_{\leqslant \ell}$, we may have to remove two players from the domain of φ in order to maintain the properties of φ. Lemma 5.2(iii) puts a lower bound on the size of the domain of φ. When deriving lower bound for the total value of the thin resources in the stack, the players in $\bar{P}_{M^*}$ that are not competing players and outside $X_{\leqslant \ell} \cup I$ also play a role. Lemma 5.2(iv) will allow us to prove that a large subset of such players are still addable after we finish adding edges to $\mathcal{X}_\ell$ during the construction of layer L_ℓ. Each of these addable players contributes a large worth of thin resources to the stack.

▶ **Lemma 5.2.** *Let M^* be a maximum matching of G induced by some optimal allocation. For any state $(M, \mathcal{E}, \mathcal{I}, (L_1, \ldots, L_\ell))$ of the algorithm, there exists an injection φ such that*

(i) *The domain* D_φ *and image* Im_φ *of* φ *are subsets of* $X_{\leqslant \ell}$ *and* $\bar{P}_{M^*}$*, respectively.*
(ii) *For every player* $p \in \mathrm{D}_\varphi$*, when* p *was added to* X_k *for some* $k \in [2, \ell]$*,* $\varphi(p)$ *was also an addable player at that time.*
(iii) $|\mathrm{D}_\varphi| \geqslant 2|X_{\leqslant \ell}| - \sum_{i=1}^{\ell} z_i$.
(iv) $f_M(\bar{P}_M, (\bar{P}_{M^*} \setminus \mathrm{Im}_\varphi) \cup X_{\leqslant \ell}) = |\bar{P}_M|$.

Proof. Our proof is by induction on the chronological order of the build and collapse phases. In the base case, $\ell = 1$, $X_1 = \emptyset$, and $z_1 = 0$. The existence of φ is trivial as its domain $D_\varphi \subseteq X_1 = \emptyset$. So $\mathrm{Im}_\varphi = \emptyset$. Then, (i), (ii) and (iii) are satisfied trivially, and (iv) follows from Claim 2.1(i). We discuss how to update φ during the build and collapse phases.

Build phase. Suppose that Build begins to construct a new layer L_ℓ. X_ℓ is initialized to be empty. The value z_ℓ is computed only at the completion of L_ℓ. However, in this proof, we initialize $z_\ell = 0$, increment z_ℓ whenever we add an edge to X_ℓ, and show the validity of (i)–(iv) inductively.

Since $X_\ell = \emptyset$ and $z_\ell = 0$ initially, properties (i)–(iv) are satisfied by the current φ by inductive assumption.

Step 2 of Build does not change X_ℓ, and so φ needs no update.

Consider step 3 of Build. Suppose that a thin edge incident to player q_1 is added to $\mathcal{X}_\ell$. So q_1 is addable. For clarity, we use X'_ℓ, z'_ℓ, φ', $\mathrm{D}_{\varphi'}$, and $\mathrm{Im}_{\varphi'}$ to denote the updated X_ℓ, z_ℓ, φ, D_φ, and Im_φ, respectively. Clearly, $X'_\ell = X_\ell \cup \{q_1\}$ and $z'_\ell = z_\ell + 1$. We set $\mathrm{D}_{\varphi'} := \mathrm{D}_\varphi \cup \{q_1\}$. For every $p \in \mathrm{D}_{\varphi'} \setminus \{q_1\}$, we set $\varphi'(p) := \varphi(p)$. We set $\varphi'(q_1)$ as follows.

Let Π_1 be an optimal solution of $G_M(Y_{\leqslant \ell-1}, X_{\leqslant \ell} \cup I \cup \{q_1\})$. We have $q_1 \in \mathit{sink}(\Pi_1)$ since otherwise we would have $f_M(Y_{\leqslant \ell-1}, X_{\leqslant \ell} \cup I \cup \{q_1\}) = f_M(Y_{\leqslant \ell-1}, X_{\leqslant \ell} \cup I)$, contradicting the addability of q_1. Similarly, $q_1 \notin X_{\leqslant \ell}$. As $q_1 \in \mathit{sink}(\Pi_1)$, q_1 must be unmatched in $M \oplus \Pi_1^+$, i.e., $q_1 \in \bar{P}_{M \oplus \Pi_1^+}$. Let Π_2 be an optimal solution of $G_{M \oplus \Pi_1^+}(\bar{P}_{M \oplus \Pi_1^+}, (\bar{P}_{M^*} \setminus \mathrm{Im}_\varphi) \cup X_{\leqslant \ell})$. We have $|\Pi_2| = f_{M \oplus \Pi_1^+}(\bar{P}_{M \oplus \Pi_1^+}, (\bar{P}_{M^*} \setminus \mathrm{Im}_\varphi) \cup X_{\leqslant \ell}) = f_M(\bar{P}_M, (\bar{P}_{M^*} \setminus \mathrm{Im}_\varphi) \cup X_{\leqslant \ell})$ by Claim 2.1(ii). Then, inductive assumption gives $|\Pi_2| = |\bar{P}_M| = |\bar{P}_{M \oplus \Pi_1^+}|$ (both M and $M \oplus \Pi_1$ are maximum matchings). So $\bar{P}_{M \oplus \Pi_1^+} = \mathit{source}(\Pi_2)$, implying that there is a path $\pi \in \Pi_2$ originating from q_1. Let $q_2 = \mathit{sink}(\pi)$.

We claim that $q_2 \notin X_{\leqslant \ell}$. If π is a trivial path, the claim is true because $q_2 = q_1 \notin X_{\leqslant \ell}$. Suppose that π is non-trivial. Suppose, for the sake of contradiction, that $q_2 \in X_{\leqslant \ell}$. This allows us to apply Claim 2.4 and use π to convert Π_1 to an equal-sized set of node-disjoint paths from $Y_{\leqslant \ell-1}$ to $X_{\leqslant \ell} \cup I$. But then $f_M(Y_{\leqslant \ell-1}, X_{\leqslant \ell} \cup I) \geqslant |\Pi_1| = f_M(Y_{\leqslant \ell-1}, X_{\leqslant \ell} \cup I \cup \{q_1\}) \geqslant f_M(Y_{\leqslant \ell-1}, X_{\leqslant \ell} \cup I)$. That is, $f_M(Y_{\leqslant \ell-1}, X_{\leqslant \ell} \cup I \cup \{q_1\}) = f_M(Y_{\leqslant \ell-1}, X_{\leqslant \ell} \cup I)$, contradicting the addability of q_1. This proves our claim that $q_2 \notin X_{\leqslant \ell}$.

Observe that $q_2 \in \bar{P}_{M^*} \setminus \mathrm{Im}_\varphi$ because $q_2 \in \mathit{sink}(\Pi_2) \subseteq (\bar{P}_{M^*} \setminus \mathrm{Im}_\varphi) \cup X_{\leqslant \ell}$ and $q_2 \notin X_{\leqslant \ell}$. This allows us to set $\varphi'(q_1) := q_2$ and keep φ' injective.

Properties (i) and (iii) are straightforwardly satisfied by φ', z'_ℓ, $\mathrm{D}_{\varphi'}$, and X'_ℓ.

By induction assumption, (ii) holds for players in $\mathrm{D}_{\varphi'} \setminus \{q_1\} = \mathrm{D}_\varphi$. It remains to check the validity of (ii) for $\varphi'(q_1) = q_2$. If π is a trivial path, then (ii) holds because $q_2 = q_1$ and q_1 is addable. Assume that π is non-trivial. By Claim 2.4, we can use π to convert Π_1 to an equal-sized set of node-disjoint paths in G_M from $Y_{\leqslant \ell-1}$ to $X_{\leqslant \ell} \cup I \cup \{q_2\}$. Thus, $f_M(Y_{\leqslant \ell-1}, X_{\leqslant \ell} \cup I \cup \{q_2\}) \geqslant |\Pi_1| = f_M(Y_{\leqslant \ell-1}, X_{\leqslant \ell} \cup I \cup \{q_1\}) = f_M(Y_{\leqslant \ell-1}, X_{\leqslant \ell} \cup I) + 1$ as q_1 is addable. Therefore, q_2 is also an addable player at the time when $\mathcal{X}_\ell$ gains a thin edge incident to q_1.

Consider (iv). If π is a trivial path, i.e., $q_1 = q_2$, then (iv) holds because $(\bar{P}_{M^*} \setminus \mathrm{Im}_\varphi) \cup X_{\leqslant \ell} \subseteq (\bar{P}_{M^*} \setminus (\mathrm{Im}_\varphi \cup \{q_2\})) \cup X_{\leqslant \ell} \cup \{q_1\} = (\bar{P}_{M^*} \setminus \mathrm{Im}_{\varphi'}) \cup X'_{\leqslant \ell}$. Suppose that π is non-trivial. Recall that Π_2 is an optimal solution of $G_{M \oplus \Pi_1^+}(\bar{P}_{M \oplus \Pi_1^+}, \bar{P}_{M^*} \setminus \mathrm{Im}_\varphi) \cup X_{\leqslant \ell})$,

and $|\Pi_2| = |\bar{P}_{M\oplus\Pi_1^+}|$. Take the maximum matching $M \oplus \Pi_1^+$ of G and flip the paths in $\Pi_2^+ \setminus \{\pi\}$ in G. This produces another maximum matching $M' = (M \oplus \Pi_1^+) \oplus (\Pi_2^+ \setminus \{\pi\})$. All $|\bar{P}_{M\oplus\Pi_1^+}|$ sinks of Π_2, except for q_2, are unmatched in M'. Player q_1 is also unmatched in M'. There are equally many unmatched players in M' and $M \oplus \Pi_1^+$. This implies that $(\mathit{sink}(\Pi_2) \setminus \{q_2\}) \cup \{q_1\}$ is exactly $\bar{P}_{M'}$. Since $\mathit{sink}(\Pi_2) \subseteq (\bar{P}_{M^*} \setminus \mathrm{Im}_\varphi) \cup X_{\leqslant \ell}$, we get $\bar{P}_{M'} \subseteq \big(\big((\bar{P}_{M^*} \setminus \mathrm{Im}_\varphi) \cup X_{\leqslant \ell}\big) \setminus \{q_2\}\big) \cup \{q_1\} \subseteq (\bar{P}_{M^*} \setminus (\mathrm{Im}_\varphi \cup \{q_2\})) \cup X_{\leqslant \ell} \cup \{q_1\} = (\bar{P}_{M^*} \setminus \mathrm{Im}_{\varphi'}) \cup X'_{\leqslant \ell}$. Then, we can apply Claim 2.1(i) to obtain $|\bar{P}_M| \geqslant f_M(\bar{P}_M, (\bar{P}_{M^*} \setminus \mathrm{Im}_{\varphi'}) \cup X'_{\leqslant \ell}) \geqslant f_M(\bar{P}_M, \bar{P}_{M'}) = |\bar{P}_M|$. Hence, (iv) holds.

Clearly, steps 4–6 of Build do not affect φ.

Collapse phase. Suppose that we are going to collapse the layer L_t. Since we will set $\ell := t$ at the end of collapsing L_t, we only need to prove (i)—(iv) with ℓ substituted by t.

Clearly, step 1 of Collapse has no effect on φ.

Consider step 2 of Collapse. Go back to the last time when L_t was either created by Build as the topmost layer or made by Collapse as the topmost layer. By the inductive assumption, there was an injection φ'' at that time that satisfies (i)–(iv). We set $\varphi := \varphi''$, $\mathrm{D}_\varphi := \mathrm{D}_{\varphi''}$, and $\mathrm{Im}_\varphi := \mathrm{Im}_{\varphi''}$.

In step 3 of Collapse, the maximum matching M may change, so only (iv) is affected. Nonetheless, by Claim 2.1(ii), the value of $f_M(\bar{P}_M, (\bar{P}_{M^*} \setminus \mathrm{Im}_\varphi) \cup X_\ell)$ remains the same after updating M. So (iv) is satisfied afterwards.

In step 4 of Collapse, we may remove some edges from $\mathcal{X}_t$ and add some of these removed edges to $\mathcal{I}$. Adding edges to $\mathcal{I}$ does not affect φ. We need to update φ when an edge is removed from $\mathcal{X}_t$. Suppose that we are going to remove from $\mathcal{X}_t$ an edge that covers a player q_1. Recall that z_t was defined in the last construction of the layer L_t, and it has remained fixed despite possible changes to $\mathcal{X}_t$ since then. Let $X'_{\leqslant t}$, φ', $\mathrm{D}_{\varphi'}$, and $\mathrm{Im}_{\varphi'}$ denote the updated $X_{\leqslant t}$, φ, D_φ, and Im_φ, respectively. Note that $X'_{\leqslant t} = X_{\leqslant t} \setminus \{q_1\}$. We show how to define φ', $\mathrm{D}_{\varphi'}$, and $\mathrm{Im}_{\varphi'}$ appropriately.

Consider property (iv). If (iv) is not affected by the deletion of q_1, that is, $f_M(\bar{P}_M, (\bar{P}_{M^*} \setminus \mathrm{Im}_\varphi) \cup X'_{\leqslant t}) = |\bar{P}_M|$, then we simply set $\mathrm{D}_{\varphi'} := \mathrm{D}_\varphi \setminus \{q_1\}$ and $\varphi'(p) := \varphi(p)$ for all $p \in \mathrm{D}_{\varphi'}$. It is easy to verify that φ' satisfies (iv). Suppose that property (iv) is affected, and therefore, $f_M(\bar{P}_M, (\bar{P}_{M^*} \setminus \mathrm{Im}_\varphi) \cup X'_{\leqslant t}) = |\bar{P}_M| - 1$. Since $f_M(\bar{P}_M, \bar{P}_{M^*}) = |\bar{P}_M|$, we have that $f_M(\bar{P}_M, \bar{P}_{M^*} \cup X'_{\leqslant t}) = |\bar{P}_M|$. Comparing the two equations above, we conclude that there must a player $q_2 \in \mathrm{D}_\varphi$ such that $f_M(\bar{P}_M, (\bar{P}_{M^*} \setminus (\mathrm{Im}_\varphi \setminus \{\varphi(q_2)\}) \cup X'_{\leqslant t}) = |\bar{P}_M|$. So we set $\mathrm{D}_{\varphi'} := \mathrm{D}_\varphi \setminus \{q_1, q_2\}$, and $\varphi'(p) := \varphi(p)$ for all $p \in \mathrm{D}_{\varphi'}$. Property (iv) is satisfied afterwards.

Irrespective of which definition of φ' above is chosen, properties (i) and (ii) trivially hold. Property (iii) holds because the left hand side decreases by at most 2 and the right hand side decreases by exactly 2. ◀

5.2 Proof of Lemma 4.1

Suppose, for the sake of contradiction, that there exists an index $k \in [1, \ell - 1]$ such that $|Y_{k+1}| < \sqrt{\mu}\,|Y_{\leqslant k}|$ but no layer below L_{k+1} is collapsible. Let k be the smallest such index. So $|Y_{i+1}| \geqslant \sqrt{\mu}\,|Y_{\leqslant i}|$ for every $i \in [1, k-1]$.

Consider the moment immediately after the last construction of the $(k+1)$-th layer. Let $(M', \mathcal{E}', \mathcal{I}', (L'_1, \ldots, L'_{k+1}))$ be the state of the algorithm at that moment. No layer below L'_{k+1} is collapsible immediately after the construction of L'_{k+1} since this is the last construction of the $(k+1)$-th layer. We will derive a few inequalities that hold given the existence of k. Then we will obtain a contradiction by showing that the system made up of these inequalities is infeasible.

We first define some notations. Let $\mathcal{X}'_i$ and $\mathcal{Y}'_i$ denote the set of blocked addable (thin) edges and the set of blocking (thin) edges associated with L'_i. Then, X'_i, Y'_i, $\mathcal{X}'_{\leqslant i}$, $\mathcal{Y}'_{\leqslant i}$, $X'_{\leqslant i}$, and $Y'_{\leqslant i}$ are correspondingly defined. Let M^* be a maximum matching induced by an optimal allocation OPT. Let φ' and $\mathrm{D}_{\varphi'}$ be the injection and its domain associated with $X'_{\leqslant t+1}$ as defined in Lemma 5.2 with respect to M^*. For all $p \in \mathrm{D}_{\varphi'}$, define $w_p := \mathit{value}(B)$, where (p, B) is the thin edge for p in $\mathcal{X}'_{\leqslant k+1}$. By invariant 1 in Table 1, w_p is well defined (as $\mathrm{D}_{\varphi'} \subseteq X'_{\leqslant k+1}$ by Lemma 5.2(i) and no player is covered by two edges in $\mathcal{X}'_{\leqslant k+1}$) and $w_p \in [\tau/\lambda, \tau + \tau/\lambda]$.

By the definition above, we already have two easy inequalities. Recall that given a set $\mathcal{S}$ of thin edges, $\mathit{value}(\mathcal{S})$ is the total value of the thin resources covered by $\mathcal{S}$.

$$\mathit{value}(\mathcal{X}'_{\leqslant k+1} \cup \mathcal{Y}'_{\leqslant k}) \geqslant \mathit{value}(\mathcal{X}'_{\leqslant k+1}) \geqslant \sum_{p \in \mathrm{D}_{\varphi'}} w_p, \quad \frac{\tau}{\lambda}|\mathrm{D}_{\varphi'}| \leqslant \sum_{p \in \mathrm{D}_{\varphi'}} w_p \leqslant (\tau + \frac{\tau}{\lambda})|\mathrm{D}_{\varphi'}|.$$

▶ **Claim 5.3.** $|\mathrm{D}_{\varphi'}| \leqslant |Y'_{\leqslant k}|$.

▶ **Claim 5.4.** $\mathit{value}(\mathcal{X}'_{\leqslant k+1} \cup \mathcal{Y}'_{\leqslant k}) \leqslant \frac{\tau}{\lambda}|\mathrm{D}_{\varphi'}| + \frac{2\tau}{\lambda}|Y'_{\leqslant k}| + \frac{\delta_1\tau}{\lambda}|Y'_{\leqslant k}|$, *where* $\delta_1 = \lambda\mu + 2\mu + 2\sqrt{\mu}$.

▶ **Claim 5.5.** $\mathit{value}(\mathcal{X}'_{\leqslant k+1} \cup \mathcal{Y}'_{\leqslant k}) \geqslant (\tau - \frac{\tau}{\lambda})(|Y'_{\leqslant k}| - |\mathrm{D}_{\varphi'}|) + \sum_{p \in \mathrm{D}_{\varphi'}}(\tau - w_p) - \frac{\delta_2\tau}{\lambda}|Y'_{\leqslant k}|$, *where* $\delta_2 = 2\lambda\mu + 2\lambda\sqrt{\mu} + 6\sqrt{\mu}$.

The proofs of above claims use Lemma 5.2. In particular, Lemma 5.2 plays a key role in the proof of Claim 5.5. Here we give a rough idea. Consider the moment we just finish adding edges to $\mathcal{X}'_{k+1}$. Lemma 5.2(iv) ensures that roughly $(|Y'_{\leqslant k}| - |\mathrm{D}_{\varphi'}|)$ players in $\bar{P}_{M^*} \setminus \mathrm{Im}_{\varphi'}$ are still addable. Since there are no more addable edges (otherwise they will be added to $\mathcal{X}'_{k+1}$), each of these addable players can access less than τ/λ worth of thin resources that are not in the stack, and hence each of them contribute at least $\tau - \tau/\lambda$ worth of thin resources to the stack. This gives the first term $(\tau - \frac{\tau}{\lambda})(|Y'_{\leqslant k}| - |\mathrm{D}_{\varphi'}|)$. For each player $\varphi'(p) \in \mathrm{Im}_{\varphi'}$, as we explained in section 5.1, it contributed at least $\tau - w_p$ worth of thin resources to the stack at the time player p was picked. This gives the second term $\sum_{p \in \mathrm{D}_{\varphi'}}(\tau - w_p)$. The third term is just slack in the analysis.

Putting all the inequalities together gives the following system.

- $\mathit{value}(\mathcal{X}_{\leqslant k+1} \cup \mathcal{Y}_{\leqslant k}) \geqslant \sum_{p \in \mathrm{D}_{\varphi'}} w_p$,
- $\frac{\tau}{\lambda}|\mathrm{D}_{\varphi'}| \leqslant \sum_{p \in \mathrm{D}_{\varphi'}} w_p \leqslant (\tau + \tau/\lambda)|\mathrm{D}_{\varphi'}|$,
- $|\mathrm{D}_{\varphi'}| \leqslant |Y'_{\leqslant k}|$,
- $\mathit{value}(\mathcal{X}'_{\leqslant k+1} \cup \mathcal{Y}'_{\leqslant k}) \leqslant \frac{\tau}{\lambda}|\mathrm{D}_{\varphi'}| + \frac{2\tau}{\lambda}|Y'_{\leqslant k}| + \frac{\delta_1\tau}{\lambda}|Y'_{\leqslant k}|$,
- $\mathit{value}(\mathcal{X}'_{\leqslant k+1} \cup \mathcal{Y}'_{\leqslant k}) \geqslant (\tau - \tau/\lambda)(|Y'_{\leqslant k}| - |\mathrm{D}_{\varphi'}|) + \sum_{p \in \mathrm{D}_{\varphi'}}(\tau - w_p) - \frac{\delta_2\tau}{\lambda}|Y'_{\leqslant k}|$.

Divide the above system by $\frac{\tau}{\lambda}|\mathrm{D}_{\varphi'}|$. To simplify the notation, define the variables $B_1 := \mathit{value}(\mathcal{X}_{\leqslant k+1} \cup \mathcal{Y}_{\leqslant k})/(\frac{\tau}{\lambda}|\mathrm{D}_{\varphi'}|)$, $B_2 := |Y'_{\leqslant k}|/|\mathrm{D}_{\varphi'}|$, and $B_3 := \sum_{p \in \mathrm{D}_{\varphi'}} w_p/(\frac{\tau}{\lambda}|\mathrm{D}_{\varphi'}|)$. Then we can write the above system equivalently as follows.

$$B_1 \geqslant B_3, \quad 1 \leqslant B_3 \leqslant \lambda + 1, \quad 1 \leqslant B_2, \quad B_1 \leqslant 1 + 2B_2 + \delta_1 B_2,$$
$$B_1 \geqslant (\lambda - 1)(B_2 - 1) + \lambda - B_3 - \delta_2 B_2.$$

The first, fourth, and fifth inequalities give $2(1 + 2B_2 + \delta_1 B_2) \geqslant B_1 + B_3 \geqslant (\lambda - 1)(B_2 - 1) + \lambda - \delta_2 B_2 \Rightarrow 2 + (4 + 2\delta_1)B_2 \geqslant (\lambda - 1 - \delta_2)B_2 + 1 \Rightarrow (\lambda - 5 - 2\delta_1 - \delta_2)B_2 \leqslant 1$. On the other hand, $\lambda - 5 - 2\delta_1 - \delta_2 > 1$ for a sufficiently small μ because when μ tends to zero, both δ_1 and δ_2 tend to 0. Hence, $(\lambda - 5 - 2\delta_1 - \delta_2)B_2 > 1$ as $B_2 \geqslant 1$ by the third inequality. But it is impossible that $(\lambda - 5 - 2\delta_1 - \delta_2)B_2 \leqslant 1$ and $(\lambda - 5 - 2\delta_1 - \delta_2)B_2 > 1$ simultaneously.

Abstract

We study the classical Node-Disjoint Paths (NDP) problem: given an undirected n-vertex graph G, together with a set $\{(s_1,t_1),\ldots,(s_k,t_k)\}$ of pairs of its vertices, called source-destination, or demand pairs, find a maximum-cardinality set $\mathcal{P}$ of mutually node-disjoint paths that connect the demand pairs. The best current approximation for the problem is achieved by a simple greedy $O(\sqrt{n})$-approximation algorithm. Until recently, the best negative result was an $\Omega(\log^{1/2-\epsilon} n)$-hardness of approximation, for any fixed ϵ, under standard complexity assumptions.

A special case of the problem, where the underlying graph is a grid, has been studied extensively. The best current approximation algorithm for this special case achieves an $\tilde{O}(n^{1/4})$-approximation factor. On the negative side, a recent result by the authors shows that NDP is hard to approximate to within factor $2^{\Omega(\sqrt{\log n})}$, even if the underlying graph is a subgraph of a grid, and all source vertices lie on the grid boundary. In a very recent follow-up work, the authors further show that NDP in grid graphs is hard to approximate to within factor $\Omega(2^{\log^{1-\epsilon} n})$ for any constant ϵ under standard complexity assumptions, and to within factor $n^{\Omega(1/(\log\log n)^2)}$ under randomized ETH.

In this paper we study the NDP problem in grid graphs, where all source vertices $\{s_1,\ldots,s_k\}$ appear on the grid boundary. Our main result is an efficient randomized $2^{O(\sqrt{\log n}\cdot\log\log n)}$-approximation algorithm for this problem. Our result in a sense complements the $2^{\Omega(\sqrt{\log n})}$-hardness of approximation for sub-graphs of grids with sources lying on the grid boundary, and should be contrasted with the above-mentioned almost polynomial hardness of approximation of NDP in grid graphs (where the sources and the destinations may lie anywhere in the grid).

Much of the work on approximation algorithms for NDP relies on the multicommodity flow relaxation of the problem, which is known to have an $\Omega(\sqrt{n})$ integrality gap, even in grid graphs, with all source and destination vertices lying on the grid boundary. Our work departs from this paradigm, and uses a (completely different) linear program only to select the pairs to be routed, while the routing itself is computed by other methods.

1 Introduction

We study the classical Node-Disjoint Paths (NDP) problem, where the input consists of an undirected n-vertex graph G and a collection $\mathcal{M} = \{(s_1, t_1), \ldots, (s_k, t_k)\}$ of pairs of its vertices, called *source-destination* or *demand* pairs. We say that a path P *routes* a demand pair (s_i, t_i) iff the endpoints of P are s_i and t_i. The goal is to compute a maximum-cardinality set $\mathcal{P}$ of node-disjoint paths, where each path $P \in \mathcal{P}$ routes a distinct demand pair in $\mathcal{M}$. We denote by NDP-Planar the special case of the problem when the underlying graph G is planar, and by NDP-Grid the special case where G is a square grid[4]. We refer to the vertices in set $S = \{s_1, \ldots, s_k\}$ as *source vertices*; to the vertices in set $T = \{t_1, \ldots, t_k\}$ as *destination vertices*, and to the vertices in set $S \cup T$ as *terminals*.

NDP is a fundamental graph routing problem that has been studied extensively in both graph theory and theoretical computer science communities. Robertson and Seymour [31, 33] explored the problem in their Graph Minor series, providing an efficient algorithm for NDP when the number k of the demand pairs is bounded by a constant. But when k is a part of input, the problem becomes NP-hard [20, 18], even in planar graphs [27], and even in grid graphs [26]. The best current approximation factor of $O(\sqrt{n})$ for NDP is achieved by a simple greedy algorithm [25]. Until recently, this was also the best approximation algorithm for NDP-Planar and NDP-Grid. A natural way to design approximation algorithms for NDP is via the multicommodity flow relaxation: instead of connecting each routed demand pair with a path, send maximum possible amount of (possibly fractional) flow between them. The optimal solution to this relaxation can be computed via a standard linear program. The $O(\sqrt{n})$-approximation algorithm of [25] can be cast as an LP-rounding algorithm of this relaxation. Unfortunately, it is well-known that the integrality gap of this relaxation is $\Omega(\sqrt{n})$, even when the underlying graph is a grid, with all terminals lying on its boundary. In a recent work, Chuzhoy and Kim [12] designed an $\tilde{O}(n^{1/4})$-approximation for NDP-Grid, thus bypassing this integrality gap barrier. Their main observation is that, if all terminals lie close to the grid boundary (say within distance $O(n^{1/4})$), then a simple dynamic programming-based algorithm yields an $O(n^{1/4})$-approximation. On the other hand, if, for every demand pair, either the source or the destination lies at a distance at least $\Omega(n^{1/4})$ from the grid boundary, then the integrality gap of the multicommodity flow relaxation improves, and one can obtain an $\tilde{O}(n^{1/4})$-approximation via LP-rounding. A natural question is whether the integrality gap improves even further, if all terminals lie further away from the grid boundary. Unfortunately, the authors show in [12] that the integrality gap remains at least $\Omega(n^{1/8})$, even if all terminals lie within distance $\Omega(\sqrt{n})$ from the grid boundary. The $\tilde{O}(n^{1/4})$-approximation algorithm for NDP-Grid was later extended and generalized to an $\tilde{O}(n^{9/19})$-approximation algorithm for NDP-Planar [13].

On the negative side, until recently, only an $\Omega(\log^{1/2-\epsilon} n)$-hardness of approximation was known for the general version of NDP, for any constant ϵ, unless NP $\subseteq$ ZPTIME$(n^{\text{poly}\log n})$ [4, 3], and only APX-hardness was known for NDP-Planar and NDP-Grid [12]. In a recent

[4] We use the standard convention of denoting $n = |V(G)|$, and so the grid has dimensions $(\sqrt{n} \times \sqrt{n})$; we assume that $\sqrt{n}$ is an integer.

work [15], the authors have shown that NDP is hard to approximate to within a $2^{\Omega(\sqrt{\log n})}$ factor unless $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{O(\log n)})$, even if the underlying graph is a planar graph with maximum vertex degree at most 3, and all source vertices lie on the boundary of a single face. The result holds even when the input graph G is a vertex-induced subgraph of a grid, with all sources lying on the grid boundary. In a very recent work [14], the authors show that NDP-Grid is $2^{\Omega(\log^{1-\epsilon} n)}$-hard to approximate for any constant ϵ assuming $\mathsf{NP} \not\subseteq \mathsf{BPTIME}(n^{\mathrm{poly}\log n})$, and moreover, assuming randomized ETH, the hardness of approximation factor becomes $n^{\Omega(1/(\log\log n)^2)}$. We note that the instances constructed in these latter hardness proofs require all terminals to lie far from the grid boundary.

In this paper we explore NDP-Grid. This important special case of NDP was initially motivated by applications in VLSI design, and has received a lot of attention since the 1960's. We focus on a restricted version of NDP-Grid, that we call Restricted NDP-Grid: here, in addition to the graph G being a square grid, we also require that all source vertices $\{s_1, \ldots, s_k\}$ lie on the grid boundary. We do not make any assumptions about the locations of the destination vertices, that may appear anywhere in the grid. The best current approximation algorithm for Restricted NDP-Grid is the same as that for the general NDP-Grid, and achieves a $\tilde{O}(n^{1/4})$-approximation [12]. Our main result is summarized in the following theorem.

▶ **Theorem 1.** *There is an efficient randomized $2^{O(\sqrt{\log n}\cdot\log\log n)}$-approximation algorithm for* Restricted NDP-Grid.

This result in a sense complements the $2^{\Omega(\sqrt{\log n})}$-hardness of approximation of NDP on sub-graphs of grids with all sources lying on the grid boundary of [15][5], and should be contrasted with the recent almost polynomial hardness of approximation of [14] for NDP-Grid mentioned above. Our algorithm departs from previous work on NDP in that it does not use the multicommodity flow relaxation. Instead, we define sufficient conditions that allow us to route a subset $\mathcal{M}'$ of demand pairs via disjoint paths, and show that there exists a subset of demand pairs satisfying these conditions, whose cardinality is at least $\mathsf{OPT}/2^{O(\sqrt{\log n}\cdot\log\log n)}$, where OPT is the value of the optimal solution. It is then enough to compute a maximum-cardinality subset of the demand pairs satisfying these conditions. We write an LP-relaxation for this problem and design a $2^{O(\sqrt{\log n}\cdot\log\log n)}$-approximation LP-rounding algorithm for it. We emphasize that the linear program is only used to select the demand pairs to be routed, and not to compute the routing itself.

We then generalize this result to instances where the source vertices lie within a prescribed distance from the grid boundary.

▶ **Theorem 2.** *For every integer $\delta \geq 1$, there is an efficient randomized $\left(\delta \cdot 2^{O(\sqrt{\log n}\cdot\log\log n)}\right)$-approximation algorithm for the special case of* NDP-Grid *where all source vertices lie within distance at most δ from the grid boundary.*

We note that for instances of NDP-Grid where both the sources and the destinations are within distance at most δ from the grid boundary, it is easy to obtain an efficient $O(\delta)$-approximation algorithm (see, e.g. [12]).

A problem closely related to NDP is the Edge-Disjoint Paths (EDP) problem. It is defined similarly, except that now the paths chosen to route the demand pairs may share vertices,

[5] Note that the two results are not strictly complementary: our algorithm only applies to grid graphs, while the hardness result is only valid for sub-graphs of grids.

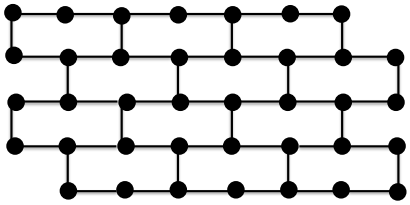

Figure 1 A wall graph.

and are only required to be edge-disjoint. The approximability status of EDP is very similar to that of NDP: there is an $O(\sqrt{n})$-approximation algorithm [10], and an $\Omega(\log^{1/2-\epsilon} n)$-hardness of approximation for any constant ϵ, unless NP $\subseteq$ ZPTIME$(n^{\text{poly}\log n})$ [4, 3]. As in the NDP problem, we can use the standard multicommodity flow LP-relaxation of the problem, in order to obtain the $O(\sqrt{n})$-approximation algorithm, and the integrality gap of the LP-relaxation is $\Omega(\sqrt{n})$ even in planar graphs. Recently, Fleszar et al. [19] designed an $O(\sqrt{r}\cdot\log(kr))$-approximation algorithm for EDP, where r is the feedback vertex set number of the input graph $G=(V,E)$ — the smallest number of vertices that need to be deleted from G in order to turn it into a forest.

Several special cases of EDP have better approximation algorithms: an $O(\log^2 n)$-approximation is known for even-degree planar graphs [9, 8, 22], and an $O(\log n)$-approximation is known for nearly-Eulerian uniformly high-diameter planar graphs, and nearly-Eulerian densely embedded graphs, including grid graphs [5, 24, 23]. Furthermore, an $O(\log n)$-approximation algorithm is known for EDP on 4-edge-connected planar, and Eulerian planar graphs [21]. It appears that the restriction of the graph G to be Eulerian, or near-Eulerian, makes the EDP problem on planar graphs significantly simpler, and in particular improves the integrality gap of the standard multicommodity flow LP-relaxation.

The analogue of the grid graph for the EDP problem is the wall graph (see Figure 1): the integrality gap of the multicommodity flow relaxation for EDP on wall graphs is $\Omega(\sqrt{n})$. The $\tilde{O}(n^{1/4})$-approximation algorithm of [12] for NDP-Grid extends to EDP on wall graphs, and the $2^{\Omega(\sqrt{\log n})}$-hardness of approximation of [15] for NDP-Planar also extends to EDP on sub-graphs of walls, with all sources lying on the top boundary of the wall. The recent hardness result of [14] for NDP-Grid also extends to an $2^{\Omega(\log^{1-\epsilon} n)}$-hardness of EDP on wall graphs, assuming NP $\not\subseteq$ BPTIME$(n^{\text{poly}\log n})$, and to $n^{\Omega(1/(\log\log n)^2)}$-hardness assuming randomized ETH. We extend our results to EDP and NDP on wall graphs:

▶ **Theorem 3.** *There is an efficient randomized $2^{O(\sqrt{\log n}\cdot\log\log n)}$-approximation algorithm for* EDP *and for* NDP *on wall graphs, when all source vertices lie on the wall boundary.*

Other related work

Cutler and Shiloach [17] studied an even more restricted version of NDP-Grid, where all source vertices lie on the top row R^* of the grid, and all destination vertices lie on a single row R' of the grid, far enough from its top and bottom boundaries. They considered three different settings of this special case. In the packed-packed setting, all sources appear consecutively on R^*, and all destinations appear consecutively on R' (but both sets may appear in an arbitrary order). They show a necessary and a sufficient condition for all demand pairs to be routable via node-disjoint paths in this setting. The second setting is the packed-spaced setting. Here, the sources again appear consecutively on R^*, but all destinations are at a distance at least

d from each other. For this setting, the authors show that if $d \geq k$, then all demand pairs can be routed. We note that [12] extended their algorithm to a more general setting, where the destination vertices may appear anywhere in the grid, as long as the distance between any pair of the destination vertices, and any destination vertex and the boundary of the grid, is at least $\Omega(k)$. Robertson and Seymour [32] provided sufficient conditions for the existence of node-disjoint routing of a given set of demand pairs in the more general setting of graphs drawn on surfaces, and they designed an algorithm whose running time is $\text{poly}(n) \cdot f(k)$ for finding the routing, where $f(k)$ is at least exponential in k. Their result implies the existence of the routing in grids, when the destination vertices are sufficiently far from each other and from the grid boundaries, but it does not provide an efficient algorithm to compute such a routing. The third setting studied by Cutler and Shiloach is the spaced-spaced setting, where the distances between every pair of source vertices, and every pair of destination vertices are at least d. The authors note that they could not come up with a better algorithm for this setting, than the one provided for the packed-spaced case. Aggarwal, Kleinberg, and Williamson [1] considered a special case of NDP-Grid, where the set of the demand pairs is a permutation: that is, every vertex of the grid participates in exactly one demand pair. They show that $\Omega(\sqrt{n}/\log n)$ demand pairs are routable in this case via node-disjoint paths. They further show that if all terminals are at a distance at least d from each other, then at least $\Omega(\sqrt{nd}/\log n)$ pairs are routable.

A variation of the NPD and EDP problems, where small congestion is allowed, has been a subject of extensive study, starting with the classical paper of Raghavan and Thompson [29] that introduced the randomized rounding technique. We say that a set $\mathcal{P}$ of paths causes congestion c, if at most c paths share the same vertex or the same edge, for the NDP and the EDP settings respectively. A recent line of work [9, 28, 2, 30, 11, 16, 7, 6] has lead to an $O(\text{poly}\log k)$-approximation for both NDP and EDP problems with congestion 2. For planar graphs, a constant-factor approximation with congestion 2 is known [34].

Organization

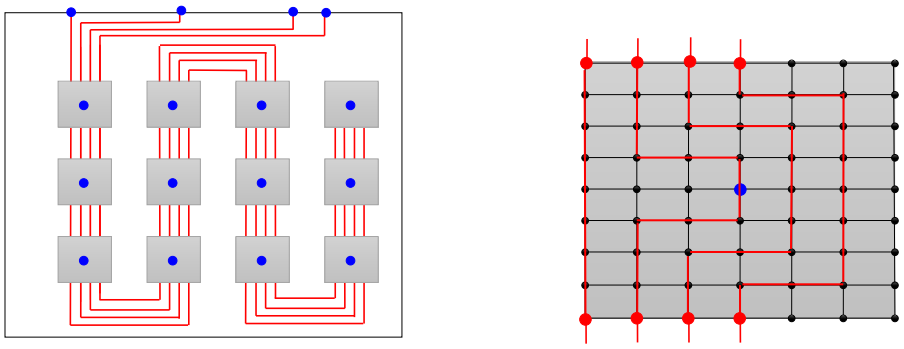
The majority of this extended abstract is dedicated to a detailed but informal overview of the proofs of Theorem 1 and Theorem 2. The formal proofs, as well as the extension to EDP and NDP on wall graphs, are deferred to the full version of the paper.

2 High-Level Overview of the Algorithm

The goal of this section is to provide an informal high-level overview of the main result of the paper – the proof of Theorem 1. With this goal in mind, the values of various parameters are given imprecisely in this section, in a way that best conveys the intuition. The full version of the paper contains a formal description of the algorithm and the precise settings of all parameters.

We first consider an even more restricted special case of NDP-Grid, where all source vertices appear on the top boundary of the grid, and all destination vertices appear far enough from the grid boundary, and design an efficient randomized $2^{O(\sqrt{\log n \cdot \log\log n})}$-approximation algorithm $\mathcal{A}$ for this problem. We later show how to reduce Restricted NDP-Grid to this special case of the problem; we focus on the description of the algorithm $\mathcal{A}$ for now.

We assume that our input graph G is the $(\ell \times \ell)$-grid, and we denote by $n = \ell^2$ the number of its vertices. We further assume that the set of the demand pairs is $\mathcal{M} = \{(s_1, t_1), \ldots, (s_k, t_k)\}$, with the vertices in set $S = \{s_1, \ldots, s_k\}$ called source vertices; the vertices in set $T = \{t_1, \ldots, t_k\}$ called destination vertices; and the vertices in $S \cup T$ called



(a) Global routing. In this figure, the sub-grids B_i are aligned vertically and horizontally. A similar (but somewhat more complicated) routing can be performed even if they are not aligned. For convenience we did not include all source vertices and all paths.

(b) Local routing inside B_i

Figure 2 Schematic view of routing of spaced-out instances.

terminals. Let OPT denote the value of the optimal solution to the NDP instance $(G, \mathcal{M})$. We assume that the vertices of S lie on the top boundary of the grid, that we denote by R^*, and the vertices of T lie sufficiently far from the grid boundary – say, at a distance at least OPT from it. For a subset $\mathcal{M}' \subseteq \mathcal{M}$ of the demand pairs, we denote by $S(\mathcal{M}')$ and $T(\mathcal{M}')$ the sets of the source and the destination vertices of the demand pairs in $\mathcal{M}'$, respectively. As our starting point, we consider a simple observation of Chuzhoy and Kim [12], that generalizes the results of Cutler and Shiloach [17]. Suppose we are given an instance of NDP-Grid with k demand pairs, where the sources lie on the top boundary of the grid, and the destination vertices may appear anywhere in the grid, but the distance between every pair of the destination vertices, and every destination vertex and the boundary of the grid, is at least $(8k + 8)$ – we call such instances *spaced-out instances*. In this case, all demand pairs in $\mathcal{M}$ can be efficiently routed via node-disjoint paths, as follows. Consider, for every destination vertex $t_i \in T$, a square sub-grid B_i of G, of size $(2k \times 2k)$, such that t_i lies roughly at the center of B_i. We construct a set $\mathcal{P}$ of k node-disjoint paths, that originate at the vertices of S, and traverse the sub-grids B_i one-by-one in a snake-like fashion (see a schematic view on Figure 2a). We call this part of the routing *global routing*. The *local routing* needs to specify how the paths in $\mathcal{P}$ traverse each box B_i. This is done in a straightforward manner, while ensuring that the unique path originating at vertex s_i visits the vertex t_i (see Figure 2b). By suitably truncating the final set $\mathcal{P}$ of paths, we obtain a routing of all demand pairs in $\mathcal{M}$ via node-disjoint paths.

Unfortunately, in our input instance $(G, \mathcal{M})$, the destination vertices may not be located sufficiently far from each other. We can try to select a large subset $\mathcal{M}' \subseteq \mathcal{M}$ of the demand pairs, so that every pair of destination vertices in $T(\mathcal{M}')$ appear at a distance at least $\Omega(|\mathcal{M}'|)$ from each other; but in some cases the largest such set $\mathcal{M}'$ may only contain $O(\mathsf{OPT}/\sqrt{k})$ demand pairs (for example, suppose all destination vertices lie consecutively on a single row of the grid). One of our main ideas is to generalize this simple algorithm to a number of recursive levels.

For simplicity, let us first describe the algorithm with just two recursive levels. Suppose we partition the top row of the grid into z disjoint intervals, $I_1, \ldots, I_z$. Let $\mathcal{M}' \subseteq \mathcal{M}$ be a set of demand pairs that we would like to route. Denote $|\mathcal{M}'| = k'$, and assume that we are given a collection $\mathcal{Q}$ of square sub-grids of G, of size $(4k' \times 4k')$ each (that we call *squares*),

such that every pair $Q, Q' \in \mathcal{Q}$ of distinct squares is at a distance at least $4k'$ from each other. Assume further that each such sub-grid $Q \in \mathcal{Q}$ is assigned a color $\chi(Q) \in \{c_1, \ldots, c_z\}$, such that, if Q is assigned the color c_j, then all demand pairs $(s,t) \in \mathcal{M}'$ whose destination t lies in Q have their source $s \in I_j$ (so intuitively, each color c_j represents an interval I_j). Let $\mathcal{M}'_j \subseteq \mathcal{M}'$ be the set of all demand pairs $(s,t) \in \mathcal{M}'$ with $s \in I_j$. We would like to ensure that $|\mathcal{M}'_j|$ is roughly k'/z, and that all destination vertices of $T(\mathcal{M}'_j)$ are at a distance at least $|\mathcal{M}'_j|$ from each other. We claim that if we could find the collection $\{I_1, \ldots, I_z\}$ of the intervals of the first row, a collection $\mathcal{Q}$ of sub-grids of G, a coloring $\chi : \mathcal{Q} \to \{c_1, \ldots, c_z\}$, and a subset $\mathcal{M}' \subseteq \mathcal{M}$ of the demand pairs with these properties, then we would be able to route all demand pairs in $\mathcal{M}'$.

In order to do so, for each square $Q \in \mathcal{Q}$, we construct an augmented square Q^+, by adding a margin of k' rows and columns around Q. Our goal is to construct a collection $\mathcal{P}$ of node-disjoint paths routing the demand pairs in $\mathcal{M}'$. We start by constructing a global routing, where all paths in $\mathcal{P}$ originate from the vertices of $S(\mathcal{M}')$ and then visit the squares in $\{Q^+ \mid Q \in \mathcal{Q}\}$ in a snake-like fashion, just like we did for the spaced-out instances described above (see Figure 2a). Consider now some square $Q \in \mathcal{Q}$ and the corresponding augmented square Q^+. Assume that $\chi(Q) = c_j$, and let $\mathcal{P}_j \subseteq \mathcal{P}$ be the set of paths originating at the source vertices that lie in I_j. While traversing the square Q^+, we ensure that only the paths in $\mathcal{P}_j$ enter the square Q; the remaining paths use the margins on the left and on the right of Q in order to traverse Q^+. This can be done because the sources of the paths in $\mathcal{P}_j$ appear consecutively on R^*, relatively to the sources of all paths in $\mathcal{P}$. In order to complete the local routing inside the square Q, observe that the destination vertices appear far enough from each other, and so we can employ the simple algorithm for spaced-out instances inside Q.

In order to optimize the approximation factor that we achieve, we extend this approach to $\rho = O(\sqrt{\log n})$ recursive levels. Let $\eta = 2^{\lceil \sqrt{\log n} \rceil}$. We define auxiliary parameters $d_1 > d_2 > \cdots > d_\rho > d_{\rho+1}$. Roughly speaking, we can think of $d_{\rho+1}$ as being a constant (say 16), of d_1 as being comparable to OPT, and for all $1 \leq h \leq \rho$, $d_{h+1} = d_h/\eta$. The setup for the algorithm consists of three ingredients: (i) a hierarchical decomposition $\tilde{\mathcal{H}}$ of the grid into square sub-grids (that we refer to as squares); (ii) a hierarchical partition $\mathfrak{I}$ of the first row R^* of the grid into intervals; and (iii) a hierarchical coloring f of the squares in $\tilde{\mathcal{H}}$ with colors that correspond to the intervals of $\mathfrak{I}$, together with a selection of a subset $\mathcal{M}' \subseteq \mathcal{M}$ of the demand pairs to route. We define sufficient conditions on the hierarchical system $\tilde{\mathcal{H}}$ of squares, the hierarchical partition $\mathfrak{I}$ of R^* into intervals, the coloring f and the subset $\mathcal{M}'$ of the demand pairs, under which a routing of all pairs in $\mathcal{M}'$ exists and can be found efficiently. For a fixed hierarchical system $\tilde{\mathcal{H}}$ of squares, a triple $(\mathfrak{I}, f, \mathcal{M}')$ satisfying these conditions is called a *good ensemble*. We show that a good ensemble with a large enough set $\mathcal{M}'$ of demand pairs exists, and then design an approximation algorithm for computing a good ensemble maximizing $|\mathcal{M}'|$. We now describe each of these ingredients in turn.

2.1 A Hierarchical System of Squares.

A hierarchical system $\tilde{\mathcal{H}}$ of squares consists of a sequence $\mathcal{Q}_1, \mathcal{Q}_2, \ldots, \mathcal{Q}_\rho$ of sets of sub-grids of G. For each $1 \leq h \leq \rho$, $\mathcal{Q}_h$ is a collection of disjoint sub-grids of G (that we refer to as *level-h squares*); every such square $Q \in \mathcal{Q}_h$ has size $(d_h \times d_h)$, and every pair of distinct squares $Q, Q' \in \mathcal{Q}_h$ are within distance at least d_h from each other (see Figure 3). We require that for each $1 < h \leq \rho$, for every square $Q \in \mathcal{Q}_h$, there is a unique square $Q' \in \mathcal{Q}_{h-1}$ (called the *parent-square* of Q) that contains Q. We say that a demand pair (s,t) *belongs* to the hierarchical system $\tilde{\mathcal{H}} = (\mathcal{Q}_1, \mathcal{Q}_2, \ldots, \mathcal{Q}_\rho)$ of squares iff $t \in \bigcup_{Q \in \mathcal{Q}_\rho} Q$. We show a

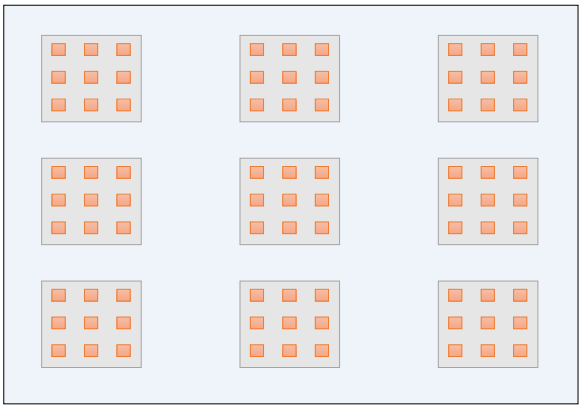


Figure 3 A schematic view of a hierarchical system of squares with 2 levels.

simple efficient algorithm to construct $2^{O(\sqrt{\log n})}$ such hierarchical systems of squares, so that every demand pair belongs to at least one of them. Each such system $\tilde{\mathcal{H}}$ of squares induces an instance of NDP — the instance is defined over the same graph G, and the set $\tilde{\mathcal{M}} \subseteq \mathcal{M}$ of demand pairs that belong to the system $\tilde{\mathcal{H}}$. It is then enough to obtain a factor $2^{O(\sqrt{\log n} \cdot \log\log n)}$-approximation algorithm for each resulting instance $(G, \tilde{\mathcal{M}})$ separately. From now on we fix one such hierarchical system $\tilde{\mathcal{H}} = (\mathcal{Q}_1, \mathcal{Q}_2, \ldots, \mathcal{Q}_\rho)$ of squares, together with the set $\tilde{\mathcal{M}} \subseteq \mathcal{M}$ of demand pairs, containing all pairs (s,t) that belong to $\tilde{\mathcal{H}}$, and focus on designing a $2^{O(\sqrt{\log n} \cdot \log\log n)}$-approximation algorithm for instance $(G, \tilde{\mathcal{M}})$.

2.2 A Hierarchical Partition of the Top Grid Boundary

Recall that R^* denotes the first row of the grid. A hierarchical partition $\mathfrak{I}$ of R^* is a sequence $\mathcal{I}_1, \mathcal{I}_2, \ldots, \mathcal{I}_\rho$ of sets of sub-paths of R^*, such that for each $1 \leq h \leq \rho$, the paths in $\mathcal{I}_h$ (that we refer to as *level-h intervals*) partition the vertices of R^*. We also require that for all $1 < h \leq \rho$, every level-h interval $I \in \mathcal{I}_h$ is contained in a unique level-$(h-1)$ interval $I' \in \mathcal{I}_{h-1}$, that we refer to as the *parent-interval* of I. For every level $1 \leq h \leq \rho$, we define a collection χ_h of colors, containing one color $c_h(I)$ for each level-h interval $I \in \mathcal{I}_h$. If $I' \in \mathcal{I}_h$ is a parent-interval of $I \in \mathcal{I}_{h+1}$, then we say that color $c_h(I')$ is a *parent-color* of $c_{h+1}(I)$.

2.3 Coloring the Squares and Selecting Demand Pairs to Route

The third ingredient of our algorithm is an assignment f of colors to the squares, and a selection of a subset of the demand pairs to be routed. For every level $1 \leq h \leq \rho$, for every level-h square $Q \in \mathcal{Q}_h$, we would like to assign a single level-h color $c_h(I) \in \chi_h$ to Q, denoting $f(Q) = c_h(I)$. Intuitively, if color $c_h(I)$ is assigned to Q, then the only demand pairs (s,t) with $t \in Q$ that we may route are those whose source vertex s lies on the level-h interval I. We require that the coloring is consistent across levels: that is, for all $1 < h \leq \rho$, if a level-h square is assigned a level-h color c_h, and its parent-square is assigned a level-$(h-1)$ color c_{h-1}, then c_{h-1} must be a parent-color of c_h. We call such a coloring f a *valid coloring* of $\tilde{\mathcal{H}}$ with respect to $\mathfrak{I}$.

Finally, we would like to select a subset $\mathcal{M}' \subseteq \tilde{\mathcal{M}}$ of the demand pairs to route. Consider some demand pair (s,t) and some level $1 \leq h \leq \rho$. Let I_h be the level-h interval to which s belongs. Then we say that s has the level-h color $c_h(I_h)$. Therefore, for each level $1 \leq h \leq \rho$,

vertex s is assigned the unique level-h color $c_h(I_h)$, and for $1 \leq h < \rho$, $c_h(I_h)$ is the parent-color of $c_{h+1}(I_{h+1})$. Let $Q_\rho \in \mathcal{Q}_\rho$ be the level-ρ square to which t belongs. We may only add (s,t) to $\mathcal{M}'$ if the level-ρ color of Q_ρ is $c_\rho(I_\rho)$ (that is, it is the same as the level-ρ color of s). Notice that in particular, this means that for every level $1 \leq h \leq \rho$, if Q_h is the level-h square containing t, and it is assigned the color $c_h(I_h)$, then s is assigned the same level-h color, and so $s \in I_h$. Finally, we require that for all $1 \leq h \leq \rho$, for every level-h color c_h, the total number of all demand pairs $(s,t) \in \mathcal{M}'$, such that the level-h color of s is c_h, is no more than $d_{h+1}/16$ (if $h = \rho$, then the number is no more than 1). If $\mathcal{M}'$ has all these properties, then we say that it *respects the coloring* f. We say that $(\mathfrak{I}, f, \mathcal{M}')$ is a *good ensemble* iff $\mathfrak{I}$ is a hierarchical partition of R^* into intervals; f is a valid coloring of the squares in $\tilde{\mathcal{H}}$ with respect to $\mathfrak{I}$; and $\mathcal{M}' \subseteq \tilde{\mathcal{M}}$ is a subset of the demand pairs that respects the coloring f. The *size* of the ensemble is $|\mathcal{M}'|$.

2.4 The Routing

We show that, if we are given a good ensemble $(\mathfrak{I}, f, \mathcal{M}')$, then we can route all demand pairs in $\mathcal{M}'$. The routing itself follows the high-level idea outlined above. We gradually construct a collection $\mathcal{P}$ of node-disjoint paths routing the demand pairs in $\mathcal{M}'$. At the highest level, all these paths depart from their sources and then visit the level-1 squares one-by-one, in a snake-like fashion, as in Figure 2a. Consider now some level-1 square Q, and assume that its level-1 color is $c_1(I)$, where $I \in \mathcal{I}_1$ is some level-1 interval of R^*. Then only the paths $P \in \mathcal{P}$ that originate at the vertices of I will enter the square Q; the remaining paths will exploit the spacing between the level-1 squares in order to bypass it; the spacing between the level-1 squares is sufficient to allow this. Once we have defined this global routing, we need to specify how the routing is carried out inside each square. We employ the same procedure recursively. Consider some level-1 square Q, and let $\mathcal{P}' \subseteq \mathcal{P}$ be the set of all paths that visit Q. Assume further that the level-1 color of Q is $c_1(I)$. Since we are only allowed to have at most $d_2/16$ demand pairs in $\mathcal{M}'$ whose level-1 color is $c_1(I)$, $|\mathcal{P}'| \leq d_2/16$. Let $\mathcal{Q}' \subseteq \mathcal{Q}_2$ be the set of all level-2 squares contained in Q. The paths in $\mathcal{P}'$ will visit the squares of $\mathcal{Q}'$ one-by-one in a snake-like fashion (but this part of the routing is performed inside Q). As before, for every level-2 square $Q' \subseteq Q$, if the level-2 color of Q' is $c_2(I')$, then only those paths of $\mathcal{P}'$ that originate at the vertices of I' will enter Q'; the remaining paths will use the spacing between the level-2 squares to bypass Q'. Since $|\mathcal{P}'| \leq d_2/16$, and all level-2 squares are at distance at least d_2 from each other, there is a sufficient spacing to allow this routing. We continue this process recursively, until, at the last level of the recursion, we route at most one path per color, to its destination vertex.

In order to complete the proof of the theorem, we need to show that there exists a good ensemble $(\mathfrak{I}, f, \mathcal{M}')$ of size $|\mathcal{M}'| \geq |\mathsf{OPT}|/2^{O(\sqrt{\log n \cdot \log\log n})}$, and that we can find such an ensemble efficiently.

2.5 The Existence of the Ensemble

The key notion that we use in order to show that a large good ensemble $(\mathfrak{I}, f, \mathcal{M}')$ exists is that of a *shadow property*. Suppose Q is some $(d \times d)$ sub-grid of G, and let $\hat{\mathcal{M}} \subseteq \mathcal{M}$ be some subset of the demand pairs. Among all demand pairs $(s,t) \in \hat{\mathcal{M}}$ with $t \in Q$, let (s_1, t_1) be the one with s_1 appearing earliest on the first row R^* of G, and let (s_2, t_2) be the one with s_2 appearing latest on R^*. The *shadow of* Q *with respect to* $\hat{\mathcal{M}}$ is the sub-path of R^* between s_1 and s_2. Let $N_{\hat{\mathcal{M}}}(Q)$ be the number of all demand pairs $(s,t) \in \hat{\mathcal{M}}$ with s lying in the shadow of Q (that is, s lies between s_1 and s_2 on R^*). We say that $\hat{\mathcal{M}}$ has the

shadow property with respect to Q iff $N_{\hat{\mathcal{M}}}(Q) \leq d$. We say that $\hat{\mathcal{M}}$ has the *shadow property with respect to the hierarchical system* $\tilde{\mathcal{H}} = (\mathcal{Q}_1, \ldots, \mathcal{Q}_\rho)$ *of squares*, iff $\hat{\mathcal{M}}$ has the shadow property with respect to every square in $\bigcup_{h=1}^{\rho} \mathcal{Q}_h$. Let $\mathcal{P}^*$ be the optimal solution to the instance $(G, \tilde{\mathcal{M}})$ of NDP, where $\tilde{\mathcal{M}}$ only includes the demand pairs that belong to $\tilde{\mathcal{H}}$. Let $\mathcal{M}^* \subseteq \tilde{\mathcal{M}}$ be the set of the demand pairs routed by $\mathcal{P}^*$. For every demand pair $(s,t) \in \mathcal{M}^*$, let $P(s,t) \in \mathcal{P}^*$ be the path routing this demand pair. Intuitively, it feels like $\mathcal{M}^*$ should have the shadow property. Indeed, let $Q \in \bigcup_{h=1}^{\rho} \mathcal{Q}_h$ be some square of size $(d_h \times d_h)$, and let $(s_1,t_1), (s_2,t_2) \in \mathcal{M}^*$ be defined for Q as before, so that the shadow of Q with respect to $\mathcal{M}^*$ is the sub-path of R^* between s_1 and s_2. Let P be any path of length at most $2d_h$ connecting t_1 to t_2 in Q, and let γ be the closed curve consisting of the union of $P(s_1,t_1)$, P, $P(s_2,t_2)$, and the shadow of Q. Consider the disc D whose boundary is γ. The intuition is that, if $(s,t) \in \mathcal{M}^*$ is a demand pair whose source lies in the shadow of Q, and destination lies outside of D, then $P(s,t)$ must cross the path P, as it needs to escape the disc D. Since path P is relatively short, only a small number of such demand pairs may exist. The main difficulty with this argument is that we may have a large number of demand pairs (s,t), whose source lies in the shadow of Q, and the destination lies in the disc D. Intuitively, this can only happen if $P(s_1,t_1)$ and $P(s_2,t_2)$ "capture" a large area of the grid. We show that, in a sense, this cannot happen too often, and that there is a subset $\mathcal{M}^{**} \subseteq \mathcal{M}^*$ of at least $|\mathcal{M}^*|/2^{O(\sqrt{\log n} \cdot \log\log n)}$ demand pairs, such that $\mathcal{M}^{**}$ has the shadow property with respect to $\tilde{\mathcal{H}}$.

Finally, we show that there exists a good ensemble $(\mathfrak{I}, f, \mathcal{M}')$ with $|\mathcal{M}'| \geq |\mathcal{M}^{**}|/2^{O(\sqrt{\log n} \cdot \log\log n)}$. We construct the ensemble over the course of ρ iterations, starting with $\mathcal{M}' = \mathcal{M}^{**}$. In the hth iteration we construct the set $\mathcal{I}_h$ of the level-h intervals of R^*, assign level-h colors to all level-h squares of $\tilde{\mathcal{H}}$, and discard some demand pairs from $\mathcal{M}'$. Recall that $\eta = 2^{\lceil \sqrt{\log n} \rceil}$. In the first iteration, we let $\mathcal{I}_1$ be a partition of the row R^* into intervals, each of which contains roughly $\frac{d_1}{16\eta} = \frac{d_2}{16} \leq \frac{|\mathcal{M}^*|}{\eta}$ vertices of $S(\mathcal{M}')$. Assume that these intervals are $I_1, \ldots, I_r$, and that they appear in this left-to-right order on R^*. We call all intervals I_j where j is odd *interesting intervals*, and the remaining intervals I_j *uninteresting intervals*. We discard from $\mathcal{M}'$ all demand pairs (s,t), where s lies on an uninteresting interval. Consider now some level-1 square Q, and let $\mathcal{M}(Q) \subseteq \mathcal{M}'$ be the set of all demand pairs whose destination lies in Q. Since the original set $\mathcal{M}^{**}$ of demand pairs had the shadow property with respect to Q, it is easy to verify that all source vertices of the demand pairs in $\mathcal{M}(Q)$ must belong to a single interesting interval of $\mathcal{I}_1$. Let I be that interval. Then we color the square Q with the level-1 color $c_1(I)$ corresponding to the interval I. This completes the first iteration. Notice that for each level-1 color $c_1(I)$, at most $d_2/16$ demand pairs $(s,t) \in \mathcal{M}'$ have $s \in I$. In the following iteration, we similarly partition every interesting level-1 interval into level-2 intervals that contain roughly $d_3/16 \leq |\mathcal{M}^*|/\eta^2$ source vertices of $\mathcal{M}'$ each, and then define a coloring of all level-2 squares similarly, while suitably updating the set $\mathcal{M}'$ of the demand pairs. We continue this process for ρ iterations, eventually obtaining a good ensemble $(\mathfrak{I}, f, \mathcal{M}')$. Since we only discard a constant fraction of the demand pairs of $\mathcal{M}'$ in every iteration, at the end, $|\mathcal{M}'| \geq |\mathcal{M}^{**}|/2^{\rho} = |\mathcal{M}^{**}|/2^{O(\sqrt{\log n})} \geq |\mathcal{M}^*|/2^{O(\sqrt{\log n} \cdot \log\log n)}$.

2.6 Finding the Good Ensemble

In our final step, our goal is to find a good ensemble $(\mathfrak{I}, f, \mathcal{M}')$ maximizing $|\mathcal{M}'|$. We show an efficient randomized $2^{O(\sqrt{\log n} \cdot \log\log n)}$-approximation algorithm for this problem. First, we show that, at the cost of losing a small factor in the approximation ratio, we can restrict our attention to a small collection $\mathfrak{I}_1, \mathfrak{I}_2, \ldots, \mathfrak{I}_z$ of hierarchical partitions of R^* into intervals,

and that it is enough to obtain a $2^{O(\sqrt{\log n}\cdot\log\log n)}$-approximate solution for the problem of finding the largest ensemble $(\mathfrak{I}_j, f, \mathcal{M}')$ for each such partition $\mathfrak{I}_j$ separately.

We then fix one such hierarchical partition $\mathfrak{I}_j$, and design an LP-relaxation for the problem of computing a coloring f of $\tilde{\mathcal{H}}$ and a collection $\mathcal{M}'$ of demand pairs, such that $(\mathfrak{I}_j, f, \mathcal{M}')$ is a good ensemble, while maximizing $|\mathcal{M}'|$. Finally, we design an efficient randomized LP-rounding $2^{O(\sqrt{\log n}\cdot\log\log n)}$-approximation algorithm for the problem.

2.7 Completing the Proof of Theorem 1

So far we have assumed that all source vertices lie on the top boundary of the grid, and all destination vertices are at a distance at least $\Omega(\mathsf{OPT})$ from the grid boundary. Let $\mathcal{A}$ be the randomized efficient $2^{O(\sqrt{\log n}\cdot\log\log n)}$-approximation algorithm for this special case. We now extend it to the general Restricted NDP-Grid problem. For every destination vertex t, we identify the closest vertex $\tilde{t}$ that lies on the grid boundary. Using standard grouping techniques, at the cost of losing an additional $O(\log n)$ factor in the approximation ratio, we can assume that all source vertices lie on the top boundary of the grid, all vertices in $\left\{\tilde{t} \mid t \in T(\mathcal{M})\right\}$ lie on a single boundary edge of the grid (assume for simplicity that it is the bottom boundary), and that there is some integer d, such that for every destination vertex $t \in T(\mathcal{M})$, $d \leq d(t,\tilde{t}) < 2d$. We show that we can define a collection $\mathcal{Z} = \{Z_1, \ldots, Z_r\}$ of disjoint square sub-grids of G, and a collection $\mathcal{I} = \{I_1, \ldots, I_r\}$ of disjoint sub-intervals of R^*, such that the bottom boundary of each sub-grid Z_i is contained in the bottom boundary of G, the top boundary of Z_i is within distance at least OPT from R^*, $Z_1, \ldots, Z_r$ appear in this left-to-right order in G, and $I_1, \ldots, I_r$ appear in this left-to-right order on R^*. For each $1 \leq j \leq r$, we let $\mathcal{M}_j$ denote the set of all demand pairs with the sources lying on I_j and the destinations lying in Z_j. For each $1 \leq j \leq r$, we then obtain a new instance $(G, \mathcal{M}_j)$ of the NDP problem. We show that there exist a collection $\mathcal{Z}$ of squares and a collection $\mathcal{I}$ of intervals, such that the value of the optimal solution to each instance $(G, \mathcal{M}_j)$, that we denote by OPT_j, is at most d, while $\sum_{j=1}^{r} \mathsf{OPT}_j \geq \mathsf{OPT}/2^{O(\sqrt{\log n}\cdot\log\log n)}$. Moreover, it is not hard to show that, if we can compute, for each $1 \leq j \leq r$, a routing of some subset $\mathcal{M}'_j \subseteq \mathcal{M}_j$ of demand pairs in G, then we can also route all demand pairs in $\bigcup_{j=1}^{r} \mathcal{M}'_j$ simultaneously in G.

There are two problems with this approach. First, we do not know the set $\mathcal{Z}$ of sub-grids of G and the set $\mathcal{I}$ of intervals of R^*. Second, it is not clear how to solve each resulting problem $(G, \mathcal{M}_j)$. To address the latter problem, we define a simple mapping of all source vertices in $S(\mathcal{M}_j)$ to the top boundary of grid Z_j, obtaining an instance of Restricted NDP-Grid, where all source vertices lie on the top boundary of the grid Z_j, and all destination vertices lie at a distance at least $\mathsf{OPT}_j \leq d$ from its boundary. We can then use algorithm $\mathcal{A}$ in order to solve this problem efficiently. It is easy to see that, if we can route some subset $\mathcal{M}'_j$ of the demand pairs via node-disjoint paths in Z_j, then we can extend this routing to the corresponding set of original demand pairs, whose sources lie on R^*.

Finally, we employ dynamic programming in order to find the set $\mathcal{Z}$ of sub-grids of G and the set $\mathcal{I}$ of intervals of I. For each such potential sub-grid Z and interval I, we use algorithm $\mathcal{A}$ in order to find a routing of a large set of demand pairs of the corresponding instance defined inside Z, and then exploit the resulting solution values for each such pair (I, Z) in a simple dynamic program, that allows us to compute the set $\mathcal{Z}$ of sub-grids of G, the set $\mathcal{I}$ of intervals of I, and the final routing.

3 Approximation Algorithm for the Special Case with Sources Close to the Grid Boundary

In this section we provide a sketch of the proof of Theorem 2. We assume that we are given an instance $(G, \mathcal{M})$ of NDP-Grid and an integer $\delta > 0$, such that every source vertex is at a distance at most δ from the grid boundary. Our goal is to design an efficient randomized factor-$(\delta \cdot 2^{O(\sqrt{\log n} \cdot \log\log n)})$-approximation algorithm for this special case. For every terminal $v \in S(\mathcal{M}) \cup T(\mathcal{M})$, let $\tilde{v}$ be the vertex lying closest to v on the boundary of the grid G. Using standard grouping techniques, at the cost of losing an $O(\log n)$-factor in the approximation ratio, we can assume that there is some integer d, such that for all $t \in T(\mathcal{M})$, $d \leq d(t, \tilde{t}) < 2d$.

Assume first that $d \leq \delta \cdot 2^{O(\sqrt{\log n} \log\log n)}$. Let $\hat{\mathcal{M}} = \left\{(\tilde{s}, \tilde{t}) \mid (s,t) \in \mathcal{M}\right\}$ be a new set of demand pairs, so that all vertices participating in these demand pairs lie on the boundary of G. We can efficiently find an optimal solution to the NDP problem instance $(G, \hat{\mathcal{M}})$ using standard dynamic programming. We then show that $\mathsf{OPT}(G, \hat{\mathcal{M}}) = \Omega(\mathsf{OPT}(G, \mathcal{M})/(\delta \cdot 2^{O(\sqrt{\log n} \cdot \log\log n)}))$, obtaining an $(\delta \cdot 2^{O(\sqrt{\log n} \cdot \log\log n)})$-approximation algorithm.

From now on we assume that $d > \delta \cdot 2^{\Omega(\sqrt{\log n} \log\log n)}$. Next, we define a new set $\tilde{\mathcal{M}}$ of demand pairs: $\tilde{\mathcal{M}} = \{(\tilde{s}, t) \mid (s,t) \in \mathcal{M}\}$, so all source vertices of the demand pairs in $\tilde{\mathcal{M}}$ lie on the boundary of G, obtaining an instance of Restricted NDP-Grid. Let OPT' be the value of the optimal solution to problem $(G, \tilde{\mathcal{M}})$. We show that $\mathsf{OPT}' \geq \Omega(\mathsf{OPT}(G, \mathcal{M})/\delta)$.

We then focus on instance $(G, \tilde{\mathcal{M}})$ of Restricted NDP-Grid. We say that a path P routing a demand pair $(\tilde{s}, t) \in \tilde{\mathcal{M}}$ is *canonical* iff it contains the original source s. The crux of the proof is to show that we can modify the routing produced by the $2^{O(\sqrt{\log n} \cdot \log\log n)}$-approximation algorithm to instance $(G, \tilde{\mathcal{M}})$, so that in the resulting routing all paths are canonical. In order to do so, we utilize the fact that the destination vertices lie much further from the grid boundaries than the source vertices. This creates sufficient margins around the grid boundaries that allow us to modify the routing to turn it a canonical one.

Abstract

Hash tables are a ubiquitous class of dictionary data structures. However, standard hash table implementations do not translate well into the external memory model, because they do not incorporate locality for insertions.

Iacono and Pătraşu established an update/query tradeoff curve for external-hash tables: a hash table that performs insertions in $O(\lambda/B)$ amortized IOs requires $\Omega(\log_\lambda N)$ expected IOs for queries, where N is the number of items that can be stored in the data structure, B is the size of a memory transfer, M is the size of memory, and λ is a tuning parameter. They provide a complicated hashing data structure, which we call the **IP hash table**, that meets this curve for λ that is $\Omega(\log\log M + \log_M N)$.

In this paper, we present a simpler external-memory hash table, the **Bundle of Arrays Hash Table** (BOA), that is optimal for a narrower range of λ. The simplicity of BOAs allows them to be readily modified to achieve the following results:

- A new external-memory data structure, the **Bundle of Trees Hash Table** (BOT), that matches the performance of the IP hash table, while retaining some of the simplicity of the BOAs.
- The **Cache-Oblivious Bundle of Trees Hash Table** (COBOT), the first cache-oblivious hash table. This data structure matches the optimality of BOTs and IP hash tables over the same range of λ.

1 Introduction

Dictionaries are among the most heavily used data structures. A dictionary maintains a collection of key-value pairs $\mathcal{S} \subseteq \mathcal{U} \times \mathcal{V}$, under operations[1] INSERT$(x, v, \mathcal{S})$, DELETE$(x, \mathcal{S})$, and QUERY$(x, \mathcal{S})$, which returns the value corresponding to x when $x \in S$. When data fits in memory, there are many solutions to the dictionary problem.

When data is too large to fit in memory, comparison-based dictionaries can be quite varied. They include the B$^\varepsilon$-tree [8], the write-optimized skip list [6], and the cache-optimized look-ahead array (COLA) [2,3,5]. These are optimal in the **external-memory comparison model** in that they match the bound established by Brodal and Fagerberg [8] who showed that for any dictionary in this model, if insertions can be performed in $O\left(\frac{\lambda \log_\lambda N}{B}\right)$ amortized IOs, then there exists a query that requires at least $\Omega(\log_\lambda N)$ IOs, where N is the number of items that can be stored in the data structure, B is the size of a memory transfer, and λ is a tuning parameter. In the following M will be the size of memory, and $B = \Omega(\log n)$. This trade off has since been extended in several ways [1, 4].

Iacono and Pătraşcu showed that in the DAM model, in which operations beyond comparisons are allowed on keys, that a better tradeoff exists:

▶ **Theorem 1** ([11]). *If insertions into an external memory dictionary can be performed in $O(\lambda/B)$ amortized IOs, then queries require an expected $\Omega(\log_\lambda N)$ IOs.*

They further describe an external-memory hashing algorithm, which we refer to here as the **IP hash table**, that performs insertions in $O\left(\frac{1}{B}\left(\lambda + \log_{\frac{M}{B}} N + \log\log N\right)\right)$ IOs and queries in $O(\log_\lambda N)$ IOs w.h.p. Therefore, for $\lambda = \Omega\left(\log_{M/B} N + \log\log N\right)$, the IP hash table meets the tradeoff curve of Theorem 1 and is thus optimal.

In dictionaries that do not support successors and predecessors, we can assume that keys are hashed, that is, that they are uniformly distributed and satisfy some independence properties. The IP hash table and the following results hash all keys before insertion and query in the dictionary by a $\Theta(\log N)$-independent hash function.

The base result of this paper is a simple external-memory hashing scheme, the **Bundle of Arrays Hash Table** (BOA), that meets the optimal Theorem 1 trade off curve for large enough λ. Specifically, we show:

▶ **Theorem 2.** *A BOA supports N insertions and deletions with amortized per entry cost of $O\left(\left(\lambda + \log_{\frac{M}{B}} N + \log_\lambda N\right)/B\right)$ IOs, for any $\lambda > 1$. A query for a key K costs $O(D_K \log_\lambda N)$ IOs w.h.p., where D_K is the number of times K has been inserted or deleted.*

Thus BOAs are optimal for $\lambda = \Omega(\log_{\frac{M}{B}} N + \log_\lambda N)$. They are readily modified to provide several variations, notably the **Bundle of Trees Hash Table** (BOT). BOTs are optimal for the same range of λ as the IP hash table:

▶ **Theorem 3.** *A BOT supports N insertions and deletions with amortized per entry cost of $O\left(\left(\lambda + \log_{\frac{M}{B}} N + \log\log M\right)/B\right)$ IOs for any $\lambda > 1$. A query for a key K costs $O(D_K \log_\lambda N)$ IOs w.h.p., where D_K is the number of times K has been inserted or deleted.*

[1] We do not consider dictionaries that also support the SUCC$(x, \mathcal{S})$ and PRED$(x, \mathcal{S})$. SUCC$(x, \mathcal{S})$ return $\min\{y | y > x \wedge y \in \mathcal{S}\}$ and PRED$(x, \mathcal{S})$ is defined symmetrically.

We further introduce the first cache-oblivious hash table, the **Cache-Oblivious Bundle of Trees Hash Table** (COBOT), which matches the IO performance of BOTs and IP hash tables.

The BOT can also be adapted to models in which disk reads and writes incur different costs. The β-asymmetric BOT adjusts the merging schedule of a regular BOT to trade some writes for more reads. We leave the details for the full version [**?**].

▶ **Theorem 4.** *A β-asymmetric BOT supports N insertions and deletions with amortized per entry cost of $O\left(\frac{1}{B}\left(\lambda + \frac{1}{\beta}\log_\lambda N\right)\right)$ writes and $O\left(\frac{1}{B}(\lambda+\beta)\right)$ reads for any $\lambda > 1$ and $\beta \leq \left\lfloor \log_\lambda \frac{M}{B \log_\lambda N} \right\rfloor$. A query for a key K performs $O(D_K \log_\lambda N)$ reads, where D_K is the number of times K has been inserted or deleted.*

2 Preliminaries

Fingerprints and Hashing. In order to achieve our bounds, we need $\Theta(\log N)$-wise independent hash functions, which, once again matches IP hash tables. We note that a k-wise independent hash function is also k-wise independent on individual bits. Furthermore, the following Chernoff-type bound holds:

▶ **Lemma 5** ([14]). *Let $X_1, X_2, \ldots, X_N$ be $\lceil \mu\delta \rceil$-wise independent binary random variables, $X = \sum_{i=1}^{N} X_i$ and $\mu = \mathrm{E}[X]$. Then $\mathrm{P}(X > \mu\delta) = O\left(1/\delta^{\mu\delta}\right)$, for sufficiently large δ.*

In the following, we use **fingerprint** to refer to any key that has been hashed using a $\Theta(\log N)$-wise independent hash function. Such hash functions have a compact representation and can be specified using $\Theta(\log N)$ words. The universe that is hashed into is assumed to have size $\Theta(N^k)$ for $k \geq 2$. We ignore collisions, but these can be handled as in [12].

For a fingerprint K, it will be convenient to interpret the bits of K as a string of $\log \lambda$ (where lambda is a given parameter) bit characters, $K = K_0 K_1 K_2 \cdots$.

Delta Encoding. We will frequently encounter sorted lists of fingerprint prefixes (possibly with duplicates), together with some data about each. When the size of the list is dense in the space of prefixes, we can compress it using **delta encoding**, where the difference between prefixes is stored rather than the prefixes themselves.

▶ **Lemma 6.** *A list of delta-encoded prefixes with density D, that is there are D prefixes in the list for every possible prefix, requires $O(-\log_\lambda D)$ characters per prefix.*

Proof. The average difference between consecutive prefixes is $1/D$. Because logarithms are convex, the average number of characters required to represent this difference is therefore $O(-\log_\lambda D)$. ◀

Log-structured Merge Trees. Log-structured merge trees (LSMs) are (a family of) external-memory dictionary data structures. They come in two varieties: **level-tiered LSMs** (LT-LSMs) and **size-tiered LSMs** (ST-LSMs). Both kinds are suboptimal in that they do not meet the optimal insertion-query tradeoff [8], although the COLA [3] is an optimal variant of the LT-LSMs.

An LSM consists of sets of either B-trees or sorted arrays called **runs**. In this paper, we describe them in terms of runs, since we use runs below.

An LT-LSM consists of a cascade of levels, where each level consists of at most one run. Each level has a **capacity** that is λ times greater than the level below it, where λ is called

the **growth factor**.[2] When a level reaches capacity, it is merged into the next level (perhaps causing a merge cascade). The amortized IO cost for insertions is small because sequential merging is fast, although each item will participate in $\lambda/2$ merges on average. The IO cost for a query is high because a query must be performed independently on each of $O(\log_\lambda N)$ levels (although Bloom filters [5, 7] are sometimes used to mitigate this cost).

An ST-LSM further improves insertion IOs at the expense of queries. Each level contains fewer than λ runs. Every run on a given level has the same size, which is λ times larger than the runs on the level beneath it. When λ runs are present at a level, they are merged into one run and placed at the next level. There are therefore $O(\log_\lambda N)$ levels. Insertions are faster than in LT-LSMs because each item is only merged once on each level. Queries are slower because each query must be perform $O(\lambda)$ times at each level.

In LSMs, deletions can be implemented by the use of **upsert messages** [9, 13], which are a type of insertion with a message that indicates that the key has been deleted. A query for a key K then fetches all the matching key-value pairs and if the last one (temporally) is a deletion upsert, it returns false. To this end, the merges must maintain the temporal order of key-value pairs with the same key. Because a query for a key K must fetch every instance of K, the cost of a query is proportional to the number of times the key has been inserted and deleted, which we refer to as the **duplication count**, D_K of K. When $N/2$ deletions have been made, the structure is rebuilt to reclaim space. In what follows, deletions will be implemented using the same mechanism.

3 Bundle of Arrays Hashing

A **Bundle of Arrays Hash Table** (BOA) is an external-memory dictionary based on ST-LSMs. In this section, we describe a simple version which is optimal in the sense of Theorem 1, but where the query cost meets the bound only in expectation, not w.h.p. In Section 4, we give a version that satifies Theorem 2.

As a first step, we show that runs with uniformly distributed, $\Theta(\log N)$-wise independent fingerprints can be searched more quickly than in an ST-LSMs. In this section

▶ **Lemma 7.** *Let A be a sorted array of N uniformly distributed $\Theta(\log N)$-wise independent keys in the range $[0, K)$, and assume $B = \Omega(\log N)$. Then A can be written to external memory using $O(N)$ space and $O(N/B)$ IOs so that membership in A can be determined in $O(1)$ IOs with high probability.*

Proof. First note that, by Lemma 5 and Bonferroni's inequality, if N balls are thrown into $\Theta(N/\log N)$ bins uniformly and $\Theta(\log N)$-wise independently, then every bin has $\Theta(\log N)$ balls with high probability.

Divide the range of keys into N/B uniformly sized buckets; that is, bucket i contains keys in the range $[(i-1)KB/N, iKB/N)$. Because the keys in A are distributed uniformly, and $B = \Omega(\log N)$, every bucket contains $\Theta(B)$ keys with high probability. Let F be the number of items in the fullest bucket, and write the keys in each bucket to disk in order using F space for each. Because $F = \Theta(B)$, this takes the desired space and IOs.

Now, to find a key, compute which bucket it belongs to. A constant number of IOs will fetch that bucket, whose address is known because all buckets have the same size. ◀

[2] Sometimes this and related structures are analyzed with a growth factor of B^ϵ. The two are equivalent. We use λ rather than ϵ as the tuning parameter for consistency with the external-memory hashing literature.

▶ **Corollary 8.** *If an ST-LSM contains uniformly distributed and $\Theta(\log N)$-wise independent fingerprints and has growth factor λ, then a query for K can be performed in $O(D_K \lambda \log_\lambda N)$ IOs by writing the levels as in Lemma 7. The insertion/deletion cost is unchanged: $O\left(\frac{1}{B}\left(\log_\lambda N + \log_{\frac{M}{B}} N\right)\right)$ amortized IOs.*

While the query performance improves by a factor of $\log N$, the ST-LSM is still off the optimal tradeoff curve of Theorem 1. In particular, queries can be at least exponentially slower than optimal. The BOA use additional structure in order to reduce this query cost.

3.1 Routing Filters

The main result of this section is an auxiliary data structure, the **routing filter**, that improves the query cost of an ST-LSM by a factor of λ by further exploiting the log-wise independence of fingerprints. Combining these routing filters with fast interpolation search will yield the BOA, a hashing data structure that is optimal for large enough λ.

The purpose of the routing filter is to indicate probabilistically, at each level, which run contains the fingerprint we are looking for. Each level will have its own routing filter, defined as follows. For each level ℓ, let h_ℓ be some number, to be specified below. Let $P_\ell(K)$ be the prefix consisting of the first h_ℓ characters of K. The routing filter F_ℓ for level ℓ is a λ^{h_ℓ}-character array, where $F_\ell[i] = j$ if the jth run $R_{\ell,j}$ contains a fingerprint K such that the $P_\ell(K) = i$, and no later run $R_{\ell,j'}$ (i.e. with $j' > j$) contains such a fingerprint.

We also modify each run $R_{\ell,j}$ during the merge so that each fingerprint-value pair contains a **previous field** of 1 additional character used to specify the previous run containing a fingerprint with the same prefix, or j to indicate no such run exists. Thus these fingerprint-value pairs now form a singly linked list whose fingerprint share the same prefix, and the routing filter points to the run containing the head.

During a query for a fingerprint K, first $F_\ell[P_\ell(K)]$ is checked to find the latest run containing a fingerprint with a matching prefix. Once that fingerprint-value pair is found, its previous field indicates the next run which needs to be checked and so on until all fingerprints with matching prefix in the level are found. Each fingerprint $K' \neq K$ that matches K's prefix is a false positive.

Such routing filters induce a space/cost tradeoff. The greater h_ℓ is, the more space the table takes but the less likely it is that many runs will have false positives. The rest of this section shows that when $h_\ell = \log_\lambda B + \ell$, in other words, when prefixes grow by a character per level, the BOA lies on the optimal tradeoff curve of Theorem 1.

Define β, the **routing table ratio**, to be the ratio of the number of buckets in the routing filter to the size of a run. The number of entries in a run on level ℓ is $B\lambda^{\ell-1}$, so $\beta = \lambda^{h_\ell}/B\lambda^{\ell-1}$. We first analyze the per-level insertion/deletion cost, and then we compute the expected number of false positives in order to analyze the overall query cost.

▶ **Lemma 9.** *For a BOA with growth factor λ and routing table ratio β, merging a level incurs $\Theta\left(\frac{1}{B}\left(1 + \log_{\frac{M}{B}} \lambda + \beta \log_N \lambda\right)\right)$ IOs per fingerprint.*

Proof. Merging a level requires merging its runs as well as updating the next level's routing filter. Merging λ sorted arrays takes $\Theta\left(\frac{1}{B}\left(1 + \log_{M/B} \lambda\right)\right)$ IOs per fingerprint.

The routing filter is updated by iterating through it and the new run sequentially. For each fingerprint K appearing in the run, $F_{\ell+1}[P_{h_{\ell+1}}(K)]$ is copied to the previous field in the run, and $F_{\ell+1}[P_{h_{\ell+1}}(K)]$ is set to the number of the current run. Each entry in the routing filter is a character, and the routing filter has β entries for each new fingerprint. Thus, it requires $\Theta\left(\frac{\beta}{B} \log_N \lambda\right)$ IOs per fingerprint to update sequentially. ◀

▶ **Lemma 10.** *For a BOA with growth factor λ and routing table ratio β, querying a fingerprint K on a given level incurs at most $\frac{\lambda}{\beta}$ false positives in expectation.*

Proof. Given some enumeration of the fingerprints in level ℓ, which are not equal to K, denote the ith such fingerprint by K_i. Some of these may be the duplicates. Let X_i be the indicator random variable, which is 1 if $P_\ell(K) = P_\ell(K_i)$ and 0 otherwise. K and K_i are uniformly distributed and their bits are pairwise independent. Thus $\mathrm{E}[X_i] \leq \frac{1}{\lambda^{h_\ell}}$. The expected number of fingerprints (excluding K) in the level with prefix $P_\ell(K)$ is thus at most $\sum_{i=1}^{B\lambda^\ell} \mathrm{E}[X_i] \leq \frac{B\lambda^\ell}{\lambda^{h_\ell}} = \frac{\lambda}{\beta}$. ◀

▶ **Lemma 11.** *A BOA with growth factor λ and routing table ratio β has insertion/deletion cost $O\left(\frac{1}{B}\left(\beta + \log_{\frac{M}{B}} N + \log_\lambda N\right)\right)$. A query for fingerprint K has expected cost $O\left(\frac{\lambda}{\beta} D_K \log_\lambda N\right)$, where D_K is the duplication count of K.*

Proof. Because a BOA has $\log_\lambda N$ levels, the insertion cost follows from Lemma 9.

To query for a fingerprint K, the routing filter on each level is checked, which incurs $O(\log_\lambda N)$ IOs. These routing filters return a collection of runs which contain up to D_K true positives and an expected $O\left(\frac{\lambda}{\beta} \log_\lambda N\right)$ false positives, by Lemma 10. By Lemma 7, each run can be checked in $O(1)$ IOs. ◀

So for a fixed λ, there is no advantage to choosing $\beta = \omega(\lambda)$. On the other hand, $\beta = o(\lambda)$ is suboptimal, because then choosing $\beta' = \lambda' = \beta$ changes a linear factor in the query cost to a logarithmic one. Therefore, it is optimal to choose $\beta = \Theta(\lambda)$, and in what follows we will fix $\beta = \lambda$. Thus,

▶ **Lemma 12.** *A BOA supports N insertions and deletions with amortized per entry cost of $O\left(\left(\lambda + \log_{\frac{M}{B}} N + \log_\lambda N\right)/B\right)$ IOs, for any $\lambda > 1$. A query for a key K costs $O(D_K \log_\lambda N)$ IOs in expectation, where D_K is the duplication count of K.*

4 Refined Bundle of Arrays Hashing

In order to obtain high probability bounds for a BOA, we need a stronger guarantee on the number of false positives. This is achieved by including an additional character, the **check character** from each fingerprint in the routing filter, which is also checked during queries and thus eliminates most false positives. To support this, we will need to refine the routing filter so it can maintain check characters even when there are collisions.

The ith check character $C_i(K)$ of a fingerprint K is the ith character from the end of the string representation of K. As described in Section 2, we assume that the fingerprints are taken from a universe of size at least N^2 so that the check characters do not overlap with the characters used in the prefixes of the routing filters, and by $\Theta(\log N)$-wise independence, the check characters of $O(1)$ fingerprints are independent. Now each fingerprint in the filter has a check character and a array pointer, and we refer to this data as the **sketch** of the fingerprint.

When level i of the BOA is queried for a fingerprint K, the refined routing filter (described below) returns a list of sketches, one for each fingerprint in the level with prefix $P_i(K)$. The array indicated in the sketch is only checked if the check character matches $C_i(K)$, which reduces the number of false positives by a factor of λ.

Refined Routing Filter. The routing filter described in Section 3.1 handles prefix collisions by returning only the last run containing the queried fingerprint and then chaining in the

runs. Whereas, to support check characters, we need to return a list instead, while having the same performance guarantees.

The idea behind the refined routing filter is to keep the prefix-sketch pairs in a sorted list and use a hash table on prefixes to point queries to the appropriate place. Each pointer may require as many as $\Omega(\log N)$ bits, and we require the routing filter to have $O(1)$ characters per fingerprint. Therefore the hash table must use shorter prefixes so as to reduce the number of buckets and thus reduce its footprint. In particular, it uses prefixes which are $\log_\lambda \log_\lambda N$ characters shorter, which we refer to as **pivot prefixes**.

The list delta encodes the prefix for each fingerprint K, together with its sketch. In addition, the first entry following each pivot prefix contains the full prefix, rather then just the difference. Otherwise, when the hash table routes a query to that place in the list, the full prefix wouldn't be immediately computable.

▶ **Lemma 13.** *A refined routing filter can be updated using $O\left(\frac{\lambda \log \lambda}{B \log N}\right)$ IOs per new entry, and performs lookups in $O(D^*_K)$ IOs w.h.p., where D^*_K is the number of times K appears in the level.*

Proof. We prove first the update bound and then the query bound.

Let C be the capacity of the level. There are at most $\frac{C}{\log_\lambda N}$ pivot prefixes. For each pivot prefix, the hash table stores the bit position in a list with at most C entries, where $C \leq N$. Each entry is at most $\log N$ bits, so this position can be written using $O(\log N)$ bits.

For each fingerprint in the node, the list contains $O(1)$ characters by Lemma 6, or $O(\log \lambda)$ bits. Additionally, each pivot prefix has to an initial entry of length $O(\log N)$ bits, so the list all together uses $O(C \log \lambda + \frac{C}{\log_\lambda N} \cdot \log N) = O(C \log \lambda)$ bits.

When the refined routing filter is updated, the old version is read sequentially and the new version is written out sequentially. C/λ fingerprints are added at a time, so this incurs $O\left(\frac{\lambda \log \lambda}{B \log N}\right)$ IOs per entry.

During a query, the pivot bit string of a fingerprint and its successor are accessed from the hash table in $O(1)$ IOs. This returns the beginning and ending bit positions in the list. Because the fingerprints are distributed uniformly and are pairwise independent to K, there are $O(\log_\lambda N + D^*_K)$ fingerprints matching the pivot prefix in expectation. From Lemma 5 with $\delta = \log \lambda$, there are $O(\log N + D^*_K)$ fingerprints matching the pivot prefix w.h.p. The encoding of each fingerprint is less than a word, and $B = \Omega(\log N)$ by assumption, so this is $O(D^*_K)$ IOs. ◀

BOA Performance. We now can show:

▶ **Theorem 2.** *A BOA supports N insertions and deletions with amortized per entry cost of $O\left(\left(\lambda + \log_{\frac{M}{B}} N + \log_\lambda N\right)/B\right)$ IOs, for any $\lambda > 1$. A query for a key K costs $O(D_K \log_\lambda N)$ IOs w.h.p., where D_K is the number of times K has been inserted or deleted.*

Proof. The insertion/deletion cost is given by Lemma 13 and Theorem 12.

During a query for a fingerprint K, the expected number of false positives on level i (fingerprints which match the prefix $P_i(K)$ and check character $C_i(K)$ but are not K) is $O\left(\frac{1}{\lambda}\right)$. Thus, the number of false positives across levels is $O\left(\frac{\log_\lambda N}{\lambda}\right)$, so by Lemma 5, the number of false positives is $O\left(\log_\lambda N\right)$ w.h.p. ◀

Thus, a BOA is optimal for large enough λ:

▶ **Corollary 14.** *Let $\mathcal{B}$ be a BOA with growth factor λ containing N entries. If $\lambda = \Omega\left(\log_{\frac{M}{B}} N + \frac{\log N}{\log \log N}\right)$, then $\mathcal{B}$ is an optimal unsorted dictionary.*

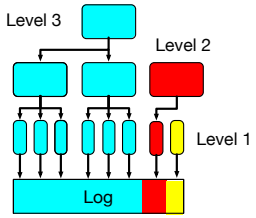

Figure 1 The routing trees in a 3 level BOT. The trees cover contiguous portions of the log. The highest level covers the beginning of the log, the next level the beginning of the remainder of the log, and so on.

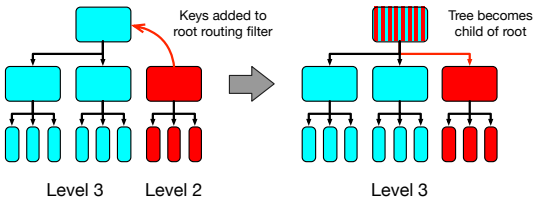

Figure 2 When the routing tree on level i fills, it is merged into the routing tree on level $i+1$. The now-full routing tree from level $i+1$ becomes a child of the root on level $i+1$. Its fingerprints are added to the root routing filter. Note that the tree is not moved.

5 Bundle of Trees Hashing

In order for a BOA to be an optimal dictionary, its growth factor λ must be $\Omega(\log N/\log\log N)$. Otherwise, the cost of insertion is dominated by the cost of merging, which in slow because it effectively sorts the fingerprints using a λ-ary merge sort. In this section, we present the **Bundle of Trees Hash Table** (BOT), which is a BOA-like structure. A BOT stores the fingerprints in a log in the order in which they arrive. Each level of the BOT is like a level of a BOA, where the bundle of arrays on each level is replaced by an search structure on the log (the **routing tree**) and a data structure needed to merge routing trees (the **character queue**). The character queue performs a delayed sort on the characters needed at each level, thus increasing the arity of the sort and decreasing the IOs.

A BOT has $s = \lceil \log_\lambda N/B \rceil$ levels, each of which contains a routing tree. The root of the routing tree has degree less than λ and all internal nodes have degree λ. Each node of a routing tree contains a routing filter. As in Section 4, each routing filter takes as input a fingerprint K and outputs a list of sketches corresponding to fingerprints with the same prefix as K. Each sketch consists of a pointer to a child, a check character and some auxiliary information discussed below.

Each leaf points to a block of B fingerprints in the log. The deepest level s uses a height-s tree to index the beginning of the fingerprint log, the next level then indexes the next section and so forth, as shown in Figure 1. Insertions and deletions (as upsert messages) are appended to the log until they form a block, at which point they are added to the tree in the 1st level of the BOT.

When a level i in the BOT fills, its routing tree is merged into the routing tree of level $i+1$, thus increasing the degree of the target routing tree by 1 (and perhaps filling level $i+1$, which triggers a merge of level $i+1$ into $i+2$, and so on). The merge of level i into level $i+1$ consists of adding the prefix-sketch pairs of the fingerprints from level i to the routing filter of the root on level $i+1$. The child pointers of these pairs will point to the root of the formerly level-i routing tree, so it becomes a child of the root of the level $i+1$ routing tree, although it isn't moved or copied. See Figure 2. In this way, a BOT resembles an LT-LSM, described in Section 2.

In order to add a fingerprint K from level i to the root routing filter on level $i+1$, the prefix $P_{i+1}(K)$ must be known. However, the root routing filter on level i only stores the prefix $P_i(K)$ for each fingerprint K it contains, so that in particular the last character of $P_{i+1}(K)$ is missing. As described in Section 5.2, each level has a character queue, which provides this character, as well as the check characters, in order to merge the routing trees efficiently.

5.1 Queries in a BOT

A query to the BOT for a fingerprint K is performed independently at each level, beginning at the root of each routing tree. When a node is queried, its routing filter returns a list of sketches. The sketches whose check characters match the queried fingerprint indicate to which children the query is passed. This process continues until the query reaches a block of the log, which is then searched in full. In this way queries are "routed" down the tree on each level to the part of log where the fingerprint and its associated value are. Note that as queries descend the routing tree, they may generate false positives which are likewise routed down towards the log.

In this section, we refine routing trees so that they offer two guarantees about false positives. The first is that at each level, the probability that a given false positive is not elinimated is at most $\frac{1}{\lambda}$. The second is that false positives can only be created in the root, so that as the query descends the tree, the number of false positives cannot increase.

During a query to a node of height h for a fingerprint K, the routing filter returns a list of sketches corresponding to fingerprints which match K's prefix. The query only proceeds on those children whose check characters also match the check character $C_h(K)$. Since the characters of the fingerprint are uniformly distributed and $\Theta(\log N)$-wise independent, the check character of each false positive matches with probability $\frac{1}{\lambda}$. Moreover, the characters of each level are non-overlapping, so for fingerprints K, K' the event that $V_h(K) = V_h(K')$ is independent of the event that $V_{h-1}(K) = V_{h-1}(K')$.

To prevent new false positives from being generated when a query passes from a parent to a child, the **next character** of each fingerprint is also kept in its sketch in the routing filter. For a fingerprint K in a node of height h, the next character is just the next character that follows the prefix, $P_h(K)$, so that its prefix in the parent, $P_{h+1}(K)$, can be obtained. A false positive in a child which is not in the parent will not match this next character and can be eliminated.

When there are multiple prefix-matching fingerprints in both a parent and its child, we would like to be able to align the lists returned by the routing filters so that known false positives in the parent (either from check or next characters) can be eliminated in the child. Otherwise the check character in the child of a known false positive in the parent may match the queried fingerprint, and therefore more than $\frac{1}{\lambda}$ of the false positives may survive. To this end, we require the routing filter to return the list of sketches in the order their fingerprint-value pairs appear in the log. Then after the sketches in the child list whose next characters do not match the parent are eliminated, the remaining phrases will be in the same order as in the parent. In this way, known false positives can also be eliminated in the child.

Now we can show:

▶ **Lemma 15.** *During a query to a routing tree, the following are true:*

1. *A false positive can only be generated in the root.*
2. *At each level, a given false positive survives with probability at most* $\frac{1}{\lambda}$.

Proof. Because of the next characters, false positives may only be created in the root of the routing tree. Each false positive in the root corresponds to a fingerprint K' in the level. At each node on the path to K''s location in the log, we use the ordering to determine which returned sketch corresponds to K', so that the false positive corresponding to K' is eliminated with probability $\frac{1}{\lambda}$. ◀

5.2 Character Queue

The purpose of the character queue is to store all the sketches of fingerprints contained in a level i that will be needed during a merge in the future. When level i is merged into level $i+1$, the character queue outputs a sorted list of the delta-encoded prefix-sketch pairs of all the fingerprints, which is used to update the root routing tree. The character queue is then merged into the character queue on level $i+1$.

The character queue effectively performs a merge sort on the sketches. If it were to merge all the sketches as soon as they are available, this would consist of λ-ary merges. In order to increase the arity of the merges, it defers merging sketches which are not needed immediately. The sketches are stored collection of **series**, by which we mean a collection of sorted runs. Each series stores a continuous range of sketches $S_i(K), S_{i+1}(K), \ldots, S_{i+j}(K)$ for each fingerprint K, together with the prefix up to the first sketch, $P_{i-1}(K)$. These prefixes are delta encoded in their run. Thus the size of an entry is determined by the number of sketches in the range and the length of the prefix relative to the size of the run (by Lemma 6).

The character queue tradeoff. We are faced with the following tradeoff. If the character queue merges a series frequently, the delta encoding is more efficient, which decreases the cost of the merging. However the arity is lower, which increases it. The character queue uses a merging schedule which balances this tradeoff and thus achieves optimal insertions.

The character queue merging schedule. The character queue on level i (here we consider blocks of the log to be level 0) contains the sketches $S_{i+1}(K), S_{i+2}(K), \ldots S_s(K)$ of each fingerprint K in the level. These characters are stored in a collection of series $\{\sigma_{j_q}\}$, where j_q is the smallest multiple of 2^q greater than i. Series σ_{j_q} contains the sketches $S_{j_q}(K), \ldots, S_{j_{q+1}-1}(K)$. Each series consists of a collection of sorted runs each of which stores the delta encoded prefix of each fingerprint together with its sketches.

Initially, when a block of the log is written, all the series σ_{2^q} for $q = 1, 2, 3, \ldots$ are created. When level i fills, the runs in the series σ_{i+1} are merged, and the character queue outputs the delta encoded prefix-sketch pairs, $(P_{i+1}(K), S_{i+1}(K))$ to update the root routing filter on level $i+1$. If $2^{\rho(i+q)}$ is the greatest power of 2 dividing $i+1$ (ρ is sometimes referred to as the **ruler function** [15]), then σ_{i+1} also contains the next $2^{\rho(i+1)}-1$ sketches of each fingerprint. These are batched and delta encoded to become runs in the series σ_{j_q} for $q = [0, \rho(i+1)]$. The runs in the remaining series of level i becomes runs of their respective series on level $i+1$.

Note that for the lower levels, some runs in may be shorter than B due to the delta encoding. For a run in a series σ_q, this is handled by buffering them with the runs σ_q of higher levels and writing them out once they are of size B. Note that this requires $O(B \log\log N)$ memory.

This leads to the following merging pattern: σ_j batches $2^{\rho(j)}$ sketches, and has delta encoded prefixes of $2^{\rho(j)}$ characters on average, by Lemma 6. Therefore,

▶ **Lemma 16.** *A series σ_j in a character queue contains $O(2^{\rho(j)})$ characters per fingerprint.*

This leads to a merging schedule where the characters per item merged on the jth level is $O(2^{\rho(j)})$. Starting from 1 this is $1, 2, 1, 4, 1, 2, 1, 8, 1, 2, 1, 4, 1, 2, 1, 16, \ldots$, which resemble the tick marks of a ruler, hence the name ruler function.

We now analyze the cost of maintaining the character queues.

▶ **Lemma 17.** *The total per-insertion/deletion cost to update the character queues in a BOT is $\Theta\left(\frac{1}{B}\left(\log_{\frac{M}{B}} N + \log\log M\right)\right)$.*

Proof. When σ_j is merged, $\lambda^{2^{\rho(j)}}$ runs are merged, which has a cost of $O\left(\frac{2^{\rho(j)}}{B}\left\lceil \log_{M/B}\left(\lambda^{2^{\rho(j)}}\right)\right\rceil\right)$ characters per fingerprint.

There are $\log_\lambda \frac{N}{B} = O(\log_\lambda N)$ levels, so this leads to the following total cost in terms of characters:

$$\begin{aligned} O\left(\sum_{i=1}^{\log_\lambda N} 2^{\rho(j)}\left\lceil \log_{\frac{M}{B}}\left(\lambda^{2^{\rho(j)}}\right)\right\rceil\right) &= O\left(\sum_{k=0}^{\log\log_\lambda N} \frac{\log_\lambda N}{2^k}\cdot 2^k\left\lceil \log_{\frac{M}{B}}\left(\lambda^{2^k}\right)\right\rceil\right) \\ &= O\left(\log_\lambda N\left(\log\log M + \sum_{k=\log\log M}^{\log\log_\lambda N} 2^k \log_{\frac{M}{B}}\lambda\right)\right) \\ &= O\left(\log_\lambda N\left(\log\log M + \log_{\frac{M}{B}} N\right)\right), \end{aligned}$$

where the last equality is because the RHS sum is dominated by its last term. Because there are $\log_\lambda N$ characters in a word, and all reads and writes are performed sequentially in runs of size at lease B, the result follows. ◀

5.3 Performance of the BOT

We can now prove Theorem 3:

▶ **Theorem 3.** *A BOT supports N insertions and deletions with amortized per entry cost of $O\left(\left(\lambda + \log_{\frac{M}{B}} N + \log\log M\right)/B\right)$ IOs for any $\lambda > 1$. A query for a key K costs $O(D_K \log_\lambda N)$ IOs w.h.p., where D_K is the number of times K has been inserted or deleted.*

Proof. By Lemma 13, the cost of updating the routing filters is $O\left(\frac{\lambda}{B}\right)$, since there are $O(\log_\lambda N)$ levels. This, together with the cost of updating the character queues, given by Lemma 17, is the insertion cost.

By Lemma 15, a query for fingerprint K on level i incurs $O\left(\frac{1}{\lambda}\right)$ false positives in the root, and $O(1)$ nodes are accessed along each of their root-to-leaf paths. By Lemma 13, each false positive thus incurs $O(D_K)$ IOs.

There are an expected $O\left(\frac{\log_\lambda N}{\lambda}\right)$ false positives across all levels, so, using Lemma 5 with $\delta = \lambda$, $O(D_K \log_\lambda N)$ nodes are accessed due to false positives w.h.p. For each time K appears in the BOT, $O(\log_\lambda N)$ nodes are accessed on its root-to-leaf path. By Lemma 13 the node accesses along each path incur $O(D_K \log_\lambda)$ IOs w.h.p., so accessing the nodes incurs $O(\log_\lambda N)$ IOs w.h.p.

A block of the log is scanned at most D_K times for true positives and also whenever a false positive from the level-i root survives i times. The expected number of such false positives for level i is $1/\lambda^i$, so the expected number across levels is $O\left(\frac{1}{\lambda}\right)$. Therefore by Lemma 5, the number of blocks scanned is $O(D_K \log_\lambda N)$ w.h.p. ◀

▶ **Corollary 18.** *Let $\mathcal{B}$ be a BOT with growth factor λ containing N entries. If $\lambda = \Omega\left(\log_{\frac{M}{B}} N + \log\log M\right)$, then $\mathcal{B}$ is an optimal dictionary.*

6 Cache-Oblivious BOTs

In this section, we show how to modify a BOT to be cache oblivious. We call the resulting structure a cache-oblivious hash tree (COBOT).

Much of the structure of the BOT translates directly into the cache-oblivious model. However, some changes are necessary. In particular, when the series of character queues are merged, this merge must be performed cache-obliviously using funnels [10], rather than with an (up to) M/B-way merge. Also, the log cannot be buffered into sections of size $O(B)$, and so instead they are buffered into sections of constant size, items are immediately added to routing filter, and the extra IOs are eliminated by optimal caching.

When an insertion is made into a COBOT, its fingerprint-value pair is appended to the log, and it is immediately inserted into level 1. Thus, the leaves of the routing trees point to single entries in the log.

The series of the character queues must be placed more carefully as well. In particular the runs of series σ_j must be laid out back-to-back for all j (rather than just small j as in Section 5.2), so that the caching algorithm can buffer them appropriately.

The series are merged using a **partial funnelsort**. Funnelsort is a cache-oblivious sorting algorithm that makes use of K-funnels [10]. A K-funnel is a CO data structure that merges K sorted lists of total length N. We make use of the the following lemma.

▶ **Lemma 19** ([10]). *A K-funnel merges K sorted lists of total length $N \geq K^3$ in $O\left(\frac{N}{B}\log_{M/B}\frac{N}{B} + K + \frac{N}{B}\log_K\frac{N}{B}\right)$ IOs, provided the tall cache assumption that $M = \Omega(B^2)$ holds.*

The partial funnelsort used to merge K runs of a series with total length L (in words) performs a single merge with a K-funnel if $L \geq K^3$ and recursively merges the run in groups of $K^{1/3}$ runs otherwise.

▶ **Corollary 20.** *A partial funnelsort merges K runs of total word length L in $O\left(\frac{L}{B}\log_{M/B}\frac{L}{B} + \frac{L}{B}\log_K\frac{L}{B}\right)$ IOs, provided the tall cache assumption that $M = \Omega(B^2)$ holds.*

Proof. The base case of the recursion occurs either when there is only 1 list remaining or the remaining lists fit in memory. In any other case of the recursion, since $L = \Omega(B^2)$ by the tall cache assumption, the K term in Lemma 19 is dominated.

The recurrence is dominated by the cost of the funnel merges, which yields the result. ◀

▶ **Theorem 21.** *If $M = \Omega(B^2)$, then a COBOT with N entries and growth factor λ has amortized insertion/deletion cost $\Theta\left(\frac{1}{B}\left(\lambda + \log\log M + \log_{M/B} N/B\right)\right)$. A query for key K has cost $\Theta\left(D_K \log_\lambda N\right)$, w.h.p., where D_K is the duplication count of K.*

Proof. We may assume that the caching algorithm sets aside enough memory that the last B items in the log, together with the subtree rooted at their least common ancestor, are cached. Thus the log is updated at a per-item cost of $O(1/B)$.

The proof of Theorem 3 now carries over to the COBOT. The routing filters are updated the same way, and the cost of updating the character queues is unchanged, by Corollary 20.

Queries are performed as in Section 5.1, except that now the level 1 nodes cover $O(1)$ fingerprints, but the depth of the tree is unchanged, so the cost is the same. ◀

Abstract

In this paper, we relate a beautiful theory by Lovász with a popular heuristic algorithm for the graph isomorphism problem, namely the color refinement algorithm and its k-dimensional generalization known as the Weisfeiler-Leman algorithm. We prove that two graphs G and H are indistinguishable by the color refinement algorithm if and only if, for all trees T, the number $\mathsf{Hom}(T, G)$ of homomorphisms from T to G equals the corresponding number $\mathsf{Hom}(T, H)$ for H.

There is a natural system of linear equations whose nonnegative integer solutions correspond to the isomorphisms between two graphs. The nonnegative real solutions to this system are called fractional isomorphisms, and two graphs are fractionally isomorphic if and only if the color refinement algorithm cannot distinguish them (Tinhofer 1986, 1991). We show that, if we drop the nonnegativity constraints, that is, if we look for arbitrary real solutions, then a solution to the linear system exists if and only if, for all t, the two graphs have the same number of length-t walks.

We lift the results for trees to an equivalence between numbers of homomorphisms from graphs of tree width k, the k-dimensional Weisfeiler-Leman algorithm, and the level-k Sherali-Adams relaxation of our linear program. We also obtain a partial result for graphs of bounded path width and solutions to our system where we drop the nonnegativity constraints.

A consequence of our results is a quasi-linear time algorithm to decide whether, for two given graphs G and H, there is a tree T with $\mathsf{Hom}(T, G) \neq \mathsf{Hom}(T, H)$.

1 Introduction

An old result due to Lovász [16] states a graph G can be characterized by counting homomorphisms from all graphs F to G. That is, two graphs G and H are isomorphic if and only if, for all F, the number $\mathsf{Hom}(F, G)$ of homomorphisms from F to G equals the number $\mathsf{Hom}(F, H)$ of homomorphism from F to H. This simple result has far reaching consequences,

because mapping graphs G to their *homomorphism vectors* $\mathsf{HOM}(G) := \big(\mathsf{Hom}(F,G)\big)_{F \text{ graph}}$ (or suitably scaled versions of these infinite vectors) allows us to apply tools from functional analysis in graph theory. This is the foundation of the beautiful theory of graph limits, developed by Lovász and others over the last 15 years (see [17]).

However, from a computational perspective, representing graphs by their homomorphism vectors has the disadvantage that the problem of computing the entries of these vectors is NP-complete. To avoid this difficulty, we may want to restrict the homomorphism vectors to entries from a class of graphs for which counting homomorphisms is tractable. That is, instead of considering the full homomorphism vector $\mathsf{HOM}(G)$ we consider the vector $\mathsf{HOM}_{\mathcal{F}}(G) := \big(\mathsf{Hom}(F,G)\big)_{F\in\mathcal{F}}$ for a class $\mathcal{F}$ of graphs such that the problem of computing $\mathsf{Hom}(F,G)$ for given graphs $F \in \mathcal{F}$ and G is in polynomial time. Arguably the most natural example of such a class $\mathcal{F}$ is the class of all trees. More generally, computing $\mathsf{Hom}(F,G)$ for given graphs $F \in \mathcal{F}$ and G is in polynomial time for all classes $\mathcal{F}$ of bounded tree width, and under a natural assumption from parameterized complexity theory, it is not in polynomial time for any class $\mathcal{F}$ of unbounded tree width [10]. This immediately raises the question what the vector $\mathsf{HOM}_{\mathcal{F}}(G)$, for a class $\mathcal{F}$ of bounded tree width, tells us about the graph G.

A first nice example (Proposition 9) is that the vector $\mathsf{HOM}_{\mathcal{C}}(G)$ for the class $\mathcal{C}$ of all cycles characterizes the spectrum of a graph, that is, for graphs G, H we have $\mathsf{HOM}_{\mathcal{C}}(G) = \mathsf{HOM}_{\mathcal{C}}(H)$ if and only if the adjacency matrices of G and H have the same eigenvalues with the same multiplicities. This equivalence is a basic observation in spectral graph theory (see [23, Lemma 1]). Before we state deeper results along these lines, let us describe a different (though related) motivation for this research.

Determining the similarity between two graphs is an important problem with many applications, mainly in machine learning, where it is known as "graph matching" (e.g. [9]). But how can the similarity between graphs be measured? An obvious idea is to use the *edit distance*, which simply counts how many edges and vertices have to be deleted from or added to one graph to obtain the other. However, two graphs that have a small edit distance can nevertheless be structurally quite dissimilar (e.g. [17, Section 1.5.1]). The edit distance is also very hard to compute as it is closely related to the notoriously difficult quadratic assignment problem (e.g. [3, 19]).

Homomorphism vectors offer an alternative, more structurally oriented approach to measuring graph similarity. After suitably scaling the vectors, we can can compare them using standard vector norms. This idea is reminiscent of the "graph kernels" used in machine learning (e.g. [24]). Like the homomorphism vectors, many graph kernels are based on the idea of counting certain patterns in graphs, such as paths, walks, cycles or subtrees, and in fact any inner product on the homomorphism vectors yields a graph kernel.

A slightly different type of graph kernel is the so-called Weisfeiler-Leman (subtree) kernel [20]. This kernel is derived from the *color refinement* algorithm (a.k.a. the *1-dimensional Weisfeiler-Leman algorithm*), which is a simple and efficient heuristic to test whether two graphs are isomorphic (e.g. [11]). The algorithm computes a coloring of the vertices of a graph based on the iterated degree sequences, we give the details in Section 3. To use it as an isomorphism test, we compare the color patterns of two graphs. If they are different, we say that color refinement *distinguishes* the graphs. If the color patterns of the two graphs turn out to be the same, the graphs may still be non-isomorphic, but the algorithm fails to detect this.

Whether color refinement is able to distinguish two graphs G and H has a very nice linear-algebraic characterization due to Tinhofer [21, 22]. Let V and W be the vertex sets and let $A \in \{0,1\}^{V\times V}$ and $B \in \{0,1\}^{W\times W}$ be the adjacency matrices of G and H, respectively.

Now consider the system $\mathsf{F}_{\text{iso}}(G,H)$ of linear equations:

$$\mathsf{F}_{\text{iso}}(G,H): \quad \begin{cases} AX = XB & \text{(F1)} \\ X\mathbf{1}_W = \mathbf{1}_V & \text{(F2)} \\ \mathbf{1}_V^T X = \mathbf{1}_W^T & \text{(F3)} \end{cases}$$

In these equations, X denotes a $(V \times W)$-matrix of variables and $\mathbf{1}_U$ denotes the all-1 vector over the index set U. Equations (F2) and (F3) simply state that all row and column sums of X are supposed to be 1. Thus the nonnegative integer solutions to $\mathsf{F}_{\text{iso}}(G,H)$ are permutation matrices, which due to (F1) describe isomorphisms between G and H. The nonnegative real solutions to $\mathsf{F}_{\text{iso}}(G,H)$, which in fact are always rational, are called *fractional isomorphisms* between G and H. Tinhofer proved that two graphs are fractionally isomorphic if and only if color refinement does not distinguish them.

For every $k \geq 2$, color refinement has a generalization, known as the *k-dimensional Weisfeiler-Leman algorithm (k-WL)*, which colors not the vertices of the given graph but k-tuples of vertices. Atserias and Maneva [4] (also see [18]) generalized Tinhofer's theorem by establishing a close correspondence between k-WL and the level-k Sherali-Adams relaxation of $\mathsf{F}_{\text{iso}}(G,H)$.

Our results

How expressive are homomorphism vectors $\mathsf{HOM}_{\mathcal{F}}(G)$ for restricted graph classes $\mathcal{F}$? We consider the class $\mathcal{T}$ of trees first, where the answer is surprisingly clean.

▶ **Theorem 1.** *For all graphs G and H, the following are equivalent:*

i $\mathsf{HOM}_{\mathcal{T}}(G) = \mathsf{HOM}_{\mathcal{T}}(H)$.
ii *Color refinement does not distinguish G and H.*
iii *G and H are fractionally isomorphic, that is, the system $\mathsf{F}_{\text{iso}}(G,H)$ of linear equations has a nonnegative real solution.*

As mentioned before, the equivalence between ii and iii is due to Tinhofer [21, 22]. An unexpected consequence of our theorem is that we can decide in time $O((n+m)\log n)$ whether $\mathsf{HOM}_{\mathcal{T}}(G) = \mathsf{HOM}_{\mathcal{T}}(H)$ holds for two given graphs G and H with n vertices and m edges. (If two graphs have a different number of vertices or edges, then their homomorphism counts already differ on the 1-vertex or 2-vertex trees.) This is remarkable, because every known algorithm for computing the entry $\mathsf{Hom}(T,G)$ of the vector $\mathsf{HOM}_{\mathcal{T}}(G)$ requires quadratic time when T and G are given as input.

It is a consequence of the proof of Theorem 1 that, in order to characterize an n-vertex graph G up to fractional isomorphisms, it suffices to restrict the homomorphism vector $\mathsf{HOM}_{\mathcal{T}}(G)$ to trees of height at most $n-1$. What happens if we restrict the structure of trees even further? In particular, let us restrict the homomorphism vector to its path entries, that is, consider $\mathsf{HOM}_{\mathcal{P}}(G)$ for the class $\mathcal{P}$ of all paths. Figure 1 shows an example of two graphs G and H with $\mathsf{HOM}_{\mathcal{P}}(G) = \mathsf{HOM}_{\mathcal{P}}(H)$ and $\mathsf{HOM}_{\mathcal{T}}(G) \neq \mathsf{HOM}_{\mathcal{T}}(H)$.

Despite their weaker distinguishing capabilities, the vectors $\mathsf{HOM}_{\mathcal{P}}(G)$ are quite interesting. They are related to graph kernels based on counting walks, and they have a clean algebraic description: it is easy to see that $\mathsf{Hom}(P_k,G)$, the number of homomorphisms from the path P_k of length k to G, is equal to the number of length-k walks in G, which in turn is equal to $\mathbf{1}^T A^k \mathbf{1}$, where A is the adjacency matrix of G and $\mathbf{1}$ is the all-1 vector of appropriate length.

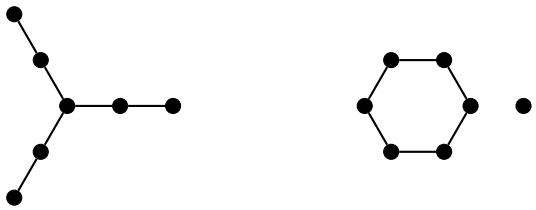

Figure 1 Two fractionally non-isomorphic graphs with the same path homomorphism counts.

▶ **Theorem 2.** *For all graphs G and H, the following are equivalent:*

i $\mathsf{HOM}_{\mathcal{P}}(G) = \mathsf{HOM}_{\mathcal{P}}(H)$.

ii *The system $\mathsf{F}_{\text{iso}}(G,H)$ of linear equations has a real solution.*

While the proof of Theorem 1 is mainly graph-theoretic—we establish the equivalence between the assertions i and ii by expressing the "colors" of color refinement in terms of specific tree homomorphisms—the proof of Theorem 2 is purely algebraic. We use spectral techniques, but with a twist, because neither does the spectrum of a graph G determine the vector $\mathsf{HOM}_{\mathcal{P}}(G)$ nor does the vector determine the spectrum. This is in contrast with $\mathsf{HOM}_{\mathcal{C}}(G)$ for the class $\mathcal{C}$ of all cycles, which, as we already mentioned, distinguishes two graphs if and only if they have the same spectrum.

Let us now turn to homomorphism vectors $\mathsf{HOM}_{\mathcal{T}_k}(G)$ for the class $\mathcal{T}_k$ of all graphs of tree width at most k. We will relate these to k-WL, the k-dimensional generalization of color refinement. We also obtain a corresponding system of linear equations. Let G and H be graphs with vertex sets V and W, respectively. Instead of variables X_{vw} for vertex pairs $(v,w) \in V \times W$, as in the system $\mathsf{F}_{\text{iso}}(G,H)$, the new system has variables X_π for $\pi \subseteq V \times W$ of size $|\pi| \leq k$. We call $\pi = \{(v_1,w_1),\dots,(v_\ell,w_\ell)\} \subseteq V \times W$ a *partial bijection* if $v_i = v_j \iff w_i = w_j$ holds for all i,j, and we call it a *partial isomorphism* if in addition $v_iv_j \in E(G) \iff w_iw_j \in E(H)$ holds for all i,j. Now consider the following system $\mathsf{L}^k_{\text{iso}}(G,H)$ of linear equations:

$$\mathsf{L}^k_{\text{iso}}(G,H): \begin{cases} \displaystyle\sum_{v\in V} X_{\pi\cup\{(v,w)\}} = X_\pi & \text{for all } \pi \subseteq V\times W \text{ of size } |\pi| \leq k-1 \text{ and all } w \in W \quad \text{(L1)} \\ \displaystyle\sum_{w\in W} X_{\pi\cup\{(v,w)\}} = X_\pi & \text{for all } \pi \subseteq V\times W \text{ of size } |\pi| \leq k-1 \text{ and all } v \in V \quad \text{(L2)} \\ X_\pi = 0 & \text{for all } \pi \subseteq V\times W \text{ of size } |\pi| \leq k \text{ such that } \pi \text{ is not a partial isomorphism from } G \text{ to } H \quad \text{(L3)} \\ X_\emptyset = 1 & \quad \text{(L4)} \end{cases}$$

This system is closely related to the Sherali-Adams relaxations of $\mathsf{F}_{\text{iso}}(G,H)$: Every solution for the level-k Sherali-Adams relaxation of $\mathsf{F}_{\text{iso}}(G,H)$ yields a solution to $\mathsf{L}^k_{\text{iso}}(G,H)$, and every solution to $\mathsf{L}^k_{\text{iso}}(G,H)$ yields a solution to the level $k-1$ Sherali-Adams relaxation of $\mathsf{F}_{\text{iso}}(G,H)$ [4, 12]. Our result is this:

▶ **Theorem 3.** *For all $k \geq 1$ and for all graphs G and H, the following are equivalent:*

i $\mathsf{HOM}_{\mathcal{T}_k}(G) = \mathsf{HOM}_{\mathcal{T}_k}(H)$.

ii *k-WL does not distinguish G and H.*

iii $\mathsf{L}^{k+1}_{\text{iso}}(G,H)$ *has a nonnegative real solution.*

The equivalence between ii and iii is implicit in previous work [14, 4, 12]. The system $\mathsf{L}^k_{\mathrm{iso}}(G,H)$ has another nice interpretation related to the proof complexity of graph isomorphism: it is shown in [7] that $\mathsf{L}^k_{\mathrm{iso}}(G,H)$ has a real solution if and only if a natural system of polynomial equations encoding the isomorphisms between G and H has a degree-k solution in the Hilbert Nullstellensatz proof system [6, 8]. In view of Theorem 2, it is tempting to conjecture that the solvability of $\mathsf{L}^{k+1}_{\mathrm{iso}}(G,H)$ characterizes the expressiveness of the homomorphism vectors $\mathsf{HOM}_{\mathcal{P}_k}(G)$ for the class $\mathcal{P}_k$ of all graphs of path width k. Unfortunately, we only prove one direction of this conjecture.

▶ **Theorem 4.** *Let k be an integer with $k \geq 2$ and let G, H be graphs. If $\mathsf{L}^{k+1}_{\mathrm{iso}}(G,H)$ has a real solution, then $\mathsf{HOM}_{\mathcal{P}_k}(G) = \mathsf{HOM}_{\mathcal{P}_k}(H)$.*

Combining this theorem with a recent result from [13] separating the nonnegative from arbitrary real solutions of our systems of equations, we obtain the following corollary.

▶ **Corollary 5.** *For every k, there are graphs G and H with $\mathsf{HOM}_{\mathcal{P}_k}(G) = \mathsf{HOM}_{\mathcal{P}_k}(H)$ and $\mathsf{HOM}_{\mathcal{T}_2}(G) \neq \mathsf{HOM}_{\mathcal{T}_2}(H)$.*

2 Preliminaries

Basics. Graphs in this paper are simple, undirected, and finite (even though our results transfer to directed graphs and even to weighted graphs). For a graph G, we write $V(G)$ for its vertex set and $E(G)$ for its edge set. For $v \in V(G)$, the set of neighbors of v are denoted with $N_G(v)$. For $S \subseteq V(G)$, we denote with $G[S]$ the subgraph of G induced by the vertices of S. A *rooted graph* is a graph G together with a designated root vertex $r(G) \in V(G)$. We write multisets using the notation $\{\!\{1,1,6,2\}\!\}$.

Matrices. An LU-decomposition of a matrix A consists of a lower triangular matrix L and an upper triangular matrix U such that $A = LU$ holds. Every finite matrix A over $\mathbf{R}$ has an LU-decomposition. We also use *infinite matrices* over $\mathbf{R}$, which are functions $A : I \times J \to \mathbf{R}$ where I and J are locally finite posets and countable. The matrix product AB is defined in the natural way via $(AB)_{ij} = \sum_k A_{ik}B_{kj}$ if all of these inner products are finite sums, and otherwise we leave it undefined. An $n \times n$ real symmetric matrix has real eigenvalues and a corresponding set of orthogonal eigenspaces. The spectral decomposition of a real symmetric matrix M is of the form $M = \lambda_1 P_1 + \cdots + \lambda_l P_l$ where $\lambda_1, \ldots, \lambda_l$ are the eigenvalues of M with corresponding eigenspaces $W_1, \ldots, W_l$. Moreover, each P_j is the projection matrix corresponding to the projection onto the eigenspace W_j. Usually, P_j is expressed as $P_j = UU^T$ for a matrix U whose columns form an orthonormal basis of W_j.

Homomorphism numbers. Recall that a mapping $h : V(F) \to V(G)$ is a homomorphism if $h(e) \in E(G)$ holds for all $e \in E(F)$ and that $\mathsf{Hom}(F,G)$ is the number of homomorphisms from F to G. Let $\mathsf{Surj}(F,G)$ be the number of homomorphisms from F to G that are surjective on both the vertices and edges of G. Let $\mathsf{Inj}(F,G)$ be the number of injective homomorphisms from F to G. Let $\mathsf{Sub}(F,G) = \mathsf{Inj}(F,G)/\mathsf{Aut}(F)$, where $\mathsf{Aut}(F)$ is the number of automorphisms of F. Observe that $\mathsf{Sub}(F,G)$ is the number of subgraphs of G that are isomorphic to F. Where convenient, we view the objects Hom, Surj, and Inj as infinite matrices; the matrix indices are all unlabeled graphs, sorted by their size. However, we only use one representative of each isomorphism class, called the *isomorphism type* of the graphs in the class, as an index in the matrix. Then Surj is lower triangular and Inj is upper triangular, so $\mathsf{Hom} = \mathsf{Surj} \cdot \mathsf{Sub}$ is an LU-decomposition of Hom. Finally, $\mathsf{Ind}(F,G)$ is

the number of times F occurs as an induced subgraph in G. Similarly to the homomorphism vectors $\mathsf{HOM}_{\mathcal{F}}(G)$ we define vectors $\mathsf{INJ}_{\mathcal{F}}(G)$ and $\mathsf{IND}_{\mathcal{F}}(G)$. Finally, let G, H be rooted graphs. A homomorphism from G to H is a graph homomorphism that maps the root of G to the root of H. Moreover, two rooted graphs are isomorphic if there is an isomorphism mapping the root to the root.

3 Homomorphisms from trees

3.1 Color refinement and tree unfolding

Color refinement iteratively colors the vertices of a graph in a sequence of *refinement rounds*. Initially, all vertices get the same color. In each refinement round, any two vertices v and w that still have the same color get different colors if there is some color c such that v and w have a different number of neighbors of color c; otherwise they keep the same color. We stop the refinement process if the vertex partition that is induced by the colors does not change anymore, that is, all pairs of vertices that have the same color before the refinement round still have the same color after the round. More formally, we define the sequence $C_0^G, C_1^G, C_2^G, \dots$ of colorings as follows. We let $C_0^G(v) = 1$ for all $v \in V(G)$, and for $i \geq 0$ we let $C_{i+1}^G(v) = \{\!\{ C_i^G(u) : u \in N_G(v) \}\!\}$. We say that color refinement *distinguishes* two graphs G and H if there is an $i \geq 0$ with

$$\{\!\{ C_i^G(v) : v \in V(G) \}\!\} \neq \{\!\{ C_i^H(v) : v \in V(H) \}\!\}. \tag{1}$$

We argue now that the color refinement algorithm implicitly constructs a tree at v obtained by simultaneously taking all possible walks starting at v (and not remembering nodes visited in the past). For a rooted tree T with root r, a graph G, and a vertex $v \in V(G)$, we say that T is *a tree at* v if there is a homomorphism f from T to G such that $f(r) = v$ and, for all non-leaves $t \in V(T)$, the function f induces a bijection between the set of children of t in in T and the set of neighbors of $f(t)$ in G. In other words, f is a homomorphism from T to G that is *locally bijective*. If T is an infinite tree at v and does not have any leaves, then T is uniquely determined up to isomorphisms, and we call this *the infinite tree at* v (or the *tree unfolding* of G at v), denoted with $T(G, v)$. For an infinite rooted tree T, let $T_{\leq d}$ be the finite rooted subtree of T where all leaves are at depth exactly d. For all finite trees T of depth d, define $\mathsf{Cr}(T, G) \in \{0, \dots, |V(G)|\}$ to be the number of vertices $v \in V(G)$ for which T is isomorphic to $T(G, v)_{\leq d}$. Note that this number is zero if not all leaves of T are at the same depth d or if some node of T has more than $n - 1$ children. The CR-vector of G is the vector $\mathsf{CR}(G) = (\mathsf{Cr}(T, G))_{T \in \mathcal{T}_r}$, where $\mathcal{T}_r$ denotes the family of all rooted trees. The following connection between the color refinement algorithm and the CR-vector is known.

▶ **Lemma 6** (Angluin [2], also see Krebs and Verbitsky [15, Lemma 2.5])**.** *For all graphs G and H, color refinement distinguishes G and H if and only if $\mathsf{CR}(G) \neq \mathsf{CR}(H)$ holds.*

3.2 Proof of Theorem 1

Throughout this section, we work with rooted trees. For a rooted tree T and an (unrooted) graph G, we simply let $\mathsf{Hom}(T, G)$ be the number of homomorphisms of the plain tree underlying T to G, ignoring the root.

Let T and T' be rooted trees. A homomorphism h from T to T' is *depth-preserving* if, for all vertices $v \in V(T)$, the depth of v in T is equal to the depth of $h(v)$ in T'. Moreover, a homomorphism h from T to T' is *depth-surjective* if the image of T under h contains vertices

at every depth present in T'. We define $\overrightarrow{\mathsf{Hom}}(T,T')$ as the number of homomorphisms from T to T' that are both depth-preserving and depth-surjective. Note that $\overrightarrow{\mathsf{Hom}}(T,T') = 0$ holds if and only if T and T' have different depths.

▶ **Lemma 7.** *Let T be a rooted tree and let G be a graph. We have*

$$\mathsf{Hom}(T,G) = \sum_{T'} \overrightarrow{\mathsf{Hom}}(T,T') \cdot \mathsf{Cr}(T',G)\,, \tag{2}$$

where the sum is over all unlabeled rooted trees T'. In other words, the matrix identity $\mathsf{Hom} = \overrightarrow{\mathsf{Hom}} \cdot \mathsf{Cr}$ holds.

Proof. Let d be the depth of T and let r be the root of T. Every T' with $\overrightarrow{\mathsf{Hom}}(T,T') \neq 0$ has depth d too and there are at most n non-isomorphic rooted trees T' of depth d with $\mathsf{Cr}(T',G) \neq 0$. Thus the sum in (2) has only finitely many non-zero terms and is well-defined.

For a rooted tree T' and a vertex $v \in V(G)$, let $H(T',v)$ be the set of all homomorphisms h from T to G such that $h(r) = v$ holds and the tree unfolding $T(G,v)_{\leq d}$ is isomorphic to T'. Let $H(T') = \bigcup_{v \in V(G)} H(T',v)$ and observe $|H(T',v)| = \overrightarrow{\mathsf{Hom}}(T,T')$. Since $\mathsf{Cr}(T',G)$ is the number of $v \in V(G)$ with $T(G,v)_{\leq d} \cong T'$, we thus have $|H(T')| = \overrightarrow{\mathsf{Hom}}(T,T') \cdot \mathsf{Cr}(T',G)$. Since each homomorphism from T to G is contained in exactly one set $H(T')$, we obtain the desired equality (2). ◀

For rooted trees T and T', let $\overrightarrow{\mathsf{Surj}}(T,T')$ be the number of depth-preserving and surjective homomorphisms from T to T'. In particular, not only do these homomorphisms have to be depth-surjective, but they should hit every vertex of T'. For rooted trees T and T' of the same depth, let $\overrightarrow{\mathsf{Sub}}(T,T')$ be the number of subgraphs of T' that are isomorphic to T (under an isomorphism that maps the root to the root); if T and T' have different depths, we set $\overrightarrow{\mathsf{Sub}}(T,T') = 0$.

▶ **Lemma 8.** $\overrightarrow{\mathsf{Hom}} = \overrightarrow{\mathsf{Surj}} \cdot \overrightarrow{\mathsf{Sub}}$ *is an LU-decomposition of* $\overrightarrow{\mathsf{Hom}}$*, and* $\overrightarrow{\mathsf{Surj}}$ *and* $\overrightarrow{\mathsf{Sub}}$ *are invertible.*

As is the case for finite matrices, the inverse of a lower (upper) triangular matrix is lower (upper) triangular. As the matrix $\overrightarrow{\mathsf{Surj}}$ is lower triangular and the matrix $\overrightarrow{\mathsf{Sub}}$ is upper triangular, their inverses are as well. We are ready to prove our first main theorem.

Proof of Theorem 1. We only need to prove the equivalence between assertions i and ii. For every graph G, let $\mathsf{HOM}_r(G) := \big(\mathsf{Hom}(T,G)\big)_{T \in \mathcal{T}_r}$. By our convention that for a rooted tree T and an unrooted graph G we let $\mathsf{Hom}(T,G)$ be the number of homomorphisms of the plain tree underlying T to G, for all G and H we have $\mathsf{HOM}_r(G) = \mathsf{HOM}_r(H) \iff \mathsf{HOM}(G) = \mathsf{HOM}(H)$. By Lemma 6, it suffices to prove for all graph G, H that

$$\mathsf{CR}(G) = \mathsf{CR}(H) \iff \mathsf{HOM}_r(G) = \mathsf{HOM}_r(H)\,. \tag{3}$$

We view the vectors $\mathsf{HOM}_r(G)$ and $\mathsf{CR}(G)$ as infinite column vectors. By Lemma 7, we have

$$\mathsf{HOM}_r(G) = \overrightarrow{\mathsf{Hom}} \cdot \mathsf{CR}(G) \text{ and } \mathsf{HOM}_r(H) = \overrightarrow{\mathsf{Hom}} \cdot \mathsf{CR}(H)\,. \tag{4}$$

The forward direction of (3) now follows immediately.

It remains to prove the backward direction. Since $\overrightarrow{\mathsf{Hom}} = \overrightarrow{\mathsf{Surj}} \cdot \overrightarrow{\mathsf{Sub}}$ holds by Lemma 8 for two invertible matrices $\overrightarrow{\mathsf{Surj}}$ and $\overrightarrow{\mathsf{Sub}}$, we can first left-multiply with $\overrightarrow{\mathsf{Surj}}^{-1}$ to obtain the equivalent identities

$$\overrightarrow{\mathsf{Surj}}^{-1} \cdot \mathsf{HOM}_r(G) = \overrightarrow{\mathsf{Sub}} \cdot \mathsf{CR}(G) \text{ and } \overrightarrow{\mathsf{Surj}}^{-1} \cdot \mathsf{HOM}_r(H) = \overrightarrow{\mathsf{Sub}} \cdot \mathsf{CR}(H)\,. \tag{5}$$

Now suppose $\mathsf{HOM}_r(G) = \mathsf{HOM}_r(H)$ holds, and set $\boldsymbol{v} = \mathsf{HOM}_r(G)$. Then $\overrightarrow{\mathsf{Surj}}^{-1} \cdot \boldsymbol{v}$ is well-defined, because $\overrightarrow{\mathsf{Surj}}$ and its inverse are lower triangular. Thus we obtain $\overrightarrow{\mathsf{Sub}} \cdot \mathsf{CR}(G) = \overrightarrow{\mathsf{Sub}} \cdot \mathsf{CR}(H)$ and set $\boldsymbol{w} = \mathsf{CR}(G)$. Unfortunately, $\overrightarrow{\mathsf{Sub}}^{-1} \cdot \boldsymbol{w}$ may be undefined, since $\overrightarrow{\mathsf{Sub}}^{-1}$ is upper triangular. While we can still use a matrix inverse, the argument becomes a bit subtle. The crucial observation is that $\mathsf{Cr}(T', G)$ is non-zero for at most n different trees T', and all such trees have maximum degree at most $n-1$. Thus we do not need to look at *all* trees but only those with maximum degree n. Let $\widetilde{\mathcal{T}}$ be the set of all unlabeled rooted trees of maximum degree at most n. Let $\mathsf{CR}' = \mathsf{CR}|_{\widetilde{\mathcal{T}}}$, let $\boldsymbol{w}' = \boldsymbol{w}|_{\widetilde{\mathcal{T}}}$, and let $\overrightarrow{\mathsf{Sub}}' = \overrightarrow{\mathsf{Sub}}|_{\widetilde{\mathcal{T}} \times \widetilde{\mathcal{T}}}$. Then we still have the following for all $T \in \widetilde{\mathcal{T}}$ and G:

$$\boldsymbol{w}'_T = \sum_{T' \in \widetilde{\mathcal{T}}} \overrightarrow{\mathsf{Sub}}'(T, T') \cdot \mathsf{Cr}'(T', G)\,. \tag{6}$$

The new matrix $\overrightarrow{\mathsf{Sub}}'$ is a principal minor of $\overrightarrow{\mathsf{Sub}}$ and thus remains invertible. Moreover, $\overrightarrow{\mathsf{Sub}}'^{-1} \cdot \boldsymbol{w}'$ is well-defined, since

$$\sum_{T' \in \widetilde{\mathcal{T}}} \overrightarrow{\mathsf{Sub}}'^{-1}(T, T') \cdot \boldsymbol{w}'_{T'} \tag{7}$$

is a finite sum for each T: The number of (unlabeled) trees $T' \in \widetilde{\mathcal{T}}$ that have the same depth d as T is bounded by a function in n and d. Thus $\overrightarrow{\mathsf{Sub}}'^{-1} \cdot \boldsymbol{w}' = \mathsf{CR}'(G)$. By a similar argument, we obtain $\overrightarrow{\mathsf{Sub}}'^{-1} \cdot \boldsymbol{w}' = \mathsf{CR}'(H)$. This implies $\mathsf{CR}'(G) = \mathsf{CR}'(H)$ and thus $\mathsf{CR}(G) = \mathsf{CR}(H)$. ◀

4 Homomorphisms from cycles and paths

While the arguments we saw in the proof of Theorem 1 are mainly graph-theoretic, the proof of Theorem 2 uses spectral techniques. To introduce the techniques, we first prove a simple, known result already mentioned in the introduction. We call two square matrices *co-spectral* if they have the same eigenvalues with the same multiplicities, and we call two graphs *co-spectral* if their adjacency matrices are co-spectral.

▶ **Proposition 9** (e.g. [23, Lemma 1])**.** *Let $\mathcal{C}$ be the class of all cycles (including the degenerate cycle of length 0, which is just a single vertex). For all graphs G and H, we have $\mathsf{HOM}_{\mathcal{C}}(G) = \mathsf{HOM}_{\mathcal{C}}(H)$ if and only if G and H are co-spectral.*

For the proof, we review a few simple facts from linear algebra. The trace $\operatorname{tr}(A)$ of a square matrix $A \in \mathbb{R}^{n \times n}$ is the sum of the diagonal entries. If the eigenvalues of A are $\lambda_1, \dots, \lambda_n$, then $\operatorname{tr}(A) = \sum_{i=1}^n \lambda_i$. Moreover, for each $\ell \geq 0$ the eigenvalues of the matrix A^ℓ are $\lambda_1^\ell, \dots, \lambda_n^\ell$, and thus $\operatorname{tr}(A^\ell) = \sum_{i=1}^n \lambda_i^\ell$. The following technical lemma encapsulates the fact that the information $\operatorname{tr}(A^\ell)$ for all $\ell \in \mathbf{N}$ suffices to reconstruct the spectrum of A with multiplicities. We use the same lemma to prove Theorem 2, but for Proposition 9 a less general version would suffice.

▶ **Lemma 10.** *Let $X, Y \subseteq \mathbf{R}$ be two finite sets and let $c \in \mathbf{R}^X_{\neq 0}$ and $d \in \mathbf{R}^Y_{\neq 0}$ be two vectors. If the equation*

$$\sum_{x \in X} c_x x^\ell = \sum_{y \in Y} d_y y^\ell \tag{8}$$

holds for all $\ell \in \mathbf{N}$, then $X = Y$ and $c = d$.

Proof. We prove the claim by induction on $k := |X| + |Y|$. For $k = 0$, the claim is trivially true since both sums in (8) are equal to zero by convention.

Let $\hat{x} = \arg\max\{\, |x| : x \in X \cup Y \,\}$ and let $\hat{x} \in X$ without loss of generality. If $\hat{x} = 0$, then $X = \{0\}$ and we claim that $Y = \{0\}$ holds. Clearly (8) for $\ell = 0$ yields $0 \neq c_0 = \sum_{y \in Y} d_y$. In particular, $Y \neq \emptyset$ holds. Since $\hat{x} = 0$ is the maximum of $X \cup Y$ in absolute value, we have $Y = \{0\}$ and thus also $c = d$.

Now suppose that $\hat{x} \neq 0$ holds. We consider the sequences $(a_\ell)_{\ell \in \mathbf{N}}$ and $(b_\ell)_{\ell \in \mathbf{N}}$ with

$$a_\ell = \frac{1}{\hat{x}^\ell} \cdot \sum_{x \in X} c_x x^\ell \quad \text{and} \quad b_\ell = \frac{1}{\hat{x}^\ell} \cdot \sum_{y \in Y} d_y y^\ell \,. \tag{9}$$

Note that $a_\ell = b_\ell$ holds for all $\ell \in \mathbf{N}$ by assumption. Observe the following simple facts:
1) If $-\hat{x} \notin X$, then $\lim_{\ell \to \infty} a_\ell = c_{\hat{x}}$.
2) If $-\hat{x} \in X$, then $\lim_{\ell \to \infty} a_{2\ell} = c_{\hat{x}} + c_{-\hat{x}}$ and $\lim_{\ell \to \infty} a_{2\ell+1} = c_{\hat{x}} - c_{-\hat{x}}$.
As well as the following exhaustive case distinction for Y:
a) If $\hat{x}, -\hat{x} \notin Y$, then $\lim_{\ell \to \infty} b_\ell = 0$.
b) If $\hat{x} \in Y$ and $-\hat{x} \notin Y$, then $\lim_{\ell \to \infty} b_\ell = d_{\hat{x}}$.
c) If $\hat{x} \notin Y$ and $-\hat{x} \in Y$, then $\lim_{\ell \to \infty} b_{2\ell} = d_{-\hat{x}}$ and $\lim_{\ell \to \infty} b_{2\ell+1} = -d_{-\hat{x}}$.
d) If $\hat{x}, -\hat{x} \in Y$, then $\lim_{\ell \to \infty} b_{2\ell} = d_{\hat{x}} + d_{-\hat{x}}$ and $\lim_{\ell \to \infty} b_{2\ell+1} = d_{\hat{x}} - d_{-\hat{x}}$.
If $-\hat{x} \notin X$ holds, we see from 1) that a_ℓ converges to the non-zero value $c_{\hat{x}}$. Since the two sequences are equal, the sequence b_ℓ also converges to a non-zero value. The only case for Y where this happens is b), and we get $\hat{x} \in Y$, $-\hat{x} \notin Y$, and $c_{\hat{x}} = d_{\hat{x}}$. On the other hand, if $-\hat{x} \in X$, we see from 2) that a_ℓ does not converge, but the even and odd subsequences do. The only cases for Y where this happens for b_ℓ too are c) and d). We cannot be in case c), since the two accumulation points of b_ℓ just differ in their sign, while the two accumulation points of a_ℓ do not have the same absolute value. Thus we must be in case d) and obtain $x, \hat{x} \in Y$ as well as

$$c_{\hat{x}} + c_{-\hat{x}} = d_{\hat{x}} + d_{-\hat{x}} \quad \text{and} \quad c_{\hat{x}} - c_{-\hat{x}} = d_{\hat{x}} - d_{-\hat{x}} \,.$$

This linear system has full rank and implies $c_{\hat{x}} = d_{\hat{x}}$ and $c_{-\hat{x}} = d_{-\hat{x}}$.

Either way, we can remove $\{\hat{x}\}$ or $\{\hat{x}, -\hat{x}\}$ from both X and Y and apply the induction hypothesis on the resulting instance X', Y', c', d'. Then $(X, c) = (Y, d)$ follows as claimed. ◀

Proof of Proposition 9. For all $\ell \geq 0$, the number of homomorphisms from the cycle C_ℓ of length ℓ to a graph G with adjacency matrix A is equal to the number of closed length-ℓ walks in G, which in turn is equal to the trace of A^ℓ. Thus for graphs G, H with adjacency matrices A, B, we have $\mathsf{HOM}_{\mathcal{C}}(G) = \mathsf{HOM}_{\mathcal{C}}(H)$ if and only if $\operatorname{tr}(A^\ell) = \operatorname{tr}(B^\ell)$ holds for all $\ell \geq 0$.

If A and B have the same spectrum $\lambda_1, \ldots, \lambda_n$, then $\operatorname{tr}(A^\ell) = \lambda_1^\ell + \cdots + \lambda_n^\ell = \operatorname{tr}(B^\ell)$ holds for all $\ell \in \mathbf{N}$. For the reverse direction, suppose $\operatorname{tr}(A^\ell) = \operatorname{tr}(B^\ell)$ for all $\ell \in \mathbf{N}$. Let $X \subseteq \mathbf{R}$ be the set of eigenvalues of A and for each $\lambda \in X$, let $c_\lambda \in \{1, \ldots, n\}$ be the multiplicity of the eigenvalue λ. Let $Y \subseteq \mathbf{R}$ and d_λ for $\lambda \in Y$ be the corresponding eigenvalues and multiplicities for B. Then for all $\ell \in \mathbf{N}$, we have

$$\sum_{\lambda \in X} c_\lambda \lambda^\ell = \operatorname{tr}(A^\ell) = \operatorname{tr}(B^\ell) = \sum_{\lambda \in Y} d_\lambda \lambda^\ell \,.$$

By Lemma 10, this implies $(X, c) = (Y, d)$, that is, the spectra of A and B are identical. ◀

In the following example, we show that the vectors $\mathsf{HOM}_{\mathcal{C}}$ for the class $\mathcal{C}$ of cycles and $\mathsf{HOM}_{\mathcal{T}}$ for the class $\mathcal{T}$ of trees are incomparable in their expressiveness.

Figure 2 Two co-spectral graphs

▶ **Example 11.** The graphs G and H shown in Figure 2 are co-spectral and thus $\mathsf{HOM}_{\mathcal{C}}(G) = \mathsf{HOM}_{\mathcal{C}}(H)$, but it is easy to see that $\mathsf{HOM}_{\mathcal{P}}(G) \neq \mathsf{HOM}_{\mathcal{P}}(H)$ for the class $\mathcal{P}$ of all paths.

Let G' be a cycle of length 6 and H' the disjoint union of two triangles. Then obviously, $\mathsf{HOM}_{\mathcal{C}}(G') \neq \mathsf{HOM}_{\mathcal{C}}(H')$. However, color refinement does not distinguish G' and H' and thus $\mathsf{HOM}_{\mathcal{T}}(G') = \mathsf{HOM}_{\mathcal{T}}(H')$.

Let us now turn to the proof of Theorem 2.

Proof of Theorem 2. Let A and B be the adjacency matrices of G and H, respectively. Since A is a symmetric and real matrix, its eigenvalues are real and the corresponding eigenspaces are orthogonal and span $\mathbf{R}^n$. Let $\mathbf{1}$ be the n-dimensional all-1 vector, and let $X = \{\lambda_1, \dots, \lambda_k\}$ be the set of all eigenvalues of A whose corresponding eigenspaces are not orthogonal to $\mathbf{1}$. We call these eigenvalues the *useful* eigenvalues of A and without loss of generality assume $\lambda_1 > \cdots > \lambda_k$. The n-dimensional all-1 vector $\mathbf{1}$ can be expressed as a direct sum of eigenvectors of A corresponding to useful eigenvalues. In particular, there is a unique decomposition $\mathbf{1} = \sum_{i=1}^{k} u_i$ such that each u_i is a non-zero eigenvector in the eigenspace of λ_i. Moreover, the vectors $u_1, \dots, u_k$ are orthogonal. For the matrix B, we analogously define its set of useful eigenvalues $Y = \{\mu_1, \dots, \mu_{k'}\}$ and the direct sum $\mathbf{1} = \sum_{i=1}^{k'} v_i$.

We prove the equivalence of the following three assertions (of which the first and third appear in the statement of Theorem 2).

1. $\mathsf{HOM}_{\mathcal{P}}(G) = \mathsf{HOM}_{\mathcal{P}}(H)$.
2. A and B have the same set of useful eigenvalues $\lambda_1, \dots, \lambda_k$ and $\|u_i\| = \|v_i\|$ holds for all $i \in \{1, \dots, k\}$. Here, $\|.\|$ denotes the Euclidean norm with $\|x\|^2 = \sum_j x_j^2$.
3. The system $\mathsf{F}_{\text{iso}}(G, H)$ of linear equations has a real solution.

Note that in 2, we do not require that the useful eigenvalues occur with the same multiplicities in A and B. We show the implications $(1 \Rightarrow 2)$, $(2 \Rightarrow 3)$, and $(3 \Rightarrow 1)$.

$(1 \Rightarrow 2)$: Suppose that $\mathsf{Hom}(P_\ell, G) = \mathsf{Hom}(P_\ell, H)$ holds for all paths P_ℓ. Equivalently, this can be stated in terms of the adjacency matrices A and B: for all $\ell \in \mathbf{N}$, we have $\mathbf{1}^T A^\ell \mathbf{1} = \mathbf{1}^T B^\ell \mathbf{1}$. We claim that A and B have the same useful eigenvalues, and that the projections of $\mathbf{1}$ onto the corresponding eigenspaces have the same lengths.

Note that $A^\ell \mathbf{1} = \sum_{i=1}^{k} \lambda_i^\ell u_i$ holds. Thus we have

$$\mathbf{1}^T A^\ell \mathbf{1} = \left(\sum_{i=1}^{k} u_i^T \right) \left(\sum_{i=1}^{k} \lambda_i^\ell u_i \right) = \sum_{i=1}^{k} \|u_i\|^2 \cdot \lambda_i^\ell \,. \tag{10}$$

The term $\mathbf{1}^T B^\ell \mathbf{1}$ can be expanded analogously, which together yields

$$\sum_{i=1}^{k} \|u_i\|^2 \cdot \lambda_i^\ell = \sum_{i=1}^{k'} \|v_i\|^2 \cdot \mu_i^\ell \quad \text{for all } \ell \in \mathbf{N}. \tag{11}$$

Since all coefficients $c_{\lambda_i} = \|u_i\|^2$ and $d_{\mu_i} = \|v_i\|^2$ are non-zero, we are in the situation of Lemma 10. We obtain $k = k'$ and, for all $i \in \{1, \dots, k\}$, we obtain $\lambda_i = \mu_i$ and $\|u_i\| = \|v_i\|$. This is exactly the claim that we want to show.

($2 \Rightarrow 3$): We claim that the $(n \times n)$-matrix X defined via

$$X = \sum_{i=1}^{k} \frac{1}{\|u_i\|^2} \cdot u_i v_i^T \tag{12}$$

satisfies the F_{iso} equations $AX = XB$ and $X\mathbf{1} = \mathbf{1} = X^T\mathbf{1}$. Indeed, we have

$$AX = \sum_{i=1}^{k} \frac{1}{\|u_i\|^2} \cdot Au_i v_i^T = \sum_{i=1}^{k} \frac{\lambda_i}{\|u_i\|^2} \cdot u_i v_i^T = \sum_{i=1}^{k} \frac{1}{\|u_i\|^2} \cdot u_i v_i^T B^T = XB^T = XB\,, \tag{13}$$

This follows, since $Au_i = \lambda_i u_i$, $Bv_i = \lambda_i v_i$, and B is symmetric. Moreover, we have

$$X\mathbf{1} = \sum_{i=1}^{k} \frac{1}{\|u_i\|^2} \cdot Au_i v_i^T \mathbf{1} = \sum_{i=1}^{k} \frac{1}{\|u_i\|^2} \cdot u_i v_i^T \sum_{j=1}^{k} v_j = \sum_{i=1}^{k} \frac{1}{\|u_i\|^2} \cdot u_i \cdot v_i^T v_i = \mathbf{1}\,. \tag{14}$$

This holds by definition of u_i and v_i and from $v_i^T v_i = \|v_i\|^2 = \|u_i\|^2$. The claim $X^T\mathbf{1} = \mathbf{1}$ follows analogously.

($3 \Rightarrow 1$): Suppose there is a matrix X with $X^T\mathbf{1} = X\mathbf{1} = \mathbf{1}$ and $AX = XB$. We obtain $A^\ell X = XB^\ell$ by induction for all $\ell \in \mathbf{N}_{>0}$. For $\ell = 0$, this also holds since $A^0 = I_n$ by convention. As a result, we have $\mathbf{1}^T A^\ell \mathbf{1} = \mathbf{1}^T A^\ell X\mathbf{1} = \mathbf{1}^T XB^\ell \mathbf{1} = \mathbf{1}^T B^\ell \mathbf{1}$ for all $\ell \in \mathbf{N}$. Since these scalars count the length-ℓ walks in G and H, respectively, we obtain $\mathsf{Hom}(P_\ell, G) = \mathsf{Hom}(P_\ell, H)$ for all paths P_ℓ as claimed. ◀

5 Homomorphisms from bounded tree width and path width

We briefly outline the main ideas of the proofs of Theorems 3 and 4; the technical details are deferred to the full version of this paper. In Theorem 3, the equivalence between ii and iii is essentially known, so we focus on the equivalence between i and ii. The proof is similar to the proof of Theorem 1 in Section 3.

Let us fix $k \geq 2$. The idea of the k-WL algorithm is to iteratively color k-tuples of vertices. Initially, each k-tuple $(v_1, \dots, v_k)$ is colored by its *atomic type*, that is, the isomorphism type of the labeled graph $G[\{v_1, \dots, v_k\}]$. Then in the refinement step, to define the new color of a k-tuple $\bar{v}$ we look at the current color of all k-tuples that can be reached from k by adding one vertex and then removing one vertex.

Similar to the tree unfolding of a graph G at a vertex v, we define the *Weisfeiler-Leman tree unfolding* at a k-tuple $\bar{v}$ of vertices. These objects have some resemblance to the pebbling comonad, which was defined by Abramsky, Dawar, and Wang [1] in the language of category theory. The WL-tree unfolding describes the color of $\bar{v}$ computed by k-WL; formally it may be a viewed as a pair (T, F) consisting of a graph F together with a "rooted" tree decomposition (potentially infinite, but again we cut it off at some finite depth). Similar to the numbers $\mathsf{Cr}(T, G)$ and the vector $\mathsf{CR}(G)$, we now have numbers $\mathsf{WL}((T, F), G)$ and a vector $\mathsf{WL}(G)$ such that $\mathsf{WL}(G) = \mathsf{WL}(H)$ holds if and only if k-WL does not distinguish G and H. Then we define a linear transformation Φ with $\mathsf{HOM}_{\mathcal{T}_k}(G) = \Phi\mathsf{WL}(G)$. The existence of this linear transformation directly yields the implication ii $\Longrightarrow$ i of Theorem 3. To prove the converse, we show that the transformation Φ is invertible by giving a suitable LU-decomposition of full rank. This completes our sketch of the proof of Theorem 3.

The proof of Theorem 4 requires a different argument, because now we have to use a solution (X_π) of the system $\mathsf{L}_{\text{iso}}^{k+1}(G,H)$ to prove that the path width k homomorphism vectors $\mathsf{HOM}_{\mathcal{P}_k}(G)$ and $\mathsf{HOM}_{\mathcal{P}_k}(H)$ are equal. The key idea is to express entries of a suitable variant of $\mathsf{HOM}_{\mathcal{P}_k}(G)$ as a linear combinations of entries of the corresponding vector for H using the values X_π as coefficients.

6 Conclusions

We have studied the homomorphism vectors $\mathsf{HOM}_{\mathcal{F}}(G)$ for various graph classes $\mathcal{F}$, focusing on classes $\mathcal{F}$ where it is tractable to compute the entries $\mathsf{Hom}(F,G)$ of the vector. Our main interest was in the "expressiveness" of these vectors, that is, in the question what $\mathsf{HOM}_{\mathcal{F}}(G)$ tells us about the graph G. For the classes $\mathcal{C}$ of cycles, $\mathcal{T}$ of trees, $\mathcal{T}_k$ of graphs of tree width at most k, and $\mathcal{P}$ of paths, we have obtained surprisingly clean answers to this question, relating the homomorphism vectors to various other well studied formalisms that on the surface have nothing to do with homomorphism counts.

Some interesting questions remain open. The most obvious is whether the converse of Theorem 4 holds, that is, whether for two graphs G, H with $\mathsf{HOM}_{\mathcal{P}_k}(G) = \mathsf{HOM}_{\mathcal{P}_k}(H)$, the system $\mathsf{L}_{\text{iso}}^{k+1}(G,H)$ has a real solution (and hence the Nullstellensatz propositional proof system has no degree-$(k+1)$ refutation of G and H being isomorphic).

Another related open problem in spectral graph theory is to characterize graphs which are identified by their spectrum, up to isomorphism. In our framework, Proposition 9 ensures that we can equivalently ask for the following characterization: for which graphs G does the vector $\mathsf{HOM}_{\mathcal{C}}(G)$ determine the entire homomorphism vector $\mathsf{HOM}(G)$?

Despite the computational intractability, it is also interesting to study the vectors $\mathsf{HOM}_{\mathcal{F}}(G)$ for classes $\mathcal{F}$ of unbounded tree width. Are there natural classes $\mathcal{F}$ (except of course the class of all graphs) for which the vectors $\mathsf{HOM}_{\mathcal{F}}(G)$ characterize G up to isomorphism? For example, what about classes of bounded degree or the class of planar graphs? And what is the complexity of deciding whether $\mathsf{HOM}_{\mathcal{F}}(G) = \mathsf{HOM}_{\mathcal{F}}(H)$ holds when G and H are given as input? Our results imply that this problem is in polynomial time for the classes $\mathcal{T}$, $\mathcal{T}_k$, and $\mathcal{P}$. For the class of all graphs, it is in quasi-polynomial time by Babai's quasi-polynomial isomorphism test [5]. Yet it seems plausible that there are classes $\mathcal{F}$ (even natural classes decidable in polynomial time) for which the problem is co-NP-hard.

Maybe the most interesting direction for further research is to study the graph similarity measures induced by homomorphism vectors. A simple way of defining an inner product on the homomorphism vectors is by letting

$$\Big\langle \mathsf{HOM}_{\mathcal{F}}(G), \mathsf{HOM}_{\mathcal{F}}(H) \Big\rangle := \sum_{\substack{k \geq 1 \\ \mathcal{F}_k \neq \emptyset}} \frac{1}{k^k |\mathcal{F}_k|} \sum_{F \in \mathcal{F}_k} \mathsf{Hom}(F,G)\mathsf{Hom}(F,H),$$

where $\mathcal{F}_k$ denotes the class of all graph $F \in \mathcal{F}$ with k vertices. The mapping $(G,H) \mapsto \langle \mathsf{HOM}_{\mathcal{F}}(G), \mathsf{HOM}_{\mathcal{F}}(H) \rangle$ is what is known as a *graph kernel* in machine learning. It induces a (pseudo)metric $d_{\mathcal{T}}$ on the class of graphs. It is an interesting question how it relates to other graph similarity measures, for example, the metric induced by the Weisfeiler-Leman graph kernel. Our Theorem 1 implies that the metric $d_{\mathcal{T}}$ for the class $\mathcal{T}$ of trees and the metric induced by the Weisfeiler-Leman graph kernel have the same graphs of distance zero.

Abstract

We study the problem of testing identity against a given distribution with a focus on the high confidence regime. More precisely, given samples from an unknown distribution p over n elements, an explicitly given distribution q, and parameters $0 < \varepsilon, \delta < 1$, we wish to distinguish, *with probability at least* $1 - \delta$, whether the distributions are identical versus ε-far in total variation distance. Most prior work focused on the case that $\delta = \Omega(1)$, for which the sample complexity of identity testing is known to be $\Theta(\sqrt{n}/\varepsilon^2)$. Given such an algorithm, one can achieve arbitrarily small values of δ via black-box amplification, which multiplies the required number of samples by $\Theta(\log(1/\delta))$.

We show that black-box amplification is suboptimal for any $\delta = o(1)$, and give a new identity tester that achieves the optimal sample complexity. Our new upper and lower bounds show that the optimal sample complexity of identity testing is

$$\Theta\left(\frac{1}{\varepsilon^2}\left(\sqrt{n\log(1/\delta)} + \log(1/\delta)\right)\right)$$

for any n, ε, and δ. For the special case of uniformity testing, where the given distribution is the uniform distribution U_n over the domain, our new tester is surprisingly simple: to test whether $p = U_n$ versus $d_{\mathrm{TV}}(p, U_n) \geq \varepsilon$, we simply threshold $d_{\mathrm{TV}}(\widehat{p}, U_n)$, where $\widehat{p}$ is the empirical probability distribution. The fact that this simple "plug-in" estimator is sample-optimal is surprising, even in the constant δ case. Indeed, it was believed that such a tester would not attain sublinear sample complexity even for constant values of ε and δ.

An important contribution of this work lies in the analysis techniques that we introduce in this context. First, we exploit an underlying strong convexity property to bound from below the expectation gap in the completeness and soundness cases. Second, we give a new, fast method for obtaining provably correct empirical estimates of the true worst-case failure probability for a broad class of uniformity testing statistics over all possible input distributions – including all previously studied statistics for this problem. We believe that our novel analysis techniques will be useful for other distribution testing problems as well.

1 Introduction

Distribution property testing [15, 4, 5], originating in statistical hypothesis testing [18, 17], studies problems of the form: given sample access to one or more unknown distributions, determine whether they satisfy some global property or are "far" from satisfying the property. (See Section 1.1 for a formal definition.) During the past two decades problems of this form have received significant attention within the computer science community. See [20, 6] for two recent surveys.

Research in this field has primarily centered on determining tight bounds on the sample complexity of testing various properties *in the constant probability of success regime*. That is, the testing algorithm must succeed with a probability of (say) at least 2/3. This constant confidence regime is fairly well understood. For a range of fundamental properties [19, 7, 22, 12, 11, 1, 10, 9] we now have *sample-optimal* testers that use provably optimal number of samples (up to constant factors) in this regime.

In sharp contrast, the high confidence regime – i.e., the case where the desired failure probability is subconstant – is poorly understood even for the most basic properties. For essentially all distribution property testing problems studied in the literature, the standard amplification method is the only way known to achieve a high confidence success probability. Amplification is a black-box method that can boost the success probability to any desired accuracy. However, using it increases the number of required samples beyond what is necessary to obtain constant confidence. Specifically, to achieve a high confidence success probability of $1 - \delta$ via amplification, the number of samples required increases by a factor of $\Theta(\log(1/\delta))$ compared to the constant confidence regime.

This discussion raises the following natural questions: *For a given distribution property testing problem, does black-box amplification give sample-optimal testers for obtaining a high confidence success probability? Specifically, is the* $\Theta(\log(1/\delta))$ *multiplicative increase in the sample size the best possible? If not, can we design testers that have optimal sample complexity in terms of all relevant problem parameters, including the error probability* δ*?*

We believe that these are fundamental questions that merit theoretical investigation in their own right. As Goldreich notes [14], "eliminating the error probability as a parameter does not allow to ask whether or not one may improve over the straightforward error reduction". From a practical perspective, understanding this high confidence regime is important to applications of hypothesis testing (e.g., in biology), because the failure probability δ of the test can be reported as a p-value. (The family of distribution testing algorithms with success probability $1 - \delta$ for a given problem is equivalent to the family of statistical tests whose p-value (probability of Type I error) and probability of Type II error are both at most δ.) Standard techniques for addressing the problem of multiple comparisons, such as Bonferroni correction, require vanishingly small p-values.

Perhaps surprisingly, with one exception [16], this basic problem has not been previously investigated in the finite sample regime. A conceptual contribution of this work is to raise this problem as a fundamental goal in distribution property testing. We note here that

the analogous question in the context of *distribution learning* has been intensely studied in statistics and probability theory (see, e.g., [23, 8]) and tight bounds are known in a range of settings.

1.1 Formal Framework

The focus of this work is on the task of identity testing, which is arguably *the* most fundamental distribution testing problem.

▶ **Definition 1** (Distribution Identity Testing Problem). Given a target distribution q with domain D of size n, parameters $0 < \varepsilon, \delta < 1$, and sample access to an unknown distribution p over the same domain, we want to distinguish *with probability at least* $1 - \delta$ between the following cases:

- Completeness: $p = q$.
- Soundness: $d_{\mathrm{TV}}(p, q) \geq \varepsilon$.

We call this the problem of (ε, δ) *testing identity to* q. The special case of q being uniform is known as *uniformity testing*. An algorithm that solves one of these problems will be called an (ε, δ)-*tester* for identity/uniformity.

Note that $d_{\mathrm{TV}}(p, q)$ denotes the total variation distance or statistical distance between distributions p and q, i.e., $d_{\mathrm{TV}}(p, q) \stackrel{\text{def}}{=} \frac{1}{2} \cdot \|p - q\|_1$. The goal is to characterize the sample complexity of the problem: i.e., the number of samples that are necessary and sufficient to correctly distinguish between the completeness and soundness cases with probability $1 - \delta$.

1.2 Our Results

Our main result is a complete characterization of the worst-case sample complexity of identity testing in the high confidence regime. For this problem, we show that black-box amplification is suboptimal for *any* $\delta = o(1)$, and give a new identity tester that achieves the optimal sample complexity:

▶ **Theorem 2** (Main Result). *There exists a computationally efficient* (ε, δ)*-identity tester for discrete distributions of support size* n *with sample complexity*

$$\Theta\left(\frac{1}{\varepsilon^2}\left(\sqrt{n\log(1/\delta)} + \log(1/\delta)\right)\right). \tag{1}$$

Moreover, this sample size is information-theoretically optimal, up to a constant factor, for all n, ε, δ.

As we explain in Section 1.3, [16] gave a tester that achieves the optimal sample complexity when the sample size is $o(n)$. However this tester *completely* fails with $\Omega(n)$ samples, as may be required when either ε or δ are sufficiently small. Theorem 2 provides a complete characterization of the worst-case sample complexity of the problem with a *single* statistic for all settings of parameters n, ε, δ.

Brief Overview of Techniques. To analyze our tester, we introduce two new techniques for the analysis of distribution testing statistics, which we describe in more detail in Section 1.4. Our techniques leverage a simple common property of numerous distribution testing statistics which does not seem to have been previously exploited in their analysis: their convexity. Our first technique crucially exploits an underlying strong convexity property to bound from below the expectation gap between the completeness and soundness cases.

We remark that this is a contrast to most known distribution testers where bounding the expectation gap is easy, and the challenge is in bounding the variance of the statistic.

Our second technique implies a new, fast method for obtaining empirical estimates of the true worst-case failure probability of any member of a broad class of uniformity testing statistics. This class includes all uniformity testing statistics studied in the literature. Critically, these estimates come with provable guarantees about the worst-case failure probability of the statistic over all possible input distributions, and have tunable additive error. We elaborate in Section 1.4.

1.3 Discussion and Prior Work

Uniformity testing is the first and one of the most well-studied problems in distribution testing [15, 19, 22, 12, 9]. As already mentioned, the literature has almost exclusively focused on the case of constant error probability δ. The first uniformity tester, introduced by Goldreich and Ron [15], counts the number of collisions among the samples and was shown to work with $O(\sqrt{n}/\varepsilon^4)$ samples [15]. A related tester proposed by Paninski [19], which relies on the number of distinct elements in the set of samples, was shown to have the optimal $m = \Theta(\sqrt{n}/\varepsilon^2)$ sample complexity, as long as $m = o(n)$. Recently, a chi-squared based tester was shown in [22, 12] to achieve the optimal $\Theta(\sqrt{n}/\varepsilon^2)$ sample complexity without any restrictions. Finally, the original collision-based tester of [15] was very recently shown to also achieve the optimal $\Theta(\sqrt{n}/\varepsilon^2)$ sample complexity [9]. Thus, the situation for constant values of δ is well understood.

The problem of identity testing against an arbitrary (explicitly given) distribution was studied in [3], who gave an $(\varepsilon, 1/3)$-tester with sample complexity $\tilde{O}(n^{1/2})/\mathrm{poly}(\varepsilon)$. The tight bound of $\Theta(n^{1/2}/\varepsilon^2)$ was first given in [22] using a chi-squared type tester (inspired by [7]). In subsequent work, a similar chi-squared tester that also achieves the same sample complexity bound was given in [1]. (We note that the [22, 1] testers have sub-optimal sample complexity in the high confidence regime, even for the case of uniformity.) In a related work, [12] obtained a reduction of identity to uniformity that preserves the sample complexity, up to a constant factor, in the constant error probability regime. More recently, Goldreich [13], building on [10], gave a different reduction of identity to uniformity that preserves the error probability. We use the latter reduction in this paper to obtain an optimal identity tester starting from our new optimal uniformity tester.

Since the sample complexity of identity testing is $\Theta(\sqrt{n}/\varepsilon^2)$ for $\delta = 1/3$ [22, 12], standard amplification gives a sample upper bound of $\Theta(\sqrt{n}\log(1/\delta)/\varepsilon^2)$ for this problem. It is not hard to observe that this naive bound cannot be optimal for all values of δ. For example, in the extreme case that $\delta = 2^{-\Theta(n)}$, this gives a sample complexity of $\Theta(n^{3/2}/\varepsilon^2)$. On the other hand, one can *learn* the underlying distribution (and therefore test for identity) with $O(n/\varepsilon^2)$ samples for such values of δ[4].

The case where $1 \gg \delta \gg 2^{-\Theta(n)}$ is more subtle, and it is not a priori clear how to improve upon naive amplification. Theorem 2 provides a smooth transition between the extremes of $\Theta(\sqrt{n}/\varepsilon^2)$ for constant δ and $\Theta(n/\varepsilon^2)$ for $\delta = 2^{-\Theta(n)}$. It thus provides a quadratic improvement in the dependence on δ over the naive bound for all $\delta \geq 2^{-\Theta(n)}$, and shows that this is the best possible. For $\delta < 2^{-\Theta(n)}$, it turns out that the additive $\Theta(\log(1/\delta)/\varepsilon^2)$ term is necessary, as outlined in Section 1.4, so learning the distribution is optimal for such values of δ.

[4] This follows from the fact that, for any distribution p over n elements, the empirical probability distribution $\widehat{p}_m$ obtained after $m = \Omega((n + \log(1/\delta))/\varepsilon^2)$ samples drawn from p is ε-close to p in total variation distance with probability at least $1 - \delta$.

We obtain the first sample-optimal *uniformity tester* for the high confidence regime. Our sample-optimal identity tester follows from our uniformity tester by applying the recent result of Goldreich [13], which provides a black-box reduction of identity to uniformity. We also show a matching information-theoretic lower bound on the sample complexity.

The sample-optimal uniformity tester we introduce is remarkably simple: to distinguish between the cases that p is the uniform distribution U_n over n elements versus $d_{\mathrm{TV}}(p, U_n) \geq \varepsilon$, we simply compute $d_{\mathrm{TV}}(\widehat{p}, U_n)$ for the empirical distribution $\widehat{p}$. The tester accepts that $p = U_n$ if the value of this statistic is below some well-chosen threshold, and rejects otherwise.

It should be noted that such a tester was not previously known to work with sub-learning sample complexity – i.e., fewer than $\Theta(n/\varepsilon^2)$ samples – even in the constant confidence regime. Surprisingly, in a literature with several different uniformity testers [15, 19, 22, 12], no one has previously used the empirical total variation distance. On the contrary, it would be natural to assume – as was suggested in [4, 5] – that this tester cannot possibly work. A likely reason for this is the following observation: When the sample size m is smaller than the domain size n, the empirical total variation distance is very far from the true distance to uniformity. This suggests that the empirical distance statistic gives little, if any, information in this setting.

Despite the above intuition, we prove that the natural "plug-in" estimator relying on the empirical distance from uniformity actually works for the following reason: the empirical distance from uniformity is *noticeably smaller* for the uniform distribution than for "far from uniform" distributions, *even with a sub-linear sample size*. Moreover, we obtain the stronger statement that the "plug-in" estimator is a sample-optimal uniformity tester for all parameters n, ε and δ.

In [16], it was shown that the distinct-elements tester of [19] achieves the optimal sample complexity of $m = \Theta(\sqrt{n \log(1/\delta)}/\varepsilon^2)$, as long as $m = o(n)$. When $m = \Omega(n)$, as is the case in many practically relevant settings (see, e.g., the Polish lottery example in [21] with $n < \sqrt{n}/\varepsilon^2 \ll n/\varepsilon^2$), this tester is known to fail completely even in the constant confidence regime. On the other hand, in such settings the sample size is *not* sufficiently large so that we can actually *learn* the underlying distribution.

It is important to note that *all* previously considered uniformity testers [15, 19, 22, 12] do not achieve the optimal sample complexity (as a function of all parameters, including δ), and this is *inherent*, i.e., not just a failure of previous analyses. Roughly speaking, since the collision statistic [15] and the chi-squared based statistic [22, 12] are not Lipschitz, it can be shown that their high-probability performance is poor. Specifically, in the completeness case ($p = U_n$), if many samples happen to land in the same bucket (domain element), these test statistics become quite large, leading to their suboptimal behavior *for all* $\delta = o(1)$. (For a formal justification, the reader is referred to Section V of [16]). On the other hand, the distinct-elements tester [19] does not work for $m = \omega(n)$. For example, if ε or δ are sufficiently small to necessitate $m \gg n \log n$, then typically all n domain elements will appear in both the completeness and soundness cases, hence the test statistic provides no information.

1.4 Our Techniques

1.4.1 Upper Bound for Uniformity Testing

We would like to show that the test statistic $d_{\mathrm{TV}}(\widehat{p}, U_n)$ is with high probability larger when $d_{\mathrm{TV}}(p, U_n) \geq \varepsilon$ than when $p = U_n$. We start by showing that among all possible alternative distributions p with $d_{\mathrm{TV}}(p, U_n) \geq \varepsilon$, it suffices to consider those in a very simple family. We then show that the test statistic is highly concentrated around its expectation, and that the expectations are significantly different in the two cases. The main technical components of our paper are our techniques for accomplishing these tasks.

To simplify the structure of p, it can be shown that if p majorizes another distribution q, then the test statistic $d_{\mathrm{TV}}(\widehat{p}, U_n)$ stochastically dominates $d_{\mathrm{TV}}(\widehat{q}, U_n)$. (In fact, this statement holds for *any* test statistic that is a convex symmetric function of the empirical histogram.) We defer this proof to the full version. Therefore, for any p, if we average out the large and small entries of p, the test statistic becomes harder to distinguish from uniform.

We remark as a matter of independent interest that this stochastic domination lemma immediately implies a fast algorithm for performing rigorous empirical comparisons of test statistics. A major difficulty in empirical studies of distribution testing is that it is not possible to directly check the failure probability of a tester over every possible distribution as input, because the space of such distributions is quite large. Our structural lemma reduces the search space dramatically for uniformity testing: for any convex symmetric test statistic (which includes all existing ones), the worst case distribution will have αn coordinates of value $(1+\varepsilon/\alpha)/n$, and the rest of value $(1-\varepsilon/(1-\alpha))/n$, for some α. Hence, there are only n possible worst-case distributions for any ε. Notably, this reduction does not lose anything, so it could be used to identify the non-asymptotic optimal constants that a distribution testing statistic achieves for a given set of parameters.

Returning to our uniformity tester, at the cost of a constant factor in ε we can assume $\alpha = 1/2$. As a result, we only need to consider p to be either U_n or of the form $\frac{1\pm\varepsilon}{n}$ in each coordinate. We now need to separate the expectation of the test statistic in these two situations. The challenge is that both expectations are large, and we do not have a good analytic handle on them. We therefore introduce a new technique for showing a separation between the completeness and soundness cases that utilizes the strong convexity of the test statistic. Specifically, we obtain an explicit expression for the Hessian of the expectation, as a function of p. The Hessian is diagonal, and for our two situations of $p_i \approx 1/n$ each entry is within constant factors of the same value, giving a lower bound on its eigenvalues. Since the expectation is minimized at $p = U_n$, strong convexity implies an expectation gap. Specifically, we prove that this gap is $\varepsilon^2 \cdot \min(m^2/n^2, \sqrt{m/n}, 1/\varepsilon)$.

Finally, we need to show that the test statistic concentrates about its expectation. For $m \geq n$, this follows from McDiarmid's inequality: since the test statistic is $1/m$-Lipschitz in the m samples, with probability $1-\delta$ it lies within $\sqrt{\log(1/\delta)/m}$ of its expectation. When m is larger than the desired sample complexity given in (1), this is less than the expectation gap above. The concentration is trickier when $m < n$, since the expectation gap is smaller, so we need to establish tighter concentration. We get this by using a Bernstein variant of McDiarmid's inequality, which is stronger than the standard version of McDiarmid in this context. We note that the use of the stochastic domination is also crucial here. Since our statistic is a symmetric convex function of the histogram values, we show (details deferred to the full version) that for each soundness case distribution, there is a different distribution that has possible probability mass values exclusively in the set $\{\frac{1+\varepsilon'}{n}, \frac{1}{n}, \frac{1-\varepsilon'}{n}\}$, for some $\varepsilon' = O(\varepsilon)$, and is harder to distinguish from the uniform distribution. However, we could show that this distribution has a stronger Lipschitz-type property than the other soundness case distributions. Therefore, we are able to use a stronger concentration bound via McDiarmid's inequality and argue that even though other soundness case distributions may have weaker concentration, they still have smaller error due to our stochastic domination argument.

1.4.2 Upper Bound for Identity Testing

In [13], it was shown how to reduce ε-testing of an arbitrary distribution q over $[n]$ to $\varepsilon/3$-testing of U_{6n}. This reduction preserves the error probability δ, so applying it gives an identity tester with the same sample complexity as our uniformity tester, up to constant

factors.

1.4.3 Sample Complexity Lower Bound
