Abstract

Computability and semicomputability of compact subsets of the Euclidean spaces are important notions, that have been investigated for many classes of sets including fractals (Julia sets, Mandelbrot set) and objects with geometrical or topological constraints (embedding of a sphere). In this paper we investigate one of the simplest classes, namely the filled triangles in the plane. We study the properties of the parameters of semicomputable triangles, such as the coordinates of their vertices. This problem is surprisingly rich. We introduce and develop a notion of semicomputability of points of the plane which is a generalization in dimension 2 of the left-c.e. and right-c.e. numbers. We relate this notion to Solovay reducibility. We show that semicomputable triangles admit no finite parametrization, for some notion of parametrization.

1 Introduction

The notions of computable and computably enumerable sets of discrete objects such as $\mathbb{N}$ have been extended to sets of continuous objects such as real numbers. Arguably the most successful notions are defined for closed subsets of $\mathbb{R}^n$, especially $\mathbb{R}^2$ where they have a graphical interpretation. A computable subset of $\mathbb{R}^2$ corresponds to the intuitive notion of a set that can be drawn on a screen with arbitrary resolution by a single program. The computability of famous sets have been investigated in many articles. Whether the Mandelbrot set is computable is an open problem [6], related to a conjecture in complex

dynamics. It has been shown that filled Julia sets are computable, while their boundaries are not always computable [2]. The computability of the Lorenz attractor has been addressed in [5] and is still an open problem.

While the computability of such sets is usually a difficult question, the mathematical definitions of these sets immediately enable one to *semicompute* them, in the same way as one can only semicompute the halting problem: if a pixel does not intersect the set then this can be recognized in finite time, but if it does not then one may never know. For instance, the set of fixed-points of a computable function is semicomputable: if $x \neq f(x)$ then it can be eventually discovered by computing $f(x)$ with sufficient precision, but if $x = f(x)$ then we will never know.

Several studies have shown that topological or geometrical constraints on a semicomputable set make it computable [9, 8, 3].

In this paper, we study one of the simplest family of geometrical objects, namely filled triangles in $\mathbb{R}^2$. Part of the study extends to other classes of compact convex subsets of $\mathbb{R}^2$. While a filled triangle is computable if and only if the parameters defining it (coordinates, lengths, angles, etc.) are computable, the case of semicomputable triangles is less clear and leads us to several investigations.

We give a first characterization of semicomputable triangles. We introduce the notion of a semicomputable point, which is essentially a point that can be computably approximated from a limited set of directions. We show that determining whether a triangle is semicomputable reduces to identifying the semicomputability ranges of its vertices. We then study the properties of the semicomputability range and develop tools to help determining it, notably the quantitative version of Solovay reducibility which was independently introduced and studied in [1, 10].

We study the (non-)computability of several parameters associated to triangles by investigating the properties of generic semicomputable triangles, which are in a sense the most typical ones and are far from being computable.

We end this paper with a slightly different viewpoint, by showing that the problem is inherently complex in that the semicomputability of a triangle cannot be reduced to the semicomputability of its parameters, for any *finite* parametrization. This result is proved for a particular notion of parametrization, but other notions are possible and should be studied in the future.

Several proofs are not included due to space limitations. A full version of the article including all the proofs is available at `https://hal.inria.fr/hal-01770562`.

1.1 Background

A real number x is ***computable*** if there is a computable sequence of rationals q_i such that $|x - q_i| < 2^{-i}$. A real number x is ***left-c.e.*** if there is a computable increasing sequence of rationals converging to x, and ***right-c.e.*** if there is a computable decreasing sequence converging to x. A real number is ***difference-c.e.*** or ***d-c.e.*** if it is a difference of two left-c.e. numbers.

A rational box $B \subseteq \mathbb{R}^n$ is a product of n open intervals with rational endpoints. Let $(B_i)_{i\in\mathbb{N}}$ be a canonical enumeration of the rational boxes. A set $U \subseteq \mathbb{R}^d$ is an ***effective open set*** if it is a the union of a computable sequence of rational boxes. A ***semicomputable set*** is the complement of an effective open set. An ***effectively compact set*** is a compact set $K \subseteq \mathbb{R}^d$ such that the set $\{\langle i_1, \dots, i_k\rangle : K \subseteq B_{i_1} \cup \dots \cup B_{i_k}\}$ is c.e. ($\langle . \rangle : \mathbb{N}^* \to \mathbb{N}$ is a computable bijection). Equivalently, K is effectively compact if and only if K is bounded and semicomputable.

A function $f : A \subseteq \mathbb{R}^d \to \mathbb{R}^e$ is ***computable*** if the sets $f^{-1}(R_i)$ are uniformly effective open sets on A, i.e. if there exist uniformly effective open sets $U_i \subseteq \mathbb{R}^d$ such that $f^{-1}(R_i) = U_i \cap A$. A function $f : A \subseteq \mathbb{R}^d \to \mathbb{R}$ is ***left-c.e.*** if the sets $f^{-1}(q_i, +\infty)$ are uniformly effective open sets on A. Every bounded left-c.e. function $f : A \subseteq \mathbb{R}^d \to \mathbb{R}$ has a left-c.e. extension $\hat{f} : \mathbb{R}^d \to \mathbb{R}$.

Let $f : \mathbb{R}^d \times \mathbb{R}^e \to \mathbb{R}$ be left-c.e.

- If $K \subseteq \mathbb{R}^e$ is a non-empty effectively compact set then the function $f_{\min} : \mathbb{R}^d \to \mathbb{R}$ defined by $f_{\min}(x) = \min_{y \in K} f(x, y)$ is left-c.e.
- If $U \subseteq \mathbb{R}^e$ is an effective open set then $f_{\sup} : \mathbb{R}^d \to \mathbb{R}$ defined by $f_{\sup}(x) = \sup_{y \in U} f(x, y)$ is left-c.e.

2 Semicomputability of convex sets

In dimension 1, a compact convex set is simply a closed interval. Such a set $[a, b]$ is semicomputable exactly when a is left-c.e. and b is right-c.e., i.e. when the extremal points of the set have computable approximations oriented inwards the set. It can be generalized to certain compact convex sets of the plane. While in $\mathbb{R}$ there are only two possible directions, in $\mathbb{R}^2$ there are infinitely many ones, represented by angles.

Let $A = (x, y)$ be a point of the plane. For $\theta \in \mathbb{R}$, the θ-coordinate of A is $A_\theta = x \cos\theta + y \sin\theta = (OA, u_\theta)$, i.e., the inner product of the vector $OA = (x, y)$ with $u_\theta = (\cos\theta, \sin\theta)$ ($O = (0, 0)$ is the origin). Observe that the computability properties of A_θ do not depend on the choice of the origin, as long as it is computable.

▶ **Definition 2.1.** If θ is computable then we say that A is ***θ-c.e.*** if A_θ is left-c.e. For a closed interval $I = [a, b]$, we say that A is ***I-c.e.*** if the function mapping $\theta \in I$ to A_θ is left-c.e.

For a non-empty compact convex set S and $\theta \in \mathbb{R}$, define $S_\theta = \min_{X \in S} X_\theta$, and for an extremal point V of S let $J_V^S = \{\theta \in \mathbb{R} : S_\theta = V_\theta\}$. J_V^S is a closed interval modulo 2π.

▶ **Proposition 2.2.** *A non-empty compact convex set S is semicomputable iff the function mapping θ to S_θ is left-c.e. iff for $\theta \in \mathbb{Q}$, S_θ is uniformly left-c.e.*

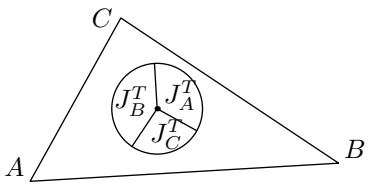
Proof. Assume that S is semicomputable, or equivalently effectively compact. The function $(A, \theta) \mapsto A_\theta$ is computable so the function $\theta \mapsto \min_{A \in S} A_\theta$ is left-c.e.

Conversely, assume that the function $\theta \mapsto S_\theta$ is left-c.e. For each θ let H_θ be the closed half-plane defined by $H_\theta = \{P \in \mathbb{R}^2 : P_\theta \geq S_\theta\}$. H_θ is semicomputable relative to and uniformly in θ, so $S = \bigcap_{\theta \in [0, 2\pi]} H_\theta$ is semicomputable as $[0, 2\pi]$ is effectively compact.

The function $\theta \mapsto S_\theta$ is L-Lipschitz for some L, so if for all $q \in \mathbb{Q}$, the number S_q is uniformly left-c.e. then the function is left-c.e. as $S_\theta = \sup\{S_q - L|q - \theta| : q \in \mathbb{Q}\}$. ◀

For a triangle, and more generally a convex polygon, the number of extremal points is finite and Proposition 2.2 can be improved as follows.

▶ **Theorem 2.3.** *A filled triangle $T = ABC$ is semicomputable iff each vertex $V \in \{A, B, C\}$ is J_V^T-c.e.*



In order to prove the theorem, we need the following Lemma.

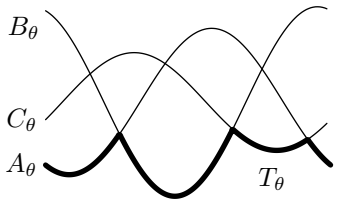
▶ **Lemma 2.4.** *Let $f : [a, b] \to \mathbb{R}$ be left-c.e. and such that there exists $\epsilon > 0$ such that f is non-increasing on $[a, a+\epsilon)$ and non-decreasing on $(b-\epsilon, b]$. There exists a left-c.e. extension $\hat{f} : \mathbb{R} \to \mathbb{R}$ of f that is non-increasing on $(a-\epsilon, a+\epsilon)$ and non-decreasing on $(b-\epsilon, b+\epsilon)$ and $\hat{f} = +\infty$ outside $(a-\epsilon, b+\epsilon)$.*

Proof. Let f_0 be a left-c.e. extension of f. Let $q, q', r, r' \in \mathbb{Q}$ satisfy $q < a < q' < r' < b < r$, $q' - q < \epsilon$ and $r - r' < \epsilon$. Define $\hat{f}(x) = f(x)$ if $x \in [q', r']$, $\hat{f}(x) = \sup_{[x,q']} f_0$ if $x \in [q, q']$, $\hat{f}(x) = \sup_{[r',x]} f_0$ if $x \in [r', r]$, $\hat{f}(x) = +\infty$ if $x < q$ or $x > r$. ◀

Proof of Theorem 2.3. If T is semicomputable then the function $\theta \mapsto T_\theta$ is left-c.e. It coincides with the function $\theta \mapsto V_\theta$ on J_V^T, so V is J_V^T-c.e.

Conversely assume that each vertex $V \in \{A, B, C\}$ is J_V^T-c.e. We show that the function mapping θ to T_θ is left-c.e. We know that it is left-c.e. on each J_V^T, and $\bigcup_{V\in\{A,B,C\}} J_V^T = \mathbb{R}$, but we must show how to merge the three algorithms. Let us assume that the origin of the Euclidean plane lies inside the triangle. If it is not the case, then one can translate the triangle by a rational vector, which preserves all the computability properties of T and its vertices.

If the origin is inside the triangle then for each vertex $V \in \{A, B, C\}$, if $J_V^T = [a, b]$ then there exists $\epsilon > 0$ such that the function V_θ is non-increasing on $(a-\epsilon, a+\epsilon)$ and non-decreasing on $(b-\epsilon, b+\epsilon)$, so by Lemma 2.4 there is a left-c.e. function $\hat{V}_\theta$ that coincides with V_θ on J_V^T, is non-increasing on $(a-\epsilon, a+\epsilon)$, non-decreasing on $(b-\epsilon, b+\epsilon)$ and $\hat{V}_\theta = +\infty$ for θ outside $(a-\epsilon, b+\epsilon)$. As a result, $T_\theta = \min\{A_\theta, B_\theta, C_\theta\} = \min\{\hat{A}_\theta, \hat{B}_\theta, \hat{C}_\theta\}$. ◀



So the semicomputability of the triangle can be decomposed in terms of the properties of the vertices treated separately, which leads us to investigate the properties of a single point.

3 Semicomputable point

The following is a generalization of left-c.e. and right-c.e. reals to points of the plane.

▶ **Definition 3.1.** A point A is ***semicomputable*** if there exist $\theta, \theta' \in \mathbb{Q}$ such that $\theta \neq \theta' \bmod \pi$ and A_θ and $A_{\theta'}$ are left-c.e.

Note that for a point, being semicomputable does not mean that the set $\{A\}$ is semicomputable. The latter is equivalent to saying that A is computable.

The vertices of a (non-degenerate) semicomputable triangle are necessarily semicomputable. We need tools to understand the directions in which the point is left-c.e.

▶ **Proposition 3.2.** *Let θ_1, θ_2 be computable such that $\theta_1 < \theta_2 < \theta_1 + \pi$. A point A is $[\theta_1, \theta_2]$-c.e. iff A_{θ_1} and A_{θ_2} are left-c.e.*

Proof. For $\theta \in [\theta_1, \theta_2]$, $A_\theta = \frac{\sin(\theta_2-\theta)}{\sin(\theta_2-\theta_1)} A_{\theta_1} + \frac{\sin(\theta-\theta_1)}{\sin(\theta_2-\theta_1)} A_{\theta_2} = \alpha(\theta)A_{\theta_1} + \beta(\theta)A_{\theta_2}$ where $\alpha(\theta)$ and $\beta(\theta)$ are nonnegative computable functions. ◀

▶ **Proposition 3.3.** *Let $I = [\alpha, \beta]$ with $\alpha < \beta$. A is I-c.e. iff A_θ is left-c.e. uniformly in $\theta \in (\alpha, \beta) \cap \mathbb{Q}$.*

Proof. The forward direction is straightforward. Let us prove the other direction. Assume that A_θ is left-c.e. uniformly in $\theta \in (\alpha, \beta) \cap \mathbb{Q}$. The function $\theta \mapsto A_\theta$ is L-Lipschitz for some L, so it is computable on the closure of $(\alpha, \beta) \cap \mathbb{Q}$, which is $[\alpha, \beta]$. Indeed, given $\theta \in [\alpha, \beta]$, take a sequence of rationals $\theta_i \in (\alpha, \beta)$ such that $|\theta - \theta_i| < 2^{-i}$, then $A_\theta = \sup_i A_{\theta_i} - L2^{-i}$. The sequence θ_i can be computed as follows: fix some rational $q \in (\alpha, \beta)$ and some k such that $\beta - q > 2^{-k}$ and $q - \alpha > 2^{-k}$, start from some rational sequence θ'_i such that $|\theta - \theta'_i| < 2^{-i}$ and define, for $i \geq k$, $\theta_i = \theta'_{i+1} + 2^{-i-1}$ if $\theta'_{i+1} \leq q$, $\theta_i = \theta'_{i+1} - 2^{-i-1}$ if $\theta'_{i+1} > q$, and $\theta_i = \theta_k$ for $i < k$. ◀

▶ **Definition 3.4.** Let A be a semicomputable point. Its ***semicomputability range*** I_A is defined as the union of the sets $[\alpha, \beta] \mod 2\pi$, for all $\alpha < \beta$ such that A is $[\alpha, \beta]$-c.e.

The range I_A is a connected subset of $\mathbb{R}/2\pi\mathbb{Z}$, i.e. is the set of equivalence classes of all the reals in an interval of $\mathbb{R}$. By abuse of notation we will often act as if I_A was a subset of $\mathbb{R}$. For instance if $\theta \in \mathbb{R}$ then when we write $\theta \in I_A$ we mean that the equivalence class of θ belongs to I_A. By $I_A = [\alpha, \beta]$ we mean that $I_a = [\alpha, \beta] \mod 2\pi$. By $\inf I_A$ we mean the equivalence class of $\inf I$ where $I \subseteq \mathbb{R}$ is any interval such that $I_A = I \mod 2\pi$.

The length of I_A is at most π, unless A is computable.

▶ **Proposition 3.5.** *A is computable $\iff$ $I_A = [0, 2\pi]$ $\iff$ $|I_A| > \pi$.*

Proof. We prove that if $|I_A| > \pi$ then A is computable, the other implications are obvious. Take $\theta, \theta' \in \mathbb{Q}$ such that $\theta, \theta + \pi, \theta', \theta' + \pi$ are pairwise distinct modulo 2π and all belong to I_A. One has $A_\theta = -A_{\theta+\pi}$ and $A_{\theta'} = -A_{\theta'+\pi}$ so all these numbers are computable, and the coordinates of A are linear combinations with computable coefficients of these numbers, so they are computable. ◀

For a computable angle θ, A_θ is left-c.e. $\iff$ $\theta \in I_A$. The uniformity in θ depends on whether the interval I_A is closed or open at each endpoint.

- If I_A is closed at an endpoint, A_θ is *uniformly* left-c.e. for θ around that endpoint,
- If I_A is open at an endpoint, A_θ is *non-uniformly* left-c.e. for θ around that endpoint,
- In particular, I_A is closed iff A is I_A-c.e. iff for $\theta \in I_A \cap \mathbb{Q}$, A_θ is left-c.e. *uniformly* in θ.

Using the last property and Definition 3.4, Theorem 2.3 can be reformulated as follows:

▶ **Corollary 3.6.** *A filled triangle $T = ABC$ is semicomputable iff each vertex $V \in \{A, B, C\}$ is semicomputable and $J_V^T \subseteq I_V$.*

In particular, if the filled triangle ABC is semicomputable then $|I_A| + |I_B| + |I_C| \geq 2\pi$ and $I_A \cup I_B \cup I_C = [0, 2\pi]$. This condition is not sufficient, as the intervals I_V must have the right orientations.

3.1 Semicomputable points and converging sequences

The intervals I for which a point A is I-c.e. are related to the regions containing computable sequences of points converging to A. However this is not an exact correspondence.

A two-dimensional cone with endpoint at A and delimited by the semi-lines starting at A with angles α, β, $\alpha \leq \beta < \alpha + \pi$, is denoted by $C(A, \alpha, \beta)$ and can be formally defined as $\{P \in \mathbb{R}^2 : (PA)_{\alpha - \pi/2} \geq 0 \text{ and } (PA)_{\beta + \pi/2} \geq 0\}$, where $(PA)_\theta = A_\theta - P_\theta$. Observe that this definition depends on the equivalence classes of α and β modulo 2π, so strictly speaking we do not need $\alpha \leq \beta < \alpha + \pi$ but $\alpha \leq \beta + 2k\pi < \alpha + \pi$ for some $k \in \mathbb{Z}$.

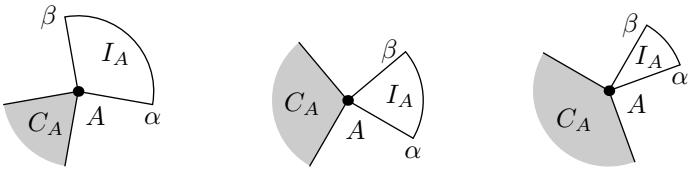


Figure 1 The semicomputability range (in white) and the Solovay cone (in gray) of the point $A = (x, y)$. (i) x, y are left-c.e., (ii) only x is left-c.e., (iii) x, y are not left-c.e.

▶ **Definition 3.7.** If A is semicomputable then we define its ***Solovay cone*** as $C_A = C(A, \beta + \pi/2, \alpha - \pi/2)$ where $\alpha = \inf I_A$ and $\beta = \sup I_A$.

The name will be explained in Section 4.

▶ **Proposition 3.8.** *C_A is the intersection of all the cones containing computable sequences converging to A.*

However there is not necessarily a computable sequence converging to A contained in C_A (an example will be given in Theorem 5.4).

▶ **Proposition 3.9.** *Let $I = [\alpha, \beta]$ with $\alpha < \beta \leq \alpha + \pi$ and A be I-c.e.*

- *If α left-c.e. and β right-c.e. then there exists a computable sequence A_i converging to A in the cone $C(A, \beta + \pi/2, \alpha - \pi/2)$.*
- *If α is $\emptyset'$-right-c.e. and β is $\emptyset'$-left-c.e. then there exists a computable sequence A_i converging to A and converging* to *the cone $C(A, \beta + \pi/2, \alpha - \pi/2)$, i.e., eventually contained in $C(A, \beta + \pi/2 - \epsilon, \alpha - \pi/2 + \epsilon)$ for every $\epsilon > 0$.*

We now identify the numbers α, β which can be endpoints of I_A for semicomputable A, when I_A is closed at these endpoints.

▶ **Theorem 3.10.** *For a real number α, the following are equivalent:*

- *α is $\emptyset'$-left-c.e.,*
- *$\alpha = \min I_A$ for some semicomputable point A.*

Symmetrically, β is $\emptyset'$-right-c.e. iff $\beta = \max I_A$ for some semicomputable point A.

4 Solovay derivatives

We have seen that the semicomputability of a triangle can be reduced to the semicomputability of its vertices and more precisely to their semicomputability ranges. Therefore we need tools to determine the range of a semicomputable point. This can be done using Solovay reducibility and its quantitative versions.

The coordinates of a semicomputable $A = (x, y)$ are d-c.e. and might not be either left-c.e. nor right-c.e. However, there is always a rotation with a rational angle mapping A to a semicomputable point $A' = (x', y')$ whose range $I_{A'}$ contains 0 i.e. such that x' is left-c.e. If $|I_A| > \pi/2$ then one can even take $I_{A'}$ containing 0 and $\pi/2$, i.e. one can take both x' and y' left-c.e. Hence in the study of semicomputable points one can restrict for simplicity to points (x, y) where x is left-c.e.

We first recall Solovay's notion of reduction between left-c.e. real numbers. We then define its quantitative version and study it. It has been independently introduced and studied in [1, 10], but the overlap is small.

4.1 Solovay derivatives

More on Solovay reducibility can be found in [11, 4]. It was originally defined for left-c.e. reals and has been extended to arbitrary reals in [15, 12].

Let $b_i \nearrow b$ denote that the sequence b_i is increasingly converging to b.

▶ **Definition 4.1.** Let b be left-c.e. We say that a is ***Solovay reducible*** to b if there exists a constant q and computable sequences $a_i \to a, b_i \nearrow b$ such that $|a - a_i| \leq q(b - b_i)$ for all i.

It is denoted by $a \leq_S b$. Equivalently, $a \leq_S b$ if there exists $q \in \mathbb{Q}$ such that $qb - a$ is left-c.e. and $-qb - a$ is right-c.e., which implies that a is d-c.e. We are interested in the optimal constants q and r such that $qb - a$ is left-c.e. and $rb - a$ is right-c.e.

Let b be left-c.e. If q is rational and $qb - a$ is left-c.e. then for every rational $q' > q$, $q'b - a$ is left-c.e. as well. In other words, the set $\{q \in \mathbb{Q} : qb - a \text{ is left-c.e.}\}$ is closed upwards. Similarly, the set $\{q \in \mathbb{Q} : qb - a \text{ is right-c.e.}\}$ is closed downwards. The following quantities have also been defined in [1].

▶ **Definition 4.2.** Let b be left-c.e. We define the ***upper and lower Solovay derivatives*** of a w.r.t. b as, respectively,

$$\overline{S}(a, b) = \inf\{q \in \mathbb{Q} : qb - a \text{ is left-c.e.}\},$$
$$\underline{S}(a, b) = \sup\{q \in \mathbb{Q} : qb - a \text{ is right-c.e.}\}.$$

The use of the word *derivative* will be justified in the sequel. By definition, $a \leq_S b \iff \overline{S}(a, b) < +\infty$ and $\underline{S}(b, a) > -\infty$. When $\underline{S}(a, b) = \overline{S}(a, b)$, we denote this value by $S(a, b)$. For instance it was proved in [1] and generalized in [10] that when b is Solovay complete $\underline{S}(a, b) = \overline{S}(a, b)$.

4.2 Basic properties

Here we investigate the possible values of $\underline{S}(a, b)$ and $\overline{S}(a, b)$ and their relationship. When a and b are both computable, $\underline{S}(a, b) = +\infty$ and $\overline{S}(a, b) = -\infty$.

▶ **Proposition 4.3.** *Let b be left-c.e. The following conditions are equivalent:*
1. $\overline{S}(a, b) < \underline{S}(a, b)$,
2. $\overline{S}(a, b) = -\infty$ *and* $\underline{S}(a, b) = +\infty$,
3. a, b *are computable.*

Proof. $3 \Rightarrow 2 \Rightarrow 1$ is direct. We prove $1 \Rightarrow 3$. If $\overline{S}(a, b) < \underline{S}(a, b)$ then for rationals $q < r$ in between, $qb - a$ is left-c.e. and $rb - a$ is right-c.e. which implies, by performing linear combinations, that a and b are computable. ◀

We consider this case as degenerate. In the other cases, i.e. when a, b are not both computable, one has $\underline{S}(a, b) \leq \overline{S}(a, b)$. The possible values of $(\underline{S}(a, b), \overline{S}(a, b))$ are:

	b computable	b left-c.e. not computable
a computable	$(+\infty, -\infty)$	$\underline{S}(a, b) = \overline{S}(a, b) = 0$
a left-c.e. not computable	$(+\infty, +\infty)$	$0 \leq \underline{S}(a, b) \leq \overline{S}(a, b)$
a right-c.e. not computable	$(-\infty, -\infty)$	$\underline{S}(a, b) \leq \overline{S}(a, b) \leq 0$
a d-c.e. not left/right-c.e.	$(-\infty, +\infty)$	$\underline{S}(a, b) \leq 0 \leq \overline{S}(a, b)$

The name "Solovay derivative" is partly justified by the next property which relates the quantities $\underline{S}(a, b)$ and $\overline{S}(a, b)$ to the difference quotient when approximating a and b computably. We will see later a strong connexion with the usual notion of derivative.

▶ **Proposition 4.4.** *Let a, b be d-c.e. and left-c.e. respectively, not both computable. If $a_i \to a$ and $b_i \nearrow b$ are computable sequences then*

$$\liminf \frac{a-a_i}{b-b_i} \leq \underline{S}(a,b) \leq \overline{S}(a,b) \leq \limsup \frac{a-a_i}{b-b_i}.$$

Proof. If $\limsup \frac{a-a_i}{b-b_i} < q$ then $a - a_i < q(b-b_i)$ for sufficiently large i, so $\overline{S}(a,b) \leq q$. Similarly, if $\liminf \frac{a-a_i}{b-b_i} > q$ then $a - a_i > q(b-b_i)$ for sufficiently large i, so $\underline{S}(a,b) \geq q$. ◀

In particular, if there are computable sequences $a_i \to a$ and $b_i \nearrow b$ such that $\frac{a-a_i}{b-b_i}$ has a limit s, then $\underline{S}(a,b) = \overline{S}(a,b) = s$.

▶ **Question 1.** *Are there always computable sequences $a_i \to a$ and $b_i \nearrow b$ such that*

$$\liminf \frac{a-a_i}{b-b_i} = \underline{S}(a,b) \leq \overline{S}(a,b) = \limsup \frac{a-a_i}{b-b_i}?$$

4.3 Calculation of the Solovay derivatives

We give formulas to derive the values of $\underline{S}(a,b)$ and $\overline{S}(a,b)$ in several situations.

▶ **Proposition 4.5** (Properties)**.**

1. *(Reflexivity) $\underline{S}(b,b) = \overline{S}(b,b) = 1$ if b is left-c.e. not computable.*
2. *When both a and b are left-c.e., one has $\underline{S}(a,b) = 1/\overline{S}(b,a)$.*
3. *(Transitivity) For all d-c.e. real a and left-c.e. reals b, c such that $a \leq_S b \leq_S c$,*
   - *If $\overline{S}(a,b) \geq 0$ then $\overline{S}(a,c) \leq \overline{S}(a,b)\overline{S}(b,c)$, otherwise $\overline{S}(a,c) \leq \overline{S}(a,b)\underline{S}(b,c)$.*
   - *If $\underline{S}(a,b) \geq 0$ then $\underline{S}(a,c) \geq \underline{S}(a,b)\underline{S}(b,c)$, otherwise $\underline{S}(a,c) \geq \underline{S}(a,b)\overline{S}(b,c)$.*
4. *In some cases we can also derive equalities. For all d-c.e. real a and left-c.e. reals b, c such that $a \leq_S b \leq_S c$ and $\underline{S}(a,b) = \overline{S}(a,b) =: S(a,b)$,*
   - *If $S(a,b) \geq 0$ then $\overline{S}(a,c) = S(a,b)\overline{S}(b,c)$ and $\underline{S}(a,c) = S(a,b)\underline{S}(b,c)$.*
   - *If $S(a,b) \leq 0$ then $\overline{S}(a,c) = S(a,b)\underline{S}(b,c)$ and $\underline{S}(a,c) = S(a,b)\overline{S}(b,c)$.*

4.3.1 Differentiation

The name Solovay derivative is justified by the following result, also obtained in [10] when b is Solovay complete.

▶ **Proposition 4.6.** *Let b be a non-computable left-c.e. real. If f is computable and differentiable at b then*

$$\underline{S}(f(b),b) = \overline{S}(f(b),b) = f'(b).$$

Proof. It is a direct application of Proposition 4.4. Let $b_i \nearrow b$ be a computable sequence. The sequence $f(b_i)$ is computable and $\lim(f(b) - f(b_i))/(b - b_i) = f'(b)$. ◀

It also implies that if f, g are computable, differentiable and $f'(b)$ and $g'(b)$ are positive then

$$S(f(a), g(b)) = \frac{f'(a)}{g'(b)} S(a,b).$$

This is proved by applying two times Proposition 4.5, item 4.

▶ **Example 4.7.** For instance, if b is not computable then $S(2b, b) = 2$ and $S(b^2, b) = 2b$ and $\overline{S}(\log(a), \log(b)) = b\overline{S}(a,b)/a$ and $\underline{S}(\log(a), \log(b)) = a\underline{S}(a,b)/a$.

In particular, for $a, b > 0$, $\overline{S}(a,b) = \frac{a}{b} \inf\{q \in \mathbb{Q} : \frac{b^q}{a} \text{ is left-c.e.}\}$.

Proposition 4.6 can be extended to bivariate differentiable functions.

▶ **Theorem 4.8.** *Let $f : \mathbb{R}^2 \to \mathbb{R}$ be totally differentiable and computable. Let y be left-c.e. and assume that x, y are not both computable.*

- *If* $\frac{\partial f}{\partial x}(x,y) > 0$, *then* $\begin{cases} \underline{S}(f(x,y),y) = \underline{S}(x,y)\frac{\partial f}{\partial x}(x,y) + \frac{\partial f}{\partial y}(x,y), \\ \overline{S}(f(x,y),y) = \overline{S}(x,y)\frac{\partial f}{\partial x}(x,y) + \frac{\partial f}{\partial y}(x,y). \end{cases}$
- *If* $\frac{\partial f}{\partial x}(x,y) < 0$, *then* $\begin{cases} \underline{S}(f(x,y),y) = \overline{S}(x,y)\frac{\partial f}{\partial x}(x,y) + \frac{\partial f}{\partial y}(x,y), \\ \overline{S}(f(x,y),y) = \underline{S}(x,y)\frac{\partial f}{\partial x}(x,y) + \frac{\partial f}{\partial y}(x,y). \end{cases}$
- *If* $\frac{\partial f}{\partial x}(x,y) = 0$ *and* $x \leq_S y$ *then* $\underline{S}(f(x,y),y) = \overline{S}(f(x,y),y) = \frac{\partial f}{\partial y}(x,y)$.

In particular, if $\frac{\partial f}{\partial x}(x,y) \neq 0$ then $f(x,y) \leq_{\mathrm{S}} y$ implies $x \leq_{\mathrm{S}} y$.

▶ Remark. In the remaining case where $\frac{\partial f}{\partial x}(x,y) = 0$ and $x \not\leq_{\mathrm{S}} y$, the values of $\underline{S}(f(x,y),y)$ and $\overline{S}(f(x,y),y)$ cannot be expressed in terms of $\underline{S}(x,y)$, $\overline{S}(x,y)$ and $\frac{\partial f}{\partial y}(x,y)$ only.

▶ **Example 4.9.**

- One has $\overline{S}(a+b,a) = 1 + \overline{S}(b,a)$, $\underline{S}(a+b,a) = 1 + \underline{S}(b,a)$.
- One has $\overline{S}(ab,a) = b + a\overline{S}(ab,a)$ and $\underline{S}(ab,a) = b + a\underline{S}(ab,a)$.

4.4 Back to semicomputable points

We now relate the semicomputability range of a point $A = (x,y)$ to the quantities $\overline{S}(y,x)$ and $\underline{S}(y,x)$, when x is left-c.e.

▶ **Proposition 4.10.** *Let $A = (x,y)$ be semicomputable but not computable with x left-c.e. and let $\alpha = \inf I_A$ and $\beta = \sup I_A$. One has $-\pi \leq \alpha \leq 0 \leq \beta \leq \pi$ and*

$$\alpha = \arctan(\overline{S}(y,x)) - \pi/2 \qquad \overline{S}(y,x) = \tan(\alpha + \pi/2)$$
$$\beta = \arctan(\underline{S}(y,x)) + \pi/2 \qquad \underline{S}(y,x) = \tan(\beta - \pi/2).$$

The functions tan and arctan are understood as functions between $[-\pi/2, \pi/2]$ and $[-\infty, +\infty]$.

Therefore the slopes of the Solovay cone C_A are $\underline{S}(y,x)$ and $\overline{S}(y,x)$, which explains the name of the cone.

We now give examples of semicomputable points and calculate their ranges. Let $A = (x,y)$ with x left-c.e.

- If x, y are Solovay incomparable left-c.e. reals then $\underline{S}(y,x) = 0$ and $\overline{S}(y,x) = +\infty$. The point $A = (x,y)$ is semicomputable with $I_A = [0, \pi/2]$.
- Let $x = \Omega$ be some Solovay complete left-c.e. real.
  - If y is left-c.e. incomplete then $S(y,\Omega) = 0$ and $I_A = (-\pi/2, \pi/2]$,
  - If y is right-c.e. incomplete then $S(y,\Omega) = 0$ and $I_A = [-\pi/2, \pi/2)$,
  - If y is d-c.e., neither left-c.e. nor right-c.e. then $S(y,\Omega) = 0$ and $I_A = (-\pi/2, \pi/2)$,
  - If $y = \Omega$ then $S(y,\Omega) = 1$ and $I_A = [-\pi/4, \pi/4]$.
- Let $y = f(x)$ where $f : \mathbb{R} \to \mathbb{R}$ is such that f' is computable and monotonic. One has $S(y,x) = f'(x)$ and $I_A = [\arctan(f'(x)) - \pi/2, \arctan(f'(x)) + \pi/2]$.

It is proved in [10] that every $\emptyset'$-computable (or Δ^0_2) number can be obtained as $S(b,\Omega)$ for some d-c.e. b and Solovay complete Ω. The proof of Theorem 3.10 shows that every $\emptyset'$-left-c.e. can be obtained this way, and symmetrically every $\emptyset'$-right-c.e. hence every $\emptyset'$-d-c.e. It gives a partial answer to Question 2.7 in [10].

▶ **Question 2.** *Can every Δ^0_3 real be obtained as $S(b,\Omega)$ for some left-c.e./d-c.e. real b?*

5 Generic triangles

All the classical parameters (like the angles or the coordinates of the centroid) of a semicomputable triangle are d-c.e. numbers, because the function mapping a triangle to a parameter is computable and Lipschitz. Some of them, like the sides lengths, the area or the perimeter, are always right-c.e.

In this section we show that these upper bounds on the effectiveness of the parameters are optimal. To do this we prove the existence of semicomputable triangles with prescribed properties. However instead of building them explicitly we use the existence of semicomputable triangles that are *generic* in some sense, and then investigate the properties of such triangles. We first give the minimal material needed, taken from [7].

▶ **Definition 5.1.** Let X be an effective Polish space and $A \subseteq X$. A point $x \in A$ is ***generic inside*** A if for every effective open set $U \subseteq X$, either $x \in U$ or there exists a neighborhood B of x such that $B \cap U \cap A = \emptyset$.

▶ **Example 5.2.**

- Taking $A = X$, being generic inside X amounts to being 1-generic,
- Every x is obviously generic inside $\{x\}$,
- In the space of real numbers with the Euclidean topology, a real number $x \in (0, 1)$ is ***right-generic*** if x is generic inside $[x, 1]$,
- The space of filled triangles is a subspace of the space of non-empty compact subsets of $\mathbb{R}^2$ with the Hausdorff metric and is an effective Polish space. A triangle T is ***inner-generic*** if it is generic inside $S(T) := \{T' \in \mathcal{T}, T' \subseteq T\}$. In other words, for every effective open set $\mathcal{U} \subseteq \mathcal{T}$, if T contains arbitrarily close (in the Hausdorff metric) triangles $T' \in \mathcal{U}$, then $T \in \mathcal{U}$.

The latter two examples are particular instances of the following general situation.

If τ' is a weaker topology on X then we define $S(x)$ as the closure of x in the topology τ', which is the intersection of the τ'-open sets containing x. Equivalently, $S(x) = \{y \in X : x \leq_{\tau'} y\}$ where $\leq_{\tau'}$ is the specialization pre-order defined by $x \leq y$ iff every τ'-neighborhood of x contains y.

▶ **Theorem 5.3** (Theorem 4.1.1 in [7]). *Let (X, τ) be an effective Polish space and τ' an effectively weaker topology, such that emptiness of finite intersections of basic open sets in τ, τ' is decidable. There exists a point x that is computable in (X, τ') and generic inside $S(x)$.*

For instance, $\mathbb{R}$ with the Euclidean topology is effective Polish, the topology τ' generated by the semi-lines $(q, +\infty)$ is effectively weaker, and its specialization pre-order is the natural ordering $\leq$ on $\mathbb{R}$. Theorem 5.3 implies the existence of right-generic left-c.e. reals.

In the effective Polish space $\mathcal{T}$ of filled triangles, we take the topology τ' generated by the following open sets: given a finite union U of open metric balls in $\mathbb{R}^2$, the set of triangles contained in U is a basic open set of the topology τ'. The specialization ordering is the reversed inclusion. Theorem 5.3 implies the existence of inner-generic semicomputable triangles.

Now we have the tools to prove the main result of this section.

▶ **Theorem 5.4.** *Let $T = ABC$ be an inner-generic semicomputable triangle.*

- *Each vertex A, B, C is generic inside T,*
- *For each vertex $V \in \{A, B, C\}$, $I_V = J_V^T$,*
- *For each vertex V, there is no computable sequence converging to V in the cone C_V,*

- *The slopes of the sides of T are 1-generic d-c.e. reals,*
- *The angles of T are 1-generic d-c.e. reals,*
- *A is not computable relative to the pair (B, C) (idem for B and C),*
- *The area of T is a left-generic right-c.e. real,*
- *The centroid of T is a 1-generic point with d-c.e. coordinates.*

This list could of course be extended *ad nauseam*.

6 Parametrizations

In the one-dimensional case, there is a simple parametrization of the semicomputable compact convex subsets of $\mathbb{R}$: they are exactly the closed intervals $[a, b]$ where a is left-c.e. and b is right-c.e. Apart from the fact that $a \leq b$, the two parameters a and b are independent. In this section we investigate the possibility of having a similar parametrization for classes of semicomputable compact convex subsets of $\mathbb{R}^2$, for instance the filled triangles. We show that for some definition of parametrization, no finite parametrization is possible.

A ***numbered set*** is a pair $\mathcal{S} = (S, \nu)$ where S is a countable set and $\nu_S : \mathrm{dom}(\nu) \subseteq \mathbb{N} \to S$ is surjective. If $\mathcal{S} = (S, \nu)$ is a numbered set then each $T \subseteq S$ has a canonical numbering, given by the restriction of ν to $\nu^{-1}(T)$. A ***morphism*** from $\mathcal{S} = (S, \nu)$ to $\mathcal{S}' = (S', \nu')$ is a function $\phi : S \to S'$ such that there exists a computable function $\varphi : \mathrm{dom}(\nu) \to \mathrm{dom}(\nu')$ such that $\nu' \circ \varphi = \phi \circ \nu$.

▶ **Definition 6.1.** Let $\mathcal{S} = (S, \nu_S)$ and $\mathcal{P} = (P, \nu_P)$ be numbered sets. A ***$\mathcal{P}$-parametrization*** of $\mathcal{S}$ is an isomorphism between $\mathcal{S}$ and a subset of $\mathcal{P}$.

We are interested in the case where $\mathcal{S}$ is the class of semicomputable triangles and $\mathcal{P} = \mathbb{R}^d_{\mathrm{lce}}$ is the class of vectors of d left-c.e. numbers, both with their canonical numberings. Proposition 2.2 implies the existence of a $\mathbb{R}^{\mathbb{N}}_{\mathrm{lce}}$-parametrization of the semicomputable filled triangles, i.e. that each such triangle T can be represented by a sequence of uniformly left-c.e. real numbers T_{θ_i}, where $(\theta_i)_{i\in\mathbb{N}}$ is a canonical enumeration of the rational numbers. We prove that no finite parametrization exists.

▶ **Theorem 6.2.** *For each $d \in \mathbb{N}$, there is no $\mathbb{R}^d_{\mathrm{lce}}$-parametrization of the semicomputable filled triangles.*

Proof. We first observe that an isomorphism between $\mathcal{T}$ and a subset of $\mathbb{R}^d_{\mathrm{lce}}$ would be order-preserving in both directions, where $\mathcal{T}$ is endowed with the reverse inclusion $\supseteq$ and $\mathbb{R}^d_{\mathrm{lce}}$ with the component-wise natural ordering $\leq$. This is a consequence of the generalization of the Myhill-Shepherdson theorem to effective continuous directed complete partial orders (dcpo's) [14]. It would imply that $(\mathcal{T}, \supseteq)$ embeds in $(\mathbb{R}^d, \leq)$, which we show is not possible. For this we use the order-theoretic notion of dimension and show that $(\mathcal{T}, \supseteq)$ is infinite-dimensional, while $(\mathbb{R}^d, \leq)$ is d-dimensional.

All the details about the dimension of partially ordered sets can be found in [13], we only give the key notions. A partially ordered set (poset) $(P, \leq)$ has dimension k if there exist k linear extensions of $\leq$ whose intersection is $\leq$, and k is minimal with this property. The standard n-dimensional ordering is $S_n = \{a_1, \ldots, a_n, A_1, \ldots, A_n\}$ with $a_i < A_j$ if $i \neq j$. If a poset $(P, \leq_P)$ embeds into a poset $(Q, \leq_Q)$ then the dimension of $(P, \leq_P)$ is no more than the dimension of $(Q, \leq_Q)$. The poset $(\mathbb{R}^d, \leq)$ has dimension d and we show that $(\mathcal{T}, \supseteq)$ is not finite-dimensional by embedding the standard ordering S_d into $(\mathcal{T}, \supseteq)$, for each $d \in \mathbb{N}$.

For each i, $a_i \in S_d$ is mapped to a large triangle t_i and $A_i \in S_d$ is mapped to a small triangle T_i such that $t_i \supseteq T_j \iff i \neq j$. This is achieved by starting from a regular polygon

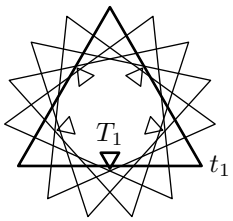

Figure 2 Embedding the standard 5-dimensional ordering in the poset of triangles. Note that T_1 is *not* contained in t_1.

with d vertices $v_1, \dots, v_d$, taking for each i a large triangle t_i containing all the vertices except v_i, and a small triangle T_i containing v_i. We simply show a picture for $d = 5$, but it can be generalized to any $d \in \mathbb{N}$. ◀

One could relax the notion of parametrization in different ways:

- If one requires a morphism from a subset of $\mathbb{R}^d_{\text{lce}}$ onto $\mathcal{T}$ then there is a $\mathbb{R}^2_{\text{lce}}$-parametrization, essentially because all the elements of the anti-diagonal of $\mathbb{R}^d_{\text{lce}}$ are pairwise incomparable.
- If one requires a one-to-one morphism from $\mathcal{T}$ to $\mathbb{R}^d_{\text{lce}}$ then there is a $\mathbb{R}_{\text{lce}}$-parametrization because $\mathcal{T}$ embeds in $\mathbb{R}^{\mathbb{N}}_{\text{lce}}$ and there is a one-to-one morphism from $\mathbb{R}^{\mathbb{N}}_{\text{lce}}$ to $\mathbb{R}_{\text{lce}}$.

In both cases, the parametrizations are not satisfactory because they are not geometrically meaningful. Other variations on the definition of parametrizations should be investigated.

The argument in the proof of Theorem 6.2 is actually very general and can be extended to many classes of sets.

▶ **Theorem 6.3.** *Let $\mathcal{F}$ be a class of compact semicomputable subsets of $\mathbb{R}^2$ that contains a set with non-empty interior and is closed under translations, scaling and rotations with rational parameters. There is no $\mathbb{R}^d$-parametrization of $\mathcal{F}$ for any $d \in \mathbb{N}$.*

Proof. We embed the standard d-dimensional ordering in $(\mathcal{F}, \supseteq)$.

Let $S \in \mathcal{F}$ be a set with non-empty interior. There exists a closed ball $\overline{B}(c, r)$ contained in S and intersecting the boundary ∂S of S in exactly one point. Indeed, take c_0 in the interior of S and $r_0 = d(c_0, \partial S)$. $\overline{B}(c_0, r_0)$ is contained in S and intersects ∂S in at least one point p. Let $c = (c_0 + p)/2$ and $r = r_0/2$. One easily checks that $\overline{B}(c, r)$ intersects ∂S in exactly one point.

Given $d \in \mathbb{N}$, let $(S_i)_{1 \leq i \leq d}$ be d distinct copies of S, rotated around c. The disk $\overline{B}(c, r)$ is contained in each S_i and intersects its boundary in exactly one point p_i. Therefore, for $i \neq j$, p_i belongs to the interior of S_j. For each i, let s_i be a small scaled copy of S containing p_i in its interior. As $p_i \in \partial S_i$, s_i is not contained in S_i. One can take s_i sufficiently small so that it is contained in each S_j, $j \neq i$. The family of sets S_i and s_i is an embedding of the standard d-dimensional ordering in $\mathcal{F}$. ◀

On Computing the Total Variation Distance of Hidden Markov Models

Stefan Kiefer
University of Oxford, United Kingdom

Abstract

We prove results on the decidability and complexity of computing the total variation distance (equivalently, the L_1-distance) of hidden Markov models (equivalently, labelled Markov chains). This distance measures the difference between the distributions on words that two hidden Markov models induce. The main results are: (1) it is undecidable whether the distance is greater than a given threshold; (2) approximation is #P-hard and in PSPACE.

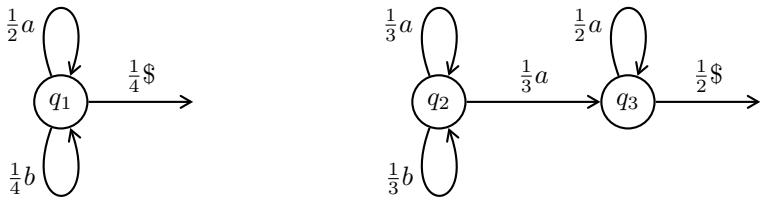
1 Introduction

A (discrete-time, finite-state, finite-word) *labelled Markov chain (LMC)* (often called *hidden Markov model*) has a finite set Q of states and for each state a probability distribution over its outgoing transitions. Each outgoing transition is labelled with a letter from an alphabet Σ and leads to a target state, or is labelled with an end-of-word symbol \$. Here are two LMCs:



The LMC starts in a given initial state (or in a random state according to a given initial distribution), picks a random transition according to the state's distribution over the outgoing transitions, outputs the transition label, moves to the target state, and repeats until the end-of-word label \$ is emitted. This induces a probability distribution over finite words (excluding the end-of-word label \$). In the example above, if q_1 and q_2 are the initial states then the LMCs induce distributions π_1, π_2 with $\pi_1(aa) = \frac{1}{2} \cdot \frac{1}{2} \cdot \frac{1}{4}$ and $\pi_2(aa) = \frac{1}{3} \cdot \frac{1}{3} \cdot \frac{1}{2} + \frac{1}{3} \cdot \frac{1}{2} \cdot \frac{1}{2}$. LMCs are widely employed in fields such as speech recognition (see [23] for a tutorial), gesture recognition [4], signal processing [8], and climate modeling [1]. LMCs are heavily used in computational biology [12], more specifically in DNA modeling [6] and biological

sequence analysis [11], including protein structure prediction [17] and gene finding [2]. In computer-aided verification, LMCs are the most fundamental model for probabilistic systems; model-checking tools such as Prism [18] or Storm [9] are based on analyzing LMCs efficiently.

A fundamental yet non-trivial question about LMCs is whether two LMCs generate the same distribution on words. This problem itself has applications in verification [16] and can be solved in polynomial time using algorithms that are based on linear algebra [24, 22, 7]. If two such distributions are not equal, one may ask how different they are. There exist various *distances* between discrete distributions, see, e.g., [7, Section 3]. One of them is the total variation distance (in the following just called *distance*), which can be defined by $d(\pi_1, \pi_2) = \max_{W \subseteq \Sigma^*} |\pi_1(W) - \pi_2(W)|$ in the case of LMCs. That is, $d(\pi_1, \pi_2)$ is the largest possible difference between probabilities that π_1 and π_2 assign to the same set of words. This distance is, up to a factor 2, equal to the L_1-norm of the difference between π_1 and π_2, i.e., $2d(\pi_1, \pi_2) = \sum_{w \in \Sigma^*} |\pi_1(w) - \pi_2(w)|$. Clearly, π_1 and π_2 are equal if and only if their distance is 0.

It is immediate from the definition of the distance that if L is a family of LMCs whose pairwise distances are bounded by $b \geq 0$ then for any event $W \subseteq \Sigma^*$ and any two LMCs $\mathcal{M}_1, \mathcal{M}_2 \in L$ we have $|\pi_1(W) - \pi_2(W)| \leq b$. From a verification point of view, this means that one needs to model check only one LMC in the family to obtain an approximation within b for the probabilities that the LMCs satisfy a given property W. Therefore, computing or approximating the distance can make model checking more efficient. It is shown in [3] that the *bisimilarity pseudometric* defined in [10] is an upper bound on the total variation distance and can be computed in polynomial time. The bisimilarity pseudometric has more direct bearings on *branching-time* system properties, which, in addition to emitted labels, take LMC states into account (not considered in this paper).

The problem of computing the distance was first studied in [20]: they show that computing the distance is NP-hard. In [7] it was shown that even approximating the distance within an $\varepsilon > 0$ given in binary is NP-hard. In this paper we improve these results. We show that it is undecidable whether the distance is greater than a given threshold. Further we show that approximating the distance is #P-hard and in PSPACE. The #P-hardness construction is relatively simple, perhaps simpler than the construction underlying the NP-hardness result in [7]. In contrast, our PSPACE algorithm requires a combination of special techniques: rounding-error analysis in floating-point arithmetic and Ladner's result [19] on counting in polynomial space.

2 Preliminaries

Let Q be a finite set. We view elements of $\mathbb{R}^Q$ as *vectors*, more specifically as row vectors. We write $\mathbf{1}$ for the all-1 vector, i.e., the element of $\{1\}^Q$. For a vector $\mu \in \mathbb{R}^Q$, we denote by $\mu^\top$ its transpose, a column vector. A vector $\mu \in [0,1]^Q$ is a *distribution over* Q if $\mu \mathbf{1}^\top = 1$. For $q \in Q$ we write δ_q for the (*Dirac*) distribution over Q with $\delta_q(q) = 1$ and $\delta_q(r) = 0$ for $r \in Q \setminus \{q\}$. We view elements of $\mathbb{R}^{Q \times Q}$ as *matrices*. A matrix $M \in [0,1]^{Q \times Q}$ is called *stochastic* if each row sums up to one, i.e., $M\mathbf{1}^\top = \mathbf{1}^\top$.

▶ **Definition 1.** A *labelled (discrete-time, finite-state, finite-word) Markov chain (LMC)* is a quadruple $\mathcal{M} = (Q, \Sigma, M, \eta)$ where Q is a finite set of states, Σ is a finite alphabet of labels, the mapping $M : \Sigma \to [0,1]^{Q \times Q}$ specifies the transitions, and $\eta \in [0,1]^Q$, with $\eta^\top + \sum_{a \in \Sigma} M(a)\mathbf{1}^\top = \mathbf{1}^\top$, specifies the end-of-word probability of each state.

Intuitively, if the LMC is in state q, then with probability $M(a)(q, q')$ it emits a and moves to state q', and with probability $\eta(q)$ it stops emitting labels. For the complexity results

in this paper, we assume that all numbers in η and in the matrices $M(a)$ for $a \in \Sigma$ are rationals given as fractions of integers represented in binary. We extend M to the mapping $M : \Sigma^* \to [0,1]^{Q \times Q}$ with $M(a_1 \cdots a_k) = M(a_1) \cdots M(a_k)$ for $a_1, \ldots, a_k \in \Sigma$. Intuitively, if the LMC is in state q then with probability $M(w)(q,q')$ it emits the word $w \in \Sigma^*$ and moves (in $|w|$ steps) to state q'. We require that each state of an LMC have a positive-probability path to some state q with $\eta(q) > 0$.

Fix an LMC $\mathcal{M} = (Q, \Sigma, M, \eta)$ for the rest of this section. To an (initial) distribution π over Q we associate the discrete probability space $(\Sigma^*, 2^{\Sigma^*}, \Pr_\pi)$ with $\Pr_\pi(w) := \Pr_\pi(\{w\}) := \pi M(w) \eta^\top$. To avoid clutter and when confusion is unlikely, we may identify the distribution $\pi \in [0,1]^Q$ with its induced probability measure $\Pr_\pi$; i.e., for a word or set of words W we may write $\pi(W)$ instead of $\Pr_\pi(W)$.

Given two initial distributions π_1, π_2, the *(total variation) distance* between π_1 and π_2 is defined as follows:[1]

$$d(\pi_1, \pi_2) \;:=\; \sup_{W \subseteq \Sigma^*} |\pi_1(W) - \pi_2(W)| \,.$$

As $\pi_1(W) - \pi_2(W) = \pi_2(\Sigma^* \setminus W) - \pi_1(\Sigma^* \setminus W)$, we have $d(\pi_1, \pi_2) = \sup_{W \subseteq \Sigma^*} (\pi_1(W) - \pi_2(W))$. The following proposition follows from basic principles, see, e.g., [21, Lemma 11.1]. In particular, it says that the supremum is attained and the total variation distance is closely related to the L_1-distance:

▶ **Proposition 2.** *Let $\mathcal{M}$ be an LMC. For any two initial distributions π_1, π_2 we have:*

$$d(\pi_1, \pi_2) \;=\; \max_{W \subseteq \Sigma^*} (\pi_1(W) - \pi_2(W)) \;=\; \frac{1}{2} \sum_{w \in \Sigma^*} |\pi_1(w) - \pi_2(w)|$$

The maximum is attained by $W = \{w \in \Sigma^* : \pi_1(w) \geq \pi_2(w)\}$.

In view of this proposition, all complexity results on the (total variation) distance hold equally for the L_1-distance.

An LMC $\mathcal{M}$ is called *acyclic* if its transition graph is acyclic. Equivalently, $\mathcal{M}$ is acyclic if for all $q \in Q$ we have that $\Pr_{\delta_q}$ has finite support, i.e., $\{w \in \Sigma^* : \Pr_{\delta_q}(w) > 0\}$ is finite.

3 The Threshold-Distance Problem

In [20, Section 6] (see also [7, Theorem 7]), a reduction is given from the *clique* decision problem to show that computing the distance in LMCs is NP-hard. In that reduction the distance is rational and its bit size polynomial in the input. It was shown in [5, Proposition 12] that the distance d can be irrational. Define the *non-strict (resp. strict) threshold-distance* problem as follows: Given an LMC, two initial distributions π_1, π_2, and a threshold $\tau \in [0,1] \cap \mathbb{Q}$, decide whether $d(\pi_1, \pi_2) \geq \tau$ (resp. $d(\pi_1, \pi_2) > \tau$). In [5, Proposition 14] it was shown that the non-strict threshold-distance problem is NP-hard with respect to Turing reductions.

In the following two subsections we consider the threshold-distance problem for general and acyclic LMCs, respectively.

[1] One could analogously define the total variation distance between two LMCs $\mathcal{M}_1 = (Q_1, \Sigma, M_1, \eta_1)$ and $\mathcal{M}_2 = (Q_2, \Sigma, M_2, \eta_2)$ with initial distributions π_1 and π_2 over Q_1 and Q_2, respectively. Our definition is without loss of generality, as one can take the LMC $\mathcal{M} = (Q, \Sigma, M, \eta)$ where Q is the disjoint union of Q_1 and Q_2, and M, η are defined using M_1, M_2, η_1, η_2 in the straightforward manner.

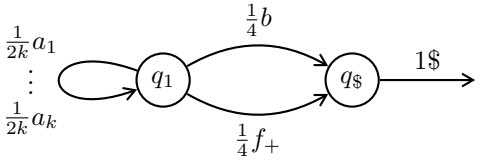
3.1 General LMCs

We show:

▶ **Theorem 3.** *The strict threshold-distance problem is undecidable.*

Proof. We reduce from the emptiness problem for probabilistic automata. A *probabilistic automaton* is a tuple $\mathcal{A} = (Q, \Sigma, M, \alpha, F)$ where Q is a finite set of states, Σ is a finite alphabet of labels, the mapping $M : \Sigma \to [0,1]^{Q\times Q}$, where $M(a)$ is a stochastic matrix for each $a \in \Sigma$, specifies the transitions, $\alpha \in [0,1]^Q$ is an initial distribution, and $F \subseteq Q$ is a set of accepting states. Extend M to $M : \Sigma^* \to [0,1]^{Q\times Q}$ as in the case of LMCs. In the case of a probabilistic automaton, $M(w)$ is a stochastic matrix for each $w \in \Sigma^*$. For each $w \in \Sigma^*$ define $\Pr_{\mathcal{A}}(w) := \alpha M(w)\eta^\top$ where $\eta \in \{0,1\}^Q$ denotes the characteristic vector of F. The probability $\Pr_{\mathcal{A}}(w)$ can be interpreted as the probability that $\mathcal{A}$ accepts w, i.e., the probability that after inputting w the automaton $\mathcal{A}$ is in an accepting state. The *emptiness problem* asks, given a probabilistic automaton $\mathcal{A}$, whether there is a word $w \in \Sigma^*$ such that $\Pr_{\mathcal{A}}(w) > \frac{1}{2}$. This problem is known to be undecidable [22, p. 190, Theorem 6.17].

In the following we assume $\Sigma = \{a_1, \ldots, a_k\}$. Given a probabilistic automaton $\mathcal{A}$ as above, construct an LMC $\mathcal{M} = (Q \cup \{q_1, q_\$\}, \Sigma \cup \{b, f_+, f_-\}, \overline{M}, \delta_{q_\$})$ such that $q_1, q_\$$ are fresh states, and b, f_+, f_- are fresh labels. The transitions originating in the fresh states $q_1, q_\$$ are as follows:

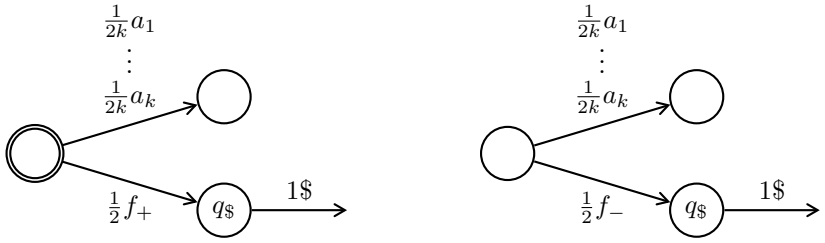


Here and in the subsequent pictures we use a convention that there be a state $q_\$$ with $\eta(q_\$) = 1$ and that $\eta(q) = 0$ hold for all other states.

Define $\pi_1 := \delta_{q_1}$. Then for all $w \in \Sigma^*$ we have:

$$\pi_1(wb) \;=\; \pi_1(wf_+) \;=\; \left(\frac{1}{2k}\right)^{|w|} \cdot \frac{1}{4} \tag{1}$$

The transitions originating in the states in Q are defined so that all $q \in Q$ emit each $a \in \Sigma$ with probability $\frac{1}{2k}$ (like q_1). For all $q \in F$ there is a transition to $q_\$$ labelled with $\frac{1}{2}$ and f_+; for all $q \in Q \setminus F$ there is a transition to $q_\$$ labelled with $\frac{1}{2}$ and f_-:



Formally, for $q, r \in Q$ and $a \in \Sigma$ set $\overline{M}(a)(q,r) := \frac{1}{2k} M(a)(q,r)$. For $q \in F$ set $\overline{M}(f_+)(q, q_\$) := \frac{1}{2}$, and for $q \in Q \setminus F$ set $\overline{M}(f_-)(q, q_\$) := \frac{1}{2}$. Define $\pi_2 := \alpha$ (in the natural way, i.e., with $\pi_2(q_1) = \pi_2(q_\$) = 0$). Then for all $w \in \Sigma^*$ we have:

$$\begin{aligned} \pi_2(wf_+) &= \left(\frac{1}{2k}\right)^{|w|} \cdot \Pr_{\mathcal{A}}(w) \cdot \frac{1}{2} \qquad \text{and} \\ \pi_2(wf_-) &= \left(\frac{1}{2k}\right)^{|w|} \cdot (1 - \Pr_{\mathcal{A}}(w)) \cdot \frac{1}{2} \end{aligned} \tag{2}$$

Consider $L := \Sigma^*\{b, f_+\}$. We have $\pi_1(L) = 1$. One can compute $\pi_2(L)$ in polynomial time by computing the probability of reaching a transition labelled by f_+ (the label b is not reachable). We claim that there is $w \in \Sigma^*$ with $\Pr_{\mathcal{A}}(w) > \frac{1}{2}$ if and only if $d(\pi_1, \pi_2) > \pi_1(L) - \pi_2(L)$. It remains to prove this claim.

Suppose there is no $w \in \Sigma^*$ with $\Pr_{\mathcal{A}}(w) > \frac{1}{2}$. Then, by (1) and (2), for all $w \in \Sigma^*$ we have $\pi_1(wf_+) \geq \pi_2(wf_+)$. Hence:

$$\{w \in (\Sigma \cup \{b, f_+, f_-\})^* : \pi_1(w) > 0,\ \pi_1(w) \geq \pi_2(w)\} \quad = \quad L$$

By Proposition 2 it follows $d(\pi_1, \pi_2) = \pi_1(L) - \pi_2(L)$.

Conversely, suppose there is $w \in \Sigma^*$ with $\Pr_{\mathcal{A}}(w) > \frac{1}{2}$. Consider $L' := L \setminus \{wf_+\}$. We have:

$$\begin{aligned} d(\pi_1, \pi_2) &\geq \pi_1(L') - \pi_2(L') && \text{Proposition 2} \\ &= \pi_1(L) - \pi_1(wf_+) - \pi_2(L) + \pi_2(wf_+) && \text{definition of } L' \\ &= \pi_1(L) - \pi_2(L) + \left(\frac{1}{2k}\right)^{|w|} \cdot \left(\frac{1}{2}\Pr_{\mathcal{A}}(w) - \frac{1}{4}\right) && \text{by (1) and (2)} \\ &> \pi_1(L) - \pi_2(L) && \Pr_{\mathcal{A}}(w) > \frac{1}{2} \end{aligned}$$

◀

Cortes, Mohri, and Rastogi [7] conjectured "that the problem of computing the [...] distance [...] is in fact undecidable", see the discussion after the proof of [7, Theorem 7]. Theorem 3 proves *one interpretation* of that conjecture. But the distance can be approximated with arbitrary precision, cf. Section 4, so the distance is "computable" in this sense.

In [5, Theorem 15] it was shown that there is a polynomial-time many-one reduction from the square-root-sum problem to the non-strict threshold-distance problem for LMCs. Decidability of the non-strict threshold-distance problem remains open.

3.2 Acyclic LMCs

It was shown in [20, Section 6] and [5, Proposition 14] that the non-strict threshold-distance problem is NP-hard with respect to Turing reductions, even for acyclic LMCs. We improve this result to PP-hardness:

▶ **Proposition 4.** *The non-strict and strict threshold-distance problems are PP-hard, even for acyclic LMCs and even with respect to many-one reductions.*

The proof uses the connection between PP and #P. Consider the problem #NFA, which is defined as follows: given a nondeterministic finite automaton (NFA) $\mathcal{A}$ over alphabet Σ, and a number $n \in \mathbb{N}$ in unary, compute $|L(\mathcal{A}) \cap \Sigma^n|$, i.e., the number of accepted words of length n. The problem #NFA is #P-complete [14]. The following lemma forms the core of the proof of Proposition 4:

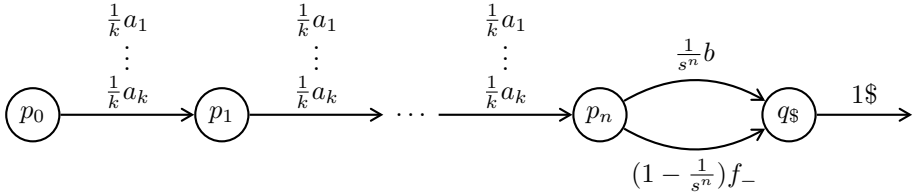
▶ **Lemma 5.** *Given an NFA $\mathcal{A} = (Q, \Sigma, \delta, q^{(1)}, F)$ and a number $n \in \mathbb{N}$ in unary, one can compute in polynomial time an acyclic LMC $\mathcal{M}$ and initial distributions π_1, π_2 and a rational number y such that*

$$d(\pi_1, \pi_2) \;=\; y + \frac{|\Sigma^n \setminus L(\mathcal{A})|}{|\Sigma|^n |Q|^n}\,.$$

Proof. In the following we assume $Q = \{q^{(1)}, \ldots, q^{(s)}\}$ and $\Sigma = \{a_1, \ldots, a_k\}$. Construct the acyclic LMC $\mathcal{M} = (Q', \Sigma \cup \{b, f_+, f_-\}, M)$ such that

$$Q' \;=\; \{p_0, p_1, \ldots, p_n, q_\$\} \;\cup\; \{q_i^{(j)} : 0 \le i \le n,\ 1 \le j \le s\} \;\cup\; \{r_i : 0 \le i \le n\}$$

and b, f_+, f_- are fresh labels. The transitions and end-of-word probabilities originating in the states $p_0, \ldots, p_n, q_\$$ are as follows:



Define $\pi_1 := \delta_{p_0}$. Then for all $w \in \Sigma^n$ we have:

$$\pi_1(wb) \;=\; \frac{1}{k^n} \cdot \frac{1}{s^n} \tag{3}$$

$$\pi_1(wf_-) \;=\; \frac{1}{k^n} \cdot \Big(1 - \frac{1}{s^n}\Big) \tag{4}$$

The transitions originating in the states $q_i^{(j)}, r_i$ are as follows. For each $a \in \Sigma$ and each $i \in \{0, \ldots, n-1\}$ set:

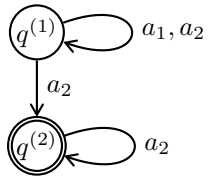
$$M(a)\big(q_i^{(j)}, q_{i+1}^{(j')}\big) \;:=\; \frac{1}{k} \cdot \frac{1}{s} \qquad \forall\, j \in \{1, \ldots, s\} \quad \forall\, q^{(j')} \in \delta(q^{(j)}, a)$$

$$M(a)\big(q_i^{(j)}, r_{i+1}\big) \;:=\; \frac{1}{k} \cdot \Big(1 - \frac{|\delta(q^{(j)}, a)|}{s}\Big) \qquad \forall\, j \in \{1, \ldots, s\}$$

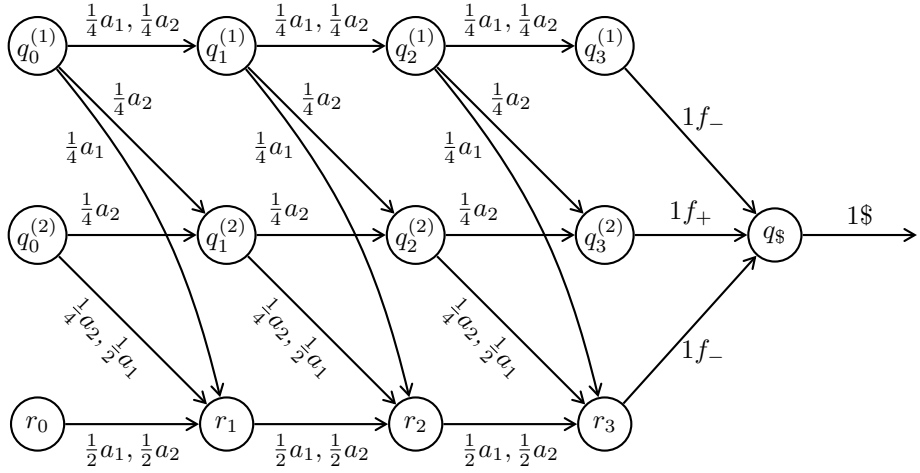
$$M(a)\big(r_i, r_{i+1}\big) \;:=\; \frac{1}{k}$$

Observe that if $i \in \{0, \ldots, n-1\}$ then r_i and all $q_i^{(j)}$ emit each $a \in \Sigma$ with probability $1/k$. For each $q^{(j)} \in F$ set $M(f_+)(q_n^{(j)}, q_\$) := 1$. For each $q^{(j)} \notin F$ set $M(f_-)(q_n^{(j)}, q_\$) := 1$. Finally, set $M(f_-)(r_n, q_\$) := 1$.

▶ **Example 6.** We illustrate this construction with the following NFA $\mathcal{A}$ over $\Sigma = \{a_1, a_2\}$:



For $n = 3$ we obtain the following transitions:



Define $\pi_2 := \delta_{q_0^{(1)}}$. For all $w \in \Sigma^*$ write $\#acc(w)$ for the number of accepting w-labelled runs of the automaton $\mathcal{A}$, i.e., the number of w-labelled paths from $q^{(1)}$ to a state in F. For all $w \in \Sigma^n$ we have:

$$\pi_2(wf_+) \;=\; \frac{1}{k^n} \cdot \frac{\#acc(w)}{s^n} \tag{5}$$

$$\pi_2(wf_-) \;=\; \frac{1}{k^n} \cdot \Big(1 - \frac{\#acc(w)}{s^n}\Big) \tag{6}$$

Define $B := \Sigma^n\{b, f_-\}$. By (3), (4) we have $\pi_1(B) = 1$. One can compute $\pi_2(B)$ in polynomial time by computing the probability of reaching a transition labelled by f_- (the label b is not reachable). Set $y := \pi_1(B) - \pi_2(B)$.

It follows from Proposition 2 that $d(\pi_1, \pi_2) = \pi_1(L) - \pi_2(L)$ holds for

$$L \;:=\; \{w \in (\Sigma \cup \{b, f_+, f_-\})^* : 0 < \pi_1(w) \geq \pi_2(w)\}\,.$$

Observe that $L(\mathcal{A}) = \{w \in \Sigma^n : \#acc(w) \geq 1\}$. Hence it follows with (3), (4), (6):

$$L \;=\; \Sigma^n\{b\} \;\cup\; (\Sigma^n \cap L(\mathcal{A}))\{f_-\}$$

Defining $\overline{L(\mathcal{A})} := \Sigma^n \setminus L(\mathcal{A})$ we can write:

$$L \;=\; B \setminus \big(\overline{L(\mathcal{A})}\{f_-\}\big)$$

Thus we have:

$$\begin{aligned} d(\pi_1, \pi_2) \;&=\; \pi_1\Big(B \setminus \big(\overline{L(\mathcal{A})}\{f_-\}\big)\Big) - \pi_2\Big(B \setminus \big(\overline{L(\mathcal{A})}\{f_-\}\big)\Big) && \text{as argued above} \\ &=\; y + \pi_2\big(\overline{L(\mathcal{A})}\{f_-\}\big) - \pi_1\big(\overline{L(\mathcal{A})}\{f_-\}\big) && \text{definition of } y \end{aligned}$$

Observe that $\overline{L(\mathcal{A})} = \{w \in \Sigma^n : \#acc(w) = 0\}$. Hence we can continue:

$$\begin{aligned} &=\; y + \frac{\big|\overline{L(\mathcal{A})}\big|}{k^n} - \frac{\big|\overline{L(\mathcal{A})}\big|}{k^n} \cdot \Big(1 - \frac{1}{s^n}\Big) && \text{by (6), (4)} \\ &=\; y + \frac{\big|\overline{L(\mathcal{A})}\big|}{k^n s^n} \;=\; y + \frac{|\Sigma^n \setminus L(\mathcal{A})|}{|\Sigma|^n |Q|^n} && \text{definitions} \end{aligned}$$

◀

The PP lower bound from Proposition 4 is tight for acyclic LMCs:

▶ **Theorem 7.** *The non-strict and strict threshold-distance problems are PP-complete for acyclic LMCs.*

▶ **Remark 8.** The works [20, 7] also consider the L_k-distances for integers k:

$$d_k(\pi_1, \pi_2) \;:=\; \sum_{w \in \Sigma^*} |\pi_1(w) - \pi_2(w)|^k$$

For any fixed even k one can compute d_k in polynomial time, see, e.g., [7, Theorem 6]. In contrast, it is NP-hard to compute or even approximate d_k for any odd k [7, Theorems 7 and 10]. Our PP- and #P-hardness results (Proposition 4 and Theorem 9) hold for d_1 (due to Proposition 2) but the reductions do not apply in an obvious way to d_k for any $k \geq 2$. However, the argument in the proof of Theorem 7 for the PP upper bound does generalize to all d_k, see [15].

4 Approximation

As the strict threshold-distance problem is undecidable (Theorem 3), one may ask whether the distance can be approximated. It is not hard to see that the answer is yes. In fact, it was shown in [5, Corollary 8] that the distance can be approximated within an arbitrary additive error even for *infinite-word* LMCs, but no complexity bounds were given. In this section we provide bounds on the complexity of approximating the distance for (finite-word) LMCs.

4.1 Hardness

Lemma 5 implies hardness of approximating the distance:

▶ **Theorem 9.** *Given an LMC and initial distributions π_1, π_2 and an error bound $\varepsilon > 0$ in binary, it is #P-hard to compute a number x with $|d(\pi_1, \pi_2) - x| \leq \varepsilon$, even for acyclic LMCs.*

Proof. Recall that the problem #NFA is #P-complete [14]. Let $\mathcal{A}$ be the given NFA and $n \in \mathbb{N}$. Let $\mathcal{M}, \pi_1, \pi_2, y$ be as in Lemma 5. Approximate $d(\pi_1, \pi_2)$ within $1/(3|\Sigma|^n|Q|^n)$ and call the approximation $\tilde{d}$. It follows from Lemma 5 that $|L(\mathcal{A}) \cap \Sigma^n|$ is the unique integer u with

$$\left| y + \frac{|\Sigma|^n - u}{|\Sigma|^n |Q|^n} - \tilde{d} \right| \;\leq\; \frac{1}{3|\Sigma|^n|Q|^n} \,.$$

Such u can be computed in polynomial time. ◀

Theorem 9 improves the NP-hardness result of [5, Proposition 9]. In fact, PP and #P are substantially harder than NP: By Toda's theorem [25], the polynomial-time hierarchy (PH) is contained in $\mathrm{P}^{\mathrm{PP}} = \mathrm{P}^{\#\mathrm{P}}$. Therefore, any problem in PH can be decided in deterministic polynomial time with the help of an oracle for the threshold-distance problem or for approximating the distance.

4.2 Acyclic LMCs

Towards approximation algorithms, define $W_2 := \{w \in \Sigma^* : \pi_1(w) \geq \pi_2(w)\}$ and $W_1 := \{w \in \Sigma^* : \pi_1(w) < \pi_2(w)\}$. By Proposition 2 we have:

$$d(\pi_1, \pi_2) \;=\; \pi_1(W_2) - \pi_2(W_2) \;=\; 1 - \pi_1(W_1) - \pi_2(W_2) \tag{7}$$

Therefore, to approximate $d(\pi_1, \pi_2)$ it suffices to approximate $\pi_i(W_i)$. A simple sampling scheme leads to the following theorem:

▶ **Theorem 10.** *There is a randomized algorithm, R, that, given an acyclic LMC $\mathcal{M}$ and initial distributions π_1, π_2 and an error bound $\varepsilon > 0$ and an error probability $\delta \in (0,1)$, does the following:*

- *R computes, with probability at least $1-\delta$, a number x with $|d(\pi_1,\pi_2) - x| \leq \varepsilon$;*
- *R runs in time polynomial in $\frac{\log \delta}{\varepsilon}$ and in the encoding size of $\mathcal{M}$ and π_1, π_2.*

Note that $\frac{1}{\varepsilon}$ is not polynomial in the bit size of ε, so combining Theorems 9 and 10 does not imply breakthroughs in computational complexity.

Proof. Let $i \in \{1,2\}$. The length of a longest word w with $\pi_i(w) > 0$ is polynomial in the encoding of the (acyclic) LMC $\mathcal{M}$. Thus, one can sample, in time polynomial in the encoding of $\mathcal{M}, \pi_1, \pi_2$, a word w according to $\Pr_{\pi_i}$; i.e., any w is sampled with probability $\pi_i(w)$. Similarly, one can check in polynomial time whether $w \in W_i$. If m samples are taken, the proportion, say $\hat{p}_i$, of samples w such that $w \in W_i$ is an estimation of $\pi_i(W_i)$. By Hoeffding's inequality, we have $|\hat{p}_i - \pi_i(W_i)| \geq \varepsilon/2$ with probability at most $2e^{-m\varepsilon^2/2}$. Choose $m \geq -\frac{2}{\varepsilon^2} \ln \frac{\delta}{4}$. It follows that $|\hat{p}_i - \pi_i(W_i)| > \varepsilon/2$ with probability at most $\delta/2$. Therefore, by (7), the algorithm that returns $1 - \hat{p}_1 - \hat{p}_2$ has the required properties. ◀

4.3 General LMCs

Finally we aim at an algorithm that approximates the distance within ε, for ε given in binary. By Theorem 9 such an algorithm cannot run in polynomial time unless P = PP. For LMCs that are not necessarily acyclic, words of polynomial length may have only small probability, so sampling approaches need to sample words of exponential length. Thus, a naive extension of the algorithm from Theorem 10 leads to a randomized exponential-time algorithm. We will develop a non-randomized PSPACE algorithm, resulting in the following theorem:

▶ **Theorem 11.** *Given an LMC, and initial distributions π_1, π_2, and an error bound $\varepsilon > 0$ in binary, one can compute in PSPACE a number x with $|d(\pi_1,\pi_2) - x| \leq \varepsilon$.*

The approximation algorithm combines special techniques. The starting point is again the expression for the distance in (7). The following lemma allows the algorithm to neglect words that are longer than exponential:

▶ **Lemma 12.** *Given an LMC, and initial distributions π_1, π_2, and a rational number $\lambda > 0$ in binary, one can compute in polynomial time a number $n \in \mathbb{N}$ in binary such that*

$$\pi_i(\Sigma^{>n}) \;\leq\; \lambda \qquad \text{for both } i \in \{1,2\}\,.$$

For n as in Lemma 12 and both $i \in \{1,2\}$, define $W_i' := W_i \cap \Sigma^{\leq n}$. By Lemma 12 it would suffice to approximate $\pi_i(W_i')$ for both i, as we have by (7):

$$\pi_1(W_1') + \pi_2(W_2') \quad\leq\quad 1 - d(\pi_1,\pi_2) \quad\leq\quad \pi_1(W_1') + \pi_2(W_2') + 2\lambda \tag{8}$$

However, it not obvious if $\pi_i(W_i')$ can be approximated efficiently, as for exponentially long words w it is hard to check if $w \in W_i'$ holds. Indeed, $\pi_i(w)$ may be very small and may have exponential bit size. The main trick of our algorithm will be to approximate $\pi_i(w)$ using floating-point arithmetic with small *relative* error, say $\widetilde{\pi}_i(w) \in [\pi_i(w)(1-\theta), \pi_i(w)(1+\theta)]$ for small $\theta > 0$. This allows us to approximate $\pi_1(W_1') + \pi_2(W_2')$ (crucially, not the two summands individually). Indeed, define approximations for W_1' and W_2' by

$$\widetilde{W_1} \;:=\; \{w \in \Sigma^{\leq n} : \widetilde{\pi}_1(w) < \widetilde{\pi}_2(w)\} \qquad \text{and} \qquad \widetilde{W_2} \;:=\; \{w \in \Sigma^{\leq n} : \widetilde{\pi}_1(w) \geq \widetilde{\pi}_2(w)\}\,.$$

Then we have:

$$\begin{aligned}
\pi_2(w) \;\le\; \pi_1(w) \;<\; \pi_2(w) + \theta\pi_1(w) + \theta\pi_2(w) \qquad & \text{for } w \in \widetilde{W}_1 \cap W_2' \\
\pi_1(w) \;<\; \pi_2(w) \;\le\; \pi_1(w) + \theta\pi_1(w) + \theta\pi_2(w) \qquad & \text{for } w \in \widetilde{W}_2 \cap W_1'
\end{aligned}$$

It follows:

$$\begin{aligned}
\pi_2(\widetilde{W}_1 \cap W_2') \;\le\; \pi_1(\widetilde{W}_1 \cap W_2') \;\le\; \pi_2(\widetilde{W}_1 \cap W_2') + 2\theta \\
\pi_1(\widetilde{W}_2 \cap W_1') \;\le\; \pi_2(\widetilde{W}_2 \cap W_1') \;\le\; \pi_1(\widetilde{W}_2 \cap W_1') + 2\theta
\end{aligned} \tag{9}$$

Hence we have:

$$\begin{aligned}
\pi_1(W_1') + \pi_2(W_2') \;&=\; \pi_1(\widetilde{W}_1 \cap W_1') + \pi_2(\widetilde{W}_1 \cap W_2') + \pi_2(\widetilde{W}_2 \cap W_2') + \pi_1(\widetilde{W}_2 \cap W_1') \\
&\overset{(9)}{\le}\; \pi_1(\widetilde{W}_1) + \pi_2(\widetilde{W}_2) \\
&\overset{(9)}{\le}\; \pi_1(W_1') + \pi_2(W_2') + 4\theta
\end{aligned}$$

By combining this with (8) we obtain:

$$\pi_1(\widetilde{W}_1) + \pi_2(\widetilde{W}_2) - 4\theta \quad\le\quad 1 - d(\pi_1, \pi_2) \quad\le\quad \pi_1(\widetilde{W}_1) + \pi_2(\widetilde{W}_2) + 2\lambda \tag{10}$$

It remains to tie two loose ends:

1. develop a PSPACE method to approximate $\pi_i(w)$ within *relative* error θ for any $\theta > 0$ in binary, where w is an at most exponentially long word (given on a special input tape);
2. based on this method, approximate $\pi_i(\widetilde{W}_i)$ in PSPACE.

For item 1 we use floating-point arithmetic, for item 2 we use Ladner's result [19] on counting in polynomial space.

For $k \in \mathbb{N}$, define $\mathbb{F}_k := \{m \cdot 2^z : z \in \mathbb{Z},\ 0 \le m \le 2^k - 1\}$, the set of *$k$-bit floating-point numbers*. For our purposes, nonnegative floating-point numbers suffice, and there is no need to bound the exponent z, as all occurring exponents will have polynomial bit size. We define rounding as usual: for $x \ge 0$ write $\langle x \rangle_k$ for the number in $\mathbb{F}_k$ that is nearest to x (break ties in an arbitrary but deterministic way). Then there is δ with $\langle x \rangle_k = x \cdot (1 + \delta)$ and $|\delta| < 2^{-k}$, see [13, Theorem 2.2]. A standard analysis of rounding errors in finite-precision arithmetic [13, Chapter 3] yields the following lemma:

▶ **Lemma 13.** *Let π be an initial distribution and $0 < \theta < 1$. Let $k \in \mathbb{N}$ be such that $2^k \ge 2(n+1)|Q|/\theta$. Let $w = a_1 a_2 \cdots a_m \in \Sigma^*$ with $m \le n$. Compute $\widetilde{\pi}(w)$ as*

$$((\cdots((\pi \cdot M(a_1)) \cdot M(a_2)) \cdots) \cdot M(a_m)) \cdot \eta^\top ,$$

where rounding $\langle \cdot \rangle_k$ is applied after each individual (scalar) multiplication and addition. Then $\widetilde{\pi}(w) \in [\pi(w)(1-\theta), \pi(w)(1+\theta)]$.

Proof. For all $i \in \mathbb{N}$ write $\gamma_i := i \cdot 2^{-k}/(1 - i \cdot 2^{-k})$. By [13, Equation (3.11)] there are matrices $\Delta_1, \ldots, \Delta_m$ and a vector $\widetilde{\eta}$ such that

$$\widetilde{\pi}(w) \;=\; \pi \cdot (M(a_1) + \Delta_1) \cdot (M(a_2) + \Delta_2) \cdots (M(a_m) + \Delta_m) \cdot (\eta + \widetilde{\eta})^\top$$

and $|\Delta_i| \le \gamma_{|Q|} M(a_i)$ and $|\widetilde{\eta}| \le \gamma_{|Q|}\eta$, where by $|\Delta_i|$ and $|\widetilde{\eta}|$ we mean the matrix and vector obtained by taking the absolute value componentwise. (In words, the result $\widetilde{\pi}(w)$ of the

floating-point computation is the result of applying an exact computation with slightly perturbed data—a "backward error" result.) It follows:

$$\begin{aligned}
|\widetilde{\pi}(w) - \pi(w)| &\leq \left(-1 + \prod_{j=1}^{m+1} \left(1 + \gamma_{|Q|}\right) \right) \pi(w) && \text{by [13, Lemma 3.8]} \\
&\leq \gamma_{(m+1)\cdot|Q|}\pi(w) && \text{by [13, Lemma 3.3]} \\
&\leq 2(n+1)|Q| \cdot 2^{-k}\pi(w) && \text{as } (n+1)|Q| \cdot 2^{-k} \leq 1/2 \\
&\leq \theta\pi(w)
\end{aligned}$$

◀

The development so far suggests the following approximation approach: Let $\varepsilon > 0$ be the error bound from the input. Let $n \in \mathbb{N}$ be the number from Lemma 12, where λ is such that $2\lambda = \varepsilon/2$. Let $k \in \mathbb{N}$ be the smallest number such that $2^k \geq 2(n+1)|Q|/\theta$, where θ is such that $4\theta = \varepsilon/2$. Observe that k (the bit size of 2^k) is polynomial in the input. Define, for each word w and both i, the approximation $\widetilde{\pi}_i(w)$ as in Lemma 13. This defines also $\widetilde{W}_1, \widetilde{W}_2$. By (10) we have:

$$\pi_1(\widetilde{W}_1) + \pi_2(\widetilde{W}_2) - \frac{\varepsilon}{2} \quad \leq \quad 1 - d(\pi_1, \pi_2) \quad \leq \quad \pi_1(\widetilde{W}_1) + \pi_2(\widetilde{W}_2) + \frac{\varepsilon}{2}$$

Thus we can complete the proof of Theorem 11 by proving the following lemma:

▶ **Lemma 14.** *For both i, one can approximate $\pi_i(\widetilde{W}_i)$ within $\varepsilon/4$ in PSPACE.*

Proof. We discuss only the approximation of $\pi_1(\widetilde{W}_1)$; the case of $\pi_2(\widetilde{W}_2)$ is similar.

Construct a "probabilistic PSPACE Turing machine" $\mathcal{T}$ that samples a random word w according to $\Pr_{\pi_1}$. For that, $\mathcal{T}$ uses probabilistic branching according to the transition probabilities in M. While producing w in this way, but without storing w as a whole, $\mathcal{T}$ computes also the values $\widetilde{\pi}_1(w), \widetilde{\pi}_2(w)$ according to Lemma 13. If and when w gets longer than n then $\mathcal{T}$ rejects. If $\widetilde{\pi}_1(w) < \widetilde{\pi}_2(w)$ then $\mathcal{T}$ accepts; otherwise $\mathcal{T}$ rejects. The probability that $\mathcal{T}$ accepts equals $\pi_1(\widetilde{W}_1)$. This probability can be computed in PSPACE by Ladner's result [19] on counting in polynomial space. To be precise, note that this probability is a fraction p/q of two natural numbers p, q of at most exponential bit size. By Ladner's result one can compute arbitrary bits of p, q in PSPACE. Hence an approximation within $\varepsilon/4$ can also be computed in PSPACE. Technical details about how we apply Ladner's result are provided in [15]. ◀

5 Open Problems

In this paper we have considered the total variation distance between the distributions on finite words that are generated by two LMCs. In a more general version of LMCs, the end-of-word probabilities are zero, so that the LMC generates infinite words. The production of finite words $w \in \Sigma^*$ can be simulated by producing $w\$\$\$\cdots$ where \$ is an end-of-word symbol. It follows that the undecidability and hardness results of this paper apply equally to infinite-word LMCs. In fact, all these results strengthen those from [5], where the total variation distance between infinite-word LMCs is studied. The PSPACE approximation algorithm in this paper (Theorem 11) applies only to finite words, and the author does not know if it can be generalized to infinite-word LMCs. Whether the non-strict threshold-distance problem is decidable is open, both for finite- and for infinite-word LMCs.

Another direction concerns LMCs that are *not hidden*, i.e., where each emitted label identifies the next state; or, slightly more general, *deterministic* LMCs, i.e., where each state

and each emitted label identify the next state. The reduction that shows square-root-sum hardness in [5, Theorem 15] also applies to the threshold-distance problem for deterministic finite-word LMCs, but the author does not know a hardness result for approximating the distance between deterministic LMCs.

Abstract

We prove that if a group generated by a bireversible Mealy automaton contains an element of infinite order, then it must have exponential growth. As a direct consequence, no infinite virtually nilpotent group can be generated by a bireversible Mealy automaton.

2012 ACM Subject Classification Theory of computation → Models of computation, Theory of computation → Formal languages and automata theory → Automata over infinite objects

Keywords and phrases automaton groups, growth of a group, exponential growth

Funding This work was partially supported by the French *Agence Nationale pour la Recherche*, through the Project **MealyM** ANR-JS02-012-01.

Acknowledgements The author is very grateful to Dmytro Savchuk for suggesting Corollary 16.

The study on how (semi)groups grow has been highlighted since Milnor's question on the existence of groups of intermediate growth (faster than any polynomial and slower than any exponential) in 1968 [13], and since the very first example of such a group was given by Grigorchuk [5]. Uncountably many examples have followed this first one, see for instance [6]. Bartholdi and Erschler have even obtained results on precise computations of growth, in particular they proved that if a function satisfies some frame property, then there exists a finitely generated group with growth equivalent to it [1]. Besides, until Nekrashevych's very recent work [14], all the known examples of intermediate growth groups were automaton groups or based on automaton groups.

There exists no sufficient or necessary criterion to test whether a Mealy automaton generates a group of intermediate growth and it is not even known if this property is decidable. However, there is no known example in the literature of a bireversible Mealy automaton generating an intermediate growth group and it is legitimate to wonder whether it is possible. This is the scope of the present article, which can be seen as an extension of earlier results on the two-state case [8, 9]. We prove that if a group generated by a bireversible Mealy automaton has an element of infinite order, then it must have exponential growth. It has been conjectured, and proved in some cases [4], that an infinite group generated by a bireversible Mealy automaton always has an element of infinite order, which suggests that, indeed, a group generated by a bireversible Mealy automaton either is finite, or has exponential growth. Note that a similar result has been proved for a very different family of Mealy automata, namely reset automata [15]: since a Mealy automaton which is simultaneously reset and bireversible has a unique state, these families are somehow orthogonal; moreover the proof we present here is completely different from the proof in [15], in particular it is not based on the potential existence of a free subsemigroup of rank 2.

Finally, let us mention the work by Brough and Cain to obtain some necessary criteria to decide whether a semigroup is an automaton semigroup [2]. Our work can be seen as partially answering a similar question: can a given group be generated by a bireversible Mealy automaton? A consequence of our result is that no infinite virtually nilpotent group (and in particular no abelian group) can be.

This article is organized as follows. In Section 1, we define automaton groups and the growth of a group, and give some properties of the connected components of the powers of a Mealy automaton. In Section 2, we study the behavior of certain equivalence classes of words on the state set of a Mealy automaton. Finally, the main result and some of its consequences appear in Section 3.

1 Basic notions

Throughout the paper, the cardinality of a finite set E is denoted by $|E|$. A *finite word* of *length* n on E is a finite sequence of n elements of E and is denoted classically as the concatenation of its elements. The set of finite words over E is denoted by E^*, the set of non-empty finite words by E^+, and the set of words of length n by E^n. In general the elements of E are written in plain letters, *e.g.* q, while the words on E are written in bold letters, *e.g.* $\mathbf{u}$. The length of $\mathbf{u}$ is denoted by $|\mathbf{u}|$, its letters are numbered from 0 to $|\mathbf{u}|-1$ and, if i is an integer, its $(i \mod |\mathbf{u}|)$-th letter is denoted by $\mathbf{u}\{i\}$; for example its first letter is $\mathbf{u}\{0\}$, while its last letter is $\mathbf{u}\{-1\}$. If L is a set of words on E, $L\{i\}$ denotes the set $\{\mathbf{u}\{i\} \mid \mathbf{u} \in L\}$.

1.1 Semigroups and groups generated by Mealy automata

We first recall the formal definition of an automaton. A *(finite, deterministic, and complete) automaton* is a triple $\big(Q, \Sigma, \delta = (\delta_i \colon Q \to Q)_{i\in\Sigma}\big)$, where the *state set* Q and the *alphabet* Σ are non-empty finite sets, and the δ_i are functions.

A *Mealy automaton* is a quadruple $\mathcal{A} = (Q, \Sigma, \delta, \rho)$, such that (Q, Σ, δ) and (Σ, Q, ρ) are both automata. In other terms, a Mealy automaton is a complete, deterministic, letter-to-letter transducer with the same input and output alphabet. Its *size* is the cardinality of its state set and is denoted by $\#\mathcal{A}$.

The graphical representation of a Mealy automaton is standard, see Figure 1. But, for practical reasons, we use sometimes other graphical representations for the transitions. For example the transition from x to z with input letter 0 and output letter 1 in the automaton of Figure 1 can be represented

either by $x \xrightarrow{0|1} z$, or by  .

Let $\mathcal{A} = (Q, \Sigma, \delta, \rho)$ be a Mealy automaton. Each state $q \in Q$ defines a mapping from Σ^* into itself, recursively by:

$$\forall i \in \Sigma,\ \forall \mathbf{s} \in \Sigma^*, \qquad \rho_q(i\mathbf{s}) = \rho_q(i)\rho_{\delta_i(q)}(\mathbf{s})\ .$$

The image of the empty word is itself. For each $q \in Q$, the mapping ρ_q is length-preserving and prefix-preserving. We say that $\rho_q : \Sigma^* \to \Sigma^*$ is the *action induced* by q. For $\mathbf{u} = q_1 \cdots q_n \in Q^n$ with $n > 0$, set $\rho_{\mathbf{u}} \colon \Sigma^* \to \Sigma^*, \rho_{\mathbf{u}} = \rho_{q_n} \circ \cdots \circ \rho_{q_1}$.

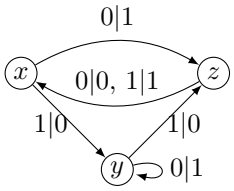

Figure 1 The Aleshin automaton.

The semigroup of mappings from Σ^* to Σ^* generated by $\{\rho_q, q \in Q\}$ is called the *semigroup generated by* $\mathcal{A}$ and is denoted by $\langle \mathcal{A} \rangle_+$.

We extend to δ the former notation on ρ, in a natural way. Hence $\delta_i \colon Q^* \to Q^*, i \in \Sigma$, are the functions extended to Q^*, and for $\mathbf{s} = i_1 \cdots i_n \in \Sigma^n$ with $n > 0$, we set $\delta_{\mathbf{s}} \colon Q^* \to Q^*$, $\delta_{\mathbf{s}} = \delta_{i_n} \circ \cdots \circ \delta_{i_1}$.

A Mealy automaton $\mathcal{A} = (Q, \Sigma, \delta, \rho)$ is *invertible* if the functions ρ_q are permutations of the alphabet Σ. In this case, the actions induced by the states are permutations on words of the same length and thus we may consider the group of mappings from Σ^* to Σ^* generated by $\{\rho_q, q \in Q\}$: it is called the *group generated by* $\mathcal{A}$ and is denoted by $\langle \mathcal{A} \rangle$.

When $\mathcal{A}$ is invertible, define its *inverse* $\mathcal{A}^{-1}$ as the Mealy automaton with state set Q^{-1}, a disjoint copy of Q, and alphabet Σ, where the transition $p^{-1} \xrightarrow{j|i} q^{-1}$ belongs to $\mathcal{A}^{-1}$ if and only if the transition $p \xrightarrow{i|j} q$ belongs to $\mathcal{A}$. Clearly the action induced by the state p^{-1} of $\mathcal{A}^{-1}$ is the reciprocal of the action induced by the corresponding state p in $\mathcal{A}$.

A Mealy automaton $(Q, \Sigma, \delta, \rho)$ is *reversible* if the functions δ_i induced on Q by the input letters of the transitions are permutations. The connected components of a reversible automaton are strongly connected. In a reversible automaton of state set Q and alphabet Σ, for any word $\mathbf{s} \in \Sigma^*$ and any state q, there exists exactly one path in the automaton with label $\mathbf{s}$ and final state q, hence we can consider the *backtrack action* induced by q: it associates to $\mathbf{s}$ the output label $\mathbf{t} \in \Sigma^{|\mathbf{s}|}$ of this single path.

A Mealy automaton is *coreversible* if the functions induced on Q by the letters as output letters of the transitions are permutations.

A Mealy automaton is *bireversible* if it is both reversible and coreversible. It is quite simple to see that the actions and the backtrack actions induced by the states of a bireversible automaton are both permutations.

Two Mealy automata are said to be *isomorphic* if they are identical up to the labels of their states.

1.2 Growth of a semigroup or a group

Let H be a semigroup generated by a finite set S. The *length* of an element g of the semigroup, denoted by $|g|$, is the length of its shortest decomposition as a product of generators:

$$|g| = \min\{n \mid \exists s_1, \ldots, s_n \in S,\ g = s_1 \cdots s_n\}\,.$$

The *growth function* γ_H^S of the semigroup H with respect to the generating set S enumerates the elements of H with respect to their length:

$$\gamma_H^S(n) = |\{g \in H\,;\, |g| \leq n\}|\,.$$

The *growth functions* of a group are defined similarly by taking symmetrical generating sets.

The growth functions corresponding to two generating sets are equivalent [12], so we may define the *growth* of a group or a semigroup as the equivalence class of its growth functions. Hence, for example, a finite (semi)group has bounded growth, while an infinite abelian (semi)group has polynomial growth, and a non-abelian free (semi)group has exponential growth.

It is quite easy to obtain groups of polynomial or exponential growth. Answering a question of Milnor [13], Grigorchuk gave an example of an automaton group of intermediate growth [5]: faster than any polynomial, slower than any exponential, opening thus a new classification criterion for groups, that has been deeply studied since this seminal article (see [7] and references therein). Besides, let us mention that until Nekrashevych's very recent work [14], all the known examples of intermediate growth groups were automaton groups or based on automaton groups.

Note an important point for our purpose: let G be a finitely generated group and let $(I_n)_{n>0}$ a sequence of subsets of G, compatible with the length function, *i.e.* the sets I_n are pairwise distinct and the elements of I_n have all length less than or equal to n. The growth function of $(I_n)_{n>0}$ is given by $(\sum_{k\leq n} |I_k|)_{n>0}$; if it grows exponentially, then so does G. In the same spirit, a group which admits a subgroup of exponential growth grows exponentially.

1.3 The powers of a Mealy automaton and their connected components

The powers of a Mealy automaton have been shown to play an important role in the finiteness and the order problems for an automaton (semi)group, as highlighted in [9, 11, 4]. The *n-th power* of the automaton $\mathcal{A} = (Q, \Sigma, \delta, \rho)$ is the Mealy automaton

$$\mathcal{A}^n = \left(Q^n, \Sigma, (\delta_i \colon Q^n \to Q^n)_{i\in\Sigma}, (\rho_{\mathbf{u}} \colon \Sigma \to \Sigma)_{\mathbf{u}\in Q^n} \right) .$$

Note that the powers of a reversible (*resp.* bireversible) Mealy automaton are reversible (*resp.* bireversible). It is straightforward to see that the action induced by a word $\mathbf{u}$ of states of $\mathcal{A}$ is in fact the action induced by $\mathbf{u}$ seen as a state of $\mathcal{A}^{|\mathbf{u}|}$. The backtrack action induced by $\mathbf{u}$ can be defined in the same spirit.

The (semi)group generated by a connected component of some power of $\mathcal{A}$ is a sub(semi)group of the (semi)group generated by $\mathcal{A}$.

Let $\mathbf{u}$ and $\mathbf{v}$ be elements of Q^+ and $\mathcal{C}$ be a connected component of some power of $\mathcal{A}$: $\mathbf{v}$ *can follow* $\mathbf{u}$ *in* $\mathcal{C}$ if $\mathbf{uv}$ is the prefix of some state of $\mathcal{C}$. We denote by $\{\mathbf{u}? \hookrightarrow \mathcal{C}\}$ the set of states that can follow $\mathbf{u}$ in $\mathcal{C}$:

$$\{\mathbf{u}? \hookrightarrow \mathcal{C}\} = \{q \in Q \mid \mathbf{u}q \text{ is the prefix of some state of } \mathcal{C}\} .$$

We define similarly the fact that $\mathbf{v}$ *can precede* $\mathbf{u}$ in $\mathcal{C}$ if $\mathbf{vu}$ is the suffix of some state of $\mathcal{C}$, and we introduce the set

$$\{?\mathbf{u} \hookrightarrow \mathcal{C}\} = \{q \in Q \mid q\mathbf{u} \text{ is the suffix of some state of } \mathcal{C}\} .$$

The aim of this section is to give some intuition on the links between the connected components of consecutive powers of $\mathcal{A}$. Since a word can be extended with a prefix or a suffix, most of the results exposed here are expressed in both cases, but only the first result is proved in both cases, to show how bireversibility allows to consider similarly the actions and the backtrack actions.

▶ **Lemma 1.** *Let $\mathcal{A}$ be a bireversible Mealy automaton with state set Q and $\mathcal{C}$ a connected component of one of its powers. If $\mathbf{u} \in Q^+$ is a proper prefix of some state of $\mathcal{C}$, then the cardinality of the set $\{\mathbf{u}? \looparrowright \mathcal{C}\}$ depends only on the length of $\mathbf{u}$.*

Proof. Suppose that $\mathbf{u}'$ is such that $\mathbf{u}\mathbf{u}'$ is a state of $\mathcal{C}$, and let $\mathbf{v}$ be a prefix of some state $\mathbf{v}\mathbf{v}'$ of $\mathcal{C}$ with the same length as $\mathbf{u}$. Since $\mathcal{C}$ is a connected component in a reversible Mealy automaton, it is strongly connected, so there exists a word $\mathbf{s} \in \Sigma^*$ such that $\delta_{\mathbf{s}}(\mathbf{u}\mathbf{u}') = \mathbf{v}\mathbf{v}'$. Now, consider the action induced by $\mathbf{s}$ on $\mathbf{u}p$, for $p \in \{\mathbf{u}? \looparrowright \mathcal{C}\}$:

$$\begin{array}{ccc} & \mathbf{s} & \\ \mathbf{u} & \to & \mathbf{v} \\ & \mathbf{s}' & \\ p & \to & p' \end{array}$$

Since the automaton $\mathcal{A}$ is reversible, the action induced by $\mathbf{s}'$ is a permutation of Q, and we have

$$|\{\mathbf{u}? \looparrowright \mathcal{C}\}| \leq |\{\mathbf{v}? \looparrowright \mathcal{C}\}| .$$

The reciprocal inequality is obtained symmetrically. ◀

▶ **Lemma 2.** *Let $\mathcal{A}$ be a bireversible Mealy automaton with state set Q and $\mathcal{C}$ a connected component of one of its powers. If $\mathbf{u} \in Q^+$ is a proper suffix of some state of $\mathcal{C}$, then the cardinality of the set $\{?\mathbf{u} \looparrowright \mathcal{C}\}$ depends only on the length of $\mathbf{u}$.*

Proof. Suppose that $\mathbf{u}'$ is such that $\mathbf{u}'\mathbf{u}$ is a state of $\mathcal{C}$, and let $\mathbf{v}$ be a suffix of some state $\mathbf{v}'\mathbf{v}$ of $\mathcal{C}$ with the same length as $\mathbf{u}$. Since $\mathcal{C}$ is a connected component in a reversible Mealy automaton, it is strongly connected, so there exist words $\mathbf{s}, \mathbf{t} \in \Sigma^*$ such that $\delta_{\mathbf{s}}(\mathbf{u}'\mathbf{u}) = \mathbf{v}'\mathbf{v}$ and $\rho_{\mathbf{u}'\mathbf{u}}(\mathbf{s}) = \mathbf{t}$:

$$\begin{array}{ccc} & \mathbf{s} & \\ \mathbf{u}' & \to & \mathbf{v}' \\ & \mathbf{s}' & \\ \mathbf{u} & \to & \mathbf{v} \\ & \mathbf{t} & \end{array}$$

Now, consider the backtrack action induced by $\mathbf{t}$ on $p\mathbf{u}$, for $p \in \{?\mathbf{u} \looparrowright \mathcal{C}\}$:

$$\begin{array}{ccc} p & \to & p' \\ & \mathbf{s}' & \\ \mathbf{u} & \to & \mathbf{v} \\ & \mathbf{t} & \end{array}$$

Since the automaton $\mathcal{A}$ is bireversible, the backtrack action induced by $\mathbf{s}'$ is a permutation of Q, and we have

$$|\{?\mathbf{u} \looparrowright \mathcal{C}\}| \leq |\{?\mathbf{v} \looparrowright \mathcal{C}\}| .$$

The reciprocal inequality is obtained symmetrically. ◀

Consider a state q of $\mathcal{A}$. For any integer $n > 0$, we denote by $\mathrm{cc}(q^n)$ the connected component of q^n in $\mathcal{A}^n$. The sequence of such components has some properties which we give here. These properties can be seen as properties of the branch represented by q^ω in the Schreier trie of $\mathcal{A}$ (also known as the orbit tree of the dual of $\mathcal{A}$) which has been introduced in [11, 4] (to keep this article self-contained, we give here only the properties of this branch, but for a more global intuition on the constructions, the reader can consult these references).

The first point is given by Lemma 1: for any $n > 0$, the component $\mathrm{cc}(q^{n+1})$ can be seen as several full copies of the component $\mathrm{cc}(q^n)$; indeed, if $\mathbf{u}$ and $\mathbf{v}$ are states of $\mathrm{cc}(q^n)$, then in $\mathrm{cc}(q^{n+1})$ there are as many states with prefix $\mathbf{u}$ as states with prefix $\mathbf{v}$, *i.e.*

$$\forall \mathbf{u} \in \mathrm{cc}(q^n), \forall \mathbf{v} \in \mathrm{cc}(q^n),\ |\{\mathbf{u}? \looparrowright \mathrm{cc}(q^{n+1})\}| = |\{\mathbf{v}? \looparrowright \mathrm{cc}(q^{n+1})\}| \,.$$

Hence the ratio between the size of $\mathrm{cc}(q^{n+1})$ and the size of $\mathrm{cc}(q^n)$ is necessarily an integer: it is the cardinality of the set $\{\mathbf{u}? \looparrowright \mathrm{cc}(q^{n+1})\}$ for any state $\mathbf{u}$ of $\mathrm{cc}(q^n)$, and in particular for $\mathbf{u} = q^n$.

We define by

$$\left(\frac{\#\,\mathrm{cc}(q^{n+1})}{\#\,\mathrm{cc}(q^n)}\right)_{n>0} = \left(|\{q^n? \looparrowright \mathrm{cc}(q^{n+1})\}|\right)_{n>0}$$

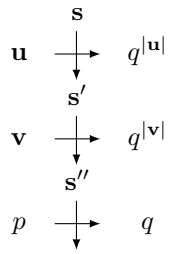
the *sequence of ratios* associated to the state q.

▶ **Lemma 3.** *Let $\mathcal{A}$ be a bireversible Mealy automaton with state set Q, $q \in Q$ a state of $\mathcal{A}$, and $\mathbf{u}$ and $\mathbf{v}$ be two elements of Q^+. If $\mathbf{uv}$ is a state of $\mathrm{cc}(q^{|\mathbf{uv}|})$, then $\mathbf{v}$ is a state of $\mathrm{cc}(q^{|\mathbf{v}|})$ and*

$$\{\mathbf{uv}? \looparrowright \mathrm{cc}(q^{|\mathbf{uv}|+1})\} \subseteq \{\mathbf{v}? \looparrowright \mathrm{cc}(q^{|\mathbf{v}|+1})\} \,.$$

Proof. Take $\mathcal{A} = (Q, \Sigma, \delta, \rho)$ and let $p \in \{\mathbf{uv}? \looparrowright \mathrm{cc}(q^{|\mathbf{uv}|+1})\}$.

Since $\mathcal{A}$ is reversible, there exists a word $\mathbf{s} \in \Sigma^*$ such that $\delta_{\mathbf{s}}(\mathbf{uv}p) = q^{|\mathbf{uv}|+1}$:



Hence $\delta_{\mathbf{s}'}(\mathbf{v}) = q^{|\mathbf{v}|}$ and so $\mathbf{v} \in \mathrm{cc}(q^{|\mathbf{v}|})$, and $\delta_{\mathbf{s}'}(\mathbf{v}p) = q^{|\mathbf{v}|+1}$, which means that $p \in \{\mathbf{v}? \looparrowright \mathrm{cc}(q^{|\mathbf{v}|+1})\}$. ◀

▶ **Lemma 4.** *Let $\mathcal{A}$ be a bireversible Mealy automaton with state set Q, $q \in Q$ a state of $\mathcal{A}$, and $\mathbf{u}$ and $\mathbf{v}$ be two elements of Q^+. If $\mathbf{uv}$ is a state of $\mathrm{cc}(q^{|\mathbf{uv}|})$, then $\mathbf{u}$ is a state of $\mathrm{cc}(q^{|\mathbf{u}|})$ and*

$$\{?\mathbf{uv} \looparrowright \mathrm{cc}(q^{|\mathbf{uv}|+1})\} \subseteq \{?\mathbf{u} \looparrowright \mathrm{cc}(q^{|\mathbf{u}|+1})\} \,.$$

As $\{q^{n+1}? \looparrowright \mathrm{cc}(q^{n+2})\} \subseteq \{q^n? \looparrowright \mathrm{cc}(q^{n+1})\}$ by Lemma 3, it is straightforward to see that the sequence of ratios associated to q decreases:

$$\forall n > 0,\ \frac{\#\,\mathrm{cc}(q^{n+2})}{\#\,\mathrm{cc}(q^{n+1})} \leq \frac{\#\,\mathrm{cc}(q^{n+1})}{\#\,\mathrm{cc}(q^n)} \,,$$

and hence is ultimately constant. We say that q *has a constant ratio* if this sequence is in fact constant, and then the unique value of the sequence of ratios associated to q is called the *ratio of* q.

It has been proven in [11, Prop. 6] that q induces an action of infinite order if and only if the sizes of the components $(\mathrm{cc}(q^n))_{n>0}$ are unbounded, *i.e.* the limit of the sequence of ratios associated to q is greater than 1.

We study now some properties of followers and predecessors in the components $\mathrm{cc}(q^n)$, when q has a constant ratio.

The next lemma is an improvement of Lemma 3.

▶ **Lemma 5.** *Let $\mathcal{A}$ be a bireversible Mealy automaton, and q be a state of $\mathcal{A}$ of constant ratio. Let $\mathbf{u}$ and $\mathbf{v}$ be two elements of Q^+ such that $\mathbf{uv}$ is a state of $\mathrm{cc}(q^{|\mathbf{uv}|})$. We have:*

$$\{\mathbf{uv}? \rightsquigarrow \mathrm{cc}(q^{|\mathbf{uv}|+1})\} = \{\mathbf{v}? \rightsquigarrow \mathrm{cc}(q^{|\mathbf{v}|+1})\}\,.$$

Proof. The left part is a subset of the right one by Lemma 3 and both sets have the same cardinality, which is the ratio of q, by hypothesis. ◀

In particular, by taking the word $\mathbf{v}$ of length 1 in the previous lemma, we can see that the set of followers of a word $\mathbf{w}$ in $\mathrm{cc}(q^n)$ only depends on its last letter $\mathbf{w}\{-1\}$.

We obtain the symmetrical result by considering the mirror Mealy automaton obtained by inverting the direction of the transitions.

▶ **Lemma 6.** *Let $\mathcal{A}$ be a bireversible Mealy automaton of state set Q, q be a state of $\mathcal{A}$ of constant ratio, and $n > 1$ be an integer. If $\mathbf{u} \in Q^+$ is a suffix of some state of $\mathrm{cc}(q^n)$, then the set $\{?\mathbf{u} \rightsquigarrow \mathrm{cc}(q^n)\}$ only depends on $\mathbf{u}\{0\}$, the first letter of $\mathbf{u}$.*

The next lemma links up the sets of followers and of predecessors in $\mathrm{cc}(q^n)$ when q has a constant ratio.

▶ **Lemma 7.** *Let $\mathcal{A}$ be a bireversible Mealy automaton of state set Q, q be a state of $\mathcal{A}$ of constant ratio, and $n > 1$ be an integer. The sets of followers and of predecessors in $\mathrm{cc}(q^n)$ have the same cardinality which is the ratio of q.*

Proof. By Lemmas 5 and 6, we only have to prove that

$$|\{q? \rightsquigarrow \mathrm{cc}(q^n)\}| = |\{?q \rightsquigarrow \mathrm{cc}(q^n)\}|\,.$$

Even simpler: notice that if $\mathbf{u}$ is a prefix of some state of $\mathrm{cc}(q^n)$, then it is also a prefix of some state in $\mathrm{cc}(q^{n+k})$ for any $k > 0$, and it has the same set of followers in both. Of course, an equivalent property holds for the sets of predecessors.

So it is sufficient to prove that

$$|\{q? \rightsquigarrow \mathrm{cc}(q^2)\}| = |\{?q \rightsquigarrow \mathrm{cc}(q^2)\}|\,,$$

which is true because

$$|\,\mathrm{cc}(q^2)| = |\,\mathrm{cc}(q)| \times |\{q? \rightsquigarrow \mathrm{cc}(q^2)\}| = |\{?q \rightsquigarrow \mathrm{cc}(q^2)\}| \times |\,\mathrm{cc}(q)|\,.$$ ◀

2 Several equivalences on words

2.1 Minimization and Nerode classes

Let $\mathcal{A} = (Q, \Sigma, \delta, \rho)$ be a Mealy automaton.

The *Nerode equivalence* $\equiv$ *on* Q is the limit of the sequence of increasingly finer equivalences $(\equiv_k)$ recursively defined by:

$$\begin{aligned} \forall p, q \in Q, \qquad & p \equiv_0 q \iff \rho_{p|\Sigma} = \rho_{q|\Sigma}\,, \\ \forall k \geqslant 0,\ & p \equiv_{k+1} q \iff \big(p \equiv_k q \quad \wedge \quad \forall i \in \Sigma,\ \delta_i(p) \equiv_k \delta_i(q)\big)\,. \end{aligned}$$

Since the set Q is finite, this sequence is ultimately constant. For every element q in Q, we denote by $[q]$ the class of q w.r.t. the Nerode equivalence, called the *Nerode class* of q. Extending to the n-th power of $\mathcal{A}$, we denote by $[\mathbf{u}]$ the Nerode class in Q^n of $\mathbf{u} \in Q^n$.

Two states of a Mealy automaton belong to the same Nerode class if and only if they represent the same element in the generated (semi)group, *i.e.* if and only if they induce the same action on Σ^*. Two words on Q of the same length n are *equivalent* if they belong to the same Nerode class in Q^n. By extension, any two words on Q are *equivalent* if they induce the same action.

The *minimization* of $\mathcal{A}$ is the Mealy automaton $\mathfrak{m}(\mathcal{A}) = (Q/\equiv, \Sigma, \tilde{\delta}, \tilde{\rho})$, where for every (q, i) in $Q \times \Sigma$, $\tilde{\delta}_i([q]) = [\delta_i(q)]$ and $\tilde{\rho}_{[q]} = \rho_q$. This definition is consistent with the standard minimization of "deterministic finite automata" where instead of considering the mappings $(\rho_q \colon \Sigma \to \Sigma)_q$, the computation is initiated by the separation between terminal and non-terminal states.

A Mealy automaton is *minimal* if it has the same size as its minimization.

Two states of two different connected reversible minimal Mealy automata with the same alphabet induce the same action if and only if the automata are isomorphic and both states are in correspondence by this isomorphism (which can be formally defined by considering the union of the involved Mealy automata). As a direct consequence, if two connected reversible minimal Mealy automata have different sizes, then any two states of each of them cannot be equivalent.

As we have seen in Section 1.3, a state q of an invertible-reversible Mealy automaton induces an action of infinite order if and only if the sizes of the $(\mathrm{cc}(q^n))_{n>0}$ are unbounded. The proof of [11, Prop. 6] can be easily adapted to see that q induces an action of infinite order if and only if the sizes of the $(\mathfrak{m}(\mathrm{cc}(q^n)))_{n>0}$ are unbounded, but you can see it by a direct argument: if the sizes are bounded, there is an infinite set $I \subseteq \mathbb{N}$ such that all the element $(\mathfrak{m}(\mathrm{cc}(q^n)))_{n\in I}$ are isomorphic, and in this sequence there exist at least two different integer $i \neq j$ such that q^i and q^j are represented by the same state in the minimal automata, and so they induce the same action; if the sizes are unbounded, the sequence $(\#\,\mathfrak{m}(\mathrm{cc}(q^n)))_{n>0}$ has infinitely many values, and there are infinitely many powers of the action induced by q that are pairwise different.

Note that the Nerode classes of a connected reversible Mealy automaton have the same cardinality. The size of the minimization of an automaton in this case is the ratio between the size of the former automaton and the cardinality of the Nerode classes.

▶ **Lemma 8.** *Let $\mathcal{A}$ be a connected bireversible Mealy automaton, N a Nerode class of a connected component of one of its powers, and p and q two elements of $N\{-1\}$. There are as many elements of N with last letter p as with last letter q.*

Proof. The proof of this lemma is quite similar to the proof of Lemma 5 considering not words of length 1 as predecessors, but words of length $n-1$, where n is the length of the states in N. ◀

2.2 Restricted Nerode classes

When the considered automaton is not connected, it can be interesting to consider the restriction of the Nerode class of an element to its connected component: we denote it by $[\![q]\!]$ and call it the *restricted Nerode class* of q. The restricted Nerode class of a state coincide with its Nerode class in the case of a connected Mealy automaton.

▶ **Lemma 9.** *The restricted Nerode classes of two elements in the same connected component of a reversible Mealy automaton have the same cardinality.*

Let $\mathcal{A} = (Q, \Sigma, \delta, \rho)$ be a bireversible automaton and q a state of $\mathcal{A}$. As it will be discussed in Section 3, the result of this article is somehow a generalization of a much simpler but similar result proved in [10]: in the case where all the powers of $\mathcal{A}$ are connected, the group generated by $\mathcal{A}$ has exponential growth. The strategy used in [10] is based on the fact that $[\![q^n]\!]q \subseteq [\![q^{n+1}]\!]$ when all the powers of $\mathcal{A}$ are connected. However in the more general case we study here, this fact is false: a priori there is no inclusion link between $[\![q^n]\!]$ and $[\![q^{n+1}]\!]$, because if $\mathbf{u}$ is a state of $[\![q^n]\!]$, then nothing ensures that $\mathbf{u}q$ belongs to $\mathrm{cc}(q^{n+1})$; hence we have to find a different strategy. For this purpose, we introduce the *q-restricted Nerode class* of q^n, *i.e.* the set of states of $[\![q^n]\!]$ which admit q as a suffix: $[\![q^n]\!] = [\![q^n]\!] \cap Q^*q$.

The aim of this section is to study the sequence $([\![q^n]\!])_{n>0}$, in particular in the case where q has a constant ratio.

▶ **Lemma 10.** *The sequence of q-restricted Nerode classes satisfies the following inclusion property:*

$$\forall n > 0,\ [\![q^n]\!] q \subseteq [\![q^{n+1}]\!] .$$

Proof. Let $\mathbf{u}$ be an element of $[\![q^n]\!]$: $\mathbf{u}$ is a state of $\mathrm{cc}(q^n)$, and $\{\mathbf{u}? \rightsquigarrow \mathrm{cc}(q^{n+1})\}$ depends only on $\mathbf{u}\{-1\} = q$ by Lemma 5. In particular q can follow $\mathbf{u}$ since $q \in \{q? \rightsquigarrow \mathrm{cc}(q^{n+1})\}$. Since $\mathbf{u}$ and q^n induce the same action, so do $\mathbf{u}q$ and q^{n+1}. ◀

The next results give more information on the growth of the q-restricted Nerode classes of q^n with respect to n.

▶ **Proposition 11.** *Let $\mathcal{A}$ be a bireversible Mealy automaton, and q be a state of $\mathcal{A}$ of constant ratio k. The ratio between the sizes of $[\![q^{n+1}]\!]$ and $[\![q^n]\!]$ is an integer and:*

$$\forall n > 0,\ \frac{|\,[\![q^{n+1}]\!]\,|}{|\,[\![q^n]\!]\,|} = |[\![q^{n+1}]\!]\{-2\}| .$$

In particular this ratio cannot be greater than k.

Proof. Let $p \in [\![q^{n+1}]\!]\{-2\}$. By this choice, p can precede the final q in $[\![q^{n+1}]\!]$. Now, take $\mathbf{u} \in Q^{n-1}p$: we have $\mathbf{u}q \in [\![q^{n+1}]\!]$ if and only if $\mathbf{u} \in [\![q^n]\!]$ (the direct sense is obtained by Lemma 5 and the reciprocal sense by Lemma 10). Hence by Lemma 8, $|[\![q^n]\!] \cap Q^*p| = |\,[\![q^n]\!]\,|$ (which means somehow that we can pinpoint the Nerode class by p instead of q, without changing the cardinality).

Consequently, the sets $[\![q^{n+1}]\!] \cap Q^*pq$ and $[\![q^{n+1}]\!] \cap Q^*qq$ have the same cardinality.

Since $p \in [\![q^{n+1}]\!]\{-2\}$ can precede q in $\mathrm{cc}(q^{n+1})$, we obtain the bound $k = \{?q \rightsquigarrow \mathrm{cc}(q^2)\}$ by Lemmas 6 and 7. ◀

▶ **Proposition 12.** *Let $\mathcal{A}$ be a bireversible Mealy automaton, and q be a state of $\mathcal{A}$ of constant ratio k. The sequence*

$$\left(\frac{|\,[\![\, q^{n+1} \,]\!]\,|}{|\,[\![\, q^{n} \,]\!]\,|}\right)_{n>0}$$

is ultimately increasing to a limit less than or equal to k.

Proof. Consider the sequence $([\![\, q^n \,]\!])_{n>0}$ and particularly the sequence $([\![\, q^n \,]\!]\{0\})_{n>0}$: by Lemma 10, this last sequence is increasing (for inclusion). Denote by Q_1 its limit: $Q_1 = [\![\, q^n \,]\!]\{0\}$ for n large enough, say $n \geq N$; in particular this set contains q.

Now, suppose $n > N$ and take $p \in [\![\, q^{n+1} \,]\!]\{-2\}$: clearly $([\![\, q^{n+1} \,]\!] \cap Q^*pq)\{0\}$ is a subset of $Q_1 = [\![\, q^{n+1} \,]\!]\{0\} = [\![\, q^n \,]\!]\{0\}$; since it has the same cardinality as the set $([\![\, q^{n+1} \,]\!] \cap Q^*qq)\{0\} = [\![\, q^n \,]\!]\{0\}$ by Lemma 8, it is in fact equal to Q_1. But q belongs to Q_1, so it means that the set $[\![\, q^{n+1} \,]\!] \cap qQ^*pq$ is not empty, take $\mathbf{u}$ one of its elements. By Lemma 6, q can precede $\mathbf{u}$ in $\mathrm{cc}(q^{n+2})$ and $q\mathbf{u} \in [\![\, q^{n+2} \,]\!]$. Hence any penultimate letter in $[\![\, q^{n+1} \,]\!]$ is also a penultimate letter in $[\![\, q^{n+2} \,]\!]$:

$$[\![\, q^{n+1} \,]\!]\{-2\} \subseteq [\![\, q^{n+2} \,]\!]\{-2\}\,.$$

The result is now a direct consequence of Proposition 11 ◀

3 Main result

Because all the elements of a semigroup generated by an invertible-reversible Mealy automaton, all whose powers are connected, have infinite order [11, Prop. 6], the main result of this article, Theorem 14, is somehow a generalization of this previous result obtained in [10]:

▶ **Theorem 13.** *A semigroup generated by an invertible-reversible Mealy automaton, all of whose powers are connected, has exponential growth.*

To prove this generalization, we need to reinforce the hypothesis on the structure of the automaton which is supposed here to be bireversible and not only invertible-reversible, but we do not use anymore the really strong hypothesis on the connected powers. Since it is (easily) decidable if a Mealy automaton is bireversible, while the condition on the powers is not known to be decidable, except in very restricted cases, the result here is much more interesting and powerful, but it is also trickier to establish. The question of the existence of elements of infinite order in a semigroup generated by a bireversible automaton has been under study for several years now and has been solved in quite a few cases [9, 11, 4].

Here is the generalized version of the former theorem we prove in this section:

▶ **Theorem 14.** *A group generated by a bireversible Mealy automaton which contains an element of infinite order has exponential growth.*

Note that the result still holds for the generated semigroup and the proof is easily adaptable.

Proof. Let $\mathcal{A} = (Q, \Sigma, \delta, \rho)$ be a bireversible Mealy automaton and $\mathbf{u} \in (Q \sqcup Q^{-1})^*$ which induces an action of infinite order. The Mealy automaton $(\mathcal{A} \cup \mathcal{A}^{-1})^{|\mathbf{u}|}$ is bireversible, $\mathbf{u}$ is one of its states, and this automaton generates a subgroup of $\langle \mathcal{A} \rangle$. So without loss of generality, we can suppose that $\mathbf{u}$ is in fact a state of $\mathcal{A}$. To be consistent with the rest of the article, let us call it q.

For any integer $i > 0$, denote $r_i = \frac{\#\,\mathrm{cc}(q^{i+1})}{\#\,\mathrm{cc}(q^i)}$. The sequence of ratios associated to q is of the form $(r_1, r_2, \ldots, r_j, r_{j+1} = r_j, \ldots)$, where $r_i \geq r_{i+1}$ for any $i \geq 1$ and $r_i = r_j$ for any $i \geq j$. Now, consider the component $\mathrm{cc}(q^j)$ as a Mealy automaton and $\mathbf{q} = q^j$ as its state: the state $\mathbf{q}$ induces an action of infinite order and the sequence of ratios associated to $\mathbf{q}$ is of the form $(r_j^j, r_j^j, \ldots)$: $\mathbf{q}$ has constant ratio. Moreover, $\mathrm{cc}(\mathbf{q})$ generates a subgroup of the group $\langle\mathcal{A}\rangle$, so if we prove that $\langle\mathrm{cc}(\mathbf{q})\rangle$ has exponential growth, so has $\langle\mathcal{A}\rangle$. So, without loss of generality we can suppose that q has a constant ratio, say k.

Note that the following inequalities hold:

$$\forall n > 0,\ \frac{|\,\mathrm{cc}(q^n)|}{|Q| \times |\,[\![\, q^n \,]\!]\,|} \leq \frac{|\,\mathrm{cc}(q^n)|}{|[\![q^n]\!]|} \leq \frac{|\,\mathrm{cc}(q^n)|}{|\,[\![\, q^n \,]\!]\,|}\,. \tag{1}$$

Indeed, the second inequality is a consequence of the fact that $[\![\, q^n \,]\!] \subseteq [\![q^n]\!]$, and the first inequality follows from Lemma 8 and the fact that $[\![q^n]\!] = \cup_{p\in Q}([\![q^n]\!] \cap Q^*p)$.

The central part in (1) is in fact the size of the minimization of $\mathrm{cc}(q^n)$, and the cardinality of $\mathrm{cc}(q^n)$ is equal to $|Q| \times k^{n-1}$ since q has constant ratio k, so (1) can be re-written as:

$$\forall n > 0,\ \frac{k^{n-1}}{|\,[\![\, q^n \,]\!]\,|} \leq \#\,\mathfrak{m}(\mathrm{cc}(q^n)) \leq \frac{|Q| \times k^{n-1}}{|\,[\![\, q^n \,]\!]\,|}\,. \tag{2}$$

Let us prove that for n large enough, $|\,[\![\, q^{n+1} \,]\!]\,| < k \times |\,[\![\, q^n \,]\!]\,|$. From Proposition 11 we know that the corresponding non strict inequality is satisfied. Now, from Propositions 11 and 12 we know that for N large enough, if the equality holds at rank N, it also holds at every rank greater than N: for any $n \geq N$, $|\,[\![\, q^{n+1} \,]\!]\,| = k \times |\,[\![\, q^n \,]\!]\,|$. This means that for n large enough: $|\,[\![\, q^n \,]\!]\,| = bk^{n-1}$, where b does not depend on n. Hence by the right part of Equation (2), the minimizations of the connected powers of q have bounded size, which implies that q has finite order as seen in Section 2.1, in contradiction with the hypotheses. So the equality does not hold for any N.

Denote by ℓ the limit of the sequence

$$\left(\frac{|\,[\![\, q^{n+1} \,]\!]\,|}{|\,[\![\, q^n \,]\!]\,|}\right)_{n>0}$$

(it exists from Proposition 12): $\ell < k$ from the above paragraph, so for n large enough, there exists a constant c such that $|\,[\![\, q^n \,]\!]\,| = \frac{\ell^n}{kc}$.

So Equation (2) becomes:

$$\forall n > N,\ c\left(\frac{k}{\ell}\right)^n \leq \#\,\mathfrak{m}(\mathrm{cc}(q^n)) \leq c|Q|\left(\frac{k}{\ell}\right)^n\,. \tag{3}$$

Since $\ell < k$, there exists α such that $\left(\frac{k}{l}\right)^\alpha > |Q|$. Let us denote $\mathbf{u} = q^\alpha$ and $K = \left(\frac{k}{\ell}\right)^\alpha$, we have that for n large enough:

$$c \cdot K^n \leq \#\,\mathfrak{m}(\mathrm{cc}(\mathbf{u}^n)) \leq c \cdot |Q| \cdot K^n < c \cdot K^{n+1} \leq \#\,\mathfrak{m}(\mathrm{cc}(\mathbf{u}^{n+1})) \leq c \cdot |Q| \cdot K^{n+1}\,. \tag{4}$$

Consequently, the minimizations of the components $\mathrm{cc}(\mathbf{u}^n)$ are pairwise not isomorphic, for n large enough, because they do not have the same size. So their states induce different elements of the group $\langle\mathcal{A}\rangle$. Hence the sets

$$I_n = \{\rho_{\mathbf{v}} \mid \mathbf{v} \text{ is a state of } \mathfrak{m}(\mathrm{cc}(\mathbf{u}^n))\}$$

are pairwise disjoint. By Equation (4), the growth of the sequence $(I_n)_{n>0}$ is exponential, and so is the growth of $\mathcal{A}$. ◀

By combining Theorem 14 with the fact that connected bireversible Mealy automata of prime size cannot generate infinite Burnside groups [4], we have:

▶ **Corollary 15.** *Any infinite group generated by a bireversible connected Mealy automaton of prime size has exponential growth.*

Another consequence of Theorem 14 concerns virtually nilpotent groups. This class is important in the classification of groups and contains in particular all the abelian groups. It is known that any infinite virtually nilpotent group contains an element of infinite order [3, Proposition 10.48] and has polynomial growth [16]. This leads to

▶ **Corollary 16.** *No infinite virtually nilpotent group can be generated by a bireversible Mealy automaton.*

Abstract

We study the identity problem for matrices, i.e., whether the identity matrix is in a semigroup generated by a given set of generators. In particular we consider the identity problem for the *special linear group* following recent NP-completeness result for $\mathrm{SL}(2,\mathbb{Z})$ and the undecidability for $\mathrm{SL}(4,\mathbb{Z})$ generated by 48 matrices. First we show that there is no embedding from pairs of words into 3×3 integer matrices with determinant one, i.e., into $\mathrm{SL}(3,\mathbb{Z})$ extending previously known result that there is no embedding into $\mathbb{C}^{2\times 2}$. Apart from theoretical importance of the result it can be seen as a strong evidence that the computational problems in $\mathrm{SL}(3,\mathbb{Z})$ are decidable. The result excludes the most natural possibility of encoding the Post correspondence problem into $\mathrm{SL}(3,\mathbb{Z})$, where the matrix products extended by the right multiplication correspond to the Turing machine simulation. Then we show that the *identity problem* is decidable in polynomial time for an important subgroup of $\mathrm{SL}(3,\mathbb{Z})$, the Heisenberg group $\mathrm{H}(3,\mathbb{Z})$. Furthermore, we extend the decidability result for $\mathrm{H}(n,\mathbb{Q})$ in any dimension n. Finally we are tightening the gap on decidability question for this long standing open problem by improving the undecidability result for the identity problem in $\mathrm{SL}(4,\mathbb{Z})$ substantially reducing the bound on the size of the generator set from 48 to 8 by developing a novel reduction technique.

1 Introduction

The dynamics of many systems can be represented by matrices and matrix products. The analysis of such systems lead to solving reachability questions in matrix semigroups which is essential part in verification procedures, control theory questions, biological systems'

predictability, security etc. [9, 10, 16, 17, 20, 21, 28, 33, 35, 36, 37]. Many nontrivial algorithms for decision problems on matrix semigroups have been developed for matrices under different constraints on the dimension, the size of a generating set or for specific subclasses of matrices: e.g., commutative matrices [2], row-monomial matrices [30] or 2×2 matrix semigroups generated by non-singular integer matrices [41], upper-triangular integer matrices [25], matrices from the special linear group [4, 15], etc.

Despite visible interest in this research domain, we still see a significant lack of algorithms and complexity results for answering decision problems in matrix semigroups. Many computational problems for matrix (semi)groups are computationally hard starting from dimension two and very often become undecidable from dimensions three or four even in the case of integer matrices. The central decision problem in matrix semigroups is the membership problem, which was originally considered by A. Markov in 1947 [32]. Let $S = \langle G \rangle$ be a matrix semigroup finitely generated by a generating set of square matrices G. The *membership problem* is to decide whether or not a given matrix M belongs to the matrix semigroup S. By restricting M to be the identity matrix we call the problem the *identity problem*.

▶ **Problem 1** (Identity problem). *Let $S = \langle G \rangle$, where G is a finite set of n-dimensional matrices over $\mathbb{K} = \mathbb{Z}, \mathbb{Q}, \mathbb{R}, \mathbb{C}, \ldots$. Is the identity matrix in the semigroup, i.e., does $\boldsymbol{I} \in S$ hold?*

The identity problem is computationally equivalent to another fundamental problem – the *subgroup problem* (i.e., to decide whether a semigroup contains a subgroup) as any subset of matrices, which can form a product leading to the identity also generate a group [15][1].

The decidability status of the identity problem was unknown for a long time for matrix semigroups of any dimension, see Problem 10.3 in "Unsolved Problems in Mathematical Systems and Control Theory" [10], but it was shown in [6] to be undecidable for 48 matrices from $\mathbb{Z}^{4\times4}$ by proving that the identity correspondence problem (a variant of the Post correspondence problem over a group alphabet) is undecidable, and embedding pairs of words over free group alphabet into $\mathrm{SL}(4,\mathbb{Z})$ as two blocks on the main diagonal and by a morphism f as follows $f(a) = \left(\begin{smallmatrix} 1 & 2 \\ 0 & 1 \end{smallmatrix}\right)$, $f(a^{-1}) = \left(\begin{smallmatrix} 1 & -2 \\ 0 & 1 \end{smallmatrix}\right)$, $f(b) = \left(\begin{smallmatrix} 1 & 0 \\ 2 & 1 \end{smallmatrix}\right)$ and $f(b^{-1}) = \left(\begin{smallmatrix} 1 & 0 \\ -2 & 1 \end{smallmatrix}\right)$. In the seminal paper of Paterson in 1970, see [39], an injective morphism from pairs of words in alphabet $\Sigma = \{a, b\}$ into 3×3 integral matrices, $g(u, v) = \begin{pmatrix} n^{|u|} & 0 & 0 \\ 0 & n^{|v|} & 0 \\ \sigma(u) & \sigma(v) & 1 \end{pmatrix}$ (where σ represents each word as an n-adic number), was used to prove undecidability of the mortality problem (i.e., the membership problem of the zero matrix) and which later led to many undecidability results of matrix problems in dimension three, e.g., [12, 24]. Finding new injective morphisms is hard, but having them gives an opportunity to prove new undecidability results.

In 1999, Cassaigne, Harju and Karhumäki significantly boosted the research on finding algorithmic solutions for 2×2 matrix semigroups by showing that there is no injective semigroup morphism from pairs of words over any finite alphabet (with at least two elements) into complex 2×2 matrices [12]. This result led to substantial interest in finding algorithmic solutions for such problems as the identity problem, mortality, membership, vector reachability, freeness etc. for 2×2 matrices.

For example, in 2007 Gurevich and Schupp [23] showed that the membership problem is decidable in polynomial time for the finitely generated subgroups of the modular group and later in 2017 Bell, Hirvensalo and Potapov proved that the identity problem for a semigroup

[1] The product of matrices which is equal to the identity is still the identity element after a cyclic shift, so every element from this product has the inverse.

generated by matrices from $\mathrm{SL}(2,\mathbb{Z})$ is NP-complete by developing a new effective technique to operate with compressed word representations of matrices and closing the gap on complexity improving the original EXPSPACE solution proposed in 2005 [15]. The first algorithm for the membership problem which covers the cases beyond $\mathrm{SL}(2,\mathbb{Z})$ and $\mathrm{GL}(2,\mathbb{Z})$ has been proposed in [41] and provides the solution for a semigroup generated by non-singular 2×2 integer matrices. Later, these techniques have been applied to build another algorithm to solve the membership problem in $\mathrm{GL}(2,\mathbb{Z})$ extended by singular matrices [42]. The current limit of decidability is standing for 2×2 matrices which are defined over hypercomplex numbers (quaternions) for which most of the problems have been shown to be undecidable in [5] and correspond to reachability problems for 3-sphere rotation.

In our paper, we show that there is no embedding from pairs of words into 3×3 integer matrices with determinant one (i.e., into $\mathrm{SL}(3,\mathbb{Z})$), which is a strong evidence that computational problems in $\mathrm{SL}(3,\mathbb{Z})$ are decidable as all known undecidability techniques for low-dimensional matrices are based on encoding of Turing machine computations via the Post correspondence problem (PCP) which cannot be applied in $\mathrm{SL}(3,\mathbb{Z})$ following our result. In case of the PCP encoding the matrix products extended by the right multiplication correspond to the Turing machine simulation and the only known proof alternatives are recursively enumerable sets and Hilbert's tenth problem that provide undecidability for matrix equations, but of very high dimensions [3, 13, 26].

So in analogy to 1999 result from [12] on non-existence of embedding into 2×2 matrix semigroups over complex numbers, we expand a horizon of decidability area for matrix semigroups and show that there is no embedding from a set of pairs of words over a semigroup alphabet to any matrix semigroup in $\mathrm{SL}(3,\mathbb{Z})$. It follows almost immediately that there is no embedding from a set of pairs of group words into $\mathbb{Z}^{3\times 3}$.[2] The matrix semigroup in $\mathrm{SL}(3,\mathbb{Z})$ has attracted a lot of attention recently as it can be represented by a set of generators and relations [18, 19] similar to $\mathrm{SL}(2,\mathbb{Z})$ where it was possible to convert numerical problems into symbolic problems and solve them with novel computational techniques; see [4, 15, 41, 42]. Comparing to the relatively simple representation of $\mathrm{SL}(2,\mathbb{Z}) = \langle S,T \mid S^4 = \boldsymbol{I}_2, (ST)^6 = \boldsymbol{I}_2\rangle$, where $S = \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$ and $T = \left(\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right)$ the case of $\mathrm{SL}(3,\mathbb{Z}) = \langle X,Y,Z \mid X^3 = Y^3 = Z^2 = (XZ)^3 = (YZ)^3 = (X^{-1}ZXY)^2 = (Y^{-1}ZYX)^2 = (XY)^6 = \boldsymbol{I}_3\rangle$ looks more challenging containing both non-commutative and partially commutative elements.

As the decidability status of the *identity problem* in dimension three is still a long standing open problem, we look for an important subgroup of $\mathrm{SL}(3,\mathbb{Z})$, the Heisenberg group $\mathrm{H}(3,\mathbb{Z})$, for which the *identity problem* could be decidable following our result on non-existence of embedding. The Heisenberg group is an important subgroup of $\mathrm{SL}(3,\mathbb{Z})$ which is useful in the description of one-dimensional quantum mechanical systems [11, 22, 29]. We show that the *identity problem* for a matrix semigroup generated by matrices from $\mathrm{H}(3,\mathbb{Z})$ and even $\mathrm{H}(3,\mathbb{Q})$ is decidable in polynomial time. Furthermore, we extend the decidability result for $\mathrm{H}(n,\mathbb{Q})$ in any dimension n. Moreover we tighten the gap between (un)decidability results for the *identity problem* substantially reducing the bound on the size of the generator set from 48 (see [6]) to 8 in $\mathrm{SL}(4,\mathbb{Z})$ by developing a novel reduction technique.

[2] The idea that such result may hold was motivated by analogy from combinatorial topology, where the identity problem is decidable for the braid group B_3 which is the universal central extension of the modular group $\mathrm{PSL}(2,\mathbb{Z})$ [40], an embedding for a set of pairs of words into the braid group B_5 exists, see [7], and non-existence of embeddings were proved for B_4 in [1]. So $\mathrm{SL}(3,\mathbb{Z})$ was somewhere in the goldilocks zone between B_3 and B_5.

2 Preliminaries

We say that a semigroup S is *generated* by a subset G of S if each element of S can be expressed as a composition of elements of G. In this case, we call G the *generating set* of S. Given an *alphabet* $\Sigma = \{a_1, \ldots, a_m\}$, a finite *word* u is an element of semigroup Σ^*. The *empty word* is denoted by ε. Let $\Gamma = \{a_1, \ldots, a_\ell, a_1^{-1}, \ldots, a_\ell^{-1}\}$ be a generating set of a free group $\mathrm{FG}(\Gamma)$. The elements of $\mathrm{FG}(\Gamma)$ are all *reduced* words over Γ, i.e., words not containing $a_i a_i^{-1}$ or $a_i^{-1} a_i$ as a subword. In this context, we call Γ a finite *group alphabet*, i.e., an alphabet with an involution. The multiplication of two elements (reduced words) $u, v \in \mathrm{FG}(\Gamma)$ corresponds to the unique reduced word of the concatenation uv. This multiplication is called *concatenation* throughout the paper. Later in the encoding of words over a group alphabet we denote a^{-1} by $\overline{a}$ and the alphabet of inverse letters is denoted as $\Sigma^{-1} = \{a^{-1} \mid a \in \Sigma\}$.

In the next lemma, we present an encoding from an arbitrary group alphabet to a binary group alphabet used in Section 5. The result is crucial as it allows us to present the results of the above section over the smallest domain.

▶ **Lemma 2** (Birget, Margolis [8]). *Let $\Gamma = \{z_1, \ldots, z_\ell, \overline{z_1}, \ldots, \overline{z_\ell}\}$ be a group alphabet and $\Gamma_2 = \{c, d, \bar{c}, \bar{d}\}$ be a binary group alphabet. Define the mapping $\alpha : \Gamma \to \mathrm{FG}(\Gamma_2)$ by $\alpha(z_i) = c^i d \bar{c}^i$, and $\alpha(\overline{z_i}) = c^i \bar{d} \bar{c}^i$, where $1 \leq i \leq \ell$. Then α is a monomorphism, that is, an injective morphism. Note that α can be extended to domain $\mathrm{FG}(\Gamma)$ in the usual way.*

The special linear group is $\mathrm{SL}(n, \mathbb{K}) = \{M \in \mathbb{K}^{n \times n} \mid \det(M) = 1\}$, where $\mathbb{K} = \mathbb{Z}, \mathbb{Q}, \mathbb{R}, \mathbb{C}, \ldots$. The *identity matrix* is denoted by $\boldsymbol{I}_n$ and the *zero matrix* is denoted by $\mathbf{0}_n$. The *Heisenberg group* $\mathrm{H}(3, \mathbb{K})$ is formed by the 3×3 matrices of the form $M = \left(\begin{smallmatrix} 1 & a & c \\ 0 & 1 & b \\ 0 & 0 & 1 \end{smallmatrix}\right)$, where $a, b, c \in \mathbb{K}$. It is easy to see that the Heisenberg group is a non-commutative subgroup of $\mathrm{SL}(3, \mathbb{K})$. We can consider the Heisenberg group as a set of all triples with the following group law: $(a_1, b_1, c_1) \otimes (a_2, b_2, c_2) = (a_1 + a_2, b_1 + b_2, c_1 + c_2 + a_1 b_2)$. By $\psi(M)$ we denote the triple $(a, b, c) \in \mathbb{K}^3$ which corresponds to the upper-triangular coordinates of M. Let M be a matrix in $\mathrm{H}(3, \mathbb{K})$ such that $\psi(M) = (a, b, c)$. We define the *superdiagonal vector* of M to be $\vec{v}(M) = (a, b)$. Given two vectors $\mathbf{u} = (u_1, u_2)$ and $\mathbf{v} = (v_1, v_2)$, the *cross product* of $\mathbf{u}$ and $\mathbf{v}$ is defined as $\mathbf{u} \times \mathbf{v} = u_1 v_2 - u_2 v_1$. Two vectors are *parallel* if the cross product is zero.

The Heisenberg group can be also defined in higher dimensions. The Heisenberg group of dimension n over $\mathbb{K}$ is denoted by $\mathrm{H}(n, \mathbb{K})$ and is the group of square matrices in $\mathbb{K}^{n \times n}$ of the form $\left(\begin{smallmatrix} 1 & \mathbf{a}^\mathsf{T} & c \\ 0 & \boldsymbol{I}_{n-2} & \mathbf{b} \\ 0 & 0 & 1 \end{smallmatrix}\right)$, where $\mathbf{a}, \mathbf{b} \in \mathbb{K}^{n-2}, c \in \mathbb{K}$. Similar to the Heisenberg group in dimension three, we can also consider the Heisenberg group in dimension n for any integer $n \geq 3$ as a set of all triples with the following group law: $(\mathbf{a}_1, \mathbf{b}_1, c_1) \otimes (\mathbf{a}_2, \mathbf{b}_2, c_2) = (\mathbf{a}_1 + \mathbf{a}_2, \mathbf{b}_1 + \mathbf{b}_2, c_1 + c_2 + \mathbf{a}_1 \cdot \mathbf{b}_2)$, where $\mathbf{a}_1, \mathbf{a}_2, \mathbf{b}_1, \mathbf{b}_2 \in \mathbb{K}^{n-2}$ and $\mathbf{a}_1 \cdot \mathbf{b}_2$ is the dot product of vectors $\mathbf{a}_1$ and $\mathbf{b}_2$.

We extend the function ψ to n-dimensional Heisenberg group: For a matrix M, $\psi(M)$ is the triple $(\mathbf{a}, \mathbf{b}, c) \in (\mathbb{K}^{n-2})^2 \times \mathbb{K}$ which corresponds to the upper-triangular coordinates of M. The product $M_1 M_2$ has $c_1 + c_2 + \mathbf{a}_1 \cdot \mathbf{b}_2$ in the upper-right corner whereas $M_2 M_1$ has $c_1 + c_2 + \mathbf{a}_2 \cdot \mathbf{b}_1$. The other coordinates are identical as we add numbers in the same coordinate. Clearly, the two products are equivalent if and only if $\mathbf{a}_1 \cdot \mathbf{b}_2 = \mathbf{a}_2 \cdot \mathbf{b}_1$ holds.

▶ **Lemma 3.** *Let M_1 and M_2 be two matrices from the Heisenberg group $\mathrm{H}(n, \mathbb{K})$ and $\psi(M_i) = (\mathbf{a}_i, \mathbf{b}_i, c_i)$ for $i = 1, 2$. Then $M_1 M_2 = M_2 M_1$ holds if and only if $\mathbf{a}_1 \cdot \mathbf{b}_2 = \mathbf{a}_2 \cdot \mathbf{b}_1$.*[3]

[3] Note that, in dimension three, the condition can be stated as superdiagonal vectors of M_1 and M_2 being parallel.

3 On embedding from pairs of words into $\mathrm{SL}(3,\mathbb{K})$

In this section, we show that there is no embedding from a set of pairs of words over a semigroup alphabet to the special linear group $\mathrm{SL}(3,\mathbb{Z})$, which can be seen as a strong evidence about decidability of computational problems for this class. If the injective morphism would exist, then we could encode Turing machine computations via the PCP which would provide undecidability proofs for various membership problems in $\mathrm{SL}(3,\mathbb{Z})$.

Let $\Sigma = \{0,1\}$. The monoid $\Sigma^* \times \Sigma^*$ has a generating set $S = \{(0,\varepsilon),(1,\varepsilon),(\varepsilon,0),(\varepsilon,1)\}$, where ε is the empty word. We simplify the notation by setting $a = (0,\varepsilon)$, $b = (1,\varepsilon)$, $c = (\varepsilon,0)$ and $d = (\varepsilon,1)$. It is easy to see that we have the following relations:

$$ac = ca, \qquad bc = cb, \qquad ad = da, \qquad bd = db. \tag{1}$$

In other words, a and b commute with c and d. Furthermore, these are the only relations. That is, a and b do not commute with each other, and neither do c and d. The monoid $\Sigma^* \times \Sigma^*$ is a partially commutative monoid or a trace monoid. A necessary and sufficient conditions for existence of an embedding of trace monoids into $\mathbb{N}^{2\times 2}$ was given in [14] but, to the authors' best knowledge, there are no similar results even for $\mathbb{N}^{3\times 3}$. Let $\varphi : \Sigma^* \times \Sigma^* \to \mathrm{SL}(3,\mathbb{K})$ be an injective morphism and denote $A = \varphi(a)$, $B = \varphi(b)$, $C = \varphi(c)$ and $D = \varphi(d)$. Our goal is to show that φ does not exist for $\mathbb{K} = \mathbb{Z}$. Additionally, we provide an embedding for $\mathbb{K} = \mathbb{Q}$. Unfortunately, the technique developed in [12], where the contradiction was derived from simple relations, resulting from matrix multiplication, cannot be used for a case of $\mathrm{SL}(3,\mathbb{Z})$ as it creates a large number of equations which do not directly limit the existence of φ. We found new techniques to show non-existence of φ by analysis of eigenvalues and the Jordan normal forms.

In the next theorem, we show that if we embed the generators of $\Sigma^* \times \Sigma^*$ into $\mathrm{SL}(3,\mathbb{Z})$, then, for each Jordan normal form, the matrices should satisfy additional equations.

▶ **Theorem 4.** *There is no injective morphism $\varphi : \Sigma^* \times \Sigma^* \to \mathrm{SL}(3,\mathbb{Z})$ for any $|\Sigma| \geq 2$.*

Proof (Sketch). Due to the obvious symmetries, it is enough to show that the claim holds for A. We conjugate the generators to transform A into Jordan normal form. Note that Jordan normal form J of an integer matrix A does not have to be integer or even real, but the contradictions we derive apply also to the original matrices. Also note that matrices J and A have integer trace and determinants are one. There are six possible Jordan normal forms for 3×3 matrices: $\left(\begin{smallmatrix}\lambda&0&0\\0&\mu&0\\0&0&\nu\end{smallmatrix}\right)$, $\left(\begin{smallmatrix}\lambda&0&0\\0&\mu&0\\0&0&\mu\end{smallmatrix}\right)$, $\left(\begin{smallmatrix}\lambda&0&0\\0&\mu&1\\0&0&\mu\end{smallmatrix}\right)$, $\left(\begin{smallmatrix}\lambda&0&0\\0&\lambda&0\\0&0&\lambda\end{smallmatrix}\right)$, $\left(\begin{smallmatrix}\lambda&1&0\\0&\lambda&0\\0&0&\lambda\end{smallmatrix}\right)$, or $\left(\begin{smallmatrix}\lambda&1&0\\0&\lambda&1\\0&0&\lambda\end{smallmatrix}\right)$. The first and the fourth normal forms can be ruled out as the matrices commute with diagonal matrices, and then we prove that C and D commute with each other. In the second form, it follows from the fact that A has an integer trace and the determinant is one, that the eigenvalues are $\lambda = 2$ and $\mu = \frac{1}{2}$. Then, we can rule this form out as also the trace of A^2 should be an integer which does not hold for these eigenvalues. The third form is ruled out as from the relations $AC = CA$ and $AD = DA$, we can solve C and D, and see that necessary also $CD = DC$ holds. The final form is similar to the third Jordan normal form and is ruled out in a similar manner. The fifth form requires additional considerations. We solve most of the elements of $C = \left(\begin{smallmatrix}a&b&c\\d&e&f\\g&h&\ell\end{smallmatrix}\right)$ and $D = \left(\begin{smallmatrix}a'&b'&c'\\d'&e'&f'\\g'&h'&\ell'\end{smallmatrix}\right)$ from equations $AC = CA$ and $AD = DA$. To solve the remaining elements, we need to do further case analysis and we prove that matrices C and D do not commute if and only if $ch' \neq c'h$. We further solve B from $BC = CB$ and $BD = DB$, and show that necessarily $CD = DC$, which is not a valid relation. This is a brief sketch of high-level steps of showing that the injective morphism does not exist; see the complete proof in [27]. ◀

Note that some of the Jordan normal forms of the previous theorem can be ruled out even without assuming that the original matrices were in $\mathrm{SL}(3,\mathbb{Z})$. Using these additional constraints on matrices, we are able to find an embedding into $\mathrm{SL}(3,\mathbb{Q})$.

▶ **Theorem 5.** *Let* $\Sigma = \{0,1\}$. *The morphism* $\varphi : \Sigma^* \times \Sigma^* \to \mathrm{SL}(3,\mathbb{Q})$, *defined by* $\varphi((0,\varepsilon)) = \begin{pmatrix} 4 & 0 & 0 \\ 0 & \frac{1}{2} & 0 \\ 0 & 0 & \frac{1}{2} \end{pmatrix}$, $\varphi((1,\varepsilon)) = \begin{pmatrix} 9 & \frac{1}{3} & 0 \\ 0 & \frac{1}{3} & 0 \\ 0 & 0 & \frac{1}{3} \end{pmatrix}$, $\varphi((\varepsilon,0)) = \begin{pmatrix} \frac{1}{2} & 0 & 0 \\ 0 & \frac{1}{2} & 0 \\ 0 & 0 & 4 \end{pmatrix}$ *and* $\varphi((\varepsilon,1)) = \begin{pmatrix} \frac{1}{3} & 0 & 0 \\ 0 & \frac{1}{3} & 0 \\ 0 & \frac{1}{3} & 9 \end{pmatrix}$ *is an embedding.*

We can further extend the non-existence result to words over group alphabets. The only known results for undecidability of the identity problem rely on embedding of pairs of group words into matrices (Theorem 13 and [6]) suggesting that the problem might be decidable in dimension three over integers.

▶ **Corollary 6.** *There is no injective morphism* $\varphi : \mathrm{FG}(\Gamma) \times \mathrm{FG}(\Gamma) \to \mathbb{Z}^{3\times 3}$ *for any binary group alphabet* Γ.

Proof. We proceed by contradiction. Assume that there exists such an injective morphism φ from the set of pairs of words over a group alphabet to the set of matrices in $\mathbb{Z}^{3\times 3}$. Suppose that $A = \varphi((a,\varepsilon))$, where $a \in \Gamma$. Then the inverse matrix A^{-1} corresponding to $(\bar{a},\varepsilon)$ must be in $\mathbb{Z}^{3\times 3}$. This implies that the determinant of A is ± 1 because otherwise the determinant of A^{-1} becomes a non-integer. Consider then a morphism ψ such that $\psi(x) = \varphi(x)\varphi(x)$ for each $x \in \mathrm{FG}(\Gamma) \times \mathrm{FG}(\Gamma)$. It is clear that also ψ is injective and that the determinant of the image is 1. By Theorem 4, such injective morphism ψ does not exist even from semigroup alphabets and hence neither does φ. ◀

4 Decidability of the identity problem in the Heisenberg group

In this section, we prove that the identity problem is decidable for the Heisenberg group which is an important subgroup of the special linear group. First, we provide more intuitive solution for dimension three, i.e., $\mathrm{H}(3,\mathbb{Q})$, which still requires a number of techniques to estimate possible values of elements under permutations in matrix products. In the end of the section, we generalize the result for $\mathrm{H}(n,\mathbb{Q})$ using analogies in the solution for $\mathrm{H}(3,\mathbb{Q})$.

We prove that the identity problem for the Heisenberg group over rationals is decidable by analysing the behaviour of multiplications especially in the upper-right coordinate of matrices. From Lemma 3, it follows that the matrix multiplication is commutative in the Heisenberg group if and only if matrices have pairwise parallel superdiagonal vectors. So we analyse two cases of products for matrices with pairwise parallel and none pairwise parallel superdiagonal vectors and then provide algorithms that solve the problem in polynomial time. The most difficult part is showing that only limited number of conditions must be checked to guarantee the existence of a product that results in the identity.

▶ **Lemma 7.** *Let* $G = \{M_1,\ldots,M_r\} \subseteq \mathrm{H}(3,\mathbb{Q})$ *be a set of matrices from the Heisenberg group such that superdiagonal vectors of matrices are pairwise parallel. If there exists a sequence of matrices* $M = M_{i_1}\cdots M_{i_k}$, *where* $i_j \in [1,r]$ *for all* $1 \le j \le k$, *such that* $\psi(M) = (0,0,c)$ *for some* $c \in \mathbb{Q}$, *then,* $c = \sum_{j=1}^{k}(c_{i_j} - \frac{q}{2}a_{i_j}^2)$ *for some* $q \in \mathbb{Q}$ *dependent only on* G.

Proof. Consider the sequence $M_{i_1}\cdots M_{i_k}$ and let $M_i = \begin{pmatrix} 1 & a_i & c_i \\ 0 & 1 & b_i \\ 0 & 0 & 1 \end{pmatrix}$ for each $i \in [1,r]$. Since the superdiagonal vectors are parallel, i.e., $a_i b_j = b_i a_j$ for any $i,j \in [1,r]$, we have $q = \frac{b_i}{a_i} \in \mathbb{Q}$

and thus $a_i q = b_i$ for all $i \in [1, r]$. Let us consider the product of the matrices. Then the value c is equal to

$$c = \sum_{j=1}^{k} c_{i_j} + \sum_{\ell=1}^{k-1} \left(\sum_{j=1}^{\ell} a_{i_j} \right) a_{i_{\ell+1}} q = \sum_{j=1}^{k} c_{i_j} + \frac{q}{2} \left(\sum_{\ell=1}^{k} \sum_{j=1}^{k} a_{i_\ell} a_{i_j} - \sum_{j=1}^{k} a_{i_j}^2 \right) = \sum_{j=1}^{k} (c_{i_j} - \frac{q}{2} a_{i_j}^2).$$

Note that if $a_{i_j} = 0$ for some $i_j \in [1, r]$, then due to superdiagonal vectors being parallel, $a_{i_j} = 0$ for all i_j and the value c is equal to $\sum_{j=1}^{k} c_{i_j}$. ◀

Note that the previous lemma also holds for $\mathrm{H}(3, \mathbb{R})$. From the previous lemma we further see that the value c is preserved if the matrices are reordered due to their commutativity.

It is worth mentioning that the identity problem in the Heisenberg group is decidable if any two matrices have pairwise parallel superdiagonal vectors since now the problem reduces to solving a system of two linear homogeneous Diophantine equations. Hence, it remains to consider the case when there exist two matrices with non-parallel superdiagonal vectors in the sequence generating the identity matrix. In the following, we prove that the identity matrix is always constructible if we can construct any matrix with the zero superdiagonal vector by using matrices with non-parallel superdiagonal vectors.

▶ **Lemma 8.** *Let $S = \langle M_1, \ldots, M_r \rangle \subseteq \mathrm{H}(3, \mathbb{Q})$ be a finitely generated matrix semigroup. Then the identity matrix exists in S if there exists a sequence of matrices $M_{i_1} \cdots M_{i_k}$, where $i_j \in [1, r]$ for all $1 \leq j \leq k$, satisfying the following properties:*

(i) *$\psi(M_{i_1} \cdots M_{i_k}) = (0, 0, c)$ for some $c \in \mathbb{Q}$, and*

(ii) *$\vec{v}(M_{i_{j_1}})$ and $\vec{v}(M_{i_{j_2}})$ are not parallel for some $j_1, j_2 \in [1, k]$.*

To prove Lemma 8, we show that from a matrix $M = M_{i_1} \cdots M_{i_k}$, such that $\psi(M) = (0, 0, c)$, satisfying the conditions of the lemma, we can construct a matrix M' such that $\psi(M') = (0, 0, c')$ and $cc' < 0$. Given that M_i is the ith generator and $\psi(M_i) = (a_i, b_i, c_i)$, we have $\sum_{j=1}^{k} a_{i_j} = 0$ and $\sum_{j=1}^{k} b_{i_j} = 0$. Without loss of generality, $c > 0$, and the following also holds:

$$c = \sum_{\ell=1}^{k-1} \sum_{j=1}^{\ell} a_{i_j} b_{i_{\ell+1}} + \sum_{j=1}^{k} c_{i_j} > 0. \tag{2}$$

If the matrix semigroup $S \subseteq \mathrm{H}(3, \mathbb{Q})$ has two different matrices N_1 and N_2 such that $\psi(N_1) = (0, 0, c_1)$ and $\psi(N_2) = (0, 0, c_2)$ and $c_1 c_2 < 0$, then the identity matrix exists in S. Indeed, let $\psi(N_1) = (0, 0, \frac{p_1}{q_1})$ and $\psi(N_2) = (0, 0, \frac{p_2}{q_2})$, where $p_1, q_1, q_2 \in \mathbb{Z}$ are positive and $p_2 \in \mathbb{Z}$ is negative. Then it is easy to see that the matrix $N_1^{-q_1 p_2} N_2^{q_2 p_1}$ exists in S and that $\psi(N_1^{-q_1 p_2} N_2^{q_2 p_1}) = (0, 0, 0)$.

To construct the matrix M', we first classify the matrices into four types as follows. A matrix with a superdiagonal vector (a, b) is classified as

1) the $(+,+)$-type if $a, b > 0$,
2) the $(+,-)$-type if $a \geq 0$ and $b \leq 0$,
3) the $(-,-)$-type if $a, b < 0$, and
4) the $(-,+)$-type if $a < 0$ and $b > 0$.

Let $G = \{M_1, \ldots, M_r\}$ be the generating set of the matrix semigroup S. Then $G = G_{(+,+)} \sqcup G_{(+,-)} \sqcup G_{(-,-)} \sqcup G_{(-,+)}$ such that $G_{(\xi_1, \xi_2)}$ is the set of matrices of the (ξ_1, ξ_2)-type, where $\xi_1, \xi_2 \in \{+, -\}$.

Recall that we assume $M = M_{i_1} \cdots M_{i_k}$ and $\psi(M) = (0, 0, c)$ for some $c > 0$. The main idea of the proof is to generate a matrix M' such that $\psi(M') = (0, 0, c')$ for some $c' < 0$ by duplicating the matrices in the sequence $M = M_{i_1} \cdots M_{i_k}$ multiple times and

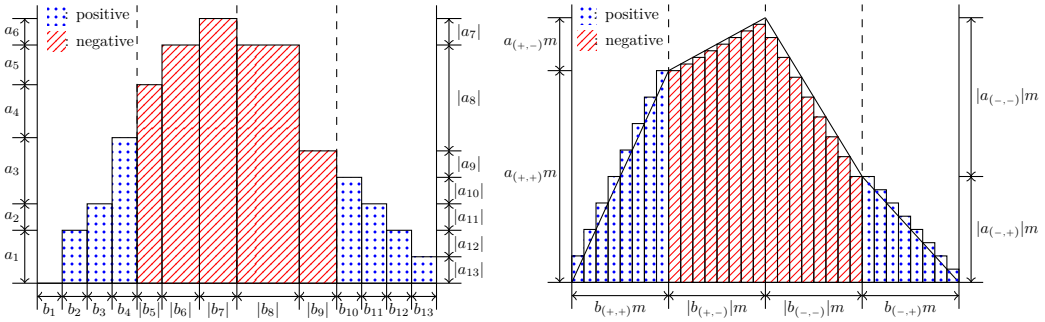

Figure 1 The histogram on the left describes how the upper-right corner of $M_1 \cdots M_{13}$ is computed by multiplications. The blue dotted (red lined) area implies the value which will be added to (subtracted from) the upper-right corner of the final matrix after multiplications of matrices in the sequence. The histogram on the right describes how the upper-right corner of $M^m_{(+,+)}M^m_{(+,-)}M^m_{(-,-)}M^m_{(-,+)}$ is computed by multiplications. Here $m = 8$.

reshuffling. Note that any permutation of the sequence generating the matrix M such that $\psi(M) = (0, 0, c)$ still generates matrices M' such that $\psi(M') = (0, 0, c')$ since the multiplication of matrices exchanges the first two coordinates in a commutative way. Also note that there exists a permutation such that $c \neq c'$ as we assumed that at least two matrices in the sequence do not commute. Moreover, we can still obtain matrices M'' such that $\psi(M'') = (0, 0, c'')$ for some $c'' \in \mathbb{Q}$ if we shuffle two different permutations of the sequence $M_{i_1} \cdots M_{i_k}$ by the same reason.

Let us illustrate the idea with the following example. See Figure 1 for pictorial descriptions of the idea. Let $\{M_i \mid 1 \leq i \leq 4\} \subseteq G_{(+,+)}$, $\{M_i \mid 5 \leq i \leq 7\} \subseteq G_{(+,-)}$, $\{M_i \mid 8 \leq i \leq 9\} \subseteq G_{(-,-)}$, and $\{M_i \mid 10 \leq i \leq 13\} \subseteq G_{(-,+)}$. Then assume that $M_1 \cdots M_{13} = \left(\begin{smallmatrix} 1 & 0 & x \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{smallmatrix}\right)$, where x is computed by (2). As we mentioned above, x changes if we change the order of multiplicands. In this example, we first multiply $(+,+)$-type matrices and accumulate the values in the superdiagonal coordinates since these matrices have positive values in the coordinates. Indeed, the blue dotted area implies the value we add to the upper-right corner by multiplying such matrices. Then we multiply $(+,-)$-type matrices and still increase the 'a'-value. The 'b'-values in $(+,-)$-type matrices are negative thus, the red lined area is subtracted from the upper-right corner. We still subtract by multiplying $(-,-)$-type matrices since the accumulated 'a'-value is still positive and 'b'-values are negative. We finish the multiplication by adding exactly the last blue dotted area to the upper-right corner. It is easy to see that the total subtracted value is larger than the total added value.

However, we cannot guarantee that x is negative since $\sum_{i=1}^{13} c_i$ could be larger than the contribution from the superdiagonal coordinates. This is why we need to copy the sequence of matrices generating the matrix corresponding to the triple $(0, 0, c)$ for some $c \in \mathbb{Q}$. In Figure 1, we describe an example where we duplicate the sequence eight times and shuffle and permute it in order to minimize the value in the upper-right corner. Now the lengths of both axes are m ($m = 8$ in this example) times larger than before and it follows that the area also grows quadratically in m. Since the summation $m \cdot \sum_{i=1}^{13} c_i$ grows linearly in m, we have $x < 0$ for large enough m. In [27], we formally prove this by bounding contributions of each matrix type and showing that the coefficient of the highest power of m is negative.

It should be noted that there are some subcases where some matrix types are not present in the product. In each case we need to show that the same idea can be used to construct a matrix M' such that $\psi(M') = (0, 0, c')$, where $c' < 0$. The full analysis of all cases can be found in [27].

▶ **Theorem 9.** *The identity problem for a semigroup generated by matrices from* $\mathrm{H}(3,\mathbb{Q})$ *is in polynomial time.*

Proof. Let S be the matrix semigroup in $\mathrm{H}(3,\mathbb{Q})$ generated by the set $G = \{M_1, \ldots, M_r\}$. There are two possible cases of having the identity matrix in the matrix semigroup in $\mathrm{H}(3,\mathbb{Q})$. Either the identity matrix is generated by a product of matrices where all superdiagonal vectors are parallel or there are at least two matrices with non-parallel superdiagonal vectors.

Consider the first case. Lemma 7 provides a formula to compute the value in the top corner regardless of the order of the multiplications. That is, we need to solve a system of linear homogeneous Diophantine equations with solutions over non-negative integers. We partition the set G into several disjoint subsets $G_1, \ldots, G_s$, where s is at most r, and each subset contains matrices with parallel superdiagonal vectors. Since superdiagonal vectors being parallel is a transitive and symmetric property, each matrix needs to be compared to a representative of each subset. If there are no matrices with parallel superdiagonal vectors, then there are r subsets G_i containing exactly one matrix and $O(r^2)$ tests were done. Let us consider $G_i = \{M_{k_1}, \ldots, M_{k_{s_i}}\}$, i.e., one of the subsets containing s_i matrices and $\psi(M_{k_j}) = (a_{k_j}, b_{k_j}, c_{k_j})$. By Lemma 7, the value $c_{k_j} - \frac{q_i}{2}a_{k_j}^2$, for a fixed $q_i \in \mathbb{Q}$, is added to the top corner when matrix M_{k_j} is multiplied.

We solve the system of two linear homogeneous Diophantine equations $A\mathbf{y} = \mathbf{0}$, where

$$A = \begin{pmatrix} a_{k_1} & a_{k_2} & \cdots & a_{k_{s_i}} \\ c_{k_1} - \frac{q_i}{2}a_{k_1}^2 & c_{k_2} - \frac{q_i}{2}a_{k_2}^2 & \cdots & c_{k_{s_i}} - \frac{q_i}{2}a_{k_{s_i}}^2 \end{pmatrix}$$

and $\mathbf{y}^\mathsf{T} \in \mathbb{N}^{s_i}$. The first row is the constraint that guarantees that the first component of the superdiagonal is zero in the matrix product constructed from a solution. Since the superdiagonal vectors are parallel, it also implies that the whole vector is zero. The second row guarantees that the upper corner is zero.

It is obvious that the identity matrix is in the semigroup if we have a solution in the system of two linear homogeneous Diophantine equations for any subset G_i. That is, we need to solve at most r systems of two linear homogeneous Diophantine equations.

Next, we consider the second case, where by Lemma 8, it is enough to check whether there exists a sequence of matrices generating a matrix with zero superdiagonal vector and containing two matrices with non-parallel superdiagonal vectors. Let us say that $M_{i_1}, M_{i_2} \in G$, where $1 \leq i_1, i_2 \leq r$ are the two matrices. Recall that $G = \{M_1, \ldots, M_r\}$ is a generating set of the matrix semigroup and let $\psi(M_i) = (a_i, b_i, c_i)$ for all $1 \leq i \leq r$. We can see that there exists such a product containing the two matrices by solving a system of two linear homogeneous Diophantine equations of the form $B\mathbf{y} = \mathbf{0}$, where $B = \left(\begin{smallmatrix} a_1 & a_2 & \cdots & a_r \\ b_1 & b_2 & \cdots & b_r \end{smallmatrix}\right)$, with an additional constraint that the numbers in the solution $\mathbf{y}$ that correspond to M_{i_1} and M_{i_2} are non-zero since we must use these two matrices in the product. We repeat this process at most $r(r-1)$ times until we find a solution. Therefore, the problem reduces again to solving at most $O(r^2)$ systems of two linear homogeneous Diophantine equations.

Finally, we conclude the proof by mentioning that the identity problem for matrix semigroups in the Heisenberg group over rationals $\mathrm{H}(3,\mathbb{Q})$ can be decided in polynomial time as the problem of existence of a positive integer solution to a system of linear homogeneous Diophantine equations is in polynomial time. Note that if the system is non-homogeneous, then solvability of a system of linear Diophantine equations with solutions over positive integers is an NP-complete problem; see for example [38]. Indeed, a system of linear homogeneous Diophantine equations with solutions over non-negative integers can be converted to a linear programming problem with a solution over rationals which is known to be solvable in polynomial time; see e.g., [43]. It is easy to add additional constraints to the linear programming

that ensure that solutions are positive and non-zero. As the system is homogeneous, any solution can be converted to an integer solution by multiplying by the denominators. ◀

Next, we generalize the above algorithm for the identity problem in the Heisenberg group $\mathrm{H}(3,\mathbb{Q})$ to the domain of the Heisenberg groups for any dimension over the rational numbers. Similarly to the case of dimension three, we establish the following result for the case of matrices where multiplication is commutative.

▶ **Lemma 10.** *Let $G = \{M_1, \ldots, M_r\} \subseteq \mathrm{H}(n,\mathbb{Q})$ be a set of matrices from the Heisenberg group such that $\psi(M_i) = (\mathbf{a}_i, \mathbf{b}_i, c_i)$ and $\psi(M_j) = (\mathbf{a}_j, \mathbf{b}_j, c_j)$ and $\mathbf{a}_i \cdot \mathbf{b}_j = \mathbf{a}_j \cdot \mathbf{b}_i$ for any $1 \leq i \neq j \leq r$. If there exists a sequence of matrices $M = M_{i_1} \cdots M_{i_k}$, where $i_j \in [1,r]$ for all $1 \leq j \leq k$, such that $\psi(M) = (\mathbf{0}, \mathbf{0}, c)$ for some $c \in \mathbb{Q}$, then $c = \sum_{j=1}^{k}(c_{i_j} - \frac{1}{2}\mathbf{a}_{i_j} \cdot \mathbf{b}_{i_j})$.*

Lemma 8 does not generalize to $\mathrm{H}(n,\mathbb{Q})$ in the same way as we cannot classify matrices according to types to control the value in upper-right corner, so we use a different technique to prove that the value in the upper corner will be diverging to both positive and negative infinity quadratically as we repeat the same sequence generating any matrix M such that $\psi(M) = (\mathbf{0}, \mathbf{0}, c)$.

▶ **Lemma 11.** *Let $S = \langle M_1, \ldots, M_r\rangle \subseteq \mathrm{H}(n,\mathbb{Q})$ be a finitely generated matrix semigroup. Then the identity matrix exists in S if there exists a sequence of matrices $M_{i_1} \cdots M_{i_k}$, where $i_j \in [1,r]$ for all $1 \leq j \leq k$, satisfying the following properties:*

(i) *$\psi(M_{i_1} \cdots M_{i_k}) = (\mathbf{0}, \mathbf{0}, c)$ for some $c \in \mathbb{Q}$, and*

(ii) *$\mathbf{a}_{i_{j_1}} \cdot \mathbf{b}_{i_{j_2}} \neq \mathbf{a}_{i_{j_2}} \cdot \mathbf{b}_{i_{j_1}}$ for some $j_1, j_2 \in [1,k]$, where $\psi(M_i) = (\mathbf{a}_i, \mathbf{b}_i, c_i)$ for $1 \leq i \leq r$.*

Proof. From the first property claimed in the lemma, we know that any permutation of the sequence of matrix multiplications of $M_{i_1} \cdots M_{i_k}$ results in matrices M' such that $\psi(M') = (\mathbf{0}, \mathbf{0}, y)$ for some $y \in \mathbb{Q}$ since the multiplication of matrices in the $\mathrm{H}(n,\mathbb{Q})$ performs additions of vectors which is commutative in the top row and the rightmost column excluding the upper-right corner. From the commutative behaviour in the horizontal and vertical vectors of matrices in the Heisenberg group, we also know that if we duplicate the matrices in the sequence $M_{i_1} \cdots M_{i_k}$ and multiply the matrices in any order, then the resulting matrix has a non-zero coordinate in the upper triangular coordinates only in the upper right corner.

Now let $j_1, j_2 \in [1,k]$ be two indices such that $\mathbf{a}_{i_{j_1}} \cdot \mathbf{b}_{i_{j_2}} \neq \mathbf{a}_{i_{j_2}} \cdot \mathbf{b}_{i_{j_1}}$ as claimed in the lemma. Then consider the following matrix M_d that can be obtained by duplicating the sequence $M_{i_1} \cdots M_{i_k}$ of matrices into ℓ copies and shuffling the order as follows: $M_d = M_{i_{j_1}}^{\ell} M_{i_{j_2}}^{\ell} M_x^{\ell}$, where M_x is a matrix that is obtained by multiplying the matrices in $M_{i_1} \cdots M_{i_k}$ except the two matrices M_{j_1} and M_{j_2}. Then it is clear that $\psi(M_d) = (\mathbf{0}, \mathbf{0}, d)$ for some d. Let $\psi(M_x) = (\mathbf{a}_x, \mathbf{b}_x, c_x)$. Then it is easy to see that $\mathbf{a}_{i_{j_1}} + \mathbf{a}_{i_{j_2}} + \mathbf{a}_x = \mathbf{0}$ and $\mathbf{b}_{i_{j_1}} + \mathbf{b}_{i_{j_2}} + \mathbf{b}_x = \mathbf{0}$. Consider then a product, where order of M_{j_1} and M_{j_2} is swapped. That is, $M_e = M_{i_{j_2}}^{\ell} M_{i_{j_1}}^{\ell} M_x^{\ell}$ and let us denote $\psi(M_e) = (\mathbf{0}, \mathbf{0}, e)$ for some $e \in \mathbb{Q}$. By solving values d and e, we notice that the coefficient of ℓ^2 in d is $\mathbf{a}_{i_{j_1}} \cdot \mathbf{b}_{i_{j_2}} - \mathbf{a}_{i_{j_2}} \cdot \mathbf{b}_{i_{j_1}}$ and in e is $\mathbf{a}_{i_{j_2}} \cdot \mathbf{b}_{i_{j_1}} - \mathbf{a}_{i_{j_1}} \cdot \mathbf{b}_{i_{j_2}}$. As we assumed that $\mathbf{a}_{i_{j_1}} \cdot \mathbf{b}_{i_{j_2}} \neq \mathbf{a}_{i_{j_2}} \cdot \mathbf{b}_{i_{j_1}}$, the coefficients are of different sign. Hence, for sufficiently large ℓ, the values d and e have opposite signs. Then, as in the proof Lemma 8, the identity matrix always exists in the semigroup as we can multiply these two matrices correct number of times to have zero in the upper right coordinate as well. ◀

Next, we prove that the identity problem is decidable for n-dimensional Heisenberg matrices. In contrast to Theorem 9, we do not claim that the problem is decidable in polynomial time since one of the steps of the proof is to partition matrices according to dot products which cannot be extended to higher dimensions than three. For higher dimensions,

partitioning matrices according to dot products takes an exponential time in the number of matrices in the generating set. Note that if the size of the generating set is fixed, i.e., only the matrices are part of the input, then the problem remains in P.

▶ **Theorem 12.** *The identity problem for a semigroup generated by matrices from* $\mathrm{H}(n,\mathbb{Q})$ *is decidable.*

Proof. Similarly to the proof of Theorem 9, there are two ways the identity matrix can be generated. Either all the matrices commute or there are at least two matrices that do not commute. Let S be the matrix semigroup in $\mathrm{H}(n,\mathbb{Q})$ generated by the set $G = \{M_1,\ldots,M_r\}$. Consider matrices N_1, N_2 and N_3, such that $\psi(N_1) = (\mathbf{a}_1,\mathbf{b}_1,c_1)$, $\psi(N_2) = (\mathbf{a}_2,\mathbf{b}_2,c_2)$ and $\psi(N_3) = (\mathbf{a}_3,\mathbf{b}_3,c_3)$. If $\mathbf{a}_1\cdot\mathbf{b}_2 = \mathbf{a}_2\cdot\mathbf{b}_1$ and $\mathbf{a}_2\cdot\mathbf{b}_3 = \mathbf{a}_3\cdot\mathbf{b}_2$, it does not imply that $\mathbf{a}_1\cdot\mathbf{b}_3 = \mathbf{a}_3\cdot\mathbf{b}_1$. Therefore, the number of subsets of G, where each subset contains matrices that commute with other matrices in the same subset, is exponential in r as two subsets are not necessarily disjoint. Now we examine whether it is possible to generate the identity matrix by multiplying matrices in each subset by Lemma 10. If it is not possible, we need to consider the case of having two matrices that do not commute with each other in the product with zero values in the upper-triangular coordinates except the corner. Let us say that $M_{i_1}, M_{i_2} \in G$, where $1 \le i_1, i_2 \le r$ are the two matrices. Recall that $G = \{M_1,\ldots,M_r\}$ is a generating set of the matrix semigroup and let $\psi(M_i) = (\mathbf{a}_i,\mathbf{b}_i,c_i)$ for all $1 \le i \le r$.

Then we can see that there exists such a product by solving a system of $2(n-2)$ linear homogeneous Diophantine equations of the form $B\mathbf{y} = \mathbf{0}$, where $B = \begin{pmatrix} \mathbf{a}_1^{\mathsf{T}}\cdots\mathbf{a}_r^{\mathsf{T}} \\ \mathbf{b}_1^{\mathsf{T}}\cdots\mathbf{b}_r^{\mathsf{T}} \end{pmatrix}$, with an additional constraint that the values in the solution $\mathbf{y}$ that correspond to M_{i_1} and M_{i_2} are non-zero since we must use these two matrices in the product. We repeat this process at most $r(r-1)$ times until we find a solution. Hence, we can view the identity problem in $\mathrm{H}(n,\mathbb{Q})$ as the problem of solving systems of $2(n-2)$ linear homogeneous Diophantine equations with some constraints on the solution. As we can solve systems of linear homogeneous Diophantine equations, we conclude that the identity problem in $\mathrm{H}(n,\mathbb{Q})$ is also decidable. ◀

5 The identity problem in matrix semigroups in dimension four

Now we tighten the decidability gap proving undecidability for 4×4 matrices, when the generating set has eight matrices (reducing from 48), with a new technique exploiting the anti-diagonal entries.

▶ **Theorem 13.** *Given a semigroup S generated by eight 4×4 integer matrices with determinant one, determining whether the identity matrix belongs to S is undecidable.*

Proof. We prove the claim by reducing from the PCP. We shall use an encoding to embed an instance of the PCP into a set of 4×4 integer matrices. An *instance* of the PCP consists of two morphisms $g,h:\Sigma^*\to B^*$, where Σ and B are alphabets. A nonempty word $u\in\Sigma^*$ is a *solution* of an instance (g,h) if it satisfies $g(u) = h(u)$.

Let α be the mapping of Lemma 2. We also define a monomorphism $f:\mathrm{FG}(\Gamma_2)\to\mathbb{Z}^{2\times 2}$ as $f(a) = \left(\begin{smallmatrix}1&2\\0&1\end{smallmatrix}\right)$, $f(\bar{a}) = \left(\begin{smallmatrix}1&-2\\0&1\end{smallmatrix}\right)$, $f(b) = \left(\begin{smallmatrix}1&0\\2&1\end{smallmatrix}\right)$ and $f(\bar{b}) = \left(\begin{smallmatrix}1&0\\-2&1\end{smallmatrix}\right)$. Recall that the matrices $\left(\begin{smallmatrix}1&2\\0&1\end{smallmatrix}\right)$ and $\left(\begin{smallmatrix}1&0\\2&1\end{smallmatrix}\right)$ generate a free subgroup of $\mathrm{SL}(2,\mathbb{Z})$ [31]. The composition of two monomorphisms α and f gives us the embedding from an arbitrary group alphabet into $\mathrm{SL}(2,\mathbb{Z})$. We use the composition of two monomorphisms α and f to encode a set of pairs of words over an arbitrary group alphabet into a set of 4×4 integer matrices in $\mathrm{SL}(4,\mathbb{Z})$ and denote it by β.

Let (g,h) be an instance of the PCP, where $g,h:\{a_1,\ldots,a_n\}^*\to\Sigma_2^*$, where $\Sigma_2 = \{a,b\}$. Without loss of generality, we can assume that the solution starts with the letter

a_1. Moreover, we assume that this is the only occurence of a_1. We define the alphabet $\Gamma = \Sigma_2 \cup \Sigma_2^{-1} \cup \Sigma_B \cup \Sigma_B^{-1}$, where $\Sigma_B = \{q_0, q_1, p_0, p_1\}$ is the alphabet for the border letters that enforce the form of a solution.

Let us define the following sets of words $W_1 \cup W_2 \subseteq \mathrm{FG}(\Gamma) \times \mathrm{FG}(\Gamma)$, where

$$W_1 = \{(q_0 a \overline{q_0}, p_0 a \overline{p_0}),\ (q_0 b \overline{q_0}, p_0 b \overline{p_0}) \mid a, b \in \Sigma_2,\ \ q_0, p_0 \in \Sigma_B\} \text{ and}$$

$$W_2 = \left\{(q_0 \overline{g(a_1)} \overline{q_1}, p_0 \overline{h(a_1)} \overline{p_1}),\ (q_1 \overline{g(a_i)} \overline{q_1}, p_1 \overline{h(a_i)} \overline{p_1}) \mid 1 < i \leq n,\ \ q_0, q_1, p_0, p_1 \in \Sigma_B\right\}.$$

Intuitively, the words from set W_1 are used to construct words over Σ_2 and the words from set W_2 to cancel them according to the instance of the PCP.

Let us prove that $(q_0\overline{q_1}, p_0\overline{p_1}) \in \mathrm{FG}(W_1 \cup W_2)$ if and only if the PCP has a solution. It is easy to see that any pair of non-empty words in $\mathrm{FG}(W_1)$ is of the form $(q_0 w \overline{q_0}, p_0 w \overline{p_0})$ for $w \in \Sigma_2^+$. Then there exists a pair of words in $\mathrm{FG}(W_2)$ of the form $(q_0 \overline{w} \overline{q_1}, p_0 \overline{w} \overline{p_1})$ for some word $w \in \Sigma_2^+$ if and only if the PCP has a solution. Thus, $(q_0\overline{q_1}, p_0\overline{p_1})$ can be constructed by concatenating pairs of words in W_1 and W_2 if and only if the PCP has a solution.

For each pair of words $(u, v) \in \mathrm{FG}(W_1 \cup W_2)$, we define a matrix $A_{u,v}$ to be $\begin{pmatrix} \beta(u) & \mathbf{0}_2 \\ \mathbf{0}_2 & \beta(v) \end{pmatrix} \in \mathrm{SL}(4, \mathbb{Z})$, where $\mathbf{0}_2$ is the zero matrix in $\mathbb{Z}^{2\times 2}$. Moreover, we define the following matrix

$$B_{q_1\overline{q_0}, p_1\overline{p_0}} = \begin{pmatrix} \mathbf{0}_2 & \beta(q_1\overline{q_0}) \\ \beta(p_1\overline{p_0}) & \mathbf{0}_2 \end{pmatrix} \in \mathrm{SL}(4, \mathbb{Z}).$$

Let S be a matrix semigroup generated by the set $\{A_{u,v}, B_{q_1\overline{q_0}, p_1\overline{p_0}} \mid (u, v) \in W_1 \cup W_2\}$. We already know that the pair $(q_0\overline{q_1}, p_0\overline{p_1})$ of words can be generated by concatenating words in W_1 and W_2 if and only if the PCP has a solution. The matrix semigroup S has the corresponding matrix $A_{q_0\overline{q_1}, p_0\overline{p_1}}$ and thus, $\begin{pmatrix} \beta(q_0\overline{q_1}) & \mathbf{0}_2 \\ \mathbf{0}_2 & \beta(p_0\overline{p_1}) \end{pmatrix}\begin{pmatrix} \mathbf{0}_2 & \beta(q_1\overline{q_0}) \\ \beta(p_1\overline{p_0}) & \mathbf{0}_2 \end{pmatrix} = \begin{pmatrix} \mathbf{0}_2 & \beta(\varepsilon) \\ \beta(\varepsilon) & \mathbf{0}_2 \end{pmatrix} \in S$. Now, the identity matrix $\boldsymbol{I}_4$ exists in the semigroup S by repeating this product twice.

Now we prove that the identity matrix does not exist in S if the PCP has no solution. It is easy to see that we cannot obtain the identity matrix only by multiplying 'A' matrices since there is no possibility of cancelling every border letter. We need to multiply the matrix $B_{q_1\overline{q_0}, p_1\overline{p_0}}$ with a product of 'A' matrices at some point to reach the identity matrix. Note that the matrix $B_{q_1\overline{q_0}, p_1\overline{p_0}}$ cannot be the first matrix of the product, followed by the 'A' matrices, because the upper right block of $B_{q_1\overline{q_0}, p_1\overline{p_0}}$, which corresponds to the first word of the pair, should be multiplied with the lower right block of 'A' matrix, which corresponds to the second word of the pair.

Suppose that the 'A' matrix is of form $\begin{pmatrix} \beta(q_0 u \overline{q_1}) & \mathbf{0}_2 \\ \mathbf{0}_2 & \beta(p_0 v \overline{p_1}) \end{pmatrix}$. Since the PCP instance has no solution, either u or v is not the empty word. We multiply $B_{q_1\overline{q_0}, p_1\overline{p_0}}$ to the matrix and then obtain the following matrix $\begin{pmatrix} \beta(q_0 u \overline{q_1}) & \mathbf{0}_2 \\ \mathbf{0}_2 & \beta(p_0 v \overline{p_1}) \end{pmatrix}\begin{pmatrix} \mathbf{0}_2 & \beta(q_1\overline{q_0}) \\ \beta(p_1\overline{p_0}) & \mathbf{0}_2 \end{pmatrix} = \begin{pmatrix} \mathbf{0}_2 & \beta(q_0 u \overline{q_0}) \\ \beta(p_0 v \overline{p_0}) & \mathbf{0}_2 \end{pmatrix}$. We can see that either the upper right part or the lower left part cannot be $\beta(\varepsilon)$, which actually corresponds to the identity matrix in $\mathbb{Z}^{2\times 2}$. Now the only possibility of reaching the identity matrix is to multiply matrices which have $\mathrm{SL}(2, \mathbb{Z})$ matrices in the anti-diagonal coordinates like $B_{q_1\overline{q_0}, p_1\overline{p_0}}$. However, we cannot cancel the parts because the upper right block (the lower left block) of the left matrix is multiplied with the lower left block (the upper right block) of the right matrix as follows $\left(\begin{smallmatrix} \mathbf{0}_2 & A \\ B & \mathbf{0}_2 \end{smallmatrix}\right)\left(\begin{smallmatrix} \mathbf{0}_2 & C \\ D & \mathbf{0}_2 \end{smallmatrix}\right) = \left(\begin{smallmatrix} AD & \mathbf{0}_2 \\ \mathbf{0}_2 & BC \end{smallmatrix}\right)$, where A, B, C and D are matrices in $\mathbb{Z}^{2\times 2}$. As the first word of the pair is encoded in the upper right block of the matrix and the second word is encoded in the lower left block, it is not difficult to see that we cannot cancel the remaining blocks.

Currently, the undecidability bound for the PCP is five [34] and thus the semigroup S is generated by eight matrices. Recall that in the beginning of the proof, we assumed that letter a_1 of the PCP is used exacly once and is the first letter of a solution. This property is in fact present in [34]. ◀

Theorem 13 implies smaller undecidability bounds for the *special diagonal membership problem* from 14 [24] to eight and for the identity problem in $\mathbb{H}(\mathbb{Q})^{2\times 2}$ from 48 to eight [6].

Abstract

We consider the extension of first-order logic FO by unary counting quantifiers and generalise the notion of Gaifman normal form from FO to this setting. For formulas that use only ultimately periodic counting quantifiers, we provide an algorithm that computes equivalent formulas in Gaifman normal form. We also show that this is not possible for formulas using at least one quantifier that is not ultimately periodic.

Now let d be a degree bound. We show that for any formula φ with arbitrary counting quantifiers, there is a formula γ in Gaifman normal form that is equivalent to φ on all finite structures of degree $\leqslant d$. If the quantifiers of φ are decidable (decidable in elementary time, ultimately periodic), γ can be constructed effectively (in elementary time, in worst-case optimal 3-fold exponential time).

For the setting with unrestricted degree we show that by using our Gaifman normal form for formulas with only ultimately periodic counting quantifiers, a known fixed-parameter tractability result for FO on classes of structures of bounded local tree-width can be lifted to the extension of FO with ultimately periodic counting quantifiers (a logic equally expressive as FO+MOD, i.e., first-oder logic with modulo-counting quantifiers).

1 Introduction

As database specialists know very well, when evaluating a query (i.e., a formula) in a database (i.e., a relational structure), it is often advantageous to first transform the formula into an equivalent one and then evaluate this new formula in the given structure. Using this approach, one also gets algorithmic meta-theorems stating that the evaluation of formulas from a certain logic in structures from a certain class is fixed-parameter tractable. For example, this is known for formulas from monadic second-order logic MSO and its extension CMSO with modulo-counting predicates and the class of labeled trees [5, 27] or classes of bounded tree-width [3, 1]. For first-order logic FO, it is known for classes of structures of bounded degree [25], for the class of planar graphs and, more generally, for classes of bounded local tree-width [9], for classes of locally bounded expansion [6], and for classes that are effectively nowhere dense [12].

Gaifman's normal form theorem [10] provides an approach to this formula transformation, and it has been applied for obtaining several of the results on FO mentioned above. It is the aim of this paper to demonstrate that this approach does not only work for first-order logic, but also for its extension FO+MOD by modulo-counting quantifiers (these quantifiers allow to make statements of the form "the number of witnesses x for a formula φ is congruent r modulo m", for fixed integers r and m). The logic FO+MOD has been well-studied, see e.g., [26, 18, 24, 23, 14, 17]. Its expressivity lies strictly between that of FO and CMSO. It is known that all FO+MOD-queries are Gaifman-local [18]. But an extension of Gaifman's normal form theorem [10] from FO to FO+MOD has not been achieved in the literature.

Recall that a first-order formula is in Gaifman normal form if it is a Boolean combination of (1) first-order properties of the neighbourhood of the free variables and (2) statements that express the existence of mutually far-apart elements whose neighbourhoods share a first-order property. Gaifman's normal form theorem states that every first-order formula is effectively equivalent to such a formula in Gaifman normal form.

We propose a notion of Gaifman normal form for FO+MOD and, more generally, for the extension of first-order logic by unary counting quantifiers FO($\mathbf{Q}$): it is a Boolean combination of (1) FO($\mathbf{Q}$)-properties of the neighbourhood of the free variables, (2) statements that express the existence of mutually far-apart elements whose neighbourhoods share an FO($\mathbf{Q}$)-property, and (3) statements that depend on the total number of elements whose neighbourhoods share an FO($\mathbf{Q}$)-property. We show that if a formula uses only ultimately periodic counting quantifiers (and therefore is equivalent to a formula of FO+MOD), then Gaifman's theorem holds *mutatis mutandis*: any such formula can be transformed effectively into an equivalent formula in Gaifman normal form using the same counting quantifiers. The proof of this result extends the original proof for first-order logic from [10]; a crucial ingredient is an effective Feferman-Vaught decomposition [8] for FO($\mathbf{Q}$) that we prove first. Adapting [4], we show that the size of the resulting formula cannot be bounded by an elementary function. Furthermore, we prove that formulas with non-ultimately periodic counting quantifiers (e.g., the set of primes) do not have equivalent formulas in Gaifman normal form.

The situation changes when we restrict attention to classes of finite structures of bounded degree. Call two formulas "finitely d-equivalent" if they are equivalent on all finite structures of degree $\leqslant d$. We show that (1) for a formula with ultimately periodic counting quantifiers, one can compute in (worst-case optimal) 3-fold exponential time a finitely d-equivalent formula in Gaifman normal form; (2) from a formula with computable counting quantifiers, we can effectively compute a finitely d-equivalent formula in Gaifman normal form; and (3) if we allow arbitary counting quantifiers, then we get at least the existence of finitely d-equivalent Gaifman normal forms. In other words, by restricting the class of structures, the complexity drops from non-elementary to 3-fold exponential (for ultimately periodic counting quantifiers), from non-existent to computable (for computable quantifiers), and from non-existent to existent (for arbitrary quantifiers). The proofs of these results do not follow Gaifman's original proof, but generalise a proof for first-order logic from [16] that, in turn, builds on [2]. In the present setting of FO($\mathbf{Q}$), we first transform the original FO($\mathbf{Q}$)-formula in elementary time into a formula in "(weak) Hanf normal form" [17, 19], and afterwards we transform this formula into Gaifman normal form by a construction similar to the one in [16].

We also provide an algorithmic application that demonstrates the usefulness of our normal form: By applying our Gaifman normal form algorithm, we lift the result of [9] from FO to FO+MOD, showing that the model-checking problem for FO+MOD-sentences on classes of finite relational structures of bounded local tree-width is fixed-parameter tractable.

The rest of the paper is structured as follows. Section 2 provides the basic definitions and introduces our notion of Gaifman normal form. Section 3 provides effective Feferman-Vaught decompositions for the extension of first-order logic by ultimately periodic counting quantifiers. The sections 4 and 5 present our results in the setting without and with a degree bound, respectively. Section 6 provides an algorithmic application.

2 Preliminaries

We write $\mathcal{P}(S)$ to denote the power set of a set S. For an n-tuple $\overline{x} = (x_1, \ldots, x_n)$ we write $|\overline{x}|$ to denote the tuple's length n. We write $\mathbb{N}$ for the set of non-negative integers, and we let $\mathbb{N}_{\geqslant 1} = \mathbb{N} \setminus \{0\}$. For $m, n \in \mathbb{N}$ with $m \leqslant n$, we write $[m, n]$ for the set $\{i \in \mathbb{N} : m \leqslant i \leqslant n\}$. For a real number $r > 0$, we write $\log(r)$ to denote the logarithm of r with respect to base 2. We use the standard $\mathcal{O}$-notation, and by $\mathrm{poly}(n)$ we mean $n^{\mathcal{O}(1)}$. We say that a function f from $\mathbb{N}$ to the set $\mathbb{R}_{\geqslant 0}$ of non-negative reals is *at most k-fold exponential*, for some $k \in \mathbb{N}$, if there exists a number $c > 0$ such that for all sufficiently large $n \in \mathbb{N}$ we have $f(n) \leqslant \exp_k(n^c)$, where $\exp_k(m)$ is a tower of 2s of height k with an m on top, i.e., $\exp_0(m) = m$ and $\exp_{k+1}(m) = 2^{\exp_k(m)}$ for all $k, m \geqslant 0$. A function f is *elementary* if it is at most k-fold exponential for some $k \geqslant 0$. The function $\mathrm{tower}\colon \mathbb{N} \to \mathbb{N}$, defined via $\mathrm{tower}(h) := \exp_h(1)$ for all $h \in \mathbb{N}$, is not elementary.

Structures and formulas. A *signature* σ is a *finite* set of relation symbols and constant symbols. Associated with every relation symbol R is a positive integer $\mathrm{ar}(R)$ called the *arity* of R. We call a signature *relational* if it only contains relation symbols. A *σ-structure* $\mathcal{A}$ consists of a non-empty set A called the *universe* of $\mathcal{A}$, a relation $R^{\mathcal{A}} \subseteq A^{\mathrm{ar}(R)}$ for each relation symbol $R \in \sigma$, and an element $c^{\mathcal{A}} \in A$ for each constant symbol $c \in \sigma$. Note that according to this definition, all signatures considered in this paper are finite while structures can be infinite. We write $\mathcal{A} \cong \mathcal{B}$ to indicate that two σ-structures $\mathcal{A}$ and $\mathcal{B}$ are isomorphic.

We use the standard notation concerning first-order logic and extensions thereof, cf. [7, 20]. By $\mathrm{FO}[\sigma]$ we denote the class of all first-order formulas of signature σ, and by FO we denote the union of all $\mathrm{FO}[\sigma]$ for arbitrary signatures σ. By $\mathrm{free}(\varphi)$ we denote the set of all *free variables* of the formula φ. A *sentence* is a formula φ with $\mathrm{free}(\varphi) = \emptyset$. We write $\varphi(\overline{x})$, for $\overline{x} = (x_1, \ldots, x_n)$ with $n \geqslant 0$, to indicate that $\mathrm{free}(\varphi) \subseteq \{x_1, \ldots, x_n\}$. If $\mathcal{A}$ is a σ-structure and $\overline{a} = (a_1, \ldots, a_n) \in A^n$, by $\mathcal{A} \models \varphi(\overline{a})$ or $(\mathcal{A}, \overline{a}) \models \varphi$ we indicate that the formula $\varphi(\overline{x})$ is satisfied in $\mathcal{A}$ when interpreting the free occurrences of the variables $x_1, \ldots, x_n$ with the elements $a_1, \ldots, a_n$.

Unary counting quantifiers. In addition to the existential quantifier $\exists$ we consider *unary counting quantifiers* (for short: counting quantifiers), which are defined as subsets of $\mathbb{N}$. We will use the terms "set (of natural numbers)" and "counting quantifier" interchangeably. For a set $\mathbf{Q} \subseteq \mathcal{P}(\mathbb{N})$ of counting quantifiers we write $\mathrm{FO}(\mathbf{Q})[\sigma]$ to denote the *extension of* $\mathrm{FO}[\sigma]$ *with the quantifiers from* $\mathbf{Q}$. Precisely, we add the following formation rule for formulas:

If $\varphi(\overline{x}, y) \in \mathrm{FO}(\mathbf{Q})[\sigma]$, $\mathsf{Q} \in \mathbf{Q}$, and $k \in \mathbb{N}$, then also $(\mathsf{Q}{+}k)y\,\varphi$ belongs to $\mathrm{FO}(\mathbf{Q})[\sigma]$.

For $(\mathsf{Q}{+}0)y\,\varphi$ we write the more succinct $\mathsf{Q}y\,\varphi$. The formula $(\mathsf{Q}{+}k)y\,\varphi(\overline{x}, y)$ expresses that the number of witnesses y for $\varphi(\overline{x}, y)$ belongs to the set $(\mathsf{Q}{+}k) := \{q + k : q \in \mathsf{Q}\}$. Equivalently, this means that the formula $(\mathsf{Q}{+}k)y\,\varphi(\overline{x}, y)$ is satisfied by a σ-structure $\mathcal{A}$ and an interpretation $\overline{a}$ of the variables $\overline{x}$ iff $|\{b \in A : \mathcal{A} \models \varphi(\overline{a}, b)\}| - k \in \mathsf{Q}$. Here, for an *infinite* set B we use the convention that $|B| = \infty \notin \mathbb{N}$, where ∞ is larger than any integer,

and $\infty - k = \infty$ for all integers k. Every formula can be transformed into an equivalent exponentially larger *displacement-free* formula, meaning that counting quantifiers appear only in the form $(\mathsf{Q} + 0)$.

▶ **Example 2.1.** For $m \geqslant 2$, the quantifier $\mathsf{D}_m = m \cdot \mathbb{N}$ contains the multiples of m. Let $\mathbf{D} = \{\mathsf{D}_m : m \in \mathbb{N}, m \geqslant 2\}$ denote the collection of all these *divisibility quantifiers*. Then the logic FO($\mathbf{D}$) is equally expressive as the logic FO+MOD (cf. [26, 24]).

The quantifier rank $\mathrm{qr}(\varphi)$ of an FO($\mathbf{Q}$)-formula φ is defined as the maximal nesting depth of *all* quantifiers. For a number $\ell \in \mathbb{N}_{\geqslant 1}$ and a formula $\varphi(\overline{x}, y)$, we write $\exists^{\geqslant \ell} y\, \varphi$ to denote a formula expressing that there are at least ℓ witnesses y which satisfy φ.

Gaifman graph. The *Gaifman graph* $G_{\mathcal{A}}$ of a σ-structure $\mathcal{A}$ is the undirected, loop-free graph with vertex set A and an edge between two distinct vertices $a, b \in A$ iff there exist a relation symbol $R \in \sigma$ and a tuple $(a_1, \ldots, a_{\mathrm{ar}(R)}) \in R^{\mathcal{A}}$ such that $a, b \in \{a_1, \ldots, a_{\mathrm{ar}(R)}\}$. The *degree* of a σ-structure $\mathcal{A}$ is the degree of its Gaifman graph $G_{\mathcal{A}}$. If this degree is at most d, then we call $\mathcal{A}$ *d-bounded*. Two formulas $\varphi(\overline{x})$ and $\psi(\overline{x})$ of signature σ are called *finitely d-equivalent* if $\mathcal{A} \models \forall \overline{x}\, (\varphi \leftrightarrow \psi)$ holds for every finite d-bounded σ-structure $\mathcal{A}$.

The *distance* $\mathrm{dist}^{\mathcal{A}}(a, b)$ between two elements $a, b \in A$ is the minimal length (i.e., the number of edges) of a path from a to b in $G_{\mathcal{A}}$, and if no such path exists, we set $\mathrm{dist}^{\mathcal{A}}(a, b) = \infty$. For a tuple $\overline{a} \in A^m$ and an element $b \in A$, we let $\mathrm{dist}^{\mathcal{A}}(\overline{a}, b) = \min\{\mathrm{dist}^{\mathcal{A}}(a_i, b) : 1 \leqslant i \leqslant m\}$.

For any signature σ and any $k, r \in \mathbb{N}$, there exists a formula $\mathrm{dist}_{<r}(\overline{x}, y) \in \mathrm{FO}[\sigma]$ with $\overline{x} = (x_1, \ldots, x_k)$ such that for any σ-structure $\mathcal{A}$, any $\overline{a} \in A^k$, and any $b \in A$ we have $(\mathcal{A}, \overline{a}, b) \models \mathrm{dist}_{<r}(\overline{x}, y)$ iff $\mathrm{dist}^{\mathcal{A}}(\overline{a}, b) < r$. We write $\mathrm{dist}(\overline{x}, y) < r$ for the formula $\mathrm{dist}_{<r}(\overline{x}, y)$, and $\mathrm{dist}(\overline{x}, y) > r$ for the formula $\neg\, \mathrm{dist}_{<r+1}(\overline{x}, y)$.

Gaifman normal forms. Let $\mathbf{Q}$ be a set of counting quantifiers and σ a signature. A formula $\lambda(\overline{x}) \in \mathrm{FO}(\mathbf{Q})[\sigma]$ is *local* if all quantifications in λ are restricted to the neighborhood of the variables $\overline{x}$. The precise inductive definition proceeds as follows:

- Atomic formulas are *r-local* for any $r \in \mathbb{N}$.
- If $\lambda(\overline{x}, y)$ is r-local, $\overline{z}$ is a non-empty sub-tuple of $\overline{x}$, and $r' \in \mathbb{N}$, then the formula $\exists y \big(\mathrm{dist}(\overline{z}, y) \leqslant r' \wedge \lambda(\overline{x}, y)\big)$ is $(r' + r)$-*local*, and for all $\mathsf{Q} \in \mathbf{Q}$ and $k \in \mathbb{N}$, the formula $(\mathsf{Q}{+}k) y \big(\mathrm{dist}(\overline{z}, y) \leqslant r' \wedge \lambda(\overline{x}, y)\big)$ is $(r' + r)$-*local* as well.
- If $\lambda_1(\overline{x})$ and $\lambda_2(\overline{x})$ are r-local, then $(\lambda_1 \wedge \lambda_2)$ and $\neg\lambda_1$ are *r-local* as well.

An r-local formula is also $(r + 1)$-local. A formula is *local* if it is r-local for some $r \in \mathbb{N}$.

For a σ-structure $\mathcal{A}$, a tuple $\overline{a} = (a_1, \ldots, a_n) \in A^n$ and a number $r \in \mathbb{N}$, the *r-ball* $N_r^{\mathcal{A}}(\overline{a})$ of $\overline{a}$ is the set of all $b \in A$ with $\mathrm{dist}^{\mathcal{A}}(\overline{a}, b) \leqslant r$. If σ is a *relational* signature, then the *r-neighbourhood* $\mathcal{N}_r^{\mathcal{A}}(\overline{a})$ of $\overline{a}$ is the substructure of $\mathcal{A}$ induced on the set $N_r^{\mathcal{A}}(\overline{a})$.

Let $\lambda(\overline{x})$ be an r-local formula and let $\overline{a} \in A^{|\overline{x}|}$. When determining whether $\mathcal{A} \models \lambda(\overline{a})$, quantification is restricted to elements of distance at most r from $\overline{a}$, i.e., to elements in $N_r^{\mathcal{A}}(\overline{a})$. Hence we get $\mathcal{A} \models \lambda(\overline{a}) \iff \mathcal{N}_r^{\mathcal{A}}(\overline{a}) \models \lambda(\overline{a})$.

Let $\mathrm{L} \subseteq \mathrm{FO}(\mathbf{Q})$. A *counting sentence* over L is a sentence of the form $(\mathsf{Q}{+}k) x\, \lambda(x)$, where $\lambda \in \mathrm{L}$ is local, $\mathsf{Q} \in \mathbf{Q}$, and $k \in \mathbb{N}$. A *basic local sentence* over L is a sentence of the form $\exists x_1 \cdots \exists x_m \Big(\bigwedge_{1 \leqslant i < j \leqslant m} \mathrm{dist}(x_i, x_j) > 2r \ \wedge \bigwedge_{1 \leqslant i \leqslant m} \lambda(x_i) \Big)$, where $m \in \mathbb{N}_{\geqslant 1}$, $r \in \mathbb{N}$, and $\lambda \in \mathrm{L}$ is r-local. Such a basic local sentence expresses that there are m witnesses for λ of mutual distance at least $2r + 1$.

▶ **Definition 2.2.** A formula $\varphi(\overline{x}) \in \mathrm{FO}(\mathbf{Q})[\sigma]$ is *in Gaifman normal form* if it is a Boolean combination of local formulas $\lambda(\overline{x})$, of counting sentences $(\mathsf{Q}{+}k) y\, \lambda(y)$, and of basic local sentences over $\mathrm{FO}(\mathbf{Q})[\sigma]$.

If $\mathbf{Q} = \emptyset$, then a formula in Gaifman normal form consists of local formulas and basic local sentences over FO. In other words, our definition of Gaifman normal form for formulas from FO($\emptyset$) coincides with the traditional one for formulas from FO [10, 11]. The following is known about the existence and computability of formulas in Gaifman normal form:

▶ **Theorem 2.3.** *Let* $\mathbf{Q} = \emptyset$*, i.e.,* $\mathrm{FO}(\mathbf{Q}) = \mathrm{FO}$.

(1) *From a formula* $\varphi(\overline{x}) \in \mathrm{FO}$*, one can compute an equivalent formula* $\gamma(\overline{x}) \in \mathrm{FO}$ *in Gaifman normal form [10].*

(2) *The size of the equivalent formula in Gaifman normal form cannot be bounded by an elementary function in the size of the formula* $\varphi(\overline{x})$ *[4].*

(3) *From a formula* $\varphi(\overline{x}) \in \mathrm{FO}$ *and a degree bound* d*, one can compute in 3-fold exponential time a finitely* d*-equivalent formula* $\gamma(\overline{x})$ *in Gaifman normal form [16].*

It is the aim of this paper to study to what extent this theorem holds for the extension of first-order logic with unary counting quantifiers. A special role is played by ultimately periodic quantifiers that we introduce now.

Ultimately periodic sets. Let $p \in \mathbb{N}_{\geqslant 1}$ and $n_0 \in \mathbb{N}$. A set $\mathsf{Q} \subseteq \mathbb{N}$ is *ultimately* p*-periodic with offset* n_0 if $n \in \mathsf{Q} \iff n+p \in \mathsf{Q}$ holds for all $n \geqslant n_0$. A set Q is *ultimately* p*-periodic* if there exists an n_0 such that Q is ultimately p-periodic with offset n_0, and Q is *ultimately periodic* (cf. e.g. [22]) if it is ultimately p-periodic for some $p \in \mathbb{N}_{\geqslant 1}$. The *period* of Q is the *minimal* p for which Q is ultimately p-periodic.

We write $\mathbf{U}$ to denote the set of all ultimately periodic sets $\mathsf{Q} \subseteq \mathbb{N}$.

The *characteristic sequence* χ_{Q} of a set $\mathsf{Q} \subseteq \mathbb{N}$ is the ω-word $w = w_0 w_1 w_2 \cdots \in \{0,1\}^\omega$ with $\mathsf{Q} = \{n \in \mathbb{N} : w_n = 1\}$. Note that Q is ultimately periodic iff there are finite words $\alpha, \pi \in \{0,1\}^*$ with $\chi_{\mathsf{Q}} = \alpha\pi^\omega$. We represent an ultimately periodic set Q by the shortest word $\mathrm{rep}(\mathsf{Q}) := \alpha\#\pi$ satisfying $\chi_{\mathsf{Q}} = \alpha\,\pi^\omega$. The *size* $\|\mathsf{Q}\|$ of Q is defined as the length of the word $\mathrm{rep}(\mathsf{Q})$. The size of an FO($\mathbf{U}$)-formula φ of signature σ is its length when viewed as a word over the alphabet $\sigma \cup \mathrm{Var} \cup \{,\} \cup \{=, \exists, \neg, \vee, (,), 0, 1, +, \#\}$, where Var is a countable set of variables, each quantifier $\mathsf{Q} \in \mathbf{U}$ is represented by the word $\mathrm{rep}(\mathsf{Q})$, and each number k is given in binary (in subformulas of the form $(\mathsf{Q}{+}k)y\,\varphi$). The set $\mathbf{D}$ of all divisibility quantifiers (see Example 2.1) is a subset of $\mathbf{U}$. With every set of ultimately periodic quantifiers $\mathbf{Q} \subseteq \mathbf{U}$, we associate the set $\mathbf{D}_{\mathbf{Q}} \subseteq \mathbf{D}$ of divisibility quantifiers which consists of precisely those $\mathsf{D}_p = p \cdot \mathbb{N}$ for which $p \geqslant 2$ is the period of some $\mathsf{Q} \in \mathbf{Q}$.

▶ **Lemma 2.4** ([16, 17])**.** *Let* $\mathbf{Q} \subseteq \mathcal{P}(\mathbb{N})$ *be a set of counting quantifiers.*

(a) *Let* $\mathsf{Q} \in \mathbf{Q}$ *be ultimately* p*-periodic with offset* n_0*, and let* $k \in \mathbb{N}$*. Every formula from* $\mathrm{FO}(\mathbf{Q} \cup \mathbf{D}_{\mathbf{Q}})$ *of the shape* $(\mathsf{Q}{+}k)y\,\varphi$ *is equivalent to a Boolean combination of formulas of the form* $(\mathsf{D}_p{+}\ell)y\,\varphi$ *and* $\exists^{\geqslant m} y\,\varphi$ *with* $\ell < p$ *and* $m < n_0{+}k{+}p$*. This Boolean combination can be computed from* $\mathrm{rep}(\mathsf{Q}), k, \varphi$ *in polynomial time.*

(b) *Let* $\mathsf{Q} \in \mathbf{Q}$ *be ultimately periodic with period* $p \geqslant 2$*.*
Every formula from $\mathrm{FO}(\mathbf{Q} \cup \mathbf{D}_{\mathbf{Q}})$ *of the shape* $(\mathsf{D}_p{+}k)y\,\varphi$*, for a* $k \geqslant 0$*, is equivalent to a Boolean combination of formulas of the shape* $(\mathsf{Q}{+}\ell)y\,\varphi$ *and* $\exists^{\geqslant \ell} y\,\varphi$ *with* $\ell < \|\mathsf{Q}\| + p + k$*. This Boolean combination can be computed from* $\mathrm{rep}(\mathsf{Q}), k, \varphi$ *in polynomial time.*

(c) *Let* $\mathrm{L} \subseteq \mathrm{FO}(\mathbf{Q})$ *be a set of formulas that contains all atomic formulas and is closed under Boolean combinations and existential quantification.*
Every sentence $\exists^{\geqslant \ell} y\,\lambda(y)$*, where* $\lambda \in \mathrm{L}$ *is a local formula, is equivalent to a Boolean combination of basic local sentences over* L*.*
This Boolean combination can be computed from λ *and* ℓ *in time* $\mathcal{O}(\|\lambda\|) \cdot 2^{\mathcal{O}(\ell \log \ell)}$*.*

As an immediate consequence, we obtain:

▶ **Corollary 2.5.** *Let* $\mathbf{Q} \subseteq \mathbf{U}$ *and let* $\mathbf{D_Q}$ *be the associated set of divisibility quantifiers.*

(1) *For every* FO($\mathbf{Q}$)*-formula* φ*, we can compute an equivalent* FO($\mathbf{D_Q}$)*-formula and vice versa.*

(2) *For every* FO($\mathbf{D_Q}$)*-formula* ψ *in Gaifman normal form, we can compute an equivalent* FO($\mathbf{Q}$)*-formula in Gaifman normal form.*

Feferman-Vaught decompositions. A crucial tool in the construction of Gaifman normal forms for first-order logic (i.e., in the proof of Theorem 2.3(1)) is a result by Feferman and Vaught [8]. In its simplest form (which is all that is needed in this context) it expresses that the first-order theory of the disjoint sum of two structures is determined by the first-order theories of the two structures. Our proof of the generalisation of Theorem 2.3(1) to logics of the form FO($\mathbf{Q}$) will proceed similarly to Gaifman's proof for FO, and this requires us to first provide a generalisation of the result by Feferman and Vaught.

Let σ be a relational signature and let $\mathcal{A}$ and $\mathcal{B}$ be disjoint σ-structures (i.e., their universes A and B are disjoint). The *disjoint sum* $\mathcal{A} \oplus \mathcal{B}$ of $\mathcal{A}$ and $\mathcal{B}$ is the structure $\big(A \cup B,\, A,\, B,\, (R^{\mathcal{A}} \cup R^{\mathcal{B}})_{R\in\sigma}\big)$ over the signature σ_2 with two additional unary relation symbols (that we denote A and B). Since this is only defined for disjoint structures, the relations A and B form a partition of the universe of the σ_2-structure $\mathcal{A} \oplus \mathcal{B}$. Furthermore, no edge of the Gaifman graph of $\mathcal{A} \oplus \mathcal{B}$ connects nodes from A with nodes from B.

▶ **Definition 2.6.** Let $\mathbf{Q}$ be a set of counting quantifiers and $\varphi(\overline{x}, \overline{y}) \in \mathrm{FO}(\mathbf{Q})[\sigma_2]$ a formula with $\overline{x} = (x_1, \ldots, x_k)$ and $\overline{y} = (y_1, \ldots, y_\ell)$. Furthermore, let Δ be a finite set of pairs of formulas $(\alpha(\overline{x}), \beta(\overline{y}))$ from FO($\mathbf{Q}$)[σ]. The set Δ is a *decomposition of* φ *w.r.t.* $(\overline{x}; \overline{y})$ if

$$\mathcal{A} \oplus \mathcal{B} \;\models\; \varphi(\overline{a}, \overline{b}) \quad\Longleftrightarrow\quad \text{there exists } (\alpha, \beta) \in \Delta \text{ with } \mathcal{A} \models \alpha(\overline{a}) \text{ and } \mathcal{B} \models \beta(\overline{b})$$

holds for all disjoint σ-structures $\mathcal{A}$ and $\mathcal{B}$ and all tuples $\overline{a} \in A^k$ and $\overline{b} \in B^\ell$.

The following is known about the existence and computability of decompositions:

▶ **Theorem 2.7.** *Let* $\mathbf{Q} = \emptyset$*, i.e.,* FO($\mathbf{Q}$) = FO*.*

(1) *From a formula* $\varphi(\overline{x}, \overline{y}) \in \mathrm{FO}[\sigma_2]$*, one can compute a decomposition w.r.t.* $(\overline{x}; \overline{y})$ *[8].*

(2) *The size of the decomposition cannot be bounded by an elementary function in the size of the formula* $\varphi(\overline{x}, \overline{y})$ *[4].*

A more general definition of the notion "decomposition" replaces the condition "there exists $(\alpha, \beta) \in \Delta$ with ..." by a Boolean combination of statements of the form "$\mathcal{A} \models \alpha(\overline{a})$" and "$\mathcal{B} \models \beta(\overline{b})$"; and with this definition, a "decomposition" can be computed in 3-fold exponential time from any $\varphi \in \mathrm{FO}(\mathbf{D})[\sigma_2]$ and for any fixed $d \geqslant 0$; but this decomposition is only equivalent to φ provided $\mathcal{A}$ and $\mathcal{B}$ are finite and of degree at most d [15, Theorem 5.2.1] (see [13] for the first-order case). Another result in this direction is due to Courcelle who considers the extension CMSO of monadic second-order logic by predicates expressing the size of a set modulo some fixed number. In this context, Courcelle also proves a result analogous to Theorem 2.7(1) [3, Lemma 4.5]. More results in this vein can be found in [21].

3 Feferman-Vaught decompositions for FO(Q)

If $\mathbf{Q}$ is a set of counting quantifiers and $\mathsf{S} \in \mathbf{Q}$ is not ultimately periodic, then there is no decomposition for the sentence $\mathsf{S}x\, x{=}x$ [15, Theorem 8.5.2]. Here, we prove that if Q contains only ultimately periodic counting quantifiers, decompositions exist and can be computed:

▶ **Theorem 3.1.** *Let* $\mathbf{Q} \subseteq \mathbf{U}$ *and let* σ *be a relational signature. From a formula* $\varphi(\overline{x},\overline{y}) \in \mathrm{FO}(\mathbf{Q})[\sigma_2]$*, one can construct a decomposition for* φ *w.r.t.* $(\overline{x};\overline{y})$*.*

Proof. By Corollary 2.5(1), the logics $\mathrm{FO}(\mathbf{Q})$ and $\mathrm{FO}(\mathbf{D}_\mathbf{Q})$ for $\mathbf{Q} \subseteq \mathbf{U}$ are effectively equally expressive. Therefore, it suffices to prove the theorem for sets of divisibility quantifiers, i.e., for the case where $\mathbf{Q} \subseteq \mathbf{D}$. The proof proceeds by induction on the construction of the formula $\varphi(\overline{x},\overline{y})$. The cases of atomic formulas, Boolean combinations, and existential quantification are as in the first-order case, see e.g. [11, Lemma 2.3]. Here, we sketch the remaining case where $\varphi(\overline{x},\overline{y})$ is of the form $\mathsf{D}_m z\, \psi(\overline{x},\overline{y},z)$ for some $m \geqslant 2$. Let $\overline{x} = (x_1,\ldots,x_k)$ and $\overline{y} = (y_1,\ldots,y_\ell)$. For $n \in \{0,1,\ldots,m{-}1\}$, consider the formulas

$$\chi_n(\overline{x},\overline{y}) := (\mathsf{D}_m{+}n)z\,\big(A(z) \wedge \psi(\overline{x},\overline{y},z)\big) \quad \text{and} \quad \xi_n(\overline{x},\overline{y}) := (\mathsf{D}_m{+}n)z\,\big(B(z) \wedge \psi(\overline{x},\overline{y},z)\big).$$

Let $\varphi'(\overline{x},\overline{y})$ be the disjunction of all formulas $\chi_{n_1}(\overline{x},\overline{y}) \wedge \xi_{n_2}(\overline{x},\overline{y})$ where $n_1, n_2 \in \{0,\ldots,m{-}1\}$ and $n_1 + n_2 \equiv 0 \pmod m$. Clearly, $\mathcal{A} \oplus \mathcal{B} \models (\varphi \leftrightarrow \varphi')(\overline{a},\overline{b})$ holds for all disjoint structures $\mathcal{A}$ and $\mathcal{B}$ and all $\overline{a} \in A^k$ and $\overline{b} \in B^\ell$. Therefore, every decomposition of φ' is also a decomposition of φ. Furthermore, note that a decomposition for φ' can be computed from decompositions for the formulas $\chi_n(\overline{x},\overline{y})$ and $\xi_n(\overline{x},\overline{y})$ for $n \in \{0,\ldots,m{-}1\}$. All that remains to be done is to construct decompositions w.r.t. $(\overline{x};\overline{y})$ for each of the formulas $\chi_n(\overline{x},\overline{y})$ and $\xi_n(\overline{x},\overline{y})$. By symmetry, we only consider the formula ξ_n.

By the induction hypothesis, there is a decomposition $\{(\alpha_i(\overline{x}),\beta_i(\overline{y},z)) : i \in I\}$ of $\psi(\overline{x},\overline{y},z)$ w.r.t. $(\overline{x};\overline{y}z)$. We can, w.l.o.g., assume that the formulas $\alpha_i(\overline{x})$ are mutually exclusive, i.e., $\alpha_i(\overline{x}) \wedge \alpha_j(\overline{x})$ is unsatisfiable for $i \neq j$. Then, the set $\big\{\,\big(\,\alpha_i(\overline{x})\,,\,(\mathsf{D}_m{+}n)z\,\beta_i(\overline{y},z)\,\big) \;:\; i \in I\,\big\}$ is a decomposition of $\xi_n(\overline{x},\overline{y})$ w.r.t. $(\overline{x};\overline{y})$. ◀

In the inductive proof of Theorem 3.1, the size of the decomposition (i.e., the number of pairs) increases exponentially with every negation and every quantification. It follows that the size of the formulas in the resulting decomposition can be bounded by a tower of 2s whose height is proportional to the size of the formula. We can adopt and simplify the proof of [4, Theorem 3] to also obtain a non-elementary lower bound:

▶ **Proposition 3.2.** *Let* $\sigma = \{E\}$ *with* $\mathrm{ar}(E) = 2$*. There is a sequence* $(\varphi_h)_{h\geqslant 0}$ *of* $\mathrm{FO}[\sigma]$*-sentences of size* $\mathcal{O}(h)$ *such that for every elementary function* $f\colon \mathbb{N} \to \mathbb{N}$*, there is* $h \in \mathbb{N}$ *such that every decomposition* Δ_h *in* $\mathrm{FO}(\mathbf{U})$ *of* φ_h *contains some sentence of length* $> f(h)$*.*

We finish this section with a corollary to Theorem 3.1 that will be used in the construction of Gaifman normal forms in the next section.

▶ **Corollary 3.3.** *Let* $\mathbf{Q} \subseteq \mathbf{U}$ *be a set of ultimately periodic quantifiers and let* $r \in \mathbb{N}$*. From an* r*-local formula* $\lambda(\overline{x},y) \in \mathrm{FO}(\mathbf{Q})$*, one can compute a finite set* Δ' *of pairs of* r*-local* $\mathrm{FO}(\mathbf{Q})$*-formulas* $(\alpha'(\overline{x}),\beta'(y))$ *such that the following two formulas are equivalent:*

$$\mathrm{dist}(\overline{x},y) > 2r{+}1 \;\wedge\; \lambda(\overline{x},y) \qquad \textit{and} \qquad \mathrm{dist}(\overline{x},y) > 2r{+}1 \;\wedge \bigvee_{(\alpha',\beta')\in\Delta'} \big(\alpha'(\overline{x}) \wedge \beta'(y)\big)\,.$$

4 Equivalent Gaifman normal forms

The main result of this section is:

▶ **Theorem 4.1.** *Let* $\mathbf{Q}$ *be a set of unary counting quantifiers.*

(1) *If* $\mathbf{Q} \subseteq \mathbf{U}$ *contains only ultimately periodic quantifiers then, from a formula* $\varphi \in \mathrm{FO}(\mathbf{Q})$*, one can compute an equivalent formula* $\gamma \in \mathrm{FO}(\mathbf{Q})$ *in Gaifman normal form.*

(2) *If* $\mathbf{Q}$ *contains a quantifier* S *that is not ultimately periodic, then there is a sentence* $\eta \in \mathrm{FO}(\mathbf{Q})$ *such that no* $\mathrm{FO}(\mathbf{Q})$*-sentence in Gaifman normal form is equivalent to* η.

The two statements of the theorem are proved in the next two subsections.

4.1 Ultimately periodic quantifiers

Proof of Theorem 4.1(1)**.** In the light of Corollary 2.5, it suffices to consider sets $\mathbf{Q} \subseteq \mathbf{D}$ of divisibility quantifiers.

The construction of γ proceeds by structural induction following the construction of φ. The cases of atomic formulas φ as well as of Boolean combinations are trivial. If φ is of the form $\exists y\, \psi$, we can argue as in the first-order case ([10], see also [11, Sect. 4.1]), but since ψ is from $\mathrm{FO}(\mathbf{Q})$, we use Corollary 3.3 instead of Feferman-Vaught decompositions for FO (cf. [11, Lemma 2.3]). So it remains to consider the case where $\varphi(\overline{x})$ is of the form $\mathsf{D}_m y\, \psi(\overline{x}, y)$ for some $\mathsf{D_m} \in \mathbf{Q}$. By the induction hypothesis we can assume that ψ is in Gaifman normal form. Hence there are a finite set I, sentences χ_i in Gaifman normal form, and local formals $\lambda_i(\overline{x}, y)$ for all $i \in I$, such that φ is equivalent to the formula $\varphi' := \mathsf{D}_m\, y \Big(\bigvee_{i\in I} \big(\chi_i \wedge \lambda_i(\overline{x}, y) \big) \Big)$.

W.l.o.g. we can assume that the sentences χ_i are mutually exclusive, i.e., $\chi_i \wedge \chi_j$ is unsatisfiable for $i \neq j$.

Set $r' := 2r + 1$. Then, $\varphi(\overline{x})$ is equivalent to a Boolean combination of the formulas

$$\gamma_n(\overline{x}) \;:=\; (\mathsf{D}_m{+}n)\, y \,\Big(\operatorname{dist}(\overline{x}, y) \leqslant r' \;\wedge \bigvee_{i\in I} \big(\chi_i \wedge \lambda_i(\overline{x}, y) \big) \Big) \qquad \text{and}$$

$$\delta_n(\overline{x}) \;:=\; (\mathsf{D}_m{+}n)\, y \,\Big(\operatorname{dist}(\overline{x}, y) > r' \;\wedge \bigvee_{i\in I} \big(\chi_i \wedge \lambda_i(\overline{x}, y) \big) \Big)$$

with $n \in \{0, \ldots, m{-}1\}$, and it suffices to transform each of these formulas into Gaifman normal form. Since the sentences χ_i are mutually exclusive, $\gamma_n(\overline{x})$ is equivalent to

$$\bigvee_{i\in I} \big(\chi_i \;\wedge\; (\mathsf{D}_m{+}n)\, y \,\big(\operatorname{dist}(\overline{x}, y) \leqslant r' \;\wedge\; \lambda_i(\overline{x}, y) \big) \big)\,,$$

which is in Gaifman normal form. Similarly, $\delta_n(\overline{x})$ is equivalent to

$$\bigvee_{i\in I} \big(\chi_i \;\wedge\; (\mathsf{D}_m{+}n)\, y \,\big(\operatorname{dist}(\overline{x}, y) > r' \;\wedge\; \lambda_i(\overline{x}, y) \big) \big)\,.$$

Let $i \in I$. By Corollary 3.3, we can construct a finite set J and r-local formulas $\alpha_j(\overline{x})$ and $\beta_j(y)$ for $j \in J$, such that the formulas

$$\operatorname{dist}(\overline{x}, y) > r' \;\wedge\; \lambda_i(\overline{x}, y) \qquad \text{and} \qquad \operatorname{dist}(\overline{x}, y) > r' \;\wedge \bigvee_{j\in J} \big(\alpha_j(\overline{x}) \;\wedge\; \beta_j(y) \big)$$

are equivalent. Again, we can assume that the formulas $\alpha_j(\overline{x})$ are mutually exclusive. Then, $\delta_n(\overline{x})$ is equivalent to the formula

$$\bigvee_{(i,j)\in I\times J} \big(\chi_i \;\wedge\; \alpha_j(\overline{x}) \;\wedge\; (\mathsf{D}_m{+}n)\, y \,\big(\operatorname{dist}(\overline{x}, y) > r' \;\wedge\; \beta_j(y) \big) \big)\,.$$

Finally, the formula $(\mathsf{D}_m{+}n)\, y \big(\operatorname{dist}(\overline{x}, y) > r' \wedge \beta_j(y) \big)$ is equivalent to a Boolean combination of formulas of the form $(\mathsf{D}_m{+}n_1)\, y \big(\operatorname{dist}(\overline{x}, y) \leqslant r' \wedge \beta_j(y) \big)$ and $(\mathsf{D}_m{+}n_2)\, y\, \beta_j(y)$ with $n_1, n_2 \in \{0, \ldots, m{-}1\}$. Note that the first formula is $(r' + r)$-local, and the second formula is a counting sentence, i.e., both these formulas are in Gaifman normal form. ◀

In the inductive proof of Theorem 4.1(1), the size of the Gaifman normal form increases at least exponentially with every (existential or counting) quantifier, since we build the disjunctive normal form to get the formula φ' defined at the beginning of the proof. Consequently, we only obtain a non-elementary upper bound on the size of the formula in Gaifman normal form. We can complement this with a non-elementary lower bound (the sequence of formulas is the same as in Proposition 3.2):

▶ **Proposition 4.2.** *Let $\sigma = \{E\}$ with $\mathrm{ar}(E) = 2$. There is a sequence of $\mathrm{FO}[\sigma]$-sentences $(\varphi_h)_{h\geqslant 0}$ of size $\mathcal{O}(h)$ such that for every elementary function $f\colon \mathbb{N} \to \mathbb{N}$, there is $h \in \mathbb{N}$ such that no $\mathrm{FO}(\mathbf{U})$-sentence in Gaifman normal form of length $< f(h)$ is equivalent to φ_h.*

4.2 Non-ultimately periodic quantifiers

Theorem 4.1(2) is an immediate consequence of the following slightly stronger result.

▶ **Proposition 4.3.** *Let $\mathbf{Q}$ be a set of counting quantifiers, let $\mathsf{S} \in \mathbf{Q}$, let $\sigma_\sim = \{\sim\}$ be the signature with $\mathrm{ar}(\sim) = 2$, and let η be the $\mathrm{FO}(\mathbf{Q})$-sentence*

$$\exists x_1\, \exists x_2 \left(\begin{array}{ll} & \neg\,(x_1 \sim x_2) \;\wedge\; \mathsf{S}z\,(x_1 \sim z \;\vee\; x_2 \sim z) \\ \wedge & \forall y\,\big(\,\mathsf{S}z\,(\,x_1 \sim z \;\vee\; y \sim z\,) \;\vee\; \mathsf{S}z\,(\,x_2 \sim z \;\vee\; y \sim z\,)\,\big) \end{array} \right).$$

If S is not ultimately periodic, then no sentence from $\mathrm{FO}(\mathbf{Q})[\sigma_\sim]$ in Gaifman normal form is equivalent to η (not even on the class of finite equivalence structures).

A *finite equivalence structure* is a $\sigma_\sim$-structure $\mathcal{A} = (A, \sim^{\mathcal{A}})$ where A is finite and $\sim^{\mathcal{A}}$ is an equivalence relation on A. In such structures, the formula η expresses that there are two distinct equivalence classes $[a_1]$ and $[a_2]$ with $|[a_1] \cup [a_2]| \in \mathsf{S}$ such that $|[a_1] \cup [b]| \in \mathsf{S}$ or $|[a_2] \cup [b]| \in \mathsf{S}$ for any equivalence class $[b]$. We will prove that this property cannot be expressed by any sentence in Gaifman normal form.

Let $\lambda(x)$ be a local $\mathrm{FO}(\mathbf{Q})[\sigma_\sim]$-formula, let $\mathcal{A}$ be a finite equivalence structure, and let $a \in A$. Since λ is local, the question whether or not $\mathcal{A} \models \lambda(a)$ is determined solely by the size of the equivalence class $[a]$. In case that $\lambda(x)$ is a first-order formula, it is equivalent to a Boolean combination of statements of the form $|[a]| \geqslant k$ for $k \in \{0, \ldots, r\}$, where r is the formula's quantifier rank. If the formula $\lambda(x)$ also uses counting quantifiers from $\mathbf{Q}$, then we can also express that $|[a]| - \ell \in \mathsf{Q}$, for $\mathsf{Q} \in \mathbf{Q}$; but this is only possible for $\ell \in \{0, \ldots, r'\}$, where r' is a number that only depends on the formula λ, but not on the considered equivalence structure $\mathcal{A}$. These observations lead to the following limitation of the expressiveness of local formulas:

▶ **Lemma 4.4.** *For every local $\mathrm{FO}(\mathbf{Q})[\sigma_\sim]$-formula $\lambda(x)$ there exists an $r \in \mathbb{N}$ such that the following is true for all finite equivalence structures $\mathcal{A}$ and $\mathcal{B}$, all $a \in A$, and all $b \in B$.*
If the equivalences

$$|[a]| \geqslant \ell \iff |[b]| \geqslant \ell \qquad \text{and} \qquad |[a]| - \ell \in \mathsf{Q} \iff |[b]| - \ell \in \mathsf{Q}$$

are satisfied for all $\ell \in \{0, \ldots, r\}$ and all counting quantifiers $\mathsf{Q} \in \mathbf{Q}$ that appear in λ, then $\mathcal{A} \models \lambda(a) \iff \mathcal{B} \models \lambda(b)$.

Proof of Proposition 4.3. Suppose S is not ultimately periodic and suppose, for contradiction, that γ is an $\mathrm{FO}(\mathbf{Q})[\sigma_\sim]$-sentence in Gaifman normal form that is equivalent to η. Let $\mathbf{Q}_\gamma$ consist of all counting quantifiers that appear in γ. We apply Lemma 4.4 to all local formulas $\lambda(x)$ that occur in basic-local sentences or in counting sentences which are

subformulas of γ, and we let $\hat{r}$ be the maximum of all the numbers r provided by Lemma 4.4 for each such $\lambda(x)$.

Since $\mathsf{Q}_\gamma \cup \{\mathsf{S}\}$ is finite and S is not ultimately periodic, one can prove the existence of natural numbers $m, n \geqslant \hat{r}$ and $k \geqslant 1$ such that $m + k \notin \mathsf{S}$, $n + k \in \mathsf{S}$, and for all $\mathsf{Q} \in \mathbf{Q}_\gamma \cup \{\mathsf{S}\}$ and all $\ell \in \{0, \dots, \hat{r}\}$ we have $m - \ell \in \mathsf{Q} \iff n - \ell \in \mathsf{Q}$.

We use the numbers $m, n, k, \hat{r}$ to define two finite equivalence structures $\mathcal{B}$ and $\mathcal{C}$:

- $\mathcal{B}$ has $\hat{r}$ many equivalence classes of size k and m many equivalence classes of size n.
- $\mathcal{C}$ has $\hat{r}$ many equivalence classes of size k and n many equivalence classes of size m.

By Lemma 4.4, no local formula appearing in γ can distinguish equivalence classes of size m from equivalence classes of size n. It follows that $\mathcal{B} \models \gamma \iff \mathcal{C} \models \gamma$.

To prove that $\mathcal{B} \models \eta$, one chooses for x_1 and x_2 elements from equivalence classes of size k and n, respectively. When trying to satisfy η in $\mathcal{C}$, one has to choose for x_1 and x_2 elements from equivalence classes of the same size since $m + k \notin \mathsf{S}$. But there is some y whose equivalence class has different size, and hence $|[x_i]| + |[y]|$ cannot belong to S. Thus, η distinguishes $\mathcal{B}$ from $\mathcal{C}$, but γ does not. ◀

5 Finitely d-equivalent Gaifman normal forms

5.1 Ultimately periodic quantifiers

In Section 4.1 we obtained an algorithm that transforms a given FO(**U**)-formula over a relational signature into an equivalent FO(**U**)-formula in Gaifman normal form. Just as in Gaifman's original locality theorem, the algorithm's runtime is non-elementary in the size of the input formula; and from Proposition 4.2 we know that a non-elementary blow-up in formula size (and hence also runtime) cannot be avoided.

In [16] it was shown that for plain first-order logic FO, the non-elementary blow-up can be improved into a (worst-case optimal) 3-fold exponential running time if we drop the requirement that the Gaifman normal form formula has to be equivalent to the original formula on *all* structures and are content with a *finitely d-equivalent* formula in Gaifman normal form. We can generalise this result to FO(**U**) as follows.

▶ **Theorem 5.1.** *Upon input of a number $d \in \mathbb{N}$ and an* FO(**U**)*-formula φ over some relational signature σ, a finitely d-equivalent formula ψ in Gaifman normal form can be computed in time $2^{d^{2^{O(\|\varphi\|)}}}$ for $d \geqslant 3$, and in time $2^{2^{\mathrm{poly}(\|\varphi\|)}}$ for $d < 3$.*
Furthermore, ψ uses at most the quantifiers from φ and the quantifier $\exists$.

We proceed in the same way as the proof of [16], but instead of building upon the Hanf normal form algorithm for FO of [2] we build upon the Hanf normal form algorithm for FO(**U**) of [17]. For the precise statement of the result of [17], we need the following notation.

Let σ be a relational signature. For every $r \in \mathbb{N}$ and $n \in \mathbb{N}_{\geqslant 1}$, a *type with n centres and radius at most r* is structure of the form $\tau = (\mathcal{N}_r^{\mathcal{A}}(\overline{a}), \overline{a})$ where $\mathcal{A}$ is a σ-structure and $\overline{a} \in A^n$. Such a type is called d-bounded if the structure $\mathcal{N}_r^{\mathcal{A}}(\overline{a})$ is d-bounded.

The following is straightforward. The universe of a d-bounded type τ with n centres and radius $\leqslant r$ has size at most $n \cdot d^{r+1}$ (provided that $d \geqslant 2$). Given τ and r, one can construct an FO[σ]-formula[2] $\mathrm{sph}_\tau(\overline{x})$ with n free variables $\overline{x} = (x_1, \dots, x_n)$ such that for every σ-structure $\mathcal{A}$ and every tuple $\overline{a} \in A^n$ we have $\mathcal{A} \models \mathrm{sph}_\tau(\overline{a}) \iff (\mathcal{N}_r^{\mathcal{A}}(\overline{a}), \overline{a}) \cong \tau$. We

[2] The formula $\mathrm{sph}_\tau(\overline{x})$ also depends on r, although this is not reflected by the notation here.

can assume w.l.o.g. that the formula $\mathrm{sph}_\tau(\overline{x})$ is r-local and has size at most $(n{\cdot}d^{r+1})^{\mathcal{O}(\|\sigma\|)}$, where $\|\sigma\|$ is defined as the sum of the arities of the relation symbols in σ.

Formulas of the form $\mathrm{sph}_\tau(\overline{x})$ are called (d-bounded) *sphere-formulas* of signature σ. Let $\mathbf{Q}$ be a set of counting quantifiers. An FO($\mathbf{Q}$)-*Hanf-sentence* of signature σ is a sentence of the form $(\mathsf{Q}{+}k)y\,\mathrm{sph}_\rho(y)$ or of the form $\exists^{\geqslant k}y\,\mathrm{sph}_\rho(y)$, where $k \in \mathbb{N}$, $\mathsf{Q} \in \mathbf{Q}$, and ρ is a type of signature σ and with a single centre. An FO($\mathbf{Q}$)-formula in *Hanf normal form* and of signature σ is a Boolean combination of sphere-formulas and FO($\mathbf{Q}$)-Hanf-sentences of signature σ. The proof of Theorem 5.1 follows by combining Lemma 2.4(c) and:

▶ **Theorem 5.2** ([17]). *Upon input of a number $d \in \mathbb{N}$ and an* FO($\mathbf{U}$)*-formula φ over some relational signature σ, a finitely d-equivalent* FO($\mathbf{U}$)*-formula ψ in Hanf normal form and of signature σ can be computed in time $2^{d^{2^{\mathcal{O}(\|\varphi\|)}}}$ for $d \geqslant 3$, and in time $2^{2^{\mathrm{poly}(\|\varphi\|)}}$ for $d < 3$.*

5.2 General quantifiers

In Section 4.2 we showed that if a set $\mathbf{Q}$ contains a quantifier that is *not* ultimately periodic, then there is an FO($\mathbf{Q}$)-sentence that is not equivalent to any FO($\mathbf{Q}$)-sentence in Gaifman normal form (not even on the class of finite structures). Somewhat surprisingly, it turns out that if we drop the requirement that the Gaifman normal form formula has to be equivalent to the original formula on *all* structures and are content with a *finitely d-equivalent* formula, Gaifman normal forms do exist for *arbitrary* sets $\mathbf{Q}$ of counting quantifiers. Precisely, we obtain the following result, in which the size $\|\varphi\|$ of an FO($\mathbf{Q}$)-formula φ of signature σ is defined analogously as the size of FO($\mathbf{U}$)-formulas, but now each quantifier $\mathsf{Q} \in \mathbf{Q}$ is viewed as an abstract symbol of length 1.

▶ **Theorem 5.3.** *Let $\mathbf{Q}$ be an arbitrary set of counting quantifiers and let $d \in \mathbb{N}$. For every* FO($\mathbf{Q}$)*-formula φ over some relational signature σ, there exists a finitely d-equivalent* FO($\mathbf{Q}$)*-formula ψ in Gaifman normal form. Moreover, if the sets $\mathsf{Q} \in \mathbf{Q}$ are uniformly decidable (in elementary time), then ψ can be computed from φ and d (in elementary time).*

The proof proceeds in a similar way as the proof of Theorem 5.1, but instead of building upon Theorem 5.2, it uses a result of [19] that can be viewed as a generalisation of Theorem 5.2 to FO($\mathbf{Q}$) for arbitrary sets $\mathbf{Q}$ of unary counting quantifiers. For the precise statement of this result, we need the following notation. An FO($\mathbf{Q}$)-*weak-Hanf-sentence* of signature σ is a sentence of the form $(\mathsf{Q}{+}k)y\,\bigvee_{\theta\in T}\theta(y)$ or of the form $\exists^{\geqslant k}y\,\bigvee_{\theta\in T}\theta(y)$, where T is a finite set of sphere-formulas of signature σ, each of them with a single centre and all of the same radius r. An FO($\mathbf{Q}$)-formula in *weak Hanf normal form* and of signature σ is a Boolean combination of sphere-formulas and FO($\mathbf{Q}$)-weak-Hanf-sentences of signature σ. The proof of Theorem 5.3 follows by combining Lemma 2.4(c) and:

▶ **Theorem 5.4** ([19]). *Let $\mathbf{Q}$ be an arbitrary set of counting quantifiers and let $d \in \mathbb{N}$. For every* FO($\mathbf{Q}$)*-formula φ over some relational signature σ, there exists a finitely d-equivalent* FO($\mathbf{Q}$)*-formula ψ in weak Hanf normal form and of signature σ. Moreover, if the sets $\mathsf{Q} \in \mathbf{Q}$ are uniformly decidable (in elementary time), then ψ can be computed from φ and d (in elementary time).*

One may wonder if, analogously to the statement of Theorem 5.1, the last statement of Theorem 5.3 can be improved to a 3-fold exponential running time. To refute this, one observes that from a formula in Gaifman normal form, one can construct an equivalent formula in weak Hanf normal form with the same number of counting sentences. Then a lower bound result of [19] for weak Hanf normal forms implies the following:

▶ **Proposition 5.5.** *There exists a* $\mathsf{Q} \subseteq \mathbb{N}$ *such that for* $\mathbf{Q} := \{\mathsf{Q}\}$*, there is a sequence* $(\varphi_n)_{n\geqslant 1}$ *of* $\mathrm{FO}(\mathbf{Q})$*-sentences of the same relational signature and of size* $\mathcal{O}(n)$ *such that, for all* $n \geqslant 1$*, every* $\mathrm{FO}(\mathbf{Q})$*-sentence in Gaifman normal form that is finitely 3-equivalent to* φ_n *contains at least* $\exp_4(n)$ *distinct subformulas of the form* $(\mathsf{Q}{+}k)y\,\lambda(y)$*.*

From our proof it follows that $\{n^n : n \in \mathbb{N}\}$, $\{n! : n \in \mathbb{N}\}$, and $\{\lfloor 2^{n^c} \rfloor : n \in \mathbb{N}\}$ for all reals $c > 1$, are examples of sets Q for which the statement of Proposition 5.5 holds.

6 An algorithmic meta-theorem for FO(U)

The model-checking problem for a logic L and a class $\mathcal{C}$ of finite relational structures receives as input a sentence $\varphi \in \mathrm{L}$ and a structure $\mathcal{A} \in \mathcal{C}$, and the task is to decide if $\mathcal{A} \models \varphi$. This problem is said to be *fixed-parameter tractable* if it can be solved in time $f(\|\varphi\|)\cdot\mathrm{poly}(\|\mathcal{A}\|)$ where f is a computable function, $\|\varphi\|$ is the size of the formula, and $\|\mathcal{A}\|$ is the size of the structure (defined as $\|\mathcal{A}\| := |A| + \sum_{R\in\sigma} \mathrm{ar}(R)\cdot|R^{\mathcal{A}}|$). Recall from Section 1 the list of examples of logics L and classes $\mathcal{C}$ for which the model-checking problem is known to be fixed-parameter tractable. The aim of this section is to demonstrate that by using our Gaifman normal form result for $\mathrm{FO}(\mathbf{U})$ (Theorem 4.1(1)), the model-checking algorithm for classes of bounded local tree-width of [9] can be generalised from FO to $\mathrm{FO}(\mathbf{U})$.

To provide a precise formulation of the result, we need some further notation. We assume that the reader is familiar with the basic concept of a tree-decomposition and the tree-width $\mathrm{tw}(\mathcal{A})$ of a structure $\mathcal{A}$ (precise definitions can be found in [9] and will not be necessary for understanding the remainder of this section). The *local tree-width* of $\mathcal{A}$ is the function $\mathrm{ltw}^{\mathcal{A}}\colon \mathbb{N} \to \mathbb{N}$ defined by $\mathrm{ltw}^{\mathcal{A}}(r) := \max\{\mathrm{tw}(\mathcal{N}_r^{\mathcal{A}}(a)) : a \in A\}$ for all $r \in \mathbb{N}$. A class $\mathcal{C}$ of structures has *(effectively) bounded local tree-width* if there is a (computable) function $g\colon \mathbb{N} \to \mathbb{N}$ such that $\mathrm{ltw}^{\mathcal{A}}(r) \leqslant g(r)$ for all $\mathcal{A} \in \mathcal{C}$ and all $r \in \mathbb{N}$. As shown in [9], examples for classes of bounded local tree-width are classes of trees, classes of structures of tree-width at most w (for each fixed $w \in \mathbb{N}$), classes of degree at most d (for each fixed $d \in \mathbb{N}$), the class of planar graphs, and classes of graphs of genus at most g (for each fixed $g \in \mathbb{N}$).

The overall approach of [9] has been described in [12] as follows: *"Using Gaifman's theorem, the problem to decide whether a general first-order formula φ is true in a graph can be reduced to testing whether a formula is true in r-neighbourhoods in the graph, where the radius r only depends on φ, and solving a variant of the (distance d) independent set problem. Hence, if $\mathcal{C}$ is a class of graphs where r-neighbourhoods have a simple structure, such as the class of planar graphs or classes of bounded local tree-width, this method gives an easy way for deciding properties definable in first-order logic."*

Here, the "(distance d) independent set problem" corresponds to the essence of evaluating a basic local sentence. Our Gaifman normal form for $\mathrm{FO}(\mathbf{U})$-sentences consists of basic local sentences (which can be evaluated in the same way as described in [9]) and counting sentences of the form $(\mathsf{Q}{+}k)x\,\lambda(x)$, and evaluating these boils down to (1) computing the set of all nodes x whose r-neighbourhood satisfies $\lambda(x)$ and (2) checking if the size of this set belongs to $(\mathsf{Q}{+}k)$. The task (1) has been solved in [9] for r-local FO-formulas and can easily be gerneralised to r-local $\mathrm{FO}(\mathbf{U})$-formulas, and the task (2) is straightforward. In summary, by combining the approach of [9] with our Theorem 4.1(1) we obtain:

▶ **Corollary 6.1.** *Let $\mathcal{C}$ be a class of finite relational structures of bounded local tree-width and let φ be an $\mathrm{FO}(\mathbf{U})$-sentence. Then, for every $k \geqslant 1$, there is an algorithm deciding in time $\mathcal{O}(\|A\|^{1+(1/k)})$ whether a given structure $\mathcal{A} \in \mathcal{C}$ satisfies φ.*

To keep the runtime analysis of Corollary 6.1 simple, we formulated the corollary in a way which uses the $\mathcal{O}$-notation to hide factors that depend on the sentence φ or the number k. A closer inspection of the proof shows that, for any class of effectively bounded local tree-width, the algorithm's runtime can be bounded by $f(\|\varphi\|, k) \cdot \|\mathcal{A}\|^{1+(1/k)}$, for some computable function f. Thus, in particular, we obtain that for every class $\mathcal{C}$ of effectively bounded local tree-width, the model-checking problem for FO(**U**)-sentences on $\mathcal{C}$ is fixed-parameter tractable. To close this paper, let us mention that we believe that by a similar, but substantially more involved construction also the result of [12] for model-checking on nowhere dense classes can be lifted from FO to FO(**U**) – we plan to do this as future work.

Polynomial Vector Addition Systems With States

Jérôme Leroux[1]
Univ.Bordeaux, CNRS, Bordeaux-INP, Talence, France
jerome.leroux@labri.fr

Abstract

The reachability problem for vector addition systems is one of the most difficult and central problems in theoretical computer science. The problem is known to be decidable, but despite intense investigation during the last four decades, the exact complexity is still open. For some sub-classes, the complexity of the reachability problem is known. Structurally bounded vector addition systems, the class of vector addition systems with finite reachability sets from any initial configuration, is one of those classes. In fact, the reachability problem was shown to be polynomial-space complete for that class by Praveen and Lodaya in 2008. Surprisingly, extending this property to vector addition systems with states is open. In fact, there exist vector addition systems with states that are structurally bounded but with Ackermannian large sets of reachable configurations. It follows that the reachability problem for that class is between exponential space and Ackermannian. In this paper we introduce the class of polynomial vector addition systems with states, defined as the class of vector addition systems with states with size of reachable configurations bounded polynomially in the size of the initial ones. We prove that the reachability problem for polynomial vector addition systems is exponential-space complete. Additionally, we show that we can decide in polynomial time if a vector addition system with states is polynomial. This characterization introduces the notion of iteration scheme with potential applications to the reachability problem for general vector addition systems.

1 Introduction

Vector addition systems or equivalently Petri nets are one of the most popular formal methods for the representation and the analysis of parallel processes [4]. The reachability problem is central since many computational problems (even outside the parallel processes) reduce to the reachability problem. In 1981, Mayr [13] provided the first decidability proof of the reachability problem. Later, that proof was first simplified by Kosaraju [7], and then ten years later by Lambert [9]. This last proof still remains difficult and the complexity upper bound of the corresponding algorithm is just known to be non-primitive recursive [11]. Nowadays, up to some details, there are only two different known reachability algorithms for general vector addition systems; one based on the Kosaraju-Lambert-Mayr (KLM) decomposition; and a recent one based on Presburger inductive invariants [10]. Despite intense investigation during the last four decades, it is still an open problem whether an elementary complexity upper bound for the reachability problem exists.

When the reachability set of a vector addition system is finite, the KLM decomposition degenerates and it just corresponds to the regular language of all possible executions of the vector addition system from an initial configuration to a final one. Even in that case, the complexity of the KLM algorithm is Ackermannian and no better complexity upper bound are known.

In 2008, Praveen and Lodaya proved that the reachability problem for structurally bounded vector addition systems, the class of vector addition systems with finite reachability sets from any initial configuration is polynomial-space complete [17]. Surprisingly, extending this property to vector addition systems with states is open. In fact, there exist vector addition systems with states that are structurally bounded but with Ackermannian large sets of reachable configurations. It follows that the reachability problem for that class is between exponential space and Ackermannian.

Intuitively, for structurally bounded vector addition systems with states, the KLM algorithm fails to avoid enumerating all the possible reachable configurations since it tries to detect cycles of edges that can be iterated to obtain arbitrarily large components (such a cycle cannot exists due to the structurally bounded condition). Characterizing indexes that can be very large but not necessarily arbitrarily large should provide new insights on how to overcome the Ackermannian complexity of the KLM algorithm.

Our contributions

In this paper we introduce the class of *polynomial vector addition systems with states* defined as the vector addition systems with states such that reachable configurations have sizes polynomially bounded with respect to sizes of initial configurations. We prove that a vector addition system with states is not polynomial if, and only if, it contains a so-called *iteration scheme* that can increase some components. We prove that we can decide in polynomial time if a vector addition system with states is polynomial, and we show that the reachability problem for polynomial vector addition systems with states is exponential-space complete. Up to our knowledge, our notion of iteration scheme is new and provide a potential application to patch the KLM algorithm.

Outline

In Section 2 we introduce vector addition systems with states (VASS for short), and the subclass of polynomial VASS. Iteration schemes are defined in Section 3. Intuitively iteration schemes are sequences of cycles that can be iterated many times (at least an exponential number of times). Indexes that can be increased by an iteration scheme are called iterable indexes, and edges that occur in iteration schemes are called iterable edges. We show that reachable configurations cannot be polynomially bounded with respect to the size of the initial configurations on any iterable index. It follows that VASS with iterable indexes cannot be polynomial. In Section 4, we recall some general properties about the Kirchoff's functions and the Euler's lemma. Those definitions are used in Section 5 to prove the correctness of a polynomial-time algorithm inspired by the Kosaraju-Sullivan algorithm for computing the set of iterable indexes and the set of iterable edges. In Section 6 we show that reachable configurations are polynomially bounded on the non-iterable indexes with respect to the size of the initial configurations. Finally in Section 7 we show that we can decide in polynomial time if a VASS is polynomial and we prove that the reachability problem for polynomial VASS is exponential-space complete.

2 Polynomial Vector Addition Systems With States

In this section we first introduce the vector addition systems, and the structurally bounded ones. Then, we recall how the reachability problem for that subclass can be solved in polynomial space[17]. Next, we introduce the vector addition systems with states (VASS) and we show that the previous approach for VAS no longer apply to VASS. Finally, we introduce the class of polynomial VASS, the main class of VASS studied in this paper.

Concerning notations used in this paper, we denote by $\mathbb{Z}, \mathbb{N}, \mathbb{Q}$ the set of *integers*, *natural numbers*, and *rational numbers*. The absolute value of a *rational* $\lambda \in \mathbb{Q}$ is denoted by $|\lambda|$. Let $d \in \mathbb{N}$ be a natural number. *Vectors* in $\mathbb{Q}^d$ are denoted in bold face, and we denote by $\mathbf{v}[1], \ldots, \mathbf{v}[d]$ the components of $\mathbf{v}$, i.e. $\mathbf{v} = (\mathbf{v}[1], \ldots, \mathbf{v}[d])$. Every operations are performed component-wise on the vectors; for instance the sum $\mathbf{x} + \mathbf{y}$ of two vectors in $\mathbb{Q}^d$ is the vector $\mathbf{z}$ in $\mathbb{Q}^d$ satisfying $\mathbf{z}[i] = \mathbf{x}[i] + \mathbf{y}[i]$ for every $i \in \{1, \ldots, d\}$. We write $\mathbf{x} \leq \mathbf{y}$ if $\mathbf{x}[i] \leq \mathbf{y}[i]$ for every $1 \leq i \leq d$, and we write $\mathbf{x} < \mathbf{y}$ if $\mathbf{x} \leq \mathbf{y}$ and $\mathbf{x} \neq \mathbf{y}$. We denote by $\mathbf{u}_i$ the ith *unit vector* of $\mathbb{Q}^d$ defined by $\mathbf{u}_i[j] = 0$ if $j \neq i$ and $\mathbf{u}_i[i] = 1$. Notice that $\mathbf{x} = \sum_{i=1}^{d} \mathbf{x}[i]\mathbf{u}_i$ with our notations. The *norm* of a vector $\mathbf{v} \in \mathbb{Q}^d$ is the rational number $||\mathbf{v}|| = \max_i |\mathbf{v}[i]|$. The *norm* of a finite set $\mathbf{V} \subseteq \mathbb{Q}^d$ is defined as $||\mathbf{V}|| = \max_{\mathbf{v} \in \mathbf{V}} ||\mathbf{v}||$. We introduce the sets $|\mathbf{v}|^+ = \{i \mid \mathbf{v}[i] > 0\}$ and $|\mathbf{v}|^- = \{i \mid \mathbf{v}[i] < 0\}$. The *dot product* of two vectors $\mathbf{x}, \mathbf{y} \in \mathbb{Q}^d$ is the rational number $\sum_i \mathbf{x}[i] \cdot \mathbf{y}[i]$ denoted as $\mathbf{x} \cdot \mathbf{y}$.

2.1 Vector Addition Systems

A *vector addition system* (*VAS* for short) is a non-empty finite set $\mathbf{A} \subseteq \mathbb{Z}^d$ of *actions*. A vector in $\mathbb{N}^d$ is called a *configuration* of the VAS $\mathbf{A}$. The *semantics* is defined thanks to the binary relation $\to$ over the configurations by $\mathbf{x} \to \mathbf{y}$ if $\mathbf{y} = \mathbf{x} + \mathbf{a}$ for some action $\mathbf{a} \in \mathbf{A}$. The reflexive and transitive closure of $\to$ is denoted as $\xrightarrow{*}$ and it is called the *reachability relation*. If $\mathbf{x} \xrightarrow{*} \mathbf{y}$, we say that $\mathbf{y}$ is *reachable* from $\mathbf{x}$.

The reachability problem consists in deciding for a triple $(\mathbf{x}, \mathbf{A}, \mathbf{y})$ where $\mathbf{x}, \mathbf{y}$ are two configurations of a VAS $\mathbf{A}$, if $\mathbf{x} \xrightarrow{*} \mathbf{y}$. The problem is decidable [14] but its complexity remains elusive; the problem is known to be exponential-space hard [12], and the best known upper bound is non-primitive recursive [11].

A VAS $\mathbf{A}$ is said to be *bounded* from an initial configuration $\mathbf{x}$ if the set of configurations reachable from $\mathbf{x}$ is finite. The boundedness problem is known to be exponential-space complete [18]. Since the size of reachable configurations are at most Ackermannian in that case [15, 5], it follows that the reachability problem can be decided in Ackermannian complexity (space and time are equivalent for that class of complexity). This is the best known upper bound, far from the exponential-space lower bound [12].

When enforcing the VAS to be bounded for any initial configuration, we obtain the so-called structurally bounded VAS. More formally, a VAS is said to be *structurally bounded* if it is bounded from any initial configuration. In polynomial time, one can decide if a VAS is structurally bounded. In fact, a VAS $\mathbf{A}$ is not structurally bounded if, and only if, the following linear system is satisfiable over the non negative rational numbers: $(\lambda_{\mathbf{a}})_{\mathbf{a} \in \mathbf{A}}$:

$$\sum_{\mathbf{a} \in \mathbf{A}} \lambda_{\mathbf{a}} \mathbf{a} > \mathbf{0}$$

The previous observation combined with the Farkas Lemma [19] shows that a VAS is structurally bounded if, and only if, there exists a vector $\mathbf{v}$ in $\mathbb{N}^d$, called a *place invariant* such that $\mathbf{v}[i] > 0$ for every i, and such that $\mathbf{v} \cdot \mathbf{a} \leq 0$ for every action $\mathbf{a}$ in $\mathbf{A}$.

▶ **Example 1.** The VAS $\mathbf{A} = \{2\mathbf{u}_{i+1} - \mathbf{u}_i \mid 1 \leq i < d\}$ admits the place invariant $\mathbf{v} \in \mathbb{N}^d$ defined by $\mathbf{v}[i] = 2^{d-i}$ for every i.

Notice that if $\mathbf{x} \xrightarrow{*} \mathbf{y}$ then $\mathbf{v} \cdot \mathbf{y} \leq \mathbf{v} \cdot \mathbf{x}$ for any place invariant $\mathbf{v}$. We deduce that $||\mathbf{y}|| \leq (\sum_{i=1}^{d} \mathbf{v}[i])||\mathbf{x}||$. The norm of reachable configurations is therefore bounded linearly in the norm of the initial one. As observed by Praveen and Lodaya [17], the norm of the vector $\mathbf{v}$ can be bounded thanks to a small solution theorem of Borosh and Treybig [1] in such a way the reachability problem for structurally bounded VAS is decidable in polynomial space. Based on the reduction of QBF to the reachability problem of structurally bounded VAS, Praveen and Lodaya deduced the following result.

▶ **Theorem 2** (Theorem 3.10 and Theorem 3.11 of [17])**.** *The reachability problem for structurally bounded VAS is polynomial-space complete.*

2.2 Vector Addition Systems With States

The previous approach no longer apply for structurally bounded vector addition systems with states. Formally, a *vector addition systems with states* (*VASS* for short) is a graph $G = (Q, \mathbf{A}, E)$ where Q is a non empty finite set of states, $\mathbf{A}$ is a VAS, and $E \subseteq Q \times \mathbf{A} \times Q$ is a finite set of *edges*. A *configuration* is a pair $(q, \mathbf{x})$ in $Q \times \mathbb{N}^d$ denoted as $q(\mathbf{x})$ in the sequel. The semantics of an edge e is defined thanks to the binary relation $\xrightarrow{e}$ over the configurations by $p(\mathbf{x}) \xrightarrow{e} q(\mathbf{y})$ if $e = (p, \mathbf{y} - \mathbf{x}, q)$. We associate to a word $\pi = e_1 \dots e_k$ of edges the binary relation $\xrightarrow{\pi}$ over the configurations defined as the following composition:

$$\xrightarrow{e_1} \cdots \xrightarrow{e_k}$$

Notice that $\xrightarrow{\varepsilon}$ is the identity binary relation. The *reachability relation* of a VASS G is the binary relation $\xrightarrow{*}$ defined as the union $\bigcup_{\pi \in E^*} \xrightarrow{\pi}$. A configuration $q(\mathbf{y})$ is said to be *reachable* from a configuration $p(\mathbf{x})$ if $p(\mathbf{x}) \xrightarrow{*} q(\mathbf{y})$.

The following lemma states the so-called *VASS monotony property*. We refer to that lemma when we mention a monotony property in the sequel.

▶ **Lemma 3.** *We have $p(\mathbf{x} + \mathbf{c}) \xrightarrow{\pi} q(\mathbf{y} + \mathbf{c})$ for every $p(\mathbf{x}) \xrightarrow{\pi} q(\mathbf{y})$ and for every $\mathbf{c} \in \mathbb{N}^d$.*

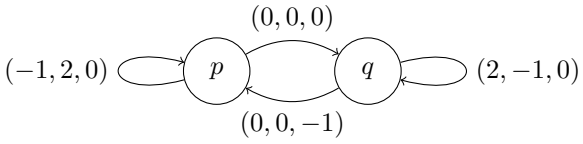
Proof. By induction on the length of π. ◀

We associate to a VASS $G = (Q, \mathbf{A}, E)$ the functions $\mathrm{src}, \mathrm{tgt} : E \to Q$ and $\Delta : E \to \mathbf{A}$ satisfying $e = (\mathrm{src}(e), \Delta(e), \mathrm{tgt}(e))$ for every $e \in E$. The states $\mathrm{src}(e)$ and $\mathrm{tgt}(e)$ are respectively called the *source* and *target* states. The vector $\Delta(e)$ is called the *displacement* of e. We extend the displacement function to words $\pi = e_1 \dots e_k$ of edges by $\Delta(\pi) = \Delta(e_1) + \cdots + \Delta(e_k)$. Given a sequence $\pi_1, \dots, \pi_k$ of words of edges, the vector $\Delta(\pi_1) + \cdots + \Delta(\pi_k)$ is also called the *displacement* of the sequence. A word $\pi = e_1 \dots e_k$ of edges is called a *path* of G from a state p to a state q, if there exists a sequence $q_0, \dots, q_k$ of states with $q_0 = p$ and $q_k = q$ such that $(\mathrm{src}(e_j), \mathrm{tgt}(e_j)) = (q_{j-1}, q_j)$ for every $1 \leq j \leq k$. A path is said to be *simple* if $q_i = q_j$ implies $i = j$. A *cycle* on a state q is a path from q to q. A cycle is said to be *elementary* if $q_i = q_j$ and $i < j$ implies $i = 0$ and $j = k$.

Let $T \subseteq E$ be a subset of edges. An edge e of T is said to be *recurrent* for T if there exists a path from $\mathrm{tgt}(e)$ to $\mathrm{src}(e)$ in T, otherwise, it is said to be *transient* for T. We denote by $\mathrm{rec}(T)$ the set of edges of T that are recurrent for T. The set T is said to be *reccurent* if every edge in T is recurrent, i.e. $\mathrm{rec}(T) = T$. We observe $\mathrm{rec}(T)$ is recurrent for any set

T. We associate to a subset T the equivalence relation $\sim_T$ over $\mathrm{rec}(T)$ defined by $e \sim_T e'$ if there exists a path from $\mathrm{tgt}(e)$ to $\mathrm{src}(e')$ and a path from $\mathrm{tgt}(e')$ to $\mathrm{src}(e)$. The equivalence classes of $\sim_T$ are called the strongly connected components of T, and they are denoted as $\mathcal{SCC}(T)$. The set T is said to be *strongly connected* if $\mathcal{SCC}(T) = \{T\}$. We also denote by $\mathcal{SCC}(G)$ the set $\mathcal{SCC}(E)$, and we say that G is strongly connected if E is strongly connected.

▶ **Example 4.** We adapt the VASS introduced in [6] by introducing the following VASS:



Notice that $p(1,0,n) \xrightarrow{*} p(4^n,0,0)$ for every natural number n since for every $n, m \in \mathbb{N}$ with $n \geq 1$, we have:

$$p(m,0,n) \xrightarrow{(p,(-1,2,0),p)^m (p,(0,0,0),q)(q,(2,-1,0),q)^{2m} (q,(0,0,-1),p)} p(4m,0,n-1)$$

A VASS G is said to be *bounded* from an initial configuration $p(\mathbf{x})$ if the reachability set from that configuration is finite. Let us recall that the boundedness problem is decidable in exponential space since the boundedness problem for VASS is logspace reducible to the boundedness for VAS using for instance the encoding of control states as additional counters [6]. A VASS is said to be *structurally bounded* if it is bounded from any initial configuration. Let us recall that a VASS G is not structurally bounded if, and only if, there exists a *cycle* σ such that $\Delta(\sigma) > \mathbf{0}$. Moreover, this property is decidable in polynomial time using the Kosaraju-Sullivan algorithm [8].

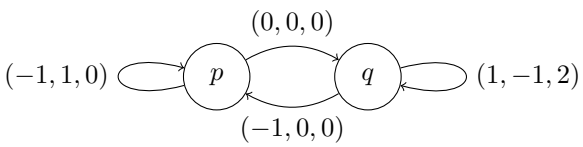
Example 4 shows that reachable configurations of structurally bounded VASS can be exponentially larger than the initial configuration. Unfortunately, it can even be larger by observing that the Ackermannian VASS introduced in [15] are structurally bounded. It follows that the best complexity upper bound for the reachability problem for structurally bounded VASS is Ackermannian. Concerning the lower bound, by observing that Lipton's construction [12, 3] also produces structurally bounded VASS, it follows that the reachability problem is exponential-space hard.

2.3 Polynomial VASS

In this paper we consider a subclass of the structurally bounded VASS, called the polynomial VASS.

▶ **Definition 5.** A VASS is said to be *polynomial* if there exists a polynomial function f such that $||\mathbf{y}|| \leq f(||\mathbf{x}||)$ for every $p(\mathbf{x}) \xrightarrow{*} q(\mathbf{y})$.

▶ **Example 6.** We introduce the following VASS:



We have $p(n,0,0) \xrightarrow{*} p(0,0,n^2+n))$ for every $n \in \mathbb{N}$ since for every $n, m \in \mathbb{N}$ with $m \geq 1$, we have:

$$p(m,0,n) \xrightarrow{(p,(-1,1,0),p)^m (p,(0,0,0),q)(q,(1,-1,2),q)^m (q,(-1,0,0),p)} p(m-1,0,n+2m)$$

We will prove in Example 13 that the VASS is polynomial.

▶ Remark. The VASS given in Example 4 is not polynomial.

We notice that since the Lipton's construction [12, 3] produces polynomial VASS, it follows that the reachability problem is exponential-space hard for polynomial VASS. In this paper we show that (1) we can decide in polynomial time if a VASS is polynomial, (2) the reachability problem is exponential-space complete for polynomial VASS.

3 Iteration Schemes

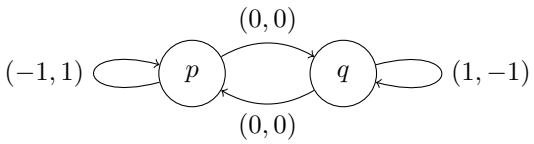
An *iteration scheme* of a VASS G is a finite sequence $\sigma_1, \ldots, \sigma_k$ of cycles such that:

$$\bigwedge_{j=1}^{k} \left[|\Delta(\sigma_j)|^- \subseteq |\Delta(\sigma_1) + \cdots + \Delta(\sigma_k)|^+ \right]$$

Observe that the displacement of an iteration scheme is necessarily a vector in $\mathbb{N}^d$. An index $i \in \{1, \ldots, d\}$ such that there exists an iteration scheme with a displacement strictly positive on i is called an *iterable index*. An edge t that occurs in an iteration scheme is called an *iterable edge*. By concatenating iteration schemes, notice that there exists an iteration scheme with a displacement strictly positive on every iterable index, and such that every iterable edge occurs in the scheme.

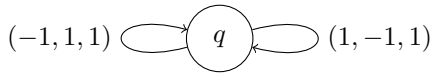
▶ **Example 7.** Let us come back to the VASS introduced in Example 4. Notice that the cycles $(p,(-1,2,0),p)$ and $(q,(2,-1,0),q)$ forms an iteration scheme with a displacement equal to $(1,1,0)$. It follows that the two first indexes are iterable.

▶ **Example 8.** We introduce the following VASS:



Notice that the cycles $(p,(-1,1),p)$ and $(q,(1,-1),q)$ do not form an iteration scheme.

▶ **Example 9.** We cannot restrict iteration schemes to sequences of *elementary* cycles. In fact, let us introduce the following VASS:



Notice that the cycle $(q,(-1,1,1),q)(q,(1,-1,1),q)$ is an iteration scheme proving that the third index is iterable. However notice that any non-empty sequence of elementary cycles is not an iteration scheme.

The following lemma shows that if a strongly connected VASS admits an iteration scheme with a non-zero displacement, then the VASS is not polynomial.

▶ **Lemma 10.** *For every strongly-connected VASS, there exists a rational number $\lambda > 1$ such that for every $n \in \mathbb{N}$ there exists an execution $p_n(\mathbf{x}_n) \xrightarrow{\pi_n} q_n(\mathbf{y}_n)$ such that:*

- $||\mathbf{x}_n|| \geq n$.
- $\mathbf{y}_n[i] \geq \lambda^{||\mathbf{x}_n||}$ *for every iterable index* i.
- *Every iterable edge occurs in* π_n *at least* $\lambda^{||\mathbf{x}_n||}$ *times.*

Proof. The proof is given in a technical report. Intuitively, iteration schemes can be iterated an exponential number of times. ◀

In section 6, we prove that conversely, indexes that are not iterable can be bounded with a polynomial, as well as non iterable edges occur at most a bounded polynomial number of times.

4 Kirchoff's Functions and Euler's Lemma

We recall some classical results about Kirchoff's functions and Euler's lemma. We assume that $G = (Q, \mathbf{A}, E)$ is a VASS.

A *multiset of edges* is a function $\phi : E \to \mathbb{N}$. The set $\{e \in E \mid \phi(e) \neq 0\}$ is called the *domain* of ϕ and it is denoted by $\mathrm{dom}(\phi)$. Given a subset $T \subseteq E$ and a multiset of edges ϕ, we denote by $\phi \cap T$ the multiset of edges defined as follows:

$$\phi \cap T(t) = \begin{cases} \phi(t) & \text{if } t \in T \\ 0 & \text{otherwise} \end{cases}$$

The *Parikh image* of a word π of edges is the multiset of edges ϕ such that $\phi(e)$ is the number of occurrences in π of e for every edge $e \in E$.

The displacement function Δ is extended over the multiset of edges ϕ by $\Delta(\phi) = \sum_{e \in E} \phi(e)\Delta(e)$. The vector $\Delta(\phi)$ are called the *displacement* of ϕ. Notice that if ϕ is the Parikh image of a word π of edges then $\Delta(\phi) = \Delta(\pi)$.

A *Kirchoff* function ϕ is a multiset of edges such that for every $q \in Q$:

$$\sum_{e \in E \mid \mathrm{tgt}(e) = q} \phi(e) = \sum_{e \in E \mid \mathrm{src}(e) = q} \phi(e)$$

Let us recall that a finite sum of Parikh images of cycles is a Kirchoff function and every Kirchoff function is a finite sum of Parikh images of elementary cycles. It follows that the domain of a Kirchoff function is recurrent. The *Euler's Lemma* claims that a Kirchoff function is the Parikh image of a cycle if, and only if, its domain is strongly connected.

5 Computing the Set of Iterable Indexes and Edges

In this section, we show that the set of iterable indexes and the set of iterable edges of a VASS $G = (Q, \mathbf{A}, E)$ are computable in polynomial time. Given a pair (I, T) where I is a subset of $\{1, \ldots, d\}$ and T is a subset of edges, a sequence $\sigma_1, \ldots, \sigma_k$ of cycles of T is called an (I, T)-constrained iteration scheme if

$$\bigwedge_{j=1}^{k} |\Delta(\sigma_j)|^- \subseteq |\Delta(\sigma_1) + \cdots + \Delta(\sigma_k)|^+ \subseteq I$$

We denote by $\Gamma(I,T)$ the pair (I',T') where I' is the set of indexes $i \in I$ such that there exists an (I,T)-constrained iteration scheme with a displacement strictly positive on i, and where T' is the set of edges that occurs in an (I,T)-constrained iteration scheme. Observe that $\Gamma(\{1,\dots,d\},E)$ is the pair (I',T') where I' is the set of iterable indexes and T' is the set of iterable edges.

We are going to compute $\Gamma(I,T)$ inductively by reducing the pair (I,T) into a pair (I',T') such that $\Gamma(I,T) = \Gamma(I',T')$ and such that $\Gamma(I,T) = (I,T)$ if it is not possible to reduce (I,T) anymore. Such an approach is similar to the one used by the Kosaraju-Sullivan algorithm [8, 2] for computing from a VASS the set of edges occurring in cycles with zero displacements. The pair (I',T') is obtained by computing $\Omega(I,T)$ defined as follows.

▶ **Definition 11.** Let (I,T) be a pair such that $I \subseteq \{1,\dots,d\}$ and $T \subseteq E$, and let us consider the following linear system over the variables $(\mu_i)_{i\in I}$ and $(\lambda_t)_{t\in T}$ ranging over the non-negative rational numbers:

$$\bigwedge_{q\in Q} \sum_{t\in T\mid \mathrm{tgt}(t)=q} \lambda_t = \sum_{t\in T\mid \mathrm{src}(t)=q} \lambda_t$$

$$\bigwedge_{S\in \mathcal{SCC}(T)} \bigwedge_{i\notin I} \sum_{t\in S} \lambda_t \Delta(t)[i] = 0$$

$$\bigwedge_{i\in I} \sum_{t\in T} \lambda_t \Delta(t)[i] = \mu_i$$

Then $\Omega(I,T)$ is defined as the pair (I',T') where:

- I' is the set of indexes $i \in I$ satisfying the previous linear system and $\mu_i > 0$, and
- T' is the set of edges $t \in T$ satisfying the previous linear system and $\lambda_t > 0$.

▶ **Example 12.** Let us come back to Example 4. We observe that $\Omega^n(\{1,2,3\},E)$ is equal to $(\{1,2\},E)$ if $n=1$, and it is equal to $(\{1,2\},\{(p,(-1,2,0),p),(q,(2,-1,0),q)\})$ if $n \geq 2$.

▶ **Example 13.** Let us come back to Example 6. We observe that $\Omega^n(\{1,2,3\},E)$ is equal to $(\{3\},E)$ if $n=1$, $(\{3\},\{(p,(-1,1,0),p),(q,(1,-1,2),q)\})$ if $n=2$, and $(\emptyset,\emptyset)$ if $n \geq 3$.

▶ **Example 14.** Let us come back to Example 8. We observe that $\Omega^n(\{1,2\},E)$ is equal to $(\emptyset,E)$ for every $n \geq 1$.

Notice that $\Omega(I,T)$ is computable in polynomial time and $\Omega(I,T)$ reduces the pair (I,T). The following lemma shows that this reduction let unchanged the value of $\Gamma(I,T)$.

▶ **Lemma 15.** *We have* $\Gamma(I,T) = \Gamma(\Omega(I,T))$.

Proof. Let $(I',T') = \Omega(I,T)$. Since $(I',T') \subseteq (I,T)$ we get $\Gamma(I',T') \subseteq \Gamma(I,T)$. For the converse inclusion, we just have to prove that any (I,T)-constrained iteration scheme $\sigma_1,\dots,\sigma_k$ is an (I',T')-constrained iteration scheme. Let ϕ_j be the Parikh image of σ_j, and let $\phi = \sum_{j=1}^{k} \phi_j$. Notice that $(\mu_i)_{i\in I}$ and $(\lambda_t)_{t\in T}$ defined as $\mu_i = \Delta(\phi)[i]$ and $\lambda_t = \phi(t)$ is a solution of the linear system introduced in Definition 11. It follows that $\mu_i > 0$ implies $i \in I'$ and $\lambda_t > 0$ implies $t \in T'$. Hence $\sigma_1,\dots,\sigma_k$ is an (I',T')-constrained iteration scheme. ◀

Finally, the following lemma shows that $\Gamma(I,T)$ is equal to (I,T) if (I,T) cannot be reduced anymore.

▶ **Lemma 16.** *We have* $\Gamma(I,T) = (I,T)$ *if, and only if,* $\Omega(I,T) = (I,T)$.

Proof. Assume that $\Gamma(I,T) = (I,T)$. Lemma 15 shows that $\Omega(I,T) = (I,T)$. Conversely, assume that $\Omega(I,T) = (I,T)$. By adding many solutions of the linear system introduced in Definition 11, we obtain a solution $(\mu_i)_{i\in I}$ and $(\lambda_t)_{t\in T}$ such that $\mu_i > 0$ for every $i \in I$ and $\lambda_t > 0$ for every $t \in T$. By multiplying that solution by a large natural number, we can assume that the solution is over the natural numbers. Now, just notice that the multiset of edges ϕ defined by $\phi(t) = \lambda_t$ if $t \in T$ and $\phi(t) = 0$ otherwise is a Kirchoff function satisfying $\mathrm{dom}(\phi) = T$, $|\Delta(\phi)|^+ = I$, and such that $\Delta(\phi \cap S)[i] = 0$ for every $S \in \mathcal{SCC}(T)$ and for every $i \notin I$, and such that $\Delta(\phi)[i] \geq 0$ for every $i \in I$. Euler's Lemma shows that for every $S \in \mathcal{SCC}(T)$, there exists a cycle σ_S with a Parikh image equal to $\phi \cap S$. Notice that $|\Delta(\sigma_S)|^- = |\Delta(\phi \cap S)|^- \subseteq I$. Moreover $|\sum_S \Delta(\sigma_S)|^+ = I$. It follows that $(\sigma_S)_{S\in\mathcal{SCC}(T)}$ is an (I,T)-constrained iteration scheme. This scheme shows that $(I,T) \subseteq \Gamma(I,T)$. Therefore $\Gamma(I,T) = (I,T)$. ◀

Now, let us introduce $\Omega^\infty(I,T) = \bigcap_{n\in\mathbb{N}} \Omega^n(I,T)$. Since $(\Omega^n(I,T))_{n\in\mathbb{N}}$ is a non-increasing sequence, there exists $n \leq |I|.|T|$ such that $\Omega^{n+1}(I,T) = \Omega^n(I,T)$ and for such an n, we have $\Omega^\infty(I,T) = \Omega^n(I,T)$. We deduce that $\Omega^\infty(I,T)$ is computable in polynomial time. Moreover, from Lemma 15 and Lemma 16, we deduce that $\Gamma(I,T) = \Omega^\infty(I,T)$. We have proved the following theorem.

▶ **Theorem 17.** *Iterable indexes and iterable edges are computable in polynomial time.*

6 Non-iterable case

In this section we prove the following theorem.

▶ **Theorem 18.** *Let $G = (Q, \mathbf{A}, E)$ be a strongly connected VASS. For every $p(\mathbf{x}) \xrightarrow{\pi} q(\mathbf{y})$, the values $\mathbf{y}[i]$ where i is a non iterable index, and the number of occurrences of non iterable edges in π are bounded by:*

$$[(1 + ||\mathbf{x}||)^2 d^2 (3||\mathbf{A}||\,|Q|)^{15d^4}]^{4^{d|E|}}$$

We are now ready for proving the following lemma.

▶ **Lemma 19.** *Let $G = (Q, \mathbf{A}, E)$ be a VASS such that $||\mathbf{A}|| \geq 1$, $I \subseteq \{1, \ldots, d\}$, and T be a recurrent set of edges. We consider a path π such that $p(\mathbf{x}) \xrightarrow{\pi} q(\mathbf{y})$. Let $m \geq 1$ satisfying:*

- *The number of occurrences in π of edges not in T is bounded by m, and*
- *$\mathbf{x}[i] + \Delta(\pi')[i] \leq m$ for every every prefix π' of π and for every $i \notin I$.*

Then m', I', T' defined as follows:

$$m' = m^4(1 + ||\mathbf{x}||)^2 d^2 (3\mu)^{15d^4}$$
$$(I', T') = \Omega(I, T)$$

Where $\mu = ||\mathbf{A}||\,|Q|$ satisfies:

- *The number of occurrences in π of edges not in T' is bounded by m', and*
- *$\mathbf{x}[i] + \Delta(\pi')[i] \leq m'$ for every every prefix π' of π and for every $i \notin I'$.*

Proof. Notice that it is sufficient to prove that the number of occurrences in π of edges not in T' is bounded by m', and $\mathbf{y}[i] \leq m'$ for every $i \notin I'$. In fact, the more general bound $\mathbf{x}[i] + \Delta(\pi')[i] \leq m'$ for every prefix π' of π and for every $i \notin I'$ can be obtained as a corollary.

Let k be the number of occurrences in π of edges not in T. It follows that π can be decomposed into: $\pi = \pi_0 t_1 \pi_1 \ldots t_k \pi_k$ where $\pi_0, \ldots, \pi_k$ are paths in T and $t_1, \ldots, t_k$ are not in T. We introduce the sequences $(p_j(\mathbf{x}_j))_{1\leq j\leq k}$ and $(q_j(\mathbf{y}_j))_{0\leq j\leq k}$ of configurations such

that $p_j(\mathbf{x}_j) \xrightarrow{\pi_j} q_j(\mathbf{y}_j)$ for every $0 \leq j \leq k$, $q_{j-1}(\mathbf{y}_{j-1}) \xrightarrow{t_j} p_j(\mathbf{x}_j)$ for every $1 \leq j \leq k$, and such that $p_0(\mathbf{x}_0) = p(\mathbf{x})$ and $q_k(\mathbf{y}_k) = q(\mathbf{y})$. Notice that $\mathbf{x}_j[i], \mathbf{y}_j[i] \leq m$ for every $i \notin I$ and for every $0 \leq j \leq k$ since $\mathbf{x}_j$ and $\mathbf{y}_j$ can be obtained trivially as vectors of the form $\mathbf{x} + \Delta(\pi')$ for some prefixes π' of π.

Let us observe that since π_j is a path in T and since T is recurrent, it follows that there exists $S_j \in \mathcal{SCC}(T)$ such that π_j is a path in S_j. We decompose the Parikh image α_j of π_j into $\alpha_j = \phi_j + \sum_{\ell \in L_j} \psi_{j,\ell}$ where ϕ_j is the Parikh image of a simple path in S_j, and $\psi_{j,\ell}$ is a Parikh image of an elementary cycle in S_j for every ℓ in a finite set L_j.

We introduce the set $\mathbf{Z}$ of displacements of elementary cycles. Notice that $||\mathbf{Z}|| \leq \mu$. We associate to each $S \in \mathcal{SCC}(T)$ and each $\mathbf{z} \in \mathbf{Z}$ the cardinal $n_{S,\mathbf{z}}$ of the set $\bigcup_{j|S_j=S}\{(j,\ell) \mid \ell \in L_j \wedge \Delta(\psi_{j,\ell}) = \mathbf{z}\}$. Observe that for every S, we have:

$$\begin{aligned}\sum_{\mathbf{z}\in\mathbf{Z}} n_{S,\mathbf{z}}\mathbf{z} &= \sum_{j|S_j=S} \sum_{\ell\in L_j} \Delta(\psi_{j,\ell}) \\ &= \sum_{j|S_j=S} \Delta(\alpha_j) - \Delta(\phi_j) \\ &= \sum_{j|S_j=S} (\mathbf{y}_j - \mathbf{x}_j - \Delta(\phi_j))\end{aligned}$$

It follows that for every $i \notin I$, we have:

$$|\sum_{\mathbf{z}\in\mathbf{Z}} n_{S,\mathbf{z}}\mathbf{z}[i]| \leq (k+1)(m + |Q|||\mathbf{A}||) \leq 2m(2m\mu) \leq 4m^2\mu(1 + ||\mathbf{x}||)$$

Moreover, we have:

$$\begin{aligned}\sum_{S\in\mathcal{SCC}(T)} \sum_{\mathbf{z}\in\mathbf{Z}} n_{S,\mathbf{z}}\mathbf{z} &= \sum_{j=0}^{k} (\mathbf{y}_j - \mathbf{x}_j - \Delta(\phi_j)) \\ &= \sum_{j=0}^{k} (\mathbf{y}_j - \mathbf{x}_j) + \sum_{j=1}^{k} \Delta(t_j) - \sum_{j=0}^{k} \Delta(\phi_j) - \sum_{j=1}^{k} \Delta(t_j) \\ &= \mathbf{y} - \mathbf{x} - \sum_{j=0}^{k} \Delta(\phi_j) - \sum_{j=1}^{k} \Delta(t_j)\end{aligned}$$

If follows that for every i, we have:

$$\begin{aligned}\sum_{S\in\mathcal{SCC}(T)} \sum_{\mathbf{z}\in\mathbf{Z}} n_{S,\mathbf{z}}\mathbf{z}[i] &\geq -(||\mathbf{x}|| + (k+1)(|Q|-1)||\mathbf{A}|| + k||\mathbf{A}||) \\ &\geq -3m\mu(1 + ||\mathbf{x}||) \geq -4m^2\mu(1 + ||\mathbf{x}||)\end{aligned}$$

Let us introduce $\delta = |\mathcal{SCC}(T)|(4m^2\mu(1 + ||\mathbf{x}||)d)^2(3\mu)^{9d^4}$. Notice that $\delta \leq m^4(1 + ||\mathbf{x}||)^2 d^2 (3\mu)^{12d^4}$. Lemma 20 shows that there exists a sequence of natural numbers $(m_{S,\mathbf{z}})_{S,\mathbf{z}}$ such that:

- $\sum_{\mathbf{z}\in\mathbf{Z}} m_{S,\mathbf{z}}\mathbf{z}[i] = \mathbf{0}$ for every S, and every $i \notin I$.
- $\sum_S \sum_{\mathbf{z}\in\mathbf{Z}} m_{S,\mathbf{z}}\mathbf{z} \geq \mathbf{0}$
- $n_{S,\mathbf{z}} > \delta$ implies $m_{S,\mathbf{z}} > 0$,
- $\sum_S \sum_{\mathbf{z}\in\mathbf{Z}} n_{S,\mathbf{z}}\mathbf{z}[i] > \delta$ implies $\sum_S \sum_{\mathbf{z}\in\mathbf{Z}} m_{S,\mathbf{z}}\mathbf{z}[i] > 0$.

It follows that:

- if $n_{S,\mathbf{z}} > \delta$ then every simple cycle of S with a displacement equal to $\mathbf{z}$ is a simple cycle of T', and

- if $\mathbf{y}[i] > ||\mathbf{x}|| + \delta + m + (k+1)(|Q|-1)||\mathbf{A}|| + k||\mathbf{A}||$ then $i \in I'$.

It follows that $\mathbf{y}[i] \leq ||\mathbf{x}|| + \delta + 3m\mu \leq 3\delta \leq m'$ for every $i \notin I'$. Moreover, it follows that for every S, the number of occurrences of cycles $\psi_{j,\ell}$ with j such that $S_j = S$, and $\ell \in L_j$ such that $\mathrm{dom}(\psi_{j,\ell}) \not\subseteq T'$ is bounded by $|\mathbf{Z}|\delta \leq m^4(1+||\mathbf{x}||)^2 d^2 (3\mu)^{13d^4}$. It follows that the number of occurrences of edges not in T' in π is bounded by $k+|\mathcal{SCC}(T)|.|Q|.m^4(1+||\mathbf{x}||)^2 d^2 (3\mu)^{13d^4} \leq m^4(1+||\mathbf{x}||)^2 d^2 (3\mu)^{15d^4} = m'$. ◀

The proof of the previous lemma was based on the following one, a kind of "small solution" theorem [16].

▶ **Lemma 20.** *Let $(n_{s,\mathbf{z}})_{s,\mathbf{z}}$ be a sequence of natural numbers indexes by s in a non-empty finite set S, and by $\mathbf{z}$ in a finite subset $\mathbf{Z} \subseteq \{-\mu, \ldots, \mu\}^d$ for some $\mu \geq 1$. Let $I \subseteq \{1, \ldots, d\}$ and $m \geq 1$ such that:*

- $|\sum_{\mathbf{z}\in\mathbf{Z}} n_{s,\mathbf{z}}\mathbf{z}[i]| \leq m$ *for every* $s \in S$ *and for every* $i \notin I$, *and*
- *The vector* $\mathbf{v}$ *defined as* $\sum_{s\in S}\sum_{\mathbf{z}\in\mathbf{Z}} n_{s,\mathbf{z}}\mathbf{z}$ *satisfies* $\mathbf{v}[i] \geq -m$ *for every* $i \in \{1, \ldots, d\}$.

There exists a sequence $(m_{s,\mathbf{z}})_{\mathbf{z}\in\mathbf{Z},s\in S}$ of natural numbers such that:

- $\sum_{\mathbf{z}\in\mathbf{Z}} m_{s,\mathbf{z}}\mathbf{z}[i] = 0$ *for every* $s \in S$ *and for every* $i \notin I$, *and*
- *The vector* $\mathbf{w}$ *defined as* $\sum_{s\in S}\sum_{\mathbf{z}\in\mathbf{Z}} m_{s,\mathbf{z}}\mathbf{z}$ *satisfies* $\mathbf{w} \geq \mathbf{0}$

and such that $\delta = |S|(md)^2(3\mu)^{9d^4}$ satisfies:

- *If* $n_{s,\mathbf{z}} > \delta$ *then* $m_{s,\mathbf{z}} > 0$, *and*
- *If* $\mathbf{v}[i] > \delta$ *then* $\mathbf{w}[i] > 0$.

Proof. The proof is based on an application of a "small solution" theorem of Pottier [16] on each $s \in S$, and then, on the resulting solutions we apply again the "small solution" theorem for extracting solutions satisfying $\mathbf{w} \geq \mathbf{0}$. ◀

Let us consider $p(\mathbf{x}) \xrightarrow{\pi} q(\mathbf{y})$ and let $(I_n, T_n) = \Omega^n(\{1, \ldots, d\}, E)$. We introduce for every n the minimal number $m_n \geq 1$ such that the number of occurrences of edges in π that are not in T_n is bounded by m_n, and $\mathbf{x}[i] + \Delta(\pi')[i] \leq m_n$ for every $i \notin I_n$ and for every prefix π' of π. Notice that $m_0 = 1$, and Lemma 19 shows that for every $n \geq 0$:

$$m_{n+1} \leq m_n^4(1+||\mathbf{x}||)^2 d^2 (3\mu)^{15d^4}$$

Let us introduce the sequence $(s_n)_{n\geq 0}$ defined by $s_0 = 1$, and the induction for every $n \in \mathbb{N}$:

$$s_{n+1} = s_n^4.(1+||\mathbf{x}||)^2 d^2 (3\mu)^{15d^4}$$

Observe that $m_n \leq s_n$ for every n. Moreover, we have:

$$s_n = [(1+||\mathbf{x}||)^2.d^2(3\mu)^{15d^4}]^{4^n-1}$$

Since $\Gamma(\{1, \ldots, d\}, E) = \Omega^\infty(\{1, \ldots, d\}, E) = \Omega^{d|E|}(\{1, \ldots, d\}, E)$, we have proved Theorem 18.

7 Applications

Theorem 18 shows that a strongly connected VASS without iterable indexe is polynomial. Combined with Lemma 10, we deduce the following characterization.

▶ **Theorem 21.** *A strongly connected VASS is polynomial if, and only if, its set of iterable indexes is empty.*

As a direct consequence of Theorems 21 and 17 and the following Lemma 22, we get the following Theorem 23. Note that the restriction of a VASS $G = (Q, \mathbf{A}, E)$ to a subset $T \subseteq E$ of edges is defined as the VASS $G|_T = (Q, \mathbf{A}, T)$.

▶ **Lemma 22.** *A VASS is polynomial if, and only if, its restriction to every SCC is polynomial.*

Proof. The proof is given in a technical report. ◀

▶ **Theorem 23.** *We can decide in polynomial-time if a VASS is polynomial.*

Moreover, since Theorem 18 shows that reachable configurations are bounded exponentially in space, we derive the following result.

▶ **Theorem 24.** *The reachability problem for polynomial VASS is exponential-space complete.*

Proof. Theorem 18 shows that reachable configurations are bounded exponentially in space. It follows that the reachability problem is decidable in exponential space. We have already observed the lower bound in Section 2.2. ◀

8 Conclusion

In this paper we introduced the class of polynomial VASS and showed that the membership problem of a VASS in that class is decidable in polynomial time. Moreover, we proved that the reachability problem for polynomial VASS is exponential-space complete. Our characterization of polynomial VASS is based on the notion of iteration schemes. Intuitively, whereas a cycle of a VASS with a non-negative displacement can be iterated an arbitrarily number of times to obtain arbitrarily large values on indexes that are strictly increased by the cycle, iteration schemes can be iterated an exponential number of times and provide a way to increase by an exponential number every index that is increased by the iteration scheme. As a future work, we are interested in using iteration schemes rather than iterable cycles in the KLM algorithm to hopefully obtain better complexity upper bound for the reachability problem for general vector addition systems.

Abstract

Given a Counting Monadic Second Order (CMSO) sentence ψ, the CMSO[ψ] problem is defined as follows. The input to CMSO[ψ] is a graph G, and the objective is to determine whether $G \models \psi$. Our main theorem states that for every CMSO sentence ψ, if CMSO[ψ] is solvable in polynomial time on "globally highly connected graphs", then CMSO[ψ] is solvable in polynomial time (on general graphs). We demonstrate the utility of our theorem in the design of parameterized algorithms. Specifically we show that technical problem-specific ingredients of a powerful method for designing parameterized algorithms, recursive understanding, can be replaced by a black-box invocation of our main theorem. We also show that our theorem can be easily deployed to show fixed parameterized tractability of a wide range of problems, where the input is a graph G and the task is to find a connected induced subgraph of G such that "few" vertices in this subgraph have neighbors outside the subgraph, and additionally the subgraph has a CMSO-definable property.

1 Introduction

Algorithmic meta-theorems are general algorithmic results applicable to a whole range of problems. Many prominent algorithmic meta-theorems are about model checking; such theorems state that for certain kinds of logic L, and all classes $\mathcal{C}$ that have a certain property,

there is an algorithm that takes as input a formula $\phi \in L$ and a structure $S \in \mathcal{C}$ and efficiently determines whether $S \models \phi$. Results in this direction include the seminal theorem of Courcelle [8, 7, 9] for model checking Monadic Second Order Logic (MSO) on graphs of bounded treewidth (see also [1, 2, 4, 10, 14]), as well as a large body of work on model checking first-order (FO) logic [5, 12, 16, 18, 19, 21, 20, 23, 28].

Another kind of algorithmic meta-theorems *reduce* the task of designing one type of algorithm for a problem, to one of designing a different kind of algorithm for the same problem. The hope is, of course, that the second type of algorithms are significantly easier to design than the first. A prototype example of such results is *Bidimensionality* [13], which reduces the design of sub-exponential time parameterized algorithms for a problem on planar (or H-minor free) graphs, to the design of single exponential time algorithms for the same problem when parameterized by the treewidth of the input graph.

In this paper we prove a result of the second type for model checking Counting Monadic Second Order Logic (CMSO), an extension of MSO with atomic sentences for determining the cardinality of vertex and edge sets modulo any (fixed) integer. For every CMSO sentence ψ define the CMSO[ψ] problem as follows. The input is a graph G on n vertices, and the task is to determine whether $G \models \psi$.

Our main result states that for every CMSO sentence ψ, if there is a $\mathcal{O}(n^d)$ time algorithm ($d > 4$) for CMSO[ψ] for the special case when the input graph is required to be "highly connected everywhere", then there is a $\mathcal{O}(n^d)$ time algorithm for CMSO[ψ] without any restrictions. In other words, our main theorem reduces CMSO model checking to model checking the same formula on graphs which are "highly connected everywhere".

In order to complete the description of our main result we need to define what we mean by "highly connected everywhere". For two integers s and c, we say that a graph G is (s, c)-*unbreakable* if there does not exist a partition of the vertex set into three sets X, C, and Y such that

- C is a separator: there are no edges from X to Y,
- C is small: $|C| \leq c$, and
- X and Y are large: $|X|, |Y| \geq s$.

For example, the set of $(1, c)$-unbreakable graphs contains precisely the $(c + 1)$-connected graphs, i.e. the connected graphs for which removing any set of at most c vertices leaves the graph connected. We can now state our main result:

▶ **Theorem 1.** *Let ψ be a CMSO sentence. For all $c \in \mathbb{N}$, there exists $s \in \mathbb{N}$ such that if there exists an algorithm that solves* CMSO[ψ] *on (s, c)-unbreakable graphs in time $\mathcal{O}(n^d)$ for some $d > 4$, then there exists an algorithm that solves* CMSO[ψ] *on general graphs in time $\mathcal{O}(n^d)$.*

For Theorem 1 to be useful, there must exist problems that can be formulated in CMSO, for which it is easier to design algorithms for the special case when the input graphs are unbreakable, than it is to design algorithms that work on general graphs. Such problems can be found in abundance in *parameterized complexity*. Indeed, the *recursive understanding* technique, which has been used to solve several problems [6, 22, 24, 25, 27, 26] in parameterized complexity, is based precisely on the observation that for many graph problems it is much easier to design algorithms if the input graph can be assumed to be unbreakable.

Designing algorithms using the recursive understanding technique typically involves a technical and involved argument akin to doing dynamic programming on graphs of bounded treewidth (see Chitnis et al. [6] for an exposition). These arguments reduce the original problem on general graphs to a generalized version of the problem on (s, c)-unbreakable

graphs, for appropriate values of s and c. Then an algorithm is designed for this generalized problem on (s, c)-unbreakable graphs, yielding an algorithm for the original problem.

For all applications of the recursive understanding technique known to the authors [6, 22, 24, 25, 27, 26], the problem in question (in which recursive understanding has been applied) can be formulated as a CMSO model checking problem, and therefore, the rather cumbersome application of recursive understanding can be completely replaced by a black box invocation of Theorem 1. Using Theorem 1 in place of recursive understanding has the additional advantage that it reduces problems on general graphs to *the same* problem on unbreakable graphs, facilitating also the last step of designing an algorithm on unbreakable graphs.

As an example of the power of Theorem 1 we use it to give a fixed parameter tractable (FPT) algorithm for the Vertex Multiway Cut Uncut problem. Details can be found in the full version of the paper on arXiv.org. Here, we are given a graph G together with a set of terminals $T \subseteq V(G)$, an equivalence relation $\mathcal{R}$ on the set T, and an integer k, and the objective is to test whether there exists a set $S \subseteq V(G) \setminus T$ of at most k vertices such that for any $u, v \in T$, the vertices u and v belong to the same connected component of $G \setminus S$ if and only if $(u, v) \in \mathcal{R}$. Since finding the desired set S satisfying the above property can be formulated in CMSO, we are able to completely sidestep the necessity to define a technically involved annotated version of our problem, and furthermore, we need only focus on the base case where the graph is unbreakable. To solve the base case, a simple procedure that is based on the enumeration of connected sets with small neighborhood is sufficient. For classification purposes, our approach is significantly simpler than the problem-specific algorithm in [6]. Finally, we show how Theorem 1 can be effortlessly deployed to show fixed parameterized tractability of a wide range of problems, where the input is a graph G and the task is to find a connected induced subgraph of G of bounded treewidth such that "few" vertices outside this subgraph have neighbors inside the subgraph, and additionally the subgraph has a CMSO-definable property.

Our techniques. The proof of Theorem 1 is based heavily on the idea of graph replacement, which dates back to the work of Fellows and Langston [17]. We combine this idea with Courcelle's theorem [8, 7, 9], which states that every CMSO-definable property σ has finite state on a bounded-size separation/boundary. In other words, for any CMSO-definable property σ and fixed $t \in \mathbb{N}$, there is an equivalence relation defined on the set of all t-boundaried graphs (graphs with a set of at most t distinguished vertices) with a finite number, say ζ (where ζ depends only on σ and t) of equivalence classes such that if we replace any t-boundaried subgraph H of the given graph G with another t-boundaried graph, say H', from the same equivalence class to obtain a graph G', then G has the property σ if and only if G' has the property σ. In case of (s, c)-unbreakable graphs, $t = 2c$. Let $R_1, \ldots, R_\zeta$ denote a set containing one " minimal" $2c$-boundaried graph from each equivalence class (for the fixed CMSO-definable property σ). Let r denote the size of the largest among these minimal representatives.

The main technical content of our paper is in the description of an algorithm for a generalization of our question. To be precise, we will describe how one can, given a $2c$-boundaried graph G, locate the precise equivalence class in which G is contained and how one could compute the corresponding smallest representative from the set $\{R_1, \ldots, R_\zeta\}$. We refer to this task as "understanding" G.

In order to achieve our objective, we first give an algorithm $\mathcal{A}$ that allows one to understand $2c$-boundaried $(s - r, c)$-unbreakable graphs (for a choice of s which is sufficiently

large compared to r and c). This algorithm is built upon the following observation. The equivalence class of any $2c$-boundaried graph G is determined exactly by the subset of $\{G \oplus R_1, G \oplus R_2, \ldots, G \oplus R_\zeta\}$ on which σ evaluates to true. Here, the graph $G \oplus R_i$ is the graph obtained by taking the disjoint union of the graphs G and R_i and then identifying the vertices of the boundaries of these graphs with the same label. Since s is chosen to be sufficiently large compared to c and r, it follows that for every $i \in \{1, \ldots, \zeta\}$, the graph $G \oplus R_i$ is (s, c)-unbreakable and we can use the assumed algorithm for CMSO$[\psi]$ on (s, c)-unbreakable graphs to design an algorithm that *understands* $2c$-boundaried $(s - r, c)$-unbreakable graphs. This constitutes the 'base case' of our main algorithm.

In order to understand a general ($(s - r, c)$-breakable) $2c$-boundaried graph, we use known algorithms from [6] to compute a partition of the vertex set of G into X, C, and Y such that C is a separator, $|C| \leq c$ and $|X|, |Y| \geq \frac{s-r}{2^c}$. Let $G_1 = G[X \cup C]$ and let $G = G[Y \cup C]$. Without loss of generality, we may assume that at most half the vertices in the boundary of G lie in $X \cup C$. Consequently, the graph G_1 is a $2c$-boundaried graphs where the boundary vertices are the vertices in C along with the boundary vertices of G contained in $X \cup C$. We then recursively understand the strictly smaller $2c$-boundaried graph G_1 to find its representative $\hat{R} \in \{R_1, \ldots, R_\zeta\}$. Since the evaluation of σ on G is the same as the evaluation of σ on $G_2 \oplus \hat{R}$ (where the gluing happens along C), we only need to understand the $2c$-boundaried graph $G_2 \oplus \hat{R}$ (where the boundary is carefully defined from that of G and $\hat{R}$) and we do this by recursively executing the "understand" algorithm on this graph.

At this point we also need to remark on two drawbacks of Theorem 1. The first is that Theorem 1 is *non-constructive*. Given an algorithm for CMSO$[\psi]$ on (s, c)-unbreakable graphs, Theorem 1 allows us to infer the existence of an algorithm for CMSO$[\psi]$ on general graphs, but it does not provide us with the actual algorithm. This is due to the subroutine $\mathcal{S}$ requiring a representative $2c$-boundaried subgraph for each equivalence class, to be part of its 'source code'. Thus, the parameterized algorithms obtained using Theorem 1 are *non-uniform* (see Section 4), as opposed to the algorithms obtained by recursive understanding.

The second drawback is that Theorem 1 incurs a gargantuan constant factor overhead in the running time, where this factor depends on the formula ψ and the cut size c. We leave removing these two drawbacks as intriguing open problems.

2 Preliminaries

In order to present a rigorous proof of our lemmas in a way that is consistent with existing notation used in related work, we follow the notation from the paper [3].

Graphs and treewidth. Throughout this paper, we use the term "graph" to refer to a multigraph rather than only a simple graph. Given a graph G, we let $V(G)$ and $E(G)$ denote the vertex and edge sets of G, respectively. When G is clear from the context, we denote $n = |V(G)|$ and $m = |E(G)|$. Given two subsets of $V(G)$, A and B, we let $E(A, B)$ denote the set of edges of G with one endpoint in A and the other endpoint in B. Given $U \subseteq V(G)$, we let $G[U]$ denote the subgraph of G induced by U, and we let $N(U)$ and $N[U]$ denote the open and closed neighborhoods of U, respectively. Moreover, we denote $G \setminus U = G[V(G) \setminus U]$. Given $v \in V(G)$, we denote $N(v) = N(\{v\})$ and $N[v] = N[\{v\}]$. Given $E \subseteq E(G)$, we denote $G \setminus E = (V(G), E(G) \setminus E)$. Moreover, we let $V[E]$ denote the set of every vertex in $V(G)$ that is incident to at least one edge in E, and we define $G[E] = (V[E], E)$. A graph G is a *cluster graph* if there exists a partition $(V_1, V_2, \ldots, V_r)$ of $V(G)$ for some $r \in \mathbb{N}_0$ of $V(G)$ such that for all $i \in [r]$, $G[V_i]$ is a clique, and for all $j \in [r] \setminus \{i\}$, $E(V_i, V_j) = \emptyset$.

▶ **Definition 2.** A *tree decomposition* of a graph G is a pair (T, β) of a tree T and $\beta : V(T) \to 2^{V(G)}$, such that (a) $\bigcup_{t \in V(T)} \beta(t) = V(G)$, and (b) for any edge $e \in E(G)$, there exists a node $t \in V(T)$ such that both endpoints of e belong to $\beta(t)$, and (c) for any vertex $v \in V(G)$, the subgraph of T induced by the set $T_v = \{t \in V(T) : v \in \beta(t)\}$ is a tree.

The *width* of (T, β) is $\max_{v \in V(T)}\{|\beta(v)|\} - 1$. The *treewidth* of G is the minimum width of a tree decomposition of G.

Unbreakability. To formally introduce the notion of unbreakability, we rely on the definition of a separation:

▶ **Definition 3** (Separation)**.** A pair (X, Y) where $X \cup Y = V(G)$ is a *separation* if $E(X \setminus Y, Y \setminus X) = \emptyset$. The order of (X, Y) is $|X \cap Y|$.

Roughly speaking, a graph is breakable if it is possible to "break" it into two large parts by removing only a small number of vertices. Formally,

▶ **Definition 4** ((s, c)-Unbreakable graph)**.** Let G be a graph. If there exists a separation (X, Y) of order at most c such that $|X \setminus Y| > s$ and $|Y \setminus X| > s$, called an (s, c)-*witnessing separation*, then G is (s, c)-*breakable*. Otherwise, G is (s, c)-*unbreakable*.

The following lemma implies that it is possible to determine (approximately) whether a graph is unbreakable or not, and lemmata similar to it can be found in [6].

▶ **Lemma 5.** *There exists an algorithm,* Break-ALG*, that given $s, c \in \mathbb{N}$ and a graph G, in time $2^{\mathcal{O}(c \log(s+c))} \cdot n^3 \log n$ either returns an $(\frac{s}{2^c}, c)$-witnessing separation or correctly concludes that G is (s, c)-unbreakable.*

Boundaried Graphs. Roughly speaking, a boundaried graph is a graph where some vertices are labeled. Formally,

▶ **Definition 6** (Boundaried graph)**.** A *boundaried graph* is a graph G with a set $\delta(G) \subseteq V(G)$ of distinguished vertices called *boundary vertices*, and an injective labeling $\lambda_G : \delta(G) \to \mathbb{N}$. The set $\delta(G)$ is the *boundary* of G, and the *label set* of G is $\Lambda(G) = \{\lambda_G(v) \mid v \in \delta(G)\}$.

We remark that we also extend the definition of (s, c)-(un)breakability from graphs, to boundaried graphs in the natural way. That is, we ignore the boundary vertices when considering the existence of an (s, c)-witnessing separation. For ease of presentation, we sometimes abuse notation and treat equally-labeled vertices of different boundaried graphs, as well as the vertex that is the result of the identification of two such vertices, as the same vertex. Given a finite set $I \subseteq \mathbb{N}$, $\mathcal{F}_I$ denotes the class of all boundaried graphs whose label set is I, and $\mathcal{F}_{\subseteq I} = \bigcup_{I' \subseteq I} \mathcal{F}_{I'}$. A boundaried graph in $\mathcal{F}_{\subseteq [t]}$ is called a t-*boundaried* graph. Finally, $\mathcal{F}$ denotes the class of all boundaried graphs. The main operation employed to unite two boundaried graphs is the one that glues their boundary vertices together. Formally,

▶ **Definition 7** (Gluing by $\oplus$)**.** Let G_1 and G_2 be two boundaried graphs. Then, $G_1 \oplus G_2$ is the (not-boundaried) graph obtained from the disjoint union of G_1 and G_2 by identifying equally-labeled vertices in $\delta(G_1)$ and $\delta(G_2)$.[4]

[4] Each edge in G_1 (or G_2) whose endpoints are boundaried vertices in G_1 (or G_2) is preserved as a unique edge in $G_1 \oplus G_2$.

Structures. We first define the extension of graphs to *structures* in the context of our paper.

▶ **Definition 8** (Structure)**.** A *structure* α is a tuple whose first element is a graph, denoted by G_α, and each of the remaining elements is a subset of $V(G_\alpha)$, a subset of $E(G_\alpha)$, a vertex in $V(G_\alpha)$ or an edge in $E(G_\alpha)$. The number of elements in the tuple is the *arity* of the structure.

Given a structure α of arity p and an integer $i \in [p]$, we let $\alpha[i]$ denote the i'th element of α. Note that $\alpha[1] = G_\alpha$. By *appending* a subset S of $V(G_\alpha)$ (or $E(G_\alpha)$) to a structure α of arity p, we produce a new structure, denoted by $\alpha' = \alpha \diamond S$, of arity $p+1$ with the first p elements of α' being the elements of α and $\alpha'[p+1] = S$. For example, consider the structure $\alpha = (G_\alpha, S, e)$ of arity 3, where $S \subseteq V(G_\alpha)$ and $e \in E(G_\alpha)$. Let S' be some subset of $V(G_\alpha)$. Then, appending S' to α results in the structure $\alpha' = \alpha \diamond S' = (G_\alpha, S, e, S')$.

Next, we define the notions of a *type* of a structure and a *property* of structures.

▶ **Definition 9** (Type)**.** Let α be a structure of arity p. The *type* of α is a tuple of arity p, denoted by $\mathbf{type}(\alpha)$, where the first element, $\mathbf{type}(\alpha)[1]$, is graph, and for every $i \in \{2, 3, \ldots, p\}$, $\mathbf{type}(\alpha)[i]$ is vertex if $\alpha[i] \in V(G_\alpha)$, edge if $\alpha[i] \in E(G_\alpha)$, vertex set if $\alpha[i] \subseteq V(G_\alpha)$, and edge set otherwise.[5]

▶ **Definition 10** (Property)**.** A *property* is a function σ from the set of all structures to {true, false}.

Finally, we extend the notion of unbreakability to structures.

▶ **Definition 11** ((s,c)-Unbreakable structure)**.** Let α be a structure. If G_α is an (s,c)-unbreakable graph, then we say that α is an (s,c)-*unbreakable* structure, and otherwise we say that α is an (s,c)-*breakable* structure.

Counting Monadic Second Order Logic. The syntax of Monadic Second Order Logic (MSO) of graphs includes the logical connectives $\vee$, $\wedge$, $\neg$, $\Leftrightarrow$, $\Rightarrow$, variables for vertices, edges, sets of vertices and sets of edges, the quantifiers $\forall$ and $\exists$, which can be applied to these variables, and five binary relations: (a) $u \in U$, where u is a vertex variable and U is a vertex set variable; (b) $d \in D$, where d is an edge variable and D is an edge set variable; (c) $\mathbf{inc}(d, u)$, where d is an edge variable, u is a vertex variable, and the interpretation is that the edge d is incident to u; (d) $\mathbf{adj}(u, v)$, where u and v are vertex variables, and the interpretation is that u and v are adjacent; (e) equality of variables representing vertices, edges, vertex sets and edge sets.

Counting Monadic Second Order Logic (CMSO) extends MSO by including atomic sentences testing whether the cardinality of a set is equal to q modulo r, where q and r are integers such that $0 \leq q < r$ and $r \geq 2$. That is, CMSO is MSO with the following atomic sentence: $\mathbf{card}_{q,r}(S) = \mathbf{true}$ if and only if $|S| \equiv q \pmod r$, where S is a set. We refer to [2, 8, 9] for a detailed introduction to CMSO.

Evaluation. To evaluate a CMSO-formula ψ on a structure α, we instantiate the free variables of ψ by the elements of α. In order to determine which of the free variables of ψ are instantiated by which of the elements of α, we introduce the following conventions. First, each free variable x of a CMSO-formula ψ is associated with a rank, $r_x \in \mathbb{N} \setminus \{1\}$. Thus, a

[5] Note that we distinguish between a set containing a single vertex (or edge) and a single vertex (or edge).

CMSO-formula ψ can be viewed as a string accompanied by a tuple of integers, where the tuple consists of one integer r_x for each free variable x of ψ.

Given a structure α and a CMSO-formula ψ, we say that $\mathbf{type}(\alpha)$ *matches* ψ if **(i)** the arity of α is at least $\max r_x$, where the maximum is taken over each free variable x of ψ, and **(ii)** for each free variable x of ψ, $\mathbf{type}(\alpha)[r_x]$ is compatible with the type of x. For example, if x is a vertex set variable, then $\mathbf{type}(\alpha)[r_x] =$ vertex set. Finally, we say that α *matches* ψ if $\mathbf{type}(\alpha)$ matches ψ. Given a free variable x of a CMSO sentence ψ and a structure α that matches ψ, the element corresponding to x in α is $\alpha[r_x]$.

▶ **Definition 12.** [Property σ_ψ] Given a CMSO-formula ψ, the property σ_ψ is defined as follows. Given a structure α, if α does not match ψ, then $\sigma_\psi(\alpha)$ equals false, and otherwise $\sigma_\psi(\alpha)$ equals the result of the evaluation of ψ where each free variable x of ψ is instantiated by $\alpha[r_x]$.

Note that some elements of α may not correspond to any variable of ψ. However, ψ may still be evaluated on the structure α—in this case, the evaluation of ψ does not depend on all the elements of the structure. If the arity of α is 1, then we use $\sigma_\psi(G_\alpha)$ to denote $\sigma_\psi(\alpha)$.

▶ **Definition 13.** [CMSO-definable property] A property σ is *CMSO-definable* if there exists a CMSO-formula ψ such that $\sigma = \sigma_\psi$. In this case, we say that ψ *defines* σ.

Structures. The notion of a *boundaried structure* is an extension of the notion of a *boundaried graph* and is defined as follows.

▶ **Definition 14** (Boundaried structure)**.** A *boundaried structure* is a tuple whose first element is a boundaried graph G, denoted by G_α, and each of the remaining elements is a subset of $V(G)$, a subset of $E(G)$, a vertex in $V(G)$, an edge in $E(G)$, or the symbol $\star$. The number of elements in the tuple is the *arity* of the boundaried structure.

Given a boundaried structure α of arity p and an integer $i \in [p]$, we let $\alpha[i]$ denote the i'th element of α. We remark that we extend the definition of (s, c)-(un)breakability of structures, to boundaried structures.

▶ **Definition 15** (Type)**.** Let α be a boundaried structure of arity p. The *type* of α is a tuple of arity p, denoted by $\mathbf{type}(\alpha)$, where the first element, $\mathbf{type}(\alpha)[1]$, is boundaried graph, and for every $i \in \{2, 3, \ldots, p\}$, $\mathbf{type}(\alpha)[i]$ is vertex if $\alpha[i] \in V(G_\alpha)$, edge if $\alpha[i] \in E(G_\alpha)$, vertex set if $\alpha[i] \subseteq V(G_\alpha)$, edge set if $\alpha[i] \subseteq E(G_\alpha)$ and $\star$ otherwise.

Now, given a boundaried structure and a CMSO-formula ψ, we say that $\mathbf{type}(\alpha)$ *matches* ψ if **(i)** the arity of α is at least $\max r_x$, where the maximum is taken over each free variable x of ψ, and **(ii)** for each free variable x of ψ, $\mathbf{type}(\alpha)[r_x]$ is compatible with the type of x. Moreover, we say that α matches ψ if $\mathbf{type}(\alpha)$ *matches* ψ.

Given $p \in \mathbb{N}$, $\mathcal{A}^p$ denotes the class of all boundaried structures of arity p, and given a finite set $I \subseteq \mathbb{N}$, $\mathcal{A}^p_I$ ($\mathcal{A}^p_{\subseteq I}$) denotes the class of all boundaried structures of arity p whose boundaried graph belongs to $\mathcal{F}_I$ (resp. $\mathcal{F}_{\subseteq I}$). A boundaried structure in $\mathcal{A}^p_{\subseteq [t]}$ is called a *t-boundaried structure*. Finally, we let $\mathcal{A}$ denote the class of all boundaried structures.

▶ **Definition 16** (Compatiblity)**.** Two boundaried structures α and β are *compatible* (notationally, $\alpha \sim_c \beta$) if the following conditions are satisfied.

- α and β have the same arity p.
- For every $i \in [p]$:
  - $\mathbf{type}(\alpha)[i] = \mathbf{type}(\beta)[i] \neq \star$, or

  - $\mathbf{type}(\alpha)[i] \in \{\mathsf{vertex}, \mathsf{edge}\}$ and $\mathbf{type}(\beta)[i] = \star$, or
  - $\mathbf{type}(\beta)[i] \in \{\mathsf{vertex}, \mathsf{edge}\}$ and $\mathbf{type}(\alpha)[i] = \star$.
- For every $i \in [p]$ such that both $\alpha[i]$ and $\beta[i]$ are vertices: $\alpha[i] \in \delta(G_\alpha)$, $\beta[i] \in \delta(G_\beta)$ and $\lambda_{G_\alpha}(\alpha[i]) = \lambda_{G_\beta}(\beta[i])$.
- For every $i \in [p]$ such that both $\alpha[i]$ and $\beta[i]$ are edges: $\alpha[i] \in E(G_\alpha[\delta(G_\alpha)])$, $\beta[i] \in E(G_\beta[\delta(G_\beta)])$ and $\{\lambda_{G_\alpha}(x_{\alpha[i]}), \lambda_{G_\alpha}(y_{\alpha[i]})\} = \{\lambda_{G_\beta}(x_{\beta[i]}), \lambda_{G_\beta}(y_{\beta[i]})\}$, where $\alpha[i] = (x_{\alpha[i]}, y_{\alpha[i]})$ and $\beta[i] = (x_{\beta[i]}, y_{\beta[i]})$. That is, x_j and y_j are the endpoints of the edge $j \in \{\alpha[i], \beta[i]\}$.

▶ **Definition 17** (Gluing by $\oplus$)**.** Given two compatible boundaried structures α and β of arity p, the operation $\alpha \oplus \beta$ is defined as follows.

- $\alpha \oplus \beta$ is a structure γ of arity p.
- $G_\gamma = G_\alpha \oplus G_\beta$.
- For every $i \in [p]$:
  - if $\alpha[i]$ and $\beta[i]$ are sets, $\gamma[i] = \alpha[i] \cup \beta[i]$;
  - if $\alpha[i]$ and $\beta[i]$ are vertices/edges, $\gamma[i] = \alpha[i] = \beta[i]$;
  - if $\alpha[i] = \star$, $\gamma[i] = \beta[i]$;
  - if $\beta[i] = \star$, $\gamma[i] = \alpha[i]$.

State. This subsection states a variant of the classical Courcelle's Theorem [8, 7, 9] (see also [10]), which is a central component in the proof of our main result. To this end, we first define the *compatibility equivalence relation* $\equiv_c$ on boundaried structures as follows. We say that $\alpha \equiv_c \beta$ if $\Lambda(G_\alpha) = \Lambda(G_\beta)$ and for every boundaried structure γ, $\alpha \sim_c \gamma \iff \beta \sim_c \gamma$. Now, we define the *canonical equivalence relation* $\equiv_\sigma$ on boundaried structures.

▶ **Definition 18** (Canonical equivalence)**.** Given a property σ of structures, the *canonical equivalence relation* $\equiv_\sigma$ on boundaried structures is defined as follows. For two boundaried structures α and β, we say that $\alpha \equiv_\sigma \beta$ if **(i)** $\alpha \equiv_c \beta$, and **(ii)** for all boundaried structures γ compatible with α (and thus also with β), we have $\sigma(\alpha \oplus \gamma) = \mathsf{true} \Leftrightarrow \sigma(\beta \oplus \gamma) = \mathsf{true}$.

It is easy to verify that $\equiv_\sigma$ is indeed an equivalence relation. Given a property σ of structures, $p \in \mathbb{N}$ and $I \subseteq \mathbb{N}$, we let $\mathcal{E}_{\equiv_\sigma}[\mathcal{A}^p_{\subseteq I}]$ denote the set of equivalence classes of $\equiv_\sigma$ when restricted to $\mathcal{A}^p_{\subseteq I}$.

▶ **Definition 19** (Finite state)**.** A property σ of structures is *finite state* if, for every $p \in \mathbb{N}$ and $I \subseteq \mathbb{N}$, $\mathcal{E}_{\equiv_\sigma}[\mathcal{A}^p_{\subseteq I}]$ is finite.

Given a CMSO sentence ψ, the canonical equivalence relation associated with ψ is $\equiv_{\sigma_\psi}$, and for the sake of simplicity, we denote this relation by $\equiv_\psi$. We are now ready to state the variant of Courcelle's Theorem which was proven in [3] (see also [8, 7, 9]) and which we use in this paper.

▶ **Lemma 20** ([3])**.** *Every CMSO-definable property on structures has finite state.*

Parameterized Complexity. An instance of a parameterized problem is a pair of the form (x, k), where k is a non-negative integer called the *parameter*. Thus, a parameterized problem Π is a subset of $\Sigma^* \times \mathbb{N}_0$, for some finite alphabet Σ.

Two central notions in parameterized complexity are those of *uniform fixed-parameter tractability* and *non-uniform fixed-parameter tractability*. In this paper, we are interested in the second notion, which is defined as follows.

▶ **Definition 21** (Non-uniform fixed-parameter tractability (FPT)). Let Π be a parameterized problem. We say that Π is *non-uniformly fixed-parameter tractable (*FPT*)* if there exists a fixed d such that for every fixed $k \in \mathbb{N}_0$, there exists an algorithm A_k that for every $x \in \Sigma^*$, determines whether $(x, k) \in \Pi$ in time $\mathcal{O}(|x|^d)$.

Note that in Definition 21, d is independent of k. We refer the reader to the books [15, 11] for a detailed introduction to parameterized complexity.

3 CMSO Model Checking

Given a CMSO formula ψ, the CMSO$[\psi]$ problem is defined as follows. The input of CMSO$[\psi]$ is a structure α that matches ψ, and the objective is to output $\sigma_\psi(\alpha)$. In this section, we prove the following result, which then implies Theorem 1.

▶ **Theorem 22.** *Let ψ be a CMSO formula. For all $c \in \mathbb{N}$, there exists $s \in \mathbb{N}$ such that if there exists an algorithm that solves* CMSO$[\psi]$ *on (s, c)-unbreakable structures in time $\mathcal{O}(n^d)$ for some $d > 4$, then there exists an algorithm that solves* CMSO$[\psi]$ *on general structures in time $\mathcal{O}(n^d)$.*

In the context of parameterized complexity, MIN-CMSO$[\psi]$ (MIN-EDGE-CMSO$[\psi]$) is defined as follows. The input of MIN-CMSO$[\psi]$ is a structure α, where for all $S \subseteq V(G_\alpha)$ (resp. $S \subseteq E(G_\alpha)$), $\alpha \diamond S$ matches ψ, and a parameter k. The objective is to determine whether there exists $S \subseteq V(G_\alpha)$ (resp. $S \subseteq E(G_\alpha)$) of size at most k such that $\sigma_\psi(\alpha \diamond S)$ is true. Similarly, we define MAX-CMSO$[\psi]$ (resp. MAX-EDGE-CMSO$[\psi]$), where the size of S should be at least k, and EQ-CMSO$[\psi]$ (resp. EQ-EDGE-CMSO$[\psi]$), where the size of S should be exactly k. Then, as a consequence of Theorem 22, we derive the following result.

▶ **Theorem 23.** *Let* X$\in$ {MIN,MAX,EQ,MIN-EDGE,MAX-EDGE,EQ-EDGE}*, and let $\widehat{\psi}$ be a CMSO sentence. For all $\widehat{c} : \mathbb{N}_0 \to \mathbb{N}_0$, there exists $\widehat{s} : \mathbb{N}_0 \to \mathbb{N}_0$ such that if* X-CMSO$[\widehat{\psi}]$ *parameterized by k is* FPT *on $(\widehat{s}(k), \widehat{c}(k))$-unbreakable structures, then* X-CMSO$[\widehat{\psi}]$ *parameterized by k is* FPT *on general structures.*

From now on, to prove Theorem 22, we assume a fixed CMSO formula ψ and a fixed $c \in \mathbb{N}$. Moreover, we fix p as the number of free variables of ψ, and $I = [2c]$. We also let $s \in \mathbb{N}$ be fixed, where its exact value (that depends only on ψ and c) is determined later. Finally, we assume that there exists an algorithm, Solve-Unbr-ALG, that solves CMSO$[\psi]$ on (s, c)-unbreakable structures in time $\mathcal{O}(n^d)$ for some $d > 4$.

3.1 Understanding an instance of the CMSO$[\psi]$ Problem

To solve CMSO$[\psi]$, we consider a generalization of CMSO$[\psi]$, called UNDERSTAND$[\psi]$. The definition of this generalization is based on an examination of $\mathcal{E}_{\equiv_\psi}[\mathcal{A}^p_{\subseteq I}]$. Given a boundaried structure $\alpha \in \mathcal{A}^p_{\subseteq I}$, we let E_α denote the equivalence class in $\mathcal{E}_{\equiv_\psi}[\mathcal{A}^p_{\subseteq I}]$ that contains α. For every equivalence class $E_q \in \mathcal{E}_{\equiv_\psi}[\mathcal{A}^p_{\subseteq I}]$, let α_{E_q} denote some boundaried structure in E_q such that there is no boundaried structure $\alpha \in E_q$ where the length of the string encoding α is smaller than the length of the string encoding α_{E_q}. Accordingly, denote $\mathcal{R}_{\equiv_\psi}[\mathcal{A}^p_{\subseteq I}] = \{\alpha_{E_q} : E_q \in \mathcal{E}_{\equiv_\psi}[\mathcal{A}^p_{\subseteq I}]\}$. These will be the representatives of the equivalence classes induced by $\equiv_\psi$. By Lemma 20, there is a fixed $r \in \mathbb{N}$ (that depends only on ψ and c) such that both $|\mathcal{R}_{\equiv_\psi}[\mathcal{A}^p_{\subseteq I}]|$ and the length of encoding of any boundaried structure in $\mathcal{R}_{\equiv_\psi}$ are upper bounded by r as well as $c \leq r$. Note that the encoding explicitly lists all vertices and edges. By initially choosing s appropriately, we ensure that $s \geq 2r2^c + r$.

The UNDERSTAND[ψ] problem is defined as follows. The input is a boundaried structure $\alpha \in \mathcal{A}^p_{\subseteq I}$ that matches ψ, and the objective is to output a boundaried structure $\beta \in \mathcal{R}_{\equiv_\psi}[\mathcal{A}^p_{\subseteq I}]$ such that $E_\alpha = E_\beta$. We proceed by showing that to prove Theorem 22, it is sufficient to prove that there exists an algorithm that solves UNDERSTAND[ψ] on general boundaried structures in time $\mathcal{O}(n^d)$.

▶ **Lemma 24.** *If there exists an algorithm that solves* UNDERSTAND[ψ] *on general boundaried structures in time $\mathcal{O}(n^d)$, then there exists an algorithm that solves* CMSO[ψ] *on general structures in time $\mathcal{O}(n^d)$.*

In light of Lemma 24, the rest of this section focuses on the proof of the following result.

▶ **Lemma 25.** *There exists an algorithm that solves* UNDERSTAND[ψ] *on general boundaried structures in time $\mathcal{O}(n^d)$.*

3.2 Understand[ψ] on Unbreakable Structures

Recall that $s \geq 2r2^c + r$. In this subsection, we show that Algorithm Solve-Unbr-ALG can be used as a subroutine in order to efficiently solve UNDERSTAND[ψ] on $(s-r, c)$-unbreakable boundaried structures. For this, we follow the method of test sets (see for example, [Section 12.5, [15]]). The high level idea here is as follows. We first enumerate the relevant subset of the finite set of minimal representatives. In other words, we simply list those minimal representatives which can be glued in a meaningful way to the structure under consideration, call it α. We now observe that gluing each of these representatives to α results in an (s, c)-unbreakable structure, which is what we need to call Solve-Unbr-ALG. In this way we solve the instance obtained by gluing α to each minimal representative.

Now, for every (not necessarily distinct) pair of minimal representatives, we glue them together and do the same. This way, we can identify the specific minimal representative whose behaviour when glued with *every* minimal representative, precisely resembles that of the structure α when we do the same with α. Consequently, we obtain a solution for UNDERSTAND[ψ]. We now formalize this intuition in the following lemma.

▶ **Lemma 26.** *There exists an algorithm* Understand-Unbr-ALG*, that solves* UNDERSTAND[ψ]*, where it is guaranteed that inputs are $(s-r, c)$-unbreakable boundaried structures, in time $\mathcal{O}(n^d)$.*[6]

Proof. We design the algorithm Understand-Unbr-ALG as follows. Let α be an input, which is an $(s-r, c)$-unbreakable boundaried structure. Moreover, let $\mathcal{C} = \{\gamma \in \mathcal{R}_{\equiv_\psi}[\mathcal{A}^p_{\subseteq I}] : \gamma \equiv_c \alpha\}$, and let $\mathcal{T}$ denote the set of boundaried structures in $\mathcal{R}_{\equiv_\psi}[\mathcal{A}^p_{\subseteq I}]$ that are compatible with α. In the first phase, the algorithm performs the following computation. Notice that for every $\beta \in \mathcal{T}$, since $|V(G_\beta)| \leq r$, it holds that $\alpha \oplus \beta$ is an (s, c)-unbreakable structure. Thus, for every $\beta \in \mathcal{T}$, Understand-Unbr-ALG can call Solve-Unbr-ALG with $\alpha \oplus \beta$ as input, and it lets $\mathsf{ans}(\alpha, \beta)$ denote the result.

In the second phase, the algorithm performs the following computation. Notice that for every $\gamma \in \mathcal{C}$ and $\beta \in \mathcal{T}$, since $|V(G_\beta)|, |V(G_\gamma)| \leq r$, it holds that $\gamma \oplus \beta$ is a $(2r, c)$-unbreakable structure. Thus, since $s \geq 2r2^c + r$, for all $\beta \in \mathcal{C}$ and $\gamma \in \mathcal{T}$, Understand-Unbr-ALG can call Solve-Unbr-ALG with $\gamma \oplus \beta$ as input, and it lets $\mathsf{ans}(\gamma, \beta)$ denote the result.

[6] Here, Understand-Unbr-ALG is not required to verify whether the input is an $(s-r, c)$-unbreakable boundaried structure.

Finally, in the third phase, for every $\beta \in \mathcal{C}$, the algorithm performs the following computation. It checks whether for every $\gamma \in \mathcal{T}$ it holds that $\mathsf{ans}(\alpha, \gamma) = \mathsf{ans}(\beta, \gamma)$, and if the answer is positive, then it outputs β. Since $\alpha \in \mathcal{A}^p_{\subseteq I}$, there exists $\beta' \in \mathcal{C}$ such that $E_\alpha = E_{\beta'}$, and therefore, at the latest, when $\beta = \beta'$, the algorithm terminates. Thus, the algorithm is well defined, and it is clear that it runs in time $\mathcal{O}(n^d)$.

To conclude that the algorithm is correct, it remains to show that for all $\beta \in \mathcal{C} \setminus \{\beta'\}$, there exists $\gamma \in \mathcal{T}$ such that $\mathsf{ans}(\alpha, \gamma) \neq \mathsf{ans}(\beta, \gamma)$, as this would imply that the algorithm necessarily outputs β'. For this purpose, suppose by way of contradiction that there exists $\beta \in \mathcal{C} \setminus \{\beta'\}$ such that for all $\gamma \in \mathcal{T}$ it holds that $\mathsf{ans}(\alpha, \gamma) = \mathsf{ans}(\beta, \gamma)$. We now argue that $E_\beta = E_{\beta'}$ which leads to a contradiction since each boundaried structure in $\mathcal{R}_{\equiv_\psi}[\mathcal{A}^p_{\subseteq I}]$ belongs to a different equivalence class.

For all $\gamma \in \mathcal{T}$, since it holds that $\mathsf{ans}(\alpha, \gamma) = \mathsf{ans}(\beta, \gamma)$, it also holds that $\mathsf{ans}(\beta', \gamma) = \mathsf{ans}(\beta, \gamma)$. This implies that $\sigma_\psi(\beta' \oplus \gamma) = \sigma_\psi(\beta \oplus \gamma)$. Consider some boundaried structure γ (not necessarily in $\mathcal{T}$) that is compatible with β' (and thus also with β). We claim that $\sigma_\psi(\beta' \oplus \gamma) = \sigma_\psi(\beta \oplus \gamma)$. Indeed, let γ' be the (unique) boundaried structure in $\mathcal{R}_{\equiv_\psi}[\mathcal{A}^p_{\subseteq I}]$ such that $E_{\gamma'} = E_\gamma$. Then, $\sigma_\psi(\beta' \oplus \gamma') = \sigma_\psi(\beta' \oplus \gamma)$ and $\sigma_\psi(\beta \oplus \gamma') = \sigma_\psi(\beta \oplus \gamma)$. Note that since γ' is compatible with β', it is also compatible with α, and hence $\gamma' \in \mathcal{T}$. Therefore, $\sigma_\psi(\beta' \oplus \gamma') = \sigma_\psi(\beta \oplus \gamma')$. Overall, we obtain that indeed $\sigma_\psi(\beta' \oplus \gamma) = \sigma_\psi(\beta \oplus \gamma)$.

Note that $\beta \equiv_c \beta'$, and thus, since we have shown that for every boundaried structure γ compatible with β' it holds that $\sigma_\psi(\beta' \oplus \gamma) = \sigma_\psi(\beta \oplus \gamma)$, we derive that $E_\beta = E_{\beta'}$. However, each boundaried structure in $\mathcal{R}_{\equiv_\psi}[\mathcal{A}^p_{\subseteq I}]$ belongs to a different equivalence class, and thus we have reached the desired contradiction. ◀

3.3 Understand[ψ] on General Structures

The Algorithm Understand-ALG. We start by describing an algorithm called Understand-ALG, which is based on recursion. Given an input to Understand[ψ] on general boundaried structures, which is a boundaried structure α, the algorithm works as follows. First, it calls Break-ALG (given by Lemma 5) with G_α as input to either obtain an $(\frac{s-r}{2^c}, c)$-witnessing separation (X, Y) or correctly conclude that G_α is $(s-r, c)$-unbreakable. In the second case or if $n < 2(s-r)$, it calls Understand-Unbr-ALG (given by Lemma 26), and returns its output. Next, suppose that Understand-ALG obtained an $(\frac{s-r}{2^c}, c)$-witnessing separation (X, Y) and that $n \geq 2(s-r)$. Without loss of generality, assume that $|X \cap \delta(G_\alpha)| \leq |Y \cap \delta(G_\alpha)|$. Denote $\Delta = \{v \in X \cap Y : v \notin \delta(G_\alpha)\}$.

Now, we define a boundaried structure, $\beta \in \mathcal{A}^p_{\subseteq I}$, which can serve as an instance of Understand[ψ]. First, we let the graph G_β be $G_\alpha[X]$, and we define $\delta(G_\beta) = (X \cap \delta(G_\alpha)) \cup \Delta$. Now, for all $v \in X \cap \delta(G_\alpha)$, we define $\lambda_{G_\beta}(v) = \lambda_{G_\alpha}(v)$. Since $|X \cap \delta(G_\alpha)| \leq |Y \cap \delta(G_\alpha)|$, $\alpha \in \mathcal{A}^p_{\subseteq I}$ and $|X \cap Y| \leq c$, we have that $|(X \cap \delta(G_\alpha)) \cup \Delta| \leq 2c$. Thus, to each $v \in \Delta$, we can let $\lambda_{G_\beta}(v)$ assign some unique integer from $I \setminus \lambda_{G_\alpha}(X \cap \delta(G_\alpha))$. Hence, $G_\beta \in \mathcal{F}_{\subseteq I}$. Now, for all $i \in \{2, \ldots, p\}$, we set $\beta[i]$ as follows. If $\mathbf{type}(\alpha)[i] \in \{\mathsf{vertex}, \mathsf{edge}\}$: If $\alpha[i] \in V(G_\beta) \cup E(G_\beta)$, then $\beta[i] = \alpha[i]$, and otherwise $\beta[i] = \star$. Else: $\beta[i] = \alpha[i] \cap (V(G_\beta) \cup E(G_\beta))$.

Understand-ALG proceeds by calling itself recursively with β as input, and it lets β' be the output of this call. Now, we define another boundaried structure, $\gamma \in \mathcal{A}^p_{\subseteq I}$, which can serve as an instance of Understand[ψ]. First, we define the boundaried graph G_γ as follows. Let H be the disjoint union of $G_{\beta'}$ and $G[Y]$, where both $G_{\beta'}$ and $G[Y]$ are treated as not-boundaried graphs. For all $v \in X \cap Y$, identify (in H) the vertex v of $G[Y]$ with the vertex u of $G_{\beta'}$ that satisfies $\lambda_{G_{\beta'}}(u) = \lambda_{G_\beta}(v)$, and for the sake of simplicity, let v and u also denote the identity of the resulting (unified) vertex. The graph G_γ is the result

of this process. Moreover, let Δ' denote the set of vertices in $G_{\beta'}$ whose labels belong to $G_\beta(\Delta)$. Next, set $\delta(G_\gamma) = (Y \cap \delta(G_\alpha)) \cup (\delta(G_{\beta'}) \setminus \Delta')$. Now, for all $v \in Y \cap \delta(G_\alpha)$, we define $\lambda_{G_\gamma}(v) = \lambda_{G_\alpha}(v)$, and for all $v \in \delta(G_{\beta'}) \setminus \Delta'$, we define $\lambda_{G_\gamma}(v) = \lambda_{G_{\beta'}}(v)$ (note that if a vertex belongs to both $Y \cap \delta(G_\alpha)$ and $\delta(G_{\beta'}) \setminus \Delta'$, we still assign it the same label). Hence, $G_\gamma \in \mathcal{F}_{\subseteq I}$. For the sake of simplicity, if two vertices have the same label (one in G_α and the other in G_γ), we let the identity of one of them also refer to the other and vice versa. For all $i \in \{2, \ldots, p\}$, we set $\gamma[i]$ to have the same type as $\alpha[i]$, and define it as follows. If $\mathbf{type}(\alpha)[i] \in \{\mathsf{vertex}, \mathsf{edge}\}$: If $\alpha[i] \in V(G_\gamma) \cup E(G_\gamma)$, then $\gamma[i] = \alpha[i]$, and otherwise $\gamma[i] = \star$. Else: $\gamma[i] = \alpha[i] \cap (V(G_\gamma) \cup E(G_\gamma))$. Finally, Understand-ALG calls itself recursively with γ as input, and it returns γ', the output of this call.

Correctness and running time. Finally, we prove the following two results. Along with Lemma 27, these complete the proof of Lemma 25.

▶ **Lemma 27.** *If* Understand-ALG *terminates, then it correctly solves* Understand$[\psi]$ *on general boundaried structures.*

▶ **Lemma 28.** Understand-ALG *runs in time* $\mathcal{O}(n^d)$.

4 Applications

In this section, we first show how Theorem 23 can be easily deployed to show the fixed parameter tractability of a wide range of problems of the following kind. The input is a graph G and the task is to find a connected induced subgraph of G of bounded treewidth such that "few" vertices outside this subgraph have neighbors inside the subgraph, and additionally the subgraph has a CMSO-definable property. Then, we show that technical problem-specific ingredients of a powerful method for designing parameterized algorithms called recursive understanding, can be replaced by a black-box invocation of Theorem 23.

4.1 "Pendant" Subgraphs with CMSO-Definable Properties

Formally, given a CMSO sentence ψ and a non-negative integer t, the t-Pendant$[\psi]$ problem is defined as follows. The input of t-Pendant$[\psi]$ is a graph G and a parameter k, and the objective is to determine whether there exists $U \subseteq V(G)$ such that $G[U]$ is a connected graph of treewidth at most t, $|N(U)| \leq k$ and $\sigma_\psi(G[U])$ is true.

It is straightforward to define a CMSO formula φ with free variable S such that the t-Pendant$[\psi]$ problem is equivalent to min-CMSO$[\varphi]$ as follows.

▶ **Observation 4.1.** *Let G be a graph, and let k be a parameter. Then, (G, k) is a* Yes*-instance of t-*Pendant$[\psi]$ *if and only if $((G), k)$ is a* Yes*-instance of* min-CMSO$[\varphi]$.

Next, we solve t-Pendant$[\psi]$ on unbreakable graphs with the appropriate parameters. Define $c : \mathbb{N}_0 \to \mathbb{N}_0$ as follows. For all $k \in \mathbb{N}_0$, let $\widehat{c}(k) = k + t$. Let $s : \mathbb{N}_0 \to \mathbb{N}_0$ be the function $\widehat{s}$ in Theorem 23 with $\widehat{\psi} = \varphi$ and $\widehat{c} = c$. We first prove the following lemma.

▶ **Lemma 29.** *Let (G, k) be a* Yes*-instance of t-*Pendant$[\psi]$ *parameterized by k on $(s(k), k + t)$-unbreakable graphs. Then, there exists $U \subseteq V(G)$ such that $G[U]$ is a connected graph of treewidth at most t, $|N(U)| \leq k$, $\sigma_\psi(G[U])$ is* true *and $|U| < 3(s(k) + t)$.*

Proof. Since (G, k) is a Yes-instance, there exists $U \subseteq V(G)$ such that $G[U]$ is a connected graph of treewidth at most t, $|N(U)| \leq k$ and $\sigma_\psi(G[U])$ is true. Moreover, since the

treewidth of $G[U]$ is at most t, it is easy to see that there exists a separation (X, Y) of order at most t of $G[U]$ such that $|X|, |Y| \geq |U|/3$ (see, e.g., [11]). Then, set $X' = X \cup N(U)$ and $Y' = (V(G) \setminus X) \cup (X \cap Y)$. Note that (X', Y') is a separation of order $|X \cap Y| + |N(U)| \leq k+t$. Moreover, $X \setminus Y \subseteq X' \setminus Y'$ and $Y \setminus X \subseteq Y' \setminus X'$. Thus, (X', Y') is a $(|U|/3 - t, k + t)$-witnessing separation. Since G is $(s(k), k+t)$-unbreakable graph, we have that $|U|/3 - t < s(k)$. Therefore, $|U| < 3(s(k) + t)$, which concludes the correctness of the lemma. ◀

▶ **Lemma 30.** *t-Pendant$[\psi]$ parameterized by k is* FPT *on $(s(k), k + t)$-unbreakable graphs.*

Finally, by Theorem 23, Observation 4.1 and Lemma 30, we derive the following result.

▶ **Theorem 31.** *t-Pendant$[\psi]$ parameterized by k is* FPT *on general graphs.*

Abstract

We solve two long-standing open problems on word equations. Firstly, we prove that a one-variable word equation with constants has either at most three or an infinite number of solutions. The existence of such a bound had been conjectured, and the bound three is optimal. Secondly, we consider independent systems of three-variable word equations without constants. If such a system has a nonperiodic solution, then this system of equations is at most of size 17. Although probably not optimal, this is the first finite bound found. However, the conjecture of that bound being actually two still remains open.

1 Introduction

If n words satisfy a nontrivial relation, they can be written as products of $n-1$ words. This folklore result is known as the defect theorem, and it can be seen as analogous to the simple fact of linear algebra that the dimension of the solution space of a homogeneous n-variable linear equation is $n-1$. If an independent equation is added to a system of linear equations, the dimension of the solution space decreases, which gives an upper bound n for the size of independent systems of linear equations, but no such results are known for word equations. In fact, the maximal size of independent systems of constant-free word equations has been one of the biggest open questions in combinatorics on words for many decades. In 1983, Culik and Karhumäki [4] pointed out that a conjecture of Ehrenfeucht about test sets of formal languages can be equivalently formulated as claiming that every infinite system of word equations is equivalent to a finite subsystem. Ehrenfeucht's conjecture was proved by Albert and Lawrence [1] and independently by Guba [9], and it follows that independent systems cannot be infinite, but no finite upper bounds depending only on the number of variables have been found. Independent systems of size $\Theta(n^4)$ on n variables were constructed by

Karhumäki and Plandowski [13], and the hidden constant in $\Theta(n^4)$ was improved in [14]. This is the best known lower bound.

The case of three variables is particularly interesting. In this case, it is easy to find systems of size two that are independent and have a nonperiodic solution, or systems of size three that are independent but have no nonperiodic solution, and Culik and Karhumäki conjectured that there are no larger such systems, but no finite upper bounds have been found even in this case. In fact, despite Ehrenfeucht's conjecture, even the existence of a bound is not guaranteed, because in principle it might be possible that there are unboundedly large finite independent systems. This case of three variables is very striking because it is the simplest nontrivial case, but the gap between the almost trivial lower bound and the infinite upper bound has remained huge despite the considerable attention the problem has received. Some results about systems of specific forms are known [10, 5, 6], and some upper bounds that depend on the sizes of the equations have been proved [17, 11, 16]. The best current bound is logarithmic with respect to the size of the smallest equation in the system [16].

In the above, we have considered constant-free word equations. If we add constants, the equations become more complicated. For constant-free equations, the three-variable case is the first nontrivial one, but for equations with constants, already the one-variable case is interesting. One-variable equations have been studied in many articles [8, 7, 15], and the main open question about them is the maximal number of solutions such an equation can have if we exclude equations with infinitely many solutions (if the solution set is infinite, it is known to be of a very specific form). Even finding an example with exactly two solutions is not entirely trivial, but a simple example was given by Laine and Plandowski [15]. An example with exactly three solutions was recently found [16]. No fixed upper bound, or even the existence of an upper bound, has been proved. The best known result is a bound that depends logarithmically on the number of occurrences of the variable in the equation [15]. It can be noted that the solutions of a one-variable equation can be found in linear time in the RAM model, as proved by Jeż [12].

In this article, we solve the open problem about sizes of solution sets of one-variable equations by proving that a one-variable equation has either infinitely many solutions or at most three, which is an optimal result. As a consequence, we prove the first upper bound for the sizes of independent systems of constant-free three-variable equations, thus settling the old open question about the existence of such a bound. More specifically, we prove that if an independent system of constant-free three-variable equations is independent and has a nonperiodic solution, then the system is of size at most 17 (if the system is not required to have a nonperiodic solution, then the size can be at most one larger). This bound is probably not optimal and the conjecture of Culik and Karhumäki remains open, as does the more general question about n-variable equations.

Two previous articles provide crucial tools for our proofs. The first article is [18], where new methods were introduced to solve a certain open problem on word equations. We use and further develop these methods to analyze one-variable equations. The second article is [16], where a surprising connection between the two topics we have discussed above was found: It was proved that a bound for the maximal size of a finite solution set of a one-variable equation implies a (larger) bound for the maximal size of independent systems of constant-free three-variable equations.

Some of the proofs have been omitted from this conference version to save space.

2 Preliminaries

We begin this section by considering constant-free word equations. Let Ξ be an alphabet of variables and Γ an alphabet of constants. A *constant-free word equation* is a pair $(U, V) \in \Xi^* \times \Xi^*$, and the solutions of this equation are the morphisms $h : \Xi^* \to \Gamma^*$ such that $h(U) = h(V)$. A solution h is *periodic* if there exists $p \in \Gamma^*$ such that $h(X) \in p^*$ for all $X \in \Xi$. Otherwise, h is *nonperiodic*. It is well-known that h is periodic if and only if $h(PQ) = h(QP)$ for all words $P, Q \in \Xi^*$.

▶ **Example 1.** Let $\Xi = \{X, Y, Z\}$ and consider the equation (XYZ, ZYX). For all $p, q \in \Gamma^*$ and $i, j, k \geq 0$, the morphism h defined by $h(X) = (pq)^i p$, $h(Y) = (qp)^j q$, $h(Z) = (pq)^k p$ is a solution of this equation because

$$h(XYZ) = (pq)^i p \cdot (qp)^j q \cdot (pq)^k p = (pq)^{i+j+k+1} p = (pq)^k p \cdot (qp)^j q \cdot (pq)^i p = h(ZYX).$$

Every nonperiodic solution of the equation is of this form.

A set of equations is a *system of equations*. A morphism is a solution of a system if it is a solution of every equation in the system. Two equations or systems are *equivalent* if they have exactly the same solutions. A system of equations is *independent* if it is not equivalent to any of its proper subsets.

▶ **Example 2.** Let $\Xi = \{X, Y, Z\}$ and $\Gamma = \{a, b\}$. The system of equations $S = \{(XYZ, ZYX), (XYYZ, ZYYX)\}$ is independent and has a nonperiodic solution h defined by $h(X) = a$, $h(Y) = b$, $h(Z) = a$. To see independence, note that S is not equivalent to (XYZ, ZYX), because the morphism h defined by $h(X) = a$, $h(Y) = b$, $h(Z) = aba$ is a solution of (XYZ, ZYX) but not of S, and S is not equivalent to $(XYYZ, ZYYX)$, because the morphism h defined by $h(X) = a$, $h(Y) = b$, $h(Z) = abba$ is a solution of $(XYYZ, ZYYX)$ but not of S.

The following question is a big open problem on word equations: If a system of constant-free three-variable equations is independent and has a nonperiodic solution, then how large can the system be? The largest known examples are of size two, see Example 2, and it has been conjectured that these examples are optimal. Even the following weaker conjecture is open.

▶ **Conjecture 3.** *There exists a number c such that every independent system of constant-free three-variable equations with a nonperiodic solution is of size c or less.*

Currently, the best known result is the following.

▶ **Theorem 4** ([16])**.** *Every independent system of constant-free three-variable equations is of size $O(\log n)$, where n is the length of the shortest equation.*

Next, we will consider word equations with constants. As before, let Ξ be an alphabet of variables and Γ an alphabet of constants. A *word equation with constants* is a pair $(U, V) \in (\Xi \cup \Gamma)^* \times (\Xi \cup \Gamma)^*$, and the solutions of this equation are the constant-preserving morphisms $h : (\Xi \cup \Gamma)^* \to \Gamma^*$ such that $h(U) = h(V)$. If $U = V$, then the equation is *trivial*.

In this article, we are interested in the one-variable case $\Xi = \{X\}$. We use the notation $[u]$ for the constant-preserving morphism $h : (\{X\} \cup \Gamma)^* \to \Gamma^*$ defined by $h(X) = u$. If S is a set of words, we use the notation $[S] = \{[u] \mid u \in S\}$. If $[u]$ is a solution of a one-variable equation E, then u is called a *solution word* of E. The set of all solutions of E is denoted by $\mathrm{Sol}(E)$.

▶ **Example 5.** Let $\Gamma = \{a, b\}$. The equation (Xab, abX) has infinitely many solutions $[(ab)^i]$, where $i \geq 0$. The equation $(XaXbab, abaXbX)$ has exactly two solutions $[\varepsilon]$ and $[ab]$. The equation $(XXbaaba, aabaXbX)$ has exactly two solutions $[a]$ and $[aaba]$. The equation

$$(XaXbXaabbabaXbabaabbab, abaabbabaXbabaabbXaXbX)$$

has exactly three solutions $[\varepsilon], [ab], [abaabbab]$.

The following is a well-known open problem: If a one-variable equation has only finitely many solutions, then what is the maximal number of solutions it can have? Example 5 shows that the answer is at least three, but no upper bound is known. Currently, the best known result is the following.

▶ **Theorem 6** ([15, Theorems 23, 26, 29]). *If the solution set of a one-variable equation is finite, then it has size at most* $8 \log n + O(1)$*, where* n *is the number of occurrences of the variable.*

If the solution set is infinite and the equation is not trivial, then there are words p, q *such that* pq *is primitive and the solution set is* $[(pq)^* p]$*.*

We will need the following lemma.

▶ **Lemma 7** ([7, Lemma 1]). *Let* E *be a one-variable equation and let* pq *be primitive. The set*

$$\mathrm{Sol}(E) \cap [(pq)^+ p]$$

is either $[(pq)^+ p]$ *or has at most one element.*

A connection between constant-free three-variable equations and one-variable equations with constants was recently found [16]. Here we give the relevant special case of one of the results.

▶ **Theorem 8** ([16]). *If every one-variable word equation has either infinitely many solutions or at most three, then Conjecture 3 is true for* $c = 17$*.*

In this article, we will prove that every one-variable word equation has either infinitely many solutions or at most three, and thus Conjecture 3 is true for $c = 17$.

3 Sums of words

In this section, we will give some definitions and ideas that will be used in our proofs. Most of these were introduced in [18].

We can assume that the alphabet Γ is a subset of $\mathbb{R}$. Then we can define $\Sigma(w)$ to be the sum of the letters of a word $w \in \Gamma^*$, that is, if $w = a_1 \cdots a_n$ and $a_1, \ldots, a_n \in \Gamma$, then $\Sigma(w) = a_1 + \cdots + a_n$. Words w such that $\Sigma(w) = 0$ are called *zero-sum words*. If w is zero-sum, then the morphism $[w]$ can also be called zero-sum. The largest and smallest letters in a word w can be denoted by $\max(w)$ and $\min(w)$, respectively.

The *prefix sum word* of $w = a_1 \cdots a_n$ is the word $\mathrm{psw}(w) = b_1 \cdots b_n$, where $b_i = \Sigma(a_1 \cdots a_i)$ for all i. Of course, $\mathrm{psw}(w)$ is usually not a word over Γ, but over some other alphabet. The mapping psw is injective and length-preserving. We also use the notation $\mathrm{psw}_r(w) = c_1 \cdots c_n$, where $r \in \mathbb{R}$ and $c_i = b_i + r$ for all i.

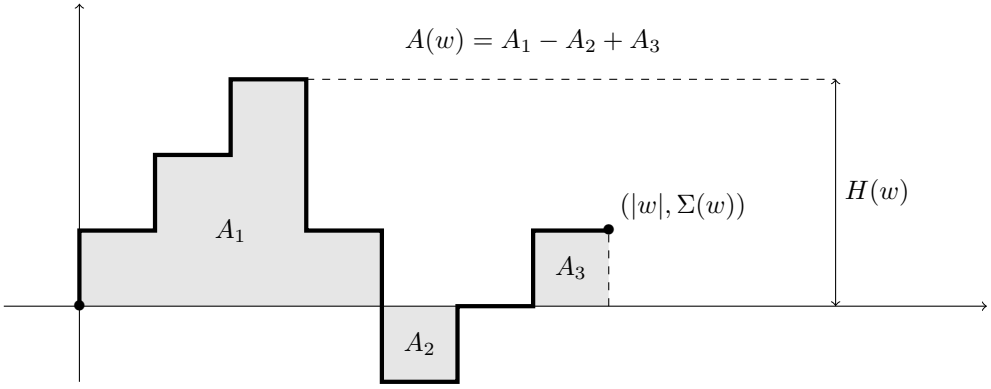

Figure 1 Representation of the word $w = aaabbaa$, where $a = 1$ and $b = -2$. We have $|w| = 7$, $\Sigma(w) = 1$, $H(w) = 3$, and $A(w) = 7$.

▶ **Example 9.** Let $w = bbcaac$, where $a = 1$, $b = 2$, and $c = -3$. We have $|w| = 6$, $\max(w) = 2$, and $\min(w) = -3$. Because $\Sigma(w) = 2 + 2 - 3 + 1 + 1 - 3 = 0$, w is a zero-sum word. The prefix sum word of w is $\mathrm{psw}(w) = 241230$, and $\max(\mathrm{psw}(w)) = 4$ and $\min(\mathrm{psw}(w)) = 0$.

For a word w, we define its *height* $H(w)$ and *area* $A(w)$:

$$H(w) = \max(\mathrm{psw}(w)) = \max\{\Sigma(u) \mid \varepsilon \neq u \sqsubseteq w\},$$
$$A(w) = \Sigma(\mathrm{psw}(w)) = \sum_{u \sqsubseteq w} \Sigma(u),$$

where $u \sqsubseteq w$ means that u is a prefix of w. For the empty word, $H(\varepsilon) = -\infty$ and $A(\varepsilon) = 0$.

These definitions have the following graphical interpretation: A word $w = a_1 \cdots a_n$ can be represented by a polygonal chain by starting at the origin, moving a_1 steps up, one step to the right, a_2 steps up, one step to the right, and so on. The end point of this curve is then $(|w|, \Sigma(w))$. The biggest y-coordinate (after the initial line segment starting at the origin) is $H(w)$. The number $A(w)$ is the area under the curve, defined in the same way as a definite integral, that is, parts below the x-axis count as negative areas. See Figure 1 for an example.

▶ **Lemma 10.** *For words $w_1, \ldots, w_n$, we have*

$$\Sigma(w_1 \cdots w_n) = \Sigma(w_1) + \cdots + \Sigma(w_n),$$
$$\mathrm{psw}(w_1 \cdots w_n) = \prod_{i=1}^{n} \mathrm{psw}_{\Sigma(w_1 \cdots w_{i-1})}(w_i),$$
$$H(w_1 \cdots w_n) = \max\{\Sigma(w_1 \cdots w_{i-1}) + H(w_i) \mid 1 \leq i \leq n\},$$
$$A(w_1 \cdots w_n) = \sum_{i=1}^{n} (A(w_i) + \Sigma(w_1 \cdots w_{i-1})|w_i|).$$

Proof. Follows easily from the definitions. ◀

When studying words from a combinatorial point of view, the choice of the alphabet is arbitrary (except for the size of the alphabet), so we can assign numerical values to the letters in any way we like, as long as no two letters get the same value. The next two lemmas show that, given any word w, the alphabet can be normalized so that w becomes a zero-sum word, and every zero-sum word can be written as a product of minimal zero-sum words in a unique way.

▶ **Lemma 11** ([18, Lemma 3]). *Let $w \in \Gamma^*$. There exists an alphabet Δ and an isomorphism $h : \Gamma^* \to \Delta^*$ such that $h(w)$ is zero-sum.*

▶ **Lemma 12** ([18, Lemma 4]). *The set of zero-sum words over Γ is a free monoid.*

4 Equations in normal form

If a one-variable equation has more occurrences of the variable on the left-hand side than on the right-hand side, or vice versa, then it is easy to see by a length argument that it can have at most one solution. Therefore every one-variable equation with more than one solution can be written in the form

$$(u_0Xu_1 \cdots Xu_n, v_0Xv_1 \cdots Xv_n), \tag{1}$$

where X is the variable, $n \geq 1$, and $u_0, \ldots, u_n, v_0, \ldots, v_n$ are constant words. Clearly, it must be $|u_0 \cdots u_n| = |v_0 \cdots v_n|$. If the equation is nontrivial, x_1, x_2 are solution words, and $|x_1| \leq |x_2|$, then it is quite easy to see that x_1 is a prefix and a suffix of x_2.

We say that the equation (1) is in *normal form* if the following conditions are satisfied:

(N1) It has the empty solution and at least one other zero-sum solution,
(N2) $|u_0 \cdots u_i| < |v_0 \cdots v_i|$ for all $i \in \{0, \ldots, n-1\}$,
(N3) $|u_0 \cdots u_i| \leq |v_0 \cdots v_{i-1}|$ for all $i \in \{0, \ldots, n\}$.

It follows from these conditions that $u_0 = v_n = \varepsilon$. By the next two lemmas, it is usually sufficient to consider equations in normal form.

▶ **Lemma 13.** *Let E be a one-variable equation,* $\mathrm{Sol}(E) = \{[x_0], \ldots, [x_m]\}$, *and $|x_0| \leq |x_i|$ for all i. There exists a one-variable equation E' such that* $\mathrm{Sol}(E') = \{[\varepsilon], [x_0^{-1}x_1], \ldots, [x_0^{-1}x_m]\}$.

Proof. If $m = 0$, the claim is clear. Otherwise, we can assume that E is of the form (1). Let E' be the equation we get from E by replacing X by x_0X:

$$E' : (u_0x_0Xu_1 \cdots x_0Xu_n, v_0x_0Xv_1 \cdots x_0Xv_n).$$

Because E is nontrivial, x_0 is a prefix of every x_i. Clearly, the word $x_0^{-1}x_i$ is a solution word of E'. On the other hand, if x is a solution word of E', then x_0x is a solution word of E. This proves the claim. ◀

Next we will give an example of how to transform an equation that satisfies Condition N1 into an equation in normal form.

▶ **Example 14.** Consider the equation

$$(XabXababXaabaXbX, abXXXababaXaXbab).$$

By a length argument, it is equivalent to the system of equations

$$(Xab, abX), (X, X), (ababX, Xabab), (a, a), (abaXbX, XaXbab).$$

We can drop the trivial equations (X, X) and (a, a), and then switch the left-hand and right-hand sides of the equations $(ababX, Xabab)$ and $(abaXbX, XaXbab)$ to get the system

$$(Xab, abX), (Xabab, ababX), (XaXbab, abaXbX).$$

Then we can combine these equations into the equation

$$(XabXababXaXbab, abXababXabaXbX),$$

which satisfies Conditions N2 and N3. (Actually, this equation is equivalent to the equation $(XaXbab, abaXbX)$.)

▶ **Lemma 15.** *Let E be a nontrivial one-variable equation with the empty solution and at least one other solution. There exists an equation in normal form that is equivalent to E up to a renaming of the letters and not longer than E.*

Proof. Omitted. ◀

5 Sums and heights of solutions

In this section, we prove lemmas about the sums and heights of solution words of one-variable equations in normal form.

▶ **Lemma 16.** *All solutions of an equation in normal form are zero-sum.*

Proof. Let the equation be (1). Let $u'_i = u_0 \cdots u_{i-1}$ and $v'_i = v_0 \cdots v_{i-1}$ for all i. After applying a solution $[x]$ on the left-hand side and taking the area we get

$$\begin{aligned}
&A(u_0 x u_1 \cdots x u_n)\\
=&\sum_{i=0}^{n}(A(u_i) + \Sigma(u_0 x u_1 \cdots u_{i-1}x)|u_i|) + \sum_{i=1}^{n}(A(x) + \Sigma(u_0 x u_1 \cdots x u_{i-1})|x|)\\
=&\sum_{i=0}^{n}(A(u_i) + \Sigma(u'_i)|u_i| + i\Sigma(x)|u_i|) + \sum_{i=1}^{n}(A(x) + \Sigma(u'_i)|x| + (i-1)\Sigma(x)|x|)\\
=&A(u_0 \cdots u_n) + \Sigma(x)\sum_{i=0}^{n} i|u_i| + nA(x) + |x|\sum_{i=1}^{n}\Sigma(u'_i) + \frac{(n-1)n}{2}\cdot\Sigma(x)|x|.
\end{aligned}$$

We get a similar formula for $A(v_0 x v_1 \cdots x v_n)$. Because $u_0 x u_1 \cdots x u_n = v_0 x v_1 \cdots x v_n$, we get

$$\begin{aligned}
0 &= A(u_0 x u_1 \cdots x u_n) - A(v_0 x v_1 \cdots x v_n)\\
&= A(u_0 \cdots u_n) - A(v_0 \cdots v_n) + \Sigma(x)\sum_{i=0}^{n} i(|u_i| - |v_i|) + |x|\sum_{i=1}^{n}(\Sigma(u'_i) - \Sigma(v'_i))\\
&= \Sigma(x)\sum_{i=0}^{n} i(|u_i| - |v_i|) + |x|\sum_{i=1}^{n}(\Sigma(u'_i) - \Sigma(v'_i)). \qquad (2)
\end{aligned}$$

By the definition of normal form, the equation has a nonempty zero-sum solution $[x_1]$. Replacing x by x_1 in (2) gives

$$0 = |x_1|\sum_{i=1}^{n}(\Sigma(u'_i) - \Sigma(v'_i)).$$

Because $|x_1| > 0$, $\sum_{i=1}^{n}(\Sigma(u'_i) - \Sigma(v'_i)) = 0$. Then (2) takes the form

$$0 = \Sigma(x)\sum_{i=0}^{n} i(|u_i| - |v_i|),$$

so either $\Sigma(x) = 0$ or $\sum_{i=0}^{n} i(|u_i| - |v_i|) = 0$. The latter is not possible, because

$$\begin{aligned}
&\sum_{i=0}^{n} i(|u_i| - |v_i|) = \sum_{i=1}^{n}(|u_i \cdots u_n| - |v_i \cdots v_n|)\\
=&\sum_{i=1}^{n}(|u_0 \cdots u_n| - |u'_i| - (|v_0 \cdots v_n| - |v'_i|)) = \sum_{i=1}^{n}(-|u'_i| + |v'_i|) > 0,
\end{aligned}$$

by Condition N2 in the definition of normal form. Thus every solution $[x]$ is zero-sum. ◀

▶ **Lemma 17.** *Consider the nontrivial equation* (1)*. Let* $s_i = \Sigma(u_0 \cdots u_{i-1})$ *and* $t_i = \Sigma(v_0 \cdots v_{i-1})$ *for all* i*. If the equation has at least two zero-sum solutions, then* $(s_1, \ldots, s_n)$ *is a permutation of* $(t_1, \ldots, t_n)$*.*

Proof. Omitted. ◀

▶ **Lemma 18.** *Let* (1) *be an equation in normal form. Let*

$$h = H(u_0 \cdots u_n) - \max\{\Sigma(u_0 \cdots u_i) \mid i \in \{0, \ldots, n-1\}\}. \tag{3}$$

If the equation has at least three nonempty solutions, then every nonempty solution is of height h*. If the equation has two nonempty solutions, then the shorter one is of height* h *and the longer one of height at least* h*.*

Proof. The idea of the proof is to look at the first occurrences of the highest points on the curves of the left-hand side and the right-hand side of the equation; these must match. If the length of the solution changes, these first occurrences often move with respect to each other so that they no longer match; this puts a limit on the number of solutions under certain conditions. A first occurrence can be either inside a constant part or inside a variable. We will see that if the first occurrences are inside constant parts on both sides, then the solution is empty, if they are inside variables on both sides, then the solution is of height at least h and there can be at most one solution of height more than h, and if the first occurrence is inside a constant part on one side and inside a variable on the other side, then the solution is of height h, and if there is a solution of height more than h, then there can be at most one solution of height h.

For any word w, let $\phi(w)$ be its shortest prefix such that $H(\phi(w)) = H(w)$. For any solution $[x]$, we have

$$\phi(u_0 x u_1 \cdots x u_n) = \phi(v_0 x v_1 \cdots x v_n). \tag{4}$$

Let $s_i = \Sigma(u_0 \cdots u_{i-1})$ and $t_i = \Sigma(v_0 \cdots v_{i-1})$ for all i. Let i and j be such that $\phi(u_0 \cdots u_n) = u_0 \cdots u_{i-1}\phi(u_i)$ and $\phi(v_0 \cdots v_n) = v_0 \cdots v_{j-1}\phi(v_j)$. Because $[\varepsilon]$ is a solution, $\phi(u_0 \cdots u_n) = \phi(v_0 \cdots v_n)$ and thus

$$|u_0 \cdots u_{i-1}| + |\phi(u_i)| = |v_0 \cdots v_{j-1}| + |\phi(v_j)|. \tag{5}$$

By (5) and Condition N3 in the definition of normal form, $i > j$.

Because $[\varepsilon]$ is a solution, $H(u_0 \cdots u_n) = H(v_0 \cdots v_n)$, and by Lemma 17,

$$\max\{\Sigma(u_0 \cdots u_i) \mid i \in \{0, \ldots, n-1\}\} = \max\{\Sigma(v_0 \cdots v_i) \mid i \in \{0, \ldots, n-1\}\},$$

so

$$h = H(v_0 \cdots v_n) - \max\{\Sigma(v_0 \cdots v_i) \mid i \in \{0, \ldots, n-1\}\}.$$

Let k and l be the smallest indices such that $s_k = \max\{s_1, \ldots, s_n\}$ and $t_l = \max\{t_1, \ldots, t_n\}$. Then

$$\phi(u_0 x u_1 \cdots x u_n) = \begin{cases} u_0 x u_1 \cdots u_{i-1} x \phi(u_i) & \text{if } H(x) < h \text{ or if } H(x) = h \text{ and } i < k, \\ u_0 x u_1 \cdots x u_{k-1} \phi(x) & \text{if } H(x) > h \text{ or if } H(x) = h \text{ and } i \geq k, \end{cases}$$

$$\phi(v_0 x v_1 \cdots x v_n) = \begin{cases} v_0 x v_1 \cdots v_{j-1} x \phi(v_j) & \text{if } H(x) < h \text{ or if } H(x) = h \text{ and } j < l, \\ v_0 x v_1 \cdots x v_{l-1} \phi(x) & \text{if } H(x) > h \text{ or if } H(x) = h \text{ and } j \geq l, \end{cases}$$

This means that, for a given x, (4) can take one of four possible forms:

(i) If $H(x) < h$ or if $H(x) = h$, $i < k$ and $j < l$, then

$$u_0xu_1\cdots u_{i-1}x\phi(u_i) = v_0xv_1\cdots v_{j-1}x\phi(v_j)$$

and thus

$$|u_0\cdots u_{i-1}| + |\phi(u_i)| + (i-j)|x| = |v_0\cdots v_{j-1}| + |\phi(v_j)|.$$

Because $i > j$, it follows that this equality can hold for at most one $|x|$, so there is only one possible x in this case, namely, the empty word.

(ii) If $H(x) = h$, $i < k$ and $j \geq l$, then

$$u_0xu_1\cdots u_{i-1}x\phi(u_i) = v_0xv_1\cdots xv_{l-1}\phi(x),$$

but

$$\begin{aligned}&|u_0xu_1\cdots u_{i-1}x\phi(u_i)| = |u_0\cdots u_{i-1}| + |\phi(u_i)| + i|x| = |v_0\cdots v_{j-1}| + |\phi(v_j)| + i|x|\\ &> |v_0\cdots v_{l-1}| + l|x| \geq |v_0xv_1\cdots xv_{l-1}\phi(x)|\end{aligned}$$

by (5) and $i > j \geq l$, a contradiction.

(iii) If $H(x) > h$ or if $H(x) = h$, $i \geq k$ and $j \geq l$, then

$$u_0xu_1\cdots xu_{k-1}\phi(x) = v_0xv_1\cdots xv_{l-1}\phi(x)$$

and thus

$$|u_0\cdots u_{k-1}| + (k-l)|x| = |v_0\cdots v_{l-1}|.$$

By Condition N2 in the definition of normal form, $k > l$. It follows that this equality can hold for at most one $|x|$, so there is only one possible x in this case.

(iv) If $H(x) = h$, $i \geq k$ and $j < l$, then

$$u_0xu_1\cdots xu_{k-1}\phi(x) = v_0xv_1\cdots v_{j-1}x\phi(v_j)$$

and thus

$$|u_0\cdots u_{k-1}| + |\phi(x)| + (k-1-j)|x| = |v_0\cdots v_{j-1}| + |\phi(v_j)|. \tag{6}$$

If x and x' are solution words, then one of them is a prefix of the other, so if they have the same height, then $\phi(x) = \phi(x')$. Therefore, (6) can hold for more than one solution word x of height h only if $k-1-j = 0$. In general, this can happen (for example, if the equation has infinitely many solutions). However, if there exists a solution word of height more than h, then it follows from Case (iii) that $k > l$. Then $j < l < k$, so $k-1 > j$ and there is at most one solution word x of height h. ◀

▶ **Example 19.** Consider the equation

$$(XaXbXaabbabaXbabaabbab, abaabbabaXbabaabbXaXbX)$$

that was mentioned in Example 5. Let $a = 1$ and $b = -1$. The equation has exactly three solutions $[\varepsilon], [ab], [abaabbab]$. All of them are zero-sum, and their heights are $-\infty$, 1, 2, respectively. If we use the notation of the proof of Lemma 18, then $i = 3$, $j = 0$, $k = 2$, $l = 1$, and $h = 1$. We have $\phi(u_i) = \phi(aabbaba) = aa$, $\phi(v_j) = \phi(abaabbaba) = abaa$, $\phi(ab) = a$, and $\phi(abaabbab) = abaa$. Then

$$\phi(xaxbxaabbabaxbabaabbab) = \begin{cases} xaxbxaa & \text{if } x = \varepsilon,\\ xa\phi(x) & \text{if } x = abaabbab \text{ or if } x = ab,\end{cases}$$

$$\phi(abaabbabaxbabaabbxaxbx) = \begin{cases} abaa & \text{if } x = \varepsilon \text{ or if } x = ab,\\ abaabbaba\phi(x) & \text{if } x = abaabbab.\end{cases}$$

6 Some Lemmas

In this section, we state many lemmas about one-variable equations that will be used in the proof of the main result. The proofs are omitted.

A subset Z of Γ^* is called a *code* if the elements of Z do not satisfy any nontrivial relations. In other words, Z is a code if and only if for all $x_1, \ldots, x_m, y_1, \ldots, y_n \in Z$, $x_1 \cdots x_m = y_1 \cdots y_n$ implies $m = n$ and $x_i = y_i$ for all $i \in \{1, \ldots, m\}$. If Z is a code, then Z^* is a free monoid, and if Δ is an alphabet of the same size as Z, then the free monoids Z^* and Δ^* are isomorphic. More information about codes can be found in the book of Berstel, Perrin and Reutenauer [2].

The next lemma can be used to compress an equation into a shorter one. We will use it with two codes Z: The set of all minimal zero-sum words (those zero-sum words which cannot be written as a product of two shorter zero-sum words), and the set of words of a specific length.

▶ **Lemma 20.** *Let E be the equation (1) and let Z be a code. If $u_i, v_i \in Z^*$ for all i, then there exists an alphabet Δ and an isomorphism $h : Z^* \to \Delta^*$, and the equation*

$$(h(u_0)Xh(u_1)\cdots Xh(u_n), h(v_0)Xh(v_1)\cdots Xh(v_n)) \tag{7}$$

has the solution set $\{[h(x)] \mid [x] \in \mathrm{Sol}(E),\ x \in Z^*\}$.

Note that the equation E in Lemma 20 can have solution words that are not in Z^*, so (7) can have less solutions than E.

The next lemma can be used to cut off part of an equation so that all solutions are preserved, except possibly the empty solution (and maybe some additional solutions are added).

▶ **Lemma 21.** *Consider the equation (1). Let $k \in \{0, \ldots, n\}$ and let*

$$d = |v_0 \cdots v_{k-1}| - |u_0 \cdots u_k| \geq 0.$$

If all nonempty solutions of the equation are of length at least d, and if y is the common prefix of length d of all nonempty solution words, then each one of the nonempty solutions is a solution of the equation

$$(u_0 X u_1 \cdots X u_k y, v_0 X v_1 \cdots v_{k-1} X). \tag{8}$$

Using Lemma 21 requires the existence of a suitable index k. The next two lemmas can sometimes be used to find such an index. The proof of Lemma 22 is somewhat similar to the proof of Lemma 18, but simpler.

▶ **Lemma 22.** *Let (1) be an equation in normal form. If it has at least three nonempty solutions, and if there exists $k \in \{1, \ldots, n-1\}$ such that*

$$\Sigma(u_0) = \cdots = \Sigma(u_{k-1}) = 0 \neq \Sigma(u_k),$$

then every nonempty solution is of length more than $|v_0 \cdots v_{k-1}| - |u_0 \cdots u_k|$.

▶ **Lemma 23.** *Let the equation (1) have the solution set $[p^*]$ for some primitive word p. Let $u_0 = v_n = \varepsilon$. Let $j \in \{0, \ldots, n\}$ be the largest index such that the lengths of $u_0, \ldots, u_{j-1}$ and $v_0, \ldots, v_{j-1}$ are divisible by $|p|$. Then $j > 0$ and $|v_0 \cdots v_{j-1}| - |u_0 \cdots u_j| \leq |p|$.*

Lemma 21 does not guarantee that the new, shorter equation would have the empty solution. Sometimes the next lemma can be used to get around this problem.

▶ **Lemma 24.** *If the equation* (1) *has a nonempty solution,* $u_n = ua^m$ *for some* $u \in \Gamma^*$, $a \in \Gamma$ *and* $m \geq 0$, *and* $u_0 \cdots u_{n-1}u$ *is a prefix of* $v_0 \cdots v_n$, *then the equation has the empty solution.*

7 Main results

Now we are ready to prove our main results.

▶ **Theorem 25.** *If a one-variable equation has only finitely many solutions, it has at most three solutions.*

Proof. Assume that there is a counterexample. Then there is one with an empty solution by Lemma 13. Of all equations with the empty solution, at least three nonempty solutions, and only finitely many solutions, let E_1 be a shortest one. We are going to prove a contradiction by showing that there exists a shorter equation with these properties. By Lemma 15, we can assume that E_1 is the equation (1) and it is in normal form. By Lemma 16, each one of its solutions is zero-sum.

The idea of the proof is to cut off part of the equation to get a shorter equation E_2 that has at least three nonempty solutions but only finitely many. Unfortunately, E_2 does not necessarily have the empty solution. We map E_2 with a length-preserving mapping to get an equation E_3 that has at least three nonempty solution and also the empty solution. Unfortunately, E_3 might have infinitely many solutions. We analyze E_3 to find another way to cut off part of E_1 to get an equation E_4, which is then modified to an equation E_5. For E_5, we can finally prove that it has the empty solution and at least three but only finitely many nonempty solutions.

If $\Sigma(u_i) = 0$ for all $i < n$, then $\Sigma(v_i) = 0$ for all $i < n$ by Lemma 17, and then also $\Sigma(u_n) = 0$, because $\Sigma(u_0 \cdots u_n) = \Sigma(v_0 \cdots v_n)$ and $v_n = \varepsilon$. Thus all u_i, v_i are zero-sum, and we can use Lemma 20 with Z the set of all minimal zero-sum words to get a shorter equation with the same number of solutions, one of them empty.

For the rest of the proof, we assume that there exists a minimal $k < n$ such that $\Sigma(u_k) \neq 0$. By symmetry, we can assume that $\Sigma(u_k) > 0$. By Lemmas 22 and 21, we get a shorter equation

$$E_2 : (u_0 X u_1 \cdots X u_k y, v_0 X v_1 \cdots v_{k-1} X)$$

that has at least all the same nonempty solutions as E_1. It might have some other solutions as well, but it cannot have infinitely many solutions, because the intersection of an infinite solution set of a nontrivial one-variable equation and a finite solution set of a one-variable equation is of size at most two by Theorem 6 and Lemma 7. If it has also the empty solution, then we are done, but we do not know yet whether this is the case. We can use Lemma 17 for E_2 to see that $(\Sigma(u_0), \ldots, \Sigma(u_0 \cdots u_{k-1}))$ and $(\Sigma(v_0), \ldots, \Sigma(v_0 \cdots v_{k-1}))$ are permutations of each other. We know that $u_0, \ldots, u_{k-1}$ are zero-sum, so also $v_0, \ldots, v_{k-1}$ are zero-sum.

Let $[x_1]$ be the shortest nonempty solution of E_1. Let $\{a, b\}$ be an alphabet and let g be the morphism that maps the letter $\min(\mathrm{psw}(x_1))$ to b and every other letter to a. Let $f = g \circ \mathrm{psw}$. Then f is length-preserving, and if w is zero-sum, then $f(ww') = f(w)f(w')$. If $[x]$ is a nonempty solution of E_1, then $[f(x)]$ is a solution of the equation

$$E_3 : (f(u_0) X f(u_1) \cdots X f(u_k y), f(v_0) X f(v_1) \cdots f(v_{k-1}) X).$$

We have $f(u_k y) = f(u_k)g(\mathrm{psw}_{\Sigma(u_k)}(y))$. Because $\Sigma(u_k) > 0$ and y is a prefix of x_1, $\min(\mathrm{psw}_{\Sigma(u_k)}(y)) > \min(\mathrm{psw}(x_1))$. Thus $g(\mathrm{psw}_{\Sigma(u_k)}(y)) \in a^*$. Because $u_0 \cdots u_k$ is a prefix of $v_0 \cdots v_{k-1}$, also $f(u_0 \cdots u_k) = f(u_0) \cdots f(u_k)$ is a prefix of $f(v_0 \cdots v_{k-1}) = f(v_0) \cdots f(v_{k-1})$. We can use Lemma 24 with $g(\mathrm{psw}_{\Sigma(u_k)}(y))$ as a^m, so E_3 has the empty solution. If it has only finitely many solutions, then we are done. For the rest of the proof, we assume that it has infinitely many solutions. Then its solution set is $[p^*]$ for some primitive word p. Consequently, the length of every solution word of E_1 is divisible by $|p|$. Because the solution word $f(x_1)$ of E_3 contains the letter b, also p must contain b. This means that p cannot be a suffix of $g(\mathrm{psw}_{\Sigma(u_k)}(y)) \in a^*$, so $|p| > |y|$.

We can use Lemma 23 for E_3 to find an index j such that the lengths of $u_0, \ldots, u_{j-1}$ and $v_0, \ldots, v_{j-1}$ are divisible by $|p|$ and, if $j < k$, $|v_0 \cdots v_{j-1}| - |u_0 \cdots u_j| \leq |p|$ (remember that f is length-preserving). By letting $z = y$ if $j = k$, or by using Lemma 21 with j as k for E_1 otherwise, we get an equation

$$E_4 : (u_0 X u_1 \cdots X u_j z, v_0 X v_1 \cdots v_{j-1} X)$$

that has at least all the same nonempty solutions as E_1. In both cases, $|z| \leq |p|$. Like in the case of E_2, we see that E_4 cannot have infinitely many solutions. The lengths of all the constant words in E_4 are divisible by $|p|$, and so are the lengths of at least three nonempty solutions (the solutions of E_1). We can use Lemma 20 with $Z = \Gamma^{|p|}$ for E_4. If h is the morphism of Lemma 20, then we get the equation

$$E_5 : (h(u_0) X h(u_1) \cdots X h(u_j z), h(v_0) X h(v_1) \cdots h(v_{j-1}) X).$$

It has at least three nonempty solutions, but only finitely many. Because $|z| \leq |p|$, $h(u_j z) = h(u)c$, where u is a prefix of u_j and c is a letter. Because $u_0 \cdots u_j$ is a prefix of $v_0 \cdots v_{j-1}$, also $h(u_0 \cdots u_{j-1} u) = h(u_0) \cdots h(u_{j-1}) h(u)$ is a prefix of $h(v_0 \cdots v_{k-1}) = h(v_0) \cdots h(v_{k-1})$. We can use Lemma 24 with c as a and $m = 1$, so E_5 has the empty solution. This contradicts the minimality of E_1. ◀

▶ **Theorem 26.** *If a system of constant-free three-variable equations is independent and has a nonperiodic solution, then it has at most 17 equations.*

Proof. Follows from Theorem 25 and Theorem 8. ◀

8 Conclusion

We have proved that the maximal size of a finite solution set of a one-variable word equation is three, and that the maximal size of an independent system of constant-free three-variable equations with a nonperiodic solution is somewhere between two and 17.

Improving the bound 17 is an obvious open problem. A possible approach would be to improve the results in [16].

Another open problem is proving similar bounds for more than three variables. The result in [16] is based on a characterization of three-generator subsemigroups of a free semigroup by Budkina and Markov [3], or alternatively a similar result by Spehner [19, 20]. This means that it is very specific to the three-variable case, and analyzing the general case would require an entirely different approach.

Finally, characterizing possible solution sets of one-variable equations would be interesting. The possible infinite solution sets are given by Theorem 6, and every singleton set is possible, but for sets of size two or three the question is open.

Abstract

We investigate a standard operator on classes of languages: unambiguous polynomial closure. We show that if $\mathcal{C}$ is a class of regular languages having some mild properties, the membership problem for its unambiguous polynomial closure $UPol(\mathcal{C})$ reduces to the same problem for $\mathcal{C}$. We give a new, self-contained and elementary proof of this result. We also show that unambiguous polynomial closure coincides with alternating left and right deterministic closure. Finally, if additionally $\mathcal{C}$ is finite, we show that the separation and covering problems are decidable for $UPol(\mathcal{C})$.

1 Introduction

Most of the interesting classes of regular languages are built using a restricted set of operators. From a class $\mathcal{C}$, one may consider its Boolean closure $Bool(\mathcal{C})$, its polynomial closure $Pol(\mathcal{C})$, and deterministic variants thereof, which yield usually a more elaborate class than $\mathcal{C}$. It is therefore desirable to investigate the operators themselves rather than individual classes.

The *polynomial closure* $Pol(\mathcal{C})$ of a class $\mathcal{C}$ is its closure under union and marked concatenation (a *marked concatenation* of K and L is a language of the form KaL for a letter a). Together with the Boolean closure, it is used to define concatenation hierarchies: starting from a given class (*level 0* in the hierarchy), level $n + \frac{1}{2}$ is the polynomial closure of level n, and level $n+1$ is the Boolean closure of level $n+\frac{1}{2}$. The importance of these hierarchies stems from the fact that they are the combinatorial counterpart of quantifier alternation hierarchies in logic, which count the number of $\forall/\exists$ alternations needed to define a language [29, 23].

The main question when investigating a class of languages is the *membership* problem: can we decide whether an input language belongs to the class? Despite decades of research on concatenation hierarchies, one knows little about it. The state of the art is that when level 0 is finite and has some mild properties, membership is decidable for levels $\frac{1}{2}$, 1, $\frac{3}{2}$, and $\frac{5}{2}$ [21, 19, 16, 17, 23]. These results encompass those that were obtained previously [3, 2, 26, 14, 15] and even go beyond by investigating the *separation problem*, a generalization of membership. This problem for a class $\mathcal{C}$ takes *two arbitrary regular* languages as input (unlike membership, which takes a single one). It asks whether there exists a third language from $\mathcal{C}$, containing the first and disjoint from the second. Membership is the special case of separation when the input consists of a language and its complement. Although more difficult than membership, separation is also more rewarding. This is witnessed by a transfer

theorem [19, 23]: membership for $Pol(\mathcal{C})$ reduces to separation for $\mathcal{C}$. The above results on membership come from this theorem and the fact that separation is decidable for $Pol(\mathcal{C})$, $BPol(\mathcal{C}) \stackrel{\text{def}}{=} Bool(Pol(\mathcal{C}))$ and $Pol(BPol(\mathcal{C}))$ when $\mathcal{C}$ is finite with some mild properties. See [12, 23] for detailed surveys on concatenation hierarchies.

Unambiguous closure. Deterministic variants of the polynomial closure are also important. The most classical example is the unambiguous closure, where marked concatenations are required to be unambiguous. A marked concatenation KaL is *unambiguous* if every word w of KaL has a *unique* factorization $w = w'aw''$ with $w' \in K$ and $w'' \in L$. The *unambiguous closure* $UPol(\mathcal{C})$ of $\mathcal{C}$ is the closure of $\mathcal{C}$ under *disjoint* union and *unambiguous* concatenation. Note that it is not clear on the definition whether $UPol(\mathcal{C})$ is a Boolean algebra, even when $\mathcal{C}$ is.

A prominent example of a class built using unambiguous concatenation is that of *unambiguous languages* [25]. It is the unambiguous polynomial closure of the Boolean algebra generated by languages of the form A^*aA^*, where A is the working alphabet. Its robustness makes it one of the most investigated classes: it enjoys a number of equivalent definitions [27, 5, 7, 6, 28].

State of the art. The class $UPol(\mathcal{C})$ was described in algebraic terms in [13], following earlier work on deterministic products by Pin [9]. Note however that [9] starts from an alternate definition that assumes closure under Boolean operations already. Both papers use elaborate mathematical tools (categories, bilateral kernel, relational morphisms) as well as black boxes (results by Schützenberger [25] in [9] and a result of Rhodes [24] in [13]). Unambiguous polynomial closure also appears in concatenation hierarchies as *intermediate levels*: Pin and Weil [14, 15] have proved that $UPol(\mathcal{C}) = Pol(\mathcal{C}) \cap co\text{-}Pol(\mathcal{C})$, where $co\text{-}Pol(\mathcal{C})$ is the class consisting of all complements of languages in $Pol(\mathcal{C})$. Finally, a reduction from $UPol(\mathcal{C})$-membership to $\mathcal{C}$-membership was obtained in [1]. This proof is indirect: it is based on the nontrivial equality $UPol(\mathcal{C}) = Pol(\mathcal{C}) \cap co\text{-}Pol(\mathcal{C})$, which itself depends on the algebraic characterizations of $UPol(\mathcal{C})$ and $Pol(\mathcal{C})$ obtained in [13, 14, 15, 4].

Contributions. Unambiguous polynomial closure was not yet investigated with respect to separation, aside from the particular case of unambiguous languages [18]. This is the starting point of this paper: we look for a generic separation result applying to $UPol(\mathcal{C})$, similar to the ones obtained for $Pol(\mathcal{C})$ and $BPol(\mathcal{C})$ in [21]. This paper presents such a result: our main theorem states that when $\mathcal{C}$ is finite and satisfies some mild hypotheses, separation for $UPol(\mathcal{C})$ is decidable. However, as it is usual with separation, we also obtain several extra results as a byproduct of our work, improving our understanding of the $UPol$ operator:

- We had to rethink the way membership is classically handled for $UPol(\mathcal{C})$ in order to lift the techniques to separation. This yields a completely new, self-contained and elementary proof that under some natural hypothesis on $\mathcal{C}$, membership for $UPol(\mathcal{C})$ reduces to membership for $\mathcal{C}$. This proof also precisely pinpoints why this result holds for $UPol(\mathcal{C})$ but not $Pol(\mathcal{C})$. More precisely, we show that the languages from $\mathcal{C}$ needed to construct an $UPol(\mathcal{C})$ expression for a language L are all recognized by any recognizer of L.
- We obtain a new proof that $UPol(\mathcal{C})$ is a quotienting Boolean algebra when $\mathcal{C}$ is one.
- We obtain a new proof that $UPol(\mathcal{C}) = Pol(\mathcal{C}) \cap co\text{-}Pol(\mathcal{C})$ using our results on $Pol(\mathcal{C})$ [23].
- We obtain a previously unknown characterization of $UPol(\mathcal{C})$ in terms of alternating left and right deterministic concatenations, which are restricted forms of unambiguous concatenation. A marked concatenation KaL is *left (resp. right) deterministic* when $KaA^* \cap K = \emptyset$ (resp. $A^*aL \cap L = \emptyset$). We prove that $UPol(\mathcal{C})$ coincides with $ADet(\mathcal{C})$, the closure of $\mathcal{C}$ under disjoint union and left and right deterministic concatenation.

Organization of the paper. Section 2 sets up the notation and the terminology. Section 3 presents a solution of the membership problem for $UPol(\mathcal{C})$ when $\mathcal{C}$ has mild closure properties. This result also yields the above byproducts. Finally, in Section 4, we present an algorithm for solving separation for $UPol(\mathcal{C})$ when $\mathcal{C}$ is additionally finite.

2 Preliminaries

Words and languages. For the whole paper, we fix an arbitrary finite alphabet A. We denote by A^* the set of all finite words over A, and by $\varepsilon \in A^*$ the empty word. Given two words $u, v \in A^*$, we write uv for their concatenation. A *language (over A)* is a subset of A^*. Abusing terminology, we denote by u the singleton language $\{u\}$. It is standard to extend concatenation to languages: given $K, L \subseteq A^*$, we write $KL = \{uv \mid u \in K \text{ and } v \in L\}$. Moreover, we also consider marked concatenation, which is less standard. Given $K, L \subseteq A^*$, *a marked concatenation* of K with L is a language of the form KaL, for some $a \in A$.

A class of languages $\mathcal{C}$ is a set of languages. We say that $\mathcal{C}$ is a *lattice* when $\emptyset \in \mathcal{C}$, $A^* \in \mathcal{C}$ and $\mathcal{C}$ is closed under finite union and finite intersection: for any $K, L \in \mathcal{C}$, we have $K \cup L \in \mathcal{C}$ and $K \cap L \in \mathcal{C}$. Moreover, a *Boolean algebra* is a lattice $\mathcal{C}$ which is additionally closed under complement: for any $L \in \mathcal{C}$, we have $A^* \setminus L \in \mathcal{C}$. Finally, a class $\mathcal{C}$ is *quotienting* if it is closed under quotients. That is, for any $L \in \mathcal{C}$ and any word $u \in A^*$, the following properties hold:

$$u^{-1}L \stackrel{\text{def}}{=} \{w \in A^* \mid uw \in L\} \quad \text{and} \quad Lu^{-1} \stackrel{\text{def}}{=} \{w \in A^* \mid wu \in L\} \quad \text{both belong to } \mathcal{C}.$$

All classes that we consider are quotienting Boolean algebras of regular languages.

Regular languages. These are the languages that can be equivalently defined by nondeterministic finite automata, finite monoids or monadic second-order logic. In the paper, we work with the definition by monoids, which we recall now.

A *monoid* is a set M endowed with an associative multiplication $(s, t) \mapsto s \cdot t$ (also denoted by st) having a neutral element 1_M, *i.e.*, such that $1_M \cdot s = s \cdot 1_M = s$ for every $s \in M$. An *idempotent* of a monoid M is an element $e \in M$ such that $ee = e$. It is folklore that for any *finite* monoid M, there exists a natural number $\omega(M)$ (denoted by ω when M is understood) such that for any $s \in M$, the element s^ω is an idempotent.

Our proofs make use of the Green relations [8], which are defined on monoids (we use them as induction parameters). We briefly recall them. Given a monoid M and $s, t \in M$,

$$\begin{array}{ll} s \leqslant_{\mathcal{J}} t & \text{when there exist } x, y \in M \text{ such that } s = xty, \\ s \leqslant_{\mathcal{L}} t & \text{when there exists } x \in M \text{ such that } s = xt, \\ s \leqslant_{\mathcal{R}} t & \text{when there exists } y \in M \text{ such that } s = ty. \end{array}$$

Clearly, $\leqslant_{\mathcal{J}}$, $\leqslant_{\mathcal{L}}$ and $\leqslant_{\mathcal{R}}$ are preorders (*i.e.*, they are reflexive and transitive). We write $<_{\mathcal{J}}$, $<_{\mathcal{L}}$ and $<_{\mathcal{R}}$ for their strict variants (for example, $s <_{\mathcal{J}} t$ when $s \leqslant_{\mathcal{J}} t$ but $t \not\leqslant_{\mathcal{J}} s$). Finally, we write $\mathcal{J}$, $\mathcal{L}$ and $\mathcal{R}$ for the corresponding equivalence relations (for example, $s \mathcal{J} t$ when $s \leqslant_{\mathcal{J}} t$ and $t \leqslant_{\mathcal{J}} s$). There are many technical results about Green relations. We shall only need the following simple lemma which applies to *finite* monoids (see [11]).

▶ **Lemma 1.** *Consider a finite monoid M and $s, t \in M$ such that $s \mathcal{J} t$. Then, $s \leqslant_{\mathcal{R}} t$ implies $s \mathcal{R} t$. Symmetrically, $s \leqslant_{\mathcal{L}} t$ implies $s \mathcal{L} t$.*

Observe that A^* is a monoid whose multiplication is concatenation (the neutral element is ε). Thus, we may consider monoid morphisms $\alpha : A^* \to M$ where M is an arbitrary monoid. Given such a morphism and some language $L \subseteq A^*$, we say that L is *recognized* by α when there exists a set $F \subseteq M$ such that $L = \alpha^{-1}(F)$.

Given any language L, there exists a canonical morphism which recognizes it. Let us briefly recall its definition. One may associate to L an equivalence $\equiv_L$ over A^*: the *syntactic congruence of* L. Given $u, v \in A^*$, $u \equiv_L v$ if and only if $xuy \in L \Leftrightarrow xvy \in L$ for any $x, y \in A^*$. It is known and simple to verify that "$\equiv_L$" is a congruence on A^*. Thus, the set of equivalence classes $M_L = A^*/\equiv_L$ is a monoid and the map $\alpha_L : A^* \to M_L$ sending any word to its equivalence class is a morphism recognizing L, called the *syntactic morphism of* L. Finally, it is known that L is regular if and only if M_L is finite (*i.e.*, $\equiv_L$ has finite index): this is Myhill-Nerode theorem. In that case, one may compute the syntactic morphism $\alpha_L : A^* \to M_L$ from any representation of L (such as a finite automaton).

Decision problems. The two problems that we consider in the paper are both parametrized by an arbitrary class of languages $\mathcal{C}$: they serve as mathematical tools for analyzing $\mathcal{C}$. The *$\mathcal{C}$-membership problem* is the simplest one. It takes as input a single regular language L and asks whether $L \in \mathcal{C}$. The second one, *$\mathcal{C}$-separation*, is more general: it takes **two** regular languages L_1, L_2 as input and asks whether L_1 is $\mathcal{C}$-separable from L_2, that is, whether there exists $K \in \mathcal{C}$ such that $L_1 \subseteq K$ and $L_2 \cap K = \emptyset$. The language K is called a *separator* of L_1 and L_2. Note that $\mathcal{C}$-membership is easily reduced to $\mathcal{C}$-separation: given any regular language L, we have $L \in \mathcal{C}$ if and only if L is $\mathcal{C}$-separable from $A^* \setminus L$ (which is also regular).

3 Unambiguous polynomial closure

In this section, we define the unambiguous polynomial closure operation, which is the main focus of the paper. Furthermore, we investigate the associated membership problem.

3.1 Definition

Given two languages $H, L \subseteq A^*$, we say that their concatenation HL is *unambiguous* when any word $w \in HL$ admits a *unique* decomposition witnessing this membership: for any $u, u' \in H$ and $v, v' \in L$, if $w = uv = u'v'$, then $u = u'$ and $v = v'$. More generally, we say that a product of n languages $L_1 \cdots L_n$ is *unambiguous* when any word $w \in L_1 \cdots L_n$ admits a *unique* decomposition witnessing this membership. Note that unambiguous *marked* concatenations are well-defined: HaL is a product of three languages, namely H, $\{a\}$ and L.

▶ Remark. Clearly, not all products are unambiguous. For example, A^*aA^* is ambiguous: $aa \in A^*aA^*$ admits two decompositions witnessing this membership (εaa and $aa\varepsilon$).

▶ Remark. Being unambiguous is a *semantic* property: whether HL is unambiguous may not be apparent on the definitions of H and L. Moreover, this depends on the *product* HL and not only on the resulting language $K = HL$. It may happen that two products represent the same language but one is unambiguous while the other is not. For example, A^*aA^* is ambiguous while $(A \setminus \{a\})^*aA^*$ (which represents the same language) is unambiguous.

In the paper, we shall only need two special kinds of unambiguous products, which we now present. Let $K, L \subseteq A^*$ and $a \in A$. We say that the marked concatenation KaL,

- is *left deterministic* when $K \cap KaA^* = \emptyset$,
- is *right deterministic* when $L \cap A^*aL = \emptyset$.

▶ **Fact 2.** *Any left or right deterministic marked concatenation is unambiguous.*

We use these definitions to introduce three standard operations on classes of languages. Consider an arbitrary class $\mathcal{C}$.

- The *polynomial closure* of $\mathcal{C}$, denoted by $Pol(\mathcal{C})$, is the smallest class containing $\mathcal{C}$ and closed under marked concatenation and union: for any $H, L \in Pol(\mathcal{C})$ and $a \in A$, we have $HaL \in Pol(\mathcal{C})$ and $H \cup L \in Pol(\mathcal{C})$. Furthermore, we denote by *co-Pol*$(\mathcal{C})$ the class containing all complements of languages in $Pol(\mathcal{C})$: $L \in$ *co-Pol*$(\mathcal{C})$ when $A^* \setminus L \in Pol(\mathcal{C})$.
- The *unambiguous polynomial closure* of $\mathcal{C}$, denoted by $UPol(\mathcal{C})$, is the smallest class containing $\mathcal{C}$ and closed under *unambiguous* marked concatenation and *disjoint* union. That is, for any $H, L \in UPol(\mathcal{C})$ and $a \in A$, if HaL is unambiguous, then $HaL \in UPol(\mathcal{C})$ and if $H \cap L = \emptyset$, then $H \uplus L \in UPol(\mathcal{C})$. Here, we denote union by "$\uplus$" to underline the fact that H and L are disjoint (we use this convention in the whole paper).
- The *alternating deterministic closure* of $\mathcal{C}$, denoted by $ADet(\mathcal{C})$, is the smallest class containing $\mathcal{C}$ and closed under *deterministic* marked concatenation and *disjoint* union. That is, for any $H, L \in ADet(\mathcal{C})$ and $a \in A$, if HaL is either left or right deterministic, then $HaL \in ADet(\mathcal{C})$ and if $H \cap L = \emptyset$, then $H \uplus L \in ADet(\mathcal{C})$.

It is immediate by definition and Fact 2 that we have $\mathcal{C} \subseteq ADet(\mathcal{C}) \subseteq UPol(\mathcal{C}) \subseteq Pol(\mathcal{C})$. In general the inclusion $UPol(\mathcal{C}) \subseteq Pol(\mathcal{C})$ is strict. On the other hand, we shall prove that when $\mathcal{C}$ is a quotienting Boolean algebra, $ADet(\mathcal{C}) = UPol(\mathcal{C})$.

It is not immediate that $Pol(\mathcal{C})$, $UPol(\mathcal{C})$ and $ADet(\mathcal{C})$ have robust closure properties beyond those explicitly stated in the definitions. However, it turns out that when $\mathcal{C}$ satisfies robust properties itself, this is the case for these three classes as well. It was shown by Arfi [3] that when $\mathcal{C}$ is a quotienting Boolean algebra of regular languages, then $Pol(\mathcal{C})$ is a quotienting lattice. Pin [10] extended the result for the case when $\mathcal{C}$ is a quotienting lattice. Here, we are mostly interested in $UPol(\mathcal{C})$. We prove the following theorem which combines and extends several results by Pin, Straubing, Thérien and Weil [13, 15].

▶ **Theorem 3.** *Let $\mathcal{C}$ be a quotienting Boolean algebra of regular languages. Then, $UPol(\mathcal{C})$ is a quotienting Boolean algebra as well. Moreover, $UPol(\mathcal{C}) = ADet(\mathcal{C}) = Pol(\mathcal{C}) \cap$ co-$Pol(\mathcal{C})$.*

That $UPol(\mathcal{C})$ is a quotienting Boolean algebra of regular languages is due to Pin, Straubing and Thérien [13]. The correspondence between $UPol(\mathcal{C})$ and $Pol(\mathcal{C}) \cap$ *co-Pol*$(\mathcal{C})$ is due to Pin and Weil [15]. The correspondence between $UPol(\mathcal{C})$ and $ADet(\mathcal{C})$ is a new result, to the best of our knowledge. Let us point out that the original proofs of these results require a stronger hypothesis on $\mathcal{C}$, which needs additionally to be closed under inverse morphic image. Moreover, these proofs require to introduce and manipulate a lot of algebraic machinery. This is because they are based on a generic algebraic characterization of $UPol(\mathcal{C})$.

While we use a similar approach (*i.e.*, we prove a generic algebraic characterization of $UPol(\mathcal{C})$), our argument is much more elementary. The only algebraic notion that we need is the syntactic morphism of a regular language.

3.2 Algebraic characterization

We now present a generic algebraic characterization of $UPol(\mathcal{C})$. It holds provided that $\mathcal{C}$ is a quotienting Boolean algebra of regular languages. It implies Theorem 3, but also that $UPol(\mathcal{C})$-membership reduces to $\mathcal{C}$-membership.

The characterization is parameterized by two relations that we define now. Let $\mathcal{C}$ be some class of languages. Consider a finite monoid M and a *surjective* morphism $\alpha : A^* \to M$ (such as the syntactic morphism of some language). Given a pair $(s, t) \in M \times M$,

- (s, t) is a *$\mathcal{C}$-pair* (for α) when **no** language of $\mathcal{C}$ can separate $\alpha^{-1}(s)$ from $\alpha^{-1}(t)$.
- (s, t) is a *weak $\mathcal{C}$-pair* (for α) when **no** language of $\mathcal{C}$ **recognized by α** can separate $\alpha^{-1}(s)$ from $\alpha^{-1}(t)$.

Note that any $\mathcal{C}$-pair is also a weak $\mathcal{C}$-pair (the converse is not true in general). By definition, we are able to compute all $\mathcal{C}$-pairs as soon as we have an algorithm for $\mathcal{C}$-separation. On the other hand, computing all weak $\mathcal{C}$-pairs boils down to deciding $\mathcal{C}$-membership, as it suffices to check which languages recognized by α (the potential separators) belong to $\mathcal{C}$.

▶ Remark. An equivalent definition of the weak $\mathcal{C}$-pairs is to introduce them as the transitive closure of the $\mathcal{C}$-pairs. We prove this in the full version. In fact, when $\mathcal{C}$ is a quotienting Boolean algebra, the weak $\mathcal{C}$-pair relation is a congruence whose equivalence classes correspond exactly to the languages recognized by α and belonging to $\mathcal{C}$.

We may now state the following characterization of $UPol(\mathcal{C})$.

▶ **Theorem 4.** *Let $\mathcal{C}$ be a quotienting Boolean algebra of regular languages. Consider a regular language L and let $\alpha : A^* \to M$ be its syntactic morphism. The following are equivalent:*

1. $L \in UPol(\mathcal{C})$.
2. $L \in ADet(\mathcal{C})$.
3. $L \in Pol(\mathcal{C}) \cap co\text{-}Pol(\mathcal{C})$.
4. *For all $\mathcal{C}$-pairs $(s,t) \in M^2$, we have $s^{\omega+1} = s^\omega t s^\omega$.*
5. *For all weak $\mathcal{C}$-pairs $(s,t) \in M^2$, we have $s^{\omega+1} = s^\omega t s^\omega$.*

Theorem 3 is a simple corollary of Theorem 4 (it is standard that any class satisfying a property such as Item (4) in the theorem is a quotienting Boolean algebra). Another consequence is that if $\mathcal{C}$ is a quotienting Boolean algebra of regular languages, $UPol(\mathcal{C})$-membership reduces to the same problem for $\mathcal{C}$. Indeed, given as input a regular language L, one may compute its syntactic morphism α. By Theorem 4, deciding whether $L \in UPol(\mathcal{C})$ amounts to checking whether α satisfies Item (5). This is possible provided that we have all weak $\mathcal{C}$-pairs for α in hand. In turn, an algorithm for $\mathcal{C}$-membership immediately yields an algorithm for computing them all. Altogether, we obtain the following corollary.

▶ **Corollary 5.** *Let $\mathcal{C}$ be a quotienting Boolean algebra of regular languages and assume that $\mathcal{C}$-membership is decidable. Then $UPol(\mathcal{C})$-membership is decidable as well.*

We now focus on proving Theorem 4. A first point is that we do not show the equivalence (3) $\Leftrightarrow$ (4): it is a simple corollary of the generic characterization of $Pol(\mathcal{C})$ which is not our main focus in the paper (a full proof is available in [23]). Here, we concentrate on proving the implications (1) $\Rightarrow$ (4) $\Rightarrow$ (5) $\Rightarrow$ (2) $\Rightarrow$ (1). The implication (2) $\Rightarrow$ (1) ($ADet(\mathcal{C}) \subseteq UPol(\mathcal{C})$) is immediate. Even though the presentation is different, the equivalence (4) $\Leftrightarrow$ (5) is a result of [1] (which investigates $Pol(\mathcal{C}) \cap co\text{-}Pol(\mathcal{C})$) and is based on algebraic manipulations. We prove this equivalence as well as the implication (1) $\Rightarrow$ (4) in the full version, to focus on (5) $\Rightarrow$ (2), which is the most interesting implication: when a language satisfies (5), we show that it belongs to $ADet(\mathcal{C})$.

We fix a quotienting Boolean algebra of regular languages $\mathcal{C}$ for the proof. Consider an arbitrary surjective morphism $\alpha : A^* \to M$ satisfying Item (5) in Theorem 4. We show that any language recognized by α belongs to $ADet(\mathcal{C})$. We start with a preliminary lemma.

▶ **Lemma 6.** *There exists a finite monoid N and a surjective morphism $\beta : M \to N$ which satisfies the following properties:*

- *For any $s,t \in M$, (s,t) is a weak $\mathcal{C}$-pair if and only if $\beta(s) = \beta(t)$.*
- *Any language recognized by the composition $\gamma = \beta \circ \alpha : A^* \to N$ belongs to $\mathcal{C}$.*

Lemma 6 is obtained by proving that the weak $\mathcal{C}$-pair relation is a congruence on M and that for any equivalence class $F \subseteq M$, we have $\alpha^{-1}(F) \in \mathcal{C}$. It then suffices to define N as the quotient of M by this congruence. The proof is presented in the full version of the paper.

Let us come back to the main proof. Let $\beta : M \to N$ and the composition $\gamma = \beta \circ \alpha$ be defined as in Lemma 6. Given any $r_1, r_2, s \in M$ and any $x \in N$, we define:

$$L_s^x[r_1, r_2] = \{w \in \gamma^{-1}(x) \mid r_1\alpha(w)r_2 = s\}.$$

The purpose of introducing $L_s^x[r_1, r_2]$ is that it provides induction parameters s, r_1, r_2 and it coincides with $\alpha^{-1}(s)$ when $x = \beta(s)$, $r_1 = r_2 = 1_M$. Our goal is to show that it is in $ADet(\mathcal{C})$.

▶ **Proposition 7.** *Let $r_1, r_2, s \in M$ and $x \in N$. Then, $L_s^x[r_1, r_2] \in ADet(\mathcal{C})$.*

Before proving this proposition, let us use it to finish the main proof. By definition, a language recognized by α is a disjoint union of sets $\alpha^{-1}(s)$ for $s \in M$. Therefore, it suffices to prove that $\alpha^{-1}(s) \in ADet(\mathcal{C})$ for any $s \in M$. Let $x = \beta(s)$. Clearly, $L_s^{\beta(s)}[1_M, 1_M] = \alpha^{-1}(s)$. Thus, Proposition 7 yields that $\alpha^{-1}(s) \in ADet(\mathcal{C})$, finishing the proof.

It remains to prove Proposition 7. We let $r_1, r_2, s \in M$ and $x \in N$. Our objective is to show that $L_s^x[r_1, r_2] \in ADet(\mathcal{C})$. Observe that we may assume without loss of generality that $\beta(s) = \beta(r_1)x\beta(r_2)$. Otherwise, $L_s^x[r_1, r_2] = \emptyset \in ADet(\mathcal{C})$ by definition and the result is immediate. The proof is an induction on the three following parameters listed by order of importance (the three of them depend on Green's relations in both M and N):

1. The *rank of* $\beta(s)$ which is the number of elements $y \in N$ such that $\beta(s) \leqslant_{\mathcal{J}} y$.
2. The *right index of* r_1 which is the number of elements $t \in M$ such that $t \leqslant_{\mathcal{R}} r_1$.
3. The *left index of* r_2 which is the number of elements $t \in M$ such that $t \leqslant_{\mathcal{L}} r_2$.

We consider three cases depending on the following properties of s, r_1, r_2 and x.

- We say that x is *smooth* when $x \mathrel{\mathcal{J}} \beta(s)$.
- We say that r_1 is *right stable* when there exists $t \in M$ such that $\beta(t) \mathrel{\mathcal{R}} x$ and $r_1 t \mathrel{\mathcal{R}} r_1$.
- We say that r_2 is *left stable* when there exists $t \in M$ such that $\beta(t) \mathrel{\mathcal{L}} x$ and $tr_2 \mathrel{\mathcal{L}} r_2$.

In the base case, we assume that all three properties hold. Otherwise, we consider two inductive cases. First, we assume that x is not smooth. Then, we assume that either r_1 is not right stable or r_2 is not left stable.

Base case. Assume that x is smooth and that r_1, r_2 are respectively right and left stable. We use this hypothesis to prove the following lemma.

▶ **Lemma 8.** *For any $u, v \in \gamma^{-1}(x)$, we have $r_1\alpha(u)r_2 = r_1\alpha(v)r_2$.*

Observe that Lemma 8 concludes the proof. Indeed, by definition of $L_s^x[r_1, r_2]$, it implies that either $L_s^x[r_1, r_2] = \gamma^{-1}(x)$ (when $r_1\alpha(w)r_2 = s$ for all $w \in \gamma^{-1}(x)$) or $L_s^x[r_1, r_2] = \emptyset$ (when $r_1\alpha(w)r_2 \neq s$ for all $w \in \gamma^{-1}(x)$). Since both of these languages belong to $\mathcal{C} \subseteq ADet(\mathcal{C})$ by Lemma 6, Proposition 7 follows. It remains to prove Lemma 8 to conclude the base case. The argument relies on the following fact (this is where we use our hypothesis on r_1 and r_2).

▶ **Fact 9.** *When Item (5) in Theorem 4 holds, the two following properties hold as well:*

- *For all $t \in M$ such that $\beta(t) \mathrel{\mathcal{R}} x$, we have $r_1 t \mathrel{\mathcal{R}} r_1$.*
- *For all $t \in M$ such that $\beta(t) \mathrel{\mathcal{L}} x$, we have $tr_2 \mathrel{\mathcal{L}} r_2$.*

Let us first use the fact to prove Lemma 8 and finish the base case. Consider $u, v \in \gamma^{-1}(x)$, *i.e.*, $\beta(\alpha(u)) = \beta(\alpha(v)) = x$. We show that $r_1\alpha(u)r_2 = r_1\alpha(v)r_2$.

By hypothesis, we have $\beta(s) = \beta(r_1)x\beta(r_2)$. Moreover, $\beta(s) \mathrel{\mathcal{J}} x$ since x is smooth by hypothesis. Thus, $x\beta(r_2) \mathrel{\mathcal{J}} x$ and $\beta(r_1)x \mathrel{\mathcal{J}} x$. Hence, since $x\beta(r_2) \leqslant_{\mathcal{R}} x$ and $\beta(r_1)x \leqslant_{\mathcal{L}} x$, Lemma 1 implies $x\beta(r_2) \mathrel{\mathcal{R}} x$ and $\beta(r_1)x \mathrel{\mathcal{L}} x$. Since $\beta(\alpha(u)) = x$, this yields $\beta(\alpha(u)r_2) \mathrel{\mathcal{R}} x$ and $\beta(r_1\alpha(u)) \mathrel{\mathcal{L}} x$. Applying Fact 9 with $t = \alpha(u)r_2$, one gets $r_1\alpha(u)r_2 \mathrel{\mathcal{R}} r_1$ and $r_1\alpha(u)r_2 \mathrel{\mathcal{L}} r_2$.

We get $p, q \in M$ such that $r_1 = r_1\alpha(u)r_2p$ and $r_2 = qr_1\alpha(u)r_2$. Let $t = qr_1\alpha(u)r_2p = r_2p = qr_1$. We combine our two equalities for r_1 and r_2 to obtain,

$$r_1 = r_1\alpha(u)t = r_1(\alpha(u)t)^\omega \quad \text{and} \quad r_2 = t\alpha(u)r_2 = (t\alpha(u))^{\omega+1}r_2. \tag{1}$$

Since $\beta(\alpha(u)) = \beta(\alpha(v))$, we know that $\beta(\alpha(u)t) = \beta(\alpha(v)t)$. Therefore, $(\alpha(u)t, \alpha(v)t)$ is a weak $\mathcal{C}$-pair by Lemma 6, and Item (5) yields $(\alpha(u)t)^{\omega+1} = (\alpha(u)t)^\omega\alpha(v)t(\alpha(u)t)^\omega$. We may now multiply by r_1 on the left and by $\alpha(u)r_2$ on the right to get,

$$r_1(\alpha(u)t)^\omega\alpha(u)(t\alpha(u))^{\omega+1}r_2 = r_1(\alpha(u)t)^\omega\alpha(v)(t\alpha(u))^{\omega+1}r_2.$$

Since we already know from (1) that $r_1 = r_1(\alpha(u)t)^\omega$ and $r_2 = (t\alpha(u))^{\omega+1}r_2$, we get as desired that $r_1\alpha(u)r_2 = r_1\alpha(v)r_2$, finishing the proof of Lemma 8. It remains to prove Fact 9.

Proof of Fact 9. By symmetry, we focus on the first property and leave the second to the reader. Let $t \in M$ such that $\beta(t) \mathrel{\mathcal{R}} x$. We show that $r_1t \mathrel{\mathcal{R}} r_1$. By hypothesis, r_1 is right stable which yields $t' \in M$ such that $\beta(t') \mathrel{\mathcal{R}} x \mathrel{\mathcal{R}} \beta(t)$ and $r_1t' \mathrel{\mathcal{R}} r_1$. Since $\beta(t') \mathrel{\mathcal{R}} \beta(t)$, we have $y \in N$ such that $\beta(t') = \beta(t)y$. Let $p \in M$ such that $\beta(p) = y$: we have $\beta(t') = \beta(tp)$. Since $r_1t' \mathrel{\mathcal{R}} r_1$, we have $q \in M$ such that $r_1 = r_1t'q$ which yields $r_1 = r_1(t'q)^\omega = r_1(t'q)^{\omega+1}$. We have $\beta(t'q) = \beta(tpq)$ which means that $(t'q, tpq)$ is a weak $\mathcal{C}$-pair by Lemma 6. Therefore, Equation (5) yields that $(t'q)^{\omega+1} = (t'q)^\omega tpq(t'q)^\omega$. Finally, we obtain,

$$r_1 = r_1(t'q)^{\omega+1} = r_1(t'q)^\omega tpq(t'q)^\omega = r_1tpq(t'q)^\omega.$$

This implies that $r_1 \leqslant_{\mathcal{R}} r_1t$. Since it is immediate that $r_1t \leqslant_{\mathcal{R}} r_1$, we get $r_1t \mathrel{\mathcal{R}} r_1$. ◀

First inductive case. We now assume that x is not smooth: x and $\beta(s)$ are not $\mathcal{J}$-equivalent. We use induction on our first parameter (the rank of $\beta(s)$). Recall that we assumed $\beta(s) = \beta(r_1)x\beta(r_2)$, which yields $\beta(s) \leqslant_{\mathcal{J}} x$. Thus, we have $\beta(s) <_{\mathcal{J}} x$ by hypothesis.

By definition, $L_s^x[r_1, r_2]$ is the disjoint union of all languages $\alpha^{-1}(t)$ where $t \in M$ satisfies $\beta(t) = x$ and $r_1tr_2 = s$. Therefore, it suffices to show that for any $t \in M$ such that $\beta(t) = x$, we have $\alpha^{-1}(t) \in ADet(\mathcal{C})$. This is immediate by induction. Indeed, since $\beta(t) = x$, we have $\alpha^{-1}(t) = L_t^x[1_M, 1_M]$. Moreover, since $\beta(s) <_{\mathcal{J}} x$, we have $\beta(s) <_{\mathcal{J}} \beta(t)$. It follows that the rank of $\beta(t)$ is strictly smaller than the one of $\beta(s)$. Hence, we may apply induction on our first and most important parameter to get $L_t^x[1_M, 1_M] \in ADet(\mathcal{C})$.

Second inductive case. We assume that either r_1 is not *right stable* or r_2 is not *left stable*. By symmetry, we treat the case when r_1 is not right stable and leave the other to the reader.

▶ Remark. We only apply induction on our two first parameters. Moreover, we show that $L_s^x[r_1, r_2]$ is built from languages in $ADet(\mathcal{C})$ (obtained from induction) using only disjoint union and left deterministic marked concatenations. Induction on our third parameter and right deterministic marked concatenations are used in the case when r_2 is not left stable.

Observe that we have $x <_{\mathcal{J}} 1_N$ (x is not maximal for $\leqslant_{\mathcal{J}}$). Indeed, otherwise, we would have $x \mathrel{\mathcal{R}} 1_N$ by Lemma 1 and r_1 would be left stable: $1_M \in M$ would satisfy $\beta(1_M) = 1_N \mathrel{\mathcal{R}} x$ and $r_11_M = r_1 \mathrel{\mathcal{R}} r_1$. Therefore, there are elements $y \in N$ such that $x <_{\mathcal{J}} y$.

We use this observation to define T as the set of all triples $(y, a, z) \in N \times A \times N$ such that $x = y\gamma(a)z$, $x <_{\mathcal{J}} y$ and $x \mathrel{\mathcal{J}} y\gamma(a)$. Using the definition of T and the fact that $x <_{\mathcal{J}} 1_N$, one may decompose $L_s^x[r_1, r_2]$ as follows (this lemma is proved in the full version).

▶ **Lemma 10.** *The language $L_s^x[r_1, r_2]$ is equal to the following disjoint union,*

$$L_s^x[r_1, r_2] = \biguplus_{(y,a,z)\in T} \left(\biguplus_{t\in\beta^{-1}(y)} \alpha^{-1}(t) \cdot a \cdot L_s^z[r_1 t\alpha(a), r_2] \right).$$

We now use Lemma 10 to show as desired that $L_s^x[r_1, r_2] \in ADet(\mathcal{C})$. Since $ADet(\mathcal{C})$ is closed under disjoint union by definition, it suffices to show that for any $(y, a, z) \in T$ and any $t \in \beta^{-1}(y)$, we have,

$$\alpha^{-1}(t) \cdot a \cdot L_s^z[r_1 t\alpha(a), r_2] \in ADet(\mathcal{C}).$$

We prove that this is a left deterministic marked concatenation of two languages in $ADet(\mathcal{C})$ which concludes the proof.

We start with $\alpha^{-1}(t) \in ADet(\mathcal{C})$. Since $y = \beta(t)$, we have $\alpha^{-1}(t) = L_t^y[1_M, 1_M]$. Moreover, since $\beta(s) = \beta(r_1)x\beta(r_2)$, we have $\beta(s) \leqslant_{\mathcal{J}} x$. Finally, by definition of T we have $x <_{\mathcal{J}} y = \beta(t)$. Altogether, we get $\beta(s) <_{\mathcal{J}} \beta(t)$: the rank of $\beta(t)$ is strictly smaller than the one of $\beta(s)$ and induction on our first parameter yields $\alpha^{-1}(t) = L_t^y[1_M, 1_M] \in ADet(\mathcal{C})$.

We turn to $L_s^z[r_1 t\alpha(a), r_2] \in ADet(\mathcal{C})$. By definition of T, we have $x \mathcal{J} y\gamma(a)$ and $x = y\gamma(a)z$ which yields that $x \mathcal{R} y\gamma(a)$ by Lemma 1. Moreover, since $y = \beta(t)$, it follows that $x \mathcal{R} \beta(t\alpha(a))$. Therefore, since we know that r_1 is **not** right stable (this is our hypothesis), it follows that r_1 and $r_1 t\alpha(a)$ are not $\mathcal{R}$-equivalent. Since it is clear that $r_1 t\alpha(a) \leqslant_{\mathcal{R}} r_1$, it follows that $r_1 t\alpha(a) <_{\mathcal{R}} r_1$: the right index of $r_1 t\alpha(a)$ is strictly smaller than the one of r_1. By induction on our second parameter, we then get that $L_s^z[r_1 t\alpha(a), r_2] \in ADet(\mathcal{C})$.

It remains to show that $\alpha^{-1}(t) \cdot a \cdot L_s^z[r_1 t\alpha(a), r_2]$ is a left deterministic marked concatenation, *i.e.*, that $\alpha^{-1}(t) \cap \alpha^{-1}(t)aA^* = \emptyset$. Since $\beta(t) = y$, we have $\alpha^{-1}(t) \subseteq \gamma^{-1}(y)$ and it suffices to show that $\gamma^{-1}(y) \cap \gamma^{-1}(y)aA^* = \emptyset$. Let $w \in \gamma^{-1}(y)$ and $w' \in \gamma^{-1}(y)aA^*$, we show that $w \neq w'$. Since $(x, a, z) \in T$, we have $x <_{\mathcal{J}} y$ and $x \mathcal{J} y\gamma(a)$. It follows that $y\gamma(a) <_{\mathcal{J}} y$. Finally, we have $\gamma(w) = y$ and $\gamma(w') = y\gamma(a)y'$ for some $y' \in N$. This implies that $\gamma(w') \leqslant_{\mathcal{J}} y\gamma(a) <_{\mathcal{J}} y = \gamma(w)$. Therefore $\gamma(w) \neq \gamma(w')$ which implies that $w \neq w'$.

4 Separation

We now turn to separation for $UPol(\mathcal{C})$ and show that the problem is decidable for any finite quotienting Boolean algebra $\mathcal{C}$. For the sake of avoiding clutter, we fix $\mathcal{C}$ for the section.

▶ Remark. This result may seem weak: our solution for $UPol(\mathcal{C})$-separation requires $\mathcal{C}$ to be finite while $UPol(\mathcal{C})$-membership reduces to $\mathcal{C}$-membership. This intuition is wrong: the result on separation is the strongest. The proof of Theorem 4 shows that when $L \in UPol(\mathcal{C})$, the basic languages in $\mathcal{C}$ needed to build L are all recognized by the syntactic morphism of L. Hence, $L \in UPol(\mathcal{C})$ if and only if $L \in UPol(\mathcal{D})$ where $\mathcal{D} \subseteq \mathcal{C}$ is a *finite class* obtained from the syntactic morphism of L. We lose this when moving to separation: the languages in $\mathcal{C}$ needed to build a potential separator in $UPol(\mathcal{C})$ may not be encoded in our two inputs.

Our algorithm is based on a general framework designed to handle separation problems and to present solutions in an elegant way. It was introduced in [20, 22]. We first summarize what we need in this framework to present our solution for $UPol(\mathcal{C})$-separation.

▶ Remark. The framework of [20, 22] is actually designed to handle a more general decision problem: covering, which generalizes separation to arbitrarily many input languages. Thus, our solution actually yields an algorithm for $UPol(\mathcal{C})$-covering as well. While we do not detail this point due to lack of space, this follows from the definitions of [20, 22].

4.1 Methodology

We briefly recall the framework of [20, 22]. We refer the reader to [22] for details. The approach is based on "rating maps", a notion designed to measure how well a language separates others.

The definition of rating maps relies on semirings. A *semiring* is a set R equipped with two binary operations $+$ and $\cdot$, called addition and multiplication, satisfying the following axioms:

- $(R, +)$ is a commutative monoid whose neutral element is denoted by 0_R.
- $(R, \cdot)$ is a monoid whose neutral element is denoted by 1_R.
- The multiplication distributes over addition: $r \cdot (s + t) = rs + rt$ and $(s + t) \cdot r = sr + tr$.
- The element 0_R is a zero for multiplication: for any $r \in R$, $0_R \cdot r = r \cdot 0_R = 0_R$.

Moreover, we say that a semiring R is *idempotent* when any element $r \in R$ is idempotent for addition: $r + r = r$. Any idempotent semiring R can be equipped with a canonical order "$\leq$": given $s, r \in R$, we have $s \leq r$ when $s + r = r$. It can be verified that this is indeed an order which is compatible with addition and multiplication (R being idempotent is required).

▶ **Example 11.** The set 2^{A^*} of all languages over A is an idempotent semiring: the addition is union and the multiplication is language concatenation. In this case, the canonical order is inclusion ($H \subseteq L$ if and only if $H \cup L = L$). Another important example is the powerset 2^M of any monoid M. Again the addition is union (therefore, the order is inclusion). The multiplication is obtained from the one of M: given $S, T \in 2^M$, $S \cdot T = \{st \mid s \in S \text{ and } t \in T\}$.

Rating maps. A rating map[1] is a *semiring morphism*, $\rho : 2^{A^*} \to R$ where R is a *finite idempotent semiring*. It can be verified that any rating map is compatible with the canonical order ($K \subseteq L \Rightarrow \rho(K) \leq \rho(L)$). For the sake of improved readability, when applying a rating map ρ to a singleton language $\{w\}$, we shall simply write $\rho(w)$ for $\rho(\{w\})$. The connection with separation only requires to consider special rating maps called "*nice*". A rating map $\rho : 2^{A^*} \to R$ is *nice* if for any language $K \subseteq A^*$, we have $\rho(K) = \sum_{w \in K} \rho(w)$ (note that this sum boils down to a finite one, as R is a finite idempotent commutative monoid for addition).

▶ Remark. Any nice rating map $\rho : 2^{A^*} \to R$ is finitely representable: it is determined by the images $\rho(a)$ of letters $a \in A$. We may speak of algorithms whose inputs are nice rating maps.

Solving $UPol(\mathcal{C})$-separation requires to consider a special class of rating maps: the *$\mathcal{C}$-compatible ones* (our algorithm is restricted to them). The definition is based on a canonical equivalence $\sim_{\mathcal{C}}$ on A^* associated to $\mathcal{C}$. Given $u, v \in A^*$, we write $u \sim_{\mathcal{C}} v$ if and only if $u \in L \Leftrightarrow v \in L$ for all $L \in \mathcal{C}$. Clearly, $\sim_{\mathcal{C}}$ is an equivalence relation. For any word $w \in A^*$, we write $[w]_{\mathcal{C}} \subseteq A^*$ for the $\sim_{\mathcal{C}}$-class of w. Moreover, since $\mathcal{C}$ is a finite quotienting Boolean algebra, we have the following classical properties.

▶ **Lemma 12.** *The equivalence $\sim_{\mathcal{C}}$ is a congruence of finite index for word concatenation. Moreover, for any language $L \subseteq A^*$, we have $L \in \mathcal{C}$ if and only if L is a union of $\sim_{\mathcal{C}}$-classes.*

Lemma 12 implies that the set $A^*/\sim_{\mathcal{C}}$ of $\sim_{\mathcal{C}}$-classes is a finite monoid and the map $w \mapsto [w]_{\mathcal{C}}$ is a morphism. For the sake of avoiding confusion with language concatenation, we shall write "$\bullet$" for the monoid multiplication of $A^*/\sim_{\mathcal{C}}$. In general, if $C, D \subseteq A^*$ are $\sim_{\mathcal{C}}$-classes, then $C \bullet D \neq CD$ (indeed, CD is not even a $\sim_{\mathcal{C}}$-class in general).

[1] What we call rating map here is called **multiplicative** rating map in [22] (the "true" rating maps are weaker and do not require a multiplication). We abuse terminology for the sake of improved readability.

We may now define $\mathcal{C}$-compatibility. We say that a rating map $\rho : 2^{A^*} \to R$ is *$\mathcal{C}$-compatible* when there exists a map $r \mapsto [\![r]\!]_{\mathcal{C}}$ from R to $2^{A^*/\sim_{\mathcal{C}}}$ such that (1) for every $K \subseteq A^*$, we have $[\![\rho(K)]\!]_{\mathcal{C}} = \{[w]_{\mathcal{C}} \mid w \in K\}$ and (2) for all $r, r' \in R$, such that $r \leq r'$, we have $[\![r]\!]_{\mathcal{C}} \subseteq [\![r']\!]_{\mathcal{C}}$.

▶ Remark. Intuitively, Condition (1) in the definition of $\mathcal{C}$-compatibility states that the image $\rho(K)$ of any language K records the $\sim_{\mathcal{C}}$-classes of words of K. The purpose of Condition (2) is to constrain the definition of the map $[\![\ ]\!]_{\mathcal{C}}$ on elements that have no preimage under ρ.

Optimal covers. We use rating maps to define objects called "optimal universal $\mathcal{D}$-covers", which encode separation-related information. We fix an arbitrary Boolean algebra $\mathcal{D}$ for which one wants a $\mathcal{D}$-separation algorithm (we are interested in the case $\mathcal{D} = \mathit{UPol}(\mathcal{C})$).

A *cover of some language* L is a *finite* set of languages $\mathbf{K}$ such that $L \subseteq \bigcup_{K \in \mathbf{K}} K$. When $L = A^*$, we speak of *universal cover*. Moreover, we say that $\mathbf{K}$ is a $\mathcal{D}$-cover when all $K \in \mathbf{K}$ belong to $\mathcal{D}$. A fixed rating map $\rho : 2^{A^*} \to R$ is used to define a "quality measure" for $\mathcal{D}$-covers which yields a notion of "best" universal $\mathcal{D}$-cover. Given a finite set of languages $\mathbf{K}$ (such as a universal $\mathcal{D}$-cover), the *ρ-imprint* $\mathcal{I}[\rho](\mathbf{K})$ of $\mathbf{K}$ is the following subset of R:

$$\mathcal{I}[\rho](\mathbf{K}) = \{r \in R \mid r \leq \rho(K) \text{ for some } K \in \mathbf{K}\}.$$

We now define the optimal universal $\mathcal{D}$-covers as those with the smallest possible ρ-imprint (with respect to inclusion). A *universal $\mathcal{D}$-cover $\mathbf{K}$ is optimal for ρ* when $\mathcal{I}[\rho](\mathbf{K}) \subseteq \mathcal{I}[\rho](\mathbf{K}')$ for any universal $\mathcal{D}$-cover $\mathbf{K}'$. In general, there can be infinitely many optimal universal $\mathcal{D}$-covers for a given rating map ρ. The crucial point is that there always exists a least one. This is simple and proved in [22]. The key idea is that there are finitely many possible ρ-imprints (since R is finite) and given two universal $\mathcal{D}$-covers, one may always build a third one which has a smaller ρ-imprint than the first two, by simple use of language intersections.

Finally, a key observation is that by definition, all optimal universal $\mathcal{D}$-covers for ρ share the same ρ-imprint. This unique ρ-imprint is a *canonical* object for $\mathcal{D}$ and ρ called the *$\mathcal{D}$-optimal universal ρ-imprint* and we denote it by $\mathcal{I}_{\mathcal{D}}[\rho]$. That is, $\mathcal{I}_{\mathcal{D}}[\rho] = \mathcal{I}[\rho](\mathbf{K})$ for any optimal universal $\mathcal{D}$-cover $\mathbf{K}$ for ρ.

The connection with separation. We may now explain how these notions are used to handle separation. This is summarized by the following lemma.

▶ **Lemma 13.** *Let $\mathcal{D}$ be a Boolean algebra. If there exists an algorithm that takes as input a nice $\mathcal{C}$-compatible rating map $\rho : 2^{A^*} \to R$ and outputs $\mathcal{I}_{\mathcal{D}}[\rho]$, then $\mathcal{D}$-separation is decidable.*

Let us sketch how to go from computing $\mathcal{D}$-optimal ρ-imprints to $\mathcal{D}$-separation (see [20, 22] for a full proof of Lemma 13). Consider two regular languages L_1 and L_2: we wish to know whether L_1 is $\mathcal{D}$-separable from L_2. Since $\mathcal{C}$ is finite, one can build a monoid morphism $\alpha : A^* \to M$, with M finite, recognizing both L_1 and L_2 as well as all languages in $\mathcal{C}$. Furthermore, one may lift α as a map $\rho : 2^{A^*} \to 2^M$ by defining $\rho(K) = \{\alpha(w) \mid w \in K\}$ for any language $K \subseteq A^*$. It is simple to verify that this map ρ is a nice $\mathcal{C}$-compatible rating map. Moreover, the two following properties (which we prove in the full version) hold:

- L_1 is $\mathcal{D}$-separable from L_2 iff for any $s_1 \in \alpha(L_1)$ and $s_2 \in \alpha(L_2)$, we have $\{s_1, s_2\} \notin \mathcal{I}_{\mathcal{D}}[\rho]$.
- When the first item holds, one may build a separator in $\mathcal{D}$ from any optimal universal $\mathcal{D}$-cover $\mathbf{K}$ for ρ: this separator is the union of all languages intersecting L_1 in $\mathbf{K}$.

By the first item, having an algorithm that computes $\mathcal{I}_{\mathcal{D}}[\rho] \subseteq 2^M$ suffices to decide whether L_1 is $\mathcal{D}$-separable from L_2. Moreover, by the second item, having an algorithm that computes an optimal universal $\mathcal{D}$-cover $\mathbf{K}$ for ρ is enough to build a separator (when it exists).

▶ Remark. Here, we only use the sets of size two in $\mathcal{I}_{\mathcal{D}}[\rho] \subseteq 2^M$. However, $\mathcal{I}_{\mathcal{D}}[\rho]$ contains more information corresponding to the more general $\mathcal{D}$-covering problem considered in [20, 22].

4.2 Computing $UPol(\mathcal{C})$-optimal universal imprints

We use the framework defined above to present an algorithm for $UPol(\mathcal{C})$-separation. We give a characterization $UPol(\mathcal{C})$-optimal imprints. It yields a procedure for computing them.

Consider a rating map $\rho : 2^{A^*} \to R$. For any subset $S \subseteq R$, we say that S is $UPol(\mathcal{C})$-*saturated* (for ρ) if it contains the set $\mathcal{I}_{triv}[\rho] = \{r \in R \mid r \leq \rho(w) \text{ for some } w \in A^*\}$ and is closed under the following operations:

1. *Downset*: for any $s \in S$, if $r \in R$ satisfies $r \leq s$, then we have $r \in S$.
2. *Multiplication*: For any $s, t \in S$, we have $st \in S$.
3. $UPol(\mathcal{C})$-*closure*: Given two $\sim_{\mathcal{C}}$-classes C, D and $s, t \in S$ such that $[\![s]\!]_{\mathcal{C}} = \{C \bullet D\}$ and $[\![t]\!]_{\mathcal{C}} = \{D \bullet C\}$, we have $s^\omega \cdot \rho(C) \cdot t^\omega \in S$.

We are ready to state the main theorem of this section: when ρ is $\mathcal{C}$-compatible, $UPol(\mathcal{C})$-saturation characterizes the $UPol(\mathcal{C})$-optimal universal ρ-imprint.

▶ **Theorem 14.** *Let $\rho : 2^{A^*} \to R$ be a $\mathcal{C}$-compatible rating map. Then, $\mathcal{I}_{UPol(\mathcal{C})}[\rho]$ is the smallest $UPol(\mathcal{C})$-saturated subset of R (with respect to inclusion).*

Clearly, given a nice $\mathcal{C}$-compatible rating map $\rho : 2^{A^*} \to R$ as input, one may compute the smallest $UPol(\mathcal{C})$-saturated subset of R with a least fixpoint algorithm. One starts from $\mathcal{I}_{triv}[\rho]$ (which is clearly computable) and saturates this set with the three above operations. Thus, we get a procedure for computing $\mathcal{I}_{UPol(\mathcal{C})}[\rho]$ from any input nice $\mathcal{C}$-compatible rating map. By Lemma 13, this yields the desired corollary: $UPol(\mathcal{C})$-separation is decidable.

▶ **Corollary 15.** *For any finite quotienting Boolean algebra $\mathcal{C}$, $UPol(\mathcal{C})$-separation is decidable.*

The proof of Theorem 14 is a difficult generalization of the argument we used to show the algebraic characterization of $UPol(\mathcal{C})$ (*i.e.*, Theorem 4). We postpone it to the full version. An interesting byproduct of this proof is an algorithm which computes optimal universal $UPol(\mathcal{C})$-covers (and therefore $UPol(\mathcal{C})$-separators when they exist, as we explained above).

5 Conclusion

We presented a new, self-contained proof that for any quotienting Boolean algebra regular languages $\mathcal{C}$, membership for $UPol(\mathcal{C})$ reduces to membership for $\mathcal{C}$. An interesting byproduct of this proof is that $UPol(\mathcal{C})$ corresponds exactly to the class $ADet(\mathcal{C})$, which is obtained by restricting the unambiguous marked concatenations to left or right deterministic ones. Moreover, we showed that when $\mathcal{C}$ is a finite quotienting Boolean algebra, $UPol(\mathcal{C})$-separation is decidable. This completes similar results of [21] for $Pol(\mathcal{C})$ and $Bool(Pol(\mathcal{C}))$ and of [16, 17] for $Pol(Bool(Pol(\mathcal{C})))$. These results raise several natural questions.

Historically, $UPol(\mathcal{C})$ was investigated together with two weaker operations: left and right deterministic closures. The left (resp. right) deterministic closure of $\mathcal{C}$, is the smallest class containing $\mathcal{C}$ closed under disjoint union and left (resp. right) deterministic marked concatenation. Our results can be adapted to these two weaker operations. In both cases, membership reduces to $\mathcal{C}$-membership when $\mathcal{C}$ is a quotienting Boolean algebra of regular languages and separation is decidable when $\mathcal{C}$ is a finite quotienting Boolean algebra. In fact, these operations are simpler to handle than $UPol(\mathcal{C})$. We leave this for further work.

Another question is whether our results can be pushed to classes built by combining unambiguous polynomial closure with other operations. A natural example is as follows. It is known [17] that $Pol(Bool(Pol(\mathcal{C})))$-separation is decidable when $\mathcal{C}$ is a finite quotienting Boolean algebra. Is this true as well for $UPol(Bool(Pol(\mathcal{C})))$? This seems difficult: the proof of [17] crucially exploits the fact that $Pol(Bool(Pol(\mathcal{C})))$ is closed under concatenation (which is not the case for $UPol(Bool(Pol(\mathcal{C}))))$ to handle the first polynomial closure.

A Superpolynomial Lower Bound for the Size of Non-Deterministic Complement of an Unambiguous Automaton

Abstract

Unambiguous non-deterministic finite automata (UFA) are non-deterministic automata (over finite words) such that there is at most one accepting run over each input. Such automata are known to be potentially exponentially more succinct than deterministic automata, and non-deterministic automata can be exponentially more succinct than them.

In this paper we establish a superpolynomial lower bound for the state complexity of the translation of an UFA to a non-deterministic automaton for the complement language. This disproves the formerly conjectured polynomial upper bound for this translation. This lower bound only involves a one letter alphabet, and makes use of the random graph methods.

The same proof also shows that the translation of sweeping automata to non-deterministic automata is superpolynomial.

1 Introduction

In many areas of computer science, the relationship between deterministic and non-deterministic devices is a subject of significant interest. An intermediate notion between deterministic and non-deterministic computation devices is the notion of unambiguous device. Such a device can make non-deterministic choices, but it is guaranteed that for every input there is at most one accepting execution trace.

For finite automata it is known that non-deterministic automata can be exponentially more succinct than deterministic automata [10]. It is also known that unambiguous automata can be exponentially more succinct than deterministic automata and in other situations they can be exponentially less succinct than non-deterministic automata [8]. The paper establishing exponential separation also defines several automata classes of limited ambiguity and provides exponential separation between some of them.

Other notions of unambiguity have been considered. Some of them (for example, structural unambiguity [9]: for all input words u and all states p, there is at most one run of the

automaton over u starting in an initial state and ending in p) describe a wider class of automata than unambiguity. Some are more restrictive than simple unambiguity (for example, strong unambiguity [14]: there is a set of result states, for every input there is exactly one way to reach a result state, and the result states can be accepting or rejecting). We do not consider these notions in the present paper.

We study the problem of representing a complement of a language specified by a finite automaton. It is easy to see that replacing the set of accepting states with its complement allows to recognize the complement of a language specified by a deterministic finite automaton without increasing the number of states. Complementing a language specified by a non-deterministic finite automaton may require an exponential number of states [1].

It has been conjectured (see for instance [3]) that every unambiguous non-deterministic one-way finite automaton (*UFA*) recognizing some language L can be converted into an *UFA* recognizing the complement of the original language L with polynomial increase in the number of states. The best known lower bound was quadratic [13], while the upper bounds were exponential [6]. The quadratic lower bound holds even for the single-letter alphabet. One of the arguments in favour of the conjecture was the fact that universality and even containment of the languages recognized by unambiguous finite automata can be decided in polynomial time [15].

The case of the single-letter alphabet has a better upper bound for the state complexity of recognizing the complement of the language of a non-deterministic finite automaton. A one-way non-deterministic finite automaton (*NFA*) with n states can be converted to a one-way deterministic finite automaton (*DFA*) with $e^{\Theta(\sqrt{n \log n})}$ states accepting the same language [11]. As a *DFA* can be converted into a *DFA* for the complement of the language without any increase in the number of states, this conversion provides an upper bound on the state complexity of recognizing the complement of the language recognized by an *NFA*. This upper bound is tight [12].

Recognizing the complement of the language of a two-way non-deterministic automaton (*2NFA*) with n states over the single-letter alphabet can be done using an *2NFA* with at most $O(n^8)$ states [4]. The same paper also shows that recognising the complement of the language of a *2DFA* with n states can be done by a $4n$-states *2DFA* for arbitrary alphabet. For the single-letter alphabet the complement of the language of a *2DFA* can be recognized by a *2DFA* with $2n + 3$ states [7].

In the present paper we show a superpolynomial lower bound for the state complexity of recognizing the complement of a language of an unambiguous finite automaton by a non-deterministic finite automaton.

▶ **Theorem 1.** *There exists a sequence of unary UFA $(A_d)_{d\in\mathbb{N}}$ such that every NFA recognising the complement of the language of A_d has size at least $|A_d|^d$.*

The size of A_d is $2^{2^{2^{d^{\Theta(1)}}}}$.

▶ **Corollary 2.** *Worst case, complementing an UFA of size z by an NFA may require more than $z^{(\log\log\log z)^{\Theta(1)}}$ states.*

In other words, complementing an *UFA* requires more than polynomial increase in size regardless of the size of the alphabet, and the bound holds even if we allow the complement to be represented by *NFA*.

We also note that the same languages (and their complements) can be recognized by sweeping deterministic finite automata with a small increase in the state complexity compared to the case of *UFA*.

The proof revolves around a connection between *UFA* and tournaments (orientations of complete graphs), and an observation about existence of tournaments with special properties described in Section 4.

The rest of the paper is structured as follows. In the next section we give the standard definitions. Then we present in Section 3 our construction of the unambiguous automata A_d. It involves the use of tournaments with special properties, and the choice of many relatively close primes. We prove the existence of the suitable tournaments in Section 4, and explain how to chose the prime numbers in Section 5. The Section 6 finishes the proof of Theorem 1. We briefly study the case of sweeping automata in Section 7. In the final section we summarize the results and outline some possible future directions.

2 Definitions

In this section we will remind the definitions of deterministic, unambiguous and non-deterministic finite automata, and their normal forms.

▶ **Definition 3.** An *non-deterministic finite automaton* (*NFA*) is defined by an *alphabet* Σ, a set of *states* Q, a subset of *initial states* $I \subseteq Q$, a subset of *accepting states* $F \subseteq Q$ and the *transition relation* $T \subseteq Q \times \Sigma \times Q$. The *size* of an *NFA* A is the number of its states, and is denoted by $|A|$. A *run* of an *NFA* over a word $u = a_1 \dots a_n$ is a sequence of states $q_0, \dots, q_n$ such that (q_{i-1}, a_i, q_i) belongs to T for all $i = 1 \dots n$ and $q_0 \in I$. The run is *accepting* if its last state is accepting, i.e. $q_n \in F$. A *language* L over alphabet Σ is an subset $L \subseteq \Sigma^*$. The *language recognized by* an automaton A is the set $L(A)$ of all words w such that there exists an accepting run of A on w. An automaton over the single-letter alphabet is called *unary*.

A *deterministic finite automaton* (*DFA*) is an *NFA* such that I is a singleton and for all states q and all letters a there is at most one transition of the form $(q, a, q') \in T$.

An *unambiguous non-deterministic finite automaton* (*UFA*) is an *NFA* such that for every word there is at most one accepting run.

A unary non-deterministic finite automaton is in the *Chrobak normal form* [2] if it consists of a path of states followed by a single nondeterministic choice to a set of disjoint cycles.

An automaton is in *simple Chrobak normal form* if it consists of a disjoint union of cycles, each of them containing exactly one initial state.

The following theorem shows that every *UFA* can be transformed into one in Chrobak normal form without increase in size, and as a consequence we sought the construction that would have this shape.

▶ **Theorem 4** ([5]). *For all regular unary languages, there exists an unambiguous automaton recognizing the language which is minimal in size and is furthermore in Chrobak normal form.*

3 The construction

We present in this section the construction of the automaton A_d involved in the proof of Theorem 1. We also establish the unambiguity of A_d in Lemma 5 and compute its size in Lemma 6.

Parameters

The construction of A_d involves several parts, and the parameters have to be adjusted carefully for the lower bound. In this section, we use many parameters, to be specified in the final proof, in Section 6.

These parameters are the following:

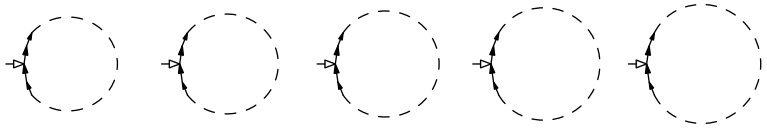
- $n \in \mathbb{N}$ is the number of cycles of the automaton A_d in simple Chrobak normal form.
- R is a tournament of size n: a tournament is an orientation of the edges of the complete undirected graph, see Section 4 for more details. The tournament R will eventually be required to have a special property, established in Lemma 7.
- $b \in \mathbb{N}$ is used as a basis for numbering, and we set $N = b^n$.
- $P = \{p_i \mid i = 0 \dots N-1\}$ is a set of N distinct primes. These will eventually be chosen sufficiently close one from each other thanks to Lemma 10.

The construction

We now construct the automaton A_d as follows.

- It consists of n disjoint cycles $C_1, \dots, C_n$, the cycle C_i having as length m_i which is the product of the primes p_j's such that the ith digit of j in base b is 0 (the digits are numbered from 1 to n). We write that p_j *belongs to* m_i if $p_j | m_i$.
- The 0th state of the cycle C_i is *initial*.
- The rth state of a cycle C_i is *accepting* if it satisfies three conditions:
  1. r is non null,
  2. r modulo p belongs to $\{0, i\}$ for all p belonging to m_i,
  3. if iRj for some j, then there exists a prime p belonging to both m_i and m_j such that $r \mod p = i$.

  And in this case, we call r an *accepting remainder for* m_i.



Let us look more precisely at the structure of this automaton.

We first note that the empty word is not accepted by this automaton, thanks to Item 1 of the definition. One can also note that each cycle is the product of b^{n-1} distinct prime numbers. Furthermore, if one computes the gcd of ℓ different m_i's, the result is the product of $b^{n-\ell}$ prime numbers. Hence there are many primes dividing a cycle, there are many primes dividing simultaneously two cycles, and so on.

Of course, the subtlety in this construction lies in the choice of the accepting remainders for each m_i. This has to respect several constraints. The remainders are chosen to be sufficiently complicated for allowing the lower bound proof, and there should be not too many of them in order to guarantee the unambiguity for A_d. In particular if Condition 3 was omitted, it would be easy find accepting remainders for two distinct m_i's that would yield ambiguity[2]. The Condition 3 is used to resolve these conflictual situations, and when an input would be accepted by two cycles, the tournament is used to "declare the winner".

Concretely, we prove:

▶ **Lemma 5.** *The automaton A_d is unambiguous.*

Proof. Assume that the automaton A_d would be ambiguous. This would mean that there exists a word, of length ℓ, such that it is accepted by two distinct cycles. Let us say by C_i and C_j. This means that $r = \ell \mod m_i$ is an accepting remainder for m_i, and $r' = \ell$

[2] Indeed, let p being a prime of m_i and p' a prime of m_j, consider, by the Chinese remainder theorem an integer ℓ that is equal to i modulo p, equal to j modulo p', and null modulo all other primes. In the absence of Assumption 3, the word of length ℓ would be accepted by both C_i and C_j.

mod m_j is an accepting remainder for m_j. Let us assume without loss of generality that iRj. This implies by Item 3 that there is a prime number p that belongs to both m_i and m_j such that $r \mod p = i$. Hence $\ell \mod p = i$ since p belongs to m_i. Hence $r' \mod p = i$ since p also belongs to m_j. However, we know that r' is an accepting remainder for m_j, therefore Item 2 requires that $r' \mod p \in \{0, j\}$. A contradiction. ◀

We conclude this section by computing the size of this automaton.

▶ **Lemma 6.** *The automaton A_d has between $n(\min P)^{n^{b-1}}$ and $n(\max P)^{n^{b-1}} = n(\max P)^{\frac{N}{b}}$ states.*

Proof. Indeed, the automaton is a union of n cycles and the length of each cycle is a product of $b^{n-1} = \frac{N}{b}$ primes from P. ◀

The rest of the proof is now devoted to showing that there are no small non-deterministic automata for the complement of the language accepted by A_d.

4 Tournaments

A *tournament graph* (or simply a *tournament*) of size n is an orientation of the complete graph. In our case, we see it as a relation over $\{1, \dots, n\}$ such that for all distinct $i, j = 1 \dots n$, either iRj and not jRi, or jRi and not iRj. By convention, iRi is assumed to never hold.

As we have seen in the previous section, a tournament is used as a parameter in the construction of the automaton A_d. For our lower bound proof to go through, we use the fact that this tournament has a special technical property, that is shown possible according to the following lemma.

▶ **Lemma 7.** *For all positive integers k, there exists a tournament R such that the following property holds: for all $E \subseteq R$, if for all vertices x there exists a vertex y such that xEy, then E contains at least k distinct edges that do not share an extremity.*

It is possible to chose a tournament with this property of size $n = 12k^2 2^{2k}$.

The rest of this section is devoted to the proof of Lemma 7. Note that this proof involves a probabilistic argument.

The core notion used in the proof, and therefore the notion at the core of the entire proof of Theorem 1, is the notion of inbound-covering sets.

▶ **Definition 8.** A set S is an *inbound-covering set* for a tournament R if for all vertices x outside S, we have xRy for some $y \in S$.

▶ **Lemma 9.** *For every positive integer h there exist a large enough integer n and a tournament of size n such that the smallest inbound-covering set has size larger than h.*

It is enough to take $n = 3h^2 2^h$.

Proof. Consider a uniformly random tournament of size n, i.e., the vertices are fixed as $1, \dots, n$, and for all $i < j$, one tosses a fair coin in order to chose whether iRj or jRi. Consider an arbitrary set $S \subset V(G)$ of size h. The probability (over the choice of a tournament) that a given vertex $v \in V(G) \setminus S$ has at least one edge from v to S is $1 - 2^{-h}$. For a given set S and $v_1, v_2, \dots \in V(G) \setminus S$, the existence of an outgoing edge from v_i towards S is independent for the different vertices (indeed for all $i \neq j$, the set of edges from v_i to S and the set of edges from v_j to S are disjoint and thus their orientations are chosen independently). Therefore the probability for a given set S to be inbound-covering is equal to $(1 - 2^{-h})^{(n-h)}$. Note that since $\log(1 - 2^{-h}) < (-2^{-h})$, this quantity is bounded from above by $e^{-2^{-h}(n-h)}$ $(\star)$.

Let us provide now an upper bound on the probability α that a tournament has an inbound covering set of size h. Since there are (less than) n^h sets of size n and using $(\star)$, we immediately get that

$$\alpha \leqslant n^h \exp\left(-\frac{n-h}{2^h}\right) = \exp\left(h\log n - \frac{n-h}{2^h}\right) .$$

We shall prove now that for $h \geqslant 8$ and $n = 3h^2 2^h$, this quantity α is smaller than one, which concludes the proof. According to the above inequality, it is sufficient for proving $\alpha < 1$ to establish that $h\log n < \frac{n-h}{2^h}$, which is equivalent to $h2^h \log n < n - h$. We establish this inequality as follows:

$$\begin{aligned} h2^h \log n &= h2^h(h\log 2 + 2\log h + \log 3) \\ &< h2^h \times (2h) \\ &= 2h^2 2^h \\ &< 3h^2 2^h - h \\ &= n - h \end{aligned}$$

◀

▶ Remark. Note that, as it is customary with probabilistic constructions, our choice of n is in fact enough to ensure that *most* tournaments have no inbound-covering sets of sizes up to h.

Now we can prove Lemma 7.

Proof. By Lemma 9 we can pick a tournament with orientation R that has no inbound-covering sets of size up to $h = 2k$. We can choose such a tournament of size $n = 3h^2 2^h = 12k^2 2^{2k}$.

Assume we have already constructed 2ℓ distinct vertices $x_1, y_1, \ldots, x_\ell, y_\ell$ forming edges $(x_1, y_1), \ldots, (x_\ell, y_\ell)$. Since $S = \{x_1, y_1, \ldots, x_\ell, y_\ell\}$ has cardinality $2\ell < 2h$, it is not an inbound-covering set. Hence, one can find a vertex $x_{\ell+1}$ such that there is an edge from all vertices of S to it. We know that E must contain some edge $(x_{\ell+1}, y_{\ell+1})$ from $x_{\ell+1}$, and this edge cannot lead to S, so the edge $(x_{\ell+1}, y_{\ell+1})$ doesn't share an extremity with any previously chosen edge. Applying this argument by induction on ℓ for $\ell = 0$ to k, we have proved Lemma 7. ◀

5 Choice of primes

▶ **Lemma 10.** *For all large enough N it is possible to select N primes no larger than $4N^2 \log N$ within a factor of $1 + \frac{1}{N}$ of each other.*

Proof. We will take the interval of length $3N\log N$ between $3N^2\log N$ and $4N^2\log N$ that contains the most primes. By the Prime number theorem there are

$$\frac{3N^2\log N}{2\log N + \log\log N + \log 3} + o(N^2) = \frac{3}{2}N^2 + o(N^2)$$

primes no larger than $3N^2\log N$ and

$$\frac{4N^2\log N}{2\log N + \log\log N + \log 4} + o(N^2) = 2N^2 + o(N^2)$$

primes no larger than $4N^2\log N$. Therefore, there are $\frac{1}{2}N^2 + o(1)$ primes between $3N^2\log N$ and $4N^2\log N$. If we divide this interval into subintervals of length $3N\log N$, the average

subinterval will contain

$$\frac{1}{2}N^2\frac{3N\log N}{N^2\log N}(1+o(1)) = \frac{3}{2}N + o(N)$$

primes, which is enough. ◀

6 The lower bound

In this section we present the main combinatorial argument of the proof, and complete the proof of Theorem 1.

▶ **Lemma 11.** *A non-deterministic automaton that accepts the complement of the language of A_d has to have at least $(\min P)^{N(1-\exp(-\frac{k}{b^2}))}$ states.*

Let us fix ourselves a non-deterministic automaton C_d that accepts the complement of the language of A_d.

The principle of the proof of Lemma 11 is the following: as we have already noticed, the word of length $\prod_{p\in P} p$, since it is congruent to 0 modulo all the m_i's, is not accepted by A_d (this follows from Condition 1 in the definition of accepting remainders). Thus it has to be accepted by C_d. Since this word is very long (the length is much larger than the bound we want to prove), the run of C_d that accepts it has to visit twice some state and perform a cycle in the mean time. We shall look at what are the words obtained by pumping this cycle, that are all accepted by C_d, and obtain from this analysis that this cycle in C_d has to be rather long.

The core combinatorial result justifying this intuition is the following.

▶ **Lemma 12.** *Let A_d be constructed from a tournament of size $n = 12k^2 2^{2k}$ satisfying the conclusion of Lemma 7.*

Let x and y be integers such that

(a) *$(\prod_{p\in P} p) = x + y$, and;*

(b) *$(xs+y) \mod m_i$ is not an accepting remainder modulo m_i for all i and all $s \geqslant 0$,*

then x has to be divisible by at least $N(1-(1-\frac{1}{b}^2)^k)$ distinct primes from P.

Proof. Consider the set $E \subseteq R$ defined as

$$E = \{(i,j) \in R \mid \gcd(m_i, m_j) | x\} .$$

The proof then goes in two steps. We shall show in step 1 that the assumption for E in Lemma 7 are fulfilled. Then we will apply Lemma 7 and conclude in step 2.

Step 1: We assume that E does not fulfill the assumptions of Lemma 7, and head toward a contradiction. This means that we assume that there exists an $i = 1 \dots n$ such that whenever iRj then $\gcd(m_i, m_j)$ does not divide x.

According to the Chinese remainder theorem and existence of inverse in $\mathbb{Z}/p\mathbb{Z}$ there exists $s > 0$ such that $(xs+y) \mod p = i$ for all primes $p \in P$ that do not divide x. Note that for a prime p that divides x, since furthermore p divides $x+y$ (assumption (a) of the lemma), we obtain $p|y$, and thus $(xs+y) \mod p = 0$. Overall, for $r = xs + y$, we have that for all primes $p \in P$:

$$r \mod p = \begin{cases} 0 & \text{if } p \text{ divides } x, \text{ and} \\ i & \text{otherwise.} \end{cases}$$

Let us show that this r is an accepting remainder:

1 Let j be such that iRj. By assumption, $\gcd(m_i, m_j) \nmid x$. Hence, there exists $p \in P$ that divides m_i but not x. For this p we know that $r \mod p = i$, therefore $r \mod m_i \neq 0$.
2 We have seen above that $r \mod p \in \{0, i\}$.
3 Let j be such that iRj. According to the assumption, $\gcd(m_i, m_j)$ does not divide x. Hence there exists a prime p that divides both m_i and m_j but not x. For this prime, we have seen that $r \mod p = i$.

However, we knew by assumption (b) of the lemma that a number of the form $xs + y$ such as r cannot be an accepting remainder. This is contradiction, and thus terminates the proof of the step 1.

Step 2: Let us now apply Lemma 7. According to the lemma, there are k distinct E-edges $(i_1, j_1), \ldots, (i_k, j_k)$ that do not share an extremity. Let us count the number of primes that divide both m_{i_t} and m_{j_t} for some $t = 1 \ldots k$ (and thus divide x). By construction of the m_i's, it contains all the primes p_v such that both the i_tth and the j_tth digits (in the base-b notation) of v are null for some $t = 1 \ldots k$.

We will first count the primes in P **not** dividing x. These are the primes p_v with v having a nonzero digit in at least one of the two positions i_t and j_t for every t. There are k pairs of positions and there are $b^2 - 1$ combinations of digits that are not $(0, 0)$. There are also $n - 2k$ positions with no such constraints. The total number of possible combinations is $(b^2-1)^k b^{n-2k} = (b^2(1-\frac{1}{b^2}))^k b^{n-2k} = b^n(1-\frac{1}{b^2})^k = N(1-\frac{1}{b^2})^k$.

The primes in P dividing x are all the other primes, and there are $N - N(1-\frac{1}{b^2})^k = N(1-(1-\frac{1}{b^2})^k)$ of them. ◀

Let us prove Lemma 11.

Proof. Let us fix a tournament of size n according to Lemma 7.

Let use fix a set of primes according to Lemma 10.

An *NFA* recognizing the complement of the language has to have a cycle, because the complement is infinite. Consider the word of length $\prod_{p \in P} p$. This length is obviously greater than $|A_d|^d$. If the *NFA* has an accepting run over the word with no cycles, it has to be very large. Otherwise, let C be a cycle of length x occurring in this run, and y be the remaining part of the run length, i.e. $\prod_{p \in P} p = x + y$ (a). The product of all the primes $\prod_{p \in P} p$ has remainder zero modulo every modulus m_i in the construction. By iterating $s \geqslant 0$ times the cycle C, we obtain that the word of length $xs + y$ has to be accepted by C_d. Thus it is not accepted by A_d, and hence $(xs + y) \mod m_i$ is not an accepting remainder for all $s \geqslant 0$ and $i = 1 \ldots n$ (b).

Hence the assumptions (a) and (b) of Lemma 12 are fulfilled. It follows that the cycle C has a length x divisible by $N(1-(1-\frac{1}{b}^2)^k)$ distinct primes from P.

This ensures that the cycle C has a length at least $(\min P)^{N(1-(1-\frac{1}{b}^2)^k)}$. Since furthermore $(1-\frac{1}{b^2})^k < \exp(-\frac{1}{b^2})^k = \exp -\frac{k}{b^2}$, this is at least $(\min P)^{N(1-\exp(-\frac{k}{b^2}))}$.

The size of the *NFA* cannot be less than that. ◀

We can finally conclude the proof of the main theorem of this paper, Theorem 1.

Proof of Theorem 1. Let us fix d. Let $b = 2d, k = b^2, n = 12k^2 2^{2k}, N = b^n$.

By Lemma 6 the size of the automaton A_d is at most $n(\max P)^{\frac{N}{b}}$ states. This automaton is unambiguous by Lemma 5.

By Lemma 11 each *NFA* recognizing the complement of the language of A_d must have at least $(\min P)^{N(1-\exp(-\frac{k}{b^2}))}$ states. As $\frac{k}{b^2} = 1$, the size of the *NFA* cannot be less than $(\min P)^{0.6N}$.

We now only need to verify that $(O(n)(\max P)^{\frac{N}{b}})^d < (\min P)^{0.6N}$. But indeed, for large enough d we have $\min P > N \gg n \gg d$ and

$$(O(n)(\max P)^{\frac{N}{b}})^d < ((O(n)(1+2\frac{1}{N})(\min P))^{\frac{N}{2d}})^d$$
$$< O(n)^{\frac{N}{2}} \exp(\frac{d}{N})(\min P)^{\frac{N}{2}} < (\min P)^{0.6N}$$

In case of d not large enough, we can replace the automaton with the automaton for the smallest large enough d.

Let us estimate the size of A_d. We know that b is linear in d, k is quadratic in d, n is $2^{\Theta(d^2)}$, N is $b^n = b^{2^{\Theta(d^2)}} = 2^{(\log b)2^{\Theta(d^2)}} = 2^{2^{\Theta(d^2)}}$. The primes in P are all $\Theta(N^2 \log N)$. Then the size of the automaton A_d is $\Theta(n(\min P)^{\frac{N}{b}}) = (\min P)^{\Theta(\frac{N}{b})} = (N^2 \log N)^{\Theta(\frac{N}{b})} = 2^{2^{\Theta(d^2)}2^{\Theta(d^2)}} = 2^{2^{2^{\Theta(d^2)}}} = 2^{2^{2^{\Theta(1)}}}$ ◀

7 Sweeping automata

We will now make some additional remarks about the application of the main construction to two-way and sweeping automata.

First we remind the definitions of two-way and sweeping automata.

▶ **Definition 13.** A two-way non-deterministic finite automaton (*2NFA*) is defined by an alphabet Σ, a set of *states* $Q \sqcup \{\top, \bot\}$, a subset of *initial states* I, and the *transition relation* $T \subseteq Q \times (\Sigma \sqcup \{\vdash, \dashv\}) \times (Q \sqcup \{\top, \bot\}) \times \{+1, -1\}$. We call $\vdash$ and $\dashv$ *endpoint markers*.

A *run* of an *2NFA* on an input word $u_1 \dots u_k$ is a list of pairs of positions and states, $(x_0 = 1, q_0 \in I), (x_1, q_1), \dots, (x_n, q_n)$ such that all transitions are allowed and the run ends with one of the special states $\top, \bot$. The exact conditions are as follows:

1. x_0 is 1;
2. q_0 is in I;
3. all x_i are between 0 and $k+1$;
4. $(q_{i-1}, w_{x_{i-1}}, q_i, x_i - x_{i-1}) \in T$ for all $i = 1 \dots n$, in which we assume that $u_0 = \vdash$ and $u_{k+1} = \dashv$;
5. the last state q_n is either $\top$ or $\bot$;
6. $x_i \neq x_{i-1}$ for all $i = 1 \dots n$.

A run is *accepting* if the last state is $\top$.

A *two-way non-deterministic finite automaton* (*2DFA*) is a *2NFA* such that for every state q and every letter a there is at most one transition of the form $(q, s, q', j) \in T$.

A *sweeping two-way deterministic finite automaton* (*swNFA*) is a *2NFA* with exactly one initial state such that for each state q all the transitions of the form (q, s, q', j) where s is in Σ have the same j.

A *swDFA* is an *swNFA* that is also a *2DFA*.

▶ **Lemma 14.** *The languages $L(A_d)$ and $\overline{L(A_d)}$ constructed in the proof of Theorem 1 can also be recognized. by a swDFA of size $|A_d|$.*

Proof. A *swDFA* can go through the word n times calculating the remainder modulo the next modulus each time. This construction requires the same number of states as the *UFA* constructed in the proof of Theorem 1. Such a *swDFA* can be constructed to recognize either the language or its complement. ◀

▶ **Theorem 15.** *Converting a unary sweeping two-way deterministic automaton to a non-deterministic finite automaton for the same language may require a superpolynomial size.*

Proof. Consider the automata constructed in Lemma 14. ◀

8 Conclusion and further directions

We have constructed a counterexample to the conjecture that the complement of a language recognized by an *UFA* can be recognized by an *UFA* with polynomial increase in the number of states. Moreover, in our example the language and its complement are easy to recognize by a *swDFA* with approximately the same number of states, but the complement requires superpolynomial number of states in the recognizing *NFA* even without the requirement of unambiguity. The example only uses the single-letter alphabet.

The construction provides a relatively weak kind of superpolynomial growth. It would be interesting to improve the lower bound. It seems likely that the number of primes used in the construction could be reduced, making the growth faster.

The question about exponential separation in the case of a general alphabet remains open. We hope that our counterexample to the conjectured polynomial upper bound for complementing *UFA* will inspire new results in this area.

Abstract

We present an algorithm for the following problem: given a context-free grammar for the word problem of a virtually free group G, compute a finite graph of groups $\mathcal{G}$ with finite vertex groups and fundamental group G. Our algorithm is non-deterministic and runs in doubly exponential time. It follows that the isomorphism problem of context-free groups can be solved in doubly exponential space. Moreover, if, instead of a grammar, a finite extension of a free group is given as input, the construction of the graph of groups is in NP and, consequently, the isomorphism problem in PSPACE.

1 Introduction

The study of algorithmic problems in group theory was initiated by Dehn [6] when he introduced the word and the isomorphism problem. The word problem asks whether a given word over a (finite) set of generators represents the identity of the group. It also can be viewed as a formal language, namely $\varphi^{-1}(1) \subseteq \Sigma^*$ for some surjective monoid homomorphism $\varphi : \Sigma^* \to G$. The isomorphism problem receives two finite presentations as input, the question is whether the groups they define are isomorphic. Although both these problems are undecidable in general [18, 3], there are many classes of groups where at least the word problem can be decided efficiently.

One of these classes are the finitely generated *virtually free* groups (groups with a free subgroup of finite index). It is easy to see that the word problem of a finitely generated virtually free group can be solved in linear time. Indeed, it forms a deterministic context-free language. A seminal paper by Muller and Schupp [16] shows the converse: every group

with a context-free word problem is virtually free. Since then, also a wide range of other characterizations of virtually free groups have emerged – for a survey we refer to [1, 9].

The isomorphism problem of virtually free groups is also decidable as Krstić showed in [15] (indeed, later Dahmani and Guirardel showed that even the isomorphism problem for the larger class of hyperbolic groups is decidable [5]). Here the input consists of two arbitrary finite presentations with the promise that both define virtually free groups. Unfortunately, the approach in [15] does not give any bound on the complexity. For the special case where the input is given as finite extensions of free groups or as context-free grammars for the word problems, Sénizergues [21, 22] showed that the isomorphism problem is primitive recursive. Krstić's and Sénizergues' approaches both compute so-called graphs of groups, which encode groups acting on trees, and then check these graph of groups for "isomorphism". By the work of Karrass, Pietrowski and Solitar [14], a finitely generated group is virtually free if and only if it is the fundamental group of a finite graph of groups with finite vertex groups.

Contribution. We improve the complexity for the isomorphism problem by showing:

- **(A)** Given a context-free grammar for the word problem of a context-free group G, a graph of groups for G with finite vertex groups can be computed in $\mathsf{NTIME}(2^{2^{\mathcal{O}(n^2)}})$ (Theorem 33).
- **(B)** Given a virtually free presentation for G, a graph of groups for G with finite vertex groups can be computed in NP (Theorem 34).
- **(C)** The isomorphism problem for context-free groups given as grammars is in $\mathsf{DSPACE}(2^{2^{\mathcal{O}(n^2)}})$ (Theorem 37).
- **(D)** The isomorphism problem for virtually free groups given as virtually free presentations is in PSPACE (Theorem 38).

Here, a *virtually free presentation* for G consists of a free group F plus a set of representatives S for the quotient $F\backslash G$ together with relations describing pairwise multiplications of elements from F and S. Typical examples of virtually free presentations are finite extensions of free groups (i. e., where the free sugroup F is normal in G). For non-deterministic function problems we use the convention, that every accepting computation must yield a correct result; but the results of different accepting computations might differ[1].

The results C and D can be seen be to follow from A and B rather easily. Indeed, we conclude from Forester's work on deformation spaces [10] that two graphs of groups with finite vertex groups and isomorphic fundamental groups can be transformed one into each other by a sequence of slide moves (Proposition 35).

Our approach for proving A and B is as follows: in both cases the algorithm simply guesses a graph of groups together with a map and afterwards it verifies deterministically whether the map is indeed an isomorphism. The latter can be done using standard results from formal language theory. The difficult part is to show the existence of a "small" graph of groups and isomorphism (within the bounds of A and B).

For this, we introduce the *structure tree* theory by Dicks and Dunwoody [7] following a slightly different approach by Diekert and Weiß [8] based on the *optimal cuts* of the Cayley graph (Section 2.3). The optimal cuts can be seen as the edge set of some tree on which the group G acts. By Bass-Serre theory, this yields the graph of groups we are aiming

[1] Thus, B means that the graph of groups can be computed in NPMV in the sense of [20]. More precisely, it can be rephrased as follows: the multi-valued function mapping a virtually free presentation for G into a pair $(\mathcal{G}, \varphi)$, where $\mathcal{G}$ is a graph of groups and $\varphi : \pi_1(\mathcal{G}) \to G$ is an isomorphism of polynomial size, is everywhere defined and belongs to the class FNP as defined in [19].

for. Vertices in the graph of groups are defined in terms of equivalence classes of optimal cuts. The key in the proof is to bound the size of the equivalence classes. Using Muller and Schupp's [16] notion of k-triangulability, Sénizergues [22] proved bounds on the size of finite subgroups and on the number of edges in a reduced graph of groups for a context-free group, from which we derive our bounds.

Outline. After fixing our notation, we recall basic facts from Bass-Serre theory and the results from [22] and give a short review on structure trees based on [8]. Section 3, develops bounds on the size of the vertices (= equivalence classes of cuts) of the structure tree. After that, we introduce virtually free presentations formally and we derive stronger bounds for this case in Section 4. Section 5 completes the proofs of A and B. Finally, in Section 6 we derive C and D and we conclude with some open questions. Due to space constraints most of the proofs are omitted; they can be found in the full version on arXiv [23].

2 Preliminaries

Complexity. We use the following convention for non-deterministic function problems: each accepting computation path must yield a correct answer – though different accepting paths can compute different correct answers. We use this convention to define the classes NP (non-deterministic polynomial time) and NTIME($f(n)$) (non-deterministic time bounded by $f(n)$). Otherwise, we use standard complexity classes P (deterministic polynomial time), PSPACE (polynomial space) and DSPACE($f(n)$) (deterministic space bounded by $f(n)$) for both decision and function problems.

Words. An *alphabet* is a (finite) set Σ; an element $a \in \Sigma$ is called a *letter*. The set Σ^n forms the set of *words* of length n. The length of $w \in \Sigma^n$ is denoted by $|w|$. The set of all words is denoted by Σ^*. It is the free monoid over Σ – its neutral element is the empty word 1.

Context-free grammars. We use standard notation for context-free grammars: a context-free grammar is a tuple $\mathbb{G} = (V, \Sigma, P, S)$ with variables V, terminals Σ, a finite set of productions rules $P \subseteq V \times (V \cup \Sigma)^*$, and a start symbol S. We denote its size by $\|\mathbb{G}\| = |V| + |\Sigma| + \sum_{A\to\alpha\in P} |\alpha|$. It is in *Chomsky normal form* if all productions are of the form $S \to 1$, $A \to a$ or $A \to BC$ with $A, B, C \in V$, $a \in \Sigma$. For further definitions, we refer to [12].

Groups. Let Σ be an alphabet and $R \subseteq \Sigma^* \times \Sigma^*$. The monoid (or group) G presented by (Σ, R) is defined as $G = \Sigma^*/R = \Sigma^*/{=_G}$ where $=_G$ is the smallest monoid congruence over Σ^* containing R. There is a canonical projection $\pi : \Sigma^* \to G$. The *word problem* of the group G is the formal language $\mathrm{WP}(G) = \{w \in \Sigma^* \mid w =_G 1\} = \pi^{-1}(1)$. A *symmetric alphabet* is an alphabet Σ endowed with an involution $a \mapsto \overline{a}$ without fixed points (i. e., $\overline{\overline{a}} = a$ and $\overline{a} \neq a$ for all $a \in \Sigma$). If Σ is a symmetric alphabet for G (i. e., $G = \Sigma^*/{=_G}$), we always assume that $a\overline{a} =_G \overline{a}a =_G 1$ for all $a \in \Sigma$ (without writing these relations explicitly).

Let Σ be a symmetric alphabet and $w \in \Sigma^*$. We say that w is *freely reduced* if w has no factor $a\overline{a}$ for any letter $a \in \Sigma$. Given an arbitrary set X, the *free group* over X is denoted by $F(X)$. It is defined as the group presented by $(X \cup \overline{X}, \{x\overline{x} \mid x \in X \cup \overline{X}\})$.

Graphs. A *graph* $\Gamma = (V, E, s, t, \bar{\cdot})$ is given by the following data: a set of vertices $V = V(\Gamma)$, a set of edges $E = E(\Gamma)$ together with two *incidence* maps $s : E \to V$ and $t : E \to V$ and an involution $E \to E$, $e \mapsto \overline{e}$ without fixed points such that $s(e) = t(\overline{e})$. The *degree* of a vertex u is the number of incident edges. An *undirected edge* is a set $\{e, \overline{e}\}$. For the cardinality of sets of edges we usually count the number of undirected edges.

A (finite) *path* from v_0 to v_n is a pair of sequences $((v_0,\dots,v_n),(e_1,\dots,e_n))$ such that $s(e_i)=v_{i-1}$ and $t(e_i)=v_i$ for all $1\le i\le n$. Similarly, a *bi-infinite path* is a pair of sequences $((v_i)_{i\in\mathbb{Z}},(e_i)_{i\in\mathbb{Z}})$ such that $s(e_i)=v_{i-1}$ and $t(e_i)=v_i$ for all $i\in\mathbb{Z}$. A path is *simple* if the vertices are pairwise distinct. It is *closed* if $v_0=v_n$. Depending on the situation we also denote paths simply by the sequence of edges or the sequence of vertices. The *distance* $d(u,v)$ between vertices u and v is defined as the length (i. e., the number of edges) of a shortest path connecting u and v. For $A,B\subseteq V(\Gamma)$ with $A,B\neq\emptyset$, the distance is defined as $d(A,B)=\min\{\,d(u,v)\mid u\in A,v\in B\,\}$.

For $S\subseteq V(\Gamma)$ we define $\Gamma-S$ to be the induced subgraph of Γ with vertices $V(\Gamma)\setminus S$. For $C\subseteq V(\Gamma)$, we write $\overline{C}$ for the complement of C, i. e., $\overline{C}=V(\Gamma)\setminus C$. We call C connected, if the induced subgraph is connected. A group G acts on a graph Γ, if it acts on both $V(\Gamma)$ and $E(\Gamma)$ and the actions preserve the incidences.

Cayley graphs. Let G be a group with a symmetric alphabet Σ. The *Cayley graph* $\Gamma=\Gamma_\Sigma(G)$ of G (with respect to Σ) is defined by $V(\Gamma)=G$ and $E(\Gamma)=G\times\Sigma$, with the incidence functions $s(g,a)=g$, $t(g,a)=ga$, and involution $\overline{(g,a)}=(ga,\overline{a})$. For $r\in\mathbb{N}$ let $B(r)=\{\,u\in V(\Gamma)\mid d(u,1)\le r\,\}$ denote the ball with radius r around the identity.

Cuts. For a subset $C\subseteq V(\Gamma)$ we define the *edge* and *vertex boundaries* of C as follows:

$$\vec{\delta}C=\{\,e\in E(\Gamma)\mid s(e)\in C,t(e)\in\overline{C}\,\}=\text{directed edge boundary},$$
$$\partial C=\{\,s(e)\mid e\in\vec{\delta}C\,\}=\text{inner vertex boundary},$$
$$\beta C=\{\,s(e)\mid e\in\vec{\delta}C\text{ or }\overline{e}\in\vec{\delta}C\,\}=\partial C\cup\partial\overline{C}=\text{vertex boundary}.$$

▶ **Definition 1.** A *cut* is a subset $C\subseteq V(\Gamma)$ such that C and $\overline{C}$ are both non-empty and connected and $\vec{\delta}C$ is finite. The *weight* of a cut is $|\vec{\delta}C|$. If $|\vec{\delta}C|\le K$, we call C a *K-cut*.

2.1 Bass-Serre theory

We give a brief summary of the basic definitions and results of Bass-Serre theory [24].

▶ **Definition 2** (Graph of Groups)**.** Let $Y=(V(Y),E(Y),s,t,\bar{\cdot})$ be a connected graph. A *graph of groups $\mathcal{G}$ over Y* is given by the following data:

- **(i)** For each vertex $P\in V(Y)$ there is a *vertex group* G_P.
- **(ii)** For each edge $y\in E(Y)$ there is an *edge group* G_y such that $G_y=G_{\overline{y}}$.
- **(iii)** For each edge $y\in E(Y)$ there is an injective homomorphism from G_y to $G_{s(y)}$, which is denoted by $a\mapsto a^y$. The image of G_y in $G_{s(y)}$ is denoted by G_y^y.

Since we have $G_y=G_{\overline{y}}$, there is also a homomorphism $G_y\to G_{t(y)}$ defined by $a\mapsto a^{\overline{y}}$. The image of G_y in $G_{t(y)}$ is denoted by $G_y^{\overline{y}}$. A graph of groups is called *reduced* if $G_y^y\neq G_{s(y)}$ whenever $s(y)\neq t(y)$ for $y\in E(Y)$. Throughout we assume that all graphs of groups are connected and finite (i. e., Y is a connected, finite graph).

Fundamental group of a graph of groups. We begin with the group $F(\mathcal{G})$. It is defined as the free product of the free group $F(E(Y))$ and the groups G_P for $P\in V(Y)$ modulo the set of defining relations $\{\,\overline{y}a^yy=a^{\overline{y}}\mid a\in G_y,\,y\in E(Y)\,\}$. As an alphabet we fix the disjoint union $\Delta=\biguplus_{P\in V(Y)}(G_P\setminus\{1\})\cup E(Y)$ throughout. Now, we have

$$F(\mathcal{G})=F(\Delta)/\{\,gh=[gh],\,\overline{y}a^yy=a^{\overline{y}}\mid P\in V(Y),\,g,h\in G_P;\,y\in E(Y),\,a\in G_y\,\},$$

where $[gh]$ denotes the element obtained by multiplying g and h in G_P.

For $P \in V(Y)$ we define a subgroup $\pi_1(\mathcal{G}, P)$ of $F(\mathcal{G})$ by the elements $g_0 y_1 \cdots g_{n-1} y_n g_n \in F(\mathcal{G})$, such that $y_1 \cdots y_n$ is a closed path from P to P and $g_i \in G_{s(y_{i+1})}$ for $0 \leq i < n$ and $g_n \in G_P$. The group $\pi_1(\mathcal{G}, P)$ is called the *fundamental group* of $\mathcal{G}$ with respect to the base point P. Since we assumed Y to be connected, there exists a spanning tree $T = (V(Y), E(T))$ of Y. The *fundamental group* of $\mathcal{G}$ with respect to T is defined as

$$\pi_1(\mathcal{G}, T) = F(\mathcal{G}) / \{ y = 1 \mid y \in T \}.$$

▶ **Proposition 3** ([24]). *The canonical homomorphism ψ from the subgroup $\pi_1(\mathcal{G}, P)$ of $F(\mathcal{G})$ to the quotient group $\pi_1(\mathcal{G}, T)$ is an isomorphism. In particular, the two definitions of the fundamental group are independent of the choice of the base point or the spanning tree.*

A word $w \in \Delta^*$ is called *reduced* if it does not contain a factor gh with $g, h \in G_P$ for some P or a factor $\overline{y} a^y y$ with $y \in E(Y)$, $a \in G_y$.

▶ **Lemma 4** ([24, Thm. I.11]). *A reduced word in $\pi_1(\mathcal{G}, P)$ represents the trivial element if and only if it is the empty word.*

The quotient of a G-tree. Graphs of groups arise in a natural way in situations where a group G acts (from the left) on some connected tree $Z = (V, E)$ without edge inversion, i. e., $\overline{e} \neq ge$ for all $e \in E$, $g \in G$. We let $Y = G \backslash Z$ be the quotient graph with vertex set $V(Y) = \{ Gv \mid v \in V \}$ and edge set $E(Y) = \{ Ge \mid e \in E \}$ and incidences and involution induced by Z. By choosing representatives we find embeddings $\iota : V(Y) \hookrightarrow V$ and $\iota : E(Y) \hookrightarrow E$ and we can assume that $\iota(V(Y))$ induces a connected subgraph of Z and that $\iota(\overline{y}) = \overline{\iota(y)}$ for all $y \in E(Y)$. For $P \in V(Y)$, $y \in E(Y)$, we define vertex and edge groups as the stabilizers of the respective representatives: $G_P = \mathrm{Stab}(\iota P) = \{ g \in G \mid g\iota P = \iota P \}$ and $G_y = \mathrm{Stab}(\iota y) = \{ g \in G \mid g\iota y = \iota y \}$. Note that as abstract groups the vertex and edge groups are independent of the choice of representatives since stabilizers in the same orbit are conjugate. Moreover, for each $y \in E(Y)$ there are $g_y, h_y \in G$ such that $s(\iota y) = g_y \iota P$ and $t(\iota y) = h_y \iota Q$ for $P = s(y)$ and $Q = t(y)$. Note that g_y and h_y are not unique; still the left cosets $g_y G_P$ resp. $h_y G_Q$ are uniquely determined. Clearly, we can choose them such that $g_y = h_{\overline{y}}$ and $h_y = g_{\overline{y}}$. This yields two embeddings:

$$G_y \to G_P, \quad a \mapsto a^y = \overline{g}_y a g_y, \qquad \text{and} \qquad G_y \to G_Q, \quad a \mapsto a^{\overline{y}} = \overline{h}_y a h_y. \tag{1}$$

Hence, we have obtained a well-defined graph of groups $\mathcal{G}$ over Y. Notice that the G_y^y and $G_y^{\overline{y}}$ depend on the choice of g_y and h_y (and change via conjugation when changing them).

We define a homomorphism $\varphi : \Delta^* \to G$ by $\varphi(g) = g$ for $g \in G_P$, $P \in V(Y)$. For $y \in E(Y)$, we set $\varphi(y) = \overline{g}_y h_y$. That means $\varphi(y)$ maps some edge in the preimage of y and terminating in $\iota t(y)$ to an edge in the preimage of y with source in $\iota s(y)$. By our assumption, we have $\overline{\varphi(y)} = \overline{h}_y g_y = \varphi(\overline{y})$. Since $\varphi(\overline{y} a^y y) = \varphi(\overline{y})\varphi(a^y)\varphi(y) = \overline{h}_y g_y a^y \overline{g}_y h_y = a^{\overline{y}} = \varphi(a^{\overline{y}})$, we obtain a well-defined homomorphism $\varphi : F(\mathcal{G}) \to G$.

▶ **Theorem 5** ([24]). *The restriction $\varphi : \pi_1(\mathcal{G}, P) \to G$ is an isomorphism.*

2.2 Context-free groups and graphs

▶ **Definition 6.** A group is called *context-free*, if its word problem is a context free language.

Notice that the word problem of a context-free group is decidable in polynomial time – even if the grammar is part of the input – by applying the CYK algorithm (see e. g. [12]).

▶ **Definition 7** (k-triangulable)**.** Let Γ be a graph. Let $k \in \mathbb{N}$ and let $\gamma = v_0, v_1, \ldots, v_n = v_0$ be a sequence of vertices Γ such that $d(v_{i-1}, v_i) \leq k$ for all $i \in \{1, \ldots, n\}$ (e. g. γ can be a closed path). Let P a convex polygon in the plane whose vertices are labeled by the vertices of γ (i.e. we consider γ as a simple closed curve in the plane). A *k-triangulation* of γ is a triangulation of P which does not introduce any additional vertices (thus only consists of "diagonal" edges) and such that vertices joined by a diagonal edge are at distance at most k. If $n < 3$, we consider γ as triangulated. If every closed path γ has a k-triangulation, then Γ is called k-triangulable and we call k the triangulation constant of Γ.

▶ **Lemma 8** ([16, Thm. I])**.** *Let (V, Σ, P, S) be a context-free grammar in Chomsky normal form for the word problem of a group G where Σ is a symmetric alphabet. Then the Cayley graph Γ can be k-triangulated for $k = 2^{|P|}$.*

Note that in [16] only the existence of some k is shown; however, an easy induction shows the bound of Lemma 8. Moreover, a slightly worse bound applies if Σ is not symmetric [23].

▶ **Lemma 9** ([17, p.65])**.** *Let Γ be k-triangulable and let $r \in \mathbb{N}$. If C is a connected component of $\Gamma - B(r)$, then* $\operatorname{diam}(\partial C) \leq 3k$.

▶ **Lemma 10.** *Let Γ be connected and k-triangulable and let $C \subseteq V(\Gamma)$ be a cut. Then* $\operatorname{diam}(\beta C) \leq \frac{3k}{2}|\vec{\delta} C|$.

This lemma is asserted (without proof) in [21, Lemma 6] with a slightly worse bound on $\operatorname{diam}(\beta C)$. For a proof see [23]. The following upper-bounds will be crucial.

▶ **Proposition 11** ([22, Prop. 1.2])**.** *Let Γ be the Cayley graph of a group G on a symmetric alphabet Σ and let Γ be k-triangulable. Then $|H| \leq |\Sigma|^{12k+10}$ for every finite subgroup $H \leq G$.*

▶ **Theorem 12** ([22, Thm. 1.4])**.** *Let Γ be the Cayley graph of a group G on a symmetric alphabet Σ and let Γ be k-triangulable. Then every reduced graph of groups $\mathcal{G}$ admitting G as fundamental group has at most $|\Sigma|^{12k+11}$ undirected edges.*

2.3 Optimal cuts and structure trees

We briefly present the construction of optimal cuts and the associated structure tree from [8, 9]. While in [8], the proof was for arbitrary accessible, co-compact, locally finite graphs, here we assume that Γ is the Cayley graph of a context-free group. We are interested in bi-infinite simple paths which can be split into two infinite pieces by some cut. For a bi-infinite simple path α denote:

$$\mathcal{C}(\alpha) = \left\{ C \subseteq V(\Gamma) \;\middle|\; C \text{ is a cut and } |\alpha \cap C| = \infty = \left|\alpha \cap \overline{C}\right| \right\},$$
$$\mathcal{C}_{\min}(\alpha) = \{ C \in \mathcal{C}(\alpha) \mid |\delta C| \text{ is minimal in } \mathcal{C}(\alpha) \},$$

where we identify α with its set of vertices. If $C \in \mathcal{C}(\alpha)$, we say that C *splits* α. We define the set of *minimal cuts* $\mathcal{C}_{\min}$ as the union of the $\mathcal{C}_{\min}(\alpha)$ over all bi-infinite simple paths α. Since every bi-infinite simple path α with $\mathcal{C}(\alpha) \neq \emptyset$ can be split by a cut which is a connected component of $\Gamma - B(m)$ for some $m \in \mathbb{N}$, the next lemma follows from Lemma 9 and 10.

▶ **Lemma 13.** *Let Γ be k-triangulable and let d denote the degree of Γ. Then for every $C \in \mathcal{C}_{\min}$ we have $|\vec{\delta} C| \leq d^{3k+2}$ and* $\operatorname{diam}(\beta C) \leq \frac{3k}{2} d^{3k+2}$.

Two cuts C and D are called *nested*, if one of the four inclusions $C \subseteq D$, $C \subseteq \overline{D}$, $\overline{C} \subseteq D$ or $\overline{C} \subseteq \overline{D}$ holds. By Lemma 13, with $K = d^{3k+3}$ for every bi-infinite simple path α with

$\mathcal{C}(\alpha) \neq \emptyset$ there exists some cut $C \in \mathcal{C}(\alpha)$ with $|\vec{\delta}C| \leq K$. We fix this number K. For a cut C let $m(C)$ denote the number of K-cuts that are not nested with C. It follows from [25] that $m(C)$ is always finite, see also [8, Lem. 3.4].

▶ **Definition 14.** The set of *optimal cuts* is defined as

$$\mathcal{C}_{\text{opt}}(\alpha) = \{\, C \in \mathcal{C}_{\min}(\alpha) \mid m(C) \leq m(D) \text{ for all } D \in \mathcal{C}_{\min}(\alpha) \,\},$$
$$\mathcal{C}_{\text{opt}} = \bigcup \{\, \mathcal{C}_{\text{opt}}(\alpha) \mid \alpha \text{ is a bi-infinite simple path} \,\}.$$

▶ **Definition 15.** A set $\mathcal{C} \subseteq \mathcal{C}(\Gamma)$ of cuts is called a *tree set*, if $\mathcal{C}$ is pairwise nested, closed under complementation and for all $C, D \in \mathcal{C}$ the set $\{\, E \in \mathcal{C} \mid C \subseteq E \subseteq D \,\}$ is finite.

▶ **Proposition 16** ([8])**.** *$\mathcal{C}_{\text{opt}}$ is a tree set.*

▶ **Definition 17.** Let $\mathcal{C}$ be a tree set. We can now define the following relation:

$$C \sim D :\Longleftrightarrow C = D \text{ or } (\overline{C} \subsetneqq D \text{ and } E \in \mathcal{C}, \overline{C} \subsetneqq E \subseteq D \Longrightarrow E = D).$$

Indeed, $\sim$ is an equivalence relation – see e. g. [7]. The intuition behind this definition is: We consider $\mathcal{C}$ as the edge set of a graph, and define two edges to be incident to the same vertex, if no other edge lies "between" them.

▶ **Definition 18.** Let $\mathcal{C}$ be a tree set and let $T(\mathcal{C})$ denote the graph defined by

$$V(T(\mathcal{C})) = \{\, [C] \mid C \in \mathcal{C} \,\}, \qquad E(T(\mathcal{C})) = \mathcal{C}.$$

The incidence maps are defined by $s(C) = [C]$ and $t(C) = [\overline{C}]$. The involution $\overline{C}$ is defined by the complementation $\overline{C} = V(\Gamma) \setminus C$; hence, we do not need to change notation.

The directed edges are in canonical bijection with the pairs $([C], [\overline{C}])$. Indeed, let $C \sim D$ and $\overline{C} \sim \overline{D}$. It follows $C = D$ because otherwise $C \subsetneqq \overline{D} \subsetneqq C$. Thus, $T(\mathcal{C})$ is an undirected graph without self-loops and multi-edges. Indeed, $T(\mathcal{C})$ is a tree [7].

▶ **Theorem 19** ([8, Thm. 5.9])**.** *Let Γ be a connected, k-triangulable, locally finite graph. Let a group G act on Γ such that $G\backslash\Gamma$ is finite and each node stabilizer G_v is finite. Then G acts on the tree $T(\mathcal{C}_{\text{opt}})$ such that all vertex and edge stabilizers are finite and $G\backslash T(\mathcal{C}_{\text{opt}})$ is finite.*

Complete cut sets. By Proposition 16 and Theorem 19, $\mathcal{C}_{\text{opt}}$ is a tree set on which G acts with finitely many orbits such that the vertex stabilizers $G_{[C]} = \{\, g \in G \mid gC \sim C \,\}$ of the structure tree are finite. We shall call a set of cuts with these properties a *complete cut set*.

3 Bounds on the structure tree

In order to prove our main result, we have to show that there exists a "small" graph of groups together with a "small" isomorphism. We start with the structure tree and bound the size of the equivalence classes and the diameter of the boundaries of the cuts in one equivalence class. As before Γ is the Cayley graph of a context-free group G.

Avoiding edge inversion. Let $\mathcal{C}$ be a tree set (e. g. $\mathcal{C} = \mathcal{C}_{\text{opt}}$). We aim to construct a graph of groups as described in Section 2.1 from the structure tree $T(\mathcal{C})$. However, if the action of G on $T(\mathcal{C})$ is with edge inversion, the construction cannot be applied directly. Instead, we switch to a subdivision $\widetilde{T}(\mathcal{C})$ of $T(\mathcal{C})$ by putting a new vertex in the middle of every edge which is inverted (in particular, $V(T(\mathcal{C})) \subseteq V(\widetilde{T}(\mathcal{C}))$). Formally, $\widetilde{T}(\mathcal{C})$ is defined as follows: for every edge C of $T(\mathcal{C})$ with $gC = \overline{C}$ for some $g \in G$ we remove C and $\overline{C}$ and instead add a new vertex $v_{\{C,\overline{C}\}}$ together with edges $C_1, \overline{C}_1, C_2, \overline{C}_2$ with $gC_1 = \overline{C}_2$, $gC_2 = \overline{C}_1$ and $s(C_1) = [C]$, $t(C_1) = v_{\{C,\overline{C}\}}$, $s(C_2) = v_{\{C,\overline{C}\}}$, and $t(C_2) = [\overline{C}]$. We extend this in a G-equivariant way to the whole tree. From now on we work with the tree $\widetilde{T}(\mathcal{C})$.

Reduced cut sets. Given a tree set $\mathcal{C}$ with a finite quotient graph $G\backslash\widetilde{T}(\mathcal{C})$, we obtain a graph of groups as in in Section 2.1. We aim to apply Theorem 12, to bound the number of edges in this graph of groups. However, the graph of groups might not be reduced. In terms of the set of cuts $\mathcal{C}$ this means that $G_{[C]} = G_C$ for some $C \in \mathcal{C}$ and either $[C]$ and $[\overline{C}]$ are not in the same G-orbit or there is some $g \in G$ with $gC = \overline{C}$. (Note that the latter case implies that the action on $T(\mathcal{C})$ is with edge inversion. Thus, the new vertex $v_{\{C,\overline{C}\}}$ is introduced and the condition of being reduced is violated for the vertex $G \cdot [C]$ of the corresponding graph of groups.) Nevertheless, in this case we can switch to a subset $\mathcal{C}' \subseteq \mathcal{C}$ such that the corresponding graph of groups is reduced: if there is some cut $C \in \mathcal{C}$ with $G_{[C]} = G_C$ and either $[C] \notin G \cdot \{[\overline{C}]\}$ or $\overline{C} \in G \cdot \{C\}$, then we can replace $\mathcal{C}$ by $\mathcal{C} \smallsetminus G \cdot \{C, \overline{C}\}$ (in terms of the structure tree this means we collapse the respective edges). If no such $C \in \mathcal{C}$ remains, we have obtained a *reduced* set of cuts $\mathcal{C}'$. Since the number of G-orbits of cuts is finite, this procedure terminates. The following lemmas are straightforward to verify.

▶ **Lemma 20.** *Let $\mathcal{C}$ be a complete cut set and let $\mathcal{C}'$ be the reduced cut set obtained by the above procedure. Then $\mathcal{C}'$ is also complete (i. e., all vertex stabilizers are still finite).*

▶ **Lemma 21.** *Let $\mathcal{C}$ be a reduced cut set and let $\widetilde{T}(\mathcal{C})$ be the associated subdivision of the structure tree without edge inversion. Then the graph of groups built on $G\backslash\widetilde{T}(\mathcal{C})$ is reduced.*

Let Ξ be an upper bound on the order of finite subgroups of G and let Θ be a bound on the number of undirected edges in a reduced graph of groups for G. Notice that by Proposition 11, we have $\Xi \leq d^{12k+10}$ and by Theorem 12 we have $\Theta \leq d^{12k+11}$ where k is the triangulation constant and d the degree of Γ. The following lemma is straightforward to prove using the fact that every orbit of cuts in $\mathcal{C}$ yields an edge in the graph of groups.

▶ **Lemma 22.** *Let $\mathcal{C}$ be a reduced complete set of cuts and let $C \sim D \in \mathcal{C}$. Then we have $|\{\, g \in G \mid gD \sim C \,\}| \leq \Xi$ and $|[C]| \leq 2 \cdot \Theta \cdot \Xi$.*

▶ **Lemma 23.** *Let $\mathcal{C}$ be a tree set of cuts and let G act on $\mathcal{C}$. Let $C \in \mathcal{C}$ and $C \in P \subseteq [C]$. Then $P \neq [C]$ if and only if there is some $E \in [C] \smallsetminus P$ with $d(\partial E, \bigcup_{D \in P} \partial D) \leq 1$.*

Proof. The if-part is clear. Thus, let $P \neq [C]$. Then there is some $E \in [C] \smallsetminus P$. Since $\overline{E} \subsetneq D$ for all $D \in P$, we have $\emptyset \neq \overline{E} \subseteq \bigcap_{D \in P} D$. Now, if $\partial\overline{E} \subseteq \bigcup_{D \in P} \partial D$, we are done. Otherwise, there is some vertex $u \in \overline{E} \subseteq \bigcap_{D \in P} D$ with $d(u, \bigcup_{D \in P} \partial D) \geq 1$. Since $\partial\big(\bigcap_{D \in P} D\big) \subseteq \bigcup_{D \in P} \partial D$, we also find a vertex $v \in \bigcap_{D \in P} D$ with $d(v, \bigcup_{D \in P} \partial D) = 1$ by following a path from u to $\partial\big(\bigcap_{D \in P} D\big)$ inside $\bigcap_{D \in P} D$. Notice that, in particular, we have

$$v \notin \beta D \cup \overline{D} \qquad \text{for all } D \in P. \tag{2}$$

Now since Γ is vertex-transitive, we can find some cut $\widetilde{E} \in \mathcal{C}$ such that $v \in \beta\widetilde{E}$. After possibly exchanging $\widetilde{E}$ with its complement, we can assume that $\widetilde{E} \subsetneq C$ or $\widetilde{E} \subseteq \overline{C}$. The

latter would imply $v \in \beta\widetilde{E} \subseteq \beta C \cup \overline{C}$ contradicting (2). Moreover, for any other $D \in P$, we have $\widetilde{E} \subseteq D$ because all other possibilities for $\widetilde{E}$ and D being nested lead to a contradiction:

- if $\overline{D} \subsetneq \widetilde{E}$, then $\overline{D} \subsetneq \widetilde{E} \subsetneq C$ contradicting $D \sim C$,
- if $D \subsetneq \widetilde{E}$, then $D \subseteq \widetilde{E} \subseteq C$ and $\overline{D} \subseteq C$ contradicting $\overline{C} \neq \emptyset$,
- if $\widetilde{E} \subseteq \overline{D}$, then $v \in \beta\widetilde{E} \subseteq \beta D \cup \overline{D}$ contradicting (2).

Thus, $\widetilde{E} \subseteq \bigcap_{D\in P} D$. Let $E \in \mathcal{C}$ be minimal with respect to inclusion such that $\widetilde{E} \subseteq \overline{E} \subsetneq C$. Then $E \sim C$, but $E \notin P$ because $v \in \beta\widetilde{E} \subseteq \beta E \cup \overline{E}$.

It remains to verify that $d(\partial E, \bigcup_{D\in P} \partial D) \leq 1$. Let $w \in \partial D$ for some $D \in P$ a vertex with $d(w, v) = 1$. Then, we have $w \in \beta D \cup \overline{D} \subseteq \beta E \cup E$. Consider the two cases: $v \in \overline{E}$ and $v \in \partial E$. If $v \in \overline{E}$, then $w \in \beta E \cap \partial D$ and hence $d(\partial E, \bigcup_{D\in P} \partial D) \leq 1$. If $v \in \partial E$, then $d(\partial E, \bigcup_{D\in P} \partial D) \leq d(v, w) = 1$. ◀

Now, an easy inductive argument shows the next lemma.

▶ **Lemma 24.** *Let $\mathcal{C}$ be a complete set of cuts and $R \in \mathbb{N}$ such that* $\mathrm{diam}\beta C \leq R$ *for all $C \in \mathcal{C}$. Let $C \in \mathcal{C}$, then* $\mathrm{diam}\Big(\bigcup_{C\sim D} \beta C\Big) \leq (R+1) \cdot |[C]|$.

▶ **Lemma 25.** *Let Γ be the Cayley graph of G. Moreover, assume that*

- *R bounds the diameter of the boundary of minimal cuts,*
- *Θ bounds the number of undirected edges of a reduced graph of groups for G,*
- *Ξ is an upper bound on the size of finite subgroups of G.*

Then there exists a graph of groups $\mathcal{G}$ over Y and an isomorphism $\varphi : \pi_1(\mathcal{G}, T) \to G$ with

(i) $|V(Y)| \leq \Theta + 1$,
(ii) $|G_P| \leq \Xi$ *for all* $P \in V(Y)$,
(iii) $|\varphi(a)| \leq 4(R+1) \cdot (\Theta+1)^2 \cdot \Xi$ *for every* $a \in \bigcup_{P\in V(Y)} G_P \cup E(Y)$.

Points i and ii of Lemma 25 are immediate. The proof iii starts with the set of optimal cuts. As described at the beginning of this section, one can switch to a reduced, complete subset $\mathcal{C}$ yielding a reduced graph of groups over $G\backslash\widetilde{T}(\mathcal{C})$ by Lemmas 20 and 21. Following the construction of the graph of groups in Section 2.1, we can choose representatives for $V(Y) \subseteq V(\widetilde{T}(\mathcal{C}))$ for $G\backslash V(\widetilde{T}(\mathcal{C}))$ such that $\partial C \subseteq B(\Lambda)$ for any $C \in P$ and $P \in V(Y)$ with $\Lambda = 2(R+1) \cdot (\Theta+1) \cdot \Theta \cdot \Xi + \Theta$. This bound follows from Lemmas 24 and 22. Thus, we have a graph of groups and it remains to bound the size of the isomorphism φ. Consider the action of G on its Cayley graph Γ: every $g \in G_P$ for $P \in V(Y)$ maps a vertex from $B(\Lambda)$ to another vertex in $B(\Lambda)$ (namely all vertices in $\bigcup_{D\in P} \partial D$). Likewise the image of an edge D maps $\partial\overline{D} \subseteq B(\Lambda+1)$ into $B(\Lambda)$. Since the action is free, iii follows. For details, see [23].

4 Stronger bounds for virtually free presentations

Let us start with a virtually free group G given as a free subgroup $F(X)$ of finite index and a system of representatives S of $F\backslash G$. That means every group element can be written in a unique way as xs with $x \in F(X)$ and $s \in S$. Moreover, this normal form can be computed in linear time from an arbitrary word by successively applying "commutation rules" of letters from S and $X \cup \overline{X} \cup S$ to the word. This gives a virtually free presentation. For this special case, we can derive stronger bounds on the triangulation constant k and other parameters.

Formally, a *virtually free presentation* $\mathcal{V}$ for G is given by the following data:

- finite sets $X, \overline{X}, S$, where $X \cup \overline{X}$ is a symmetric alphabet and $(X \cup \overline{X}) \cap S = \emptyset$,
- for all $y \in X \cup \overline{X}$, $r, t \in S$, there are words $x_{r,y}, x_{r,t} \in (X \cup \overline{X})^*$, $s_{r,y}, s_{r,t} \in S \cup \{1\}$ with

$$ry =_G x_{r,y}s_{r,y} \qquad\qquad rt =_G x_{r,t}s_{r,t} \tag{3}$$

fulfilling two properties:

(i) for all $r \in S$ there is some $r' \in S$ such that $s_{r',r} = 1$ (i. e., G is a group),

(ii) the equations (3), oriented from left to right, together with the free reductions $x\overline{x} = 1$ for $x \in X \cup \overline{X}$ form a *confluent* rewriting system (for a definition, see e. g. [2, 13]).

We write S^1 for $S \cup \{1\}$. Clearly the associated rewriting system is terminating (noetherian), $F(X)$ is a subgroup of G, $G = F(X) \cdot S^1$, and $F(X) \cap S = \emptyset$ (hence S^1 is a system of right-representatives for $F(X)$). Note that properties i and ii can be checked in polynomial time. Using this confluent rewriting system, every $g \in G$ can be uniquely written in its *normal form* $g = xs$ where $x \in (X \cup \overline{X})^*$ is a freely reduced word and $s \in S^1$. Given any word in $(X \cup \overline{X} \cup S)^*$, the normal form can be computed in linear time from left to right by applying the identities (3) and reducing freely. This is the computation of a deterministic pushdown automaton for the word problem of G:

▶ **Lemma 26.** *Let G be the group defined by a virtually free presentation $\mathcal{V}$. Then a deterministic pushdown automaton for* $\mathrm{WP}(G)$ *can be computed in polynomial time.*

Notice that a finite extension of a free group is a special case of a virtually free presentation where $F(X)$ is a normal subgroup of G (i. e., $s_{r,y} = r$ for all $r \in S$, $y \in X \cup \overline{X}$). We assume that $\mathcal{V}$ is written down in a naive way as input for algorithms: there is a table which for all $a \in X \cup \overline{X} \cup S$ and $r \in S$ contains a word $x_{r,a}$ and some $s_{r,a} \in S$. The size (number of letters) of this table is $|S| \cdot (2\,|X| + |S|) \cdot \max\left\{\, |x_{r,a}| + 1 \;\middle|\; a \in X \cup \overline{X} \cup S,\, r \in S \,\right\}$. Up to logarithmic factors, this is the number of bits required to write down $\mathcal{V}$ this way.

We can always add a disjoint copy of formal inverses $\overline{S}$ of S representing S^{-1} in G. Note that for $\overline{s} \in \overline{S}$ this yields the rule $r\overline{s} = x_{r,\overline{s}}, s_{r,\overline{s}}$ for some $s_{r,\overline{s}} \in S$ where $x_{r,\overline{s}} = x_{s_{r,\overline{s}},s}^{-1}$. In particular, $|x_{r,\overline{s}}| \leq \max\left\{\, |x_{r,a}| \;\middle|\; a \in X \cup \overline{X} \cup S,\, r \in S \,\right\}$. We define the size of $\mathcal{V}$ as $\|\mathcal{V}\| = \left|S^1\right| \cdot (2\,|X| + 2\,|S|) \cdot \max\left\{\, |x_{r,a}| + 1 \;\middle|\; a \in X \cup \overline{X} \cup S,\, r \in S \,\right\}$.

Whenever we talk about a group G given as a virtually free presentation, we denote $\Sigma = X \cup \overline{X} \cup S \cup \overline{S}$. The Cayley graph $\Gamma = \Gamma_\Sigma(G)$ is defined with respect to this alphabet. In particular, its degree is bounded by $\|\mathcal{V}\|$. The following lemma is easy to prove by considering the sequence of normal forms $x_0 s_0, \ldots, x_n s_n$ of a closed path: then $x_0, \ldots, x_n$ is $2\,\|\mathcal{V}\|$-triangulable in the Cayley graph of $F(X)$.

▶ **Lemma 27.** *Let G be the group defined by a virtually free presentation $\mathcal{V}$ and let Γ be its Cayley graph. Then Γ is k-triangulable for $k = 2\,\|\mathcal{V}\| + 2$.*

▶ **Lemma 28.** *Let G be the group defined by a virtually free presentation $\mathcal{V}$. Then for every finite subgroup $H \leq G$, we have $|H| \leq \left|S^1\right|$. Hence, in particular, $|H| \leq \|\mathcal{V}\|$.*

▶ **Lemma 29.** *Let G be the group defined by a virtually free presentation $\mathcal{V}$. Then the number of edges of a reduced graph of groups for G with finite vertex groups is at most $\|\mathcal{V}\|$.*

The proof of Lemma 29 is almost a verbatim repetition of the proof of [22, Thm. 1.4].

▶ **Lemma 30.** *Let G be the group defined by a virtually free presentation $\mathcal{V}$ and let Γ be its Cayley graph. Then every minimal cut in Γ is a K-cut for $K = \|\mathcal{V}\|^2$.*

The proof of Lemma 30 is based on the fact that all cuts of the form $C_x = \{\, ys \mid s \in S,\, x \text{ is a prefix of } y \,\}$ for $x \in (X \cup \overline{X})^*$ satisfy $|\vec{\delta} C_x| \leq \|\mathcal{V}\|^2$ and that all bi-infinite simple paths which are split by some cut also are split by some cut of the form C_x.

5 Main results: computing graphs of groups

▶ **Lemma 31.** *The uniform rational subset membership problem for virtually free groups given as virtually free presentation or as context-free grammar for the word problem can be decided in polynomial time. More precisely, the input is given as*

- *either a virtually free presentation $\mathcal{V}$ or a context-free grammar $\mathbb{G} = (V, \Sigma, P, S)$ for the word problem of a group G,*
- *a rational subset of G given as non-deterministic finite automaton or regular expression over Σ (in the case of a virtually free presentation Σ is defined as in Section 4),*
- *a word $w \in \Sigma^*$.*

The question is whether w is contained in the rational subset of G.

The proof of Lemma 31 is straightforward (for details see [23]): let $p : \Sigma^* \to G$ denote the canonical projection. Then $p(w) \in p(L) \iff 1 \in p(w^{-1}L) \iff \mathrm{WP}(G) \cap w^{-1}L \neq \emptyset$. The latter can be tested in polynomial time by standard facts from formal language theory.

▶ **Proposition 32.** *The following problem is in* P*: Given a virtually free group G either as virtually free presentation $\mathcal{V}$ or as context-free grammar $\mathbb{G}$ for its word problem and a graph of groups $\mathcal{G}$ over the graph Y (with vertex groups as multiplication tables, i. e., for all $g, h \in G_P$ the product gh is written down explicitly) together with a homomorphism $\varphi : \Delta^* \to \Sigma^*$ (where $\Delta = \bigcup_{P \in V(Y)} G_P \cup E(Y)$ and Σ is the alphabet for G defined by $\mathcal{V}$ (resp. $\mathbb{G}$)), decide whether φ induces an isomorphism $\pi_1(\mathcal{G}, T) \to G$.*

Proof. We verify that φ induces a homomorphism $\tilde{\varphi} : \pi_1(\mathcal{G}, T) \to G$ and that $\tilde{\varphi}$ is injective and surjective.

Testing that φ really induces a *homomorphism* reduces to the word problem for the group G, which can be solved in polynomial time: for every relation $a_1 \cdots a_m = 1$ of $\pi_1(\mathcal{G}, T)$ test whether $\varphi(a_1) \cdots \varphi(a_m) = 1$ in G. Testing that $\tilde{\varphi}$ is *surjective* reduces to polynomially many membership-problems for rational subsets of G: for all $a \in \Sigma$ test whether a is contained in the rational subset $\{ \tilde{\varphi}(g) \mid g \in \Delta \}^*$. By Lemma 31 this can be done in polynomial time.

It remains to test whether $\tilde{\varphi}$ is *injective*. Let $\pi : \Delta^* \to F(\mathcal{G})$ and $\psi : F(\mathcal{G}) \to \pi_1(\mathcal{G}, T)$ denote the canonical projections (note that ψ induces an isomorphism $\pi_1(\mathcal{G}, P) \xrightarrow{\sim} \pi_1(\mathcal{G}, T)$). Let $\mathcal{R} \subseteq \Delta^*$ denote the set of reduced words. With slight abuse of notation we use $\pi_1(\mathcal{G}, P)$ also to denote the set of words $g_0 y_1 \cdots g_{n-1} y_n g_n \in \Delta^*$ where $y_1 \cdots y_n$ is a closed path based at P and $g_i \in G_{s(y_{i+1})}$ for $0 \leq i < n$ and $g_n \in G_P$. Testing that $\tilde{\varphi}$ is injective amounts to test whether the language $L = \left(\pi^{-1}(\psi^{-1}(\tilde{\varphi}^{-1}(1))) \cap \pi_1(\mathcal{G}, P) \cap \mathcal{R}\right) \setminus \{1\} \subseteq \Delta^*$ is empty because 1 is the only reduced word in $\pi_1(\mathcal{G}, P)$ representing the identity, by Lemma 4.

Notice that $\pi^{-1}(\psi^{-1}(\tilde{\varphi}^{-1}(1))) = \varphi^{-1}(\mathrm{WP}(G))$. Since $\mathrm{WP}(G)$ is context-free (for virtually free presentations, see Lemma 26) and since context-free languages are closed under inverse homomorphism, $\varphi^{-1}(\mathrm{WP}(G))$ is a context-free language – and a pushdown automaton for it can be computed in polynomial time from the pushdown automaton for $\mathrm{WP}(G)$ (see e. g. [12]). Thus, L is a context-free language and we obtain a pushdown automaton for L, which can be tested for emptiness in polynomial time (see e. g. [12]). ◀

▶ **Theorem 33.** *The following problem is in* $\mathsf{NTIME}(2^{2^{\mathcal{O}(N)}})$*:*
Input: *a context-free grammar $\mathbb{G} = (V, \Sigma, P, S)$ in Chomsky normal form with $\|\mathbb{G}\| \leq N$ which generates the word problem of a group G,*
Compute *a graph of groups with finite vertex groups and fundamental group G.*

Note that if $\mathbb{G}$ is not in Chomsky normal form, it can be transformed into Chomsky normal form in quadratic time. In this case the graph of groups can be computed in $\mathsf{NTIME}(2^{2^{\mathcal{O}(N^2)}})$.

Table 1 Summary of appearing constants. The third column shows a bound in terms of the size of a context-free grammar $\mathbb{G}$ for the word problem (due to Lemma 8, Lemma 13, Proposition 11, and Theorem 12), the fourth column shows a bound in terms of the size of a virtually free presentation $\mathcal{V}$ (due to Lemma 27, Lemma 30, Lemma 10, Lemma 28, and Lemma 29).

N	size of the input	$\|\mathbb{G}\|$	$\|\mathcal{V}\|$
d	degree of Γ	N	N
k	triangulation constant	2^{N+2}	$2N+2$
K	maximal weight of a minimal cut	d^{3k+3}	N^2
$R = \frac{3kK}{2}$	maximal diameter of the boundary of a minimal cut	$\frac{3k}{2}d^{3k+3}$	$3(N+1)N^2$
Ξ	maximum cardinality of a finite subgroup	d^{12k+10}	N
Θ	maximum number of edges in a reduced graph of groups	d^{12k+11}	N

▶ **Theorem 34.** *The following problem is in* NP*:*
Input: *a group G as a virtually free presentation,*
Compute *a graph of groups with finite vertex groups and fundamental group G.*

The proofs of Theorem 34 and Theorem 33 are now straightforward: guess a graph of groups and a map $\varphi : \Delta \to \Sigma^*$ and use Proposition 32 to check that it induces an isomorphism. By Lemma 25 and Table 1, such a guess can be made within the time bounds of the theorems.

6 Slide moves and the isomorphism problem

Given two groups G_1 and G_2 one can calculate the respective graph of groups and then check with Krstić's algorithm by ([15]) whether their fundamental groups are isomorphic. A closer analysis shows that this algorithm runs in polynomial space. As the description is quite involved, we follow a different approach based on Forester's theory of deformation spaces [10, 4].

Let $\mathcal{G}$ be a graph of groups over Y. A *slide move* is the following operation on $\mathcal{G}$: let G_P be a vertex group and G_x, G_y edge groups with $s(x) = s(y) = P$. If G_x^x (the image of G_x in G_P) can be conjugated by an element of G_P into G_y^y i. e., there is some $g \in G_P$ such that $g^{-1}G_x^x g \leq G_y^y$, then x can be slid along y to $Q = t(y)$, i. e., $s(x)$ is changed to Q. The new inclusion of $G_x \to G_Q$ is then given by $\iota_{\overline{y}} \circ \iota_y^{-1} \circ c_g \circ \iota_x$ where ι_x is the inclusion $G_x \to G_P$ (likewise for $\iota_{\overline{y}}, \iota_y$) and c_g is the conjugation with g (i. e., $h \mapsto g^{-1}hg$). A slide move induces an isomorphism φ of the fundamental groups of the two graph of groups by $\varphi(h) = h$ for $h \in G_R$, $R \in V(Y)$, and $\varphi(z) = z$ for $z \in E(Y) \setminus \{x, \overline{x}\}$ and $\varphi(x) = gyx$. The following result is an immediate consequence of [10, Thm. 1.1] and [11, Thm. 7.2] (resp. [4, Cor. 3.5]). Since we are not aware of an explicit reference, we give the details in [23].

▶ **Proposition 35.** *Let $\mathcal{G}_1$ and $\mathcal{G}_2$ be reduced finite graphs of groups with finite vertex groups. Then $\pi_1(\mathcal{G}_1, P_1) \cong \pi_1(\mathcal{G}_2, P_2)$ if and only if $\mathcal{G}_1$ can be transformed into $\mathcal{G}_2$ by a sequence of slide moves.*

Clearly, any sequence of slide moves can be performed in linear space. By guessing a sequence of slide moves transforming $\mathcal{G}_1$ into $\mathcal{G}_2$, we obtain the following corollary.

▶ **Corollary 36.** *Given two graph of groups $\mathcal{G}_1$ and $\mathcal{G}_2$ where all vertex groups are given as full multiplication tables, it can be checked in* NSPACE$(\mathcal{O}(n))$ *whether $\pi_1(\mathcal{G}_1, P_1) \cong \pi_1(\mathcal{G}_2, P_2)$.*

In combination with Theorem 33 (and Savitch's theorem) and Theorem 34 this gives an algorithm to solve the isomorphism problem for virtually free groups:

▶ **Theorem 37.** *The isomorphism problem for context-free groups is in* DSPACE($2^{2^{\mathcal{O}(N)}}$). *More precisely, the input is given as two context-free grammars of size at most N which are guaranteed to generate word problems of groups.*

▶ **Theorem 38.** *The isomorphism problem for virtually free groups given as a virtually free presentation is in* PSPACE.

7 Conclusion and open questions

We have shown that the isomorphism problem for virtually free groups is in PSPACE (resp. DSPACE($2^{2^{\mathcal{O}(N)}}$)) depending on the type of input – thus, improving the previous bound (primitive recursive) significantly. The following questions remain open:

- What is the complexity of the isomorphism problem for virtually free groups given as an arbitrary presentation?
- Is the doubly exponential bound $n^{12\cdot 2^n+10}$ on the size of finite subgroups tight or is there a bound $2^{p(n)}$ for some polynomial p? This is closely related to another question:
- What is the minimal size of a context-free grammar of the word problem of a finite group? Can it be $\log\log(n)$ where n is the size of the group?
- Is there a polynomial bound on the number of slide moves necessary to transform two graphs of groups with isomorphic fundamental groups into each? This would lead to an NP algorithm for the isomorphism problem with virtually free presentations as input. We conjecture, however, that this is not true.

Unambiguous Languages Exhaust the Index Hierarchy

Michał Skrzypczak

Abstract

This work is a study of the expressive power of unambiguity in the case of automata over infinite trees. An automaton is called unambiguous if it has at most one accepting run on every input, the language of such an automaton is called an unambiguous language. It is known that not every regular language of infinite trees is unambiguous. Except that, very little is known about which regular tree languages are unambiguous.

This paper answers the question whether unambiguous languages are of bounded complexity among all regular tree languages. The notion of complexity is the canonical one, called the (parity or Rabin-Mostowski) index hierarchy. The answer is negative, as exhibited by a family of examples of unambiguous languages the cannot be recognised by any alternating parity tree automata of bounded range of priorities.

Hardness of the examples is based on the theory of signatures, previously studied by Walukiewicz. The technical core of the article is a definition of the canonical signatures together with a parity game that compares signatures of a given pair of parity games (of the same index).

1 Introduction

Non-determinism provides a machine with a very powerful ability to *guess* its choices. Depending on the actual model, it might enhance the expressive power of the considered machines or, while preserving the class of recognised languages, make the machines more succinct or effective. All these benefits come at the cost of algorithmic difficulties when handling non-deterministic devices. This complexity motivates a search of ways of restricting the power of non-determinism. One of the most natural among these restrictions is a semantic notion called *unambiguity*: a non-deterministic machine is called *unambiguous* if it has at most one accepting run on every input.

Unambiguity turns out to be very intriguing in the context of automata theory [7]. In the classical case of finite words it does not enhance the expressive power of the automata, still it

simplifies some decision problems [16]. The situation is more complex in the case of infinite trees: the language of infinite trees labelled $\{a, b\}$ containing a letter a cannot be recognised by any unambiguous parity automaton [15, 6]. This example makes the impression that very few regular languages of infinite trees are in fact unambiguous (i.e. can be recognised by an unambiguous automaton). However, there is only a couple of distinct examples of ambiguous regular tree languages [3]. Our understanding of how many (or which) regular tree languages are unambiguous is far from being complete, in particular it is not known how to decide if a given regular tree language is unambiguous.

Another way of understanding the power of unambiguous tree languages is aimed at estimating their descriptive complexity. The complexity can be measured either in terms of the topological complexity or of the parity index, i.e. the range of priorities needed for an alternating parity tree automaton to recognise a given language. Initially, it was considered plausible that all unambiguous tree languages are co-analytic ($\mathbf{\Pi}^1_1$); that is topologically not more complex than deterministic ones. Hummel in [11] gave an example of an unambiguous language that is $\mathbf{\Sigma}^1_1$-complete, in particular not $\mathbf{\Pi}^1_1$. Further improvements [8, 12] showed that unambiguous languages reach high into the second level of the index hierarchy. However, the question whether this is an upper bound on their index complexity was left open. In this paper we prove that it is not the case, as expressed by the following theorem.

▶ **Theorem 1.** *For every $i < k$ there exists an unambiguous tree language L that cannot be recognised by any alternating parity tree automaton (*ATA*) that uses priorities $\{i, \ldots, k\}$. In other words, L does not belong to the level (i, k) of the index hierarchy.*

The canonical examples of languages lying high in the index hierarchy [4, 1] are the languages $W_{i,k}$ dating back to [9, 21] (see e.g. the formulae W_n in [1]). Unfortunately, the languages $W_{i,k}$ are not unambiguous—one can interpret the choice problem [6] in such a way that witnessing unambiguously that $t \in W_{1,2}$ would indicate an MSO-definable choice function [10, 5]. Therefore, to prove Theorem 1 we will use the following corollary of [2].

▶ **Corollary 2** ([1, 2])**.** *Let L be a set of trees. If there is a continuous function f s.t. $W_{i,k} = f^{-1}(L)$ then L cannot be recognised by an ATA of index $(i{+}1, k{+}1)$.*

Our aim is to enrich in a continuous way a given tree t with some additional information denoted $f(t)$, such that an unambiguous automaton reading $f(t)$ can verify if $t \in W_{i,k}$. Although this method is based on the topological concept of a continuous mapping f, the construction provided in this paper is purely combinatorial; the core is a definition of a parity game $\mathcal{C}_P$ that compares the difficulty of a given pair of parity games.

2 Basic notions

We use $u \cdot w$ to represent the concatenation of the two sequences. The symbol $\preceq$ stands for the prefix order. By $\omega = \{0, 1, \ldots\}$ we denote the set of natural numbers.

A *(ranked) alphabet* is a non-empty finite set A of *letters* where each letter $a \in A$ comes with its own finite *arity*. A *tree* over an alphabet A is a partial function $t \colon \omega^* \rightharpoonup A$ where the domain $\mathrm{dom}(t)$ is non-empty, prefix-closed, and if $u \in \mathrm{dom}(t)$ is a *node* with a $k$ary letter $a = t(u)$ then $u \cdot l \in \mathrm{dom}(t)$ if and only if $l < k$, i.e. u (the *father*) has *children* $u \cdot 0$, $u \cdot 1$, $\ldots$, $u \cdot (k{-}1)$. The set of all trees over A is denoted Tr_A. The element $\epsilon \in \mathrm{dom}(t)$ is called the *root* of t. A *branch* of a tree t is a sequence $\alpha \in \omega^\omega$ such that for all $n \in \omega$ the finite prefix $\alpha{\restriction}n$ is a node of t. It is easy to encode ranked alphabets using alphabets of fixed arity (or even binary), however for the technical simplicity we will work with ranked ones here.

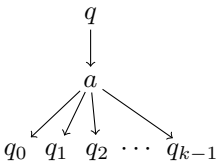

Figure 1 A representation of a transition $(q, a, q_0, \ldots, q_{k-1})$, for a $k$ary letter a.

If $u \in \mathrm{dom}(t)$ is a node of a tree t then by $t{\restriction}u$ we denote the tree $w \mapsto t(u \cdot w)$ with the domain $\{w \mid u \cdot w \in \mathrm{dom}(t)\}$. A tree of the form $t{\restriction}u$ for $u \in \mathrm{dom}(t)$ is called a *subtree* of t in u. If $a \in A$ is a $k$ary letter and $t_0, \ldots, t_{k-1}$ are trees then by $a\big(t_0, \ldots, t_{k-1}\big)$ we denote the unique tree t with $t(\epsilon) = a$ and $t{\restriction}(i) = t_i$ for $i = 0, \ldots, k{-}1$.

If $X \subseteq \mathrm{dom}(t)$ is a set of nodes of a tree t and $u \in \mathrm{dom}(t)$ then by $X{\restriction}u$ we denote the set $\{w \mid u \cdot w \in X\}$, which is a subset of $\mathrm{dom}(t{\restriction}u)$.

Automata. A *non-deterministic parity tree automaton* is a tuple $\mathcal{A} = \langle A, Q, \Delta, I, \Omega\rangle$, where A is a ranked alphabet; Q is a finite set of *states*; Δ is a finite set of *transitions*—tuples of the form $(q, a, q_0, \ldots, q_{k-1})$ where $a \in A$ is a $k$ary letter and $q, q_0, \ldots, q_{k-1}$ are states; $I \subseteq Q$ is a set of *initial states*; and $\Omega\colon Q \to \omega$ is a *priority* mapping.

A *run* of an automaton $\mathcal{A}$ over a tree t over the alphabet A is a function $\rho\colon \mathrm{dom}(t) \to Q$ such that $\rho(\epsilon) \in I$ and for every $u \in \mathrm{dom}(t)$ with a $k$ary letter $a = t(u)$, the tuple $\big(\rho(u), a, \rho(u \cdot 0), \ldots, \rho(u \cdot (k{-}1))\big)$ is a transition in Δ. A run ρ is *accepting* if for every branch α of t the lowest priority of the states appearing infinitely many times along α (i.e. $\liminf_{n\to\infty} \Omega\big(\rho(\alpha{\restriction}n)\big)$) is even. An automaton $\mathcal{A}$ *accepts* a tree t if there exists an accepting run of $\mathcal{A}$ over t. The language of an automaton $\mathcal{A}$ (denoted $\mathrm{L}(\mathcal{A})$) is the set of trees accepted by $\mathcal{A}$. A set of trees over an alphabet A is called *regular* if it is recognised by a non-deterministic parity tree automaton. For a detailed introduction to the theory of automata over infinite trees, see [18].

An automaton $\mathcal{A}$ is *unambiguous* if for every tree t there exists at most one accepting run of $\mathcal{A}$ over t. An automaton $\mathcal{A}$ is *deterministic* if $I = \{q_{\mathrm{I}}\}$ is a singleton and for every $q \in Q$ and $k$ary letter $a \in A$ it has at most one transition of the form $(q, a, q_0, \ldots, q_{k-1})$ in Δ. A language is *unambiguous* (resp. *deterministic*) if it can be recognised by an unambiguous (resp. deterministic) automaton. Clearly each deterministic automaton is unambiguous but the converse is not true. Due to [6] we know that there are regular tree languages that are ambiguous (i.e. not unambiguous).

Games. A *game* with players $\mathbf{1}$ and $\mathbf{2}$ is a tuple $\mathcal{G} = \langle V, E, v_{\mathrm{I}}, W\rangle$ where: $V = V_{\mathbf{1}} \sqcup V_{\mathbf{2}}$ is a set of *positions* split into the $\mathbf{1}$*-positions* $V_{\mathbf{1}}$ and $\mathbf{2}$*-positions* $V_{\mathbf{2}}$; $E \subseteq V \times V$ is a set of *edges*; $v_{\mathrm{I}} \in V$ is an *initial position*; and $W \subseteq V^\omega$ is a *winning condition*. We will denote by P the players, i.e. $P \in \{\mathbf{1}, \mathbf{2}\}$, $\bar{P}$ is the opponent of P. For $v \in V$ by $v \cdot E$ we denote the set of successors $\{v' \mid (v, v') \in E\}$. We assume that for each $v \in V$ the set $v \cdot E$ is non-empty. A non-empty finite or infinite sequence $\Pi \in V^{\leq\omega}$ is a *play* if $\Pi(0) = v_{\mathrm{I}}$ and for each $0 < i < |\Pi|$ there is an edge $\big(\Pi(i{-}1), \Pi(i)\big)$. Notice that if $\langle V, E\rangle$ is a tree then there is an equivalence between finite plays and positions $v \in V$. An infinite play Π is *winning for* $\mathbf{1}$ if $\Pi \in W$; otherwise Π is winning for $\mathbf{2}$.

A non-empty and prefix-closed set of plays Σ with no $\preceq$-maximal element (i.e. no leaf) is called a *behaviour*. We call a behaviour P*-full* if for every play $(v_0, \ldots, v_n) \in \Sigma$ with $v_n \in V_P$ and all $v' \in v \cdot E$ we have $(v_0, \ldots, v_n, v') \in \Sigma$. We call a behaviour P*-deterministic* if for every play $(v_0, \ldots, v_n) \in \Sigma$ with $v_n \in V_P$ there is a unique $v' \in v \cdot E$ such that $(v_0, \ldots, v_n, v') \in \Sigma$.

A *quasi-strategy* of a player P is a behaviour that is $\bar{P}$-full. A *strategy* of P is a quasi-strategy of P that is P-deterministic. A quasi-strategy is *positional* if the fact whether a play $(v_0, \ldots, v_n, v_{n+1})$ belongs to Σ depends only on v_n.

A *partial strategy* of P is a P-deterministic behaviour—it defines the unique choices of P but may not respond to some choices of $\bar{P}$. We say that a play $(v_0, \ldots, v_n, v_{n+1}) \notin \Sigma$ is *not reachable* by a partial strategy Σ if $(v_0, \ldots, v_n) \in \Sigma$ and $v_n \in V_{\bar{P}}$. If Σ is a (partial) strategy of P and $(v_0, \ldots, v_n, v') \in \Sigma$ with $v_n \in V_P$ then we say that Σ *moves to* v' in $(v_0, \ldots, v_n)$.

A strategy Σ of P is *winning* if every *infinite play of* Σ (i.e. Π such that $\forall n \in \omega.\ \Pi{\restriction}n \in \Sigma$) is winning for P. A game is (*positionally*) *determined* if one of the players has a (positional) winning strategy. We say that a position v of a game $\mathcal{G}$ is *winning for* P (resp. *losing for* P) if P (resp. $\bar{P}$) has a winning strategy in the game $\mathcal{G}$ with $v_{\mathrm{I}} := v$.

Topology. In this work we use only basic notions of descriptive set theory and topology, see [13, 19] for a broader introduction. The space Tr_A with the product topology is homeomorphic to the Cantor space. One can take as the basis of this topology the sets of the form $\{t \in \mathrm{Tr}_A \mid t(u_1){=}a_1, t(u_2){=}a_2, \ldots, t(u_n){=}a_n\}$ for finite sequences $(u_1, a_1, u_2, a_2, \ldots, u_n, a_n)$. The open sets in Tr_A are obtained as unions of basic open sets. A function $f\colon X \to Y$ is continuous if the pre-image of each basic open set in Y is open in X.

3 The languages

Let us fix a pair of numbers $i < k$. Our aim is to encode a general parity game with players $\mathbf{1}$ and $\mathbf{2}$ and priorities $\{i, \ldots, k\}$ as a tree over a fixed ranked alphabet $A_{(i,k)}$. That alphabet consists of: unary symbols $[i], [i{+}1], \ldots, [k]$ indicating priorities of positions; and binary symbols $\langle\mathbf{1}\rangle$ and $\langle\mathbf{2}\rangle$ which leave the choice of the subtree to the respective player.

The game induced by a tree $t \in \mathrm{Tr}_{A_{(i,k)}}$ is denoted $\mathcal{G}(t)$. The set of positions of $\mathcal{G}(t)$ is $\mathrm{dom}(t)$ and the edge relation contains pairs father—child. The initial position is ϵ and a position $v \in \mathrm{dom}(t)$ is a $\mathbf{1}$-position iff $t(v) = \langle\mathbf{1}\rangle$. An infinite play of that game is won by $\mathbf{1}$ if and only if the minimal priority j that occurs infinitely often during the play is even[1]. Since the graph of $\mathcal{G}(t)$ is a tree, we identify finite plays in $\mathcal{G}(t)$ with positions $v \in \mathrm{dom}(t)$. Therefore, (quasi / partial) strategies in $\mathcal{G}(t)$ can be seen as specific subsets $\Sigma \subseteq \mathrm{dom}(t)$ and infinite plays of these strategies as branches of t.

For a player $P \in \{\mathbf{1}, \mathbf{2}\}$ the language $\mathrm{W}_{P,(i,k)}$ contains a tree t if P has a winning strategy in $\mathcal{G}(t)$. It is easy to see that $\mathrm{W}_{\mathbf{1},(i,k)}$ is homeomorphic (i.e. topologically equivalent) to $W_{i,k}$ from [21] (the case of $P = \mathbf{2}$ is dual, we put $W_{i+1,k+1}$ then).

As it turns out, the languages $\mathrm{W}_{P,(i,k)}$ are not expressive enough to allow enrichment of a tree t into $f(t)$, see Proposition 22. To enlarge their expressive power we will extend the alphabet with a unary symbol $\sim$ that will correspond to a swap of the players in $\mathcal{G}(t)$. The enhanced alphabet will be denoted $A^{\sim}_{(i,k)}$. We will say that a tree t over the alphabet $A^{\sim}_{(i,k)}$ is *well-formed* if there is no branch with infinitely many symbols $\sim$.

Consider a node $u \in \mathrm{dom}(t)$ in a well-formed tree t over $A^{\sim}_{(i,k)}$. We will say that u is *switched* if there is an odd number of nodes $w \prec u$ such that $t(w) = \sim$. Otherwise u is *kept*. These notions represent the fact that each symbol $\sim$ swaps the players in $\mathcal{G}(t)$.

[1] We restrict our attention to the trees in which every second symbol on each branch is a unary symbol representing a priority (i.e. $[j]$ for $j \in \{i, \ldots, k\}$); every tree can implicitly be transformed into that format by padding with the maximal priority k (such a padding does not influence the winner of $\mathcal{G}(t)$).

If a tree t is well-formed then the game $\mathcal{G}(t)$ is well-defined in a similar way as above, a *kept* position $v \in \mathrm{dom}(t)$ is a $\mathbf{1}$-position iff $t(v) = \langle \mathbf{1} \rangle$; a *switched* position $v \in \mathrm{dom}(t)$ is a $\mathbf{1}$-position iff $t(v) = \langle \mathbf{2} \rangle$. The language $\mathrm{W}^{\sim}_{P,(i,k)}$ contains a well-formed tree t over $A^{\sim}_{(i,k)}$ if P has a winning strategy in $\mathcal{G}(t)$. The games $\mathcal{G}(t)$ have a parity winning condition and therefore are determined [9, 14], so we obtain:

▶ **Fact 3.** *If* $t \in \mathrm{Tr}_{A^{\sim}_{(i,k)}}$ *is well-formed then* $t \in \mathrm{W}^{\sim}_{P,(i,k)}$ *iff* $t \notin \mathrm{W}^{\sim}_{\bar{P},(i,k)}$ *iff* $\sim(t) \in \mathrm{W}^{\sim}_{\bar{P},(i,k)}$.

The additional information added by f will be kept under third children of new ternary variants of the symbols $\langle \mathbf{1} \rangle$ and $\langle \mathbf{2} \rangle$, denoted $\langle \mathbf{1}+ \rangle$ and $\langle \mathbf{2}+ \rangle$. Let the alphabet $A^{+\sim}_{(i,k)}$ be $A^{\sim}_{(i,k)}$ where instead of the symbols $\langle \mathbf{1} \rangle$ and $\langle \mathbf{2} \rangle$ we have $\langle \mathbf{1}+ \rangle$ and $\langle \mathbf{2}+ \rangle$ respectively.

Consider a tree r over the extended alphabet $A^{+\sim}_{(i,k)}$. By $\mathrm{shave}(r)$ we denote the tree over the non-extended alphabet $A^{\sim}_{(i,k)}$, where instead of each subtree of the form $\langle \mathbf{1}+ \rangle(t_{\mathtt{L}}, t_{\mathtt{R}}, t_2)$ one puts the subtree $\langle \mathbf{1} \rangle(t_{\mathtt{L}}, t_{\mathtt{R}})$; the same for $\langle \mathbf{2}+ \rangle$ and $\langle \mathbf{2} \rangle$. Notice that $\mathrm{dom}(\mathrm{shave}(r)) \subseteq \mathrm{dom}(r)$ and the labels of $\mathrm{shave}(r)$ correspond to the labels of r in the respective nodes (up to the additional $+$ in r). We will say that a tree r over the alphabet $A^{+\sim}_{(i,k)}$ is *well-formed* if for every its subtree $r' = r{\restriction}u$ the tree $\mathrm{shave}(r')$ is well-formed in the standard sense. In other words, r is well-formed if there is no branch of r that contains infinitely many symbols $\sim$ but only finitely many directions 2 (the direction 2 corresponds to moving outside $\mathrm{shave}(r')$).

We are now in position to define the witnesses proving Theorem 1. For that we will define an unambiguous automaton $\mathcal{U}$ recognising certain language of trees over the alphabet $A^{+\sim}_{(i,k)}$. In this section we will prove that $\mathcal{U}$ is unambiguous. In the rest of the article we show that $\mathcal{U}$ (with a restricted set of initial states) recognises a language high in the index hierarchy.

▶ **Definition 4.** The set of states of $\mathcal{U}$ is $\{0, \ldots, k{+}2\} \times \{\mathbf{1}, \mathbf{2}\} \times \{\mathtt{D}, \mathtt{L}, \mathtt{R}\}$. Let $\Omega(j, P, d) = j$. The transitions of $\mathcal{U}$ are depicted in Figure 2. The set of initial states of $\mathcal{U}$ contains all the states of the form $(0, \star, \star)$ (recall that as in Figure 2, $\star$ represents all the possible choices).

Intuitively, the first coordinate of a state q of $\mathcal{U}$ is its priority; the second coordinate is the winner for $\mathcal{G}(\mathrm{shave}(r'))$ for the current subtree r'; while the third coordinate indicates the actual strategy if there is ambiguity and $\mathtt{D}$ otherwise. The transition over $\sim$ represents that $\sim$ swaps the players; the next two transitions correspond to positions that are not controlled by a (claimed) winner P over a given subtree; and the last two transitions correspond to a position that is controlled by P. In the lower two transitions the choice of a direction $\mathtt{L}$ or $\mathtt{R}$ depends on the declared winner P in the third child of the current node.

Consider a run ρ of $\mathcal{U}$ over a tree r, let $u \in \mathrm{dom}(r)$, and assume that $\rho(u)$ is of the form $(\star, P, \star)$. In that case one can extract from the third coordinates of ρ a strategy Σ of P in $\mathcal{G}(\mathrm{shave}(r{\restriction}u))$ that will be called the *ρ-strategy in u*. This strategy is defined inductively, preserving the invariant that for each $w \in \Sigma$ the node w is *kept* in $\mathrm{shave}(r{\restriction}u)$ if and only if $\rho(u \cdot w)$ is of the form $(\star, P, \star)$. We start with Σ containing the initial position ϵ. Now consider a position w in Σ. If w is controlled by P (i.e. $r(u \cdot w) = \langle P+ \rangle$ for w *kept* and $\langle \bar{P}+ \rangle$ for w *switched*) then the strategy Σ moves to the position $w \cdot 0$ (resp. $w \cdot 1$) if the state $\rho(u \cdot w) = (\star, \star, d)$ satisfies $d = \mathtt{L}$ (resp. $d = \mathtt{R}$). In the positions $w \in \Sigma$ not controlled by P the strategy Σ has no choice and contains all the children of w in $\mathrm{shave}(r{\restriction}u)$. It is easy to check that the transitions of $\mathcal{U}$ guarantee that the invariant is preserved.

▶ **Lemma 5.** *Let ρ be a run of $\mathcal{U}$ over r. Then ρ is accepting if and only if r is well-formed and for every $u \in \mathrm{dom}(r)$ the ρ-strategy in u is winning in $\mathcal{G}\big(\mathrm{shave}(r{\restriction}u)\big)$.*

Proof. First observe that $\mathcal{U}$ uses states of priority 0 and 1 to deterministically verify that r is well-formed. Consider a well-formed tree r and a run ρ. On the branches following the

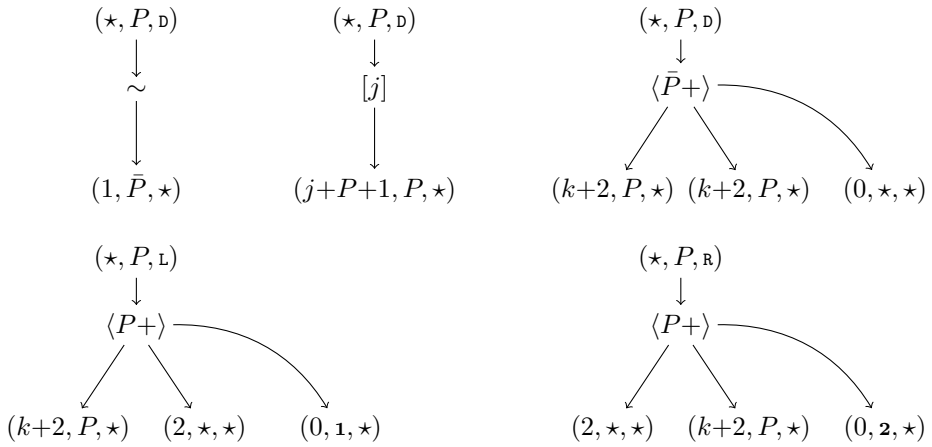

Figure 2 The transitions of the automaton $\mathcal{U}$, where $P \in \{\mathbf{1}, \mathbf{2}\}$ stands for a player; $j \in \{i, \ldots, k\}$ is a priority; and $\star$ represents all the possible choices on a given coordinate.

ρ-strategies, the priorities of ρ correspond to the priorities visited in $\mathcal{G}\big(\mathrm{shave}(r\restriction u)\big)$ (up to a shift by 1 or 2 depending on the current second coordinate of ρ). Thus, ρ satisfies the parity condition on all the branches of r if and only if all the ρ-strategies are winning. ◀

The following fact follows directly from the above lemma.

▶ **Fact 6.** *Assume that ρ is an accepting run of $\mathcal{U}$ over a tree r, $u \in \mathrm{dom}(r)$, and $\rho(u)$ is of the form $(\star, P, \star)$. Then P wins $\mathcal{G}\big(\mathrm{shave}(r\restriction u)\big)$. In particular, if ρ and ρ' are two accepting runs of $\mathcal{U}$ over the same tree r then the second coordinates of ρ and ρ' are equal.*

▶ **Lemma 7.** *If ρ and ρ' are two runs of $\mathcal{U}$ (possibly not accepting) over a tree r and the second coordinates of ρ and ρ' are equal then $\rho = \rho'$.*

Proof. The third coordinate of a run in $u \in \mathrm{dom}(r)$ depends on $r(u)$, the second coordinate of the run in u, and (if one of the lower two transitions from Figure 2 is used) the second coordinate of the run in $u \cdot 2$. Thus, the third coordinates of ρ and ρ' must agree.

The first coordinates of ρ and ρ' in the root are 0. Consider a node u and its child $u' \in \mathrm{dom}(r)$. The first coordinate of a run in u' depends on $r(u)$ and the last two coordinates of the run in u. Therefore, also the first coordinates of ρ and ρ' must agree. ◀

▶ **Definition 8.** Take $P \in \{\mathbf{1}, \mathbf{2}\}$ and let $L_{P,(i,k)}$ be the language recognised by the automaton $\mathcal{U}$ with the set of initial states restricted to the states of the form $(0, P, \star)$.

Fact 6 together with Lemma 7 imply that the languages $L_{P,(i,k)}$ are unambiguous. Thus, to complete the proof of Theorem 1, one needs to prove that the languages $L_{P,(i,k)}$ climb up the index hierarchy. This will be done using Corollary 2 in the next section.

4 Construction of f

Fix a pair $i < k$. In this section we will prove the following proposition.

▶ **Proposition 9.** *There exists a continuous function $f\colon \mathrm{Tr}_{A^{\sim}_{(i,k)}} \to \mathrm{Tr}_{A^{+\sim}_{(i,k)}}$ such that:*

- *If t is well-formed then $f(t)$ is also well-formed.*
- *For a well-formed t and a player P we have: $t \in \mathrm{W}^{\sim}_{P,(i,k)}$ if and only if $f(t) \in L_{P,(i,k)}$.*

Before proving that proposition, notice that a tree over the alphabet $A_{(i,k)}$ can be seen as a well-formed tree over $A^{\sim}_{(i,k)}$ and $\mathrm{W}^{\sim}_{\mathbf{1},(i,k)} \cap \mathrm{Tr}_{A_{(i,k)}} = \mathrm{W}_{\mathbf{1},(i,k)}$ which is topologically equivalent to $W_{i,k}$. Therefore, the above proposition implies that $f{\restriction}\mathrm{Tr}_{A_{(i,k)}}$ satisfies the assumptions of Corollary 2. As $i < k$ are arbitrary, Theorem 1 follows.

To properly define f we first need to introduce a notion that allows to compare how much a player P *prefers* one tree over another. This is achieved by assigning to each tree its *P-signature* and proving that moving to a subtree with an optimal signature guarantees that the player wins whenever possible. The theory of signatures comes from [17] and results of Walukiewicz, e.g. [20, 21]. The notion of signatures used here is more demanding than the classical ones, as we require equalities instead of inequalities in the invariants from Lemma 10.

We say that a number $j \in \omega$ is *P-losing* if $i \leq j \leq k$ and j is odd (resp. even) if $P = \mathbf{1}$ (resp. $P = \mathbf{2}$). A number $j \in \{i, \dots, k\}$ that is not P-losing is called *P-winning*. A P-signature is either ∞ or a tuple of countable ordinals $(\theta_{i'}, \theta_{i'+2}, \dots, \theta_{k'})$, indexed by P-losing numbers—i' is the minimal and k' is the maximal P-losing number. P-signatures that are not ∞ are well-ordered by the lexicographic order $\leq_{\mathrm{lex}}$ in which the ordinals with smaller indices are more important. Let ∞ be the maximal element of $\leq_{\mathrm{lex}}$.

A $\mathbf{1}$-signature $\sigma_{\mathbf{1}}(t) = (42)$ with $i = 0$ and $k = 2$ means that the best what player $\mathbf{1}$ can hope for is to visit at most 42 times a [1]-node (possibly interleaved with nodes of priority 2) before the first [0]-node is visited (if ever). After visiting a [0]-node, the $\mathbf{1}$-signature of the subtree may grow, starting again a counter of nodes of priority 1 to be visited. The $\mathbf{1}$-signature (ω) means that $\mathbf{2}$ can choose a finite number of [1]-nodes that will be visited; however the choice needs to be done before the first such node is seen.

The following two lemmas express the crucial properties of the signatures.

▶ **Lemma 10.** *There exists a unique point-wise minimal pair of assignments $t \mapsto \sigma_P(t)$ for $P \in \{\mathbf{1}, \mathbf{2}\}$ that assign to each well-formed tree t over $A^{\sim}_{(i,k)}$ a P-signature $\sigma_P(t)$ such that:*

1. *$\sigma_P(t) = \infty$ if and only if P loses $\mathcal{G}(t)$;*
2. *$\sigma_P\big(\sim(t)\big) = (0, \dots, 0)$ if P wins $\mathcal{G}\big(\sim(t)\big)$ (i.e. $\bar{P}$ wins $\mathcal{G}(t)$);*
3. *$\sigma_P\big([j](t)\big) = (\theta_{i'}, \dots, \theta_{j-1}, 0, 0 \dots, 0)$ if $\sigma_P(t) = (\theta_{i'}, \dots, \theta_{k'})$ and j is P-winning;*
4. *$\sigma_P\big([j](t)\big) = (\theta_{i'}, \dots, \theta_{j-2}, \theta_j{+}1, 0, \dots, 0)$ if $\sigma_P(t) = (\theta_{i'}, \dots, \theta_{k'})$ and j is P-losing;*
5. *$\sigma_P\big(\langle P\rangle(t_{\mathtt{L}}, t_{\mathtt{R}})\big) = \min\big\{\sigma_P(t_{\mathtt{L}}), \sigma_P(t_{\mathtt{R}})\big\}$;*
6. *$\sigma_P\big(\langle \bar{P}\rangle(t_{\mathtt{L}}, t_{\mathtt{R}})\big) = \max\big\{\sigma_P(t_{\mathtt{L}}), \sigma_P(t_{\mathtt{R}})\big\}$.*

Let us fix the functions σ_P for $P \in \{\mathbf{1}, \mathbf{2}\}$ as above. Consider a well-formed tree t over the alphabet $A^{\sim}_{(i,k)}$. We say that a strategy Σ of a player P in $\mathcal{G}(t)$ is *optimal* (or σ-optimal) if:

- In a position $u \in \mathrm{dom}(t)$ that is *kept* in t and $t{\restriction}u = \langle P\rangle\big(t_{\mathtt{L}}, t_{\mathtt{R}}\big)$ the strategy Σ moves to a subtree of a minimal value of σ_P; i.e. Σ can move to $u \cdot 0$ if $\sigma_P(t_{\mathtt{L}}) \leq_{\mathrm{lex}} \sigma_P(t_{\mathtt{R}})$ and to $u \cdot 1$ if $\sigma_P(t_{\mathtt{L}}) \geq_{\mathrm{lex}} \sigma_P(t_{\mathtt{R}})$. If the values $\sigma_P(t_{\mathtt{L}})$ and $\sigma_P(t_{\mathtt{R}})$ are equal then Σ can move in any of the two directions.
- In a position u that is *switched* in t and $t{\restriction}u = \langle \bar{P}\rangle\big(t_{\mathtt{L}}, t_{\mathtt{R}}\big)$ the strategy Σ uses the same rule as above but uses the function $\sigma_{\bar{P}}$ to compare the $\bar{P}$-signatures of the subtrees.

Notice that according to the above definition there might be more than one optimal strategy.

▶ **Lemma 11.** *If $t \in \mathrm{W}^{\sim}_{P,(i,k)}$ and Σ is an optimal strategy of P in $\mathcal{G}(t)$ then Σ is winning.*

The following lemma claims the combinatorial core of this article: it shows that one can compare the P-signatures using a continuous reduction to the languages $\mathrm{W}^{\sim}_{P,(i,k)}$.

▶ **Lemma 12.** *There exists a continuous function $c_P \colon \big(\mathrm{Tr}_{A^{\sim}_{(i,k)}}\big)^2 \to \mathrm{Tr}_{A^{\sim}_{(i,k)}}$ such that if $t_{\mathtt{L}}$ and $t_{\mathtt{R}}$ are well-formed then so is $c_P(t_{\mathtt{L}}, t_{\mathtt{R}})$ and additionally*

$$c_P(t_{\mathtt{L}}, t_{\mathtt{R}}) \in \mathrm{W}^{\sim}_{\mathbf{1},(i,k)} \quad \text{if and only if} \quad \sigma_P(t_{\mathtt{L}}) \leq_{\mathrm{lex}} \sigma_P(t_{\mathtt{R}}).$$

The rest of this section demonstrates Proposition 9. Lemma 12 is proved in the next section.

Consider a function $f\colon \mathrm{Tr}_{A^{\sim}_{(i,k)}} \to \mathrm{Tr}_{A^{+\sim}_{(i,k)}}$ defined recursively as:

$$\begin{aligned} f\big(\langle P\rangle(t_{\mathtt{L}}, t_{\mathtt{R}})\big) &= \langle P{+}\rangle\Big(f(t_{\mathtt{L}}), f(t_{\mathtt{R}}), f\big(c_P(t_{\mathtt{L}}, t_{\mathtt{R}})\big)\Big) && \text{for } P \in \{\mathtt{1}, \mathtt{2}\},\\ f\big(\sim(t)\big) &= \sim\big(f(t)\big), &&\\ f\big([j](t)\big) &= [j]\big(f(t)\big) && \text{for } j \in \{i, \dots, k\}. \end{aligned}$$

Clearly by the definition of f we know that $\mathrm{shave}\big(f(t)\big) = t$. Additionally, $f(t)$ is defined recursively using c_P which is continuous, therefore f is also continuous. As c_P maps well-formed trees to well-formed trees, so does f.

First assume that $f(t) \in L_{P,(i,k)}$ as witnessed by an accepting run ρ of $\mathcal{U}$ over $f(t)$ with $\rho(\epsilon) = (\star, P, \star)$. Fact 6 says that P wins $\mathcal{G}\big(\mathrm{shave}(f(t))\big) = \mathcal{G}(t)$, so $t \in \mathrm{W}^{\sim}_{P,(i,k)}$.

For the converse assume that P_0 wins $\mathcal{G}(t)$ for a well-formed tree t over $A^{\sim}_{(i,k)}$.

▶ **Lemma 13.** *If t is well-formed then there exists a unique run ρ of $\mathcal{U}$ over $f(t)$ such that for every $u \in \mathrm{dom}\big(f(t)\big)$ we have*

$$\rho(u) = (\star, P, \star) \quad \text{if and only if} \quad P \text{ wins } \mathcal{G}\big(\mathrm{shave}(f(t)\restriction u)\big). \tag{1}$$

Moreover, all the ρ-strategies are winning for the respective players.

Proof. The construction of ρ is inductive from the root preserving (1). The only ambiguity when choosing transitions of $\mathcal{U}$ is when we reach a node $w \in \mathrm{dom}\big(f(t)\big)$ such that $\rho(w)$ is of the form $(\star, P, \star)$ and $f(t)\restriction w = \langle P{+}\rangle\big(f(t_{\mathtt{L}}), f(t_{\mathtt{R}}), f(c_P(t_{\mathtt{L}}, t_{\mathtt{R}}))\big)$. We choose either the left or the right of the two lower transitions of $\mathcal{U}$ depending on the winner in $\mathcal{G}\big(\mathrm{shave}(f(t)\restriction w \cdot 2)\big)$ in such a way to satisfy (1) for $u = w \cdot 2$. By the symmetry assume that we used the left transition. This leaves undeclared the second coordinate of $\rho(w \cdot 1)$ (resp. $\rho(w \cdot 0)$ in the case of the right transition). Again we declare this coordinate accordingly to (1). We need to check that (1) is also satisfied for $u = w \cdot 0$ (resp. $u = w \cdot 1$) i.e. that P wins $\mathcal{G}\big(\mathrm{shave}(f(t)\restriction w \cdot 0)\big)$. To see that, we notice that the following conditions are equivalent (★):

- $\rho(w) = (\star, \star, \mathtt{L})$ [by the form of the transitions of $\mathcal{U}$]
- $\rho(w \cdot 2) = (\star, \mathtt{1}, \star)$ [by the definition of ρ]
- $\mathtt{1}$ wins in $\mathcal{G}\big(\mathrm{shave}(f(t)\restriction(w \cdot 2))\big)$ [by the form of $f(t)\restriction(w \cdot 2)$]
- $\mathtt{1}$ wins in $\mathcal{G}\big(\mathrm{shave}(f(c_P(t_{\mathtt{L}}, t_{\mathtt{R}})))\big)$ [by the equality $\mathrm{shave}\big(f(t')\big) = t'$]
- $\mathtt{1}$ wins in $\mathcal{G}\big(c_P(t_{\mathtt{L}}, t_{\mathtt{R}})\big)$ [by Lemma 12]
- $\sigma_P(t_{\mathtt{L}}) \leq_{\mathrm{lex}} \sigma_P(t_{\mathtt{R}})$.

Thus, if we choose the lower left transition of $\mathcal{U}$, we know that $\sigma_P(t_{\mathtt{L}}) \leq_{\mathrm{lex}} \sigma_P(t_{\mathtt{R}})$. By the inductive invariant we know that $\infty >_{\mathrm{lex}} \sigma_P\big(\mathrm{shave}(f(t)\restriction w)\big) = \sigma_P\big(\langle P\rangle(t_{\mathtt{L}}, t_{\mathtt{R}})\big)$. Therefore, Item 5 of Lemma 10 implies that $\sigma_P(t_{\mathtt{L}}) <_{\mathrm{lex}} \infty$ so in fact P wins $\mathcal{G}(t_{\mathtt{L}}) = \mathcal{G}\big(\mathrm{shave}(f(t_{\mathtt{L}}))\big) = \mathcal{G}\big(\mathrm{shave}(f(t)\restriction w \cdot 0)\big)$. Thus, the invariant (1) is also preserved for $u = w \cdot 0$. This concludes the inductive definition of ρ. Lemma 7 implies uniqueness.

Take $u \in \mathrm{dom}\big(f(t)\big)$ with $\rho(u) = (\star, P, \star)$. Let Σ be the ρ-strategy in u and $r' = f(t)\restriction u$. Consider a node $w \in \mathrm{dom}\big(\mathrm{shave}(r')\big)$ such that $\mathrm{shave}(r')(w) = \langle P'\rangle$ with $P' = P$ if w is *kept* and $P' = \bar{P}$ if w is *switched*. In both cases $f(t)(u \cdot w) = \langle P'{+}\rangle$. By the above equivalence (★) and the definition of a ρ-strategy, Σ makes a σ-optimal move in w. Therefore, Σ is optimal. Invariant (1) says that P wins $\mathcal{G}\big(\mathrm{shave}(r')\big)$, so Lemma 11 implies that Σ is winning. ◀

Fix the run ρ given by the above lemma. Since $\mathcal{G}(t) = \mathcal{G}\big(\mathrm{shave}(f(t))\big)$, $\rho(\epsilon) = (\star, P_0, \star)$. Since all the ρ-strategies are winning, ρ is accepting by Lemma 5 and $f(t) \in L_{P,(i,k)}$. This concludes the proof of Theorem 1 assuming that Lemma 12 holds.

5 Comparing signatures

We will now prove Lemma 12 by defining, given two trees p and s over $A^{\sim}_{(i,k)}$, a game $\mathcal{C}_P(p,s)$. To indicate the difference between the games $\mathcal{C}_P$ and $\mathcal{G}$, we denote the players of $\mathcal{C}_P$ as $\exists = \mathbf{1}$ and $\forall = \mathbf{2}$. The purpose of the game $\mathcal{C}_P$ will be to ensure that $\exists$ wins $\mathcal{C}_P(p,s)$ if and only if $\sigma_P(p) \leq_{\text{lex}} \sigma_P(s)$. The winning condition of the game $\mathcal{C}_P$ will be a parity condition, however, the game will allow certain *lookahead* (see steps (EL) and (AL) in the definition of $\mathcal{C}_P$). Then, the function c_P will just unravel the game $\mathcal{C}_P(p,s)$ into a tree over the alphabet $A^{\sim}_{(i,k)}$.

If i' and k' are the minimal and maximal P-losing numbers; j is a P-losing number; and $\sigma = (\theta_{i'}, \theta_{i'+2}, \dots, \theta_{k'})$ is a P-signature then $\sigma{\restriction}j$ is the tuple $(\theta_{i'}, \theta_{i'+2}, \dots, \theta_j)$. For completeness let $\infty{\restriction}j \stackrel{\text{def}}{=} \infty$. Clearly $\sigma{\restriction}k' = \sigma$. Notice that $\sigma{\restriction}j$ is also a P-signature (with $k = j$) and moreover if $\sigma \leq_{\text{lex}} \sigma'$ then $\sigma{\restriction}j \leq_{\text{lex}} \sigma'{\restriction}j$.

A position of the game $\mathcal{C}_P$ is a triple $\big(p, s, \ell\big)$ where $p, s \in \mathrm{Tr}_{A^{\sim}_{(i,k)}}$ and ℓ is a P-losing number. As $\mathcal{C}_P(p,s)$ we denote the game $\mathcal{C}_P$ with the initial position set to $\big(p, s, k'\big)$. The game is designed in such a way to guarantee the following claim.

▶ **Claim 14.** *A position $\big(p, s, \ell\big)$ is winning for $\exists$ in $\mathcal{C}_P$ if and only if*

$$\sigma_P(p){\restriction}\ell \;\leq_{\text{lex}}\; \sigma_P(s){\restriction}\ell. \tag{2}$$

A single round of the game $\mathcal{C}_P$ consists of a sequence of choices done by the players. It is easy to encode such a sequence using additional intermediate positions of the game. For the sake of readability, we do not specify these positions explicitly. Instead, a round moves the game from a position $\big(p, s, \ell\big)$ into a new position according to the following sequential steps:

(EL) $\exists$ can claim that P loses $\mathcal{G}(s)$. If she does so, the game ends and $\exists$ wins iff $s \notin \mathrm{W}^{\sim}_{P,(i,k)}$.

(AL) $\forall$ can claim that P loses $\mathcal{G}(p)$. If he does so, the game ends and $\forall$ wins iff $p \notin \mathrm{W}^{\sim}_{P,(i,k)}$.

(EI) $\exists$ can modify ℓ into another P-losing number $\ell' < \ell$. In that case the round ends and the next position is $\big(p', s, \ell'\big)$ where $p' = [\ell'](p)$.

(AI) $\forall$ can modify ℓ into another P-losing number $\ell' < \ell$. In that case the round ends and the next position is $\big(p, s, \ell'\big)$.

(↓) If $p = [\ell](p')$ and $s = [\ell](s')$ then the round ends and the next position is (p', s', ℓ).

(↓p) If p is not of the form $[\ell](p'')$ then a step called $\mathit{Step}\exists(p)$ is done, resulting in an immediate win of $\exists$ or a new tree p'. The round ends and the next position is (p', s, ℓ).

(↓s) Otherwise p is of the form $[\ell](p')$ and a step called $\mathit{Step}\forall(s)$ is done, resulting in an immediate win of $\forall$ or a new tree s'. The round ends and the next position is (p, s', ℓ).

The result p' of $\mathit{Step}\exists(p)$ depends on the form of p as follows:

- If $p = \langle P\rangle(p_{\mathtt{L}}, p_{\mathtt{R}})$ then $\exists$ chooses to set $p' = p_{\mathtt{L}}$ or $p' = p_{\mathtt{R}}$.
- If $p = \langle \bar{P}\rangle(p_{\mathtt{L}}, p_{\mathtt{R}})$ then $\forall$ chooses to set $p' = p_{\mathtt{L}}$ or $p' = p_{\mathtt{R}}$.
- If $p = [j](p')$ and $j > \ell$ then p' is defined and that round of $\mathcal{C}_P$ has priority $j{+}1{-}P$.
- Otherwise $\exists$ immediately wins.

Dually, the result s' of $\mathit{Step}\forall(s)$ depends on the form of s as follows:

- If $s = \langle P\rangle(s_{\mathtt{L}}, s_{\mathtt{R}})$ then $\forall$ chooses to set $s' = s_{\mathtt{L}}$ or $s' = s_{\mathtt{R}}$.
- If $s = \langle \bar{P}\rangle(s_{\mathtt{L}}, s_{\mathtt{R}})$ then $\exists$ chooses to set $s' = s_{\mathtt{L}}$ or $s' = s_{\mathtt{R}}$.
- If $s = [j](s')$ with $j > \ell$ then s' is defined and that round of $\mathcal{C}_P$ has priority $j{-}2{+}P$.
- Otherwise $\forall$ immediately wins.

The rounds of $\mathcal{C}_P$ which priority is not declared above have priority k. An infinite play Π of $\mathcal{C}_P$ is won by $\exists$ if the least priority seen infinitely often during Π is even.

▶ **Lemma 15.** *The game $\mathcal{C}_P(p,s)$ can be unravelled as a tree $c_P(p,s)$ over the alphabet $A^{\sim}_{(i,k)}$ in such a way that for well-formed trees p, s, the tree $c_P(p,s)$ is well-formed and $\exists$ wins $\mathcal{C}_P(p,s)$ if and only if $\mathtt{1}$ wins $\mathcal{G}\big(c_P(p,s)\big)$. Moreover, the function c_P is continuous.*

Proof. Notice that in both cases when a round of $\mathcal{C}_P$ has an explicitly declared priority, that priority is j or $j-1$ with $i \leq \ell < j \leq k$. Therefore, the priorities of $\mathcal{C}_P$ are within $\{i,\ldots,k\}$.

The condition $s \notin \mathrm{W}^{\sim}_{\mathbf{1},(i,k)}$ from (EL) boils down to checking if $\mathtt{1}$ wins $\mathcal{G}\big(\sim(s)\big)$. Similarly, $s \notin \mathrm{W}^{\sim}_{\mathbf{2},(i,k)}$ if and only if $\mathtt{1}$ wins $\mathcal{G}\big(s\big)$. The same for the condition $p \in \mathrm{W}^{\sim}_{P,(i,k)}$ from (AL). Continuity and well-formedness follow directly from the definition. ◀

Notice that the rules of the game $\mathcal{C}_P$ do not allow to move from a position with a tree (either p or s) of the form $\sim(t)$ to a position with the respective tree being t. Therefore, we never need to swap the considered player P into $\bar{P}$.

Claim 14 together with Lemma 15 prove Lemma 12. Thus, the rest of this section is devoted to a proof of Claim 14. Since the winning condition of $\mathcal{C}_P$ is a parity condition, that game is positionally determined. Thus, to prove Claim 14 it is enough to show that none of the following two cases is possible for a position (p,s,ℓ) of $\mathcal{C}_P$:

- (2) is true and $\forall$ has a positional winning strategy $\Sigma_\forall$ from (p,s,ℓ),
- (2) is false and $\exists$ has a positional winning strategy $\Sigma_\exists$ from (p,s,ℓ).

In both cases we will confront the assumed strategy with a specially designed positional quasi-strategy of the opponent ($\Sigma^\star_\exists$ and $\Sigma^\star_\forall$ respectively). The quasi-strategy $\Sigma^\star_\exists$ will be defined only in positions that satisfy (2) and the quasi-strategy $\Sigma^\star_\forall$ in the remaining positions.

The quasi-strategy $\Sigma^\star_\exists$ (resp. $\Sigma^\star_\forall$) of a player $\exists$ (resp. $\forall$) in a round starting in a position $\big(p,s,\ell\big)$ performs the following choices in sub-rounds (EL) to (AI):

- In (EL) $\Sigma^\star_\exists$ claims that P loses $\mathcal{G}(s)$ if and only if he really does.
- In (AL) $\Sigma^\star_\forall$ claims that P loses $\mathcal{G}(p)$ if and only if he really does.
- In (EI) $\Sigma^\star_\exists$ modifies ℓ into ℓ' if $\ell' < \ell$ is the minimal P-losing number such that $\sigma_P(p)\restriction\ell' <_{\mathrm{lex}} \sigma_P(s)\restriction\ell'$. If there is no such number, $\Sigma^\star_\exists$ does not declare ℓ'.
- In (AI) $\Sigma^\star_\forall$ modifies ℓ into ℓ' if $\ell' < \ell$ is the minimal P-losing number such that $\sigma_P(p)\restriction\ell' >_{\mathrm{lex}} \sigma_P(s)\restriction\ell'$. If there is no such number, $\Sigma^\star_\forall$ does not declare ℓ'.

Moreover, in $\mathit{Step}\exists(p)$ when $p = \langle P\rangle(p_{\mathtt{L}}, p_{\mathtt{R}})$ the quasi-strategy $\Sigma^\star_\exists$ chooses to set $p' = p_{\mathtt{L}}$ if and only if $\sigma_P(p_{\mathtt{L}}) \leq_{\mathrm{lex}} \sigma_P(p_{\mathtt{R}})$. Dually, in $\mathit{Step}\forall(s)$ when $s = \langle P\rangle(s_{\mathtt{L}}, s_{\mathtt{R}})$ the quasi-strategy $\Sigma^\star_\forall$ chooses to set $s' = s_{\mathtt{L}}$ if and only if $\sigma_P(s_{\mathtt{L}}) \leq_{\mathrm{lex}} \sigma_P(s_{\mathtt{R}})$.

Now it remains to define the choices of the quasi-strategies in the steps $\mathit{Step}\forall(s)$ and $\mathit{Step}\exists(p)$ when the given tree is of the form $\langle\bar{P}\rangle(t_{\mathtt{L}}, t_{\mathtt{R}})$. This is the place where the choices of $\Sigma^\star_\exists$ and $\Sigma^\star_\forall$ are not unique and that is why these are quasi-strategies.

▶ **Definition 16.** The quasi-strategies $\Sigma^\star_\exists$ and $\Sigma^\star_\forall$ need to satisfy the following *preservation guarantees*. First, in $\mathit{Step}\forall(s)$ when $s = \langle\bar{P}\rangle(s_{\mathtt{L}}, s_{\mathtt{R}})$ then $\Sigma^\star_\exists$ can set s' as any of the two $s_{\mathtt{L}}$, $s_{\mathtt{R}}$ that satisfies $\sigma_P(s')\restriction\ell \geq_{\mathrm{lex}} \sigma_P(p)\restriction\ell$. Second, in $\mathit{Step}\exists(p)$ when $p = \langle\bar{P}\rangle(p_{\mathtt{L}}, p_{\mathtt{R}})$ then $\Sigma^\star_\forall$ can set p' as any of the two $p_{\mathtt{L}}$, $p_{\mathtt{R}}$ that satisfies $\sigma_P(p')\restriction\ell >_{\mathrm{lex}} \sigma_P(s)\restriction\ell$.

▶ **Fact 17.** *In both cases the preservation guarantee leaves at least one possible choice.*

▶ **Lemma 18.** *Consider a position $\big(p,s,\ell\big)$. If it satisfies* (2) *and $\exists$ follows her quasi-strategy $\Sigma^\star_\exists$ then either she immediately wins or the next position also satisfies* (2)*.*

Dually, if the position violates (2) *and $\forall$ follows his quasi-strategy $\Sigma^\star_\forall$ then either he immediately wins or the next position also violates* (2)*.*

Notice that each play of $\mathcal{C}_P$ can modify the value of ℓ only bounded number of times. Moreover, because of the conditions in steps ($\downarrow\!\!\downarrow$), ($\downarrow p$), and ($\downarrow s$) we obtain the following fact.

▶ **Fact 19.** *If* Π *is an infinite play of* $\mathcal{C}_P$ *then exactly one of the following three cases holds:*

- Π *makes infinitely many* $(\twoheaddownarrow)$ *steps,*
- *from some point on* Π *makes only* $(\downarrow p)$ *steps,*
- *from some point on* Π *makes only* $(\downarrow s)$ *steps.*

Observe that each step of $\mathcal{C}_P$ of the form $Step\exists(p)$ or $Step\forall(s)$ (if it doesn't mean an immediate win) simulates in fact a round of the game $\mathcal{G}(p)$ and $\mathcal{G}(s)$ respectively. Moreover, the quasi-strategies of the players $\exists$ and $\forall$ simulate optimal strategies of P in these rounds respectively. Thus, P must win these plays, as expressed by the following lemma.

▶ **Lemma 20.** *Consider an infinite play consistent with the quasi-strategy of one of the players* ($\Sigma^\star_\exists$ *or* $\Sigma^\star_\forall$*). Then the play only finitely many times makes the* $(\twoheaddownarrow)$ *step.*

Moreover, if the play follows $\Sigma^\star_\exists$ *and from some point on makes only* $(\downarrow p)$ *steps then it is winning for* $\exists$*. Similarly, if the play follows* $\Sigma^\star_\forall$ *and from some point on makes only* $(\downarrow s)$ *steps then it is winning for* $\forall$*.*

Proof. First take an infinite play Π of the quasi-strategy $\Sigma^\star_\exists$ of $\exists$ starting from a position (p_0, s_0, ℓ_0). The subtrees of the tree p_0 seen during Π follow a (possibly finite) play α of an optimal strategy of P in $\mathcal{G}(p_0)$. Since Π is infinite, $\exists$ does not declare that P loses $\mathcal{G}(s_0)$. Therefore, $\sigma_P(s_0) <_{\text{lex}} \infty$ and by (2) we know that also $\sigma_P(p_0) <_{\text{lex}} \infty$ which implies that $p_0 \in \mathrm{W}^{\sim}_{P,(i,k)}$. By Lemma 11 the play α in $\mathcal{G}(p_0)$ follows a winning strategy of P.

We will show that the step $(\twoheaddownarrow)$ occurs only finitely many times in Π. Assume contrarily and let ℓ be the minimal number ℓ that occurs in the play Π. Using the above assumptions, we know that ℓ is the minimal priority that is seen in the tree p_0 infinitely many times on α. Therefore, the simulated play α in $\mathcal{G}(p_0)$ is infinite and losing for P, which is a contradiction.

Therefore, by Fact 19 the play Π either makes from some point on only $(\downarrow p)$ steps, or from some point on only $(\downarrow s)$ steps. In the first case it follows the play α of $\mathcal{G}(p_0)$ that is winning for P. By the choice of priorities in the step $Step\exists(p)$ we know that $\exists$ wins Π.

The case of the quasi-strategy $\Sigma^\star_\forall$ of $\forall$ is entirely dual: we use the assumption that (2) is violated to know that $\sigma_P(s) <_{\text{lex}} \infty$ so $s_0 \in \mathrm{W}^{\sim}_{P,(i,k)}$. Moreover, the choice of priorities in the step $Step\forall(s)$ implies that if Π makes $Step\forall(s)$ infinitely many times then $\forall$ wins Π. ◀

Now we move to the proof of the first case we need to exclude, i.e. that a position (p, s, ℓ) of $\mathcal{C}_P$ satisfies (2) but $\forall$ has a positional winning strategy $\Sigma_\forall$ from that position. We will prove that such a case is not possible. The second case is dual and the proof is analogous.

By Lemma 18, the positional quasi-strategy $\Sigma^\star_\exists$ always stays within positions satisfying the invariant (2). Moreover, the quasi-strategy never reaches a position that is immediately losing for $\exists$. Similarly, $\Sigma_\forall$ never reaches a position that is immediately losing for $\forall$. Thus, all the plays consistent with both $\Sigma^\star_\exists$ and $\Sigma_\forall$ must be infinite.

Notice that the values of ℓ are non-increasing during the plays of $\mathcal{C}_P$ and therefore, there exists a position that belongs to both $\Sigma^\star_\exists$ and $\Sigma_\forall$ such that the value ℓ stays constant during all the plays from that position. Without loss of generality take this as the starting position.

We can now proceed inductively in the tree obtained by unravelling the intersection of $\Sigma^\star_\exists$ and $\Sigma_\forall$: whenever the currently considered subtree contains anywhere a $(\twoheaddownarrow)$ step, we change the initial position to the result of that step. By Lemma 20 no play consistent with $\Sigma^\star_\exists$ takes the $(\twoheaddownarrow)$ step infinitely many times. Therefore, our inductive procedure has to stop at some point with no $(\twoheaddownarrow)$ steps in the current subtree. Without loss of generality we can assume that the initial position (p_0, s_0, ℓ_0) is the last position from the procedure. We know that the plays consistent with both $\Sigma^\star_\exists$ and $\Sigma_\forall$ never take the $(\twoheaddownarrow)$ step nor modify $\ell = \ell_0$.

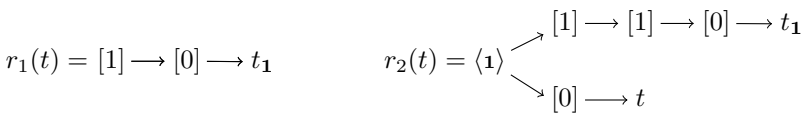

Figure 3 The pair of trees being the result of the reduction $r(t)$ from Proposition 22.

The structure of $\mathcal{C}_P$ guarantees that since the step $(\downarrow\!\!\!\downarrow)$ is not allowed, each play consistent with both $\Sigma^{\star}_{\exists}$ and $\Sigma_{\forall}$ takes only $(\downarrow p)$ steps or takes only $(\downarrow s)$ steps. Lemma 20 implies that in the former case the play would be winning for $\exists$, contradicting the assumption that $\Sigma_{\forall}$ is winning. Thus, all the considered plays take only $(\downarrow s)$ steps. In particular $p = p_0$ is constant.

The intersection of $\Sigma_{\forall}$ and $\Sigma^{\star}_{\exists}$ induces a partial strategy Σ_P of P in $\mathcal{G}(s_0)$—Σ_P is partial because it does not contain positions that cannot be reached by following $\Sigma^{\star}_{\exists}$ because of the preservation guarantees, see Definition 16. The subtrees s' of s_0 in such unreachable positions satisfy $\sigma_P(s')\restriction_{\ell_0} <_{\text{lex}} \sigma_P(p_0)\restriction_{\ell_0}$ by the definition of $\Sigma^{\star}_{\exists}$. In the positions on which Σ_P is defined it never visits a priority j with $j \leq \ell_0$ nor a node labelled $\sim$ because such a move is immediately losing for $\forall$ in $\mathit{Step}\forall(s)$. Because of the choice of the priorities in $\mathit{Step}\forall(s)$ and since $\Sigma_{\forall}$ is winning, Σ_P is winning for P on infinite plays.

Notice that since we take only $(\downarrow s)$ steps, p_0 must be of the form $[\ell_0](p'_0)$. Therefore, $\sigma_P(p_0)\restriction_{\ell_0} = (\theta_{i'}, \dots, \theta_{\ell_0} + 1)$ for $(\theta_{i'}, \dots, \theta_{\ell_0}) \stackrel{\text{def}}{=} \sigma_P(p'_0)\restriction_{\ell_0}$. It means that whenever the partial strategy Σ_P cannot reach a position with a subtree s', we know that in fact $\sigma_P(s')\restriction_{\ell_0} \leq_{\text{lex}} (\theta_{i'}, \dots, \theta_{\ell_0})$. The following lemma says that the existence of such a partial strategy Σ_P witnesses the inequality $\sigma_P(s_0)\restriction_{\ell_0} \leq_{\text{lex}} (\theta_{i'}, \dots, \theta_{\ell_0})$. By the definition of the ordinals θ_j we know that $(\theta_{i'}, \dots, \theta_{\ell_0}) <_{\text{lex}} \sigma_P(p_0)\restriction_{\ell_0}$, what contradicts (2) for (p_0, s_0, ℓ_0).

▶ **Lemma 21.** *Let $P \in \{\mathbf{1}, \mathbf{2}\}$, $t \in \mathrm{W}^{\sim}_{P,(i,k)}$, i' be the minimal P-losing number, and ℓ be some P-losing number. Assume that $(\theta_{i'}, \theta_{i'+2}, \dots, \theta_\ell)$ is a tuple of ordinals and Σ_P is a partial strategy of the player P in $\mathcal{G}(t)$ such that:*

- *Σ_P never reaches a node u with $t(u) = [j]$ with $j \leq \ell$ nor a node u with $t(u) = \sim$,*
- *infinite plays of Σ_P are winning for P,*
- *if a position $u \in \mathrm{dom}(t)$ is not reachable by Σ then $\sigma_P\big(t\restriction_u\big)\restriction_\ell \leq_{\text{lex}} (\theta_{i'}, \dots, \theta_\ell)$.*

Under all these assumptions $\sigma_P(t)\restriction_\ell \leq_{\text{lex}} (\theta_{i'}, \dots, \theta_\ell)$.

This finishes the proof of Claim 14. We conclude this section with a simple argument showing that a similar reduction c does not exist when we disallow the swapping symbol $\sim$, as expressed by the following proposition.

▶ **Proposition 22.** *There is no continuous function $c' \colon \big(\mathrm{Tr}_{A_{(0,k)}}\big)^2 \to \mathrm{Tr}_{A_{(0,k)}}$ such that*

$$c'(t_{\mathtt{L}}, t_{\mathtt{R}}) \in \mathrm{W}_{\mathbf{1},(0,k)} \quad \textit{if and only if} \quad \sigma_{\mathbf{1}}(t_{\mathtt{L}}) \leq_{\text{lex}} \sigma_{\mathbf{1}}(t_{\mathtt{R}}).$$

Proof. Assume that such a function c' exists. Fix a tree $t_{\mathbf{1}} \in \mathrm{W}_{\mathbf{1},(0,k)}$ and consider a function $r \colon \mathrm{Tr}_{A_{(0,k)}} \to \big(\mathrm{Tr}_{A_{(0,k)}}\big)^2$ defined as $r(t) = \big(r_1(t), r_2(t)\big)$ for the pair of trees from Figure 3. Clearly r is continuous. Let $t \in \mathrm{Tr}_{A_{(0,k)}}$ and $r(t) = (t_{\mathtt{L}}, t_{\mathtt{R}})$. Notice that $\sigma_{\mathbf{1}}(t_{\mathtt{L}}) = (1, 0, \dots)$. The value $\sigma_{\mathbf{1}}(t_{\mathtt{R}})$ is either $(0, 0, \dots)$ if $t \in \mathrm{W}_{\mathbf{1},(0,k)}$ or $(2, 0, \dots)$ otherwise. Therefore, $c'\big(r(t)\big) \in \mathrm{W}_{\mathbf{1},(0,k)}$ iff $\sigma_{\mathbf{1}}(t_{\mathtt{L}}) \leq_{\text{lex}} \sigma_{\mathbf{1}}(t_{\mathtt{R}})$ iff $t \notin \mathrm{W}_{\mathbf{1},(0,k)}$ iff $t \in \mathrm{W}_{\mathbf{2},(0,k)}$. Thus, $c' \circ r \colon \mathrm{Tr}_{A_{(0,k)}} \to \mathrm{Tr}_{A_{(0,k)}}$ is a continuous reduction of $\mathrm{W}_{\mathbf{2},(0,k)}$ to $\mathrm{W}_{\mathbf{1},(0,k)}$. This is a contradiction with [2, Lemma 1] (the assumption of contractivity is redundant there by Lemma 2 from the same paper). ◀

6 Conclusions

The main result of this work is the construction of the languages $L_{P,(i,k)}$ that solve the question of index bounds for unambiguous languages. Although the construction is not direct and relies heavily on an involved theory of signatures, these complications seem to be unavoidable when one wants to recognise languages like $W_{i,k}$ in an unambiguous way.

The definition of signatures given in the paper seems to be the canonical one, as witnessed by the point-wise minimality from Lemma 10. The previous ways of using signatures were mainly focused on their monotonicity and well-foundedness, thus it was enough to assume inequalities in the invariants of Lemma 10. Here, we are interested in comparing their actual values, therefore we insist on preserving these values via equalities.

Abstract

In this paper we use the framework of algebraic effects from programming language theory to analyze the Beta-Bernoulli process, a standard building block in Bayesian models. Our analysis reveals the importance of abstract data types, and two types of program equations, called commutativity and discardability. We develop an equational theory of terms that use the Beta-Bernoulli process, and show that the theory is complete with respect to the measure-theoretic semantics, and also in the syntactic sense of Post. Our analysis has a potential for being generalized to other stochastic processes relevant to Bayesian modelling, yielding new understanding of these processes from the perspective of programming.

1 Introduction

From the perspective of programming, a family of Boolean random processes is implemented by a module that supports the following interface:

```
module type ProcessFactory = sig type process
                                 val new : H → process
                                 val get : process → bool end
```

where H is some type of hyperparameters. Thus one can initialize a new process, and then get a sequence of Booleans from that process. The type of processes is kept abstract so that any internal state or representation is hidden.

One can analyze a module extensionally in terms of the properties of its interactions with a client program. In this paper, we perform this analysis for the Beta-Bernoulli process, an important building block in Bayesian models. We completely axiomatize its equational properties, using the formal framework of algebraic effects [18].

The following modules are our leading examples. (Here flip (r) tosses a coin with bias r.)

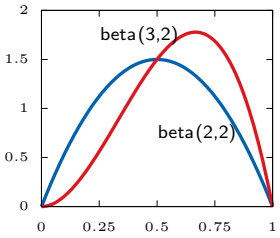
```
module Polya = (struct
  type process = (int * int) ref
  let new(i,j) = ref (i,j)
  let get p = let (i,j) = !p in
    if flip (i/(i+j)) then p := (i+1,j); true
    else p := (i,j+1); false  end : ProcessFactory)
```

```
module BetaBern = (struct
  type process = real
  let new(i,j) = sample_beta(i,j)
  let get(r) = flip(r)

end : ProcessFactory)
```

The left-hand module, Polya, is an implementation of Pólya's urn. An urn in this sense is a hidden state which contains i-many balls marked true and j-many balls marked false. To sample, we draw a ball from the urn at random; before we tell what we drew, we put back the ball we drew as well as an identical copy of it. The contents of the urn changes over time.

The right-hand module, BetaBern, is based on the beta distribution. This is the probability measure on the unit interval $[0,1]$ that measures the bias of a random source (such as a potentially unfair coin) from which true has been observed $(i-1)$ times and false has been observed $(j-1)$ times, as illustrated on the right. For instance beta$(2,2)$ describes the situation where we only know that neither true nor false are impossible; while in beta$(3,2)$ we are still ignorant but we believe that true is more likely.



It turns out that these two modules have the same observable behaviour. This essentially follows from de Finetti's theorem (e.g. [24]), but rephrased in programming terms. The equivalence makes essential use of type abstraction: if we could look into the urn, or ask precise questions about the real number, the modules would be distinguishable.

The module Polya has a straightforward operational semantics (although we don't formalize that here). By contrast, BetaBern has a straightforward denotational semantics [14]. In Section 2, we provide an axiomatization of equality, which is sound by both accounts. We show completeness of our axiomatization with respect to the denotational semantics of BetaBern (§3, Thm. 9). We use this to show that the axiomatization is in fact syntactically complete (§4, Cor. 13), which means it is complete with respect to *any* semantics.

For the remainder of this section, we give a general introduction to our axioms.

Commutativity and discardability. Commutativity and discardability are important program equations [5] that are closely related, we argue, to exchangeability in statistics.

- *Commutativity* is the requirement that when x is not free in u and y is not free in t,

$$\Big(\textsf{let x = t in let y = u in v}\Big) \quad = \quad \Big(\textsf{let y = u in let x = t in v}\Big).$$

- *Discardability* is the requirement that when x is not free in u, $\Big(\textsf{let x = t in u}\Big) = \Big(\textsf{u}\Big)$.

Together, these properties say that data flow, rather than the control flow, is what matters. For example, in a standard programming language, the purely functional total expressions are commutative and discardable. By contrast, expressions that write to memory are typically not commutative or discardable (a simple example is t=u=a++, v=(x,y)). A simple example of a commutative and discardable operation is a coin toss: we can reorder the outcomes of tossing a single coin, and we can drop some of the results (unconditionally) without changing the overall statistics.

We contend that commutativity and discardability of program expressions is very close to the basic notion of exchangeability of infinite sequences, which is central to Bayesian statistics. Informally, an infinite random process, such as an infinite random sequence, is said to be exchangeable if one can reorder and discard draws without changing the overall statistics. (For more details on exchangeable random processes in probabilistic programming languages, see [1, 28], and the references therein.) A client program for the BetaBern module is clearly exchangeable in this sense: this is roughly Fubini's theorem. For the Polya module, an elementary calculation is needed: it is not trivial because memory is involved.

Conjugacy. Besides exchangeability, the following conjugacy equation is crucial:

$$\Big(\textsf{let p=M.new(i,j) in (M.get(p), p)}\Big)$$
$$= \Big(\textsf{if flip (i/(i+j)) then (true, M.new(i+1,j)) else (false, M.new(i,j+1))}\Big).$$

This is essentially the operational semantics of the Polya module, and from the perspective of BetaBern it is the well-known conjugate-prior relationship between the Beta and Bernoulli distributions.

Finite probability. In addition to exchangeability and conjugacy, we include the standard equations of finite, discrete, rational probability theory. To introduce these, suppose that we have a module

```
Bernoulli : sig val get : int * int → bool end
```

which is built so that Bernoulli.get(i,j) samples *with single replacement* from an urn with i-many balls marked true and j-many balls marked false. (In contrast to Pólya's urn, the urn in this simple scheme does not change over time.) So Bernoulli.get(i,j) = flip $(\frac{i}{i+j})$. This satisfies certain laws, first noticed long ago by Stone [29], and recalled in §2.1.

In summary, our main contribution is that these axioms — exchangeability, conjugacy, and finite probability — entirely determine the equational theory of the Beta-Bernoulli process, in the following sense:

- *Model completeness:* Every equation that holds in the measure theoretic interpretation is derivable from our axioms (Thm. 9);
- *Syntactical completeness:* Every equation that is not derivable from our axioms is inconsistent with finite discrete probability (Cor. 13).

We argue that these results open up a new method for analyzing Bayesian models, based on algebraic effects (see §5 and [28][1]).

2 An algebraic presentation of the Beta-Bernoulli process

In this section, we present syntactic rules for well-formed client programs of the Beta-Bernoulli module, and axioms for deriving equations on those programs.

2.1 An algebraic presentation of finite probability

Recall the module Bernoulli from the introduction which provides a method of sampling with odds $(i : j)$. We will axiomatize its equational properties. Algebraic effects provide a way to axiomatize the specific features of this module while putting aside the general properties of programming languages, such as β/η laws. In this situation the basic idea is that each module induces a binary operation ${}_i?_j$ on programs by

$$t \,{}_i?_j\, u \stackrel{\text{def}}{=} \textbf{if}\ \ \mathsf{Bernoulli}.\mathsf{get}(i,j)\ \textbf{then}\ t\ \textbf{else}\ u.$$

Conversely, given a family of binary operations ${}_i?_j$, we can recover $\mathsf{Bernoulli}.\mathsf{get}(i,j) = \mathsf{true}\,{}_i?_j\,\mathsf{false}$. So to give an equational presentation of the Bernoulli module we give a equational presentation of the binary operations ${}_i?_j$. A full programming language will have other constructs and $\beta\eta$-laws but it is routine to combine these with an algebraic theory of effects (e.g. [2, 8, 9, 21]).

▶ **Definition 1.** The *theory of rational convexity* is the first-order algebraic theory with binary operations ${}_i?_j$ for all $i, j \in \mathbb{N}$ such that $i + j > 0$, subject to the axiom schemes

$$w, x, y, z \vdash (w \,{}_i?_j\, x) \,{}_{i+j}?_{k+l}\, (y \,{}_k?_l\, z) = (w \,{}_i?_k\, y) \,{}_{i+k}?_{j+l}\, (x \,{}_j?_l\, z)$$

$$x, y \vdash x \,{}_i?_j\, y = y \,{}_j?_i\, x \qquad x, y \vdash x \,{}_i?_0\, y = x \qquad x \vdash x \,{}_i?_j\, x = x$$

Commutativity $(w \,{}_i?_j\, x) \,{}_k?_l\, (y \,{}_i?_j\, z) = (w \,{}_k?_l\, y) \,{}_i?_j\, (x \,{}_k?_l\, z)$ of operations ${}_k?_l$ and ${}_i?_j$ is a derivable equation, and so is scaling $x \,{}_{ki}?_{kj}\, y = x \,{}_i?_j\, y$ for $k > 0$. Commutativity and discardability $(x \,{}_i?_j\, x = x)$ in this algebraic sense (cf. [15, 22]) precisely correspond to the program equations in Section 1 (see also [9]). The theory first appeared in [29].

2.2 A parameterized algebraic signature for Beta-Bernoulli

In the theory of convex sets, the parameters i, j for get range over the integers. These integers are not a first class concept in our equational presentation: we did not axiomatize integer arithmetic. However, in the Beta-Bernoulli process, or any module M for the ProcessFactory interface, it is helpful to understand the parameters to get as abstract, and new as generating such parameters. To interpret this, we treat these parameters to get as first class. There are still hyperparameters to new, which we do not treat as first class here. (In a more complex hierarchical system with hyperpriors, we might treat them as first class.)

As before, to avoid studying an entire programming language, we look at the constructions

$$\nu_{i,j} p.t \stackrel{\text{def}}{=} \textbf{let}\ p{=}\mathsf{M.new}(i,j)\ \textbf{in}\ t \qquad t \,?_p\, u \stackrel{\text{def}}{=} \textbf{if}\ \ \mathsf{M.get}(p)\ \textbf{then}\ t\ \textbf{else}\ u$$

[1] This paper formalizes and proves a conjecture from [28], which is an unpublished abstract.

There is nothing lost by doing this, because we can recover $\mathsf{M.new}(i,j) = \nu_{i,j}p.\,p$ and $\mathsf{M.get}(p) = \mathsf{true}\,?_p\,\mathsf{false}$. In the terminology of [18], these would be called the 'generic effects' of the algebraic operations $\nu_{i,j}$ and $?_p$. Note that $?_p$ is a parameterized binary operation. Formally, our syntax now has two kinds of variables: x, y as before, ranging over continuations, and now also p, q ranging over parameters. We notate this by having contexts with two zones, and write $x : n$ if x expects n parameters.

▶ **Definition 2.** The term formation rules for the theory of Beta-Bernoulli are:

$$\frac{-}{\Gamma \mid \Delta, x : m, \Delta' \vdash x(p_1 \dots p_m)}\ (p_1 \dots p_m \in \Gamma) \qquad \frac{\Gamma, p \mid \Delta \vdash t}{\Gamma \mid \Delta \vdash \nu_{i,j}p.t}\ (i,j > 0)$$

$$\frac{\Gamma \mid \Delta \vdash t \quad \Gamma \mid \Delta \vdash u}{\Gamma \mid \Delta \vdash t\,?_p\,u}\ (p \in \Gamma) \qquad \frac{\Gamma \mid \Delta \vdash t \quad \Gamma \mid \Delta \vdash u}{\Gamma \mid \Delta \vdash t\,{}_i?_j\,u}\ (i + j > 0)$$

where Γ is a parameter context of the form $\Gamma = (p_1, \dots, p_\ell)$ and Δ is a context of the form $\Delta = (x_1 \colon m_1, \dots, x_k \colon m_k)$. Where $x \colon 0$, we often write x for $x()$. For the sake of a well-defined notion of dimension in 3.2.4, we disallow the formation of $\nu_{i,0}$ and $\nu_{0,i}$.

We work up-to α-conversion and substitution of terms for variables must avoid unintended capture of free parameters. For example, substituting $x\,?_p\,y$ for w in $\nu_{1,1}p.w$ yields $\nu_{1,1}q.(x\,?_p\,y)$, while substituting $x\,?_p\,y$ for $z(p)$ in $\nu_{1,1}p.z(p)$ yields $\nu_{1,1}p.(x\,?_p\,y)$.

2.3 Axioms for Beta-Bernoulli

The axioms for the Beta-Bernoulli theory comprise the axioms for rational convexity (Def. 1) together with the following axiom schemes.

Commutativity. All the operations commute with each other:

$$p, q \mid w, x, y, z : 0 \vdash (w\,?_q\,x)\,?_p(y\,?_q\,z) = (w\,?_p\,y)\,?_q(x\,?_p\,z) \tag{C1}$$

$$- \mid x \colon 2 \vdash \nu_{i,j}p.(\nu_{k,l}q.x(p,q)) = \nu_{k,l}q.(\nu_{i,j}p.x(p,q)) \tag{C2}$$

$$q \mid x, y \colon 1 \vdash \nu_{i,j}p.(x(p)\,?_q\,y(p)) = (\nu_{i,j}p.x(p))\,?_q(\nu_{i,j}p.y(p)) \tag{C3}$$

$$- \mid x, y : 1 \vdash \nu_{i,j}p.(x(p)\,{}_k?_l\,y(p)) = (\nu_{i,j}p.x(p))\,{}_k?_l(\nu_{i,j}p.y(p)) \tag{C4}$$

$$p \mid w, x, y, z : 0 \vdash (w\,{}_i?_j\,x)\,?_p(y\,{}_i?_j\,z) = (w\,?_p\,y)\,{}_i?_j(x\,?_p\,z) \tag{C5}$$

Discardability. All operations are idempotent:

$$- \mid x \colon 0 \vdash (\nu_{i,j}p.x) = x \qquad\qquad p \mid x \colon 0 \vdash x\,?_p\,x = x \tag{D1–2}$$

Conjugacy.

$$- \mid x, y : 1 \vdash \nu_{i,j}p.(x(p)\,?_p\,y(p)) = (\nu_{i+1,j}p.x(p))\,{}_i?_j(\nu_{i,j+1}p.y(p)) \tag{Conj}$$

A theory of equality for terms in context is built, as usual, by closing the axioms under substitution, congruence, reflexivity, symmetry and transitivity. It immediately follows from conjugacy and discardability that $x\,{}_i?_j\,y$ is definable as $\nu_{i,j}p.(x\,?_p\,y)$ for $i, j > 0$.

As an example, consider $t(r) = (r\,?_p\,x)\,?_p(y\,?_p\,r)$ that represents tossing a coin with bias p twice, continuing with x or y if the results are different, or with r otherwise. One can show that $x\,{}_1?_1\,y$ is a unique fixed point of t, i.e. $x\,{}_1?_1\,y = t(x\,{}_1?_1\,y)$; see the full paper [27] for detail. This is exactly von Neumann's trick [31] to simulate a fair coin toss with a biased one.

(For more details on the general axiomatic framework with parameters, see [25, 26], where it is applied to predicate logic, π-calculus, and other effects.)

3 A complete interpretation in measure theory

In this section we give an interpretation of terms using measures and integration operators, the standard formalism for probability theory (e.g. [19, 24]), and we show that this interpretation is complete (Thm. 9). Even if the reader is not interested in measure theory, they may still find value in the syntactical results of §4 which we prove using this completeness result.

By the Riesz–Markov–Kakutani representation theorem, there are two equivalent ways to view probabilistic programs: as probability kernels and as linear functionals. Both are useful.

Programs as probability kernels.

Forgetting about abstract types for a moment, terms in the BetaBern module are first-order probabilistic programs. So we have a standard denotational semantics due to [14] where terms are interpreted as probability kernels and ν as integration. Let $I = [0,1]$ denote the unit interval. We write $\beta_{i,j}$ for the Beta(i,j)-distribution on I, which is given by the density function $p \mapsto \frac{1}{B(i,j)} p^{i-1}(1-p)^{j-1}$, where $B(i,j) = \frac{(i-1)!(j-1)!}{(i+j-1)!}$ is a normalizing constant.

For contexts of the form $\Gamma = (p_1, \dots, p_\ell)$ and $\Delta = (x_1 : m_1, \dots, x_k : m_k)$, we let $[\![\Delta]\!] \stackrel{\text{def}}{=} \sum_{i=1}^k I^{m_i}$ consist of a copy of I^{m_i} for every variable $x_i : m_i$. This has a σ-algebra $\Sigma([\![\Delta]\!])$ generated by the Borel sets. We interpret terms $\Gamma \mid \Delta \vdash t$ as probability kernels $[\![t]\!] : I^\ell \times \Sigma([\![\Delta]\!]) \to [0,1]$ inductively, for $\vec{p} \in I^\ell$ and $U \in \Sigma([\![\Delta]\!])$:

$$[\![x_i(p_{j_1}, \dots, p_{j_m})]\!](\vec{p}, U) = 1 \text{ if } (i, p_{j_1} \dots p_{j_m}) \in U, \text{ 0 otherwise}$$

$$[\![u \mathbin{?_j} v]\!](\vec{p}, U) = \tfrac{1}{i+j}\Big(i([\![u]\!](\vec{p}, U)) + j([\![v]\!](\vec{p}, U))\Big)$$

$$[\![u \mathbin{?_{p_j}} v]\!](\vec{p}, U) = p_j([\![u]\!](\vec{p}, U)) + (1-p_j)([\![v]\!](\vec{p}, U))$$

$$[\![\nu_{i,j} q.t]\!](\vec{p}, U) = \int_0^1 [\![t]\!]((\vec{p}, q), U)\, \beta_{i,j}(\mathrm{d}q) \quad \Big[= \int_0^1 [\![t]\!]((\vec{p}, q), U)\ \tfrac{1}{B(i,j)} q^{i-1}(1-q)^{j-1}\ \mathrm{d}q \Big]$$

▶ **Proposition 3.** *The interpretation is sound: if $\Gamma \mid \Delta \vdash t = u$ is derivable then $[\![t]\!] = [\![u]\!]$ as probability kernels $[\![\Gamma]\!] \times \Sigma([\![\Delta]\!]) \to [0,1]$.*

Proof notes. One must check that the axioms are sound under the interpretation. Each of the axioms are elementary facts about probability. For instance, commutativity (C2) amounts to Fubini's theorem, and the conjugacy axiom (Conj) is the well-known conjugate-prior relationship of Beta- and Bernoulli distributions. ◀

Interpretation as functionals

We write $\mathbb{R}^{I^m}$ for the vector space of continuous functions $I^m \to \mathbb{R}$, endowed with the supremum norm. Given a probability kernel $\kappa : I^\ell \times \Sigma\big(\sum_{j=1}^k I^{m_j}\big) \to [0,1]$ and $\vec{p} \in I^\ell$, we define a linear map $\phi_{\vec{p}} : \mathbb{R}^{I^{m_1}} \times \cdots \times \mathbb{R}^{I^{m_k}} \to \mathbb{R}$, by considering κ as an integration operator:

$$\phi_{\vec{p}}(f_1 \dots f_k) = \int f_j(r_1 \dots r_{m_j})\ \kappa(\vec{p}, \mathrm{d}(j, r_1 \dots r_{m_j}))$$

Here $\phi_{\vec{p}}$ are unital ($\phi(\vec{1}) = 1$) and positive ($\vec{f} \geq 0 \implies \phi(\vec{f}) \geq 0$).

When $\kappa = [\![t]\!]$, this $\phi_{\vec{p}}(\vec{f})$ is moreover continuous in $\vec{p}$, and hence a unital positive linear map $\phi : \mathbb{R}^{I^{m_1}} \times \cdots \times \mathbb{R}^{I^{m_k}} \to \mathbb{R}^{I^\ell}$ [6, Thm. 5.1]. It is informative to spell out the interpretation of terms $p_1, \dots, p_\ell \mid x_1 : m_1, \dots, x_k : m_k \vdash t$ as maps $[\![t]\!] : \mathbb{R}^{I^{m_1}} \times \dots \times \mathbb{R}^{I^{m_k}} \to \mathbb{R}^{I^\ell}$ since it fits the algebraic notation: we may think of the variables $x\colon m$ as ranging over functions $\mathbb{R}^{I^m}$.

▶ **Proposition 4.** *The functional interpretation is inductively given by*

$$[\![x_i(p_{j_1},\dots,p_{j_m})]\!](\vec{f})(\vec{p}) = f_i(p_{j_1},\dots,p_{j_m})$$
$$[\![u \,{}_i?_j\, v]\!](\vec{f})(\vec{p}) = \tfrac{1}{i+j}\Big(i([\![u]\!](\vec{f})(\vec{p})) + j([\![v]\!](\vec{f})(\vec{p}))\Big)$$
$$[\![u \,?_{p_j}\, v]\!](\vec{f})(\vec{p}) = p_j([\![u]\!](\vec{f})(\vec{p})) + (1-p_j)([\![v]\!](\vec{f})(\vec{p}))$$
$$[\![\nu_{i,j}q.t]\!](\vec{f})(\vec{p}) = \int_0^1 [\![t]\!](\vec{f})(\vec{p},q)\,\beta_{i,j}(\mathrm{d}q)$$

For example, $[\![- \mid x,y\colon 0 \vdash x \,{}_1?_1\, y]\!] : \mathbb{R}\times\mathbb{R}\to\mathbb{R}$ is the function $(x,y)\mapsto \frac{1}{2}(x+y)$, and $[\![- \mid x\colon 1 \vdash \nu_{1,1}p.x(p)]\!] : \mathbb{R}^I \to \mathbb{R}$ is the integration functional, $f \mapsto \int_0^1 f(p)\,\mathrm{d}p$.

(We use the same brackets $[\![-]\!]$ for both the measure-theoretic and the functional interpretations; the intended semantics will be clear from context.)

3.1 Technical background on Bernstein polynomials

▶ **Definition 5** (Bernstein polynomials)**.** For $i = 0,\dots,k$, we define the i-th basis Bernstein polynomial $b_{i,k}$ of degree k as $b_{i,k}(p) = \binom{k}{i}p^{k-i}(1-p)^i$. For a multi-index $I = (i_1,\dots,i_\ell)$ with $0 \le i_j \le k$, we let $b_{I,k}(\vec{p}) = b_{i_1,k}(p_1)\cdots b_{i_\ell,k}(p_\ell)$. A Bernstein polynomial is a linear combination of Bernstein basis polynomials.

The family $\{b_{i,k} : i = 0,\dots,k\}$ is indeed a basis of the polynomials of maximum degree k and also a partition of unity, i.e. $\sum_{i=0}^k b_{i,k} = 1$. Every Bernstein basis polynomial of degree k can be expressed as a nonnegative rational linear combination of degree $k+1$ basis polynomials.

The density function of the distribution $\beta_{i,j}$ on $[0,1]$ for $i,j > 0$ is proportional to a Bernstein basis polynomial of degree $i+j-2$. We can conclude that the measures $\{\beta_{i,j} : i,j > 0, i+j = n\}$ are linearly independent for every n. In higher dimensions, the polynomials $\{b_{I,k}\}$ are linearly independent for every k. Moreover, products of beta distributions β_{i_r,j_r} are linearly independent as long as $i_r + j_r = n$ holds for some common n. This will be a key idea for normalizing Beta-Bernoulli terms.

3.2 Normal forms and completeness

For the completeness proof of the measure-theoretic model, we proceed as follows: To decide $\Gamma \mid \Delta \vdash t = u$ for two terms t,u, we transform them into a common normal form whose interpretations can be given explicitly. We then use a series of linear independence results to show that if the interpretations agree, the normal forms are already syntactically equal.
Normalization happens in three stages.

- If we think of a term as a syntax tree of binary choices and ν-binders, we use the conjugacy axiom to push all occurrences of ν towards the leaves of the tree.
- We use commutativity and discardability to stratify the use of free parameters $?_p$.
- The leaves of the tree will now consist of chains of ν-binders, variables and ratio choices ${}_i?_j$. Those can be collected into a canonical form.

We will describe these normalization stages in reverse order because of their increasing complexity.

3.2.1 Stone's normal forms for rational convex sets

Normal forms for the theory of rational convex sets have been described by Stone [29]. We note that if $- \mid x_1 \dots x_k : 0 \vdash t$ is a term in the theory of rational convex sets (Def. 1) then

$[\![t]\!] : \mathbb{R}^k \to \mathbb{R}$ is a unital positive linear map that takes rationals to rationals. From the perspective of measures, this corresponds to a categorical distribution with k categories.

▶ **Proposition 6** (Stone). *The interpretation exhibits a bijective correspondence between terms $- \mid x_1 \dots x_k : 0 \vdash t$ built from $?_i$, modulo equations, and unital positive linear maps $\mathbb{R}^k \to \mathbb{R}$ that take rationals to rationals.*

For instance, the map $\phi(x, y, z) = \frac{1}{10}(2x + 3y + 5z)$ is unital positive linear, and arises from the term $t \stackrel{\text{def}}{=} x \,?_8 (y \,?_5 z)$. This is the only term that gives rise to the ϕ, modulo equations. In brief, one can recover t from ϕ by looking at $\phi(1, 0, 0) = \frac{2}{10}$, then $\phi(0, 1, 0) = \frac{3}{10}$, then $\phi(0, 0, 1) = \frac{5}{10}$. We will write $\begin{pmatrix} ? & x_1 & \dots & x_k \\ & w_1 & \dots & w_k \end{pmatrix}$ for the term corresponding to the linear map $(x_1 \dots x_k) \mapsto \frac{1}{\sum_{i=1}^k w_k}(w_1 x_1 + \dots + w_k x_k)$. These are normal forms for the theory of rational convex sets.

3.2.2 Characterization and completeness for ν-free terms

This section concerns the normalization of terms using free parameters but no ν. Consider a single parameter p. If we think of a term t as a syntactic tree, commutativity and discardability can be used to move all occurrences of $?_p$ to the root of the tree, making it a *tree diagram* of some depth k. Let us label the 2^k leaves with $t_{a_1 \cdots a_k}$, $a_i \in \{0, 1\}$. As a programming language expression, this corresponds to successive bindings

let a_1=M.get(p) **in** ... **let** a_k=M.get(p) **in** $t_{a_1 \cdots a_k}$

Permutations $\sigma \in S_k$ of the k first levels in the tree act on tree diagrams by permuting the leaves via $t_{a_1 \cdots a_k} \mapsto t_{a_{\sigma(1)} \cdots a_{\sigma(k)}}$. By commutativity (C1), those permuted diagrams are still equal to t, so we can replace t by the average over all permuted diagrams, since rational choice is discardable. The average commutes down to the leaves (C5), so we obtain a tree diagram with leaves $m_{a_1 \cdots a_k} = \frac{1}{k!} \sum_\sigma t_{a_{\sigma(1)} \cdots a_{\sigma(k)}}$, where the average is to be read as a rational choice with all weights 1. This new tree diagram is now by construction invariant under permutation of levels in the tree, in particular $m_{a_1 \cdots a_k}$ only depends on the sum $a_1 + \dots + a_k$. That is to say, the counts are a sufficient statistic.

This leads to the following normalization procedure for terms $p_1 \dots p_\ell \mid x_1 \dots x_n : 0 \vdash t$: Write $C_k^{p_j}(t_0, \dots, t_k)$ for the permutation invariant tree diagram of p_j-choices and depth k with leaves $t_{a_1 \cdots a_k} = t_{a_1 + \cdots + a_k}$. Then we can rewrite t as $C_k^{p_1}(t_0, \dots, t_k)$ where each t_i is p_1-free. Recursively normalize each t_i in the same way, collecting the next parameter. By discardability, we can pick the height of all these tree diagrams to be a single constant k, such that the resulting term is a nested structure of tree-diagrams $C_k^{p_j}$. We will use multi-indices $I = (i_1, \dots, i_\ell)$ to write the whole stratified term as $C_k((t_I))$ where each leaf t_I only contains rational choices. The interpretation of such a term can be given explicitly by Bernstein polynomials

$$[\![C_k((t_I))]\!](\vec{x})(\vec{p}) = \textstyle\sum_I b_{I,k}(\vec{p}) \cdot [\![t_I]\!](\vec{x})(\vec{p}).$$

For example, normalizing $(v \,?_p x) ?_p (y \,?_p v)$ gives $(v \,?_p (x \,?_1 y)) ?_p ((x \,?_1 y) \,?_p v) = C_2(v, x ?_1 y, v)$.

From this we obtain the following completeness result:

▶ **Proposition 7.** *There is a bijective correspondence between equivalence classes of terms $p_1 \dots p_\ell \mid x_1 \dots x_n : 0 \vdash t$ and linear unital maps $\phi : \mathbb{R}^n \to \mathbb{R}^{I^\ell}$ such that for every standard basis vector e_j of $\mathbb{R}^n$, $\phi(e_j)$ is a Bernstein polynomial with nonnegative rational coefficients.*

Proof. We can assume all basis polynomials to have the same degree k. If $\phi(e_j) = \sum_I w_{Ij} b_{I,k}$, then the unitality condition $\phi(1,\dots,1) = 1$ means $\sum_I \left(\sum_j w_{Ij}\right) b_{I,k} = 1$, and hence by linear independence and partition of unity, $\sum_j w_{Ij} = 1$ for every I. If we thus let t_I be the rational convex combination of the x_j with weights w_{Ij}, then $[\![C_k((t_I))]\!] = \phi$. Again by linear independence, the weights w_{IJ} are uniquely defined by ϕ. ◀

Geometric characterizations for the assumption of this theorem exist in [20, 3]. For example, a univariate polynomial is a Bernstein polynomial with nonnegative coefficients if and only if it is positive on $(0,1)$. More care is required in the multivariate case.

3.2.3 Normalization of Beta-Bernoulli

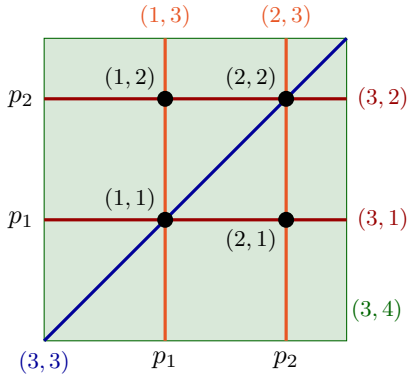
For arbitrary terms $p_1 \dots p_\ell \,|\, x_1 \colon m_1, \dots, x_s \colon m_s \vdash t$, we employ the following normalization procedure. Using conjugacy and the commutativity axioms (C2–C4), we can push all uses of ν towards the leaves of the tree, until we end up with a tree of ratios and free parameter choices only. Next, by conjugacy and discardability, we expand every instance of $\nu_{i,j}$ until they satisfy $i + j = n$ for some fixed, sufficiently large n. We then stratify the free parameters into permutation invariant tree diagrams. That is, we find a number k such that t can be written as $C_k((t_I))$ where the leaves t_I consist of ν and rational choices only.

In each t_I, commuting all the choices up to the root, we are left with a convex combination of chains of ν's of the form $\nu_{i_1,j_1} p_{\ell+1} \dots \nu_{i_d,j_d} p_{\ell+d}.x_j(p_{\tau(1)},\dots,p_{\tau(m)})$ for some $\tau : m \to \ell+d$. By discardability, we can assume that there are no unused bound parameters. We consider two chains equal if they are α-convertible into each other. Now if $c_1,\dots,c_m$ is a list of the distinct chains that occur in any of the leaves, we can give the leaves t_I the uniform shape $t_I = \begin{pmatrix} ? & c_1 & \dots & c_m \\ & w_{I1} & \dots & w_{Im} \end{pmatrix}$ for appropriate weights $w_{Ij} \in \mathbb{N}$. We will show that this representation is a unique normal form.

3.2.4 Proof of completeness

Consider a *chain* $c = \nu_{i_1,j_1} p_{\ell+1} \dots \nu_{i_d,j_d} p_{\ell+d}.\, x(p_{\tau(1)},\dots,p_{\tau(m)})$. Its measure-theoretic interpretation $[\![c]\!](p_1,\dots,p_\ell)$ is a pushforward of a product of d beta distributions, supported on a hyperplane segment that is parameterized by the map $h_\tau : I^d \to I^m, h_\tau(p_{\ell+1},\dots,p_{\ell+d}) = (p_{\tau(1)},\dots,p_{\tau(m)})$. Note that the position of the hyperplane may vary with the free parameters. To capture this geometric information, we call τ the *subspace type* of the chain and d its *dimension*. Because of α-invariance of chains, we identify subspace types that differ by a permutation of $\{\ell+1,\dots,\ell+d\}$.

For example, each chain with two free parameters p_1, p_2 and a variable $x : 2$ gives rise to a parameterized distribution on the unit square. On the right, we illustrate the ten possible supports that such distributions can have, as subspaces of the square. In the graphic we write (i,j) for $\nu p_3.\nu p_4.x(p_i,p_j)$, momentarily omitting the subscripts of ν because they do not affect the support. For instance, the upper horizontal line corresponds to $\nu p_3.x(p_3,p_2)$; the bottom-right dot corresponds to $x(p_2,p_1)$; the diagonal corresponds to $\nu p_3.x(p_3,p_3)$; and the entire square corresponds to



$\nu p_3.\nu p_4.x(p_3,p_4)$. All told there are four subspaces of dimension $d=0$, five with $d=1$, and one with $d=2$. Notice that the subspaces are all distinct as long as $p_1 \neq p_2$.

▶ **Proposition 8.** *If $c_1,\dots,c_s$ are distinct chains with $i_1+j_1=\dots=i_d+j_d=n$, then the family of functionals $\{[\![c_i]\!](-)(\vec{p}) : \mathbb{R}^{I^{m_1}} \times \dots \times \mathbb{R}^{I^{m_s}} \to \mathbb{R}\}_{i=1,\dots,s}$ is linearly independent whenever all parameters p_i are distinct.*

Proof. Fix $\vec{p}$. Chains on different variables are clearly independent, so we can restrict ourselves to a single variable $x:m$. We reason measure-theoretically. The interpretation of a chain c_i of subspace type τ_i is a pushforward measure $h_{i*}(\mu_i)$ where μ_i is a product of d beta distributions, and h_i is the affine inclusion map $h_i(p_{\ell+1},\dots,p_{\ell+d}) = (p_{\tau_i(1)},\dots,p_{\tau_i(m)})$. Let $\sum a_i h_{i*}(\mu_i) = 0$ as a signed measure. We show by induction over the dimension of the chains that all a_i vanish. Assume that $a_i=0$ whenever the dimension of c_i is less than d, and consider an arbitrary subspace τ_j of dimension d. We can define a signed Borel measure on I^d by restriction

$$\rho(A) \stackrel{\text{def}}{=} \sum_i a_i h_{i*}(\mu_i)(h_j(A)) = \sum_i a_i \mu_i(h_i^{-1}(h_j(A)))$$

as h_j sends Borel sets to Borel sets (e.g. [10, §15A]). We claim that $\rho(A) = \sum_{c_i \text{ has type } \tau_j} a_i\mu_i(A)$, as the contributions of chains c_i of different type vanish.

- If c_i has dimension $< d$, $a_i=0$ by the inductive hypothesis.
- If c_i has dimension $> d$, we note that $h_i^{-1}(h_j(A))$ only has at most dimension d. It is therefore a nullset for μ_i.
- If c_i has dimension d but a different type, and all $p_1,\dots,p_\ell$ are assumed distinct, then the hyperplanes given by h_i and h_j are not identical. Therefore their intersection is at most $(d-1)$-dimensional and $h_i^{-1}(h_j(A))$ is a nullset for μ_i.

By assumption, ρ has to be the zero measure, but the μ_i are linearly independent. Therefore $a_i=0$ for all c_i with subspace type τ_j. Repeat this for every subspace type of dimension d to conclude overall linear independence. ◀

▶ **Theorem 9** (Completeness). *If $\Gamma \mid \Delta \vdash t,t'$ and $[\![t]\!]=[\![t']\!]$, then $\Gamma \mid \Delta \vdash t=t'$.*

Proof. From the normalization procedure, we find numbers k,n, a list of distinct chains $c_1,\dots,c_s$ with $i+j=n$ and weights $(w_{Ij}),(w'_{Ij})$ such that $\Gamma \mid \Delta \vdash t = C_k((t_I))$ and $\Gamma \mid \Delta \vdash t' = C_k((t'_I))$ where $t_I = \begin{pmatrix} ? & c_1 & \dots & c_s \\ & w_{I1} & \dots & w_{Is} \end{pmatrix}$ and $t'_I = \begin{pmatrix} ? & c_1 & \dots & c_s \\ & w'_{I1} & \dots & w'_{Is} \end{pmatrix}$. The interpretations of these normal forms are given explicitly by

$$[\![t]\!](\vec{f})(\vec{p}) = \sum_j \frac{w_{Ij}}{w_I} \cdot b_{I,k}(\vec{p}) \cdot [\![c_j]\!](\vec{f})(\vec{p}) \text{ where } w_I = \sum_j w_{Ij}$$

and analogously for t'. Then $[\![t]\!]=[\![t']\!]$ implies that for all $\vec{f}$

$$\sum_j \left(\sum_I \left(\frac{w_{Ij}}{w_I} - \frac{w'_{Ij}}{w'_I} \right) b_{I,k}(\vec{p}) \right) [\![c_j]\!](\vec{f})(\vec{p}) = 0.$$

By Proposition 8, this implies $\sum_I \left(\frac{w_{Ij}}{w_I} - \frac{w'_{Ij}}{w'_I} \right) b_{I,k}(\vec{p}) = 0$ for every j and whenever the parameters p_i are distinct. By continuity of the left hand side, the expression in fact has to vanish for *all* $\vec{p}$. By linear independence of the Bernstein polynomials, we obtain $w_{Ij}/w_I = w'_{Ij}/w'_I$ for all I,j. Thus, all weights agree up to rescaling and we can conclude $\Gamma \mid \Delta \vdash t=t'$. ◀

4 Extensionality and syntactical completeness

In this section we use the model completeness of the previous section to establish some syntactical results about the theory of Beta-Bernoulli. Although the model is helpful in informing the proofs, the statements of the results in this section are purely syntactical.

The ultimate result of this section is equational syntactical completeness (Cor. 13), which says that there can be no further equations in the theory without it becoming inconsistent with discrete probability. In other words, assuming that the axioms we have included are appropriate, they must be sufficient, regardless of any discussion about semantic models or intended meaning. This kind of result is sometimes called 'Post completeness' after Post proved a similar result for propositional logic.

The key steps towards this result are two extensionality results. These are related to the programming language idea of 'contextual equivalence'. Recall that in a programming language we often define a basic notion of equivalence on closed ground terms: these are programs with no free variables that return (say) booleans. This notion is often defined by some operational consideration using some notions of observation. From this we define contextual equivalence by saying that $t \approx u$ if, for all closed ground contexts $\mathcal{C}$, $\mathcal{C}[t] = \mathcal{C}[u]$.

Contextual equivalence has a canonical appearance, but an axiomatic theory of equality, such as the one in this paper, is more compositional and easier to work with. Our notion of equality induces in particular a basic notion of equivalence on closed ground terms. Our extensionality results say that, assuming one is content with this basic notion of equivalence, the equations that we axiomatize coincide with contextual equivalence.

4.1 Extensionality

▶ **Proposition 10** (Extensionality for closed terms). *Suppose* $\Gamma, q \,|\, \Delta \vdash t$ *and* $\Gamma, q \,|\, \Delta \vdash u$. *If* $\Gamma \,|\, \Delta \vdash \nu_{i,j} q.t = \nu_{i,j} q.u$ *for all* i, j, *then also* $\Gamma \,|\, \Delta \vdash t = u$.

Proof. We show the contrapositive. By the model completeness theorem (Thm. 9), we can reason in the model rather than syntactically. So we consider t and u such that $[\![t]\!] \neq [\![u]\!]$ as functions $\mathbb{R}^{I^{m_1}} \times \mathbb{R}^{I^{m_k}} \to \mathbb{R}^{I^{l+1}}$, and show that there are i, j such that $[\![\nu_{i,j} q.t]\!] \neq [\![\nu_{i,j} q.u]\!]$. By assumption there are $\vec{f}$ and $\vec{p}, q$ such that $[\![t]\!](\vec{f})(\vec{p}, q) \neq [\![u]\!](\vec{f})(\vec{p}, q)$ as real numbers.

Now we use the following general reasoning: For any real $q \in I$ we can pick monotone sequences $i_1 < \cdots < i_n < \dots$ and $j_1 < \cdots < j_n < \dots$ of natural numbers so that $\frac{i_n}{i_n + j_n} \to q$ as $n \to \infty$. Moreover, for any continuous $h : I \to \mathbb{R}$, the integral $\int h \, \mathrm{d}\beta_{i_n, j_n}$ converges to $h(q)$ as $n \to \infty$: one way to see this is to notice that the variance of β_{i_n, j_n} vanishes as $n \to \infty$, so by Chebyshev's inequality, $\lim_n \beta_{i_n, j_n}$ is a Dirac distribution at q. Thus, $\int \left([\![t]\!](\vec{f})(\vec{p}, r) - [\![u]\!](\vec{f})(\vec{p}, r) \right) \beta_{i_n, j_n}(\mathrm{d}r)$ is non-zero as $n \to \infty$. By continuity, for some n, $\int [\![t]\!](\vec{f})(\vec{p}, r) \; \beta_{i_n, j_n}(\mathrm{d}r) \neq \int [\![u]\!](\vec{f})(\vec{p}, r) \; \beta_{i_n, j_n}(\mathrm{d}r)$. So, $[\![\nu_{i_n, j_n} q.t]\!] \neq [\![\nu_{i_n, j_n} q.u]\!]$. ◀

▶ **Proposition 11** (Extensionality for ground terms). In brief: *If* $t[{}^{v_1 \dots v_k}/_{x_1 \dots x_k}] = u[{}^{v_1 \dots v_k}/_{x_1 \dots x_k}]$ *for all suitable ground* $v_1 \dots v_k$, *then* $t = u$.

In detail: *Consider* t *and* u *with* $- \,|\, x_1 \colon m_1 \dots x_k \colon m_k \vdash t, u$. *Suppose that whenever* $v_1 \dots v_k$ *are terms with* $(p_1 \dots p_{m_1} \,|\, y, z : 0 \vdash v_1)$, $\dots$, $(p_1 \dots p_{m_k} \,|\, y, z : 0 \vdash v_k)$, *then we have* $- \,|\, y, z : 0 \vdash t[{}^{v_1 \dots v_k}/_{x_1 \dots x_k}] = u[{}^{v_1 \dots v_k}/_{x_1 \dots x_k}]$. *Then we also have* $- \,|\, x_1 \colon m_1 \dots x_k \colon m_k \vdash t = u$.

Proof. Again, we show the contrapositive. Let $\Delta = (x_1 \colon m_1 \dots x_k \colon m_k)$. Suppose we have t and u such that $\neg(- \,|\, \Delta \vdash t = u)$. Then by the model completeness theorem (Thm. 9), we have $[\![t]\!] \neq [\![u]\!]$ as linear functions $\mathbb{R}^{I^{m_1}} \times \cdots \times \mathbb{R}^{I^{m_k}} \to \mathbb{R}$. Since the functions are linear, there is an index $i \leq k$ and a continuous function $f : I^{m_i} \to \mathbb{R}$ with $[\![t]\!](0 \dots 0, f, 0 \dots 0) \neq [\![u]\!](0 \dots 0, f, 0 \dots 0)$. By the Stone-Weierstrass theorem, every such f

is a limit of polynomials, and so since $[\![t]\!]$ and $[\![u]\!]$ are continuous and linear, there has to be a Bernstein basis polynomial $b_{I,k} : \mathbb{R}^{m_i} \to \mathbb{R}$ that already distinguishes them. This function is definable, i.e. there is a a term $p_1, \ldots, p_{m_i} \mid y, z : 0 \vdash w$ with $[\![w]\!](1,0) = b_{I,k}$. Define terms $v_j = w$ for $i = j$ and $v_j = z$ for $i \neq j$. Then

$$[\![t[{}^{v_1\cdots v_k}/_{x_1\ldots x_k}]]\!](1,0) = [\![t]\!](0,\ldots,b_{I,k},\ldots,0) \neq [\![u]\!](0,\ldots,b_{I,k},\ldots,0) = [\![u[{}^{v_1\cdots v_k}/_{x_1\ldots x_k}]]\!](1,0).$$

The required $\neg\big(- \mid y, z : 0 \vdash t[{}^{v_1\cdots v_k}/_{x_1\ldots x_k}] = u[{}^{v_1\cdots v_k}/_{x_1\ldots x_k}]\big)$ follows from the above disequality because of the model soundness property (Props. 3 and 4). ◀

From the programming perspective, a term $- \mid y, z : 0 \vdash t_0$ corresponds to a closed program of type bool, for it has two possible continuations, y and z, depending on whether the outcome is true or false. From this perspective, Proposition 11 says that for closed t, u, if $\mathcal{C}[t] = \mathcal{C}[u]$ for all boolean contexts $\mathcal{C}$, then $t = u$.

4.2 Relative syntactical completeness

▶ **Proposition 12** (Neumann, [17]). *If t, u are terms in the theory of rational convexity (Def. 1), then either $t = u$ is derivable or it implies $x\,{}_i?_j\, y = x\,{}_{i'}?_{j'}\, y$ for all nonzero i, i', j, j'.*

▶ **Corollary 13.** *The theory of Beta-Bernoulli is syntactically complete relative to the theory of rational convexity, in the following sense. For all terms t and u, either $t = u$ is derivable, or it implies $x\,{}_i?_j\, y = x\,{}_{i'}?_{j'}\, y$ for all nonzero i, i', j, j'.*

This is proved by combining Propositions 10, 11 and 12. As an example for extensionality and completeness, consider the equation $\nu_{1,1}p.x(p,p) = \nu_{1,1}p.(\nu_{1,1}q.x(p,q))$. It is not derivable, as can be witnessed by the substitution $x(p,q) = (y\,?_q\,z)\,?_p\,z$. Normalizing yields $y\,{}_1?_2\,z = y\,{}_1?_3\,z$ which is incompatible with discrete probability (see the full paper [27]). In programming syntax, the candidate equation is written

LHS = **let** p = M.new(1,1) **in** (p,p)	RHS = (M.new(1,1) , M.new(1,1))

and the distinguishing context is C[−] = **let** (p,q)=(−) **in if** M.get(p) **then** M.get(q) **else** false. That is to say, the closed ground programs C[LHS] and C[RHS] necessarily have different observable statistics: this follows from the axioms.

4.3 Remark about stateful implementations

In the introduction we recalled the idea of using Pólya's urn to implement a Beta-Bernoulli process using local (hidden) state.

Our equational presentation gives a recipe for understanding the correctness of the stateful implementation. First, one would give an operational semantics, and then a basic notion of observational equivalence on closed ground terms in terms of the finite probabilities associated with reaching certain ground values. From this, an operational notion of contextual equivalence can be defined (e.g. [4, §6], [23, 32]). Then, one would show that the axioms of our theory hold up-to contextual equivalence. Finally one can deduce from the syntactical completeness result that the equations satisfied by this stateful implementation must be exactly the equations satisfied by the semantic model.

In fact, in this argument, it is not necessary to check that axioms (C1) and (D2) hold in the operationally defined contextual equivalence, because the axiomatized equality on closed ground terms is independent of these axioms. To see this, notice that our normalization procedure (§3.2.3) doesn't use (C1) or (D2) when the terms are closed and ground, since

then we can take $n = k = 0$. This is helpful because the remaining axioms are fairly straightforward, e.g. (Conj) is the essence of the urn scheme and (D1) is garbage collection.

5 Conclusion

Exchangeable random processes are central to many Bayesian models. The general message of this paper is that the analysis of exchangeable random processes, based on basic concepts from programming language theory, depends on three crucial ingredients: commutativity, discardability, and abstract types. We have illustrated this message by showing that just adding the conjugacy law to these ingredients leads to a complete equational theory for the Beta-Bernoulli process (Thm. 9). Moreover, we have shown that this equational theory has a canonical syntactic and axiomatic status, regardless of the measure theoretic foundation (Cor. 13). Our results in this paper open up the following avenues of research.

Study of nonparametric Bayesian models: We contend that abstract types, commutativity and discardability are fundamental tools for studying nonparametric Bayesian models, especially hierarchical ones. For example, the Chinese Restaurant Franchise [30] can be implemented as a module with three abstract types, f (franchise), r (restaurant), t (table), and functions $\mathsf{newFranchise}\colon() \to \mathsf{f}$, $\mathsf{newRestaurant}\colon\mathsf{f} \to \mathsf{r}$, $\mathsf{getTable}\colon\mathsf{r} \to \mathsf{t}$, $\mathsf{sameDish}\colon\mathsf{t}*\mathsf{t} \to \mathsf{bool}$. Its various exchangeability properties correspond to commutativity/discardability in the presence of type abstraction. (For other examples, see [28].)

First steps in synthetic probability theory: As is well known, the theory of rational convex sets corresponds to the monad D of rational discrete probability distributions. Commutativity of the theory amounts to commutativity of the monad D [15, 12].

As any parameterized algebraic theory, the theory of Beta-Bernoulli (§2) can be understood as a monad P on the functor category $[\mathbf{FinSet}, \mathbf{Set}]$, with the property that to give a natural transformation $\mathbf{FinSet}(\ell, -) \to P(\coprod_{j=1}^{k} \mathbf{FinSet}(m_k, -))$ is to give a term $(p_1 \dots p_\ell \,|\, x_1 \colon m_1 \dots x_k \colon m_k \vdash t)$, and monadic bind is substitution ([25, Cor. 1], [26, §VIIA]). This can be thought of as an intuitionistic set theory with an interesting notion of probability. As such this is a 'commutative effectus' [7], a synthetic probability theory (see also [13]). Like D, the global elements $1 \to P(2)$ are the rationals in $[0, 1]$ (by Prop. 7) but unlike D, the global elements $1 \to P(P(2))$ include the beta distribution.

Practical ideas for nonparametric Bayesian models in probabilistic programming: A more practical motivation for our work is to inform the design of module systems for probabilistic programming languages. For example, Anglican, Church, Hansei and Venture already support nonparametric Bayesian primitives [11, 33, 16]. We contend that abstract types are a crucial concept from the perspective of exchangeability.

Uniformization Problems for Synchronizations of Automatic Relations on Words

Sarah Winter
RWTH Aachen University, Germany
winter@cs.rwth-aachen.de

Abstract

A uniformization of a binary relation is a function that is contained in the relation and has the same domain as the relation. The synthesis problem asks for effective uniformization for classes of relations and functions that can be implemented in a specific way.

We consider the synthesis problem for automatic relations over finite words (also called regular or synchronized rational relations) by functions implemented by specific classes of sequential transducers.

It is known that the problem "Given an automatic relation, does it have a uniformization by a subsequential transducer?" is decidable in the two variants where the uniformization can either be implemented by an arbitrary subsequential transducer or it has to be implemented by a synchronous transducer. We introduce a new variant of this problem in which the allowed input/output behavior of the subsequential transducer is specified by a set of synchronizations and prove decidability for a specific class of synchronizations.

1 Introduction

A uniformization of a binary relation is a function that selects for each element in the domain of the relation a unique image that is in relation with this element. Of interest to us in this paper are uniformization problems in the setting where the relations and functions on words are defined by finite automata. Relations on words defined by finite automata extend languages defined by finite automata. Unlike for words, different finite automaton models for relations lead to different classes of relations.

Relations defined by asynchronous finite automata are referred to as rational relations. An asynchronous finite automaton is a nondeterministic finite automaton with two tapes whose reading heads can move at different speeds. An equivalent computation model are asynchronous finite transducers (see, e.g., [1]), that is, nondeterministic finite automata whose transitions are labeled by pairs of words.

A well known subclass of rational relations are synchronized rational relations (see [8]), which are defined by synchronous finite automata, that is, finite automata with two tapes whose reading heads move at the same speed. Equivalently, we speak of definability by synchronous finite transducers. The class of synchronized rational relations is also called automatic or regular, here, we use the term automatic.

One uniformization problem asks for proving that each relation in a given class has a certain kind of uniformization. For example, each rational relation can be uniformized by an unambiguous rational function (see [13]). Here, we are interested in the decision version of the problem: Given a relation from some class, does it have a uniformization in some other class? For the class of uniformizations we consider sequential transducers. A sequential transducer reads the input word in a deterministic manner and produces a unique output word for each input word.

The sequential uniformization problem relates to the synthesis problem, which asks, given a specification that relates possible inputs to allowed outputs, whether there is a program implementing the specification, and if so, construct one. This setting originates from Church's synthesis problem [4], where logical specifications over infinite words are considered. Büchi and Landweber [2] showed that for specifications in monadic second order logic, that is, specifications that can be translated into synchronous finite automata, it is decidable whether it can be realized by a synchronous sequential transducer (see, e.g., [14] for a modern presentation of this result). Later, decidability has been extended to asynchronous sequential transducers [10, 9].

Going from the setting of infinite words to finite words uniformization by subsequential [1] transducers is considered. The problem whether a relation given by a synchronous finite automaton can be realized by a synchronous subsequential transducer is decidable; this result can be obtained by adapting the proof from the infinite setting. Decidability has been extended to subsequential transducers [3]. Furthermore, for classes of asynchronous finite automata decidability results for synthesis of subsequential transducers have been obtained in [7].

A semi-algorithm in this spirit was introduced by [11], the algorithm is tasked to synthesize a subsequential transducer that selects the length lexicographical minimal output word for each input word from a given rational relation.

The decision problems that have been studied so far either ask for uniformization by a synchronous subsequential or by an arbitrary subsequential transducer. Our aim is to study the decision problem: Given a rational relation, does it have a uniformization by a subsequential transducer in which the allowed input/output behavior is specified by a given language of synchronizations? The idea is to represent a pair of words by a single word where each position is annotated over $\{1, 2\}$ indicating whether it came from the input or output component. The annotated string provides a synchronization of the pair. It is known that the class of rational relations is synchronized by regular languages [12]. More recently, main subclasses of rational relations have been characterized by their synchronizations [6].

We show decidability for a given automatic relation and a given set of synchronizations that synchronizes an automatic relation. Thus our decidability result generalizes the previously known decidability result for synthesis of synchronous subsequential transducers from automatic relations.

[1] A subsequential transducer can make a final output depending on the last state reached in a run whereas a sequential transducer can only produce output on its transitions.

The paper is structured as follows. First, in Sec. 2, we fix our notations and recap characterizations of synchronization languages established in [6]. In Sec. 3, we introduce uniformization problems with respect to synchronization languages and compare our setting with known results. In Sec. 4, we prove decidability of the question whether an automatic relation has a uniformization by a subsequential transducer in which the input/output behavior is specified by a set of synchronizations that synchronizes an automatic relation.

A full version of this paper can be found online.

2 Synchronizations of relations

Let $\mathbb{N}$ denote the set of all non-negative integers $\{0, 1, \dots\}$, and for every $k \in \mathbb{N}$, let $\mathbf{k}$ denote the set $\{1, \dots, k\}$. Given a finite set A, let $|A|$ denote its cardinality and 2^A its powerset.

Languages and relations of finite words. An *alphabet* Σ is a finite set of letters, a finite *word* is a finite sequence over Σ. The set of all finite words is denoted by Σ^* and the empty word by ε. The length of a word $w \in \Sigma^*$ is denoted by $|w|$, the number of occurrences of a letter $a \in \Sigma$ in w by $\#_a(w)$. Given $w \in \Sigma^*$, $w[i]$ stands for the ith letter of w, and $w[i, j]$ for the subword $w[i] \dots w[j]$.

A *language* L over Σ is a subset of Σ^*, and $\mathit{Pref}(L)$ is the set $\{u \in \Sigma^* \mid \exists v : uv \in L\}$ of its prefixes. The prefix relation is denoted by $\sqsubseteq$. A *relation* R over Σ is a subset of $\Sigma^* \times \Sigma^*$. The *domain* of a relation R is the set $\mathrm{dom}(R) = \{u \mid (u, v) \in R\}$, the *image* of a relation R is the set $\mathrm{img}(R) = \{v \mid (u, v) \in R\}$. For $u \in \Sigma^*$, let $R(u) = \{v \mid (u, v) \in R\}$ and write $R(u) = v$, if $R(u)$ is a singleton.

A *regular expression* r over Σ has the form $\emptyset$, ε, $\sigma \in \Sigma$, $r_1 \cdot r_2$, $r_1 + r_2$, or r_1^* for regular expressions r_1, r_2. The term r^+ is short for $r \cdot r^*$. The concatenation operator $\cdot$ is often omitted. The language associated to r is defined as usual, denoted $L(r)$, or conveniently, r.

▶ **Definition 1** (synchronization, L-controlled [6]). For $c \in \{\mathtt{i}, \mathtt{o}\}$, referring to input and output, respectively, we define two morphisms $\pi_c \colon (\mathbf{2} \times \Sigma) \to \Sigma \cup \{\varepsilon\}$ by $\pi_{\mathtt{i}}((i, a)) = a$ if $i = 1$, otherwise $\pi_{\mathtt{i}}((i, a)) = \varepsilon$, and likewise for $\pi_{\mathtt{o}}$ with $i = 2$. These morphisms are lifted to words over $(\mathbf{2} \times \Sigma)$.

A word $w \in (\mathbf{2} \times \Sigma)^*$ is a *synchronization* of a uniquely determined pair (w_1, w_2) of words over Σ, where $w_1 = \pi_{\mathtt{i}}(w)$ and $w_2 = \pi_{\mathtt{o}}(w)$. We write $[\![w]\!]$ to denote (w_1, w_2). Naturally, a set $S \subseteq (\mathbf{2} \times \Sigma)^*$ of synchronizations defines the relation $[\![S]\!] = \{[\![w]\!] \mid w \in S\}$.

A word $w = (i_1, a_1) \dots (i_n, a_n) \in (\mathbf{2} \times \Sigma)^*$ is the convolution $u \otimes v$ of two words $u = i_1 \dots i_n \in \mathbf{2}^*$ and $v = a_1 \dots a_n \in \Sigma^*$. Given a language $L \subseteq \mathbf{2}^*$, we say w is *L-controlled* if $u \in L$. A language $S \subseteq (\mathbf{2} \times \Sigma)^*$ is *L-controlled* if all its words are.

A language $L \subseteq \mathbf{2}^*$ is called a *synchronization language*. For a regular language $L \subseteq \mathbf{2}^*$, $\textsc{Rel}(L) = \{[\![S]\!] \mid S \text{ is a regular } L\text{-controlled language}\}$ is the set of relations that can be given by L-controlled synchronizations. Let $\mathcal{C}$ be a class of relations, we say L *synchronizes* $\mathcal{C}$ if $\textsc{Rel}(L) \subseteq \mathcal{C}$.

▶ **Definition 2** (lag, shift, shiftlag [6]). Given a word $w \in \mathbf{2}^*$, a position $i \leq |w|$, and $\gamma \in \mathbb{N}$. We say i is *γ-lagged* if $|\#_1(w[1, i]) - \#_2(w[1, i])| = \gamma$, and likewise, we define *$>\gamma$-lagged* and *$<\gamma$-lagged*. A *shift* of w is a position $i \in \{1, \dots, |w| - 1\}$ such that $w[i] \neq w[i + 1]$. Two shifts $i < j$ are *consecutive* if there is no shift l such that $i < l < j$. Let $\mathit{shift}(w)$ be the number of shifts in w, let $\mathit{lag}(w)$ be the maximum lag of a position in w, and let $\mathit{shiftlag}(w)$ be the maximum $n \in \mathbb{N}$ such that w contains n consecutive shifts which are $>n$-lagged.

We lift these notions to languages by taking the supremum in $\mathbb{N} \cup \{\infty\}$, e.g., $\mathit{shift}(L) = \sup\{\mathit{shift}(w) \mid w \in L\}$, and likewise for $\mathit{lag}(L)$ and $\mathit{shiftlag}(L)$.

The following characterizations for well known subclasses of rational relations were shown in [6]. Recall, rational relations are definable by asynchronous finite automata, automatic relations by synchronous finite automata, and recognizable relations are definable as finite unions of products of regular languages. We omit a formal definition of these models since it is not relevant to this paper.

▶ **Theorem 3** ([6]). *Let $L \subseteq \mathbf{2}^*$ be a regular language. Then:*
1. *L synchronizes recognizable relations iff $\mathit{shift}(L) < \infty$,*
2. *L synchronizes automatic relations iff $\mathit{shiftlag}(L) < \infty$,*
3. *L synchronizes rational relations.*

For ease of presentation, let $\Sigma_{\mathtt{io}}$, $\Sigma_{\mathtt{i}}$, and $\Sigma_{\mathtt{o}}$ be short for $\mathbf{2} \times \Sigma$, $\{1\} \times \Sigma$, and $\{2\} \times \Sigma$, respectively. If convenient, we use distinct symbols for input and output, instead of symbols annotated with 1 or 2.

For the results shown in this paper, it is useful to lift some notions introduced in [6] from words and languages over $\mathbf{2}$ to words and languages over $\Sigma_{\mathtt{io}}$.

▶ **Definition 4.** We lift the notions of *lag*, *shift*, and *shiftlag* from words and languages over $\mathbf{2}$ to words and languages over $\Sigma_{\mathtt{io}}$ in the natural way.

Furthermore, given a language $T \subseteq \Sigma_{\mathtt{io}}^*$, we say a word $w \in \Sigma_{\mathtt{io}}^*$ is T-controlled if $w \in T$. A language $S \subseteq \Sigma_{\mathtt{io}}^*$ is T-controlled if all its words are, namely, if $S \subseteq T$.

Automata on finite words. We fix our notations concerning finite automata on finite words. A *nondeterministic finite automaton* (*NFA*) is a tuple $\mathcal{A} = (Q, \Sigma, q_0, \Delta, F)$, where Q is a finite set of states, Σ is a finite alphabet, $q_0 \in Q$ is the initial state, $\Delta \subseteq Q \times \Sigma \times Q$ is the transition relation, and $F \subseteq Q$ is the set of final states. A *run* ρ of $\mathcal{A}$ on $w = a_1 \dots a_n \in \Sigma^*$ is a sequence of states $p_0 p_1 \dots p_n$ such that $(p_i, a_{i+1}, p_{i+1}) \in \Delta$ for all $i \in \{0, \dots, n-1\}$. Shorthand, we write $\mathcal{A} : p_0 \xrightarrow{w} p_n$. A run is *accepting* if it starts in q_0 and ends in a state from F. The language *recognized* by $\mathcal{A}$, written $L(\mathcal{A})$, is the set of words $w \in \Sigma^*$ that admit an accepting run of $\mathcal{A}$ on w. For $q \in Q$, let $\mathcal{A}_q$ denote the NFA obtained from $\mathcal{A}$ by setting its initial state to q. The class of languages recognized by NFAs is the class of regular languages. An NFA is *deterministic* (a *DFA*) if for each state $q \in Q$ and $a \in \Sigma$ there is at most one outgoing transition. In this case, it is more convenient to express Δ as a (partial) function $\delta : Q \times \Sigma \to Q$. Furthermore, let δ^* denote the usual extension of δ from letters to words.

We introduce some notions only applicable if an NFA recognizes a set of synchronizations. Given a regular $S \subseteq \Sigma_{\mathtt{io}}^*$, let $\mathcal{A} = (Q, \Sigma_{\mathtt{io}}, q_0, \Delta, F)$ be an NFA that recognizes S. We define $Q^{\mathtt{i}} = \{p \in Q \mid \exists a \in \Sigma, q \in Q : (p, (1, a), q) \in \Delta\}$ and $Q^{\mathtt{o}} = \{p \in Q \mid \exists a \in \Sigma, q \in Q : (p, (2, a), q) \in \Delta\}$ as the sets of states that have outgoing transitions from which input and output can be consumed, respectively. If $(Q^{\mathtt{i}}, Q^{\mathtt{o}})$ is a partition of Q, we write $Q = Q^{\mathtt{i}} \mathbin{\dot\cup} Q^{\mathtt{o}}$. We call $\mathcal{A}$ *sequential* if $\mathcal{A}$ is deterministic, and $Q = Q^{\mathtt{i}} \mathbin{\dot\cup} Q^{\mathtt{o}}$, and each $q \in Q^{\mathtt{o}}$ has at most one outgoing transition. For short, we refer to a sequential DFA as *sDFA*. Finally, we define the input automaton $\mathcal{A}_D$ of $\mathcal{A}$ as $(Q, \Sigma, q_0, \Delta', F)$, where $\Delta' = \{(p, a, q) \mid \mathcal{A} : p \xrightarrow{w} q \text{ and } \pi_{\mathtt{i}}(w) = a \in \Sigma\}$. A comparison to standard transducer models is given in the next section.

3 Uniformization problems

A *uniformization* of a relation $R \subseteq \Sigma^* \times \Sigma^*$ is a complete function $f_R : \mathrm{dom}(R) \to \Sigma^*$ with $(u, f_R(u)) \in R$ for all $u \in \mathrm{dom}(R)$. If such a function is given as a relation R_f, we write $R_f \subseteq_{\mathtt{u}} R$ to indicate that R_f is a uniformization of R.

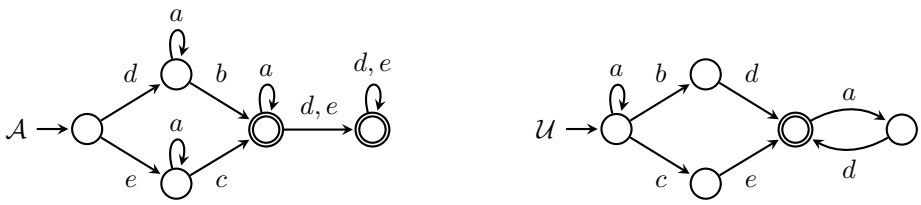

Figure 1 Cf. Ex.6; $S = L(\mathcal{A})$ and $U = L(\mathcal{U})$, we have $[\![U]\!] \subseteq_{\mathtt{u}} [\![S]\!]$.

▶ **Definition 5** (Resynchronized uniformization problem)**.** The *resynchronized uniformization problem* asks, given a regular source language $S \subseteq \Sigma^*_{\mathtt{i}\mathtt{o}}$ and a regular target language $T \subseteq \Sigma^*_{\mathtt{i}\mathtt{o}}$, whether there exists a regular language $U \subseteq T$ recognized by a sequential DFA such that $[\![U]\!] \subseteq_{\mathtt{u}} [\![S]\!]$.

▶ **Example 6.** Let $\Sigma_{\mathtt{i}} = \{a, b, c\}$ and $\Sigma_{\mathtt{o}} = \{d, e\}$, let $S \subseteq \Sigma^*_{\mathtt{i}\mathtt{o}}$ be given by $\mathcal{A}$ depicted in Fig. 1. The recognized relation is $[\![S]\!] = \{(a^i b a^j, d(d+e)^k) \mid i, j, k \geq 0\} \cup \{(a^i c a^j, e(d+e)^k) \mid i, j, k \geq 0\}$. Furthermore, let $T = \Sigma^*_{\mathtt{i}}(\Sigma_{\mathtt{i}}\Sigma_{\mathtt{o}})^+$. A T-controlled uniformization U is given by the sequential DFA $\mathcal{U}$ depicted in Fig. 1. The recognized relation is $[\![U]\!] = \{(a^i b a^j, dd^j) \mid i, j, k \geq 0\} \cup \{(a^i c a^j, ed^j) \mid i, j \geq 0\}$.

Comparing our definition of sequential DFAs with standard transducer models we notice that sequential transducers directly correspond to sequential DFAs. See, e.g., [1] for an introduction to transducers. Our model can be modified to correspond to subsequential transducers (which can make a final output after the word has ended) by slightly modifying the representation of the relation by adding a dedicated endmarker in the usual way.

In the remainder it is implicitly assumed that every given source and target language is represented with endmarkers, thus our stated results correspond to uniformization by subsequential transducers.

Our main result is the decidability of the resynchronized uniformization problem for a given automatic relation and a given set of synchronizations controlled by a language that synchronizes automatic relations. In Sec. 4 we see that our decidability result is obtained by a reduction to the following simpler uniformization problem.

▶ **Definition 7** (Subset uniformization problem)**.** The *subset uniformization problem* asks, given a regular language $S \subseteq \Sigma^*_{\mathtt{i}\mathtt{o}}$, whether there exists a regular language $U \subseteq S$ recognized by a sequential DFA such that $[\![U]\!] \subseteq_{\mathtt{u}} [\![S]\!]$.

The notion of subset uniformization directly corresponds to the notion of sequential $\mathbb{I}$-uniformization introduced in [7]. It was shown that deciding the sequential $\mathbb{I}$-uniformization problem reduces to deciding which player has a winning strategy in a safety game between In and Out. Hence, we directly obtain the following result.

▶ **Theorem 8** ([7])**.** *The subset uniformization problem is decidable.*

Now that we have formulated our uniformization problems, we link these to known uniformization problems. Asking whether a relation has a $\Sigma^*_{\mathtt{i}\mathtt{o}}$-controlled subsequential uniformization is equivalent to asking whether it has a uniformization by an arbitrary subsequential transducer. Asking whether a relation has a $(\Sigma_{\mathtt{i}}\Sigma_{\mathtt{o}})^*(\Sigma^*_{\mathtt{i}} + \Sigma^*_{\mathtt{o}})$- resp. $\Sigma^*_{\mathtt{i}}\Sigma^*_{\mathtt{o}}$-controlled subsequential uniformization is equivalent to asking whether it has a uniformization by a synchronous subsequential transducer resp. by a transducer that reads the complete input before producing output.

Table 1 Overview over decidability results. The columns list the type of relation to be uniformized. The rows list the type of synchronization used as uniformization parameter; the upper three rows list fixed languages of synchronizations, the lower three rows list parameter classes, where 'rational' means the given set of allowed synchronizations is controlled by an arbitrary synchronization language, 'automatic' (resp. 'recognizable') means the given set of allowed synchronizations is controlled by a synchronization language that synchronizes automatic (resp. recognizable) relations.

sync. \ relation	rational	deterministic rational	finite-valued	automatic	recognizable
$\Sigma^*_{\mathtt{i}\circledcirc}$	undec. [3]	dec. [7]	dec. [7]	dec. [3]	dec.
$(\Sigma_{\mathtt{i}}\Sigma_{\circledcirc})^*(\Sigma^*_{\mathtt{i}} + \Sigma^*_{\circledcirc})$	undec. [3]	?	?	dec. [2]	dec.
$\Sigma^*_{\mathtt{i}}\Sigma^*_{\circledcirc}$	?	?	?	dec. [3]	dec.
rational	undec.	?	?	?	dec.
automatic	undec.	?	?	**dec.**	dec.
recognizable	?	?	?	dec.	dec.

Table 1 provides an overview over known and new decidability results of the resynchronized uniformization problem for different types of relations and synchronization parameters. Our main result is the decidability for a given automatic relation and a given set of allowed synchronizations that is controlled by a synchronization language that synchronizes automatic relations. The decidability results in the rightmost column can be shown by a simple reduction to the subset uniformization problem which is presented in the full version of the paper. The other entries in the lower three rows are simple consequences of the results presented in the upper three rows resp. our main result.

Regarding the table entry where the relation is automatic and a desired uniformizer is $(\Sigma_{\mathtt{i}}\Sigma_{\circledcirc})^*(\Sigma^*_{\mathtt{i}} + \Sigma^*_{\circledcirc})$-controlled, there is an alternative formulation of the decision problem in the case that the given relation is $(\Sigma_{\mathtt{i}}\Sigma_{\circledcirc})^*(\Sigma^*_{\mathtt{i}} + \Sigma^*_{\circledcirc})$-controlled (the usual presentation for automatic relations, e.g., by a synchronous transducer). In this case the problem can also be stated as the question whether the relation has a subset uniformization.

We now generalize this to Parikh-injective synchronization languages. Given some $L \subseteq \mathbf{2}^*$, let $\Pi_L : L \to \mathbb{N}^2$ be the function that maps a word $w \in L$ to its *Parikh image*, that is to the vector $(\#_1(w), \#_2(w))$. We say L is *Parikh-injective* if Π_L is injective.

▶ **Proposition 9.** Let $L \subseteq \mathbf{2}^*$ be a regular Parikh-injective language, let $S \subseteq \Sigma^*_{\mathtt{i}\circledcirc}$ be an L-controlled regular language and let $T = \{w \in \Sigma^* \mid w \text{ is } L\text{-controlled}\}$. Every T-controlled uniformization of S is a subset uniformization of S.

Given L, S and T as in Proposition 9, it directly follows that the resynchronized uniformization problem is equivalent to the subset uniformization problem, which is decidable by Theorem 8.

4 Automatic uniformizations of automatic relations

Here we present our main result stating that it is decidable whether a given automatic relation has a uniformization by a subsequential transducer whose induced set of synchronizations is controlled by a given regular language that synchronizes automatic relations.

▶ **Theorem 10.** *Given a regular source language with finite shiftlag and a regular target language with finite shiftlag. Then, the resynchronized uniformization problem is decidable.*

In [6], it is shown that $(12)^*(1^* + 2^*)$ is an effective canonical representative of the class RL_{FSL} of regular languages with finite *shiftlag*. Meaning that for every $L \in \mathsf{RL}_{FSL}$ and every $R \in \textsc{Rel}(L)$, there is an effectively constructible $(12)^*(1^* + 2^*)$-controlled regular language S so that $[\![S]\!] = R$.

In the remainder of this section, let $S \subseteq \Sigma^*_{\mathtt{io}}$ be a regular source language with finite *shiftlag*. Also, let S_{can} be the equivalent $(12)^*(1^*+2^*)$-controlled language with $[\![S_{can}]\!] = [\![S]\!]$. Furthermore, let $T \subseteq \Sigma^*_{\mathtt{io}}$ be a regular target language with finite *shiftlag*.

▶ **Assumption 11.** We assume that S_{can} is recognized by a DFA $\mathcal{A} = (Q_\mathcal{A}, \Sigma_{\mathtt{io}}, q_0^\mathcal{A}, \Delta_\mathcal{A}, F_\mathcal{A})$, T is recognized by a DFA $\mathcal{B} = (Q_\mathcal{B}, \Sigma_{\mathtt{io}}, q_0^\mathcal{B}, \Delta_\mathcal{B}, F_\mathcal{B})$ and $\mathit{shiftlag}(T) < n$.

For notational convenience, given $x \in \Sigma^*_{\mathtt{i}}$ and $y \in \Sigma^*_{\mathtt{o}}$, we write $\delta^*_\mathcal{A}(q, (x, y))$ to mean $\delta^*_\mathcal{A}(q, w)$, where $w \in \Sigma_{\mathtt{io}}$ is the canonical synchronization of x and y, i.e., w is the $(12)^*(1^*+2^*)$-controlled synchronization of the pair (x, y).

The remainder of this section is devoted to the proof of Theorem 10. The proof is split in two main parts; the goal of the first part is to show that if S has a T-controlled uniformization by an sDFA, then S has a T_k-controlled uniformization by an sDFA for a regular $T_k \subseteq T$ that is less complex than T, cf. Lemma 23. The goal of the second part is to show that the set $T_k(S)$ defined by $\{w \mid w \in T_k \text{ and } [\![w]\!] \in [\![S]\!]\}$ is regular and computable (due to the form of T_k), cf. Lemma 24. Then, to conclude the proof, we show that the question whether S has a T-controlled uniformization by an sDFA can be reduced to the question whether $T_k(S)$ has a subset uniformization by an sDFA, which is decidable by Theorem 8.

Towards giving an exact description of T_k, consider the following auxiliary lemma characterizing the form of regular synchronization languages with finite *shiftlag*. Given $\nu \in \mathbb{N}$, we denote by $L_{\leq\nu}$ the regular set of words over $\mathbf{2}$ with $\leq\nu$-lagged positions, i.e., $L_{\leq\nu} = \{u \in \mathbf{2}^* \mid \mathit{lag}(u) \leq \nu\}$; we denote by $T_{\leq\nu}$ the regular set of words over $\Sigma_{\mathtt{io}}$ with $\leq\nu$-lagged positions, i.e., $T_{\leq\nu} = \{w \in \Sigma^*_{\mathtt{io}} \mid \mathit{lag}(w) \leq \nu\}$.

▶ **Lemma 12** ([6]). *Given a regular language $L \subseteq \mathbf{2}^*$ with $\mathit{shiftlag}(L) < m$. It holds that $L \subseteq L_{\leq\nu} \cdot (1^* + 2^*)^m$ with ν chosen as $2\,(m(|Q| + 1) + 1)$, where Q is the state set of an NFA recognizing L.*

Clearly, this lemma can be lifted to regular languages over $\Sigma_{\mathtt{io}}$. Based on Asm. 11 and Lemma 12, we can make the following assumption.

▶ **Assumption 13.** Assume that $T \subseteq T_{\leq\gamma} \cdot (\Sigma^*_{\mathtt{i}} + \Sigma^*_{\mathtt{o}})^n$ with $\gamma = 2\,(n(|Q_\mathcal{B}| + 1) + 1)$.

Now, we can be more specific about $T_k \subseteq T$.

▶ **Definition 14.** For $i \geq 0$, let T_i be the set $T \cap \left(T_{\leq\gamma} \cdot (\Sigma^*_{\mathtt{i}} + \Sigma^{\leq i}_{\mathtt{o}})^n\right)$, that is, the set of $w \in T$ such that after a position in w is more than γ-lagged, the number of output symbols per block is at most i.

Our aim is to show that there is a bound k such that S has either a T_k-controlled uniformization by an sDFA or no T-controlled uniformization by an sDFA. From now on, we call an sDFA implementing a uniformization simply a uniformizer.

The main difficulty in solving the resynchronized uniformization problem is that in general a uniformizer can have unbounded lag, because the waiting time between shifts can be arbitrarily long. The key insight for the proof is that if such a long waiting time for a shift from input to output is necessary, then, in order to determine the next output block, it is not necessary to store the complete input that is ahead. We show that it suffices to consider an abstraction of the input that is ahead. Therefore we will introduce input profiles based on state transformation trees we define below.

Similarly, to deal with the situation where there is a long waiting time for a shift from output to input, we introduce output profiles as an abstraction of output that is ahead.

The bound on the length of output blocks will be chosen based on the profiles. Before defining profiles, we introduce some necessary definitions and notions.

Trees. A *finite unordered unranked tree* over an alphabet, a tree for short, is a finite non-empty directed graph with a distinguished root node, such that for any node, there exists exactly one path from the root to this node. Additionally, a mapping from the nodes of the graph to the alphabet is given. More formally, a *tree* t over Σ is given by a tuple (V_t, E_t, v_t, val_t), where V_t is a non-empty set of nodes, $E_t \subseteq V_t \times V_t$ is a set of edges, v_t is the root of t, also denoted $root(t)$, and val_t is a mapping $V_t \to \Sigma$. Furthermore, it is satisfied that any node is reached by a unique path from the root. Let T_Σ denote the set of all trees over Σ. We only distinguish trees up to isomorphism.

Given a tree t and a node v of t, let $t|_v$ denote the *subtree* of t rooted at v.

An $a \in \Sigma$ can also be seen as a tree $a \in T_\Sigma$ defined by $(\{v\}, \emptyset, v, val_a)$, where $val_a(v) = a$.

For two trees t_1 and t_2 with $val_{t_1}(root(t_1)) = val_{t_2}(root(t_2))$, i.e., with the same root label, we define $t_1 \circ t_2$ as the tree t given by $(V_t, E_t, root(t_1), val_t)$, where $V_t = V_{t_1} \cup V_{t_2} \setminus \{root(t_2)\}$, $E_t = E_{t_1} \cup \{(root(t), v) \mid (root(t_2), v) \in E_{t_2}\} \cup (E_{t_2} \setminus \{(root(t_2), v) \in E_{t_2}\})$ and val_t as $val_{t_1} \cup val_{t_2}$ over nodes in V_t (assuming $V_{t_1} \cap V_{t_2} = \emptyset$).

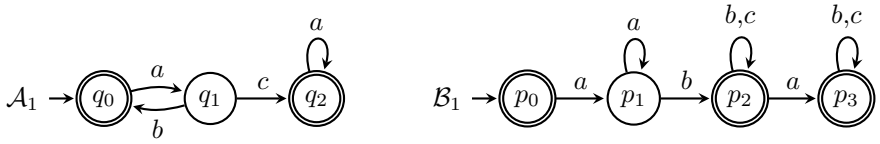
Given $a \in \Sigma$ and trees $t_1, \ldots, t_n$, we define $a(t_1 \ldots t_n)$ to be the tree (V_t, E_t, r, val_t), where $V_t = \bigcup_{i=1}^n V_{t_i} \cup \{r\}$ with a new node r, $E_t = \bigcup_{i=1}^n E_{t_i} \cup \{(r, root(t_i)) \mid 1 \leq i \leq n\}$ and val_t is defined as $val_t(r) = a$ and $\bigcup_{i=1}^n val_{t_i}$ (assuming $V_{t_i} \cap V_{t_j} = \emptyset$ for all $i \neq j$).

State transformation trees. Now that we have fixed our notations, we explain what kind of information we want to represent using state transformation trees. Basically, for an input segment that is ahead and causes lag, we are interested in how the input segment can be combined with output segments of same or smaller length and how this output can be obtained.

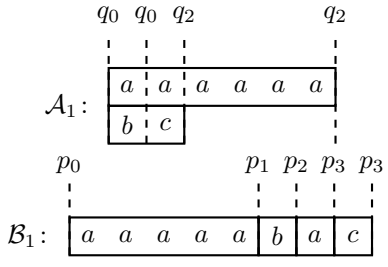
In the following we give an intuitive example.

▶ **Example 15.** Let $\Sigma_{\mathtt{i}} = \{a\}$ and $\Sigma_{\mathtt{o}} = \{b, c\}$. Consider the language $S_1 \subseteq \Sigma_{\mathtt{io}}^*$ given by the DFA $\mathcal{A}_1$ depicted in Fig. 2a, and the language $T_1 \subseteq \Sigma_{\mathtt{io}}^*$ given by the DFA $\mathcal{B}_1$ depicted in Fig. 2a. As we can see, S_1 is $(12)^*(1^* + 2^*)$-controlled, thus, already in its canonical form, and T_1 is $1^*2^*1^*2^*$-controlled. Both languages have finite *shiftlag*.

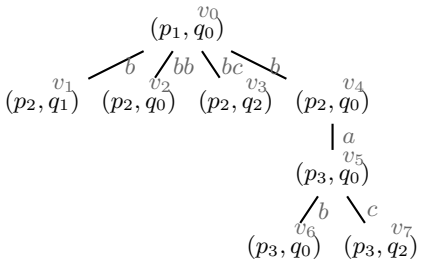
Generally, a T_1-controlled uniformizer of S_1 can have arbitrary large lag. We take a look at the runs starting from q_0 in $\mathcal{A}_1$ and starting from p_0 in $\mathcal{B}_1$ that the computation of such a uniformizer can induce. However, $\mathcal{A}_1$ can only be simulated on the part where the lag is recovered, but arbitrarily large lag can occur, thus our goal is to find an abstraction of the part that causes lag. E.g., assume that such a uniformizer reads aa without producing output. Towards defining an abstraction of aa, we are interested in how aa could be combined with outputs of same or smaller length and how these outputs could be produced by some T_1-controlled uniformizer. Such a uniformizer could read some more as and eventually must produce output. Reading as leads from p_0 to p_1 in $\mathcal{B}_1$. There are a few possibilities how output of length at most two can be produced such that it is valid from p_1 and the simulation from q_0 can be continued. It is possible to output b ($\delta^*_{\mathcal{B}_1}(p_1, b) = p_2$, $\delta^*_{\mathcal{A}_1}(q_0, aba) = q_1$), bb ($\delta^*_{\mathcal{B}_1}(p_1, bb) = p_2$, $\delta^*_{\mathcal{A}_1}(q_0, abab) = q_0$) or bc ($\delta^*_{\mathcal{B}_1}(p_1, bc) = p_2$, $\delta^*_{\mathcal{A}_1}(q_0, abac) = q_2$). Alternatively, it is possible to output b ($\delta^*_{\mathcal{B}_1}(p_1, b) = p_2$, $\delta^*_{\mathcal{A}_1}(q_0, ab) = q_0$) read another a ($\delta^*_{\mathcal{B}_1}(p_2, a) = p_3$) and then produce b ($\delta^*_{\mathcal{B}_1}(p_3, b) = p_3$, $\delta^*_{\mathcal{A}_1}(q_0, ab) = q_0$) or c ($\delta^*_{\mathcal{B}_1}(p_3, c) = p_3$, $\delta^*_{\mathcal{A}_1}(q_0, ac) = q_2$). We see that the outputs bb and bc can each be obtained in two different ways. Namely, as one single output block, or as two output blocks with an input block in



(a) $\Sigma_{\mathtt{i}} = \{a\}$, $\Sigma_{\mathtt{o}} = \{b, c\}$. $\mathcal{A}_1$ recognizes S_1, $\mathcal{B}_1$ recognizes T_1. S_1 is $(12)^*(1^* + 2^*)$-controlled and T_1 is $1^*2^*1^*2^*$-controlled, thus both have finite *shiftlag*. S_1 is already in the canonical form.



(b) Runs of $\mathcal{A}_1$ and $\mathcal{B}_1$ on synchronizations of $(aaaaaa, bc)$. $\mathcal{A}_1$ runs on the canonical synchronization, i.e., on *abacaaaa*. To illustrate this, input and output are drawn one above the other.



(c) $\mathrm{STT}^1(aa, p_1, q_0)$. The combination of both runs shown in Fig. 2b is reflected by the rightmost path in the state transformation tree.

Figure 2 A source language S_1 and a target language T_1 are given in Fig. 2a. A pair and two different synchronizations of said pair as well as runs are given in Fig. 2b. The state transformation tree $\mathrm{STT}^1(aa, p_1, q_0)$ is given in Fig. 2c, its edges are labeled with the respective associated words and its vertices are named for easier reference in Ex. 15. For a formal definition of STTs see Def. 16, for an explanation for this specific tree see Ex. 15.

between (w.r.t. $\mathcal{B}_1$, we do not care about the number of blocks w.r.t. $\mathcal{A}_1$). The maximal number of considered output blocks (w.r.t. the target synchronization) is parameterized in the formal definition.

We take a look at the tree in Fig. 2c, this tree contains all the state transformations that can be induced by the described possibilities. The possibilities to produce output in one single block is reflected by the edges (v_0, v_1), (v_0, v_2) and (v_0, v_3) representing the state transformation induced by the respective output block. The possibilities to produce output in two blocks is reflected by the edges (v_0, v_4) representing the state transformation induced by the first output block, (v_4, v_5) representing the state transformation induced by the intermediate input block, (v_5, v_6) and (v_5, v_7) representing the state transformation induced by the respective second output block.

Now that we have given some intuition, we formally introduce input state transformation trees, a graphical representation of the construction of input state transformation trees is given in Fig. 3. As seen in the example, each edge of such a tree represents the state transformation induced by an output resp. input block, alternatively.

▶ **Definition 16** (Input state transformation tree). For $i \geq 0$, $p \in Q_{\mathcal{B}}$, $q \in Q_{\mathcal{A}}$ and $x \in \Sigma_{\mathtt{i}}^*$, the *state transformation tree* $\mathrm{STT}^i(x, p, q)$ is a tree over $Q_{\mathcal{B}} \times Q_{\mathcal{A}}$ defined inductively.

- For $i = 0$, the tree $\mathrm{STT}^0(x, p, q)$ is built up as follows.
  Let $\mathrm{Reach}_0 \subseteq Q_{\mathcal{B}} \times Q_{\mathcal{A}}$ be the smallest set such that $(p', q') \in \mathrm{Reach}_0$ if there is some $y \in \Sigma_{\mathtt{o}}^*$ with $|y| \leq |x|$ such that $\delta_{\mathcal{A}}^*(q, (x, y)) = q'$ and $\delta_{\mathcal{B}}^*(p, y) = p'$.
  (This set represents state transformations induced by output blocks that fully consume x.)
  Then the tree $\mathrm{STT}^0(x, p, q)$ is defined as $(p, q)(r_1 \dots r_n)$ for $\mathrm{Reach}_0 = \{r_1, \dots, r_n\}$, meaning it contains a child for every state transformation that can be induced w.r.t. $\mathcal{A}$ and $\mathcal{B}$ starting from q and p, respectively, by the input segment x together with an output segment that consumes x (w.r.t. $\mathcal{A}$) consisting of a single output block (w.r.t. $\mathcal{B}$).

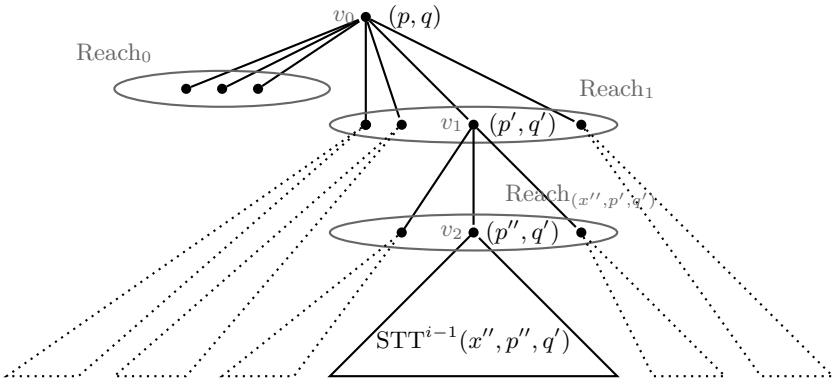


Figure 3 Schema of the input state transformation tree $\text{STT}^i(x, p, q)$ for some $i > 0$. Cf. Def. 16. Let $x'x''$ be a factorization of x with $x', x'' \in \Sigma_{\mathtt{i}}^+$, and let $y \in \Sigma_{\mathtt{o}}^+$ be such that $|x'| = |y|$ and $\delta_{\mathcal{A}}^*(q, (x', y)) = q'$ and $\delta_{\mathcal{B}}^*(p, y) = p'$, and let $\delta_{\mathcal{B}}^*(p', w) = p''$ for some $w \in \Sigma_{\mathtt{i}}^+$, then $\text{STT}^i(x, p, q)$ contains a path $v_0v_1v_2$ labeled $(p, q)(p', q')(p'', q')$ such that v_0 is the root, v_1 is the root of $t^{i-1}_{(x'',p',q')}$, and v_2 is the root of $\text{STT}^{i-1}(x'', p'', q')$.

- For $i > 0$, the tree $\text{STT}^i(x, p, q)$ is built up as follows.
  Let $\text{Reach}_1 \subseteq \Sigma_{\mathtt{i}}^* \times Q_{\mathcal{B}} \times Q_{\mathcal{A}}$ be the smallest set such that $(x'', p', q') \in \text{Reach}_1$ if
  - $x = x'x''$ with $x'' \in \Sigma_{\mathtt{i}}^+$ for an $x' \in \Sigma_{\mathtt{i}}^+$ such that there is a $y \in \Sigma_{\mathtt{o}}^+$ with $|y| = |x'|$, and
  - $\delta_{\mathcal{A}}^*(q, (x', y)) = q'$ and $\delta_{\mathcal{B}}^*(p, y) = p'$.

  (This set represents state transformations induced by output blocks that partially consume x.)
  For $(x'', p', q') \in \text{Reach}_1$, let $\text{Reach}_{(x'',p',q')} \subseteq \Sigma_{\mathtt{i}}^* \times Q_{\mathcal{B}} \times Q_{\mathcal{A}}$ be the smallest set such that $(x'', p'', q') \in \text{Reach}_{(x'',p',q')}$ if $\delta_{\mathcal{B}}^*(p', w) = p''$ for some $w \in \Sigma_{\mathtt{i}}^+$.
  (These sets represents state transformations induced by intermediate input blocks.)
  Furthermore, let the tree $t^{i-1}_{(x'',p',q')}$ be defined as $(p', q')(\text{STT}^{i-1}r_1 \dots \text{STT}^{i-1}r_n)$ for $\text{Reach}_{(x'',p',q')} = \{r_1, \dots, r_n\}$.
  Then the tree $\text{STT}^i(x, p, q)$ is defined as

  $$\text{STT}^0(x, p, q) \circ (p, q)(t^{i-1}_{s_1} \dots t^{i-1}_{s_n})$$

  for $\text{Reach}_1 = \{s_1, \dots, s_n\}$, meaning it contains a path for every sequence of state transformations that can be induced w.r.t. $\mathcal{A}$ and $\mathcal{B}$ starting from q and p, respectively, by the input segment x together with an output segment that consumes x (w.r.t. $\mathcal{A}$) consisting of at most $i + 1$ output blocks (w.r.t. $\mathcal{B}$). Additionally, for output segments that have a common prefix of output blocks the state transformations induced by the common prefix of blocks are represented by the same nodes in the tree.

Intuitively, edges in such a tree are associated with the words that induced the state transformation, e.g., as shown in Fig 2c.

Given a tree as in Def. 16, the maximal degree of such a tree depends on the input word used as parameter. Our goal is to have state transformation trees where the maximum degree is independent of this parameter. Therefore, we introduce *reduced trees*. The idea is that if for some input word different outputs induce the same state transformations then only one representation is kept in the input state transformation tree.

▶ **Definition 17** (Reduced tree). A tree $t \in T_\Sigma$ over some alphabet Σ is called *reduced* if for each node v there exist no two children u, u' of v such that the subtrees rooted at u and u' are isomorphic.

For a tree $t \in T_\Sigma$, let $red(t) \in T_\Sigma$ denote its reduced variant. The reduced variant of a tree can easily be obtained by a bottom-up computation where for each node duplicate subtrees rooted at its children are removed.

Note that for each i, the set of reduced input state transformation trees with parameter i is a finite set.

Hitherto, we have discussed how to capture state transformations induced by an input word together with output words of same or smaller length. Additionally, we need to capture state transformations induced by an output word together with input words of same or smaller length. Therefore, we introduce a notion similar to input state transformation trees, namely, *output state transformation trees*. A formal definition can be found in the full version.

Furthermore, we need a notion that captures state transformations that can be induced by an input resp. output word alone, see Def. 18 below. Then, we are ready to define profiles.

▶ **Definition 18** (State transformation function)**.** For each $w \in \Sigma_{\mathtt{i}}^* \cup \Sigma_{\mathtt{o}}^*$, we define the function $\tau_w \colon Q_{\mathcal{B}} \to Q_{\mathcal{B}}$ with $\tau_w(p) = q$ if $\delta_{\mathcal{B}}^*(p, w) = q$ called *state transformation function w.r.t. w*.

Profiles. Recall, $T \subseteq T_{\leq\gamma} \cdot (\Sigma_{\mathtt{i}}^* + \Sigma_{\mathtt{o}}^*)^n$, and our goal is to show that there is a bound k such that it suffices to focus on constructing T_k-controlled uniformizers instead of T-controlled uniformizers, meaning that we can focus on uniformizers in which the length of output blocks is bounded by k after the lag has exceeded γ at some point.

The core of the proof is to show that if the lag between input and output becomes very large ($\gg \gamma$), it is not necessary to consider the complete input that is ahead to determine the next output block, but an abstraction (in the form of profiles) suffices. Note that if the lag has exceeded γ at some point the number of remaining output blocks is at most $\lceil n/2 \rceil$.

As a result, given an input word $x \in \Sigma_{\mathtt{i}}^*$, we are interested in the state transformation that is induced by $(x, \pi_{\mathtt{o}}(w))$ in $\mathcal{A}$ (recognizing S_{can}) and by w in $\mathcal{B}$ (recognizing T) for each word $w \in \Sigma_{\mathtt{io}}^*$ such that $|\pi_{\mathtt{o}}(w)| \leq |x|$ and $shift(w) \leq \lceil n/2 \rceil$. In words, we are interested in the state transformations that can be induced by x together with outputs of same or smaller length that are composed of at most $\lceil n/2 \rceil$ different output blocks.

For $x \in \Sigma_{\mathtt{i}}^*$, this kind of information is accurately represented by the set of all reduced input state transformation trees with parameters x and $\lceil n/2 \rceil$.

The same considerations with switched input and output roles apply for an output word $y \in \Sigma_{\mathtt{o}}^*$.

▶ **Definition 19** (Input profile)**.** For $x \in \Sigma_{\mathtt{i}}^*$, we define its *profile* P_x as $(\tau_x, \mathrm{STT}_x^{\lceil n/2 \rceil})$, where

$$\mathrm{STT}_x^{\lceil n/2 \rceil} = \bigcup_{(p,q) \in Q_{\mathcal{B}} \times Q_{\mathcal{A}}} \{ red\big(\mathrm{STT}^{\lceil n/2 \rceil}(x, p, q)\big) \}.$$

Similarly, we define *output profiles*, a formal definition can be found in the full version.

A note on the number of different profiles. Profiles are based on reduced STTs with parameter $\lceil n/2 \rceil$, where n bounds $shiftlag(T)$. The size of the set of these STTs is non-elementary in n, hence also the number of profiles. This implies a non-elementary complexity of our decision procedure.

Furthermore, let $\mathcal{P}_{\mathtt{i}}$ be the set $\bigcup_{x \in \Sigma_{\mathtt{i}}^*} \{P_x\}$ of all input profiles and $\mathcal{P}_{\mathtt{o}}$ be the set $\bigcup_{y \in \Sigma_{\mathtt{o}}^*} \{P_y\}$ of all output profiles. For a $P \in \mathcal{P}_{\mathtt{i}} \cup \mathcal{P}_{\mathtt{o}}$, let z be a *representative* of P if z is a shortest word such that $P = P_z$.

We show that from the profiles of two words x_1 and x_2 one can compute the profile of the word $x_1 x_2$. Hence, the set of profiles can be equipped with a concatenation operation, i.e., for words x_1 and x_2 we let $P_{x_1} P_{x_2} = P_{x_1 x_2}$. We obtain the following.

▶ **Lemma 20.** *The set of input profiles is a monoid with concatenation; the set of output profiles is a monoid with concatenation.*

A word $x \in \Sigma_{\mathtt{i}}^*$ and its profile P_x are called *idempotent* if $P_x = P_{xx}$. As a consequence of Ramsey's Theorem (see e.g., [5]) we obtain the following lemma.

▶ **Lemma 21** (Consequence of Ramsey)**.** *There is a computable $r \in \mathbb{N}$ such that each word $x \in \Sigma_{\mathtt{i}}^*$ with $|x| \geq r$ contains a non-empty idempotent factor for the concatenation of profiles.*

Now, we have the right tools to prove that the existence of a T-controlled uniformizer implies that there also exists a T_k-controlled uniformizer for a computable k. For the remainder, we fix two bounds.

▶ **Assumption 22.** Assume r_1 is chosen as in Lemma 21 and r_2 is chosen as the smallest bound on the length of representatives of output profiles. Wlog, assume $r_1, r_2 > \gamma$.

Finally, we are ready to prove the key lemma, that is, Lemma 23, which shows that it is sufficient to consider uniformizers in which the length of output blocks is bounded.

Recall, a uniformizer works asynchronously, which leads to large lag. First, we show that if the output is lagged more than r_1 symbols, meaning, the input that is ahead contains an idempotent factor, it suffices to consider output blocks whose length depends on the idempotent factor. Secondly, we show that it suffices to consider uniformizers in which the output is ahead at most r_2 symbols. The combination of both results yields Lemma 23.

Recall, by Asm. 13, $T \subseteq T_{\leq\gamma} \cdot (\Sigma_{\mathtt{i}}^* + \Sigma_{\mathtt{o}}^*)^n$ and by Def. 14, $T_i = T \cap \left(T_{\leq\gamma} \cdot (\Sigma_{\mathtt{i}}^* + \Sigma_{\mathtt{o}}^{\leq i})^n\right)$ for $i \geq 0$.

▶ **Lemma 23.** *If S has a T-controlled uniformizer, then S has a T_k-controlled uniformizer for a computable $k \geq 0$.*

The proof of the above lemma yields that k can be chosen as $r_1 + r_2$. This concludes the first part of the proof of Theorem 10. For the second part, we prove that the problem whether S has a T_i-controlled uniformizer for an i reduces to the question whether $T_i(S)$ has a subset uniformizer for a suitable $T_i(S)$ as defined below in Lemma 24.

Reduction. The next lemma shows that from S a regular $T_i(S)$ can be obtained such that $T_i(S)$ consists of all T_i-controlled synchronizations w with $[\![w]\!] \in [\![S]\!]$.

▶ **Lemma 24.** *For $i \geq 0$, the language $T_i(S) = \{w \in \Sigma_{\mathtt{io}}^* \mid w \in T_i \text{ and } [\![w]\!] \in [\![S]\!]\}$ is a T_i-controlled effectively constructible regular language.*

We are ready to prove the main theorem of this paper.

Proof sketch of Theorem 10. By Lemma 23 we know that if S has a T-controlled uniformizer, then S has a T_k-controlled uniformizer for a computable $k \geq 0$. Let $T_k(S)$ be defined as in Lemma 24.

We can show that S has a T-controlled uniformizer iff $\mathrm{dom}([\![S]\!]) = \mathrm{dom}([\![T_k(S)]\!])$ and $T_k(S)$ has a subset uniformizer which is decidable by Theorem 8. ◀

5 Conclusion

In this paper we considered uniformization by subsequential transducers in which the allowed input/output behavior is specified by a regular set of synchronizations, the so-called resynchronized uniformization problem. An overview over our results can be found in Table 1.

For future work we want to study other problems of this kind, e.g., study whether the resynchronized uniformization problem is decidable for a given rational relation as source language and a given 'recognizable' target language in the sense that the target language is controlled by a synchronization language that synchronizes recognizable relations.

Abstract

Changing a given configuration in a graph into another one is known as a reconfiguration problem. Such problems have recently received much interest in the context of algorithmic graph theory. We initiate the theoretical study of the following reconfiguration problem: How to reroute k unsplittable flows of a certain demand in a capacitated network from their current paths to their respective new paths, in a congestion-free manner? This problem finds immediate applications, e.g., in traffic engineering in computer networks. We show that the problem is generally NP-hard already for $k = 2$ flows, which motivates us to study rerouting on a most basic class of flow graphs, namely DAGs. Interestingly, we find that for general k, deciding whether an unsplittable multi-commodity flow rerouting schedule exists, is NP-hard even on DAGs. Our main contribution is a polynomial-time (fixed parameter tractable) algorithm to solve the route update problem for a bounded number of flows on DAGs. At the heart of our algorithm lies a novel decomposition of the flow network that allows us to express and resolve reconfiguration dependencies among flows.

1 Introduction

Reconfiguration problems are combinatorial problems which ask for a transformation of one configuration into another one, subject to some (reconfiguration) rules. Reconfiguration problems are fundamental and have been studied in many contexts, including puzzles and games (such as Rubik's cube) [24], satisfiability [15], independent sets [16], vertex coloring [9], or matroid bases [17], to just name a few.

initial network invalid update: no transient flow (loop!)

Figure 1 *Example:* We are given an initial network consisting of exactly one active flow F^o (solid edges) and the inactive edges (i.e., inactive forwarding rules) of the new flow F^u to which we want to reroute (dashed edges). Together we call the two flows an (update) pair $P = (F^o, F^u)$. Updating the outgoing edges of a vertex means activating all previously inactive outgoing edges of F^u, and deactivating all other edges of the old flow F^o. Initially, the blue flow is a valid (transient) (s,t)-flow. If the update of vertex v_2 takes effect first, an invalid (not transient) flow is introduced (in pink): traffic is forwarded in a loop, hence (temporarily) invalidating the path from s to t.

Reconfiguration problems also naturally arise in the context of networking applications and routing. For example, a fundamental problem in computer networking regards the question of how to reroute traffic from the current path p_1 to a given new path p_2, by changing the forwarding rules at routers (the *vertices*) one-by-one, while maintaining certain properties *during* the reconfiguration (e.g., short path lengths [7]). Route reconfigurations (or *updates*) are frequent in computer networks: paths are changed, e.g., to account for changes in the security policies, in response to new route advertisements, during maintenance (e.g., replacing a router), to support the migration of virtual machines, etc. [13].

This paper initiates the study of a basic *multi-commodity flow rerouting problem*: how to reroute a set of *unsplittable flows* (with certain bandwidth demands) in a capacitated network, from their current paths to their respective new paths *in a congestion-free manner*. The problem finds immediate applications in traffic engineering [4], whose main objective is to avoid network congestion. Interestingly, while congestion-aware routing and traffic engineering problems have been studied intensively in the past [1, 10, 11, 12, 18, 19, 20, 22], surprisingly little is known today about the problem of how to reconfigure resp. *update* the routes of flows. Only recently, due to the advent of Software-Defined Networks (SDNs), the problem has received much attention in the networking community [3, 8, 14, 21].

Figure 1 presents a simple example of the consistent rerouting problem considered in this paper, for just a *single* flow: the flow needs to be rerouted from the solid path to the dashed path, by changing the forwarding links at routers one-by-one. The example illustrates a problem that might arise from updating the vertices in an invalid order: if vertex v_2 is updated first, a forwarding loop is introduced: the transient flow from s to t becomes invalid. Thus, router updates need to be scheduled intelligently over time: A feasible sequence of updates for this example is given in Figure 2. Note that the example is kept simple intentionally: when moving from a single flow to multiple flows, additional challenges are introduced, as the flows may compete for bandwidth and hence interfere.

Contributions. This paper initiates the algorithmic study of a fundamental unsplittable multicommodity flow rerouting problem. We present a rigorous formal model and show that the problem of rerouting flows in a congestion-free manner is NP-hard already for two flows on general graphs. This motivates us to focus on a most fundamental type of flow graphs, namely the DAG. The main results presented in this paper are the following:

1. Deciding whether a consistent network update schedule exists in general graphs is NP-hard, already for 2 flows.
2. For constant k, we present a linear-time (fixed parameter tractable) algorithm which finds a feasible update schedule on DAGs in time and space $2^{O(k \log k)}O(|G|)$, whenever such a consistent update schedule exists.

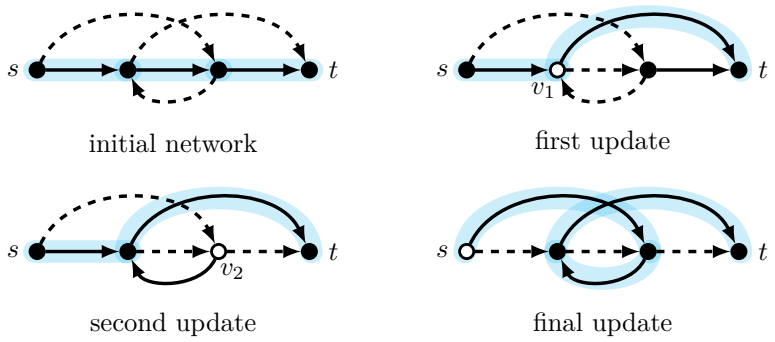

Figure 2 *Example:* We revisit the network of Figure 1 and reroute from F^o to F^u without interrupting the connection between s and t along a unique (transient) path (in blue). To avoid the problem seen in Figure 1, we first update the vertex v_1 in order to establish a shorter connection from s to t. Once this update has been performed, the update of v_2 can be performed without creating a loop. Finally, by updating s, we complete the rerouting.

3. For general k, deciding whether a feasible schedule exists is NP-hard even on loop-free networks (i.e., DAGs).

Against the backdrop that the problem of *routing* disjoint paths on DAGs is known to be $W[1]$-hard [23] and computing routes *subject to congestion* even harder [1], our finding that the multicommodity flow *rerouting* problem is fixed parameter tractable on DAGs is intriguing.

Technical Novelty. Our algorithm is based on a novel decomposition of the flow graph into so-called *blocks*. This block decomposition allows us to express dependencies between flows, and we represent dependencies between blocks by a (directed) dependency graph D. The structure of D is sophisticated, hence to analyze it, we first construct a helper graph H. In our first main technical lemma, we show that if there is an independent set I in H, then the dependency graph that corresponds to the vertices of I is a DAG (Lemma 11). So we may concentrate on a subgraph of D with a simpler structure, which we use to prove the next main technical lemma: there is a congestion-free rerouting if and only if the maximum independent set in H is large enough (Lemma 14). We are left with the challenge that finding a maximum independent set is a hard problem, even in our very restricted graph classes. We hence carefully modify H to obtain a much simpler graph of *bounded pathwidth*, without losing any critical properties. Thanks to these lemmas, the proof of the main theorem will follow.

In addition to our algorithmic contributions, we present NP-hardness proofs. These hardness proofs are based on novel and non-trivial insights into the flow rerouting problem, which might be helpful for similar problems in the future.

2 Model and Definitions

The problem can be described in terms of edge capacitated directed graphs. In what follows, we will assume basic familiarity with directed graphs and we refer the reader to [5] for more background. We denote a directed edge e with head v and tail u by $e = (u, v)$. For an undirected edge e between vertices u, v, we write $e = \{u, v\}$; u, v are called endpoints of e.

A **flow network** is a directed capacitated graph $G = (V, E, s, t, c)$, where s is the *source*, t the *terminal*, V is the set of vertices with $s, t \in V$, $E \subseteq V \times V$ is a set of ordered pairs known as edges, and $c\colon E \to \mathbb{N}$ a capacity function assigning a capacity $c(e)$ to every edge $e \in E$.

Our problem, as described above is a multi-commodity flow problem and thus may have *multiple* source-terminal pairs. To simplify the notation but without loss of generality, in what follows, we define flow networks to have exactly one source and one terminal. In fact, we can model any number of different sources and terminals by adding one super source with edges of unlimited capacity to all original sources, and one super terminal with edges of unlimited capacity leading there from all original terminals.

An (s,t)-*flow* F of capacity $d \in \mathbb{N}$ is a *directed path* from s to t in a flow network such that $d \leq c(e)$ for all $e \in E(F)$. Given a family $\mathcal{F}$ of (s,t)-flows $F_1, \ldots, F_k$ with demands $d_1, \ldots, d_k$ respectively, we call $\mathcal{F}$ a **valid flow set**, or simply **valid**, if $c(e) \geq \sum_{i\colon e \in E(F_i)} d_i$.

Recall that we consider the problem of how to reroute a current (old) flow to a new (update) flow, and hence we will consider such flows in "update pairs": An **update flow pair** $P = (F^o, F^u)$ consists of two (s,t)-flows F^o, the *old flow*, and F^u, the *update flow*, each of demand d. A graph $G = (V, E, \mathcal{P}, s, t, c)$, where (V, E, s, t, c) is a flow network, and $\mathcal{P} = \{P_1, \ldots, P_k\}$ with $P_i = (F_i^o, F_i^u)$, a family of update flow pairs of demand d_i, $V = \bigcup_{i\in[k]} V(F_i^o \cup F_i^u)$ and $E = \bigcup_{i\in[k]} E(F_i^o \cup F_i^u)$, is called **update flow network** if the two families $\mathcal{P}^o = \{F_1^o, \ldots, F_k^o\}$ and $\mathcal{P}^u = \{F_1^u, \ldots, F_k^u\}$ are valid. For an illustration, recall the initial network in Figure 2: The old flow is presented as the directed path made of solid edges and the new one is represented by the dashed edges.

Given an update flow network $G = (V, E, \mathcal{P}, s, t, c)$, an **update** is a pair $\mu = (v, P) \in V \times \mathcal{P}$. An update (v, P) with $P = (F^o, F^u)$ is *resolved* by deactivating all outgoing edges of F^o incident to v and activating all of its outgoing edges of F^u. Note that at all times, there is at most one outgoing and at most one incoming edge, for any flow at a given vertex. So the deactivated edges of F^o can no longer be used by the flow pair P (but now the newly activated edges of F^u can).

For any set of updates $U \subset V \times \mathcal{P}$ and any flow pair $P = (F^o, F^u) \in \mathcal{P}$, $G(P, U)$ is the update flow network consisting exactly of the vertices $V(F^o) \cup V(F^u)$ and the edges of P that are active after resolving all updates in U.

As an illustration, after the second update in Figure 2, one of the original solid edges is still not deactivated. However, already two of the new edges have become solid (i.e., active). So in the picture of the second update, the set $U = \{(v_1, P), (v_2, P)\}$ has been resolved.

We are now able to determine, for a given set of updates, which edges we can and which edges we cannot use for our routing. In the end, we want to describe a process of reconfiguration steps, starting from the *initial state*, in which no update has been resolved, and finishing in a state where the only active edges are exactly those of the new flows, of every update flow pair.

The flow pair P is called **transient** for some set of updates $U \subseteq V \times \mathcal{P}$, if $G(P, U)$ contains a unique valid (s,t)-flow $T_{P,U}$. If there is a family $\mathcal{P} = \{P_1, \ldots P_k\}$ of update flow pairs with demands $d_1, \ldots, d_k$ respectively, we call $\mathcal{P}$ a **transient family** for a set of updates $U \subseteq V \times \mathcal{P}$, if and only if every $P \in \mathcal{P}$ is transient for U. The family of transient flows after all updates in U are resolved is denoted by $\mathcal{T}_{\mathcal{P},\mathcal{U}} = \{T_{P_1,U}, \ldots, T_{P_k,U}\}$.

We again refer to Figure 2. In each of the different states, the transient flow is depicted as the light blue line connecting s to t and covering only solid (i.e., active) edges.

An **update sequence** $(\sigma_i)_{i\in[|V\times\mathcal{P}|]}$ is an ordering of $V \times \mathcal{P}$. We denote the set of updates that is resolved after step i by $U_i = \bigcup_{j=1}^{i} \sigma_i$, for all $i \in [|V \times \mathcal{P}|]$.

▶ **Definition 1** (Consistency Rule)**.** Let σ be an update sequence. We require that for any $i \in [|V \times \mathcal{P}|]$, there is a family of transient flow pairs $\mathcal{T}_{\mathcal{P},\mathcal{U}_i}$.

To ease the notation, we will denote an update sequence $(\sigma)_{i\in[|V\times\mathcal{P}|]}$ simply by σ and for any update (u, P) we write $\sigma(u, P)$ for the the position i of (u, P) within σ. An update sequence is **valid**, if every set U_i, $i \in [|V \times \mathcal{P}|]$, obeys the consistency rule.

We note that this consistency rule models and consolidates the fundamental properties usually studied in the literature, such as congestion-freedom [8] and loop-freedom [21].

▶ **Definition 2** (k-Network Flow Update Problem)**.** Given an update flow network G with k update flow pairs, is there a feasible update sequence σ?

3 On Hardness of 2-Flow Update in General Graphs

It is easy to see that for an update flow network with a single flow pair, feasibility is always guaranteed. However, it turns out that for two flows, the problem becomes hard in general.

▶ **Theorem 3.** *Deciding whether a feasible network update schedule exists is NP-hard already for $k = 2$ flows.*

The proof, briefly sketched in the following, is by reduction from 3-SAT. Let C be any 3-SAT formula with n variables and m clauses. Denote the variables by $X_1, \ldots, X_n$ and the clauses by $C_1, \ldots, C_m$. The resulting update flow network is denoted by $G(C)$. Assume that the variables are ordered by their indices, and their appearance in each clause respects this order.

We create 2 update flow pairs, a blue one $B = (B^o, B^u)$ and a red one $R = (R^o, R^u)$, both of demand 1. The pair B contains gadgets corresponding to the variables. The order in which the edges of each of those gadgets are updated will correspond to assigning a value to the variable. The pair R on the other hand contains gadgets representing the clauses: they have edges that are "blocked" by the variable edges of B. Therefore, we will need to update B to enable the updates of R.

4 Rerouting Flows in DAGs

We now consider the flow rerouting problem when the underlying flow graph is acyclic. In particular, we identify an important substructure arising for flow-pairs in acyclic graphs, which we call *blocks*. These blocks will play a major role in both the hardness proof and the algorithm presented in this section.

Let $G = (V, E, \mathcal{P}, s, t, c)$ be an acyclic update flow network, i.e., we assume that the graph (V, E) is a DAG. Let $\prec$ be a topological order on the vertices $V = \{v_1, \ldots, v_n\}$. Let $P_i = (F_i^o, F_i^u)$ be an update flow pair of demand d and let $v_1^i, \ldots, v_{\ell_i^o}^i$ be the induced topological order on the vertices of F_i^o; analogously, let $u_1^i, \ldots, v_{\ell_i^u}^i$ be the order on F_i^u. Furthermore, let $V(F_i^o) \cap V(F_i^u) = \{z_1^i, \ldots, z_{k_i}^i\}$ be ordered by $\prec$ as well.

The subgraph of $F_i^o \cup F_i^u$ induced by the set $\{v \in V(F_i^o \cup F_i^u) \mid z_j^i \prec v \prec z_{j+1}^i\}$, $j \in [k_i - 1]$, is called the jth *block* of the update flow pair F_i, or simply the jth *i-block*. We will denote this block by b_j^i.

For a block b, we define $\mathscr{S}(b)$ to be the *start of the block*, i.e., the smallest vertex w.r.t. $\prec$; similarly, $\mathscr{E}(b)$ is the *end of the block*: the largest vertex w.r.t. $\prec$.

Let $G = (V, E, \mathcal{P}, s, t, c)$ be an update flow network with $\mathcal{P} = \{P_1, \ldots, P_k\}$ and let $\mathcal{B}$ be the set of its blocks. We define a binary relation $<$ between two blocks as follows. For two

blocks $b_1, b_2 \in \mathcal{B}$, where b_1 is an i-block and b_2 a j-block, $i, j \in [k]$, we say $b_1 < b_2$ (b_1 *is smaller than* b_2) if one of the following holds.

i $\mathscr{S}(b_1) \prec \mathscr{S}(b_2)$,
ii if $\mathscr{S}(b_1) = \mathscr{S}(b_2)$ then $b_1 < b_2$, if $\mathscr{E}(b_1) \prec \mathscr{E}(b_2)$,
iii if $\mathscr{S}(b_1) = \mathscr{S}(b_2)$ and $\mathscr{E}(b_1) = \mathscr{E}(b_2)$ then $b_1 < b_2$, if $i < j$.

Let b be an i-block and P_i the corresponding update flow pair. For a feasible update sequence σ, we will denote the round $\sigma(\mathscr{S}(b), P_i)$ by $\sigma(b)$. We say that an i-block b is *updated*, if all edges in $b \cap F_i^u$ are active and all edges in $b \cap F_i^o \setminus F_i^u$ are inactive. We will make use of a basic, but important observation on the structure of blocks and how they can be updated. This structure is the key to our flow reconfiguration algorithm (presented below), as it allows us to consider the update of blocks as a whole, rather than vertex-by-vertex.

▶ **Lemma 4.** *Let b be a block of the flow pair $P = (F^u, F^o)$. Then in a feasible update sequence σ, all vertices (resp. their outgoing edges belonging to P) in $F^u \cap b - \mathscr{S}(b)$ are updated strictly before $\mathscr{S}(b)$. Moreover, all vertices in $b - F^u$ are updated strictly after $\mathscr{S}(b)$ is updated.*

▶ **Lemma 5.** *Let G be an update flow network and σ a valid update sequence for G. Then there exists a feasible update sequence σ' which updates every block in consecutive rounds.*

Recall that G is acyclic and every flow pair in G forms a single block. Let σ be a feasible update sequence of G. We suppose in σ, every block is updated in consecutive rounds (Lemma 5). For a single flow F, we write $\sigma(F)$ for the round where the last edge of F was updated.

4.1 Updating k-Flows in DAGs is NP-complete

We first show that if k is part of the input, the congestion-free flow reconfiguration problem is even hard on the DAG. Hence the algorithm presented in the following is essentially tight. To prove the theorem, we use a polynomial time reduction from the 3-SAT problem.

▶ **Theorem 6.** *Finding a feasible update sequence for k-flows is NP-complete, even if the update graph G is acyclic.*

4.2 Linear Time Algorithm for Constant Number of Flows on DAGs

By Theorem 6 we cannot hope to find a polynomial time algorithm that finds a feasible update sequence. However, if the problem is parameterized by the number k of flows, a rerouting sequence can be computed in FPT-linear time if the update graph is acyclic. In this subsection we describe an algorithm to solve the network update problem on DAGs in time $2^{O(k \log k)}O(|G|)$, for arbitrary k. In the remainder of this section, we assume that every block has at least 3 vertices (otherwise, postponing such block updates will not affect the solution).

We say a block b_1 *touches* a block b_2 (denoted by $b_1 \succ b_2$) if there is a vertex $v \in b_1$ such that $\mathscr{S}(b_2) \prec v \prec \mathscr{E}(b_2)$, or there is a vertex $u \in b_2$ such that $\mathscr{S}(b_1) \prec u \prec \mathscr{E}(b_1)$. If b_1 does not touch b_2, we write $b_1 \not\succ b_2$. Clearly, the relation is symmetric, i.e., if $b_1 \succ b_2$ then $b_2 \succ b_1$.

For some intuition, consider a drawing of G which orders vertices w.r.t. $\prec$ in a line. Project every edge on that line as well. Then two blocks touch each other if they have a common segment on that projection.

Proof Sketch: Before delving into details, we provide the main ideas behind our algorithm. We can think about the update problem on DAGs as follows. Our goal is to compute a feasible update order for the (out-)edges of the graph. There are at most k flows to be updated for each edge, resulting in $k!$ possible orders and hence a brute force complexity of $O(k!^{|G|})$ for the entire problem. We can reduce this complexity by considering blocks instead of edges.

The update of a given i-block b_i might depend on the update of a j-block sharing at least one edge of b_i. These dependencies can be represented as a directed graph. If this graph does not have any directed cycles, it is rather easy to find a feasible update sequence, by iteratively updating sink vertices.

There are several issues here: First of all these dependencies are not straight-forward to define. As we will see later, they may lead to representation graphs of exponential size. In order to control the size we might have to relax our definition of dependency, but this might lead to a not necessarily acyclic graph which will then need further refinement. This refinement is realized by finding a suitable subgraph, which alone is a hard problem in general. To overcome the above problems, we proceed as follows.

Let TouchSeq(b) contain all feasible update sequences for the blocks that touch b: still a (too) large number, but let us consider them for now. For two distinct blocks b, b', we say that two sequences $s \in \text{TouchSeq}(b), s' \in \text{TouchSeq}(b')$ are *consistent*, if the order of any common pair of blocks is the same in both s, s'. If for some block b, $\text{TouchSeq}(b) = \emptyset$, there is no feasible update sequence for G: b cannot be updated.

We now consider a graph H whose vertices correspond to elements of TouchSeq(b), for all $b \in \mathcal{B}$. Connect all pairs of vertices originating from the same TouchSeq(b). Connect all pairs of vertices if they correspond to inconsistent elements of different TouchSeq(b). If (and only if) we find an independent set of size $|\mathcal{B}|$ in the resulting graph, the update orders corresponding to those vertices are mutually consistent: we can update the entire network according to those orders. In other words, the update problem can be reduced to finding an independent set in the graph H.

However, there are two main issues with this approach. First, H can be very large. A single TouchSeq(b) can have exponentially many elements. Accordingly, we observe that we can assume a slightly different perspective on our problem: we linearize the lists TouchSeq(b) and define them sequentially, bounding their size by a function of k (the number of flows). The second issue is that finding a maximum independent set in H is hard. The problem is equivalent to finding a clique in the complement of H, a $|\mathcal{B}|$-partite graph where every partition has bounded cardinality. We can prove that for an n-partite graph where every partition has bounded cardinality, finding an n-clique is NP-complete. So, in order to solve the problem, we either should reduce the number of partitions in H (but we cannot) or modify H to some other graph, further reducing the complexity of the problem. We do the latter by trimming H and removing some extra edges, turning the graph into a very simple one: a graph of *bounded path width*. Then, by standard dynamic programming, we find the independent set of size $|\mathcal{B}|$ in the trimmed version of H: this independent set matches the independent set I of size $|\mathcal{B}|$ in H (if it exists). At the end, reconstructing a correct update order sequence from I needs some effort. As we have reduced the size of TouchSeq(b) and while not all possible update orders of all blocks occur, we show that they suffice to cover all possible feasible solutions. We provide a way to construct a valid update order accordingly.

With these intuitions in mind, we now present a rigorous analysis. Let $\pi_{S_1} = (a_1, \ldots, a_{\ell_1})$ and $\pi_{S_2} = (a'_1, \ldots, a'_{\ell_2})$ be permutations of sets S_1 and S_2. We define the *core* of π_{S_1} and π_{S_2} as $core(\pi_{S_1}, \pi_{S_2}) := S_1 \cap S_2$. We say that two permutations π_1 and π_2 are *consistent*, $\pi_1 \approx \pi_2$, if there is a permutation π of symbols of $core(\pi_1, \pi_2)$ such that π is a subsequence of both π_1 and π_2.

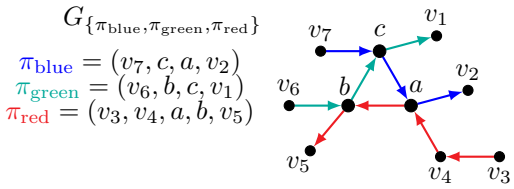

Figure 3 *Example:* The dependency graph of three pairwise consistent permutations π_{blue}, π_{green} and π_{red}. Each pair of those permutation has exactly one vertex in common and with this the cycle (a, b, c) is created. With such cycles being possible, a dependency graph does not necessarily contain sink vertices. To get rid of them, we certainly need some more refinements.

The **dependency graph** is a labelled graph defined recursively as follows. The dependency graph of a single permutation $\pi = (a_1, \ldots, a_\ell)$, denoted by G_π, is a directed path $v_1, \ldots, v_\ell$, and the label of the vertex $v_i \in V(G_\pi)$ is the element a with $\pi(a) = i$. We denote by $\text{Labels}(G_\pi)$ the set of all labels of G_π.

Let G_Π be a dependency graph of the set of permutations Π and $G_{\Pi'}$ the dependency graph of the set Π'. Then, their union (by identifying the same vertices) forms the dependency graph $G_{\Pi \cup \Pi'}$ of the set $\Pi \cup \Pi'$. Note that such a dependency graph is not necessarily acyclic (see Figure 3).

We call a permutation π of blocks of a subset $\mathcal{B}' \subseteq \mathcal{B}$ *congestion free*, if the following holds: it is possible to update the blocks in π in the graph $G_{\mathcal{B}}$ (the graph on the union of blocks in $\mathcal{B}$), in order of their appearance in π, without violating any edge capacities in $G_{\mathcal{B}}$. Note that we do not respect all conditions of our *Consistency Rule* (Definition 1) here.

In the approach we are taking, one of the main advantages we have is the nice properties of blocks when it comes to updating. The following algorithm formalizes the procedure already described in Lemma 5. The correctness follows directly from said lemma. Let $P = (F^o, F^u)$ be a given flow pair.

Algorithm 1. **Update a Free Block b**

1. Resolve (v, P) for all $v \in F^u \cap b - \mathscr{S}(b)$.
2. Resolve $(\mathscr{S}(b), P)$.
3. Resolve (v, P) for all $v \in (b - F^u)$.
4. For any edge in $E(b \cap F^u)$ check whether d_{F^u} together with the other loads currently active on e exceed $c(e)$. If so output: *Fail*.

▶ **Lemma 7.** *Let π be a permutation of the set $\mathcal{B}_1 \subseteq \mathcal{B}$. Whether π is congestion free can be determined in time $O(k \cdot |G|)$.*

The smaller relation defines a total order on all blocks in G. Let $\mathcal{B} = \{b_1, \ldots, b_{|\mathcal{B}|}\}$ and suppose the order is $b_1 < \ldots < b_{|\mathcal{B}|}$.

We define an auxiliary graph H which will help us find a suitable dependency graph for our network. We first provide some high-level definitions relevant to the construction of the graph H only. Exact definitions will follow in the construction of H, and will be used throughout the rest of this section.

Recall that $\mathcal{B}$ is the set of all blocks in G. We define another set of blocks $\mathcal{B}'$ and initialize it as $\mathcal{B}$; the construction of H is iterative, and in each iteration, we eliminate a block from $\mathcal{B}'$. At the end of the construction of H, $\mathcal{B}'$ is empty. For every block $b \in \mathcal{B}'$, we also define the set $\text{TouchingBlocks}(b)$ of blocks which touch the block b, note that this

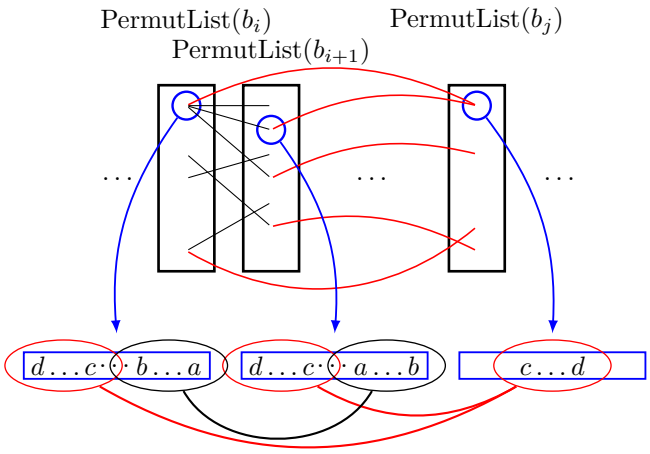

Figure 4 *Example:* The graph H consists of vertex sets PermutList(b_i), $i \in [|\mathcal{B}|]$, where each such partition contains all congestion free sequences of the at most k iteratively chosen touching blocks. In the whole graph, we then create edges between the vertices of two such partitions if and only if the corresponding sequences are inconsistent with each other, as seen in the three highlighted sequences. Later we will distinguish between such edges connecting vertices of neighbouring partitions (w.r.t. the topological order of their corresponding blocks), PermutList(b_i) and PermutList(b_{i+1}), and partitions that are further away, PermutList(b_i) and PermutList(b_j). Edges of the latter type, depicted as red in the figure, are called long edges and will be deleted in the trimming process of H.

set is dynamically defined: it depends on $\mathcal{B}'$. Another set which is defined for every block b is the set PermutList(b); this set actually corresponds to a set of vertices, each of which corresponds to a valid congestion free permutation of blocks in TouchingBlocks(b). Clearly if TouchingBlocks(b) does not contain any congestion-free permutation, then PermutList(b) is an empty set. As we already mentioned, every vertex $v \in$ PermutList(b) comes with a **label** which corresponds to some congestion-free permutation of elements of TouchingBlocks(b). We denote that permutation by Label (v).

Construction of H: We recursively construct a labelled graph H from the blocks of G as follows.

i Set $H \coloneqq \emptyset$, $\mathcal{B}' \coloneqq \mathcal{B}$, PermutList $\coloneqq \emptyset$.
ii For $i \coloneqq 1, \dots, |\mathcal{B}|$ do

1 Let $b \coloneqq b_{|\mathcal{B}|-i+1}$.
2 Let TouchingBlocks(b) $\coloneqq \{b'_1, \dots, b'_t\}$ be the set of blocks in $\mathcal{B}'$ touched by b.
3 Let $\pi \coloneqq \{\pi_1, \dots, \pi_\ell\}$ be the set of congestion free permutations of TouchingBlocks(b).
4 Set PermutList(b) $\coloneqq \emptyset$.
5 For $i \in [\ell]$ create a vertex v_{π_i} with Label(v_{π_i}) $= \pi_i$ and set PermutList(b) $\coloneqq$ PermutList(b) $\cup\, v_{\pi_i}$.
6 Set $H \coloneqq H \cup$ PermutList(b).
7 Add edges between all pairs of vertices in H[PermutList(b)].
8 Add an edge between every pair of vertices $v \in H$[PermutList(b)] and $u \in V(H) -$ PermutList(b) if the labels of v and u are inconsistent.
9 Set $\mathcal{B}' \coloneqq \mathcal{B}' - b$.

We have the following lemmas based on our construction.

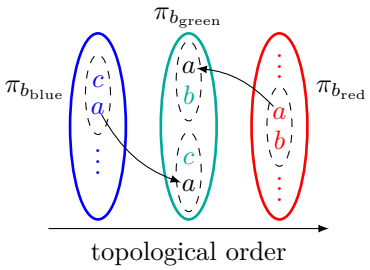

Figure 5 *Example:* Select one of the permutations of length at most k from every PermutList(b). These permutations obey the Touching Lemma. Taking the three permutations from the example in Figure 3, we can see that the Touching Lemma forces a to be in the green permutation as well. Assuming consistency, this would mean a to come *before* b and *after* c. Hence $a <_{\pi_{\text{green}}} b$ and $b <_{\pi_{\text{green}}} a$, a contradiction. So if our permutations are derived from H and are consistent, we will show that cycles cannot occur in their dependency graph.

▶ **Lemma 8.** *For Item (ii2) of the construction of H, $t \leq k$ holds.*

▶ **Lemma 9** (Touching Lemma)**.** *Let $b_{j_1}, b_{j_2}, b_{j_3}$ be three blocks (w.r.t. $<$) where $j_1 < j_2 < j_3$. Let b_z be another block such that $z \notin \{j_1, j_2, j_3\}$. If in the process of constructing H, b_z is in the touch list of both b_{j_1} and b_{j_3}, then it is also in the touch list of b_{j_2}.*

For an illustration of the property described in the Touching Lemma, see Figure 5: it refers to the dependency graph of Figure 3. This example also points out the problem with directed cycles in the dependency graph and the property of the Touching Lemma, which is crucial for Observation 10 and Lemma 11.

We prove a series of lemmas in regard to the dependency graph of elements of H, to establish the base of the inductive proof for Lemma 13.

▶ **Observation 10.** *Let π be a permutation of a set S. Then the dependency graph G_π does not contain a cycle.*

▶ **Lemma 11.** *Let π_1, π_2 be permutations of sets S_1, S_2 such that π_1, π_2 are consistent. Then the dependency graph $G_{\pi_1 \cup \pi_2}$ is acyclic.*

In the next lemma, we need a closure of the dependency graph of permutations which we define as follows.

▶ **Definition 12** (Permutation Graph Closure)**.** The *permutation graph closure*, or simply *closure*, of a permutation π is the graph G_π^+ obtained from taking the transitive closure of G_π, i.e. its vertices and labels are the same as G_π and there is an edge (u, v) in G_π^+ if there is a path starting at u and ending at v in G_π. Similarly the *permutation graph closure* of a set of permutations $\Pi = \{\pi_1, \ldots, \pi_n\}$ is the graph obtained by taking the union of $G_{\pi_i}^+$'s (for $i \in [n]$) by identifying vertices of the same label.

In the above definition, note that if Π is a set of permutations, then $G_\Pi \subseteq G_\Pi^+$. The following lemma generalizes Lemma 11 and Observation 10 and uses them as the base of its inductive proof.

▶ **Lemma 13.** *Let $I = \{v_{\pi_1}, \ldots, v_{\pi_\ell}\}$ be an independent set in H. Then the dependency graph G_Π, for $\Pi = \{\pi_1, \ldots, \pi_\ell\}$, is acyclic.*

Proof. Instead of working on G_Π, we can work on its closure G_Π^+ as defined above. First we observe that every edge in G_Π also appears in G_Π^+, so if there is a cycle in G_Π, the same cycle exists in G_Π^+.

We prove that there is no cycle in G_Π^+. By Lemma 11 and Observation 10 there is no cycle of length at most 2 in G_Π^+; otherwise there is a cycle in G_Π which consumes at most two consistent permutations.

For the sake of contradiction, suppose G_Π^+ has a cycle and let $C = (a_1, \ldots, a_n) \subseteq G_\Pi^+$ be a shortest cycle in G_Π^+. By Lemma 11 and Observation 10 we know that $n \geq 3$.

In the following, because we work on a cycle C, whenever we write any index i we consider it w.r.t. its cyclic order on C, in fact $i \mod |C| + 1$. So for example, $i = 0$ and $i = n$ are identified as the same indices; similarly for $i = n + 1, i = 1$, etc.

Recall the construction of the dependency graph where every vertex $v \in C$ corresponds to some block b_v. In the remainder of this proof we do not distinguish between the vertex v and the block b_v.

Let π_v be the label of a given vertex $v \in I$. For each edge $e = (a_i, a_{i+1}) \in C$, there is a permutation π_{v_i} such that (a_i, a_{i+1}) is a subsequence of π_{v_i} and additionally the vertex v_i is in the set I. So there is a block b^i such that π_{v_i} is a permutation of the set TouchingBlocks(b^i).

The edge $e = (a_i, a_{i+1})$ is said to *represent* b^i, and we call it the representative of π_{v_i}. For each i we fix one block b^i which is represented by the edge (a_i, a_{i+1}) (note that one edge can represent many blocks, but here we fix one of them). We define the set of those blocks as $B^I = \{b^1, \ldots, b^\ell\}$ and state the following claim.

Claim 1. For every two distinct vertices $a_i, a_j \in C$, either there is no block $b \in B^I$ such that $a_i, a_j \in$ TouchingBlocks(b) or if $a_i, a_j \in$ TouchingBlocks(b) then (a_i, a_j) or (a_j, a_i) is an edge in C. Additionally $\left|B^I\right| = |C|$.

By the above claim we have $\ell = n$. W.l.o.g. suppose $b^1 < b^2 < \ldots < b^n$. There is an $i \in [n]$ such that (a_{i-1}, a_i) represents b^1, we fix this i.

Claim 2. If (a_{i-1}, a_i) represents b^1 then (a_{i-2}, a_{i-1}) represents b^2.

Similarly we can prove the endpoints of the edges, that have a_i as their head, are in b^2.

Claim 3. If (a_{i-1}, a_i) represents b^1 then (a_i, a_{i+1}) represents b^2.

By Claims 2 and 3 we have that both (a_{i-2}, a_{i-1}) and (a_i, a_{i+1}) represent b^2 hence by Claim 1 they are the same edge. Thus there is a cycle on the vertices a_{i-1}, a_i in G_Π^+ and this gives a cycle in G_Π on at most 2 consistent permutations which is a contradiction according to Lemma 11. ◀

The following lemma is the key to establish a link between independent sets in H and feasible update sequences of the corresponding update flow network G.

▶ **Lemma 14.** *There is a feasible sequence of updates for an update network G on k flow pairs, if and only if there is an independent set of size $|\mathcal{B}|$ in H. Additionally if the independent set $I \subseteq V(H)$ of size $|\mathcal{B}|$ together with its vertex labels are given, then there is an algorithm which can compute a feasible sequence of updates for G in $O(k \cdot |G|)$.*

With Lemma 14, the update problem boils down to finding an independent set of size $|\mathcal{B}|$ in H.

Finding an independent set of size $|\mathcal{B}|$ in H is a hard problem already on very restricted class families. Hence, we trim H to avoid the above problem. We will use the special properties of the touching relation of blocks. We say that an edge $e \in E(H)$ is *long*, if one end of e is in PermutList(b_i), and the other in PermutList(b_j) where $j > i+1$. The *length* of e is $j-i$. *Delete* all long edges from H to obtain the graph R_H. We prove the following lemmas.

▶ **Lemma 15.** *There is an algorithm which computes R_H in time $O((k \cdot k!)^2 |G|)$.*

▶ **Lemma 16.** *H has an independent set I of size $|\mathcal{B}|$ if, and only if, I is also an independent set of size $|\mathcal{B}|$ in R_H.*

R_H is a much simpler graph compared to H, which helps us find a large independent set of size $|\mathcal{B}|$ (if exists). We have the following lemma.

▶ **Lemma 17.** *There is an algorithm that finds an independent set I of size exactly $|\mathcal{B}|$ in R_H if such an independent set exists; otherwise it outputs that there is no such an independent set. The running time of this algorithm is $O(|R_H|)$.*

Our main theorem is now a corollary of the previous lemmas and algorithms.

▶ **Theorem 18.** *There is a linear time FPT algorithm for the network update problem on an acyclic update flow network G with k flows (the parameter), which finds a feasible update sequence, if it exists; otherwise it outputs that there is no feasible solution for the given instance. The algorithm runs in time $O(2^{O(k \log k)} |G|)$.*

5 Conclusion

This paper initiated the study of a natural and fundamental reconfiguration problem: the congestion-free rerouting of unsplittable flows. Interestingly, we find that while *computing* disjoint paths on DAGs is $W[1]$-hard [23] and finding routes under congestion as well [1], *reconfiguring* multicommodity flows is fixed parameter tractable on DAGs. However, we also show that the problem is NP-hard for an arbitrary number of flows.

In future work, it will be interesting to chart a more comprehensive landscape of the computational complexity for the network update problem. In particular, it would be interesting to know whether the complexity can be reduced further, e.g., to $2^{O(k)}O(|G|)$. More generally, it will be interesting to study other flow graph families, especially more sparse graphs or graphs of bounded DAG width [2, 6]. Finally, besides feasibility, it remains to study algorithms to efficiently compute *short* schedules.

Abstract

In an onion routing protocol, messages travel through several intermediaries before arriving at their destinations; they are wrapped in layers of encryption (hence they are called "onions"). The goal is to make it hard to establish who sent the message. It is a practical and widespread tool for creating anonymous channels.

For the standard adversary models – passive and active – we present practical and provably secure onion routing protocols. Akin to Tor, in our protocols each party independently chooses the routing paths for his onions. For security parameter λ, our differentially private solution for the active adversary takes $O(\log^2 \lambda)$ rounds and requires every participant to transmit $O(\log^4 \lambda)$ onions in every round.

1 Introduction

Anonymous channels are a prerequisite for protecting user privacy. But how do we achieve anonymous channels in an Internet-like network that consists of point-to-point links?

If a user Alice wishes to send a message m to a user Bob, she may begin by encrypting her message m under Bob's public key to obtain the ciphertext $c_{Bob} = \mathsf{Enc}(\mathsf{pk}_{Bob}, m)$. But sending c_{Bob} directly to Bob would allow an eavesdropper to observe that Alice is in communication with Bob. So instead, Alice may designate several intermediate relays, called "mix-nodes" (typically chosen at random) and send the ciphertext through them, "wrapped" in several layers of encryption so that the ciphertext received by a mix-node cannot be linked to the ciphertext sent out by the mix-node. Each node decrypts each ciphertext it receives ("peels off" a layer of encryption) and discovers the identity of the next node and the ciphertext to send along. This approach to hiding who is talking to whom is called "onion

routing" [10] (sometimes it is also called "anonymous remailer" [13]) because the ciphertexts are layered, akin to onions; from now on we will refer to such ciphertexts as "onions".

Onion routing is attractive for several reasons: (1) simplicity: users and developers understand how it works; the only cryptographic tool it uses is encryption; (2) fault-tolerance: it can easily tolerate and adapt to the failure of a subset of mix-nodes; (3) scalability: its performance remains the same even as more and more users and mix-nodes are added to the system. As a result, onion routing is what people use to obscure their online activities. According to current statistics published by the Tor Project, Inc., Tor is used by millions of users every day to add privacy to their communications [14, 15][1].

In spite of its attractiveness and widespread use, the security of onion routing is not well-understood.

The definitional question – what notion of security do we want to achieve? – has been studied [3,20,21,28]. The most desirable notion, which we will refer to as "statistical privacy", requires that the adversary's view in the protocol be distributed statistically independently of who is trying to send messages to whom[2]. Unfortunately, a network adversary observing the traffic flowing out of Alice and flowing into Bob can already make inferences about whether Alice is talking to Bob. For example, if the adversary knows that Alice is sending a movie to someone, but there isn't enough traffic flowing into Bob's computer to suggest that Bob is receiving a movie, then Bob cannot be Alice's interlocutor. (Participants' inputs may also affect others' privacy in other ways [20].)

So let us consider the setting in which, in principle, statistical privacy can be achieved: every party wants to anonymously send and receive just one short message to and from some other party. Let us call this "the simple input-output (I/O) setting". In the simple I/O setting, anonymity can be achieved even against an adversary who can observe the entire network if there is a trusted party through whom all messages are routed. Can onion routing that does not rely on one trusted party emulate such a trusted party in the presence of a powerful adversary?

Specifically, we may be dealing with *the network adversary* that observes all network traffic; or the stronger *passive adversary* that, in addition to observing network traffic, also observes the internal states of a fraction of the network nodes; or the most realistic *active adversary* that observes network traffic and also controls a fraction of the nodes. Prior work analyzing Tor [3, 20, 21] did not consider these standard adversary models. Instead, they focused on the adversary who was entirely absent from some regions of the network, but resourceful adversaries (such as the NSA) and adversaries running sophisticated attacks (such as BGP hijacking [29]) may receive the full view of the network traffic, and may also infiltrate the collection of mix-nodes.

Surprisingly, despite its real-world importance, we were the first to consider this question.

Warm-up: An *oblivious permutation algorithm* between a memory-constrained client and an untrusted storage server enables the client to permute a sequence of (encrypted) data blocks stored on the server without the server learning anything (in the statistical sense) about the permutation.

---

[1] Tor stands for "the onion router", and even though the underlying mechanics are somewhat different from what we described above (instead of using public-key encryption, participants carry out key exchange so that the rest of the communication can be more efficient), the underlying theory is still the same.

[2] Technically, since onion routing uses encryption, the adversary's view cannot be statistically independent of the input, but at best computationally independent. However, as we will see, if we work in an idealized encryption model, such as in Canetti's $\mathcal{F}_{\mathsf{Enc}}$-hybrid model [7], statistical privacy makes sense.

▶ **Theorem 1.** *Any oblivious permutation algorithms can be adapted into a communications protocol for achieving statistical privacy from the network adversary.*

As an example, Ohrimenko et al. [26] presented a family of efficient oblivious permutation algorithms. This can be adapted into a secure and "tunable" OR protocol that can trade off between low server load and latency. Letting λ denote the security parameter, for any $B \in [\frac{\sqrt{N}}{\log^2 \lambda}]$, this protocol can be set to run in $O(\frac{\log N}{\log B})$ rounds with communication complexity overhead $O(\frac{B \log N \log^2 \lambda}{\log B})$ and server load $O(B \log^2 \lambda)$.

However, to be secure from the passive adversary, we need more resources. We prove for the first time that onion routing can provide statistical privacy from the passive adversary, while being efficient.

1. We prove that our solution, Π_p, is statistically private from any passive adversary capable of monitoring any constant $\kappa \in [0, 1)$ of the mix-nodes, while having communication complexity overhead $O(\log^2 \lambda)$, server load $O(\log^2 \lambda)$, and latency $O(\log^2 \lambda)$, where λ denotes the security parameter. (See Section 4.)

However, for most realistic input settings (not constrained to the simple I/O setting), statistical privacy is too ambitious a goal. It is not attainable even with a trusted third party. Following recent literature [3, 31], for our final result, let us *not* restrict users' inputs, and settle for a weaker notion of privacy, namely, differential privacy.

Our definition of differential privacy requires that the difference between the adversary's view when Alice sends a message to Bob and its view when she does not send a message at all or sends it to Carol instead, is small. This is meaningful; showing that the protocol achieves differential privacy gives every user a guarantee that sending her message through does not change the adversary's observations very much.

2. Our solution, Π_a, can defend against the active adversary while having communication complexity overhead $O(\log^6 \lambda)$, server load $O(\log^4 \lambda)$, and latency $O(\log^2 \lambda)$. This is the first provably secure peer-to-peer solution that also provides a level of robustness; unless the adversary forces the honest players to abort the protocol run, most messages that are not dropped by the adversary are delivered to their final destinations. (See Section 5.)

To prepare onions, we use a cryptographic scheme that is strong enough that, effectively, the only thing that the active adversary can do with onions generated by honest parties is to drop them (see the onion cryptosystem by Camenisch and Lysyanskaya [6] for an example of a sufficiently strong cryptosystem). Unfortunately, even with such a scheme, it is still tricky to protect Alice's privacy against an adversary that targets Alice specifically. Suppose that an adversarial Bob is expecting a message of a particular form from an anonymous interlocutor, and wants to figure out if it was Alice or not. If the adversary succeeds in blocking all of Alice's onions and not too many of the onions from other parties, and then Bob never receives the expected message, then the adversary's hunch that it was Alice will be confirmed.

How do we prevent this attack? For this attack to work, the adversary would have to drop a large number of onions – there is enough cover traffic in our protocol that dropping just a few onions does not do much. But once a large enough number of onions is dropped, the honest mix-nodes will detect that an attack is taking place, and will shut down before any onions are delivered to their destinations. Specifically, if enough onions survive half of the rounds, then privacy is guaranteed through having sufficient cover; otherwise, privacy is guaranteed because *no* message reaches its final destination with overwhelming probability. So the adversary does not learn anything about the destination of Alice's onions.

In order to make it possible for the mix-nodes to detect that an attack is taking place, our honest users create "checkpoint" onions. These onions don't carry any messages; instead, they are designed to be "verified" by a particular mix-node in a particular round. These checkpoint onions are expected by the mix-node, so if one of them does not arrive, the mix-node in question realizes that something is wrong. If enough checkpoint onions are missing, the mix-node determines that an attack is underway and shuts down. Two different users, Alice and Allison, use a PRF with a shared key (this shared key need not be pre-computed, but can instead be derived from a discrete-log based public-key infrastructure under the decisional Diffie-Hellman assumption) in order to determine whether Alice should create a checkpoint onion that will mirror Allison's checkpoint onion.

Related work

Encryption schemes that are appropriate for onion routing are known [2, 6]. Several papers attempted to define anonymity for communications protocols and to analyze Tor [20, 21, 28]. Backes et al. [3] were the first to consider a notion inspired by differential privacy [18] but, in analyzing Tor, they assume an adversary with only a partial view of the network. There are also some studies on anonymity protocols, other than onion routing protocols, that were analyzed using information-theoretic measures [1, 4, 8, 16, 24]. In contrast, all the protocols presented in this paper are provably secure against powerful adversaries that can observe all network traffic. The system, Vuvuzela [31], assumes that all messages travel through the same set of dedicated servers and is, therefore, impractical compared to Tor. Recently proposed systems, Stadium [30] and Atom [25] are distributed but not robust; they rely on verifiable shuffling to detect and abort. A variant of Atom is robust at a cost in security; it only achieves k-anonymity [25]. In contrast, our solution for the active adversary is distributed while maintaining low latency, and robust while being provably secure.

Achieving anonymous channels using heavier cryptographic machinery has been considered also. One of the earliest examples is Chaum's dining cryptographer's protocol [9]. Rackoff and Simon [27] use secure multiparty computation for providing security from active adversaries. Other cryptographic tools used in constructing anonymity protocols include oblivious RAM (ORAM) and private information retrieval (PIR) [11, 12]. Corrigan-Gibbs et al.'s Riposte solution makes use of a global bulletin board and has a latency of a couple of days [12]. The aforementioned Stadium [25] is another solution for a public forum. Blaze et al. [5] provided an anonymity protocol in the wireless (rather than point-to-point) setting.

2 Preliminaries

Notation

By the notation $[n]$, we mean the set $\{1, \ldots, n\}$ of integers. The output a of an algorithm A is denoted by $a \leftarrow A$. For a set S, we write $s \leftarrow S$ to represent that s is a uniformly random sample from the set S and $|S|$, to represent its cardinality. A realization d of a distribution D is denoted $d \sim D$; by $d \sim \mathbf{Binomial}(N, p)$, we mean that d is a realization of a binomial random variable with parameters N and p. By $\log(n)$, we mean the logarithm of n, base 2; and by $\ln(n)$, we mean the natural log of n.

A function $f : \mathbb{N} \to \mathbb{R}$ is negligible in λ, written $f(\lambda) = \mathbf{negl}(\lambda)$, if for every polynomial $p(\cdot)$ and all sufficiently large λ, $f(\lambda) < 1/p(\lambda)$. When λ is the security parameter, we say that an event occurs with overwhelming probability if it is the complement of an event with probability negligible in λ. Two families of distributions $\{D_{0,\lambda}\}_{\lambda \in \mathbb{N}}$ and $\{D_{1,\lambda}\}_{\lambda \in \mathbb{N}}$ are

statistically close if the statistical distance between $D_{0,\lambda}$ and $D_{1,\lambda}$ is negligible in λ; we abbreviate this notion by $D_0 \approx_s D_1$ when the security parameter is clear by context. We use the standard notion of a pseudorandom function [22, Ch. 3.6].

Onion routing

Following Camenisch and Lysyanskaya's work on cryptographic onions [6], an *onion routing scheme* is a triple of algorithms: $(\mathsf{Gen}, \mathsf{FormOnion}, \mathsf{ProcOnion})$. The algorithm, Gen, generates a public-key infrastructure for a set of parties. The algorithm, $\mathsf{FormOnion}$, forms onions; and the algorithm, $\mathsf{ProcOnion}$, processes onions.

Given a set $[N]$ of parties, for every $i \in [N]$, let $(\mathsf{pk}_i, \mathsf{sk}_i) \leftarrow \mathsf{Gen}(1^\lambda)$ be the key pair generated for party $i \in [N]$, where λ denotes the security parameter.

$\mathsf{FormOnion}$ takes as input: a message m, an ordered list $(P_1, \ldots, P_{L+1})$ of parties from $[N]$, and the public-keys $(\mathsf{pk}_{P_1}, \ldots, \mathsf{pk}_{P_{L+1}})$ associated with these parties, and a list $(s_1, \ldots, s_L)$ of (possibly empty) strings that are nonces associated with layers of the onion. The party P_{L+1} is interpreted as the *recipient* of the message, and the list $(P_1, \ldots, P_{L+1})$ is the *routing path* of the message. The output of $\mathsf{FormOnion}$ is a sequence $(O_1, \ldots, O_{L+1})$ of onions. Because it is convenient to think of an onion as a layered encryption object, where processing an onion O_r produces the next onion O_{r+1}, we sometimes refer to the process of revealing the next layer of an onion as "decrypting the onion", or "peeling the onion". For every $r \in [L]$, only party P_r can peel onion O_r to reveal the next layer, $(P_{r+1}, O_{r+1}, s_{r+1}) \leftarrow \mathsf{ProcOnion}(\mathsf{sk}_{P_r}, O_r, P_r)$, of the onion containing the "peeled" onion O_{r+1}, the "next destination" P_{r+1}, and the nonce s_{r+1}. Only the recipient P_{L+1} can peel the innermost onion O_{L+1} to reveal the message, $m \leftarrow \mathsf{ProcOnion}(\mathsf{sk}_{P_{L+1}}, O_{L+1}, P_{L+1})$.

Let O_0 be an onion formed from running $\mathsf{FormOnion}(m_0, P^0, \mathsf{pk}^0, s^0)$, and let O_1 be another onion formed from running $\mathsf{FormOnion}(m_1, P^1, \mathsf{pk}^1, s^1)$. Importantly, a party that can't peel either onion can't tell which input produced which onion. See Camenisch and Lysyanskaya's paper [6] for formal definitions.

In our protocols, a sender of a message m to a recipient j "forms an onion" by generating nonces and running the $\mathsf{FormOnion}$ algorithm on the message m, a routing path $(P_1, \ldots, P_L, j)$, the public keys $(\mathsf{pk}_{P_1}, \ldots, \mathsf{pk}_{P_L}, \mathsf{pk}_j)$ associated with the parties on the routing path, and the generated nonces; the "formed onion" is the first onion O_1 from the list of outputted onions. The sender sends O_1 to the first party P_1 on the routing path, who processes it and sends the peeled onion O_2 to the next destination P_2, and so on, until the last onion O_{L+1} is received by the recipient j, who processes it to obtain the message m.

3 Definitions

We model the network as a graph with N nodes, and we assume that these nodes are synchronized. This way, any onion can be sent from any sender to any receiver, and also its transmission occurs within a single round.

Every participant is a user client, and some user clients also serve as mix-nodes. In all the definitions, the N users participating in an communications protocol Π are labeled $1, \ldots, N$; and the number N of users is assumed to be polynomially-bounded in the security parameter λ. Every input to a protocol is an N-dimensional vector. When a protocol runs on input $\sigma = (\sigma_1, \ldots, \sigma_N)$, it means that the protocol is instantiated with each user i receiving σ_i as input. $\mathcal{M}$ denotes the (bounded) message space. A message pair (m, j) is properly formed if $m \in \mathcal{M}$ and $j \in [N]$. The input σ_i to each user $i \in [N]$ is a collection of properly formed message pairs, where $(m, j) \in \sigma_i$ means that user i intends on sending message m to

user j. Let $M(\sigma)$ denote the "messages in σ". It is the multiset of all message pairs in σ, that is $M(\sigma_1, \ldots, \sigma_N) = \bigcup_{i=1}^{N} \{(m, j) \in \sigma_i\}$.

For analyzing our solutions, it is helpful to first assume an idealized version of an encryption scheme, in which the ciphertexts are information-theoretically unrelated to the plaintexts that they encrypt and reveal nothing but the length of the plaintext. Obviously, such encryption schemes do not exist computationally, but only in a hybrid model with an oracle that realizes an ideal encryption functionality, such as that of Canetti [7]. When used in forming onions, such an encryption scheme gives rise to onions that are information-theoretically independent of their contents, destinations, and identities of the mix-nodes. Our real-life proposal, of course, will use standard computationally secure encryption [17]. We discuss the implications of this in the full version of this paper.

Views and outputs

We consider the following standard adversary models, in increasing order of capabilities:

1. **Network adversary.** A network adversary can observe the bits flowing on every link of the network. (Note that if the peer-to-peer links are encrypted in an idealized sense, then the only information that the adversary can use is the volume flow.)
2. **Passive adversary.** In addition to the capabilities of a network adversary, a passive adversary can monitor the internal states and operations of a constant fraction of the parties. The adversary's choices for which parties to monitor are made non-adaptively over the course of the execution run.
3. **Active adversary.** In addition to the capabilities of a network adversary, an active adversary can corrupt a constant fraction of the parties. The adversary's choices for which parties to corrupt are made non-adaptively over the course of the execution run. The adversary can change the behavior of corrupted parties to deviate arbitrarily from the protocol.

Let Π be a protocol, and let σ be a vector of inputs to Π. Given an adversary $\mathcal{A}$, the view $V^{\Pi,\mathcal{A}}(\sigma)$ of $\mathcal{A}$ is its observables from participating in Π on input σ plus any randomness used to make its decisions. With idealized secure peer-to-peer links, the observables for a network adversary are the traffic volumes on all links; whereas for the passive and active adversaries, the observables additionally include the internal states and computations of all monitored / corrupted parties at all times.

Given an adversary $\mathcal{A}$, the output $O^{\Pi,\mathcal{A}}(\sigma) = (O_1^{\Pi,\mathcal{A}}(\sigma), \ldots, O_N^{\Pi,\mathcal{A}}(\sigma))$ of Π on input σ is a vector of outputs for the N parties.

3.1 Privacy definitions

How do we define security for an anonymous channel? The adversary's view also includes the internal states of corrupted parties. In such case, we may wish to protect the identities of honest senders from the recipients that are in cahoots with the adversary. However, even an ideal anonymous channel cannot prevent the contents of messages (including the volumes of messages) from providing a clue on who sent the messages; thus any "message content" leakage should be outside the purview of an anonymous channel. To that end, we say that an communications protocol is secure if it is difficult for the adversary to learn who is communicating with whom, beyond what leaks from captured messages.

Below, we provide two flavors of this security notion; we will prove that our constructions achieve either statistical privacy or (ϵ, δ)-differential privacy [19, Defn. 2.4] in the idealized encryption setting.

▶ **Definition 2** (Statistical privacy). Let Σ^* be the input set consisting of every input of the form $\sigma = (\{(m_1, \pi(1))\}, \ldots, \{(m_N, \pi(N))\})$, where $\pi : [N] \to [N]$ is any permutation function over the set $[N]$, and $m_i \in \mathcal{M}$ for every $i \in [N]$. A communications protocol Π is *statistically private* from every adversary from the class $\mathbb{A}$ if for all $\mathcal{A} \in \mathbb{A}$ and for all $\sigma_0, \sigma_1 \in \Sigma^*$ that differ only on the honest parties' inputs and outputs, the adversary's views $V^{\Pi,\mathcal{A}}(\sigma_0)$ and $V^{\Pi,\mathcal{A}}(\sigma_1)$ are statistically indistinguishable, i.e., $\Delta(V^{\Pi,\mathcal{A}}(\sigma_0), V^{\Pi,\mathcal{A}}(\sigma_1)) = \mathbf{negl}(\lambda)$, where $\lambda \in \mathbb{N}$ denotes the security parameter, and $\Delta(\cdot,\cdot)$ denotes statistical distance (i.e., total variation distance). Π is perfectly secure if the statistical distance is zero instead.

▶ **Definition 3** (Distance between inputs). The *distance* $d(\sigma_0, \sigma_1)$ between two inputs $\sigma_0 = (\sigma_{0,1}, \ldots, \sigma_{0,N})$ and $\sigma_1 = (\sigma_{1,1}, \ldots, \sigma_{1,N})$ is given by $d(\sigma_0, \sigma_1) \stackrel{\text{def}}{=} \sum_{i=1}^{N} |\sigma_{0,i} \nabla \sigma_{1,i}|$, where $(\cdot \nabla \cdot)$ denotes the symmetric difference.

▶ **Definition 4** (Neighboring inputs). Two inputs σ_0 and σ_1 are *neighboring* if $d(\sigma_0, \sigma_1) \leq 1$.

▶ **Definition 5** ((ϵ, δ)-DP [19, Defn. 2.4]). Let Σ be the set of all valid inputs. A communications protocol is (ϵ, δ)-*DP* from every adversary in the class $\mathbb{A}$ if for all $\mathcal{A} \in \mathbb{A}$, for every neighboring inputs $\sigma_0, \sigma_1 \in \Sigma$ that differ only on an honest party's input and an honest party's output, and any set $\mathcal{V}$ of views, $\Pr[V^{\Pi,\mathcal{A}}(\sigma_0) \in \mathcal{V}] \leq e^{\epsilon} \cdot \Pr[V^{\Pi,\mathcal{A}}(\sigma_1) \in \mathcal{V}] + \delta$.

While differential privacy is defined with respect to neighboring inputs, it also provides (albeit weaker) guarantees for non-neighboring inputs; it is known that the security parameters degrade proportionally in the distance between the inputs [19].

3.2 Other performance metrics

Since message delivery cannot be guaranteed in the presence of an active adversary, we define correctness with respect to *passive* adversaries.

▶ **Definition 6** (Correctness). A communications protocol Π is *correct* on an input $\sigma \in \Sigma$ if for any passive adversary $\mathcal{A}$, and for every recipient $j \in [N]$, the output $O_j^{\Pi,\mathcal{A}}(\sigma)$ corresponds to the multiset of all messages for recipient j in the input vector σ. That is, $O_j^{\Pi,\mathcal{A}}(\sigma) = \{m \,|(m, j) \in M(\sigma)\}$, where $M(\sigma)$ denotes the multiset of all messages in σ.

Efficiency of OR protocols

The communication complexity blow-up of an onion routing (OR) protocol measures how many more onion transmissions are required by the protocol, compared with transmitting the messages in onions directly from the senders to the recipients (without passing through intermediaries). We assume that every message $m \in \mathcal{M}$ in the message space $\mathcal{M}$ "fits" into a single onion. The communication complexity is measured in unit onions, which is appropriate when the parties pass primarily onions to each other.

▶ **Definition 7** (Communication complexity blow-up). The *communication complexity blow-up* of an OR protocol Π is defined with respect to an input vector σ and an adversary $\mathcal{A}$. Denoted $\gamma^{\Pi,\mathcal{A}}(\sigma)$, it is the expected ratio between the total number $\Gamma^{\Pi,\mathcal{A}}(\sigma)$ of onions transmitted in protocol Π and the total number $|M(\sigma)|$ of messages in the input vector. That is, $\gamma^{\Pi,\mathcal{A}}(\sigma) \stackrel{\text{def}}{=} \mathbb{E}\left[\frac{\Gamma^{\Pi,\mathcal{A}}(\sigma)}{|M(\sigma)|}\right]$.

▶ **Definition 8** (Server load). The *server load* of an OR protocol Π is defined with respect to an input vector σ and an adversary $\mathcal{A}$. It is the expected number of onions processed by a single party in a round.

▶ **Definition 9** (Latency). The *latency* of an OR protocol Π is defined with respect to an input vector σ and an adversary $\mathcal{A}$. It is the expected number of rounds in a protocol execution.

In addition to having low (i.e., polylog in the security parameter) communication complexity blow-ups, we will show that our OR protocols have low (i.e., polylog in the security parameter) server load and low (i.e., polylog in the security parameter) latency.

4 The passive adversary

Communication patterns can trivially be hidden by sending every message to every participant in the network, but this solution is not scalable as it requires a communication complexity blow-up that is linear in the number of participants. Here, we prove that an OR protocol can provide anonymity from the passive adversary while being practical with low communication complexity and low server load.

To do this, every user must send and receive the same number of messages as any other user; otherwise, the sender-receiver relation can leak from the differing volumes of messages sent and received by the users. In other words, every user essentially commits to sending a message, be it the empty message $\perp$ to itself. Let Σ^* be the set of all input vectors of the form $\sigma = (\{(m_1, \pi(1))\}, \ldots, \{(m_N, \pi(N))\})$, where $\pi : [N] \to [N]$ is any permutation function over the set $[N]$, and $m_1, \ldots, m_N$ are any messages from the message space $\mathcal{M}$; our solution, Π_p, is presented in the setting where the input vector is constrained to Σ^*.

Let $[N]$ be the set of users, and $\mathcal{S} = \{S_1, \ldots, S_n\} \subset [N]$ the set of servers. Π_p uses a secure onion routing scheme, denoted by $\mathcal{OR} = (\mathsf{Gen}, \mathsf{FormOnion}, \mathsf{ProcOnion})$, as a primitive building block. For every $i \in [N]$, let $(\mathsf{pk}_i, \mathsf{sk}_i) \leftarrow \mathsf{Gen}(1^\lambda)$ be the key pair generated for party i, where λ denotes the security parameter.

During a setup phase, each user $i \in [N]$ creates an onion. On input $\sigma_i = \{(m, j)\}$, user i first picks a sequence $T_1, \ldots, T_L$ servers, where each server is chosen independently and uniformly at random, and then forms an onion from the message m, the routing path $(T_1, \ldots, T_L, j)$, the public keys $(\mathsf{pk}_{T_1}, \ldots, \mathsf{pk}_{T_L}, \mathsf{pk}_j)$ associated with the parties on the routing path, and a list of empty nonces. At the first round of the protocol run, user i sends the formed onion to the first hop T_1 on the routing path.

After every round $i \in [L]$ (but before round $i+1$) of the protocol run, each server processes the onions it received at round i. At round $i+1$, the resulting peeled onions are sent to their respective next destinations in random order. At round $L+1$, every user receives an onion and processes it to reveal a message.

Correctness and efficiency

Clearly, Π_p is correct. In Π_p, N messages are transmitted in each of the $L+1$ rounds of the protocol run. Thus, the communication complexity blow-up and the latency are both $L+1$. The server load is $\frac{N}{n}$.

Privacy

To prove that Π_p is statistically private from the passive adversary, we first prove that it is secure from the network adversary.

▶ **Theorem 10.** *Π_p is statistically private from the network adversary when $\frac{N}{n} = \Omega(\log^2 \lambda)$, and $L = \Omega(\log^2 \lambda)$, where $\lambda \in \mathbb{N}$ denotes the security parameter.*

Proof. Let $\frac{N}{n} = \alpha \log^2 \lambda$; so that after each round, every location receives $\alpha \log^2 \lambda$ onions in expectation. We recast our problem as a balls-in-bins problem, where the balls are the onions, and the bins, the locations. At every round of the protocol, all $\alpha n \log^2 \lambda$ balls (i.e., onions) are thrown uniformly at random into n bins (i.e., each onion is routed to one of n locations, chosen independently and uniformly at random).

Fix any target sender U, and let $X^r = (X_1^r, \ldots, X_n^r)$ be a vector of non-negative numbers summing to one, representing $\mathcal{A}$'s best estimate for the location of U's ball after r rounds (and before round $r+1$); for every $i \in [n]$, X_i^r is the likelihood that bin i contains U's ball after r rounds. Let $(X^r_{f_r(1)}, \ldots, X^r_{f_r(n)})$ be the result of sorting $(X_1^r, \ldots, X_n^r)$ in decreasing order, where $f_r : [n] \to [n]$ is a permutation function over the set $[n]$. For every $i \in [n]$, let $b_i^r = f_r(i)$ be the index of the bin with the i-th largest likelihood at round r.

W.l.o.g. we assume that n is divisible by three. We partition the bins into three groups G_1^r, G_2^r, and G_3^r; such that G_1^r contains all the *balls* in the top one-third most likely bins $b_1^r, \ldots, b_{\frac{n}{3}}^r$; G_3^r contains all the balls in the bottom one-third most likely bins $b^r_{\frac{2n}{3}+1}, \ldots, b_n^r$; and G_2^r contains all the balls in the remaining bins $b^r_{\frac{n}{3}+1}, \ldots, b^r_{\frac{2n}{3}}$.

For each $j \in [3]$, let $O_j^r \in G_j^r$ be a ball with the maximum likelihood of being U's onion among the balls in group G_j^r. For any $d \in (0,1)$, let $d' = 1 - \frac{1}{1+d}$. Let c_j^r be the bin containing O_j^r. The bin c_j^r contains at least $(1-d')\alpha \log^2 \lambda$ balls (Chernoff bounds for Poisson trials). It follows that,

$$\Pr[O_j^r \text{ is } U\text{'s onion}] \leq (1+d)\frac{X^r_{c_j^r}}{\alpha \log^2 \lambda} \leq (1+d)\frac{X^r_{\frac{(j-1)n}{3}+1}}{\alpha \log^2 \lambda} \tag{1}$$

with overwhelming probability, where $X^r_{\frac{(j-1)n}{3}+1}$ is the likelihood of the most likely bin in group G_j.

The number of balls contained in each group G_j^r is arbitrarily close to the expected number $\frac{\alpha}{3} n \log^2 \lambda$ of balls in a group (Chernoff bounds). Thus, the most probable bin b_1^{r+1} after the next round receives at most $\frac{(1+d)\alpha}{3} \log^2 \lambda$ balls from each of the three groups: G_1^r, G_2^r, and G_3^r. From (1), this implies that, with overwhelming probability, $X_1^{r+1} \leq \frac{(1+d)^2}{3} \sum_{j=1}^3 X^r_{\frac{(j-1)n}{3}+1}$. Using a symmetric argument, we can conclude that, with overwhelming probability, $X_n^{r+1} \geq \frac{(1-d)^2}{3} \sum_{j=1}^3 X^r_{\frac{jn}{3}}$, where $X^r_{\frac{jn}{3}}$ is the likelihood of the least likely bin in group G_j.

For all $r \in [L]$, define $g^r = X_1^r - X_n^r$ as the difference in likelihoods between the most and least likely bins at round r.

$$g^{r+1} \leq \frac{(1+d)^2 \sum_{j=1}^3 X^r_{\frac{(j-1)n}{3}+1}}{3} - \frac{(1-d)^2 \sum_{j=1}^3 X^r_{\frac{jn}{3}}}{3} \leq \frac{1}{2}\left(X_1^r - X_n^r\right) = \frac{g^r}{2},$$

where the latter inequality follows from telescopic cancelling, since $X^r_{\frac{n}{3}+1} \leq X^r_{\frac{n}{3}}$, and $X^r_{\frac{2n}{3}+1} \leq X^r_{\frac{2n}{3}}$.

The difference g^r is at least halved at every round. By round $\log^2 \lambda$, the difference is negligible in λ. Thus, after traveling L random hops, each onion becomes unlinked from its sender. Since everyone sends the same number of onions, and everyone receives the same number of onions; it follows that the adversary's views from any two inputs are statistically indistinguishable.

In the proof above, the bins were partitioned into three groups at every round. By partitioning the bins into an appropriately large constant number of groups, we can show that Π_p achieves statistical privacy after $L = \Omega(\log^2 \lambda)$ rounds. ◀

We are now ready to prove the main result of this section:

▶ **Theorem 11.** *Π_p is statistically private from the passive adversary capable of monitoring any constant fraction $\kappa \in [0, 1)$ of the servers when $\frac{N}{n} = \Omega(\log^2 \lambda)$, and $L = \Omega(\log^2 \lambda)$, where $\lambda \in \mathbb{N}$ denotes the security parameter.*

Proof. We prove this by cases.

In the first case, σ_1 is the same as σ_0 except that the inputs of two users are swapped, i.e., $d(\sigma_0, \sigma_1) = 2$. Using Chernoff bounds for Poisson trials, there are at least some polylog number of rounds where the swapped onions are both routed to an honest bin (not necessarily the same bin). From Theorem 10, after the polylog number of steps, the locations of these two target onions are statistically indistinguishable from each other.

In the second case, $d(\sigma_0, \sigma_1) > 2$. However, the distance between σ_0 and σ_1 is always polynomially bounded. By a simple hybrid argument, it follows that $V^{\Pi,\mathcal{A}}(\sigma_0) \approx_s V^{\Pi,\mathcal{A}}(\sigma_1)$ from case 1. ◀

Remark: Protocol Π_p is not secure from the active adversary. This is because, with non-negligible probability, any honest user will choose a corrupted party as its first hop on its onion's routing path, in which case the adversary can drop the target user's onion at the first hop and observe who does not receive an onion at the last round.

5 The active adversary

We now present an OR protocol, Π_a, that is secure from the active adversary. The setting for Π_a is different from that of our previous solution in a couple of important ways. Whereas Π_p is *statistically* private from the passive adversary, Π_a is only *differentially* private from the active adversary. The upside is that we are no longer constrained to operate in the simple I/O setting; the input can be any valid input.

We let $[N]$ be the set of N parties participating in a protocol. Every party is both a user and a server. As before, $\mathcal{OR} = (\mathsf{Gen}, \mathsf{FormOnion}, \mathsf{ProcOnion})$ is a secure onion routing scheme; and for every $i \in [N]$, $(\mathsf{pk}_i, \mathsf{sk}_i) \leftarrow \mathsf{Gen}(1^\lambda)$ denotes the key pair generated for party i, where λ is the security parameter. Further, we assume that every pair $(i, k) \in [N]^2$ of parties shares a common secret key[3], denoted by $\mathsf{sk}_{i,k}$. F is a pseudorandom function (PRF).

We describe the protocol by the setup and routing algorithms for party $i \in [N]$; each honest party runs the same algorithms.

Setup

Let $L = \beta \log^2 \lambda$ for some constant $\beta > 0$. During the setup phase, party i prepares a set of onions from its input. For every message pair $u = \{m, j\}$ in party i's input, party i picks a sequence $T_1^u, \ldots, T_L^u$ of parties, where each party T_ℓ^u is chosen independently and uniformly at random, and forms an onion from the message m, the routing path $(T_1^u, \ldots, T_L^u, j)$, the public keys $(\mathsf{pk}_{T_1^u}, \ldots, \mathsf{pk}_{T_L^u}, \mathsf{pk}_j)$, and a list of empty nonces.

Additionally, party i forms some dummy onions, where a dummy onion is an onion formed using the empty message $\perp$.

1: **for** every index $(r, k) \in [L] \times [N]$:
2: compute $b \leftarrow F(\mathsf{sk}_{i,k}, \mathsf{session} + r, 0)$, where $\mathsf{session} \in \mathbb{N}$ denotes the protocol instance.
3: **if** $b \equiv 1$ – set to occur with frequency $\frac{\alpha \log^2 \lambda}{N}$ for some constant $\alpha > 0$ – **do**:

[3] In practice, the shared keys do not need to be set up in advance; they can be generated as needed from an existing PKI, e.g., using Diffie-Hellman.

4: choose a list $T^{r,k} = (T_1^{r,k}, \ldots, T_{r-1}^{r,k}, T_{r+1}^{r,k}, \ldots, T_{L+1}^{r,k})$ parties, where each party is chosen independently and uniformly at random;
5: create a list $s^{r,k} = (s_1^{r,k}, \ldots, s_2^{r,k})$ of nonces, where $s_r^{r,k} = (\mathsf{checkpt}, F(\mathsf{sk}_{i,k}, \mathsf{session} + r, 1))$, and all other elements of $s^{r,k}$ are $\perp$; and
6: form a dummy onion using the message $\perp$, the routing path $T^{r,k}$, the public keys associated with $T^{r,k}$, and the list $s^{r,k}$ of nonces. **end if, end for**

The additional information $s_r^{r,k}$ is embedded in only the r-th layer; no additional information is embedded in any other layer. At the first round of the protocol run (after setup), all formed onions are sent to their respective first hops.

Routing

If party i forms a dummy onion with nonce $s_r^{r,k}$ embedded in the r-th layer, then it expects to receive a symmetric dummy onion at the r-th round formed by another party k that, when processed, reveals the same nonce $s_r^{r,k}$. If many checkpoint nonces are missing, then party i knows to abort the protocol run.

After every round $r \in [L]$ (but before round $r+1$), party i peels the onions it received at round r and counts the number of missing checkpoint nonces. If the count exceeds a threshold value t, the party aborts the protocol run; otherwise, at round $r+1$, the peeled onions are sent to their next destinations in random order. After the final round, party i outputs the set of messages revealed from processing its the onions it receives at round $L+1$.

Correctness and efficiency

Recalling that correctness is defined with respect to the passive adversary, Π_a is clearly correct. Moreover, unless an honest party aborts the protocol run, all messages that are not dropped by the adversary are delivered to their final destinations. In Π_a, the communication complexity blow-up is $O(\log^6 \lambda)$, since the latency is $L + 1 = O(\log^2 \lambda)$ rounds, and the server load is $O(\log^4 \lambda)$.

Privacy

To prove that Π_a is secure, we require that the thresholding mechanism does its job:

▶ **Lemma 12.** *In Π_a, if F is a random function, $t = c(1-d)(1-\kappa)^2\alpha \log^2 \lambda$ for some $c, d \in (0,1)$, and an honest party does not abort within the first r rounds of the protocol run, then with overwhelming probability, at least $(1-c)$ of the dummy onions created between honest parties survive at least $(r-1)$ rounds, even in the presence of an active adversary non-adaptively corrupting a constant fraction $\kappa \in [0,1)$ of the parties.*

The proof relies on a known concentration bound for the hypergeometric distribution [23] and can be found in the full version of this paper.

▶ **Theorem 13.** *If, in Π_a, F is a random function, $N \geq \frac{3}{1-\kappa}$, and $t = c(1-d)(1-\kappa)^2\alpha \log^2 \lambda$ for some $c, d \in (0,1)$, then, for $\alpha\beta \geq -\frac{36(1+\epsilon/2)^2 \ln(\delta/4)}{(1-c)(1-\kappa)^2\epsilon^2}$, Π_a is (ϵ, δ)-DP from the active adversary non-adaptively corrupting a constant fraction $\kappa \in [0,1)$ of the parties.*

Proof. The proof is by cases.

Case 1: All honest parties abort within the first half of the protocol run. With overwhelming probability, no onion created by an honest party will be delivered to its final destination (Chernoff bounds for Poisson trials), and so the adversary doesn't learn anything.

Case 2: Some honest party doesn't abort within the first half of the protocol run. Let $\mathcal{A}$ be any adversary that non-adaptively corrupts a constant $\kappa \in [0, 1)$ of the parties. Suppose that for every onion that survive the first half of the protocol run, a dark angel provides the adversary $\mathcal{A}$ with the second half of the onion's routing path. Further suppose that no other onions are dropped in the second half of the protocol run. (If more onions are dropped, then Π_a is secure from the post-processing theorem for differential privacy [19, Proposition 2.1].)

For any two neighboring inputs σ_0 and σ_1, the only difference in the adversary's views, $V^{\Pi_a,\mathcal{A}}(\sigma_0)$ and $V^{\Pi_a,\mathcal{A}}(\sigma_1)$, is the routing of a single onion O. If there is an honest party who does not abort within the first half of the protocol run, then from Lemma 12, some constant fraction of the dummy onions created by the honest parties survive the first half of the protocol run with overwhelming probability. So, from Theorem 11, the onions are no longer linked to their senders by the end of the first half of the protocol run. Thus, the only information that $\mathcal{A}$ could find useful is the volume of onions sent out by the sender P_s of the extra onion O and the volume of onions received by the receiver P_r of O.

Let X denote the number of dummy onions created by P_s. For every $(k, r) \in [L] \times [N]$, an honest sender P_s creates a dummy onion with probability $\frac{\alpha \log^2 \lambda}{N}$; so $X \sim \textbf{Binomial}(H, p)$, where $H = LN$, and $p = \frac{\alpha \log^2 \lambda}{N}$.

Let $Y \sim \textbf{Binomial}(G, q)$ be another binomial random variable with parameters $G = \frac{L(1-\kappa)^2 N^2}{3}$ and $q = \frac{(1-c)\alpha \log^2 \lambda}{N^2}$. For $N \geq \frac{3}{1-\kappa}$ and sufficiently small $d > 0$, $G \leq (1 - d)L\binom{(1-\kappa)N-1}{2}$; thus, with overwhelming probability, Y is less than the number of dummy onions created between honest non-P_s parties and received by P_r in the final round (Chernoff bounds).

Let $\mathcal{O} \stackrel{\text{def}}{=} \mathbb{N} \times \mathbb{N}$ be the sample space for the multivariate random variable (X, Y).

Let $\mathcal{O}_1$ be the event that $|X - \mathbb{E}[X]| \leq d'\mathbb{E}[X]$, and $|Y - \mathbb{E}[Y]| \leq d'\mathbb{E}[Y]$, where $d' = \frac{\epsilon/2}{1+\epsilon/2}$, $\mathbb{E}[X] = Hp$ is the expected value of X, and $\mathbb{E}[Y] = Gq$ is the expected value of Y; and let $\bar{\mathcal{O}_1}$ be the complement of $\mathcal{O}_1$.

For every $(x, y) \in \mathcal{O}_1$, we can show that

$$\max\left(\frac{\Pr[(X,Y) = (x,y)]}{\Pr[(X,Y) = (x+1,y+1)]}, \frac{\Pr[(X,Y) = (x+1,y+1)]}{\Pr[(X,Y) = (x,y)]}\right) \leq e^{\epsilon}. \tag{2}$$

We can also show that the probability of the tail event $\bar{\mathcal{O}_1}$ occurring is negligible in λ and at most δ when $\alpha\beta \geq -\frac{36(1+\epsilon/2)^2 \ln(\delta/4)}{(1-c)(1-\kappa)^2\epsilon^2}$. (See the full version of this paper.)

Any event $\mathcal{E}$ can be decomposed into two subsets $\mathcal{E}_1$ and $\mathcal{E}_2$, such that (1) $\mathcal{E} = \mathcal{E}_1 \cup \mathcal{E}_2$, (2) $\mathcal{E}_1 \subseteq \mathcal{O}_1$, and (3) $\mathcal{E}_2 \subseteq \bar{\mathcal{O}_1}$. It follows that, for every event $\mathcal{E}$,

$$\Pr[(X,Y) \in \mathcal{E}] \leq e^{\epsilon} \cdot \Pr[(X+1,Y+1) \in \mathcal{E}] + \delta, \text{ and} \tag{3}$$

$$\Pr[(X+1,Y+1) \in \mathcal{E}] \leq e^{\epsilon} \cdot \Pr[(X,Y) \in \mathcal{E}] + \delta. \tag{4}$$

The views $V^{\Pi_a,\mathcal{A}}(\sigma_0)$ and $V^{\Pi_a,\mathcal{A}}(\sigma_1)$ are the same except that O exists in one of the views but not in the other. Thus, (3) and (4) suffice to show that for any set $\mathcal{V}$ of views and for any $b \in \{0, 1\}$, $\Pr[V_b^{\Pi_a,\mathcal{A}} \in \mathcal{V}] \leq e^{\epsilon} \cdot \Pr[V_{\bar{b}}^{\Pi_a,\mathcal{A}} \in \mathcal{V}] + \delta$, where $\bar{b} = b + 1 \mod 2$. ◀

Remark: Our protocols are for a *single-pass* setting, where the users send out messages once. It is clear how our statistical privacy results would compose for the multi-pass case. To prove that Π_a also provides differential privacy in the multi-pass scenario – albeit for degraded security parameters – we can use the k-fold composition theorem [19]; the noise falls at a rate of the square-root of the number of runs.

Abstract

We consider a set of transmitters broadcasting simultaneously on the same frequency under the SINR model. Transmission power may vary from one transmitter to another, and a signal's strength decreases (*path loss* or *path attenuation*) by some constant power α of the distance traveled. Roughly, a receiver at a given location can hear a specific transmitter only if the transmitter's signal is stronger than the signal of all other transmitters, combined. An SINR query is to determine whether a receiver at a given location can hear any transmitter, and if yes, which one.

An approximate answer to an SINR query is such that one gets a definite YES or definite NO, when the ratio between the strongest signal and all other signals combined is well above or well below the reception threshold, while the answer in the intermediate range is allowed to be either YES or NO.

We describe several compact data structures that support approximate SINR queries in the plane in a dynamic context, i.e., where both queries and updates (insertion or deletion of a transmitter) can be performed efficiently.

Table 1 Approximate SINR queries in a static setting – previous results. φ is an upper bound on the fatness parameters of the reception regions and $\varphi' \geq \varphi^2$.

	Preprocessing	**Space**	**Query**
Uniform Power [5]	$O(n^2/\varepsilon)$ $(O(n\varepsilon^{-2.5}\log^4 n \log\log n)$ [3])	$O(n/\varepsilon)$	$O(\log n)$
Non-Uniform Power [10]	$O(\frac{\varphi'}{\varepsilon^2}n^2)$	$O(\frac{\varphi'}{\varepsilon^2}n)$	$O(\frac{\varphi}{\varepsilon}\log n)$

1 Introduction

The *Signal to Interference plus Noise Ratio (SINR) model* attempts to predict whether a wireless transmission is received successfully, in a setting consisting of multiple simultaneous transmitters in the presence of background noise. Let $S = \{s_1, \ldots, s_n\}$ be a set of n transmitters (points in the plane), and let p_i denote the transmission power of s_i, for $i = 1, \ldots, n$. Let q be a receiver (a point in the plane). According to the SINR model, q *receives* s_i if and only if

$$sinr(q, s_i) = \frac{\frac{p_i}{|qs_i|^\alpha}}{\sum_{j \neq i} \frac{p_j}{|qs_j|^\alpha} + N} \geq \beta \ ,$$

where $\alpha \geq 1$ and $\beta > 1$ are constants, N is a constant representing the background noise, and $|ab|$ is the Euclidean distance between points a and b.

Observe that, since $\beta > 1$, q may receive at most one transmitter – the one "closest" to it, namely, the one for which the value $\frac{p_i}{|qs_i|^\alpha}$ is maximum, or, equivalently, $\frac{1}{p_i^{1/\alpha}}|qs_i|$ is minimum. Thus, one can partition the plane into n not necessarily connected reception regions R_i, one per transmitter in S, plus an additional region $R_\emptyset$ consisting of all points where none of the transmitters is received. This partition is called the *SINR diagram* of S [5].

In their seminal paper, Avin et al. [5] studied properties of SINR diagrams, focusing on the *uniform power* version where $p_1 = p_2 = \cdots = p_n$. Their main result is that in this version the reception regions R_i are convex and fat. In the *non-uniform power* version, on the other hand, the reception regions are not necessarily connected, and their connected components are not necessarily convex or fat. In fact, they may contain holes [10].

An *SINR query* is: Given a receiver q, find the sole transmitter s that may be received by q and determine whether it is indeed received by q, i.e., whether or not $sinr(q, s) \geq \beta$. A natural question is how quickly can one answer an SINR query, following a preprocessing stage in which data structures of total size nearly linear in n are constructed. However, it seems unlikely that the answer is significantly sub-linear (as the degree of the polynomials describing region boundaries is high), so the research has focused on preprocessing to facilitate efficient *approximate* SINR queries.

The approach of such research has been to construct a data structure which approximates the underlying SINR diagram, and use it for answering approximate SINR queries, by performing point-location queries in this structure. That is, given a query point q, first find the sole candidate s_i that may be received at q (by searching in the appropriate Voronoi diagram), and then perform a point-location query to approximately determine whether q is in R_i or not. Two different notions of approximation have been used. In the first [5], it is guaranteed that the uncertain answer is only given infrequently, namely, the area of the uncertain region associated with R_i is at most $\varepsilon \cdot area(R_i)$, for a prespecified parameter $\varepsilon > 0$. In the second [10], it is guaranteed that for every point in the uncertain region the

SIN ratio is within an ε-neighborhood of β. See Table 1 for a summary of previous results; see also [11] for related work. In addition, Aronov and Katz [3] obtained several results for *batched* approximate SINR queries, using the latter notion of approximation; for example, one can perform n simultaneous approximate queries in a network with n transmitters at polylogarithmic amortized cost per query.

Given $\varepsilon > 0$,[4] an *approximate SINR query* is: Given a receiver q, find the sole transmitter s that may be received by q and return a value $\widetilde{sinr}(q, s)$, such that $(1 - \varepsilon)sinr(q, s) \leq \widetilde{sinr}(q, s) \leq (1 + \varepsilon)sinr(q, s)$. Thus, unless $(1 - \varepsilon)\beta \leq \widetilde{sinr}(q, s) < (1 + \varepsilon)\beta$, the value $\widetilde{sinr}(q, s)$ enables us to determine definitely whether or not s is received by q.

In this paper, we devise efficient algorithms for handling approximate SINR queries in a dynamic setting. That is, given S, α, β, and N, as above, and $\varepsilon > 0$, we describe algorithms for answering approximate SINR queries after some initial preprocessing, in a setting where transmitters may be added to or deleted from S. We analyze our algorithms by the usual measures, namely, preprocessing time, data structure size, query time, and update time.

To the best of our knowledge, these are the first data structures to support dynamic approximate SINR queries. In contrast with previous work on approximate SINR queries, our algorithms do not compute an approximation of the underlying SINR diagram. We distinguish between two main variants of the problem – the uniform power version and the non-uniform power one. The preprocessing time in both cases is $O(n \operatorname{polylog} n)$, while the update and query time is $O(\operatorname{polylog} n)$ for the uniform version, and $O(\sqrt{n} \operatorname{polylog} n)$ for the non-uniform version. Thus, our solution for the *dynamic* uniform version is comparable to the best known solutions for the *static* uniform version. For the non-uniform version, however, our solution is the first solution with bounds that depend only on n and ε and not on other parameters of the input, both in the static and dynamic settings.

In addition to the obvious motivation for devising algorithms for approximate SINR queries in a dynamic setting, we mention another important application of our results. *Successive Interference Cancellation (SIC)* is a technique that enables (in some circumstances) a receiver q to receive a specific transmitter t, even if t cannot be received at q in SINR sense. Informally, our results support SIC; if t's signal is the kth strongest at q, then, through a sequence of $O(k)$ queries and updates, we can determine whether q can decode t's signal from the combined signal; see the discussion in Section 4. In contrast, Avin et al. [4] construct a uniform-power static data structure of size $O(\varepsilon^{-1}n^{10})$ which enables one to determine in $O(\log n)$ time whether t can be received by q using SIC. Their result is not directly comparable to ours, however: They guarantee logarithmic query regardless of the number of transmitters that need to be canceled before t can be heard, and their approximation model is quite different from ours.

The missing proofs and some extensions can be found in the complete version of this paper [2].

2 Uniform power

Let q be a receiver and let s be the closest transmitter to q. Set $intrf(q) = \sum_{s' \in S \setminus \{s\}} \frac{1}{|qs'|^\alpha}$, then $sinr(q, s) = \frac{\frac{1}{|qs|^\alpha}}{intrf(q)}$.[5] When s is the transmitter closest to q, we will simply write

[4] For simplicity of presentation, we will assume hereafter that $n > 1/\varepsilon$.

[5] For clarity of presentation, we assume hereafter that there is no noise, i.e., $N = 0$. Our algorithms extend to the situation where noise is present in a straightforward manner.

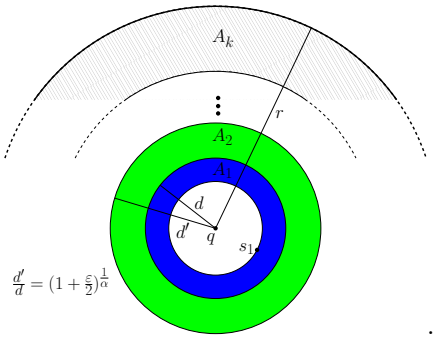

Figure 1 Partitioning $A_q(|qs_1|, r)$ into annuli.

$sinr(q)$ instead of $sinr(q, s)$. Fix $\varepsilon > 0$. We wish to compute a value $\widetilde{sinr}(q)$ such that $(1-\varepsilon)sinr(q) \leq \widetilde{sinr}(q) \leq sinr(q)$. We show below how to compute a value $\widetilde{intrf}(q)$ such that $intrf(q) \leq \widetilde{intrf}(q) \leq (1+\varepsilon)intrf(q)$ and then simply set $\widetilde{sinr}(q) = \frac{\frac{1}{|qs|^\alpha}}{\widetilde{intrf}(q)}$.

▶ **Claim 1.** *Under the above assumption,* $(1-\varepsilon)sinr(q) < \widetilde{sinr}(q) \leq sinr(q)$.

We start with a slower but easier to describe solution and then refine it.

2.1 Annuli

Let $\varepsilon > 0$. Let q be a receiver and let $s \in S$ be the closest transmitter to q. Let $s_1, \ldots, s_{n-1}$ be the transmitters in $S \setminus \{s\}$, and assume without loss of generality that s_1 is the second closest transmitter to q, among all the transmitters in S. Recall that $intrf(q) = \sum_{i=1}^{n-1} \frac{1}{|qs_i|^\alpha}$ and that we wish to compute a value $\widetilde{intrf}(q)$ such that $intrf(q) \leq \widetilde{intrf}(q) \leq (1+\varepsilon)intrf(q)$.

We will need the following simple observation.

▶ **Observation 2.** *$intrf(q)$ is the sum of $n-1$ positive terms of which $\frac{1}{|qs_1|^\alpha}$ is the largest, so we have $\frac{1}{|qs_1|^\alpha} \leq intrf(q) \leq \frac{n-1}{|qs_1|^\alpha}$.*

2.1.1 Query algorithm

Let q be a query point. First, we find s and s_1, the closest and the second closest transmitters to q, respectively. Next, we divide the transmitters in $S \setminus \{s\}$ into two subsets, S_c and S_f, where S_c consists of all transmitters that are 'close' to q and S_f consists of all transmitters that are 'far' from q. More precisely, set $r = (\frac{2n}{\varepsilon})^{1/\alpha} \cdot |qs_1|$, then S_c consists of all the transmitters in $S \setminus \{s\}$ whose distance from q is less than r, and S_f consists of all the remaining transmitters. We now approximate the contribution of each of these subsets to $intrf(q)$.

The contribution of a transmitter s_i in S_f to the sum $intrf(q)$ is

$$\frac{1}{|qs_i|^\alpha} \leq \frac{1}{r^\alpha} = \frac{\varepsilon}{2n|qs_1|^\alpha} \ ,$$

and the combined contribution of the transmitters in S_f is at most $|S_f| \cdot \frac{\varepsilon}{2n|qs_1|^\alpha} \leq \frac{\varepsilon}{2|qs_1|^\alpha}$.

We denote the annulus centered at q with inner radius r_1 and outer radius r_2 by $A_q(r_1, r_2)$. In order to approximate the overall contribution of the transmitters in S_c, we partition the annulus $A_q(|qs_1|, r)$ into k semi-open annuli, $A_1, \ldots, A_k$, such that the ratio of the outer to the inner radius of A_j is $(1+\frac{\varepsilon}{2})^{\frac{1}{\alpha}}$ (except for A_k whose ratio is at most $(1+\frac{\varepsilon}{2})^{\frac{1}{\alpha}}$); see

Figure 1. By semi-open we mean that the inner circle of A_j is contained in A_j, but the outer circle is not. Now, for each A_j, we approximate the contribution of each transmitter $s_i \in S_c \cap A_j$ by $\frac{1}{d^\alpha}$, where d is the inner radius of A_j, that is, we approximate the contribution of s_i by moving it to the inner circle of A_j. We prove below (Corollary 4) that this yields a $(1+\frac{\varepsilon}{2})$-approximation of the overall contribution of the transmitters in S_c to $intrf(q)$.

▶ **Lemma 3.** *Let $s_i \in S_c$ and let $A = A_q(d, d')$ be the annulus to which s_i belongs. Then, by moving s_i to the inner circle of A, one obtains a $(1+\frac{\varepsilon}{2})$-approximation of the contribution of s_i to $intrf(q)$.*

Proof. Since $s_i \in A$, $d \leq s_i < d'$. Moreover, by construction, $d'/d \leq (1+\frac{\varepsilon}{2})^{\frac{1}{\alpha}}$. So, the ratio of our approximation to the real contribution of s_i is

$$\frac{1/d^\alpha}{1/|qs_i|^\alpha} = \frac{|qs_i|^\alpha}{d^\alpha} < (\frac{d'}{d})^\alpha \leq 1 + \frac{\varepsilon}{2} \ . \qquad \blacktriangleleft$$

▶ **Corollary 4.** *By doing this for each transmitter in S_c, one obtains a $(1+\frac{\varepsilon}{2})$-approximation of the overall contribution of the transmitters in S_c to $intrf(q)$.*

It remains to show that $\widetilde{intrf}(q)$, which is the sum of the approximations for S_f and for S_c, satisfies the requirements, i.e., that $intrf(q) \leq \widetilde{intrf}(q) \leq (1+\varepsilon)intrf(q)$. From the description above it is clear that $\widetilde{intrf}(q) \geq intrf(q)$, so we only need to show that $\widetilde{intrf}(q) \leq (1+\varepsilon)intrf(q)$. Indeed,

$$\widetilde{intrf}(q) \leq \frac{\varepsilon}{2|qs_1|^\alpha} + (1+\frac{\varepsilon}{2}) \sum_{s_i \in S_C} \frac{1}{|qs_i|^\alpha} \leq \frac{\varepsilon}{2} intrf(q) + (1+\frac{\varepsilon}{2}) intrf(q) = (1+\varepsilon) intrf(q) \ ,$$

where the second inequality is based on Observation 2.

2.1.2 Implementation

We first show that k, the number of annuli into which the annulus $A_q(|qs_1|, r)$ is partitioned, is small; for the proof, see the complete version [2].

▶ **Lemma 5.** $k = O(\frac{1}{\varepsilon} \log n)$.

In the preprocessing stage we compute the following data structures for the set of transmitters S.

Dynamic nearest neighbor: A data structure due to Kaplan *et al.* [12] can be used for dynamic 2D nearest-neighbor queries. A set of points in the plane can be maintained dynamically in a linear-size data structure, so as to support insertions, deletions, and nearest-neighbor queries. Each insertion takes $O(\log^3 n)$ amortized deterministic time, each deletion takes $O(\log^5 n)$ amortized deterministic time, and each query takes $O(\log^2 n)$ worst-case deterministic time, where n is the size of the set of points at the time the operation is performed; see [12] and also the randomized data structure of Chan [6] with slightly worse (expected) performance.

Dynamic disk range counting: We start with the construction of Matoušek [13]: In linear space and $O(n \log n)$ time one can preprocess a set of n points in $\mathbb{R}^d$ to support semi-group halfspace range queries in $O(n^{1-1/d} \operatorname{polylog} n)$ time. A point can be deleted in $O(\log n)$ amortized time and inserted in $O(\log^2 n)$ amortized time. Lifting circles to points in $\mathbb{R}^3$ in

the standard manner, we obtain a linear-space, $O(n \log n)$ time, $O(n^{2/3} \operatorname{polylog} n)$ disk range counting query, $O(\log n)$ amortized delete, $O(\log^2 n)$ amortized insert data structure. We have not attempted to optimize this ingredient, as we replace this infrastructure with a more efficient one in the following section.

Given a query point q, we find s and s_1 (the closest and second closest transmitters) using the data structure for dynamic nearest neighbor; s_1 is found by deleting and reinserting s. Next, we compute the distance r and partition the annulus $A_q(|qs_1|, r)$ into k annuli, as described above. Now, we calculate $\widetilde{intrf}(q)$ as follows. We first compute the size of the set S_f by performing a disk counting query with the circle of radius r centered at q and subtracting the answer from $n-1$; we initialize $\widetilde{intrf}(q)$ to $|S_f| \cdot \frac{\varepsilon}{2n|qs_1|^\alpha}$. Next, for each of the k annuli, we compute the number x of points of S lying in it, as the difference in the numbers of points in the two disks defined by its bounding circles, obtained by counting queries. We then increment $\widetilde{intrf}(q)$ by $\frac{x}{d^\alpha}$, where d is the radius of the inner circle of the current annulus.

An update is performed by updating the two underlying data structures.

We omit the detailed performance analysis of this version, as a better data structure is described next.

2.2 Polygonal rings

We now present a more efficient solution similar to the previous one, except that we replace the circular annuli by polygonal rings. Set $x = (1 + \frac{\varepsilon}{2})^{\frac{1}{\alpha}}$, and consider any three circles C_0, C_1, C_2 centered at q, such that $r_1/r_0 = r_2/r_1 = \sqrt{x}$, where r_i is the radius of C_i. Set $l = \lceil \frac{\pi}{\sqrt{2 - \frac{2}{\sqrt{x}}}} \rceil$, and let B_i be the regular l-gon inscribed in C_i, so that one its vertices lies on the upward vertical ray through q, for $i = 1, 2$. We now show that C_{i-1} is contained in B_i, for $i = 1, 2$, and therefore, the polygonal ring defined by B_1 and B_2 is contained in the annulus $A_q(r_0, r_2)$. The elementary proofs of the following claims can be found in the complete version [2].

▶ **Claim 6.** *$l = O(1/\sqrt{\varepsilon})$.*

▶ **Claim 7.** *C_{i-1} is contained in B_i, for $i = 1, 2$.*

▶ **Corollary 8.** *The polygonal ring defined by B_1 and B_2 is contained in an annulus centered at q with radii ratio $x = (1 + \frac{\varepsilon}{2})^{\frac{1}{\alpha}}$.*

2.2.1 Query algorithm

We highlight the differences with the query algorithm from Section 2.1.1. Recall that we divided the transmitters into two subsets according to whether they were closer or farther than r from the query point q. We adjust the definitions slightly by setting $r' = |qs_1|x^{m/2}$, where m is the smallest integer for which $|qs_1|x^{m/2} \geq \sqrt{x}r$, and considering a transmitter close to q whenever it lies in the interior of the regular l-gon inscribed in the circle of radius r' centered at q, see Figure 2. The set of such transmitters is the new S_c; the remaining transmitters constitute S_f. The contribution of $s_i \in S_f$ to the sum $intrf(q)$ is, by Claim 7,

$$\frac{1}{|qs_i|^\alpha} \leq \frac{1}{r^\alpha} = \frac{\varepsilon}{2n|qs_1|^\alpha} \ .$$

Thus the overall contribution of the transmitters in S_f is again at most $\frac{\varepsilon}{2|qs|^\alpha}$.

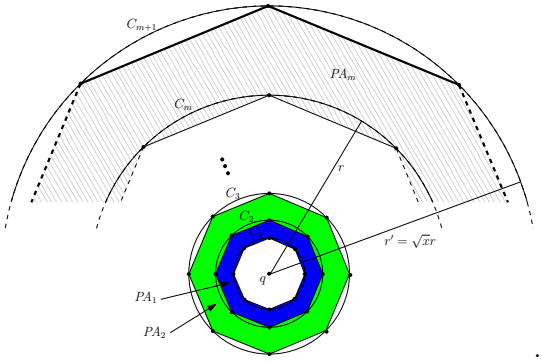

Figure 2 The polygonal rings $PA_1, \ldots, PA_m$. The ring PA_j lies between the circles C_{j-1} and C_{j+1}, for $j > 1$.

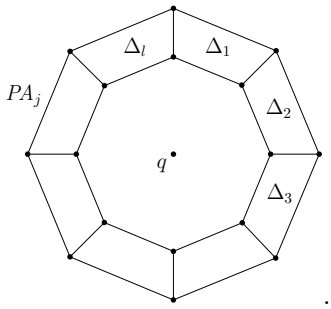

Figure 3 PA_j is the union of l trapezoids.

We now partition $A_q(|qs_1|, r')$ into m annuli, each with outer-to-inner radius ratio $\sqrt{x}$. For each of the $m+1$ circles defining these annuli, draw the regular l-gon inscribed in it. Let $PA_1, \ldots, PA_m$ be the resulting sequence of polygonal rings, numbered from the innermost outwards, see Figure 2; each ring is semi-open: it includes its inner, but not its outer boundary. By Claim 7, each PA_j, $j > 1$, is contained in the union of two consecutive annuli, which in turn is an annulus of ratio x; $S_c \cap PA_1$ is contained in the innermost annulus. Also notice that $m = O(k)$, where k is the number of annuli in the circular annulus version, so, by Lemma 5, $m = O(\frac{1}{\varepsilon} \log n)$.

For each ring PA_j, we bound from above the contribution of each $s_i \in S_c \cap PA_j$ by $1/d^\alpha$, where d is the inner radius of the annulus of ratio x containing PA_j. By Lemma 3 and the subsequent corollary, we obtain a $(1 + \frac{\varepsilon}{2})$-approximation of the overall contribution of the transmitters in S_c to $intrf(q)$; $\widetilde{intrf}(q)$ is obtained by combining the two estimates, one from S_c and one from S_f.

2.2.2 Implementation

Each polygonal ring PA_j is the union of l isosceles trapezoids; moreover the ith trapezoids of all rings are homothets of each other (refer to Figure 3) and therefore are delimited by lines of exactly three different orientations. In the preprocessing stage we compute the following data structures for the set of transmitters S.

Dynamic nearest neighbor: The data structure of Kaplan *et al.* [12] (see Section 2.1.2).

Dynamic trapezoid range counting: We use l instances of the data structure, one for each family of trapezoids. For the ith family we build a three-level orthogonal range counting structure, one for each of the three edge orientations of the trapezoids in the family. The answer to a trapezoid range counting query is the number of points of S lying in the trapezoid.

A standard three-level orthogonal range counting structure requires $O(n \log^2 n)$ space, is constructed in $O(n \log^2 n)$ time, and supports $O(\log^3 n)$-time range queries [8]. It can be modified to support insertions and deletions in $O(\log^3 n)$ amortized time using the standard partial-rebuilding technique [1, 14]. (One can use any of several different optimized variants of these structures [7, 15]. For example, He and Munro [9] describe one with linear space and $O((\log n/\log\log n)^2)$ worst-case query and amortized update time; we stay with comparison-based algorithms and do not attempt to optimize the polylogarithmic factors.)

Now given a query point q, we find its closest and second closest transmitter using the data structure for dynamic nearest neighbor in $O(\log^5 n)$ time, compute the distance r', and construct the (polygonal) rings $PA_1, \ldots, PA_m$, where $m = O(\frac{1}{\varepsilon}\log n)$. For each ring PA_j we proceed as follows. For each of the l trapezoids Δ_i forming PA_j, we perform an orthogonal range counting query in the ith data structure. Let n_j be the sum of the l results. Unless $j = 1$, we add to the value being computed the term $n_j \frac{1}{r_{j-1}^{\alpha}}$, where r_{j-1} is the radius of C_{j-1} (the inner circle of the annulus containing PA_j). If $j = 1$, we simply add the term $n_1 \frac{1}{r_1^{\alpha}}$. Finally, we add to the value being computed the term $|S_f| \cdot \frac{\varepsilon}{2n|qs_1|^{\alpha}} = (n - 1 - \sum_{j=1}^{m} n_j) \cdot \frac{\varepsilon}{2n|qs_1|^{\alpha}}$.

In summary, to implement an SINR query, we need to perform one search for the nearest and second-nearest neighbor, followed by $O(\frac{l}{\varepsilon}\log n) = O(\frac{1}{\varepsilon^{3/2}}\log n)$ range searches.

An update is applied to all the underlying data structures. The following theorem summarizes the main result of this section, while extensions can be found in the complete version [2].

▶ **Theorem 9.** *Given the locations of n uniform-power transmitters, one can preprocess them in $O((n/\sqrt{\varepsilon})\log^2 n)$ time and space into a data structure that can answer approximate SINR queries in $O(\log^5 n + (1/\varepsilon^{3/2})\log^4 n)$ time. Transmitters can be inserted in $O((1/\sqrt{\varepsilon})\log^3 n)$ and deleted in $O(\log^5 n + (1/\sqrt{\varepsilon})\log^3 n)$ amortized time.*

3 Non-uniform power

Let q be a receiver. For a transmitter $s \in S$, the *strength* of its signal at q is $nrg(s,q) = \frac{p(s)}{|qs|^{\alpha}}$ and the (multiplicatively-weighted) distance between q and s is $dist(q,s) = nrg(s,q)^{-1/\alpha} = \frac{1}{p(s)^{1/\alpha}} \cdot |qs|$. Let s be the closest transmitter to q according to $dist$. Set $intrf(q) = \sum_{s' \in S \setminus \{s\}} nrg(s', q)$, then $sinr(q,s) = \frac{nrg(s,q)}{intrf(q)}$, where we once again assume for clarity of presentation that there is no background noise, i.e., $N = 0$. When s is the closest transmitter to q, we will write $sinr(q)$ instead of $sinr(q,s)$.

Fix $\varepsilon > 0$. Again, we wish to approximate $sinr(q)$ by computing $\widetilde{intrf}(q)$ such that $intrf(q) \le \widetilde{intrf}(q) \le (1+\varepsilon)intrf(q)$ and setting $\widetilde{sinr}(q) = \frac{nrg(s,q)}{\widetilde{intrf}(q)}$. As in the uniform case, we start with a more straightforward but less efficient solution and then improve it.

3.1 Conical shells

Let q be a receiver and let $s \in S$ be the closest transmitter to q according to $dist$, i.e., the one whose signal strength at q is the highest. Let $s_1, \ldots, s_{n-1}$ be the transmitters in $S \setminus \{s\}$, and assume without loss of generality that s_1 is the second closest transmitter to q among

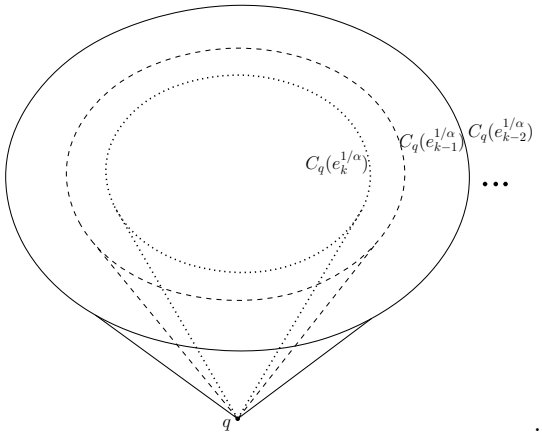

Figure 4 Partitioning $D_q(e_0^{1/\alpha}, e_k^{1/\alpha})$ into sub-shells.

the transmitters in S. Recall that $intrf(q) = \sum_{i=1}^{n-1} nrg(s_i, q)$ and that we wish to compute a value $\widetilde{intrf}(q)$ such that $intrf(q) \leq \widetilde{intrf}(q) \leq (1+\varepsilon) intrf(q)$. We will need the following simple observation.

▶ **Observation 10.** *$intrf(q)$ is the sum of $n-1$ positive terms of which $nrg(s_1, q)$ is the largest, so we have $nrg(s_1, q) \leq intrf(q) \leq (n-1) nrg(s_1, q) \leq n \cdot nrg(s_1, q)$.*

Query algorithm. Let q be a query point. First, we find s and s_1, as defined above. Next, we set $e_0 = \frac{\varepsilon}{2n} nrg(s_1, q)$, and divide the transmitters in $S \setminus \{s\}$ into two subsets, S_c and S_f, where S_c consists of the transmitters with signal strength at q greater than e_0, and S_f of the remaining ones. We now approximate the overall contribution to $intrf$ of the transmitters in S_f and in S_c separately and let $\widetilde{intrf}$ be the sum of the two approximations.

The contribution of a single transmitter $s_i \in S_f$ to the sum $intrf(q)$ is $nrg(s_i, q) \leq e_0 = \frac{\varepsilon}{2n} nrg(s_1, q)$, for a total of at most $|S_f| \cdot \frac{\varepsilon}{2n} nrg(s_1, q) \leq \frac{\varepsilon}{2} nrg(s_1, q)$ over all of S_f.

We identify the plane containing the transmitters and receivers with the xy-plane in $\mathbb{R}^3$. Let $C_q(\rho)$ denote (the surface of) the vertical cone with apex q whose z-coordinate at $t = (t_x, t_y)$ is $\rho|qt|$, where $\rho > 0$ is a constant. Let $D_q(\rho_1, \rho_2)$, $\rho_2 > \rho_1 > 0$, be the set of all points in 3-space lying above (i.e., in the interior of) the cone $C_q(\rho_1)$ and below or on (i.e., not in the interior of) the cone $C_q(\rho_2)$. Informally, $D_q(\rho_1, \rho_2)$ is the region between $C_q(\rho_1)$ and $C_q(\rho_2)$; we call it a *(conical) shell*.

Recall that $e_0 = \frac{\varepsilon}{2n} nrg(s_1, q)$. Let $e_i = (1 + \frac{\varepsilon}{2}) e_{i-1}$, for $i = 1, \ldots, k-1$, where $k-1$ is the largest integer for which $e_i < nrg(s_1, q)$, and set $e_k = nrg(s_1, q)$. We partition the range $I = (e_0, e_k]$ of signal strengths at q into k sub-ranges, $I_1 = (e_0, e_1], I_2 = (e_1, e_2], \ldots, I_k = (e_{k-1}, e_k]$, and count, for each sub-range I_j, the number of transmitters whose signal strength at q lies in I_j.

Consider a sub-range $I_j = (e_{j-1}, e_j]$; we want to count the number transmitters whose signal strength at q lies in I_j. This occurs whenever $e_{j-1}^{1/\alpha} |qs_i| < p_i^{1/\alpha} \leq e_j^{1/\alpha} |qs_i|$, or whenever the point $(s_i, p_i^{1/\alpha})$ in $\mathbb{R}^3$ lies in the shell $D_q(e_{j-1}^{1/\alpha}, e_j^{1/\alpha})$. Thus, we have reduced the problem to the difference of two conical range-counting queries.

We raise each of the transmitters $s_i \in S \setminus \{s\}$ to height $p_i^{1/\alpha}$, and preprocess the resulting set of points for conical range counting queries. If the number of points in the shell corresponding to I_j is x_j, then we add the term $e_j x_j$ to our approximation of $intrf(q)$, that is, we approximate the contribution of each transmitter s_i whose corresponding point lies in

the shell by e_j. (This corresponds to vertically projecting the point $(s_i, p_i^{1/\alpha})$ onto the cone $C_q(e_j^{1/\alpha})$.) We prove in the complete version [2] that this yields a $(1+\frac{\varepsilon}{2})$-approximation of the overall contribution of the transmitters in S_c to $intrf(q)$.

It remains to show that $\widetilde{intrf}(q)$, which is the sum of the approximations for S_f and for S_c, satisfies the requirements, i.e., that $intrf(q) \leq \widetilde{intrf}(q) \leq (1+\varepsilon)intrf(q)$. From the description above it is clear that $\widetilde{intrf}(q) \geq intrf(q)$, so we only need to establish the upper bound. Indeed, using Observation 10, we conclude that

$$\widetilde{intrf}(q) \leq \frac{\varepsilon}{2|qs_1|^\alpha} + (1+\frac{\varepsilon}{2}) \sum_{s_i \in S_C} nrg(s_i, q) \leq \frac{\varepsilon}{2} intrf(q) + (1+\frac{\varepsilon}{2}) intrf(q) = (1+\varepsilon) intrf(q) \ .$$

Implementation. A straightforward calculation shows (analogously to Lemma 5) that k, the number of shells into which $D_q(e_0^{1/\alpha}, e_k^{1/\alpha})$ is partitioned, is $O(\frac{1}{\varepsilon}\log n)$.

We preprocess the set of raised transmitters for cone range reporting/counting queries. Then, given a query point q, we find s and s_1 as follows. Pick a random sample T of $\sqrt{n}\log n$ transmitters and let $t_1 \in T$ be the transmitter whose signal strength at q is the strongest. With high probability, the number of transmitters in S that are closer to q than t_1 in terms of signal strength at q is $O(\sqrt{n})$, and we perform a range reporting query with the cone C_1 corresponding to t_1 in order to find them. The closest and second-closest points among the reported points are clearly s and s_1.

As for shell range counting queries, for each such query we issue two cone range counting queries – with the outer cone and the inner cone – and return the difference of the answers.

We omit the analysis of this version, since we describe below a more efficient variant, in which cones are replaced by pyramids.

3.2 Pyramidal shells

We now replace the conical shells by pyramidal ones to obtain an improved solution. Set $x = (1+\frac{\varepsilon}{2})^{\frac{1}{\alpha}}$, and consider any three cones $C_q(\rho_0)$, $C_q(\rho_1)$ and $C_q(\rho_2)$ with apex at q, such that $\rho_0/\rho_1 = \rho_1/\rho_2 = \sqrt{x}$. Let $P_q(\rho_i)$ be a regular l-pyramid inscribed in $C_q(\rho_i)$, where $l = \lceil \frac{\pi}{\sqrt{2-\frac{2}{\sqrt{x}}}} \rceil$. That is, $P_q(\rho_i)$'s apex is at q, its edges emanating from q are contained in (the surface of) $C_q(\rho_i)$, and the cross section of $P_q(\rho_i)$ and $C_q(\rho_i)$, using any horizontal cutting plane above q, is a regular l-gon and its circumcircle, respectively. The *pyramidal shell* defined by $P_q(\rho_2)$ and $P_q(\rho_1)$ and denoted $PS_q(\rho_2, \rho_1)$ is the semi-open region consisting of all points in the interior of $P_q(\rho_2)$ but not in the interior of $P_q(\rho_1)$. From Claim 7 and the observation above, it follows that $C_q(\rho_{i-1})$ is contained in $P_q(\rho_i)$, for $i = 1, 2$, and therefore, $PS_q(\rho_2, \rho_1)$ is contained in $D_q(\rho_2, \rho_0)$.

Query algorithm. We highlight the differences with the conical-shell based approach. First, we find s and s_1, the closest and the second-closest transmitters to q, respectively, as described in detail below. Previously, the transmitters were divided into two subsets lying close to q and lying far from it, with the threshold $e_0 = \frac{\varepsilon}{2n} \cdot nrg(s_1, q)$. Here, we set $e_0' = \frac{nrg(s_1,q)}{x^{m/2}}$, where m is the smallest integer for which $\frac{nrg(s_1,q)}{x^{m/2}} \leq \frac{e_0}{\sqrt{x}}$, and consider a transmitter close to q whenever it lies in the interior of the pyramid $P_q(e_0'^{\frac{1}{\alpha}})$, i.e., the pyramid inscribed in $C_q(e_0'^{\frac{1}{\alpha}})$. The contribution of a single transmitter $s_i \in S_f$ to the sum $intrf(q)$ is $nrg(s_i, q) \leq e_0 = \frac{\varepsilon}{2n} \cdot nrg(s_1, q)$, for a total of at most $\frac{\varepsilon}{2|qs|^\alpha}$, as before.

Consider the conical shell $D_q(e_0'^{\frac{1}{\alpha}}, nrg(s_1, q)^{\frac{1}{\alpha}})$ and partition it into m conical shells, such that the ratio between the parameters of the inner and outer cone of a shell is $\sqrt{x}$. For each

of the $m+1$ cones defining these conical shells, draw its inscribed regular l-pyramid. Let $P_q(\rho_1), ..., P_q(\rho_{m+1})$ be the resulting sequence of pyramids, where $P_q(\rho_1)$ is the innermost one, and consider the corresponding sequence of m nested pyramidal shells. Notice that $m = O(k)$, where k is the number of cones in the conical shells version, so once again $m = O(\frac{1}{\varepsilon}\log n)$. Moreover, each of the pyramidal shells, except for $PS_q(\rho_2, \rho_1)$, is contained in the union of two consecutive conical shells, which is a conical shell of ratio x. For $PS_q(\rho_2, \rho_1)$, we observe that $S_c \cap PS_q(\rho_2, \rho_1)$ is contained in the innermost conical shell.

We assign a transmitter s_i to a shell $PS_q(\rho_{j+1}, \rho_j)$ if s_i lands in the shell after being raised to height $p_i^{1/\alpha}$. Now, for each shell $PS_q(\rho_{j+1}, \rho_j)$ and each $s_i \in S_c$ assigned to it, we estimate the contribution of s_i from above by $1/\rho_{j-1}^{\alpha}$, i.e., by projecting s_i onto the inner cone of the conical shell $D_q(\rho_{j+1}, \rho_{j-1})$ containing $PS_q(\rho_{j+1}, \rho_j)$. We obtain a $(1+\frac{\varepsilon}{2})$-approximation of the overall contribution of the transmitters in S_c to $intrf(q)$, where the missing details can be found in the complete version [2]. Adding our previous estimate for those in S_f yields the promised $\widetilde{intrf}(q)$.

Implementation. Observe that each regular l-pyramid $P_q(\rho_j)$ is the union of l 3-sided wedges, where the ith wedge is defined by two planes of fixed orientation (perpendicular to the xy-plane) and a third plane containing the ith face of the pyramid.

In the preprocessing stage we construct l data structures over the set S, one for each family of wedges, supporting dynamic 3-dimensional 3-sided wedge range counting queries (a restricted form of simplex range counting in three dimensions). Each data structure handles wedges of the same "type"; the orientations of the two vertical bounding planes are fixed, while the orientation of the third plane varies (but remains perpendicular to the vertical plane bisecting the first two). The data structure for the ith family is a three-level search structure, where the first two levels allow us to represent the points of S that lie in the 2-sided wedge formed by the two vertical planes delimiting our 3-sided wedge, as a small collection of canonical subsets. For each canonical subset of the second level of the structure, we raise each of its points s_i to height $p_i^{1/\alpha}$ and then project it onto a vertical plane which is parallel to the bisector of the two vertical wedge boundaries. Finally, we construct for the resulting set of points a data structure for two-dimensional halfplane range counting queries. We will also need the corresponding reporting structure, see below.

Using standard tools for dynamic multilevel structures and, for example, Matoušek's data structure for halfplane range counting at the bottom level, we obtain a structure of $O(n \operatorname{polylog} n)$ size that supports wedge counting (and reporting) queries in $O(n^{1/2} \operatorname{polylog} n)$ time and updates in $O(\operatorname{polylog} n)$ amortized time.

Now, given a pyramidal shell $PS_q(\rho_{j+1}, \rho_j)$, we can count the number of raised points that lie in it as follows. We first perform l queries for the pyramid $P_q(\rho_{j+1})$, one in each of the l data structures, to obtain the total number of points that lie in it. We repeat the process for the pyramid $P_q(\rho_j)$ and finally subtract the latter number from the former one.

Below we describe how to find s and s_1, the closest and second-closest points to q, in randomized $O(\sqrt{n}\log n)$ time w.h.p. plus l wedge reporting queries. Once again, an update is performed by modifying the underlying data structures. We summarize the main result of this section.

▶ **Theorem 11.** *One can preprocess n arbitrary-power transmitters, in $O(\frac{n}{\sqrt{\varepsilon}} \operatorname{polylog} n)$ time and space, into a data structure that can answer approximate SINR queries in randomized $O(\frac{\sqrt{n}}{\sqrt{\varepsilon}} \operatorname{polylog} n)$ time w.h.p. and perform updates in $O(\frac{1}{\sqrt{\varepsilon}} \operatorname{polylog} n)$ amortized time.*

Finding the closest and second-closest transmitters to q. We have assumed that given a query point q, we can find the closest s and second-closest s_1 transmitters to q, efficiently. This section deals with this initial stage.

We begin by observing that we do not really need to find s_1, provided that we can obtain a sufficiently good approximation of $nrg_1 = nrg(s_1, q)$. Let $\widetilde{nrg}_1 \in \mathbb{R}$ such that $\widetilde{nrg}_1 \leq nrg_1 \leq (1+\delta)\widetilde{nrg}_1$, where $\delta > 0$ is a sufficiently small constant. Then, it is easy to modify our query algorithm so that it uses $\widetilde{nrg}_1$ instead of nrg_1. For simplicity of presentation, we refer in this paragraph to the algorithm using conical shells. Set $\tilde{e}_0 = \frac{\varepsilon}{2n}\widetilde{nrg}_1$. A transmitter will be considered close to q if and only if its signal strength at q is greater than $\tilde{e}_0$. If $s_i \in S$ is far from q, then $nrg(s_i, q) \leq \tilde{e}_0 \leq \frac{\varepsilon}{2n} nrg_1 = \frac{\varepsilon}{2n} nrg(s_1, q)$, so the overall contribution of the transmitters in S_f is bounded by $\frac{\varepsilon}{2} nrg(s_1, q)$, as before. Next, we partition the range $I = (\tilde{e}_0, (1+\delta)\widetilde{nrg}_1]$ into $k = O(\frac{1}{\varepsilon}\log n)$ sub-ranges, such that the ratio between the extreme values of a sub-range is at most $1 + \varepsilon/2$ and proceed exactly as before.

We now describe how to find s. Our algorithm may or may not find s_1. However, if it does not find s_1, it returns a transmitter $t_1 \in S$ such that $nrg(t_1, q) \leq nrg(s_1, q) \leq (1+\delta) nrg(t_1, q)$, where $\delta > 0$ is a sufficiently small constant, so we can set $\widetilde{nrg}_1 = nrg(t_1, q)$ and apply the above modified query algorithm.

Pick a random sample T of $\sqrt{n}\log n$ transmitters and let $t_1 \in T$ be the transmitter whose signal strength at q is the strongest. This can be done in $O(\sqrt{n}\log n)$ time. With high probability the number of transmitters in S that are closer to q than t_1, in terms of signal strength at q, is $O(\sqrt{n})$.

We first lift each transmitter $s = (s_x, s_y) \in S$ to the point $\hat{s} = (s_x, s_y, p(s)^{1/\alpha})$. Draw the cone C_1 corresponding to t_1, i.e., the cone whose z-coordinate above point s is $nrg(t_1, q)^{1/\alpha}|qs| = (p(t_1)^{1/\alpha}/|qt_1|)|qs|$. Let l be as above and consider the l-pyramid P_1 inscribed in C_1. Let C_0 be the cone inscribed in P_1, so that P_1 lies between C_0 and C_1. Notice that C_0 is the cone whose z-coordinate above point s is $(1+\delta) nrg(t_1, q)^{1/\alpha}|qs|$ (where we set $\delta = (1+\frac{\varepsilon}{2})^{\frac{1}{2\alpha}} - 1$).

Perform a range reporting query with P_1 (i.e., find all lifted points that lie in the interior of P_1 or on P_1). Since P_1 is inside C_1, with high probability the number of points in P_1 is $O(\sqrt{n})$. If the resulting set is non-empty, then in randomized $O(\sqrt{n})$ time w.h.p. we can find s and also s_1 (provided the number of returned points is greater than 1).

Otherwise, if P_1 is empty, we claim that the answer to the SINR query must be NO, i.e., q cannot receive any transmitter. Indeed, in the best scenario $\hat{s}$ lies on C_0, where $s \in S$ is the closest transmitter to q, and the rest of the $O(\sqrt{n})$ transmitters, lifted to 3-space, lie on the cone C_1. But this will imply that $sinr(s) < 1$. Indeed $nrg(s, q) = (1+\delta)^\alpha nrg(t_1, q)$ and, for any other of the $\sqrt{n}$ transmitters s', $nrg(s', q) = nrg(t_1, q)$, implying $sinr(s) < (1+\delta)^\alpha/\sqrt{n} \ll 1$.

If only one point lies in P_1, then we use t_1 as an approximation of s_1 as described above.

4 Successive interference cancellation (SIC)

Fix a receiver location q. SIC is a technique that enables q to receive a specific transmitter t, even when $sinr(q, t) < \beta$. More specifically, order the transmitters $s_1, \ldots, s_n$ in S by increasing signal strength at q, assume $t = s_k$, and let $sinr_i(q)$ denote the SIN ratio for the signal of s_i at q, while ignoring transmitters $s_1, \ldots, s_{i-1}$. If $sinr_1(q) = sinr(q, s_1) \geq \beta$, q can subtract s_1's signal from the combined signal. If, in addition, $sinr_2(q) \geq \beta$, q can also subtract s_2 from the combined signal of the transmitters $s_2, \ldots, s_n$, and so on. If $sinr_i(q) \geq \beta$, for $i = 1, \ldots, k$, we say that *SIC succeeds for s_k at q, in k rounds*. We can simulate this process using our data structures for approximate SINR queries via a sequence

of k queries and $k-1$ deletions, and determine (approximately) whether SIC succeeds for s_k at q. Observe that we need t only to terminate the query, while Avin et al. [4] need t to identify the part of the data structure in which to initiate the search; in particular, we can generate all the transmitters accessible via SIC given a location q in polylogarithmic time per transmitter, while they need to consult each of the n parts of the data structure. We obtain the following theorem.

▶ **Theorem 12.** *Assuming $t = s_k$, the simulation above can be performed in $O((1/\varepsilon^{3/2})k \operatorname{polylog} n)$ time in the uniform-power version, and in $O((1/\sqrt{\varepsilon})k\sqrt{n} \operatorname{polylog} n)$ time in the non-uniform version.*

Abstract

Motivated by possible applications in fault-tolerant routing, we introduce the notion of uniform mixed equilibria in network congestion games with adversarial link failures, where players need to route traffic from a source to a destination node. Given an integer $\rho \geq 1$, a ρ-uniform mixed strategy is a mixed strategy in which a player plays exactly ρ edge disjoint paths with uniform probabilities, so that a ρ-uniform mixed equilibrium is a tuple of ρ-uniform mixed strategies, one for each player, in which no player can lower her cost by deviating to another ρ-uniform mixed strategy. For games with weighted players and affine latency functions, we show existence of ρ-uniform mixed equilibria and provide a tight characterization of their price of anarchy. For games with unweighted players, instead, we extend the existential guarantee to any class of latency functions and, restricted to games with affine latencies, we derive a tight characterization of both the prices of anarchy and stability.

1 Introduction

Consider n users who need to send an unsplittable amount of traffic from a source to a destination in a network which is subject to adversarial link failures. In particular, each user u_i is coupled with an adversary a_i who, upon knowledge of the mixed strategy adopted by u_i to route her traffic, chooses which links to corrupt. Thus, every pair (u_i, a_i) is engaged in a two-player Stackelberg game in which u_i is the leader, a_i is the follower, and both are interested in the probability that the path selected by u_i as a realization of her mixed strategy fails: u_i wants to minimize it, while a_i aims at its maximization[1]. To make things more

[1] We stress that a_i is only aware of the mixed strategy chosen by u_i and not of its final realization.

interesting, all users also play an atomic congestion game among themselves, in which each of them wants to minimize the expected latency of the chosen mixed strategy. We assume that a user's priority is to route her traffic at any cost, so that she will be interested in selecting the mixed strategy of minimum expected latency among those minimizing the failure probability (of its realization). It is not difficult to see that u_i minimizes this probability if and only if she assigns uniform probabilities to the maximum number of edge disjoint paths connecting her source-destination pair.

Motivated by the above scenario, we introduce the notion of uniform mixed equilibrium for (network) congestion games (with adversarial link failures). Formally, given an integer $\rho \geq 1$, a ρ-uniform mixed strategy is a mixed strategy in which exactly ρ edge disjoint paths are chosen with uniform probabilities. Thus, given an n-tuple of positive integers $\boldsymbol{\rho} = (\rho_1, \ldots, \rho_n)$, a $\boldsymbol{\rho}$-uniform mixed profile is a mixed profile in which each user u_i adopts a ρ_i-uniform mixed strategy and a $\boldsymbol{\rho}$-uniform mixed equilibrium is a $\boldsymbol{\rho}$-uniform mixed profile in which no user u_i can lower her cost by deviating to another ρ_i-uniform mixed strategy.

As a first step in the understanding of the properties of these equilibria, we assume that $\rho_i = \rho_j := \rho$ for every pair of users u_i and u_j, and we denote $\boldsymbol{\rho} = (\rho, \ldots, \rho)$ simply as ρ. Besides defining a simple, yet interesting case, this assumption has at least two practical applications/justifications. First, it models the case of symmetric games, in which all users share the same source-destination pair; this setting has been widely studied with respect to the analysis of efficiency of Nash equilibria [21] and to the (hardness of) computation of equilibria [17, 16]. From a theoretical point of view, it is worth noting that, in this case, the value of ρ, i.e. the maximum number of edge disjoint paths connecting the common source-destination pair, can be efficiently computed by a reduction to the max-flow problem (see [1] for further details). To illustrate the second application, observe that the desire to minimize the failure probability induces each user to add even extremely costly paths to the set of her possible alternatives. It is reasonable to assume that, in some contexts, users' priorities can be restated as follows: each user wants to select the mixed strategy of minimum expected latency among those keeping the failure probability within a certain threshold θ. For the ease of exposition, assume that the adversary can corrupt just one link and that $\theta = 1/3$. By simple calculations, it is not difficult to establish that the best strategy for each user is to play $\rho = 3$ edge disjoint paths with probability $1/3$ each.

We stress that, although the notions of 1-uniform mixed equilibria and that of pure Nash equilibria [26] coincide, there are no correlations between the set of ρ-uniform mixed equilibria and that of mixed Nash equilibria of a given game when $\rho > 1$. Moreover, for $\rho > 1$, ρ-uniform mixed strategies can be interpreted as an hybridization between the notions of pure and mixed strategies. In fact, although the cost incurred by a player needs to be evaluated in expectation (as it happens when adopting mixed strategies), the fact that probabilities are superimposed by the model limits the players' choices to deciding which strategies to play (as it happens when adopting pure strategies). To the best of our knowledge, this is the first attempt towards this direction.

1.1 Our Contribution

We study the existence and efficiency of ρ-uniform mixed equilibria in (network) congestion games by distinguish between the case in which all players need to route the same amount of traffic (*unweighted congestion games*) and the general case of different traffic rates (*weighted congestion games*). In particular, we focus on networks in which the link latency functions are affine (*affine congestion games*).

Table 1 The prices of anarchy and stability of ρ-uniform mixed equilibria in affine unweighted congestion games and the price of anarchy of ρ-uniform mixed equilibria in affine weighted congestion games, for each value of $\rho \geq 1$. Bounds labeled as $*$ holds also for parallel link networks with restricted strategies, while bounds labeled as † applies to even parallel link networks with unrestricted strategies.

ρ	unweighted games		weighted games
	price of stability	price of anarchy	price of anarchy
1	$1+1/\sqrt{3}$ [11, 13]	$5/2^*$ [3, 11, 14]	$(3+\sqrt{5})/2^\dagger$[3, 5, 11, 14]
2	$1+1/\sqrt{5}$	$5/3^*$	$2^\dagger$
3	$1+1/\sqrt{7}$	$(2\sqrt{7}-1)/3^*$	$(7+\sqrt{13})/6^\dagger$
4	$4/3^\dagger$	$4/3^\dagger$	$(9+\sqrt{17})/8^\dagger$
≥ 5	$4/3^\dagger$	$4/3^\dagger$	$4\rho^2/(3\rho^2-2\rho-1)^\dagger$

We first prove that ρ-uniform mixed equilibria do exist in affine weighted congestion games, for each $\rho \geq 1$. This is done by showing that any affine weighted congestion game in which players adopt ρ-uniform mixed strategies admits a potential function. This generalizes to every value of ρ the results by [21, 22, 27] which were proved for the classical setting in which players adopt pure strategies, i.e., for $\rho = 1$. For the case of unweighted players, existential guarantees are extended to any class of latency functions. This generalizes Rosenthal's Theorem [30] which shows existence of pure Nash equilibria, i.e., existence of ρ-uniform mixed equilibria for the basic case of $\rho = 1$.

Then, for each $\rho \geq 1$, by exploiting the primal-dual method [6], we derive tight bounds on the price of anarchy of ρ-uniform mixed equilibria in affine weighted congestion games and tight bounds on both the prices of anarchy and stability of ρ-uniform mixed equilibria in affine unweighted congestion games (see the values reported in Table 1, where many lower bounds hold even for parallel link networks). It is worth noticing that our results nicely extend the ones obtained for pure Nash equilibria, i.e., the case of $\rho = 1$. In particular, for unweighted congestion games with affine latency functions, [13] proved that the price of stability is lower bounded by $1+1/\sqrt{3}$, while [11] showed that this bound is tight; [3, 14] proved that the price of anarchy is $5/2$ and [11] showed that the same (lower) bound extends to the special case of parallel link networks with restricted strategies (i.e., every player can only select a link from an allowable set of alternatives). For weighted congestion games with linear latency functions, [3, 14] proved that the price of anarchy is $(3+\sqrt{5})/2$, [11] showed that the same (lower) bound extends to the special case of parallel link networks with restricted strategies, and finally [5] proved that even parallel link networks with unrestricted strategies are enough to obtain a matching lower bound. The existential guarantee, as well as the bounds for unweighted games, are obtained by exploiting the fact that, for each $\rho \geq 1$, any unweighted congestion game in which players adopt ρ-uniform mixed strategies is isomorphic to an unweighted congestion game in which players adopt pure strategies and whose latency functions are slightly different.

Our results show that, as ρ increases, the prices of anarchy and stability of ρ-uniform mixed equilibria of affine congestion games approach the value $4/3$, that is, the price of anarchy of affine non-atomic congestion games [32]. This is in accordance with the intuition that, by arbitrarily splitting an atomic request over disjoint strategies, atomic congestion games tend to their non-atomic counterparts. The striking evidence of our findings, however, is that, for unweighted players, when such a splitting is restricted to be uniform (i.e., the same amount of traffic must be routed on each selected path), this happens for $\rho = 4$ already.

1.2 Related Work

Penn, Polukarov and Tennenholtz [28, 29] introduced congestion games with failures. In their model, each player has a task that can be executed on any resource, i.e. players only adopt singleton strategies, and each resource may fail with a certain probability, hence, for reliability reasons, a player may choose to simultaneously use multiple resources. The cost of a player is given by the minimum of the costs payable on all the selected resources that do not fail. In this setting, the existence, properties and efficiency of pure Nash equilibria are investigated.

The setting of adversarial behavior in congestion games was introduced by Karakostas and Viglas [23] for network congestion games. Babaioff, Kleinberg and Papadimitriou [4] studied the impact of malicious players on the quality of Nash equilibria for non-atomic games. In particular, [4, 23] considered two classes of players, i.e., rational players and malicious players; while rational players act aiming at minimizing their own cost, malicious ones aim at maximizing the average delay experienced by the rational players. Roth [31] applied this adversarial setting to the class of linear congestion games. Also Moscibroda et al. [25] analyzed an adversarial behavior in a different game.

1.3 Paper Organization

The paper is organized as follows. In the next section we provide the notation and definitions, together with some basic results. Section 3 is devoted to the study of affine weighted congestion games, while Section 4 to the analysis of the unweighted case. Finally, Section 5 gives some conclusive remarks and lists some interesting open problems. Due to space limitations, some proofs are omitted (see the full version of the paper).

2 Definitions and Notation

Given two integers $0 \leq k_1 \leq k_2$, let $[k_2]_{k_1}$ denote the set $\{k_1, k_1+1, \ldots, k_2-1, k_2\}$ and let $[k_1]$ denote the set $[k_1]_1$. Moreover, let $\vec{1}^n$ denote the vector $(1, \ldots, 1) \in \mathbb{R}^n_{\geq 0}$.

A *weighted congestion model* is defined by a tuple $\mathsf{CM} = (\mathsf{N}, E, (\ell_e)_{e\in E}, (w_i)_{i\in\mathsf{N}}, (\Sigma_i)_{i\in\mathsf{N}})$, where N is a set of $n \geq 2$ players, E is a set of resources, $\ell_e : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ is the latency function of resource $e \in E$, and, for each $i \in \mathsf{N}$, $w_i \geq 0$ is the weight of player i and $\Sigma_i \subseteq 2^E \setminus \emptyset$ is her set of strategies. A weighted congestion model is *symmetric* if $\Sigma_i = \Sigma$ for each $i \in \mathsf{N}$, i.e., if all players share the same strategy space. A *weighted load balancing model* is a weighted congestion model in which for each $i \in \mathsf{N}$ and $S \in \Sigma_i$, $|S| = 1$, that is, all players' strategies are singleton sets. Observe that a weighted load balancing model corresponds to a parallel link network. A weighted congestion model is *affine* if its latency functions are of the form $\ell_e(x) := \alpha_e x + \beta_e$, with $\alpha_e, \beta_e \geq 0$. An *unweighted congestion model* is a weighted congestion model such that $w_i = 1$ for each $i \in \mathsf{N}$.

Depending on the types of strategies adopted by the players, a congestion model CM may induce different classes of congestion games.

A *strategy profile* is an n-tuple of strategies $\boldsymbol{s} = (s_1, s_2, \ldots, s_n)$, that is a state in which each player $i \in \mathsf{N}$ adopts pure strategy $s_i \in \Sigma_i$. When players adopt pure strategies, CM induces a congestion game $\mathsf{CG}(\mathsf{CM})$ (usually, when CM is clear from the context, we shall drop it from the notation). For a strategy profile $\boldsymbol{s}$, the *congestion* of resource $e \in E$ in $\boldsymbol{s}$, denoted as $k_e(\boldsymbol{s}) := \sum_{i\in\mathsf{N}: e\in s_i} w_i$, is the total weight of the players using resource e in $\boldsymbol{s}$, (observe that, for unweighted games, $k_e(\boldsymbol{s})$ coincides with the number of users selecting resource e in $\boldsymbol{s}$). The

cost of player i in $\boldsymbol{s}$ is defined as $cost_i^{\mathsf{CG}}(\boldsymbol{s}) = \sum_{e \in s_i} \ell_e(k_e(\boldsymbol{s}))$ (usually, when CG is clear from the context, we shall drop it from the notation). The quality of a strategy profile in $\mathsf{CG}(\mathsf{CM})$ is measured by using the *social function* $\mathsf{SUM}(\boldsymbol{s}) = \sum_{i \in \mathsf{N}} w_i cost_i(\boldsymbol{s}) = \sum_{e \in E} k_e(\boldsymbol{s})\ell_e(k_e(\boldsymbol{s}))$, that is, the weighted sum of the players' costs. A *pure Nash equilibrium* for $\mathsf{CG}(\mathsf{CM})$ is a strategy profile $\boldsymbol{s}$ such that, for any player $i \in \mathsf{N}$ and strategy $s_i' \in \Sigma_i$, $cost_i(\boldsymbol{s}) \leq cost_i(\boldsymbol{s}_{-i}, s_i')$. We denote by $\mathsf{Eq}(\mathsf{CG}(\mathsf{CM}))$ the set of pure Nash equilibria of a weighted congestion game $\mathsf{CG}(\mathsf{CM})$. The *price of anarchy* (resp. *price of stability*) of a weighted congestion game $\mathsf{CG}(\mathsf{CM})$ is defined as $\mathsf{PoA}(\mathsf{CG}(\mathsf{CM})) = \max_{\boldsymbol{s} \in \mathsf{Eq}(\mathsf{CG}(\mathsf{CM}))} \left\{ \frac{\mathsf{SUM}(\boldsymbol{s})}{\mathsf{SUM}(\boldsymbol{s}^*)} \right\}$ (resp. $\mathsf{PoS}(\mathsf{CG}(\mathsf{CM})) = \min_{\boldsymbol{s} \in \mathsf{Eq}(\mathsf{CG}(\mathsf{CM}))} \left\{ \frac{\mathsf{SUM}(\boldsymbol{s})}{\mathsf{SUM}(\boldsymbol{s}^*)} \right\}$), where $\boldsymbol{s}^*$ is a *social optimum* for $\mathsf{CG}(\mathsf{CM})$, that is a strategy profile minimizing the social function.

A mixed strategy for player i is a probability distribution σ_i defined over Σ_i, so that $\sigma_i(s)$ is the probability that player i plays strategy $s \in \Sigma_i$. We denote by $\mathsf{supp}(\sigma_i) = \{s \in \Sigma_i : \sigma_i(s) > 0\}$ the set of strategies played with positive probability in σ_i. A *mixed profile* $\boldsymbol{\sigma}$ is an n-tuple of mixed strategies, i.e., $\boldsymbol{\sigma} = (\sigma_1, \sigma_2, \ldots, \sigma_n)$. Informally, $\boldsymbol{\sigma}$ is a state in which each player $i \in \mathsf{N}$ picks her strategy according to probability distribution σ_i, independently from the choices of other players. If σ_i is such that a pure strategy s_i is picked with probability one by player i, we write s_i instead of σ_i.

Given an integer $\rho \geq 1$ and a weighted congestion model CM in which for each player $i \in N$ there exist at least ρ pairwise disjoint strategies in Σ_i, a *ρ-uniform mixed strategy* for player i is a mixed strategy σ_i such that $|\mathsf{supp}(\sigma_i)| = \rho$, $s_1 \cap s_2 = \emptyset$ for any $s_1, s_2 \in \mathsf{supp}(\sigma_i)$ with $s_1 \neq s_2$, and $\sigma_i(s) = 1/\rho$ for each $s \in \mathsf{supp}(\sigma_i)$, i.e., a mixed strategy in which player i plays exactly ρ pairwise disjoint strategies with uniform probability. Denote by $\Delta_i^{\rho}(\mathsf{CM})$ the set of ρ-uniform mixed strategies for player i. A *ρ-uniform mixed profile* $\boldsymbol{\sigma} = (\sigma_1, \sigma_2, \ldots, \sigma_n)$ is an n-tuple of ρ-uniform mixed strategies, one for each player. When players adopt *ρ-uniform mixed strategies*, CM induces a ρ-uniform congestion game ρ-$\mathsf{CG}(\mathsf{CM})$ (again, when CM is clear from the context, we shall drop it from the notation). For a ρ-uniform mixed profile $\boldsymbol{\sigma}$, the *expected congestion* of resource $e \in E$ in $\boldsymbol{\sigma}$, denoted as $k_e(\boldsymbol{\sigma}) := \mathbb{E}_{\boldsymbol{s} \sim \boldsymbol{\sigma}} \left(\sum_{i \in \mathsf{N} : e \in s_i} w_i \right)$, is the expected total weight of the players using resource e in $\boldsymbol{\sigma}$. The cost of player i in $\boldsymbol{\sigma}$ is defined as $cost_i^{\rho\text{-}\mathsf{CG}}(\boldsymbol{\sigma}) = \mathbb{E}_{\boldsymbol{s} \sim \boldsymbol{\sigma}} \left(\sum_{e \in s_i} \ell_e(k_e(\boldsymbol{s})) \right)$ (again, when ρ-CG is clear from the context, we shall drop it from the notation). The quality of a ρ-uniform mixed profile in ρ-$\mathsf{CG}(\mathsf{CM})$ becomes $\mathsf{SUM}(\boldsymbol{\sigma}) = \mathbb{E}_{\boldsymbol{s} \sim \boldsymbol{\sigma}} \left(\sum_{i \in \mathsf{N}} w_i cost_i(\boldsymbol{s}) \right) = \sum_{e \in E} \mathbb{E}_{\boldsymbol{s} \sim \boldsymbol{\sigma}} \left(k_e(\boldsymbol{s})\ell_e(k_e(\boldsymbol{s})) \right)$, that is, the expected weighted sum of the players' costs. A *ρ-uniform mixed equilibrium* for ρ-$\mathsf{CG}(\mathsf{CM})$ is a ρ-uniform mixed profile $\boldsymbol{\sigma}$ such that, for any player $i \in \mathsf{N}$ and ρ-uniform mixed strategy $\sigma_i' \in \Delta_i^{\rho}(\mathsf{CM})$, $cost_i(\boldsymbol{\sigma}) \leq cost_i(\boldsymbol{\sigma}_{-i}, \sigma_i')$. We denote by $\mathsf{Eq}(\rho\text{-}\mathsf{CG}(\mathsf{CM}))$ the set of ρ-uniform mixed equilibria of a weighted congestion game ρ-$\mathsf{CG}(\mathsf{CM})$. The price of anarchy (resp. price of stability) of a ρ-uniform weighted congestion game ρ-$\mathsf{CG}(\mathsf{CM})$ is defined as $\mathsf{PoA}_{\rho}(\rho\text{-}\mathsf{CG}(\mathsf{CM})) = \max_{\boldsymbol{\sigma} \in \mathsf{Eq}(\rho\text{-}\mathsf{CG}(\mathsf{CM}))} \left\{ \frac{\mathsf{SUM}(\boldsymbol{\sigma})}{\mathsf{SUM}(\boldsymbol{\sigma}^*)} \right\}$ (resp. $\mathsf{PoS}_{\rho}(\rho\text{-}\mathsf{CG}(\mathsf{CM})) = \min_{\boldsymbol{\sigma} \in \mathsf{Eq}(\rho\text{-}\mathsf{CG}(\mathsf{CM})} \left\{ \frac{\mathsf{SUM}(\boldsymbol{\sigma})}{\mathsf{SUM}(\boldsymbol{\sigma}^*)} \right\}$), where $\boldsymbol{\sigma}^*$ is a *ρ-uniform social optimum* for ρ-$\mathsf{CG}(\mathsf{CM})$, that is a ρ-uniform mixed profile minimizing the social function.

Given a ρ-uniform mixed strategy σ_i, let $E(\sigma_i) = \bigcup_{s \in \mathsf{supp}(\sigma_i)} s$ denote the set of resources contained by all strategies belonging to $\mathsf{supp}(\sigma_i)$[2]. For a ρ-uniform mixed profile $\boldsymbol{\sigma}$, the *ρ-maximum congestion* of resource e in $\boldsymbol{\sigma}$, denoted as $k_{\rho,e}(\boldsymbol{\sigma}) = \sum_{i : e \in E(\sigma_i)} w_i$, is the congestion of e obtained if all players assigning non-null probability to a strategy s containing e pick s.

[2] Given $e \in E(\sigma_i)$, there exists a unique strategy of σ_i containing e, since strategies selected with non-null probability by each player are pairwise disjoint.

▶ Remark. According to the first application described in Section 1, given a symmetric congestion model CM such that the maximum number of disjoint strategies is $\rho* > \rho$, we can consider a congestion model CM' such that $\mathsf{CG}(\mathsf{CM}')$ is equivalent to $\mathsf{CG}(\mathsf{CM})$, and such that the maximum number of disjoint strategies of $\mathsf{CG}(\mathsf{CM}')$ is ρ. To this aim, it suffices considering a congestion model CM' in which $E' := E \cup \{e'_1, e'_2, \ldots, e'_\rho\}$, where e'_j is a dummy resource with $\ell'(e'_j) = 0$ for any $j \in [\rho]$, $\Sigma_i{}' := \{s \cup \{e'_j\} : s \in \Sigma_i, j \in [\rho]\}$ for any $i \in \mathsf{N}$, and all the other quantities are defined as in CM. Observe that, given ρ-disjoint strategies $s_1, s_2, \ldots, s_\rho$ in Σ, we have that $s_1 \cup \{e'_1\}, s_2 \cup \{e'_2\}, \ldots, s_\rho \cup \{e'_\rho\}$ are disjoint strategies of $\Sigma_i{}'$. Furthermore, there are no $\rho + 1$ disjoint strategies in $\Sigma_i{}'$, since, given $\rho + 1$ strategies of $\Sigma_i{}'$, there are necessarily at least two strategies $s'_1, s'_2 \in \Sigma_i{}'$ such that $e'_j \in s'_1 \cap s'_2$ for some $j \in [\rho]$. Thus, ρ is the maximum number of disjoint strategies in $\mathsf{CG}(\mathsf{CM}')$. Finally, since each strategy of $\Sigma_i{}'$ is defined as union of some strategy of Σ_i and some dummy resource having null cost, games $\mathsf{CG}(\mathsf{CM}')$ and $\mathsf{CG}(\mathsf{CM})$ are completely equivalent.

We conclude the section by providing useful equations to express the players' costs in ρ-uniform congestion games as a function of the ρ-maximum congestions only, thus getting rid of expected values. Towards this end, as shown in [6], we can assume without loss of generality that the latency functions of the games we consider are restricted to be linear, that is, of the form $\ell(x) = \alpha_e x$ for some $\alpha_e \geq 0$.

▶ **Lemma 1.** *Given an affine weighted congestion model* CM *and a* ρ*-uniform strategy profile* $\boldsymbol{\sigma}$ *for* ρ-$\mathsf{CG}(\mathsf{CM})$*, we have*

$$cost_i(\boldsymbol{\sigma}) = \sum_{e \in E(\sigma_i)} \alpha_e \left(\frac{k_{\rho,e}(\boldsymbol{\sigma})}{\rho^2} + \left(\frac{\rho - 1}{\rho^2} \right) w_i \right) \tag{1}$$

and, given $\sigma'_i \in \Delta_i^\rho(\mathsf{CM})$*, we have*

$$\begin{aligned} cost_i(\boldsymbol{\sigma}_{-i}, \sigma'_i) &= \sum_{e \in E(\sigma'_i) \setminus E(\sigma_i)} \alpha_e \left(\frac{k_{\rho,e}(\boldsymbol{\sigma})}{\rho^2} + \frac{w_i}{\rho} \right) + \sum_{e \in E(\sigma'_i) \cap E(\sigma_i)} \alpha_e \left(\frac{k_{\rho,e}(\boldsymbol{\sigma})}{\rho^2} + \left(\frac{\rho - 1}{\rho^2} \right) w_i \right) \\ &\leq \sum_{e \in E(\sigma'_i)} \alpha_e \left(\frac{k_{\rho,e}(\boldsymbol{\sigma})}{\rho^2} + \frac{w_i}{\rho} \right). \end{aligned} \tag{2}$$

3 Weighted Games

In this section, we consider the general case of ρ-uniform congestion games induced by affine weighted congestion models. We start by showing that ρ-uniform mixed equilibria are always guaranteed to exist, for each $\rho \geq 1$. In particular, by resorting to a potential function argument, we prove that, for each affine weighted congestion model CM, any better-response dynamics in ρ-$\mathsf{CG}(\mathsf{CM})$ converges to a ρ-uniform mixed equilibrium after a finite number of steps.

▶ **Theorem 2.** *For each affine weighted congestion model* CM *and* $\rho \geq 1$*,* ρ-$\mathsf{CG}(\mathsf{CM})$ *admits a potential function.*

Proof. Given an affine weighted congestion model CM and an integer $\rho \geq 1$, consider the function Φ_ρ defined on the set of ρ-uniform mixed profiles for ρ-$\mathsf{CG}(\mathsf{CM})$:

$$\Phi_\rho(\boldsymbol{\sigma}) := \sum_{e \in E} \alpha_e \left(\frac{k_{\rho,e}(\boldsymbol{\sigma})^2}{2\rho^2} + \frac{2\rho - 1}{2\rho^2} \sum_{i : e \in E(\sigma_i)} w_i^2 \right). \tag{3}$$

We prove that Φ_ρ is a weighted potential function for ρ-CG. Fix a ρ-uniform mixed profile $\boldsymbol{\sigma}$, a player $i \in \mathsf{N}$, and a ρ-uniform mixed strategy $\sigma'_i \in \Delta_i^\rho(\mathsf{CM})$. Let $\mathbb{I}_e = 1$ if $e \in \sigma'_i \setminus \sigma_i$, $\mathbb{I}_e = -1$ if $e \in \sigma_i \setminus \sigma'_i$, $\mathbb{I}_e = 0$ if $e \in \sigma'_i \cap \sigma_i$. We have

$$
\begin{aligned}
&\Phi_\rho(\boldsymbol{\sigma}_{-i}, \sigma'_i) - \Phi_\rho(\boldsymbol{\sigma}) \\
&= \sum_{e \in E} \alpha_e \left(\frac{(k_{\rho,e}(\boldsymbol{\sigma}) + \mathbb{I}_e w_i)^2}{2\rho^2} + \frac{2\rho - 1}{2\rho^2} \left(\sum_{j : e \in E(\sigma_j)} w_j^2 + \mathbb{I}_e w_i^2 \right) \right) \\
&\quad - \sum_{e \in E} \alpha_e \left(\frac{k_{\rho,e}(\boldsymbol{\sigma})^2}{2\rho^2} + \frac{2\rho - 1}{2\rho^2} \sum_{j : e \in E(\sigma_j)} w_j^2 \right) \\
&= \sum_{e \in E(\sigma'_i) \setminus E(\sigma_i)} \alpha_e \left(\frac{(k_{\rho,e}(\boldsymbol{\sigma}) + w_i)^2 - k_{\rho,e}(\boldsymbol{\sigma})^2}{2\rho^2} + \frac{2\rho - 1}{2\rho^2} w_i^2 \right) \\
&\quad - \sum_{e \in E(\sigma_i) \setminus E(\sigma'_i)} \alpha_e \left(\frac{k_{\rho,e}(\boldsymbol{\sigma})^2 - (k_{\rho,e}(\boldsymbol{\sigma}) - w_i)^2}{2\rho^2} + \frac{2\rho - 1}{2\rho^2} w_i^2 \right) \\
&= \sum_{e \in E(\sigma'_i) \setminus E(\sigma_i)} \alpha_e w_i \left(\frac{k_{\rho,e}(\boldsymbol{\sigma})}{\rho^2} + \frac{1}{\rho} w_i \right) - \sum_{e \in E(\sigma_i) \setminus E(\sigma'_i)} \alpha_e w_i \left(\frac{k_{\rho,e}(\boldsymbol{\sigma})}{\rho^2} + \frac{\rho - 1}{\rho^2} w_i \right) \\
&= w_i(cost_i(\boldsymbol{\sigma}_{-i}, \sigma'_i) - cost_i(\boldsymbol{\sigma})), \qquad (4)
\end{aligned}
$$

where (4) comes from Lemma 1. Thus, Φ_ρ is a weighted potential function for ρ-CG(CM). ◀

3.1 Price of Anarchy

In this subsection, we derive exact bounds on the price of anarchy of ρ-uniform congestion games induced by affine weighted congestion models.

▶ **Theorem 3.** *Fix an affine weighted congestion model* CM. *For any $\rho \geq 1$, we have*

$$
\mathsf{PoA}_\rho(\rho\text{-CG}(\mathsf{CM})) \leq \begin{cases} \frac{\sqrt{4\rho+1}+2\rho+1}{2\rho} & \text{if } \rho < 5, \\ \frac{4\rho^2}{3\rho^2-2\rho-1} & \text{if } \rho \geq 5. \end{cases}
$$

Proof. Given an integer $\rho \geq 1$, let CM be an arbitrary affine weighted congestion model. Let $\boldsymbol{\sigma}$ and $\boldsymbol{\sigma}^*$ be a ρ-uniform mixed equilibrium and a ρ-uniform social optimum for ρ-CG(CM), respectively. By exploiting the primal-dual technique we get the following linear program:

$$
\begin{aligned}
\max \quad & \mathsf{SUM}(\boldsymbol{\sigma}) = \sum_{i \in \mathsf{N}} w_i cost_i(\boldsymbol{\sigma}) \\
\text{s.t.} \quad & \sum_{i \in \mathsf{N}} w_i cost_i(\boldsymbol{\sigma}) \leq \sum_{i \in \mathsf{N}} w_i cost_i(\boldsymbol{\sigma}_{-i}, \sigma_i^*) \qquad (5) \\
& \mathsf{SUM}(\boldsymbol{\sigma}^*) = \sum_{i \in \mathsf{N}} w_i cost_i(\boldsymbol{\sigma}^*) = 1 \qquad (6) \\
& \alpha_e \geq 0, \quad \forall e \in E
\end{aligned}
$$

where:

- (5) has been obtained by multiplying each inequality $cost_i(\boldsymbol{\sigma}) \leq cost_i(\boldsymbol{\sigma}_{-i}, \sigma_i^*)$ by w_i, and then summing them up for each $i \in \mathsf{N}$;
- the linear coefficients α_e's are the variables of the linear program, and the other quantities are fixed parameters;

- (6) normalizes the optimal social function, so that the maximum value of the objective function (i.e. the social function of the ρ-uniform mixed equilibrium) is an upper bound on the price of anarchy.

By using Lemma 1 in the previous linear program, we get the following relaxation (relaxation comes from inequality (2), that may not be tight):

$$\begin{aligned}
\mathsf{LP}: \quad \max \quad & \sum_{e\in E}\alpha_e\left(\frac{k_{\rho,e}(\boldsymbol{\sigma})^2}{\rho^2}+\left(\frac{\rho-1}{\rho^2}\right)\sum_{i:e\in E(\sigma_i)}w_i^2\right) && (7)\\
\text{s.t.} \quad & \sum_{e\in E}\alpha_e\left(\frac{k_{\rho,e}(\boldsymbol{\sigma})^2}{\rho^2}+\left(\frac{\rho-1}{\rho^2}\right)\sum_{i:e\in E(\sigma_i)}w_i^2\right)\leq\\
& \leq\sum_{e\in E}\alpha_e\left(\frac{k_{\rho,e}(\boldsymbol{\sigma}^*)k_{\rho,e}(\boldsymbol{\sigma})}{\rho^2}+\sum_{i:e\in E(\sigma_i^*)}\frac{w_i^2}{\rho}\right) && (8)\\
& \sum_{e\in E}\alpha_e\left(\frac{k_{\rho,e}(\boldsymbol{\sigma}^*)^2}{\rho^2}+\left(\frac{\rho-1}{\rho^2}\right)\sum_{i:e\in E(\sigma_i^*)}w_i^2\right)=1 && (9)\\
& \alpha_e\geq 0, \quad \forall e\in E
\end{aligned}$$

where (7) comes from (1), as $\sum_{i\in\mathsf{N}} w_i cost_i(\boldsymbol{\sigma}) = \sum_{i\in\mathsf{N}} w_i \sum_{e\in E(\sigma_i)}\alpha_e\left(\frac{k_{\rho,e}(\boldsymbol{\sigma})}{\rho^2}+\left(\frac{\rho-1}{\rho^2}\right)w_i\right) = \sum_{e\in E}\alpha_e\left(\frac{k_{\rho,e}(\boldsymbol{\sigma})^2}{\rho^2}+\left(\frac{\rho-1}{\rho^2}\right)\sum_{i:e\in E(\sigma_i)}w_i^2\right)$, and (8) comes from (2), as $\sum_{i\in\mathsf{N}} w_i cost_i(\boldsymbol{\sigma}_{-i},\sigma_i^*) \leq \sum_{i\in\mathsf{N}} w_i \sum_{e\in E(\sigma_i^*)}\alpha_e\left(\frac{k_{\rho,e}(\boldsymbol{\sigma})}{\rho^2}+\frac{w_i}{\rho}\right) = \sum_{e\in E}\alpha_e\left(\frac{k_{\rho,e}(\boldsymbol{\sigma}^*)k_{\rho,e}(\boldsymbol{\sigma})}{\rho^2}+\sum_{i:e\in E(\sigma_i^*)}\frac{w_i^2}{\rho}\right)$. By taking the dual of LP, where we associate the dual variable x to the primal constraint (8) and the dual variable γ to the primal constraint (9), we get

$$\begin{aligned}
\mathsf{DLP}: \quad \min \quad & \gamma\\
\text{s.t.} \quad & \gamma\left(\frac{k_{\rho,e}(\boldsymbol{\sigma}^*)^2}{\rho^2}+\left(\frac{\rho-1}{\rho^2}\right)\sum_{i:e\in E(\sigma_i^*)}w_i^2\right)\geq\\
& \geq -(x-1)\left(\frac{k_{\rho,e}(\boldsymbol{\sigma})^2}{\rho^2}+\left(\frac{\rho-1}{\rho^2}\right)\sum_{i:e\in E(\sigma_i)}w_i^2\right)+\\
& \quad + x\left(\frac{k_{\rho,e}(\boldsymbol{\sigma}^*)k_{\rho,e}(\boldsymbol{\sigma})}{\rho^2}+\sum_{i:e\in E(\sigma_i^*)}\frac{w_i^2}{\rho}\right), \quad \forall e\in E && (10)\\
& x\geq 0
\end{aligned}$$

By choosing $x>1$, we have that, if $k_{\rho,e}(\boldsymbol{\sigma}^*)=0$, (10) is always satisfied. Thus, assume that $k_{\rho,e}(\boldsymbol{\sigma}^*)>0$. Let us now manipulate (10) as follows: we divide both sides by $k_{\rho,e}(\boldsymbol{\sigma}^*)^2$, so that we can rewrite it as a function of a variable $t := k_{\rho,e}(\boldsymbol{\sigma})/k_{\rho,e}(\boldsymbol{\sigma}^*)$ and of some new player's weights $u_i = w_i/k_{\rho,e}(\boldsymbol{\sigma}^*)$. Furthermore, by setting $\sum_{i:e\in E(\sigma_i)} w_i^2 = 0$ we have stronger constraints. By observing that $\sum_{i:e\in E(\sigma_i^*)} w_i = k_{\rho,e}(\boldsymbol{\sigma}^*)$, and then $\sum_{i:e\in E(\sigma_i^*)} u_i = 1$,

we obtain that the following value $\gamma(x)$ is a feasible solution of DLP for any $x > 1$:[3]

$$\gamma(x) = \sup_{\left\{n\in\mathbb{N}, t\geq 0, u_i\geq 0, \sum_{i=1}^n u_i = 1\right\}} \frac{\frac{t^2}{\rho^2} + x\left(-\frac{t^2}{\rho^2} + \frac{t}{\rho^2} + \frac{1}{\rho}\sum_{i=1}^n u_i^2\right)}{\frac{1}{\rho^2} + \frac{\rho-1}{\rho^2}\sum_{i=1}^n u_i^2}.$$

Since $\sum_{i=1}^n u_i = 1$ and $u_i \geq 0$ for each $i \in [n]$, one can replace $\sum_{i=1}^n u_i^2$ with a variable $u \in [0,1]$, so that we can set $\gamma(x) = \sup_{t\geq 0, u\in[0,1]} \gamma(x,t,u)$, where

$$\gamma(x,t,u) = \frac{\frac{t^2}{\rho^2} + x\left(-\frac{t^2}{\rho^2} + \frac{t}{\rho^2} + \frac{u}{\rho}\right)}{\frac{1}{\rho^2} + \frac{\rho-1}{\rho^2}u}.$$

We have that the monotonicity of $\gamma(x,t,u)$ with respect to u does not depend on u, thus $\gamma(x,t,u)$ is maximized either by $u = 0$ or by $u = 1$. So, we get $\gamma(x) = \sup_{t\geq 0, u\in\{0,1\}} \gamma(x,t,u)$. Note that $t = \frac{x}{2x-2}$ is the unique maximum point of $\gamma(x,t,u)$ for $u \in \{0,1\}$. Thus, we can conclude

$$\gamma(x) = \max\left\{\gamma\left(x, \frac{x}{2x-2}, 0\right), \gamma\left(x, \frac{x}{2x-2}, 1\right)\right\}.$$

Now, if $\rho < 5$, set $x = 1 + \frac{1}{\sqrt{4\rho+1}}$, otherwise set $x = \frac{4\rho}{3\rho+1}$. If $\rho < 5$, we get

$$\gamma\left(1 + \frac{1}{\sqrt{4\rho+1}}\right) = \frac{\sqrt{4\rho+1} + 2\rho + 1}{2\rho} \geq \mathsf{PoA}_\rho(\rho\text{-CG}),$$

otherwise, for $\rho \geq 5$, we get

$$\gamma\left(\frac{4\rho}{3\rho+1}\right) = \frac{4\rho^2}{3\rho^2 - 2\rho - 1} \geq \mathsf{PoA}_\rho(\rho\text{-CG}),$$

thus showing the claim. ◀

We show that the derived upper bounds are tight, even when restricting to games induced by symmetric load balancing models.

▶ **Theorem 4.** *For any $\rho \geq 1$ and $\epsilon > 0$, there exists an affine weighted symmetric load balancing model $\mathsf{CM} := \mathsf{CM}(\rho,\epsilon)$ such that*

$$\mathsf{PoA}_\rho(\rho\text{-CG}(\mathsf{CM})) \geq \begin{cases} \frac{\sqrt{4\rho+1}+2\rho+1}{2\rho} - \epsilon & \text{if } \rho < 5, \\ \frac{4\rho^2}{3\rho^2-2\rho-1} - \epsilon & \text{if } \rho \geq 5. \end{cases}$$

4 Unweighted Games

In this section, we consider the case of ρ-uniform congestion games induced by unweighted congestion models. First, we show that uniform mixed equilibria are always guaranteed to exist for any class of latency functions.

Given an unweighted congestion model CM and an integer $\rho \geq 1$, let f be a function mapping CM and ρ to another congestion model $f(\mathsf{CM},\rho)$, according to the following definition.

[3] To simplify the notation, we have written $\sum_{i=1}^n u_i$, instead of $\sum_{i:e\in E(\sigma_i^*)} u_i$.

▶ **Definition 5.** Given an unweighted congestion model

$$\mathsf{CM} = \left(\mathsf{N}, E, (\ell_e)_{e\in E}, \vec{1}^n, (\Sigma_i)_{i\in\mathsf{N}}\right),$$

define $\mathsf{CM}' = f(\mathsf{CM},\rho) = \left(\mathsf{N}', E', (\ell'_e)_{e\in E}, \vec{1}^n, (\Sigma'_i)_{i\in\mathsf{N}}\right)$ as the unweighted congestion model such that $\mathsf{N}' = \mathsf{N}$, $E' = E$, $\Sigma'_i = \{E(\sigma_i) : \sigma_i \text{ is a } \rho\text{-uniform mixed strategy for player } i \text{ in } \rho\text{-}\mathsf{CG}(\mathsf{CM})\}$ for each $i \in \mathsf{N}$, and

$$\ell'_e(x) := \frac{1}{\rho}\left(\sum_{j=0}^{x-1}\binom{x-1}{j}\left(\frac{1}{\rho}\right)^j\left(\frac{\rho-1}{\rho}\right)^{x-1-j}\ell_e(j+1)\right) \tag{11}$$

for each $e \in E'$. Moreover, given a latency function ℓ_e, let $\ell_e^{f(\rho)}$ denote the latency function defined in (11), and let $\ell_e^{-f(\rho)}$ denote the function $\overline{\ell}_e$ such that $\overline{\ell}_e^{f(\rho)} = \ell_e$.

For instance, if $\mathsf{CG}(\mathsf{CM})$ is a symmetric load balancing game, then $\mathsf{CG}(f(\mathsf{CM},\rho))$ is a ρ-uniform matroid congestion game [15], i.e. the strategies of each player are arbitrary subsets of ρ resources.

We show that ρ-$\mathsf{CG}(\mathsf{CM})$ is equivalent to $\mathsf{CG}(f(\mathsf{CM},\rho))$ for each $\rho \geq 1$. For a ρ-uniform mixed profile $\boldsymbol{\sigma}$ for ρ-$\mathsf{CG}(\mathsf{CM})$, define $\mathbf{s}'(\boldsymbol{\sigma})$ as the strategy profile for $\mathsf{CG}(f(\mathsf{CM},\rho))$ such that $\mathbf{s}'(\boldsymbol{\sigma}) := (E(\sigma_1), E(\sigma_2), \ldots, E(\sigma_n))$.

▶ **Theorem 6.** *Given $\rho \geq 1$ and an unweighted congestion model CM, we have that, for each ρ-uniform mixed profile $\boldsymbol{\sigma}$ for ρ-$\mathsf{CG}(\mathsf{CM})$ and $i \in \mathsf{N}$, $cost_i^{\rho\text{-}\mathsf{CG}(\mathsf{CM})}(\boldsymbol{\sigma}) = cost_i^{\mathsf{CG}(f(\mathsf{CM},\rho))}(\mathbf{s}'(\boldsymbol{\sigma}))$.*

As a corollary, we obtain existence of uniform mixed equilibria for each uniform congestion games induced by unweighted congestion models, regardless of which are their latency functions. In particular, we extend Rosenthal's Theorem [30], by showing that, for each $\rho \geq 1$, any ρ-uniform unweighted congestion game admits an exact potential.

▶ **Corollary 7.** *For each $\rho \geq 1$ and unweighted congestion model CM, ρ-$\mathsf{CG}(\mathsf{CM})$ admits an exact potential.*

Proof. By Rosenthal's Theorem [30], $\mathsf{CG}(f(\mathsf{CM},\rho))$ admits an exact potential function Φ. Because of Theorem 6, we have that $\Phi\circ\boldsymbol{s}'$ is an exact potential function for ρ-$\mathsf{CG}(\mathsf{CM})$. Indeed, given $i \in \mathsf{N}$, a strategy profile $\boldsymbol{\sigma}$ of ρ-$\mathsf{CG}(\mathsf{CM})$, and $\sigma'_i \in \Delta_i^\rho(\mathsf{CM})$, we get $cost_i^{\rho\text{-}\mathsf{CG}(\mathsf{CM})}(\boldsymbol{\sigma}) - cost_i^{\rho\text{-}\mathsf{CG}(\mathsf{CM})}(\boldsymbol{\sigma}_{-i},\sigma'_i) = cost_i^{\mathsf{CG}(f(\mathsf{CM},\rho))}(\boldsymbol{s}'(\boldsymbol{\sigma})) - cost_i^{\mathsf{CG}(f(\mathsf{CM},\rho))}(\boldsymbol{s}'(\boldsymbol{\sigma}_{-i},\sigma'_i)) = \Phi(\boldsymbol{s}'(\boldsymbol{\sigma})) - \Phi(\boldsymbol{s}'(\boldsymbol{\sigma}_{-i},\sigma'_i)) = (\Phi\circ\boldsymbol{s}')(\boldsymbol{\sigma}) - (\Phi\circ\boldsymbol{s}')(\boldsymbol{\sigma}_{-i},\sigma'_i)$. ◀

4.1 Price of Anarchy

In this subsection, we derive exact bounds on the price of anarchy of ρ-uniform congestion games induced by affine unweighted congestion models.

▶ **Theorem 8.** *Fix an affine unweighted congestion model CM. For any $\rho \geq 1$, we have*

$$\mathsf{PoA}_\rho(\rho\text{-}\mathsf{CG}(\mathsf{CM})) \leq \begin{cases} \frac{5}{\rho+1} & \text{if } \rho \leq 2, \\ \frac{2\sqrt{7}-1}{3} & \text{if } \rho = 3, \\ \frac{4}{3} & \text{if } \rho \geq 4. \end{cases}$$

Proof. Given an integer $\rho \geq 1$, let CM be an arbitrary affine unweighted congestion model. Let $\boldsymbol{\sigma}$ and $\boldsymbol{\sigma}^*$ be a ρ-uniform mixed equilibrium and a ρ-uniform social optimum for

ρ-CG(CM), respectively. By exploiting (1) and (2), we have that, for each $i \in \mathsf{N}$, the inequality $cost_i(\boldsymbol{\sigma}) \leq cost_i(\boldsymbol{\sigma}_{-i}, \sigma_i^*)$ becomes

$$\sum_{e \in E(\sigma_i)} \alpha_e \left(\frac{k_{\rho,e}(\boldsymbol{\sigma}) + \rho - 1}{\rho^2} \right) - \sum_{e \in E(\sigma_i^*)} \alpha_e \left(\frac{k_{\rho,e}(\boldsymbol{\sigma}) + \rho}{\rho^2} \right) \leq 0.$$

By also using (1) within SUM($\boldsymbol{\sigma}$) and SUM($\boldsymbol{\sigma}^*$), we get the following linear program:

$$\begin{aligned}
\mathsf{LP}: \quad \max \quad & \sum_{e \in E} \alpha_e \left(\frac{k_{\rho,e}(\boldsymbol{\sigma})(k_{\rho,e}(\boldsymbol{\sigma}) + \rho - 1)}{\rho^2} \right) \\
\text{s.t.} \quad & \sum_{e \in E(\sigma_i)} \alpha_e \left(\frac{k_{\rho,e}(\boldsymbol{\sigma}) + \rho - 1}{\rho^2} \right) - \sum_{e \in E(\sigma_i^*)} \alpha_e \left(\frac{k_{\rho,e}(\boldsymbol{\sigma}) + \rho}{\rho^2} \right) \leq 0, \quad \forall i \in \mathsf{N} \qquad (12) \\
& \sum_{e \in E} \alpha_e \left(\frac{k_{\rho,e}(\boldsymbol{\sigma}^*)(k_{\rho,e}(\boldsymbol{\sigma}^*) + \rho - 1)}{\rho^2} \right) = 1 \qquad (13) \\
& \alpha_e \geq 0, \quad \forall e \in E
\end{aligned}$$

By taking the dual of LP, where we associate the dual variable x_i to the ith primal constraint in (12) and the dual variable γ to the primal constraint (13), we get:

$$\begin{aligned}
\mathsf{DLP}: \quad \min \quad & \gamma \\
\text{s.t.} \quad & \sum_{i : e \in E(\sigma_i)} \left(x_i \frac{k_{\rho,e}(\boldsymbol{\sigma}) + \rho - 1}{\rho^2} \right) - \sum_{i : e \in E(\sigma_i^*)} \left(x_i \frac{k_{\rho,e}(\boldsymbol{\sigma}) + \rho}{\rho^2} \right) \\
& + \gamma \frac{k_{\rho,e}(\boldsymbol{\sigma}^*)(k_{\rho,e}(\boldsymbol{\sigma}^*) + \rho - 1)}{\rho^2} \\
& \geq \frac{k_{\rho,e}(\boldsymbol{\sigma})(k_{\rho,e}(\boldsymbol{\sigma}) + \rho - 1)}{\rho^2}, \quad \forall e \in E \qquad (14) \\
& x_i \geq 0, \quad \forall i \in \mathsf{N}
\end{aligned}$$

By using $x_i = x$ for each $i \in \mathsf{N}$, $k := k_{\rho,e}(\boldsymbol{\sigma})$ and $o := k_{\rho,e}(\boldsymbol{\sigma}^*)$ in (14), and multiplying both sides by ρ^2, we obtain the following relaxed dual constraint:

$$xk(k + \rho - 1) - xo(k + \rho) + \gamma o(o + \rho - 1) \geq k(k + \rho - 1). \qquad (15)$$

To complete the proof, we are left to provide, for each $\rho \geq 1$, a suitable value $x \geq 0$ satisfying inequality (15) where γ is set to be equal to the claimed upper bound on the ρ-uniform price of anarchy. We now proceed by case analysis.

For $\rho \leq 2$, for which we have $\gamma = \frac{5}{\rho+1}$, set $x = \frac{\rho+2}{\rho+1}$. By substituting these values in (15), we get the inequality $k^2 - k\left(o(\rho+2) + \rho + 1\right) + o(5o - \rho^2 + 3\rho - 5) \geq 0$ which can be easily shown to be satisfied for any pair of non-negative integers k, o when $\rho = 1, 2$. In fact, the discriminant of the associated equality is negative for each integer $o \geq 2$, while the cases of $o \in \{0, 1\}$ can be checked by inspection.

For $\rho = 3$, for which we have $\gamma = \frac{2\sqrt{7}-1}{3}$, set $x = 2\sqrt{7} - 4$. By substituting these values in (15), we get the inequality

$$(6\sqrt{7} - 15)k^2 - 6k\left(o(\sqrt{7} - 2) - 2\sqrt{7} + 5\right) + o\left(o(2\sqrt{7} - 1) - 14\sqrt{7} + 34\right) \geq 0,$$

which can be easily shown to be satisfied for any pair of non-negative integers k, o. In fact, the discriminant of the associated equality is negative for each integer $o \geq 2$, while the cases of $o \in \{0, 1\}$ can be checked by inspection.

For $\rho \geq 4$, for which we have $\gamma = \frac{4}{3}$, set $x = \frac{4}{3}$. By substituting these values in (15), we get the inequality $k^2 - k(4o - \rho + 1) + 4o(o-1) \geq 0$ whose left-hand side is increasing in ρ. Hence, we only need to prove that it gets satisfied for the case of $\rho = 4$, by which we get the inequality $k^2 - k(4o-3) + 4o(o-1) \geq 0$ which can be easily shown to be satisfied for any pair of non-negative integers k, o. Again, the discriminant of the associated equality is negative for each integer $o \geq 2$, while the cases of $o \in \{0, 1\}$ can be checked by inspection. ◀

We show matching lower bounds for each $\rho \leq 3$. For $\rho \geq 4$, we show in the next subsection a matching lower bound holding even for the price of stability.

▶ **Theorem 9.** *For any $\rho \leq 3$ and $\epsilon > 0$, there exists an affine unweighted load balancing model $\mathsf{CM} := \mathsf{CM}(\rho, \epsilon)$ such that*

$$\mathsf{PoA}_\rho(\rho\text{-}\mathsf{CG}(\mathsf{CM})) \geq \begin{cases} \frac{5}{\rho+1} - \epsilon & \text{if } \rho \leq 2, \\ \frac{2\sqrt{7}-1}{3} - \epsilon & \text{if } \rho = 3. \end{cases}$$

4.2 Price of Stability

In this subsection, we exhibit exact bounds on the price of stability of ρ-uniform congestion games induced by affine unweighted congestion models.

▶ **Theorem 10.** *Fix an affine unweighted congestion model CM. For any $\rho \geq 1$, we have*

$$\mathsf{PoS}_\rho(\rho\text{-}\mathsf{CG}(\mathsf{CM})) \leq \begin{cases} 1 + \frac{1}{\sqrt{2\rho+1}} & \text{if } \rho \leq 3, \\ \frac{4}{3} & \text{if } \rho \geq 4. \end{cases}$$

We also have matching lower bounds. We first consider the case of $\rho \leq 3$.

▶ **Theorem 11.** *For each $\rho \leq 3$ and $\epsilon > 0$, there exists an affine unweighted congestion model $\mathsf{CM} := \mathsf{CM}(\rho, \epsilon)$ such that $\mathsf{PoS}_\rho(\rho\text{-}\mathsf{CG}(\mathsf{CM})) \geq 1 + \frac{1}{\sqrt{2\rho+1}} - \epsilon$.*

For $\rho \geq 4$, the upper bounds are tight even when restricting to games induced by symmetric load balancing models.

▶ **Theorem 12.** *For each $\rho \geq 1$ and $\epsilon > 0$, there exists an affine unweighted symmetric load balancing model $\mathsf{CM} := \mathsf{CM}(\rho, \epsilon)$ such that $\mathsf{PoS}_\rho(\rho\text{-}\mathsf{CG}(\mathsf{CM})) \geq \frac{4}{3} - \epsilon$.*

5 Open Problems

In this paper, motivated by possible applications in fault-tolerant routing, we have introduced the notion of uniform mixed equilibria, and we have applied it to the well-studied class of (network) congestion games with affine latency functions, by providing existential results of these equilibria and by deriving tight bounds to the prices of anarchy and stability.

The main left open problem is to consider the more general definition of $\boldsymbol{\rho}$-uniform mixed equilibria, where players can use uniform mixed strategies of different support size. Another important question is the determination of lower bounds for the price of stability of ρ-unform mixed equilibria, in the setting of weighted congestion games. However, this question is open even for the price of stability of pure Nash equilibria (i.e., $\rho = 1$), for which only an upper bound equal to 2 is known, as a direct consequence of the potential function given in [20]. Following the approach used in [12, 10, 19, 9] for $\rho = 1$, it could be interesting investigating resource taxation or other strategies to improve the performance of ρ-unform mixed equilibria. Another interesting research direction is that of extending the results to other latency functions, e.g., polynomial functions, or decreasing functions as the ones inducing the Shapley cost sharing game [2, 24, 8, 7, 18].

Abstract

Gathering a group of mobile agents is a fundamental task in the field of distributed and mobile systems. This can be made drastically more difficult to achieve when some agents are subject to faults, especially the Byzantine ones that are known as being the worst faults to handle. In this paper we study, from a deterministic point of view, the task of Byzantine gathering in a network modeled as a graph. In other words, despite the presence of Byzantine agents, all the other (good) agents, starting from possibly different nodes and applying the same deterministic algorithm, have to meet at the same node in finite time and stop moving. An adversary chooses the initial nodes of the agents (the number of agents may be larger than the number of nodes) and assigns a different positive integer (called label) to each of them. Initially, each agent knows its label. The agents move in synchronous rounds and can communicate with each other only when located at the same node. Within the team, f of the agents are Byzantine. A Byzantine agent acts in an unpredictable and arbitrary way. For example, it can choose an arbitrary port when it moves, can convey arbitrary information to other agents and can change its label in every round, in particular by forging the label of another agent or by creating a completely new one.

Besides its label, which corresponds to a local knowledge, an agent is assigned some global knowledge denoted by $\mathcal{GK}$ that is common to all agents. In literature, the Byzantine gathering problem has been analyzed in arbitrary n-node graphs by considering the scenario when $\mathcal{GK} = (n, f)$ and the scenario when $\mathcal{GK} = f$. In the first (resp. second) scenario, it has been shown that the minimum number of good agents guaranteeing deterministic gathering of all of them is $f+1$ (resp. $f+2$). However, for both these scenarios, all the existing deterministic algorithms, whether or not they are optimal in terms of required number of good agents, have the major disadvantage of having a time complexity that is exponential in n and L, where L is the value of the largest label belonging to a good agent. In this paper, we seek to design a deterministic solution for Byzantine gathering that makes a concession on the proportion of Byzantine agents within the team, but that offers a significantly lower complexity. We also seek to use a global knowledge whose the length of the binary representation (that we also call size) is small. In this respect, assuming that the agents are in a *strong team* i.e., a team in which the number of good agents is at least some prescribed value that is quadratic in f, we give positive and negative results. On the positive side, we show an algorithm that solves Byzantine gathering with all strong teams in all graphs of size at most n, for any integers n and f, in a time polynomial in n and the length $|l_{min}|$ of the binary representation of the smallest label of a good agent. The algorithm works using a global knowledge of size $\mathcal{O}(\log\log\log n)$, which is of optimal order of magnitude in our context to reach a time complexity that is polynomial in n and $|l_{min}|$. Indeed, on the negative side, we show that there is no deterministic algorithm solving Byzantine gathering with all strong teams, in all graphs of size at most n, in a time polynomial in n and $|l_{min}|$ and using a global knowledge of size $o(\log\log\log n)$.

1 Introduction

1.1 Context

Gathering a group of mobile agents is a basic problem that has been widely studied in literature dedicated to mobile and distributed systems. One of the main reasons for this popularity stems from the fact that this task turns out to be an essential prerequisite to achieve more complex cooperative works. In other words, getting fundamental results on the problem of gathering implies *de facto* getting fundamental results on a large set of problems whose resolution needs to use gathering as a building block.

The scale-up when considering numerous agents is inevitably tied to the occurrence of faults among them, the most emblematic of which is the Byzantine one. Byzantine faults are very interesting under multiple aspects, especially because the Byzantine case is the most general one, as it subsumes all the others kind of faults. In fact, in the field of fault tolerance they are considered as the worst faults that can occur.

In this paper, we consider the problem of gathering in a deterministic way in a network modeled as a graph, wherein some agents are Byzantine. A Byzantine agent acts in an unpredictable and arbitrary manner. For instance it may choose to never stop or to never move. It may also convey arbitrary information to the other agents, impersonate the identity of another agent, and so on. In such a context, gathering is very challenging, and so far the power of such Byzantine agents has been offset by a huge complexity when solving this problem. In what follows, we seek a solution allowing to withstand Byzantine agents while keeping a "reasonable" complexity.

1.2 Model and problem

A team of mobile agents are initially placed by an adversary at arbitrary nodes of a network modeled as a finite, connected, undirected graph $G = (V, E)$. We assume that $|V| \leq n$. Several agents may initially share the same node and the size of the team may be larger than n. Two assumptions are made about the labelling of the two main components of the graph that are nodes and edges. The first assumption is that nodes are anonymous i.e., they do not have any kind of labels or identifiers allowing them to be distinguished from one another. The second assumption is that edges incident to a node v are locally ordered with a fixed port numbering ranging from 0 to $deg(v) - 1$ where $deg(v)$ is the degree of v. Therefore, each edge

has exactly two port numbers, one for each of both nodes it links. The port numbering is not supposed to be consistent: a given edge $(u, v) \in E$ may be the i-th edge of u but the j-th edge of v, where $i \neq j$. These two assumptions are not fortuitous. The primary motivation of the first one is that if each node could be identified by a label, gathering would become quite easy to solve as it would be tantamount to explore the graph (via e.g. a breadth-first search) and then meet in the node having the smallest label. While the first assumption is made so as to avoid making the problem trivial, the second assumption is made in order to avoid making the problem impossible to solve. Indeed, in the absence of a way allowing an agent to distinguish locally the edges incident to a node, gathering could be proven as impossible to solve deterministically in view of the fact that some agents could be precluded from traversing some edges and visit some parts of the graph.

Time is discretized into an infinite sequence of rounds. In each round, every agent, which has been previously woken up (this notion is detailed in the next paragraph), is allowed to stay in place at its current node or to traverse an edge according to a deterministic algorithm. The algorithm is the same for all agents: only the input, whose nature is specified further in the subsection, varies among agents.

Before being woken up, an agent is said to be dormant. A dormant agent may be woken up only in two different ways: either by the adversary that wakes some of the agents at possibly different rounds, or as soon as a non-dormant agent is at the starting node of the dormant agent. We assume that the adversary wakes up at least one agent. Note that, when the adversary chooses to wake up in round r a dormant agent located at a node v, all the dormant agents that are at node v wake up in round r.

When an agent is woken up in a round r, it is told the degree of its starting node. As mentioned above, in each round $r' \geq r$, the executed algorithm can ask the agent to stay idle or to traverse an edge. In the latter case, this takes the following form: the algorithm asks the agent, located at node u, to traverse the edge having port number i, where $0 \leq i \leq deg(u) - 1$. Let us denote by $(u, v) \in E$ this traversed edge. In round $r' + 1$, the agent enters node v: it then learns the degree $deg(v)$ as well as the local port number j of (u, v) at node v (recall that in general $i \neq j$). An agent cannot leave any kind of tokens or markers at the nodes it visits or the edges it traverses.

In the beginning, the adversary also assigns a different positive integer (called label) to each agent. Each agent knows its label but does not know *a priori* the labels of the other agents (except if some or all of them are inserted in the global knowledge $\mathcal{GK}$ that is introduced below). When several agents are at the same node v in the same round t, they see, for each agent x at node v, the label of agent x and all information it wants to share with the others in round t. This transmission of information is done in a "shouting" mode in one round: all the transmitted information by all agents at node v in round t becomes common knowledge for agents that are currently at node v in round t. On the other hand when two agents are not at the same node in the same round they cannot see or talk to each other: in particular, two agents traversing simultaneously the same edge but in opposite directions, and thus crossing each other on the same edge, do not notice this fact. In every round, the input of the algorithm executed by an agent a is made up of the label of agent a, the up-to-date memory of what agent a has seen and learnt since its waking up and some global knowledge denoted by $\mathcal{GK}$. Parameter $\mathcal{GK}$ is a piece of information that is initially given to all agents and common to all of them (i.e., $\mathcal{GK}$ is the same for all agents): its nature is precised at the end of this subsection. Note that in the absence of a way of distinguishing the agents, the gathering problem would have no deterministic solution in some graphs, regardless of the nature of $\mathcal{GK}$. This is especially the case in a ring in which at each node the

edge going clockwise has port number 0 and the edge going anti-clockwise has port 1: if all agents are woken up in the same round and start from different nodes, they will always have the same input and will always follow the same deterministic rules leading to a situation where the agents will always be at distinct nodes no matter what they do.

Within the team, it is assumed that f of the agents are Byzantine. A Byzantine agent has a high capacity of nuisance: it can choose an arbitrary port when it moves, can convey arbitrary information to other agents and can change its label in every round, in particular by forging the label of another agent or by creating a completely new one. All the agents that are not Byzantine are called good. We consider the task of f-Byzantine gathering which is stated as follows. The adversary wakes up at least one good agent and all good agents must eventually be in the same node in the same round, simultaneously declare termination and stop, despite the fact there are f Byzantine agents. Regarding this task, it is worth mentioning that we cannot require the Byzantine agents to cooperate as they may always refuse to be with some agents. Thus, gathering all good agents with termination is the strongest requirement we can make in such a context. The time complexity of an algorithm solving f-Byzantine gathering is the number of rounds counted from the start of the earliest good agent until the task is accomplished.

We end this subsection by explaining what we mean by global knowledge, that can be viewed as a kind of advice given to all agents. Following the paradigm of algorithms with advice [1, 25, 38, 9, 20, 19, 33], $\mathcal{GK}$ is actually a piece of information that is initially provided to the agents at the start, by an oracle knowing the initial instance of the problem. By instance, we precisely mean: the entire graph with its port numbering, the initial positions of the agents with their labels, the f agents that are Byzantine, and for each agent the round, if any, when the adversary wakes it up in case it has not been woken up before by another agent. So, for example, $\mathcal{GK}$ might correspond to the size of the network, the number of Byzantine agents, or a complete map of the network, etc. As mentionned earlier, we assume that $\mathcal{GK}$ is the same for all agents. The size of $\mathcal{GK}$ is the length of its binary representation.

1.3 Related works

When reviewing the chronology of the works that are related to the gathering problem, it can be seen that this problem has been first studied in the particular case in which the team is made of exactly two agents. Under such a limitation, gathering is generally referred to as *rendezvous*. From the first mention of the rendezvous problem in [36], this problem and its generalization, gathering, have been extensively studied in a great variety of ways. Indeed, there is a lot of alternatives for the combinations we can make when addressing the problem, e.g., by playing on the environment in which the agents are supposed to evolve, the way of applying the sequences of instructions (i.e., deterministic or randomized) or the ability to leave some traces in the visited locations, etc. In this paper, we are naturally closer to the research works that are related to deterministic gathering in networks modeled as graphs. Hence, we will mostly dwell on this scenario in the rest of this subsection. However, for the curious reader wishing to consider the matter in greater depth, we invite him to consult [8, 2, 24] that address the problem in the plane via various scenarios, especially in a system affected by the occurrence of faults or inaccuracies for the last two references. Regarding randomized rendezvous, a good starting point is to go through [3, 4, 28].

Now, let us focus on the area that concerns the present paper most directly, namely deterministic rendezvous and/or gathering in graphs. In most papers on rendezvous in networks, a synchronous scenario was assumed, in which agents navigate in the network in synchronous rounds. Under this context, a lot of effort has been dedicated to the study of

the feasibility and to the time (i.e., number of rounds) required to achieve the task, when feasible. For instance, in [16] the authors show a rendezvous algorithm polynomial in the size of the graph, in the length of the shorter label and in the delay between the starting time of the agents. In [26] and [37] solutions are given for rendezvous, which are polynomial in the first two of these parameters and independent of the delay. While these algorithms ensure rendezvous in polynomial time (i.e., a polynomial number of rounds), they also ensure it at polynomial cost where the cost corresponds here to the total number of edge traversals made by both agents until meeting. Indeed, since each agent can make at most one edge traversal per round, a polynomial time always implies a polynomial cost. However, the reciprocal may be not true, for instance when using an algorithm relying on a technique similar to "coding by silence" in the time-slice algorithm for leader election [29]: "most of the time" both agents stay idle, in order to guarantee that agents rarely move simultaneously. Thus these parameters of cost and time are not always linked to each other. This was recently highlighted in [32] where the authors studied the tradeoffs between cost and time for the deterministic rendezvous problem. Some other efforts have been also dedicated to analyse the impact on time complexity of rendezvous when in every round the agents are brought with some pieces of information by making a query to some device or some oracle, see, e.g., [14, 31]. Along with the works aiming at optimizing the parameters of time and/or cost of rendezvous, some other works have examined the amount of memory that is required to achieve deterministic rendezvous e.g., in [21, 22] for tree networks and in [12] for general networks.

Apart from the synchronous scenario, the academic literature also contains several studies focusing on a scenario in which the agents move at constant speed, which are different from each other, or even move asynchronously: in this latter case the speed of agents may then vary and is controlled by the adversary. For more details about rendezvous under such a context, the reader is referred to [30, 13, 23, 18, 27] for rendezvous in finite graphs and [5, 10] for rendezvous in infinite grids.

As stated in the previous subsection, our paper is also related to the field of fault tolerance since some agents may be prone to Byzantine faults. First introduced in [34], a Byzantine fault is an arbitrary fault occurring in an unpredictable way during the execution of a protocol. Due to its arbitrary nature, such a fault is considered as the worst fault that can occur. Byzantine faults have been extensively studied for "classical" networks i.e., in which the entities are fixed nodes of the graph (cf., e.g., the book [29] or the survey [6]). To a lesser extend, the occurrence of Byzantine faults has been also studied in the context of mobile entities evolving on a one-dimensional or two-dimensional space, cf. [2, 15, 11].

Gathering in arbitrary graphs in presence of many Byzantine agents was considered in [17, 7]. Actually, our model is borrowed from both these papers, and thus they are naturally the closest works to ours. In [17], the problem is introduced via the following question: *what is the minimum number $\mathcal{M}$ of good agents that guarantees f-Byzantine gathering in all graphs of size n?* In [17], the authors provided several answers to this problem by firstly considering a relaxed variant, in which the Byzantine agents cannot lie about their labels, and then by considering a harsher form (the same as in our present paper) in which Byzantine agents can lie about their identities. For the relaxed variant, it has been proven that the minimum number $\mathcal{M}$ of good agents that guarantees f-Byzantine gathering is precisely 1 when $\mathcal{GK} = (n, f)$ and $f + 2$ when $\mathcal{GK}$ is reduced to f only. The proof that both these values are enough, relies on polynomial algorithms using a mechanism of blacklists that are, informally speaking, lists of labels corresponding to agents having exhibited an "inconsistent" behavior. Of course, such blacklists cannot be used when the Byzantine agents can change

their labels and in particular steal the identities of good agents. Still in [17], the authors give for the harsher form of f-byzantine gathering a lower bound of $f+1$ (resp. $f+2$) on $\mathcal{M}$ and a deterministic gathering algorithm requiring at least $2f+1$ (resp. $4f+2$) good agents, when $\mathcal{GK}=(n,f)$ (resp. $\mathcal{GK}=f$). Both these algorithms have a huge complexity as they are exponential in n and L, where L is the largest label of a good agent evolving in the graph. Some advances are made in [7], via the design of an algorithm for the case $\mathcal{GK}=(n,f)$ (resp. $\mathcal{GK}=f$) that works with a number of good agents that perfectly matches the lower bound of $f+1$ (resp. $f+2$) shown in [17]. However, these algorithms also suffer from a complexity that is exponential in n and L.

1.4 Our results

As mentioned just above, the existing deterministic algorithms dedicated to f-Byzantine gathering all have the major disadvantage of having a time complexity that is exponential in n and L, when Byzantine agents are allowed to change their labels. Actually, these solutions are all based on a common strategy that consists in enumerating the possible initial configurations, and successively testing them one by one. Once the testing reaches the correct initial configuration, the gathering can be achieved. However, in order to get a significantly more efficient algorithm, such a costly strategy must be abandoned in favor of a completely new one.

In this paper, we seek to design a deterministic solution for Byzantine gathering that makes a concession on the proportion of Byzantine agents within the team, but that offers a significantly lower complexity. We also seek to use a global knowledge whose the length of the binary representation (that we also call size) is small. In this respect, assuming that the agents are in a *strong team* i.e., a team in which the number of good agents is at least the quadratic value $5f^2+6f+2$, we give positive and negative results. On the positive side, we show an algorithm that solves f-Byzantine gathering with all strong teams in all graphs of size at most n, for any integers n and f, in a time polynomial in n and $|l_{min}|$. The algorithm works using a global knowledge of size $\mathcal{O}(\log\log\log n)$, which is of optimal order of magnitude in our context to reach a time complexity that is polynomial in n and $|l_{min}|$. Indeed, on the negative side, we show that there is no deterministic algorithm solving f-Byzantine gathering with all strong teams, in all graphs of size at most n, in a time polynomial in n and $|l_{min}|$ and using a global knowledge of size $o(\log\log\log n)$.

1.5 Roadmap

The next section is dedicated to the presentation of some definitions and routines that we need in the rest of this paper. In Section 3, we give a description of our main algorithm corresponding to our positive result. In Section 4, we prove our negative result. Finally we make some concluding remarks in Section 5. Note that due to the lack of space, several details and proofs are omitted but will appear in the journal version of the paper.

2 Preliminaries

Throughout the paper, log denotes the binary logarithm. The length of the binary representation of the smallest label of a good agent in a given team will be denoted by $|l_{min}|$.

In this paper, we will use a procedure whose aim is graph exploration, i.e., visiting all nodes of the graph. This procedure, based on universal exploration sequences (UXS), is a corollary of the result of Reingold [35]. Given any positive integer n, this procedure, called

EXPLO(n), allows the executing agent to traverse all nodes of any graph of size at most n, starting from any node of this graph, using a number of edge traversals that is polynomial in n. We denote by X_n the execution time of procedure EXPLO with parameter n.

Besides this exploration procedure, we will use a label transformation derived from [16]. Let ℓ_B be the label of an agent B and $b_1 \dots b_c$ its binary representation with c its length. The binary representation of the corresponding transformed label ℓ_B^* is $10b_1b_1 \dots b_cb_c0110b_1b_1 \dots b_cb_c01$. This transformation is made to ensure the following property on which the algorithm of Section 3 partly relies.

▶ **Proposition 1.** *Let ℓ_B and ℓ_X be two labels such that $\ell_B < \ell_X$. Let $b_1^*b_2^* \dots b_{4c+8}^*$ and $x_1^*x_2^* \dots x_{4y+8}^*$ be the respective binary representations of ℓ_B^* and ℓ_X^*, with c and y the lengths of the binary representations of ℓ_B and ℓ_X respectively. There exist two positive integers $i \leq 2c+4$ and $2c+4 < j \leq 4c+8$ such that $b_i^* \neq x_i^*$ and $b_j^* \neq x_j^*$.*

To establish our main result that is presented in Section 3, we needed to design two building blocks, namely procedures GROUP and MERGE. These procedures are not trivial, but due to space restrictions we only give here the two associated theorems.

The first building block called GROUP takes as input three integers $\mathcal{T}$, n and *bin* such that $bin \in \{0; 1\}$. Let x be an integer that is at least $f+2$. Roughly speaking, subroutine GROUP($\mathcal{T}, n, bin$) ensures that $(x-f)$ good agents finish the execution of the subroutine at the same round and in the same node in a graph of size at most n provided some conditions given in the next theorem are satisfied.

▶ **Theorem 1.** *Consider a team made of at least $(x-1)(f+1)+1$ good agents in a graph of size at most n, where $x \geq f+2$. Let Δ be the first round when a good agent starts executing* GROUP($\mathcal{T}, n, bin$). *If all good agents start executing* GROUP($\mathcal{T}, n, bin$) *by round $\Delta + \mathcal{T} - 1$, and parameter bin is 0 (resp. 1) for at least one good agent, then we have the following property. After at most a time polynomial in n and $\mathcal{T}$ from Δ, at least $(x-f)$ good agents finish the execution of* GROUP *at the same round and in the same node.*

The second building block called MERGE takes as input two integers n and $\mathcal{T}$. Subroutine MERGE($\mathcal{T}, n$) allows all the good agents to finish their executions of the subroutine in the same node and at the same round, provided some conditions given in the next theorem are satisfied.

▶ **Theorem 2.** *Consider a team of agents in a graph of size at most n. Let Δ be the first round when a good agent starts executing* MERGE($\mathcal{T}, n$). *If every good agent starts executing* MERGE($\mathcal{T}, n$) *by round $\Delta + \mathcal{T} - 1$ and among them at least $4f+2$ start the execution in the same node and at the same round, then all good agents finish their executions of procedure* MERGE *in the same node and at the same round $r < \Delta + 4\mathcal{T} + 6X_n - 1$.*

3 The positive result

In this section we present an algorithm, called GATHER, that solves f-Byzantine gathering with strong teams in all graphs of size at most n, assuming that $\mathcal{GK} = \lceil \log \log n \rceil$: note that such a global knowledge can be coded using $\mathcal{O}(\log \log \log n)$ bits. The algorithm works in a time polynomial in n and $|l_{min}|$, and it makes use of the building blocks introduced in the section Preliminaries.

In the sequel, we denote by G_n the maximal time complexity of procedure $\texttt{GROUP}(X_n, n, \rho)$ with $\rho \in \{0;1\}$ in all graphs of size at most n. We also denote by M_n the maximal time complexity of procedure $\texttt{MERGE}(X_n + G_n, n)$ in all graphs of size at most n. Note that according to Theorems 1 and 2, G_n and M_n exist and are polynomials in n.

In order to better describe the high level idea of our solution, let us first consider a situation that would be ideal to solve Byzantine gathering with a strong team and that would be as follows. Instead of assigning distinct labels to all agents, the adversary assigns to each of them just one bit $\rho \in \{0;1\}$, so that there are at least one good agent for which $\rho = 0$ and at least one good agent for which $\rho = 1$. Such a situation would clearly constitute an infringement of our model, but would allow the simple protocol described in Algorithm 1 to solve the problem in a time that is polynomial in n when $\mathcal{GK} = \lceil \log \log n \rceil$. Let us briefly explain why.

Algorithm 1 Algorithm executed by every good agent in the ideal situation.

1: Let ρ be the bit assigned to me by the adversary
2: Execute $\mathcal{A}(\rho)$
3: Declare that gathering is achieved

Algorithm 2 $\mathcal{A}(\rho)$ executed by a good agent.

1: $N \leftarrow 2^{(2^{\mathcal{GK}})}$
2: Execute $\texttt{EXPLO}(N)$
3: Execute $\texttt{GROUP}(X_N, N, \rho)$
4: Execute $\texttt{MERGE}(X_N + G_N, N)$

Algorithm 1 consists mainly of a call to $\mathcal{A}(\rho)$ that is given by Algorithm 2. Since $\mathcal{GK} = \lceil \log \log n \rceil$, we know that at line 1 of Algorithm 2, N is a polynomial upperbound on n, and the execution of $\texttt{EXPLO}(N)$ in a call to $\mathcal{A}(\rho)$ by the first woken-up good agent permits to visit every node of the graph and to wake up all dormant agents. As a result, the delay between the starting times of $\texttt{GROUP}(X_N, N, \rho)$ by any two good agents of the strong team is at most X_N. According to the properties of procedure GROUP (cf. Theorem 1) and the fact that the number of good agents is at least $5f^2 + 6f + 2 = ((5f + 2) - 1)(f + 1) + 1$, this guarantees in turn that the delay between the starting times of $\texttt{MERGE}(X_N + G_N, N)$ by any two good agents is at most $X_N + G_N$, and at least $4f + 2$ good agents start this procedure at the same time in the same node. Hence, in view of the properties of procedure MERGE (cf. Theorem 2), all good agents declare gathering is achieved at the same time in the same node after a polynomial number of rounds (w.r.t n) since the wake-up time of the earliest good agent.

Unfortunately, we are not in such an ideal situation. At first glance, one might argue that it is not really a problem because all agents are assigned distinct labels that are, after all, distinct binary strings. Thus, by ensuring that each good agent applies on its label the transformation given in Section 2, and then processes one by one each bit b_i of its transformed label by executing $\mathcal{A}(b_i)$, we can guarantee (with some minor technical adjustments) that the gathering of all good agents is done in time polynomial in n and $|l_{min}|$. Indeed, in view of Proposition 1 the conditions of the ideal situation are recreated when the agents process their j-th bits for some $j \leq 2|l_{min}| + 4$. Unfortunately it is not enough for our purpose. In fact, in the ideal situation, there is just one bit to process: thus, *de facto* every good agent knows that every good agent knows that gathering will be done at the end of this single process. However, it is no longer the case when the agents have to deal with sequences of bit processes: the good agents have a priori no mean to detect collectively and simultaneously

when they are gathered. It should be noted that if the agents knew f, we could use an existing algorithmic component (cf. [17]) allowing to solve f-Byzantine gathering if at some point some good agents detect the presence of a group of at least $2f+1$ agents in the network. Such a group is necessarily constructed during the sequence of bit processes given above, but again, it cannot be a priori detected as the agents do not know f or an upperbound on it. Hence, in our goal to optimize the amount of global knowledge, we need to implement a new strategy to allow the good agents to declare gathering achieved jointly and simultaneously. It is the purpose of the rest of this subsection.

To get all good agents declare simultaneously the gathering achieved, we want to reach a round in which every good agent knows that every good agent knows that gathering is done. So, let us return to our sequence of bit processes. As mentioned above, when a good agent has finished to read the first half of its transformed label – call such an agent *experienced* – it has the guarantee that the gathering of all good agents has been done at least once. Hence, when an experienced agent starts to process the second half of its transformed label, it actually knows an approximation of the number of good agents with a margin of error of f at the most. For the sake of convenience, let us consider that an experienced agent knows the exact number μ of good agents: the general case adds a slight level of complexity that is unnecessary to understand the intuition. So, each time an experienced agent completes the process of a bit in the second half of its transformed label, it is in a node containing less than μ agents or at least μ agents. In the first case, the experienced agent is sure that the gathering is not achieved. In the second case, the experienced agent is in doubt. In our solution, we build on this doubt. How do we do that? So far, each bit process was just made of one call to procedure $\mathcal{A}$: now at the end of each bit process, we add a waiting period of some prescribed length, followed by an extra step that consists in applying $\mathcal{A}$ again, but this time according to the following rule. If during the waiting period it has just done, an agent X was in a node containing, for a sufficiently long period, an agent pretending to be experienced and in doubt (this agent may be X itself), then agent X is said to be *optimistic* and the second step corresponds to the execution of $\mathcal{A}(0)$. Otherwise, agent X is said to be *pessimistic* and the second step corresponds to the execution of $\mathcal{A}(1)$.

If at least one good agent is optimistic within a given second step, then the gathering of all good agents is done at the end of this step. Indeed, through similar arguments of partition to those used for the ideal situation, we can show it is the case when at least another agent is pessimistic. However, it is also, more curiously, the case when there is no pessimistic agents at all. This is due in part to the fact that two good experienced agents cannot have been in doubt in two distinct nodes during the previous waiting period (otherwise, we would get a contradiction with the definition of μ). Thus, all good agents start $\mathcal{A}(0)$ from at most $f+1$ distinct nodes (as the Byzantine agents can mislead the good agents in at most f distinct nodes during the waiting period), which implies by the pigeonhole principle that at least $4f+2$ good agents start it from the same node. Combined with some other technical arguments, we can show that the conditions of Theorem 2 are fulfilled when the agents execute `MERGE` at the end of $\mathcal{A}(0)$, thereby guaranteeing again gathering of all good agents.

As a result, the addition of an extra step to each bit process gives us the following interesting property: when a good agent is optimistic at the beginning of a second step, at its end the gathering is done and, more importantly, the optimistic agent knows it because its existence ensures it. Note that, it is a great progress, but unfortunately it is not yet sufficient, particularly because the pessimistic agents do not have the same kind of guarantee. The way of remedying this is to repeat once more the same kind of algorithmic ingredient as above. More precisely, at the end of each second step, we add again a waiting period of

some prescribed length, followed by a third step that consists in applying $\mathcal{A}$ in the following manner. If during the waiting period it has just done, an agent X was in a node containing, for a sufficiently long period, an agent pretending to be optimistic, then the third step of agent X corresponds to the execution of $\mathcal{A}(0)$ and it becomes optimistic if it was not. Otherwise, the third step of agent X corresponds to the execution of $\mathcal{A}(1)$ and the agent stays pessimistic.

By doing so, we made a significant move forward. To understand why, we want to invite the reader to reconsider the case when there is at least one good agent that is optimistic at the beginning of a second step. As we have seen earlier, at the end of this second step, all good agents are necessarily gathered and every optimistic agent knows it. In view of the last changes made to our solution, when starting the third step, every good agent is then optimistic. As explained above the absence of pessimistic good agent is very helpful, and using here the same arguments, we are sure that when finishing the third step, all good agents are gathered and every good agent knows it because all of them are optimistic. Actually, it is even a little more subtle: the optimistic agents of the first generation (i.e., those that were already optimistic when starting the second step) know that the gathering is done and know that every good agent knows it. Concerning the optimistic agents of the second generation (i.e., those that became optimistic only when starting the third step), they just know that the gathering is done, but do not know whether the other agents know it or not. Recall that to get all good agents declare simultaneously the gathering achieved, we want to reach a round in which every good agent knows that every good agent knows that gathering is done. We are very close to such a consensus. To reach it, at the end of a third step, the optimistic agents of the first generation make themselves known to all agents. Note that if there were at least $f+1$ agents declaring to be optimistic agents of the first generation and if f was part of $\mathcal{GK}$, the consensus would be reached. Indeed, among the agents declaring to be optimistic of the first generation, at least one is necessarily good and every agent can notice it: at this point we can show that every good agent knows that every good agent knows that gathering is done.

However, the agents do not know f. That being said, at the end of a third step, note that an optimistic agent knowing that the gathering is done can compute an approximation $\tilde{f}$ of the number of Byzantine agents. More precisely, if the number of agents gathered in its node is p, the optimistic agent knows than the number of Byzantine agents cannot exceed $\tilde{f} = max\{y|(5y+1)(y+1)+1 \leq p\}$ according to the definition of a strong team. Based on this fact, we are saved. Indeed, our algorithm is designed in such a way that all good agents correctly declare the gathering is achieved in the same round after having computed the same approximation $\tilde{f}$ and noticed at least $\tilde{f}+1$ agents that claim being optimistic of the first generation during a third step. We show that such an event necessarily occurs before any agent finishes the $(4|l_{min}|+8)$-th bit process of its transformed label, which permits to obtain the promised polynomial complexity. This is where our feat of strength is: obtaining such a complexity with a small amount of global knowledge, while ensuring that the Byzantine agents cannot confuse the good agents in any way. Actually, our algorithm is judiciously orchestrated so that the only thing Byzantine agents can really do is just to accelerate the resolution of the problem.

▶ **Theorem 3.** *Assuming that* $\mathcal{GK} = \lceil \log \log n \rceil$*, Algorithm* `GATHER` *solves* f*-Byzantine gathering with every strong team in all graph of size at most* n*, and has a time complexity that is polynomial in* n *and* $|l_{min}|$*.*

4 The negative result

Algorithm GATHER introduced in the previous section uses the value $\lceil \log \log n \rceil$ as global knowledge, which can be coded with a binary string of size $\mathcal{O}(\log \log \log n)$. In this section, we show that, to solve Byzantine gathering with all strong teams, in all graph of size at most n, in a time polynomial in n and $|l_{min}|$, the order of magnitude of the size of knowledge used by our algorithm GATHER is optimal. More precisely, we have the following theorem.

▶ **Theorem 4.** *There is no algorithm solving f-Byzantine gathering with all strong teams for all f and in all graphs of size at most n, which is polynomial in n and $|l_{min}|$ and which uses a global knowledge of size $o(\log \log \log n)$.*

Proof. Suppose by contradiction that the theorem is false. Hence, there exists an algorithm Alg that solves f-Byzantine gathering with all strong teams for all f in all graphs of size at most n, which is polynomial in n and $|l_{min}|$ and which uses a global knowledge of size $o(\log \log \log n)$. The proof relies on the construction of a family $\mathcal{F}_n$ (for any $n \geq 4$) of initial instances with strong teams such that for each of them the graph size is at most n. Our goal is to prove that there is an instance from $\mathcal{F}_n$ for which algorithm Alg needs a global knowledge whose size does not belong to $o(\log \log \log n)$, which would be a contradiction with the definition of Alg. Let us first present the construction of an infinite sequence of instances $\mathcal{I} = I_0, I_1, I_2, \ldots, I_i, \ldots$ by induction on i. Instance I_0 consists of an oriented ring of 4 nodes (i.e., a ring in which at each node the edge going clockwise has port number 0 and the edge going anti-clockwise has port 1). In this ring, there is no Byzantine agent but there are two good agents labeled 0 and 1 that are placed in diametrically opposed nodes. All the agents in I_0 wake up at the same time.

Now let us describe the construction of instance I_i with $i \geq 1$ using some features of instance I_{i-1}. Let c be the smallest constant integer such that the time complexity of algorithm Alg is at most n^c from every instance made of a graph of size at most n with a strong team in which $|l_{min}| = 1$. Let μ_{i-1} and n_{i-1} be respectively the total number of agents in I_{i-1} and the number of nodes in the graph of I_{i-1}. Instance I_i consists of an oriented ring of $(n_{i-1})^{4c}$ nodes. In this ring an agent labeled 0 is placed on a node denoted by v_0. In each of both nodes that are adjacent to v_0, $(n_{i-1})^c \cdot \mu_{i-1}$ Byzantine agents are placed (which gives a total of $2(n_{i-1})^c \cdot \mu_{i-1}$ Byzantine agents). On the node that is diametrically opposed to v_0, enough good agents are placed in order to have a strong team. The way of assigning labels to all agents that are not at v_0 is arbitrary but respects the condition that initially no two agents share the same label. Finally, all the agents in I_i wake up at the same time. This closes the description of the construction of $\mathcal{I}$, for which we have the following claim.

Claim 1. For any two instances I_j and $I_{j'}$ of $\mathcal{I}$, algorithm Alg requires a distinct global knowledge.

Proof of Claim 1. Assume by contradiction that the claim does not hold for two instances I_j and $I_{j'}$ such that $j < j'$. Consider any execution EX_j of algorithm Alg from I_j. According to the construction of $\mathcal{I}$, we know that every agent is woken up at the first round of EX_j. We denote by $r_1, r_2, \ldots, r_k$ the sequence of consecutive rounds from the first round of EX_j to the round when all good agents declare that gathering is done. We also denote by G_i the group of agents (possibly empty) that are with the good agent labeled 0 at round r_i of EX_j. Now, using execution EX_j, let us describe a possible execution $EX_{j'}$ of algorithm Alg

from $I_{j'}$: this execution is designed in such a way that it will fool the good agent labeled 0 and will induce it into premature termination. According to the construction of $\mathcal{I}$, all the agents of $I_{j'}$ are woken up in the first round of $I_{j'}$ and all the good ones are executing algorithm `Alg`. In the first round of $EX_{j'}$ the agent labeled 0 is alone (as in the first round of EX_j). Then, for each $i \in 2, \ldots, k$, the good agent labeled 0 in $EX_{j'}$ meets a group of $|G_i|$ Byzantine agents whose the multiset of labels is exactly the same as the multiset of labels belonging to the agents of G_i in the ith round of EX_j. This is always possible in view of the fact that for each $i \in 1, \ldots, k$, $|G_i| \leq \mu_j$ and the Byzantine agents of $I_{j'}$ can choose to move by ensuring that in the ith round of $EX_{j'}$ it remains at least $(k-i) \cdot \mu_j$ Byzantine agents in the node adjacent to the one occupied by the agent labeled 0 in the clockwise direction (resp. anti-clockwise direction): indeed according to the construction of $I_{j'}$, in each of both nodes adjacent to the starting node of the good agent labeled 0, there are initially $(n_{j'-1})^c \cdot \mu_{j'-1} \geq k \cdot \mu_{j'-1}$ Byzantine agents, as $k \leq (n_j)^c \leq (n_{j'-1})^c$. Finally, if algorithm `Alg` prescribes some message exchange between agents during their meetings, then the Byzantine agents in execution $EX_{j'}$ give exactly the same information to 0, as the agents with respective labels in execution EX_j. Hence, from the point of view of agent 0, the first k rounds of EX_j look exactly identical to the first k rounds of $EX_{j'}$. This is due to the actions of Byzantine agents, the fact that all nodes in I_j and $I_{j'}$ look identical, and also because $k \leq (n_j)^c$ which implies that, regardless of the algorithm `Alg`, the agent labeled 0 cannot meet any good agent in the first k rounds of $EX_{j'}$ as the distance between agent 0 and any other good agent is initially at least $\frac{(n_{j'-1})^{4c}}{2} \geq \frac{(n_j)^{4c}}{2}$. Therefore, in the kth round of execution $EX_{j'}$, the good agent labeled 0 declares having met all good agents and stops, which is incorrect, since it has not met any good agent. This contradicts the definition of algorithm `Alg` and closes the proof of this claim.

Now, consider the largest x such that in each of the $x+1$ first instances $I_0, I_1, \ldots, I_x$ of $\mathcal{I}$, the graph size is at most n: these $x+1$ instances constitute family $\mathcal{F}_n$. In view of the construction of sequence $\mathcal{I}$ and the definition of x, we have $4^{((4c)^x)} \leq n < 4^{((4c)^{x+1})}$. Hence, x belongs to $\Omega(\log\log n)$. However, according to Claim 1, the global knowledge given to distinct instances in this family must be different. Hence, there is at least one instance of $\mathcal{F}_n$ for which algorithm `Alg` uses a global knowledge of size $\Omega(\log x)$: since $x \in \Omega(\log\log n)$, we have $\Omega(\log x) \in \Omega(\log\log\log n)$. This contradicts the fact that `Alg` uses a global knowledge of size $o(\log\log\log n)$ and proves the theorem. ◀

5 Conclusion

In this paper, we designed the first polynomial algorithm w.r.t n and $|l_{min}|$ allowing to gather all good agents in presence of Byzantine ones that can act in an unpredictable way and lie about their labels. Our algorithm works under the assumption that the team evolving in the network is strong i.e., the number of good agents is roughly at least quadratic in the number f of Byzantine agents. The required global knowledge $\mathcal{GK}$ is of size $\mathcal{O}(\log\log\log n)$, which is of optimal order of magnitude to get a time complexity that is polynomial in n and $|l_{min}|$ even with strong teams.

A natural open question that immediately comes to mind is to ask if we can do the same by reducing the ratio between the good agents and the Byzantine agents. For example, could it be still possible to solve the problem in polynomial time with a global knowledge of size $\mathcal{O}(\log\log\log n)$ if the number of good agents is at most $o(f^2)$? Note that the answer to this question may be negative but then may become positive with a little bit more global knowledge. Actually, we can even easily show that the answer is true if the agents are initially

given a complete map of the graph with all port numbers, and in which each node v is associated to the list of all labels of the good agents initially occupying node v. However, the size of $\mathcal{GK}$ is then huge as it belongs to $\Omega(n^2)$. In fact, in this case what is really interesting is to find the optimal size for $\mathcal{GK}$. This observation allows us to conclude with the following open problem that is more general and appealing.

What are the trade-offs among the ratio good/Byzantine agents, the time complexity and the amount of global knowledge to solve f-Byzantine gathering?

Bringing an exhaustive and complete answer to this question appears to be really challenging but would turn out to be a major step in our understanding of the problem.

Abstract

Modern, inherently dynamic systems are usually characterized by a network structure, i.e. an underlying graph topology, which is subject to discrete changes over time. Given a static underlying graph G, a temporal graph can be represented via an assignment of a set of integer time-labels to every edge of G, indicating the discrete time steps when this edge is active. While most of the recent theoretical research on temporal graphs has focused on the notion of a temporal path and other "path-related" temporal notions, only few attempts have been made to investigate "non-path" temporal graph problems. In this paper, motivated by applications in sensor and in transportation networks, we introduce and study two natural temporal extensions of the classical problem Vertex Cover. In our first problem, Temporal Vertex Cover, the aim is to cover every edge at least once during the lifetime of the temporal graph, where an edge can only be covered by one of its endpoints at a time step when it is active. In our second, more pragmatic variation Sliding Window Temporal Vertex Cover, we are also given a natural number Δ, and our aim is to cover every edge at *least once* at *every* Δ *consecutive* time steps. In both cases we wish to minimize the total number of "vertex appearances" that are needed to cover the whole graph. We present a thorough investigation of the computational complexity and approximability of these two temporal covering problems. In particular, we provide strong hardness results, complemented by various approximation and exact algorithms. Some of our algorithms are polynomial-time, while others are asymptotically almost optimal under the Exponential Time Hypothesis (ETH) and other plausible complexity assumptions.

1 Introduction and Motivation

A great variety of both modern and traditional networks are inherently dynamic, in the sense that their link availability varies over time. Information and communication networks, social networks, transportation networks, and several physical systems are only a few examples of networks that change over time [18, 27]. The common characteristic in all these application areas is that the network structure, i.e. the underlying graph topology, is subject to *discrete changes over time*. In this paper we adopt a simple and natural model for time-varying networks which is given with time-labels on the edges of a graph, while the vertex set remains unchanged. This formalism originates in the foundational work of Kempe et al. [20].

▶ **Definition 1** (temporal graph)**.** A *temporal graph* is a pair (G, λ), where $G = (V, E)$ is an underlying (static) graph and $\lambda : E \to 2^{\mathbb{N}}$ is a *time-labeling* function which assigns to every edge of G a set of discrete-time labels.

For every edge $e \in E$ in the underlying graph G of a temporal graph (G, λ), $\lambda(e)$ denotes the set of time slots at which e is *active* in (G, λ). Due to its vast applicability in many areas, this notion of temporal graphs has been studied from different perspectives under various names such as *time-varying* [1, 14, 29], *evolving* [4, 10, 13], *dynamic* [7, 15], and *graphs over time* [24]; for a recent attempt to integrate existing models, concepts, and results from the distributed computing perspective see the survey papers [5–7] and the references therein. Data analytics on temporal networks have also been very recently studied in the context of summarizing networks that represent sports teams' activity data to discover recurring strategies and understand team tactics [22], as well as extracting patterns from interactions between groups of entities in a social network [21].

Motivated by the fact that, due to causality, information in temporal graphs can "flow" only along sequences of edges whose time-labels are increasing, most temporal graph parameters and optimization problems that have been studied so far are based on the notion of temporal paths and other "path-related" notions, such as temporal analogues of distance, diameter, reachability, exploration, and centrality [2, 3, 12, 25, 26]. In contrast, only few attempts have been made to define "non-path" temporal graph problems. Motivated by the contact patterns among high-school students, Viard et al. [31, 32], and later Himmel et al. [17], introduced and studied Δ-cliques, an extension of the concept of cliques to temporal graphs, in which all vertices interact with each other at least once every Δ consecutive time steps within a given time interval.

In this paper we introduce and study two natural temporal extensions of the problem Vertex Cover in static graphs, which take into account the dynamic nature of the network. In the first and simpler of these extensions, namely Temporal Vertex Cover (for short, TVC), every edge e has to be "covered" at least once during the lifetime T of the network (by one of its endpoints), and this must happen at a time step t when e is active. The goal is then to cover all edges with the minimum total number of such "vertex appearances". On the other hand, in many real-world applications where scalability is important, the lifetime T can be arbitrarily large but the network still needs to remain sufficiently covered. In such cases, as well as in safety-critical systems (e.g. in military applications), it may not be satisfactory

enough that an edge is covered just *once* during the *whole lifetime* of the network. Instead, every edge must be covered at least once within *every small* Δ-*window* of time (for an appropriate value of Δ), regardless of how large the lifetime is; this gives rise to our second optimization problem, namely Sliding Window Temporal Vertex Cover (for short, SW-TVC). Formal definitions of our problems TVC and SW-TVC are given in Section 2.

Our two temporal extensions of Vertex Cover are motivated by applications in sensor networks and in transportation networks. In particular, several works in the field of sensor networks considered problems of placing sensors to cover a whole area or multiple critical locations, e.g. for reasons of surveillance. Such studies usually wish to minimize the number of sensors used or the total energy required [11, 16, 23, 28, 33]. Our temporal vertex cover notions are an abstract way to economically meet such covering demands as time progresses.

To further motivate the questions raised in this work, consider a network whose links represent transporting facilities which are not always available, while the availability schedule per link is known in advance. We wish to check each transporting facility and certify "OK" at least once per facility during every (reasonably small) window of time. It is natural to assume that the checking is done in the presence of an inspecting agent at an endpoint of the link (i.e. on a vertex), since such vertices usually are junctions with local offices. The agent can inspect more than one link at the same day, provided that these links share this vertex and that they are all alive (i.e. operating) at that day. Notice that the above is indeed an application drawn from real-life, as regular checks in roads and trucks are paramount for the correct operation of the transporting sector, according to both the European Commission[1] and the American Public Transportation Association[2].

1.1 Our contribution

In this paper we present a thorough investigation of the complexity and approximability of the problems Temporal Vertex Cover (TVC) and Sliding Window Temporal Vertex Cover (SW-TVC) on temporal graphs. We first prove in Section 3 that Set Cover is equivalent to a special case of TVC on star temporal graphs (i.e. when the underlying graph G is a star), which immediately provides several complexity and algorithmic consequences for TVC. In particular, TVC remains NP-complete even on star temporal graphs, and it does not admit a polynomial-time $(1-\varepsilon)\ln n$-approximation algorithm, unless NP has $n^{O(\log\log n)}$-time deterministic algorithms. On the positive side, TVC on star temporal graphs with n vertices can be $(H_{n-1}-\frac{1}{2})$-approximated in polynomial time, where $H_n=\sum_{i=1}^{n}\frac{1}{i}\approx\ln n$ is the nth harmonic number. Similar equivalence with Hitting Set yields that for any $\varepsilon<1$, TVC on star temporal graphs cannot be optimally solved in $O(2^{\varepsilon n})$ time, assuming the Strong Exponential Time Hypothesis (SETH). We complement these results by showing that TVC on general temporal graphs admits a polynomial-time randomized approximation algorithm with expected ratio $O(\ln n)$.

In Section 4 and in the reminder of the paper we deal with our second problem, SW-TVC. We prove in Section 4.1 a strong complexity lower bound on arbitrary temporal graphs. More specifically we prove that, for *any* (arbitrarily growing) functions $f:\mathbb{N}\to\mathbb{N}$ and $g:\mathbb{N}\to\mathbb{N}$,

[1] According to the European Commission (see `https://ec.europa.eu/transport/road_safety/topics/vehicles/inspection_en`), "roadworthiness checks (such as on-the-spot roadside inspections and periodic checks) not only make sure your vehicle is working properly, they are also important for environmental reasons and for ensuring fair competition in the transport sector".

[2] According to the American Public Transportation Association (see `http://www.apta.com/resources/standards/Documents/APTA-RT-VIM-RP-019-03.pdf` "developing minimum inspection, maintenance, testing and alignment procedures maintains rail transit trucks in a safe and reliable operating condition".

there exists a constant $\varepsilon \in (0,1)$ such that SW-TVC cannot be solved in $f(T) \cdot 2^{\varepsilon n \cdot g(\Delta)}$ time, assuming the Exponential Time Hypothesis (ETH). This ETH-based lower bound turns out to be asymptotically almost tight, as we present an exact dynamic programming algorithm with running time $O(T\Delta(n+m) \cdot 2^{n(\Delta+1)})$. This worst-case running time can be significantly improved in certain special temporal graph classes. In particular, when the "snapshot" of (G,λ) at every time step has vertex cover number bounded by k, the running time becomes $O(T\Delta(n+m) \cdot n^{k(\Delta+1)})$. That is, when Δ is a constant, this algorithm is polynomial in the input size on temporal graphs with bounded vertex cover number at every time step. Notably, when every snapshot is a star (i.e. a superclass of the star temporal graphs studied in Section 3) the running time of the algorithm is $O(T\Delta(n+m) \cdot 2^{\Delta})$.

In Section 5 we prove strong inapproximability results for SW-TVC even when restricted to temporal graphs with length $\Delta = 2$ of the sliding window. In particular, we prove that this problem is APX-hard (and thus does not admit a *Polynomial Time Approximation Scheme (PTAS)*, unless P = NP), even when $\Delta = 2$, the maximum degree in the underlying graph G is at most 3, and every connected component at every graph snapshot has at most 7 vertices. Finally, in Section 6 we provide a series of approximation algorithms for the general SW-TVC problem, with respect to various incomparable temporal graph parameters. In particular, we provide polynomial-time approximation algorithms with approximation ratios (i) $O(\ln n + \ln \Delta)$, (ii) $2k$, where k is the maximum number of times that each edge can appear in a sliding Δ time window (thus implying a ratio of 2Δ in the general case), (iii) d, where d is the maximum vertex degree at every snapshot of (G,λ). Note that, for $d = 1$, the latter result implies that SW-TVC can be optimally solved in polynomial time whenever every snapshot of (G,λ) is a matching.

2 Preliminaries and notation

A theorem proving that a problem is NP-hard does not provide much information about how efficiently (although not polynomially, unless P = NP) this problem can be solved. In order to prove some useful complexity lower bounds, we mostly need to rely on some complexity hypothesis that is stronger than"P $\neq$ NP". The *Exponential Time Hypothesis (ETH)* is one of the established and most well-known such complexity hypotheses.

▶ **Exponential Time Hypothesis** (ETH [19]). *There exists an $\varepsilon < 1$ such that* 3SAT *cannot be solved in $O(2^{\varepsilon n})$ time, where n is the number of variables in the input 3-CNF formula.*

Given a (static) graph G, we denote by $V(G)$ and $E(G)$ the sets of its vertices and edges, respectively. An edge between two vertices u and v of G is denoted by uv, and in this case u and v are said to be *adjacent* in G. The maximum label assigned by λ to an edge of G, called the *lifetime* of (G,λ), is denoted by $T(G,\lambda)$, or simply by T when no confusion arises. That is, $T(G,\lambda) = \max\{t \in \lambda(e) : e \in E\}$. For every $i,j \in \mathbb{N}$, where $i \leq j$, we denote $[i,j] = \{i, i+1, \ldots, j\}$. Throughout the paper we consider temporal graphs with *finite lifetime* T, and we refer to each integer $t \in [1,T]$ as a *time slot* of (G,λ). The *instance* (or *snapshot*) of (G,λ) *at time* t is the static graph $G_t = (V, E_t)$, where $E_t = \{e \in E : t \in \lambda(e)\}$. For every $i,j \in [1,T]$, where $i \leq j$, we denote by $(G,\lambda)|_{[i,j]}$ the restriction of (G,λ) to the time slots $i, i+1, \ldots, j$, i.e. $(G,\lambda)|_{[i,j]}$ is the sequence of the instances $G_i, G_{i+1}, \ldots, G_j$. We assume in the remainder of the paper that every edge of G appears in at least one time slot until T, namely $\bigcup_{t=1}^{T} E_t = E$.

Although some optimization problems on temporal graphs may be hard to solve in the worst case, an optimal solution may be efficiently computable when the input temporal

graph (G, λ) has special properties, i.e. if (G, λ) belongs to a special *temporal graph class* (or *time-varying graph class* [5, 7]). To specify a temporal graph class we can restrict (a) the *underlying topology* G, or (b) the *time-labeling* λ, i.e. the temporal pattern in which the time-labels appear, or both.

▶ **Definition 2.** Let (G, λ) be a temporal graph and let $\mathcal{X}$ be a class of (static) graphs. If $G \in \mathcal{X}$ then (G, λ) is an $\mathcal{X}$ *temporal graph*. On the other hand, if $G_i \in \mathcal{X}$ for every $i \in [1, T]$, then (G, λ) is an *always* $\mathcal{X}$ *temporal graph*.

In the remainder of the paper we denote by $n = |V|$ and $m = |E|$ the number of vertices and edges of the underlying graph G, respectively, unless otherwise stated. Furthermore, unless otherwise stated, we assume that the labeling λ is arbitrary, i.e. (G, λ) is given with an explicit list of labels for every edge. That is, the *size* of the input temporal graph (G, λ) is $O\left(|V| + \sum_{t=1}^{T} |E_t|\right) = O(n + mT)$. In other cases, where λ is more restricted, e.g. if λ is periodic or follows another specific temporal pattern, there may exist more succinct representations of the input temporal graph.

For every $u \in V$ and every time slot t, we denote the *appearance of vertex u at time t* by the pair (u, t). That is, every vertex u has T different appearances (one for each time slot) during the lifetime of (G, λ). Similarly, for every vertex subset $S \subseteq V$ and every time slot t we denote the *appearance of set S at time t* by (S, t). With a slight abuse of notation, we write $(S, t) = \bigcup_{v \in S}(v, t)$. A *temporal vertex subset* of (G, λ) is a set $\mathcal{S} \subseteq \{(v, t) : v \in V, 1 \leq t \leq T\}$ of vertex appearances in (G, λ). Given a temporal vertex subset $\mathcal{S}$, for every time slot $t \in [1, T]$ we denote by $\mathcal{S}_t = \{(v, t) : (v, t) \in \mathcal{S}\}$ the set of all vertex appearances in $\mathcal{S}$ at the time slot t. Similarly, for any pair of time slots $i, j \in [1, T]$, where $i \leq j$, $\mathcal{S}|_{[i,j]}$ is the restriction of the vertex appearances of $\mathcal{S}$ within the time slots $i, i + 1, \ldots, j$. Note that the *cardinality* of the temporal vertex subset $\mathcal{S}$ is $|\mathcal{S}| = \sum_{1 \leq t \leq T} |\mathcal{S}_t|$.

2.1 Temporal Vertex Cover

Let $\mathcal{S}$ be a temporal vertex subset of (G, λ). Let $e = uv \in E$ be an edge of the underlying graph G and let (w, t) be a vertex appearance in $\mathcal{S}$. We say that vertex w *covers* the edge e if $w \in \{u, v\}$, i.e. w is an endpoint of e; in that case, edge e is *covered* by vertex w. Furthermore we say that the vertex appearance (w, t) *temporally covers* the edge e if (i) w covers e and (ii) $t \in \lambda(e)$, i.e. the edge e is *active* during the time slot t; in that case, edge e is *temporally covered* by the vertex appearance (w, t). We now introduce the notion of a *temporal vertex cover* and the optimization problem Temporal Vertex Cover.

▶ **Definition 3.** Let (G, λ) be a temporal graph. A *temporal vertex cover* of (G, λ) is a temporal vertex subset $\mathcal{S} \subseteq \{(v, t) : v \in V, 1 \leq t \leq T\}$ of (G, λ) such that every edge $e \in E$ is *temporally covered* by at least one vertex appearance (w, t) in $\mathcal{S}$.

Temporal Vertex Cover (TVC)
Input: A temporal graph (G, λ).
Output: A temporal vertex cover $\mathcal{S}$ of (G, λ) with the smallest cardinality $\lvert\mathcal{S}\rvert$.

Note that TVC is a natural temporal extension of the problem Vertex Cover on static graphs. In fact, Vertex Cover is the special case of TVC where $T = 1$. Thus TVC is clearly NP-complete, as it also trivially belongs to NP.

2.2 Sliding Window Temporal Vertex Cover

In the notion of a temporal vertex cover given in Section 2.1, the requirement is that every edge is temporally covered at least once during the lifetime T of the input temporal graph (G, λ). On the other hand, in many real-world applications where scalability is important, the lifetime T can be arbitrarily large. In such cases it may not be satisfactory enough that an edge is temporally covered just *once* during the whole lifetime of the temporal graph. Instead, in such cases it makes sense that every edge is temporally covered by some vertex appearance at least once during *every small period* Δ of time, regardless of how large the lifetime T is. Motivated by this, we introduce in this section a natural *sliding window* variant of the TVC problem, which offers a greater scalability of the solution concept.

For every time slot $t \in [1, T - \Delta + 1]$, we define the *time window* $W_t = [t, t + \Delta - 1]$ as the sequence of the Δ consecutive time slots $t, t + 1, \ldots, t + \Delta - 1$. Furthermore we denote by $E[W_t] = \bigcup_{i \in W_t} E_i$ the union of all edges appearing at least once in the time window W_t. Finally we denote by $\mathcal{S}[W_t] = \{(v, i) \in \mathcal{S} : i \in W_t\}$ the restriction of the temporal vertex subset $\mathcal{S}$ to the window W_t. We are now ready to introduce the notion of a *sliding Δ-window temporal vertex cover* and the optimization problem Sliding Window Temporal Vertex Cover.

▶ **Definition 4.** Let (G, λ) be a temporal graph with lifetime T and let $\Delta \leq T$. A *sliding Δ-window temporal vertex cover* of (G, λ) is a temporal vertex subset $\mathcal{S} \subseteq \{(v, t) : v \in V, 1 \leq t \leq T\}$ of (G, λ) such that, for every time window W_t and for every edge $e \in E[W_t]$, e is *temporally covered* by at least one vertex appearance (w, t) in $\mathcal{S}[W_t]$.

Sliding Window Temporal Vertex Cover (SW-TVC)

Input: A temporal graph (G, λ) with lifetime T, and an integer $\Delta \leq T$.
Output: A sliding Δ-window temporal vertex cover $\mathcal{S}$ of (G, λ) with the smallest cardinality $|\mathcal{S}|$.

Whenever the parameter Δ is a fixed constant, we will refer to the above problem as the Δ-TVC (i.e. Δ is now a part of the problem name). Note that the problem TVC defined in Section 2.1 is the special case of SW-TVC where $\Delta = T$, i.e. where there is only one Δ-window in the whole temporal graph. Another special case[3] of SW-TVC is the problem 1-TVC, whose optimum solution is obtained by iteratively solving the (static) problem Vertex Cover on each of the T static instances of (G, λ); thus 1-TVC fails to fully capture the time dimension in temporal graphs.

3 Hardness and approximability of TVC

In this section we investigate the complexity of Temporal Vertex Cover (TVC). First we prove in Section 3.1 that TVC on star temporal graphs is equivalent to both Set Cover and Hitting Set, and derive several complexity and algorithmic consequences for TVC.

In Section 3.2 we use randomized rounding technique to prove that TVC on general temporal graphs admits a polynomial-time randomized approximation algorithm with expected ratio $O(\ln n)$. This result is complemented by our results in Section 6.1 where we prove that SW-TVC (and thus also TVC) can be deterministically approximated with ratio $H_{2n\Delta} - \frac{1}{2} \approx \ln n + \ln 2\Delta - \frac{1}{2}$ in polynomial time.

[3] The problem 1-TVC has already been investigated under the name "evolving vertex cover" in the context of maintenance algorithms in dynamic graphs [8]; similar "evolving" variations of other graph covering problems have also been considered, e.g. the "evolving dominating set" [6].

3.1 Hardness on star temporal graphs

In the next theorem we reduce Set Cover to TVC on star temporal graphs, and vice versa. Our hardness results are complemented in Theorem 6 by reducing from Hitting Set.

▶ **Theorem 5.** TVC *on star temporal graphs is NP-complete and it admits a polynomial-time* $(H_{n-1} - \frac{1}{2})$*-approximation algorithm. Furthermore, for any* $\varepsilon > 0$, TVC *on star temporal graphs does not admit any polynomial-time* $(1-\varepsilon)\ln n$*-approximation algorithm, unless NP has* $n^{O(\log\log n)}$*-time deterministic algorithms.*

▶ **Theorem 6.** *For every* $\varepsilon < 1$, TVC *on star temporal graphs cannot be optimally solved in* $O(2^{\varepsilon n})$ *time, unless the Strong Exponential Time Hypothesis (SETH) fails.*

3.2 A randomized rounding algorithm for TVC

In this section we provide a linear programming relaxation of TVC, and then, with the help of a randomized rounding technique, we construct a feasible solution whose expected size is within a factor of $O(\ln n)$ of the optimal size.

▶ **Theorem 7.** *There exists a polynomial-time randomized approximation algorithm for* TVC *with expected approximation factor* $O(\ln n)$.

4 An almost tight algorithm for SW-TVC

In this section we investigate the complexity of Sliding Window Temporal Vertex Cover (SW-TVC). First we prove in Section 4.1 a strong lower bound on the complexity of optimally solving this problem on arbitrary temporal graphs. More specifically we prove that, for *any* (arbitrarily growing) functions $f : \mathbb{N} \to \mathbb{N}$ and $g : \mathbb{N} \to \mathbb{N}$, there exists a constant $\varepsilon \in (0,1)$ such that SW-TVC cannot be solved in $f(T) \cdot 2^{\varepsilon n \cdot g(\Delta)}$ time, assuming the Exponential Time Hypothesis (ETH). This ETH-based lower bound turns out to be asymptotically almost tight. In fact, we present in Section 4.2 an exact dynamic programming algorithm for SW-TVC whose running time on an arbitrary temporal graph is $O(T\Delta(n+m)\cdot 2^{n(\Delta+1)})$, which is asymptotically almost optimal, assuming ETH. In Section 4.3 we prove that our algorithm can be refined so that, when the vertex cover number of each snapshot G_i is bounded by a constant k, the running time becomes $O(T\Delta(n+m)\cdot n^{k(\Delta+1)})$. That is, when Δ is a constant, this algorithm is polynomial in the input size on temporal graphs with bounded vertex cover number at every slot. Notably, for the class of always star temporal graphs (i.e. a superclass of the star temporal graphs studied in Section 3.1) the running time of the algorithm is $O(T\Delta(n+m)\cdot 2^{\Delta})$.

4.1 A complexity lower bound

In the the following theorem we prove a strong ETH-based lower bound for SW-TVC. This lower bound is asymptotically almost tight, as we present in Section 4.2 a dynamic programming algorithm for SW-TVC with running time $O(T\Delta(n+m)\cdot 2^{n\Delta})$, where n and m are the numbers of vertices and edges in the underlying graph G, respectively.

▶ **Theorem 8.** *For* any *two (arbitrarily growing) functions* $f, g : \mathbb{N} \to \mathbb{N}$*, there exists a constant* $\varepsilon \in (0,1)$ *such that* SW-TVC *cannot be solved in* $f(T)\cdot 2^{\varepsilon n \cdot g(\Delta)}$ *time assuming ETH, where* n *is the number of vertices in the underlying graph* G *of the temporal graph.*

4.2 An exact dynamic programming algorithm

The main idea of our dynamic programming algorithm for SW-TVC is to scan the temporal graph from left to right with respect to time (i.e. to scan the snapshots G_i increasingly on i), and at every time slot to consider all possibilities for the vertex appearances at the previous Δ time slots. Let (G, λ) be a temporal graph with n vertices and lifetime T, and let $\Delta \leq T$. For every $t = 1, 2, \ldots, T - \Delta + 1$ and every Δ-tuple of vertex subsets $A_1, \ldots, A_\Delta$ of G, we define $f(t; A_1, A_2, \ldots, A_\Delta)$ to be the smallest cardinality of a sliding Δ-window temporal vertex cover $\mathcal{S}$ of $(G, \lambda)|_{[1,t+\Delta-1]}$, such that $\mathcal{S}_t = (A_1, t)$, $\mathcal{S}_{t+1} = (A_2, t+1)$, $\ldots$, $\mathcal{S}_{t+\Delta-1} = (A_\Delta, t+\Delta-1)$. If there exists no sliding Δ-window temporal vertex cover $\mathcal{S}$ of $(G, \lambda)|_{[1,t+\Delta-1]}$ with these prescribed vertex appearances in the time slots $t, t+1, \ldots, t+\Delta-1$, then we define $f(t; A_1, A_2, \ldots, A_\Delta) = \infty$. Note that, once we have computed all possible values of the function $f(\cdot)$, then the optimum solution of SW-TVC on (G, λ) has cardinality

$$\mathrm{OPT}_{\text{SW-TVC}}(G, \lambda) = \min_{A_1, A_2, \ldots, A_\Delta \subseteq V} \{f(T - \Delta + 1; A_1, A_2, \ldots, A_\Delta)\}. \tag{1}$$

▶ **Lemma 9.** *Let (G, λ) be a temporal graph, where $G = (V, E)$. Let $2 \leq t \leq T - \Delta + 1$ and let $A_1, A_2, \ldots A_\Delta$ be a Δ-tuple of vertex subsets of the underlying graph G. Suppose that $\bigcup_{i=1}^{\Delta}(A_i, t + i - 1)$ is a temporal vertex cover of $(G, \lambda)|_{[t,t+\Delta-1]}$. Then*

$$f(t; A_1, A_2, \ldots, A_\Delta) = |A_\Delta| + \min_{X \subseteq V} \{f(t-1; X, A_1, \ldots, A_{\Delta-1})\}. \tag{2}$$

Using the recursive computation of Lemma 9, we are now ready to present Algorithm 1 for computing the value of an optimal solution of SW-TVC on a given arbitrary temporal graph (G, λ). Note that Algorithm 1 can be easily modified such that it also computes the actual optimum solution of SW-TVC (instead of only its optimum cardinality). The proof of correctness and running time analysis of Algorithm 1 are given in the next theorem.

Algorithm 1 SW-TVC.

Input: A temporal graph (G, λ) with lifetime T, where $G = (V, E)$, and a natural $\Delta \leq T$.
Output: The smallest cardinality of a sliding Δ-window temporal vertex cover in (G, λ).

```
1: for t = 1 to T − Δ + 1 do
2:   for all A_1, A_2, ..., A_Δ ⊆ V do
3:     if ⋃_{i=1}^{Δ}(A_i, t + i − 1) is a temporal vertex cover of (G, λ)|_[t,t+Δ−1] then
4:       if t = 1 then
5:         f(t; A_1, A_2, ..., A_Δ) ← Σ_{i=1}^{Δ} |A_i|
6:       else
7:         f(t; A_1, A_2, ..., A_Δ) ← |A_Δ| + min_{X⊆V} {f(t − 1; X, A_1, ..., A_{Δ−1})}
8:     else
9:       f(t; A_1, A_2, ..., A_Δ) ← ∞
10: return min_{A_1,...,A_Δ⊆V} {f(T − Δ + 1; A_1, ..., A_Δ)}
```

▶ **Theorem 10.** *Let (G, λ) be a temporal graph, where $G = (V, E)$ has n vertices and m edges. Let T be its lifetime and let Δ be the length of the sliding window. Algorithm 1 computes in $O(T\Delta(n + m) \cdot 2^{n(\Delta+1)})$ time the value of an optimal solution of* SW-TVC *on (G, λ).*

4.3 Always bounded vertex cover number temporal graphs

Let k be a constant and let $\mathcal{C}_k$ be the class of graphs with the vertex cover number at most k. The next theorem follows now from the analysis of Theorem 10.

▶ **Theorem 11.** SW-TVC *on always $\mathcal{C}_k$ temporal graphs can be solved in* $O(T\Delta(n+m)\cdot n^{k(\Delta+1)})$ *time.*

In particular, in the special, yet interesting, case of always star temporal graphs, our search at every step reduces to just one binary choice for each of the previous Δ time slots, of whether to include the central vertex of a star in a snapshot or not. Hence we have the following theorem as a direct implication of Theorem 11.

▶ **Theorem 12.** SW-TVC *on always star temporal graphs can be solved in* $O(T\Delta(n+m)\cdot 2^{\Delta})$ *time.*

5 Approximation hardness of 2-TVC

In this section we study the complexity of Δ-TVC where Δ is constant. We start with an intuitive observation that, for every fixed Δ, the problem $(\Delta+1)$-TVC is at least as hard as Δ-TVC. Indeed, let $\mathcal{A}$ be an algorithm that computes a minimum-cardinality sliding $(\Delta+1)$-window temporal vertex cover of (G,λ). It is easy to see that a minimum-cardinality sliding Δ-window temporal vertex cover of (G,λ) can also be computed using $\mathcal{A}$, if we amend the input temporal graph by inserting one edgeless snapshot after every Δ consecutive snapshots of (G,λ).

Since the 1-TVC problem is equivalent to solving T instances of Vertex Cover (on static graphs), the above reduction demonstrates in particular that, for any natural Δ, Δ-TVC is at least as hard as Vertex Cover. Therefore, if Vertex Cover is hard for a class $\mathcal{X}$ of static graphs, then Δ-TVC is also hard for the class of always $\mathcal{X}$ temporal graphs. In this section, we show that the converse is not true. Namely, we reveal a class $\mathcal{X}$ of graphs, for which Vertex Cover can be solved in *linear* time, but 2-TVC is NP-hard on always $\mathcal{X}$ temporal graphs. In fact, we show the even stronger result that 2-TVC is APX-hard (and thus does not admit a PTAS, unless P = NP) on always $\mathcal{X}$ temporal graphs.

To prove the main result (in Theorem 14) we start with an auxiliary lemma, showing that Vertex Cover is APX-hard on the class $\mathcal{Y}$ of graphs which can be obtained from a cubic graph by subdividing every edge exactly 4 times.

▶ **Lemma 13.** Vertex Cover *is APX-hard on* $\mathcal{Y}$.

Let now $\mathcal{X}$ be the class of graphs whose connected components are induced subgraphs of the graph obtained from the star with three leaves by subdividing each of its edges exactly once. Clearly, Vertex Cover is linearly solvable on graphs from $\mathcal{X}$. We will show that 2-TVC is APX-hard on always $\mathcal{X}$ temporal graphs by using a reduction from Vertex Cover on $\mathcal{Y}$.

▶ **Theorem 14.** 2-TVC *is APX-hard on always* $\mathcal{X}$ *temporal graphs.*

Proof. To prove the theorem we will reduce Vertex Cover on $\mathcal{Y}$ to 2-TVC on always $\mathcal{X}$ temporal graphs. Let $H=(V,E)$ be a graph in $\mathcal{Y}$. First we will show how to construct an always $\mathcal{X}$ temporal graph (G,λ) of lifetime 2. Then we will prove that the size τ of a minimum vertex cover of H is equal to the size σ of a minimum-cardinality sliding 2-window temporal vertex cover of (G,λ).

Let $R\subseteq V$ be the set of vertices of degree 3 in H. We define (G,λ) to be a temporal graph of lifetime 2, where snapshot G_1 is obtained from H by removing the edges with both ends being at distance exactly 2 from R, and snapshot $G_2=H-R$. Figure 1 illustrates the reduction for $H=K_4$.

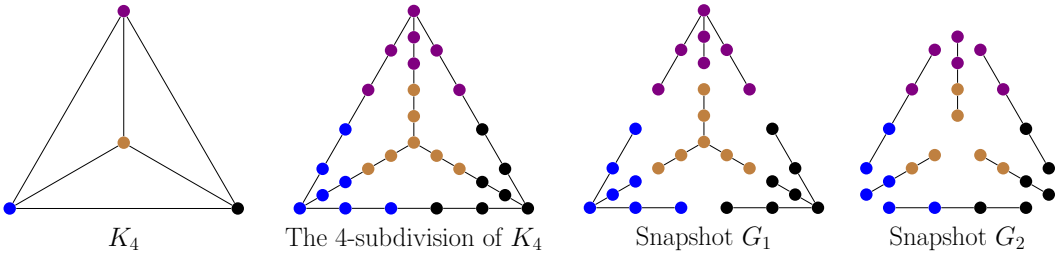

Figure 1 A cubic graph K_4, its 4-subdivision, and the corresponding snapshots G_1 and G_2

Let $\mathcal{S} = (S_1, 1) \cup (S_2, 2)$ be an arbitrary sliding 2-window temporal vertex cover of (G, λ) for some $S_1, S_2 \subseteq V$. Since every edge of H belongs to at least one of the graphs G_1 and G_2, the set $S_1 \cup S_2$ covers all the edges of H. Hence, $\tau \leq |S_1 \cup S_2| \leq |S_1| + |S_2| = |\mathcal{S}|$. As $\mathcal{S}$ was chosen arbitrarily we further conclude that $\tau \leq \sigma$.

To show the converse inequality, let $C \subseteq V$ be a minimum vertex cover of H. Let S_1 be those vertices in C which either have degree 3, or have a neighbor of degree 3. Let also $S_2 = C \setminus S_1$. We claim that $(S_1, 1) \cup (S_2, 2)$ is a sliding 2-window temporal vertex cover of (G, λ). First, let $e \in E$ be an edge in H incident to a vertex of degree 3. Then, by the construction, e is active only in time slot 1, i.e. $e \in E_1 \setminus E_2$, and a vertex v in C covering e belongs to S_1. Hence, e is temporally covered by $(v, 1)$ in (G, λ). Let now $e \in E$ be an edge in H whose both end vertices have degree 2. If one of the end vertices of e is adjacent to a vertex of degree 3 in H, then, by the construction, e is active in both time slots 1 and 2. Therefore, since $C = S_1 \cup S_2$, edge e will be temporally covered in (G, λ) in at least one of the time slots. Finally, if none of the end vertices of e is adjacent to a vertex of degree 3 in H, then e is active only in time slot 2, i.e. $e \in E_2 \setminus E_1$. Moreover, by the construction a vertex v in C covering e belongs to S_2. Hence, e is temporally covered by $(v, 2)$ in (G, λ). This shows that $(S_1, 1) \cup (S_2, 2)$ is a sliding 2-window temporal vertex cover of (G, λ), and therefore $\sigma \leq |S_1| + |S_2| = |C| = \tau$.

Note that the size of a minimum vertex cover of H is equal to the size of a minimum-cardinality sliding 2-window temporal vertex cover of (G, λ) and that any feasible solution to 2-TVC on (G, λ) of size r defines a vertex cover of H of size at most r. Thus, since Vertex Cover is APX-hard on $\mathcal{Y}$ by Lemma 13 and the reduction is approximation-preserving, it follows that 2-TVC is APX-hard as well. ◀

6 Approximation algorithms

In this section we provide several approximation algorithms for SW-TVC with respect to different temporal graph parameters. As the various approximation factors that are achieved are incomparable, the best option for approximating an optimal solution depends on the specific application domain and the specific values of those parameters.

6.1 Approximations in terms of T, Δ, and the largest edge frequency

We begin by presenting a reduction from SW-TVC to Set Cover, which proves useful for deriving approximation algorithms for the original problem. Consider an instance, (G, λ) and $\Delta \leq T$, of the SW-TVC problem. Construct an instance of Set Cover as follows: Let the universe be $U = \{(e, t) : e \in E[W_t], t \in [1, T - \Delta + 1]\}$, i.e. the set of all pairs (e, t) of an edge e and a time slot t such that e appears (and so must be temporally

covered) within window W_t. For every vertex appearance (v, s) we define $C_{v,s}$ to be the set of elements (e, t) in the universe U, such that (v, s) temporally covers e in the window W_t. Formally, $C_{v,s} = \{(e, t) : v \text{ is an endpoint of } e, e \in E_s, \text{ and } s \in W_t\}$. Let $\mathcal{C}$ be the family of all sets $C_{v,s}$, where $v \in V, s \in [1, T]$. The following lemma shows that finding a minimum-cardinality sliding Δ-window temporal vertex cover of (G, λ) is equivalent to finding a minimum-cardinality family of sets $C_{v,s}$ that covers the universe U.

▶ **Lemma 15.** *A family $\mathcal{C} = \{C_{v_1,t_1}, \ldots, C_{v_k,t_k}\}$ is a set cover of U if and only if $\mathcal{S} = \{(v_1, t_1), \ldots, (v_k, t_k)\}$ is a sliding Δ-window temporal vertex cover of (G, λ).*

$O(\ln n + \ln \Delta)$-approximation. In the instance of Set Cover constructed by the above reduction, every set $C_{v,s}$ in $\mathcal{C}$ contains at most $n\Delta$ elements of the universe U. Indeed, the vertex appearance (v, s) temporally covers at most $n-1$ edges, each in at most Δ windows (namely from window $W_{s-\Delta+1}$ up to window W_s). Thus we can apply the polynomial-time greedy algorithm from [9] for Set Cover which achieves an approximation ratio of $H_{n\Delta} - \frac{1}{2} = \sum_{i=1}^{n\Delta} \frac{1}{i} - \frac{1}{2} \approx \ln n + \ln \Delta - \frac{1}{2}$.

$2k$-approximation, where k is the maximum edge frequency. Given a temporal graph (G, λ) and an edge e of G, the Δ-frequency of e is the maximum number of time slots at which e appears within a Δ-window. Let k denote the maximum Δ-frequency over all edges of G. Clearly, for a particular Δ-window W_t, an edge $e \in E[W_t]$ can be temporally covered in W_t by at most $2k$ vertex appearances. So in the above reduction to Set Cover, every element $(e, t) \in U$ belongs to at most $2k$ sets in $\mathcal{C}$. Therefore, the optimal solution of the constructed instance of Set Cover can be approximated within a factor of $2k$ in polynomial time [30], yielding a $2k$-approximation for SW-TVC.

2Δ-approximation. Since the maximum Δ-frequency of an edge is always upper-bounded by Δ, the previous algorithm gives a worst-case polynomial-time 2Δ-approximation for SW-TVC on arbitrary temporal graphs.

6.2 Approximation in terms of maximum degree of snapshots

In this section we give a polynomial-time d-approximation algorithm for the SW-TVC problem on *always degree at most d* temporal graphs, that is, temporal graphs where the maximum degree in each snapshot is at most d. In particular, the algorithm computes an optimum solution (i.e. with approximation ratio $d = 1$) for always matching (i.e. always degree at most 1) temporal graphs. As a building block, we first provide an exact $O(T)$-time algorithm for optimally solving SW-TVC in the class of single-edge temporal graphs, namely temporal graphs whose underlying graph is a single edge.

Single-edge temporal graphs

Consider a temporal graph (G_0, λ) where G_0 is the single-edge graph, i.e. $V(G_0) = \{u, v\}$ and $E(G_0) = \{uv\}$. We reduce SW-TVC on (G_0, λ) to an instance of Interval Covering.

Interval Covering

Input: A family $\mathcal{I}$ of intervals in the line.
Output: A minimum-cardinality subfamily $\mathcal{I}' \subseteq \mathcal{I}$ such that $\bigcup_{I \in \mathcal{I}} = \bigcup_{I \in \mathcal{I}'}$.

An easy linear-time greedy algorithm for the Interval Covering picks at each iteration, among the intervals that cover the leftmost uncovered point, the one with largest finishing time. Algorithm 2 implements this simple rule in the context of the SW-TVC problem.

Algorithm 2 SW-TVC on single-edge temporal graphs.

Input: A temporal graph (G_0, λ) of lifetime T with $V(G_0) = \{u, v\}$, and $\Delta \leq T$.
Output: A minimum-cardinality sliding Δ-window temporal vertex cover $\mathcal{S}$ of (G_0, λ).

$\mathcal{S} \leftarrow \emptyset$
$t = 1$
while $t \leq T - \Delta + 1$ **do**
  if $\exists r \in [t, t + \Delta - 1]$ such that $uv \in E_t$ **then**
    choose maximum such r and add (u, r) to $\mathcal{S}$
    $t \leftarrow r + 1$
  else
    $t \leftarrow t + 1$
return $\mathcal{S}$

▶ **Lemma 16.** *Algorithm 2 solves* SW-TVC *on a single-edge temporal graph and can be implemented to work in time* $O(T)$.

Always degree at most d temporal graphs

We present now the main algorithm of this section, the idea of which is to independently solve SW-TVC for every possible single-edge temporal subgraph of a given temporal graph by Algorithm 2, and take the union of these solutions. We will show that this algorithm is a d-approximation algorithm for SW-TVC on always degree at most d temporal graphs.

Let (G, λ) be a temporal graph, where $G = (V, E)$, $|V| = n$, and $|E| = m$. For every edge $e = uv \in E$, let $(G[\{u, v\}], \lambda)$ denote the temporal graph where the underlying graph is the induced subgraph $G[\{u, v\}]$ of G and the labels of e are exactly the same as in (G, λ).

Algorithm 3 d-approximation of SW-TVC on always degree at most d temporal graphs

Input: An always degree at most d temporal graph (G, λ) of lifetime T, and $\Delta \leq T$.
Output: A sliding Δ-window temporal vertex cover $\mathcal{S}$ of (G, λ).

for $i = 1$ to T **do**
  $\mathcal{S}_i \leftarrow \emptyset$
for every edge $e = uv \in E(G)$ **do**
  Compute an optimal solution $\mathcal{S}'(uv)$ of the problem for $(G[\{u, v\}], \lambda)$ by Algorithm 2
  for $i = 1$ to T **do**
    $\mathcal{S}_i \leftarrow \mathcal{S}_i \cup \mathcal{S}'_i(uv)$
return $\mathcal{S}$

▶ **Lemma 17.** *Algorithm 3 is a* $O(mT)$*-time* d*-approximation algorithm for* SW-TVC *on always degree at most* d *temporal graphs.*

Note that, in the case of always matching temporal graphs, the maximum degree in each snapshot is $d = 1$, so the above d-approximation actually yields an exact algorithm.

▶ **Corollary 18.** SW-TVC *can be optimally solved in* $O(mT)$ *time on the class of always matching temporal graphs.*

Abstract

We study a number of graph exploration problems in the following natural scenario: an algorithm starts exploring an undirected graph from some *seed* vertex; the algorithm, for an arbitrary vertex v that it is aware of, can ask an oracle to return the set of the neighbors of v. (In the case of social networks, a call to this oracle corresponds to downloading the profile page of user v.) The goal of the algorithm is to either learn something (e.g., average degree) about the graph, or to return some random function of the graph (e.g., a uniform-at-random vertex), while accessing/downloading as few vertices of the graph as possible.

Motivated by practical applications, we study the complexities of a variety of problems in terms of the graph's mixing time $\mathrm{t_{mix}}$ and average degree $\mathrm{d_{avg}}$ – two measures that are believed to be quite small in real-world social networks, and that have often been used in the applied literature to bound the performance of online exploration algorithms.

Our main result is that the algorithm has to access $\Omega\left(\mathrm{t_{mix}}\,\mathrm{d_{avg}}\,\epsilon^{-2}\ln\delta^{-1}\right)$ vertices to obtain, with probability at least $1-\delta$, an ϵ additive approximation of the average of a bounded function on the vertices of a graph – this lower bound matches the performance of an algorithm that was proposed in the literature.

We also give tight bounds for the problem of returning a close-to-uniform-at-random vertex from the graph. Finally, we give lower bounds for the problems of estimating the average degree of the graph, and the number of vertices of the graph.

1 Introduction

Hundreds of millions of people share messages, videos and pictures on Google+ and Facebook each day – these media have an increasingly high political, economical, and social importance in today's world. Data miners have consequently devoted significant amounts of attention to the study of large social networks.

In data mining, one often seeks algorithms that can return (approximate) properties of online social networks, so to study and analyze them, but without having to download the millions, or billions, of vertices that they are made up of. The properties of interest range from the order of the graph [18, 17], to its average degree (or its degree distribution) [10, 13, 16], to the average clustering coefficient [22, 23] or triangle counting [2], to non-topological properties such as the average score that the social network's users assign to a movie or a song, or to the fraction of people that *like* a specific article or page. All these problems have trivial solutions when the graph (with its non-topological attributes) is stored in main memory, or in the disk: choosing a few independent and uniform at random vertices from the graph, and computing their contribution to the (additive) property of interest, is sufficient to estimate the (unknown) value of the graph property – the empirical average of the contributions of the randomly chosen vertices will be close to the right value with high probability, by the central limit theorem.

In applications, though, it is often impossible to have random access to the (vertices of the) graph. Consider, for instance, an online undirected social graph, such as the Facebook friendship graph. An algorithm can *download* a webpage of a given (known) user `alice` from this social graph (e.g., `http://sn.com/user.php?id=alice`), parse the HTML, and get the URLs of the pages of her friends (e.g., `http://sn.com/user.php?id=bob`, `http://sn.com/user.php?id=charles`, etc.) and that user's non-topological attributes (e.g., the set of movies she likes) – an algorithm, though, cannot download the webpage of a vertex without knowing its URL: thus, to download a generic vertex `zoe` from the graph, the algorithm first needs to download all the vertices in (at least) one path from the seed vertex (e.g., `alice`) to `zoe`.

Clearly, given enough many resources, the algorithm could crawl the whole social network (that is, download each of the social network's vertices), and then reduce the problem of computing the online graph property to the centralized one – unfortunately, it is practically infeasible to download millions, or billions, of vertices from a social network (the APIs that can be used to access the network usually enforce strict limits on how many vertices can be downloaded per day). Several techniques have been proposed in the literature for studying properties of online graphs – almost all of them assume to have access to a random oracle that returns a random vertex of the graph according to a certain distribution (usually, either uniform, or proportional to the degree), e.g., [5, 12, 18, 10, 16].

When running algorithms on online social networks, it is often hard or impossible to implement a uniform-at-random random oracle, and to get samples out of it – the complexity of this oracle is one of the main problems that we tackle in this paper.

In practice, an algorithm is given (the URL of) a seed vertex (or, some seed vertices) of the social network; the algorithm has to download that seed vertex, get the URLs of its neighbors, and then decide which of them to download next; after having downloaded the second node, the algorithm (might) learn of the existence of some other URLs/vertices, and can then decide which of the known (but unexplored) URLs to download – and so on, and so forth, until the algorithm can return a good approximation of the property to be estimated.

The natural cost function in this setting is the (random) number of vertices that the algorithm has to download, or *query*, before making its guess – the cost function is usually bounded in terms of properties of the graph (e.g., its order, its average degree, etc.), and in terms of the quality of the algorithm's guess.

Many problems of this form can be found in the literature. In this paper, we consider two natural problems, that are at the heart of many others, and whose complexity (as far as we know) was open before this work:

- the "average score problem": assuming that each vertex holds some score in $[0, 1]$, compute an approximation of the average of the scores;
- the "uniform at random sample": return a random vertex from the graph whose distribution is approximately uniform.

In a sense, the latter problem is technically more interesting than the former (a solution to the latter provides a solution to the former). In practice, though, the average score problem is much more significant (and ubiquitous), given its many applications [11, 1, 14, 21] (e.g., computing the favorability rating of a candidate, or the average star-rating of a movie). These problems are similar in flavor to some graph property testing problems [15]. Observe that our setting is similar, but different, than various graph property testing settings – many of the existing graph property testing algorithms require, as a primitive, the ability to sample a uniform at random vertex. Our work can be seen as a way of implementing that primitive using the oracles mentioned above. (See also, [4]).

A number of algorithms have been proposed for the uniform-at-random sample problem [7, 18] – the best known algorithms require roughly $\tilde{O}\left(\mathrm{t_{mix}} \cdot \mathrm{d_{avg}}\right)$ vertex queries/downloads to return a vertex whose distribution is (close to) uniform at random , where $\mathrm{t_{mix}}$ is the mixing time of the lazy random walk on the graph, and $\mathrm{d_{avg}}$ is its average degree [7][3]. These algorithms do not use any knowledge of the average degree of the graph $\mathrm{d_{avg}}$, but need to know a constant approximation of its mixing time $\mathrm{t_{mix}}$. To our knowledge, the best lower bound for the uniform-at-random sample problem before this work, was $\Omega(\mathrm{t_{mix}} + \mathrm{d_{avg}})$ [7] – one of the main results of this paper is (i) an almost tight lower bound of $\Omega(\mathrm{t_{mix}} \cdot \mathrm{d_{avg}})$ for this problem, for wide (in fact, polynomial) ranges of the two parameters.[4] The lower bound holds even for algorithms that know constant approximations of $\mathrm{d_{avg}}$.

Our lower bound construction for the uniform-at-random sample problem also provides (ii) a tight lower bound of $\Omega\left(\mathrm{d_{avg}}\,\mathrm{t_{mix}}\right)$ for the average score problem – in fact, we resolve the complexity of the average score problem by showing that our lower bound coincides with the complexity of some previously proposed algorithms, whose analysis we improve.

The same lower bound construction further resolves (iii) the complexity of the average-degree estimation problem, and (iv) entails a non-tight, but significant, lower bound for the problem of guessing the graph order (that is, the number of vertices in the graph).

It is interesting to note that all the algorithms that were proposed require $O(\log n)$ space, while our lower bounds hold for general algorithms with no space restriction. Thus, the problems we consider can be solved optimally using only tiny amounts of space.

---

[3] Real-world social networks are known to have a small average degree $\mathrm{d_{avg}}$; their mixing time $\mathrm{t_{mix}}$ has been observed [20] to be quite small, as well.

[4] Observe that the two parameters have to obey some bound for such a lower bound to hold – in general, any problem can be solved by downloading all the n vertices of the graph: thus, if $\mathrm{t_{mix}} \cdot \mathrm{d_{avg}} > \omega(n)$, one can solve the uniform-at-random sample problem with less than $o(\mathrm{t_{mix}} \cdot \mathrm{d_{avg}})$ vertex queries.

2 Preliminaries

Consider a connected and undirected graph $\mathcal{G} = \langle V_{\mathcal{G}}, E_{\mathcal{G}} \rangle$ with no self-loops (e.g., the Facebook friendship graph), and a function on its vertices $\mathcal{F} : V_{\mathcal{G}} \to [0, 1]$.[5] We aim to estimate the average value of this function, i.e., $f_{avg} = \sum_{v \in V_{\mathcal{G}}} \mathcal{F}(v)/n$ where $n = |V_{\mathcal{G}}|$.

Motivated by applications, we assume that accessing the graph is a costly operation, and that there is little or no information about its global parameters such as the average degree, the number of vertices or the maximum degree. However, we can access a "friendship" oracle: that is, an oracle which, given a vertex $v \in V_{\mathcal{G}}$, outputs references (their ids, or their URLs) to its neighbors $N_v = \{u \in V_{\mathcal{G}} | (v, u) \in E_{\mathcal{G}}\}$. In such a setting, it is natural to approximate f_{avg} by taking samples from a Markov chain based on the graph structure (see, e.g., [9, 8]). A simple random walk on the graph, though, will not serve our purposes since it samples vertices with probability proportional to their degree, while our goal is to take a uniform average of the values of $\mathcal{F}$.

On a graph $\mathcal{G} = \langle V_{\mathcal{G}}, E_{\mathcal{G}} \rangle$, a lazy simple random walk is a Markov chain which being at vertex $v \in V_{\mathcal{G}}$, stays on v with probability $1/2$ and moves to $u \in N_v$ with probability $1/(2 \deg(v))$. Given that $\mathcal{G}$ is connected, the lazy random walk will converge to its unique stationary distribution which we denote by Π^1 and which is equal to $\Pi^1(v) = \deg(v)/2|E_{\mathcal{G}}|$, $\forall v \in V_{\mathcal{G}}$.

By $\mathrm{t}_{\mathrm{mix}}(\mathcal{G})$ we refer to the mixing time of the lazy random walk on $\mathcal{G}$, which is the minimum integer satisfying: for any $\tau \geq \mathrm{t}_{\mathrm{mix}}(\mathcal{G})$, $\left|X^\tau - \Pi^1\right|_1 \leq 1/4$, where X^τ is the distribution of the lazy walk at time τ, and $|\cdot|_\ell$ is the ℓ-norm of a vector. Note that by the theory of Markov chains, by taking $\tau \geq \mathrm{t}_{\mathrm{mix}}(\mathcal{G}) \log(1/\epsilon)$ we have $\left|X^\tau - \Pi^1\right|_1 \leq \epsilon$. We denote the uniform distribution on vertices of $\mathcal{G}$ by Π^0, i.e., $\Pi^0(v) = 1/|V_{\mathcal{G}}|, \forall v \in \mathcal{G}$. In general, we denote a distribution on $V_{\mathcal{G}}$ weighing each vertex $v \in V_{\mathcal{G}}$ proportional to $\deg(v)^\zeta$ by Π^ζ. We may drop all the subscripts when doing so does not cause ambiguity.

Following the framework of [7], we consider two measures of time complexity. First the number of downloaded vertices, and second the number of steps the algorithm takes to produce the output. Note that accessing an already downloaded vertex has a negligible cost, and hence, the most relevant cost of the algorithm is the number of downloaded vertices. As mentioned in the introduction, the algorithms considered in [7] and in this paper, only require space to store constantly many vertices, while our lower bound results hold regardless of the space complexity of the algorithms.

Our Contribution. We begin by discussing the problem of producing an approximately-uniform sample vertex from an unknown graph (Problem 1); showing that some algorithm presented in the literature are optimal (Theorem 1). Then, we proceed to the problem of estimating f_{avg} for a function $\mathcal{F} : V_{\mathcal{G}} \to [0, 1]$ (Problem 2). We extend the positive results of [7]; we particularly study one algorithm, the "Maximum Degree algorithm", which we show to be suboptimal in the number of downloaded vertices. This algorithm requires knowledge of some constant approximation of the graph's mixing time, and and upper bound on its maximum degree. We also show new lower bounds for constant approximations of the order and the average degree of a graph. A summary of our contribution is presented in Table 1. We remark that, in practice, only an upper bound on the mixing time is available. In the equations of Table 1, $\mathrm{t}_{\mathrm{mix}}$ can be substituted with any upper bound on the mixing time of the graph.

[5] Note that from any bounded function we can get a function with range $[0, 1]$, through a simple affine transform. Therefore, our results can be trivially extended to functions with any bounded range.

Table 1 Upper bounds and lower bounds on number of queried vertices for algorithms which explore the graph using a neighborhood oracle and a seed vertex. As mentioned before, $\mathrm{t_{mix}}$ is the mixing time of the lazy random walk on the graph, $\mathrm{d_{avg}}$ is its average degree, $\mathcal{D}$ is an upper bound on its maximum degree, Π^1 is its stationary distribution, and ϵ and δ are the precision parameters. The lower bounds for estimating the number of vertices and the average degree hold for any constant approximation.

	Upper Bound	Lower Bound
Average of a Bounded Function	$O(\mathrm{t_{mix}}\,\mathrm{d_{avg}}\log(\delta^{-1})\epsilon^{-2})$ (Theorem 2, with an Algorithm of [7])	$\Omega(\mathrm{t_{mix}}\,\mathrm{d_{avg}}\log(\delta^{-1})\epsilon^{-2})$ (Theorem 3)
Uniform Sample	$O(\mathrm{t_{mix}}\,\mathrm{d_{avg}}\log(\epsilon^{-1}))$ ([7])	$\Omega(\mathrm{t_{mix}}\,\mathrm{d_{avg}})$ (Theorem 1)
Number of Vertices	$O(\mathrm{t_{mix}}\max\{\mathrm{d_{avg}}, \lvert\Pi^1\rvert_2^{-1/2}\}\log(\delta^{-1})\log(\epsilon^{-1})\epsilon^{-2})$ ([18])	$\Omega(\mathrm{t_{mix}}\,\mathrm{d_{avg}})$ (Theorem 4)
Average Degree	$O(\mathcal{D}^2\mathrm{t_{mix}}\,\mathrm{d_{avg}}\log(\delta^{-1})\epsilon^{-2})$ (Application of Theorem 2)	$\Omega(\mathrm{t_{mix}}\,\mathrm{d_{avg}})$ (Theorem 4)

In Section 3, we prove our lower bound results on the number of oracle calls for the following problems: sampling a vertex, learning the order, and the average degree of the graph. Estimations of these parameters in a graph are intertwined meaning that a knowledge about one of them the complexity of estimating the other one changes. For instance, Goldreich and Ron [16] show that, if a uniform sample generator is accessible at zero cost (alternatively, if the order of graph is precisely known), then the average degree is computable in $\sqrt{|V_{\mathcal{G}}|/\,\mathrm{d_{avg}}}$ steps. Our lower bounds for the aforementioned problems hold if the algorithm has no $\epsilon-$approximation of the order, and of the average degree of the graph. On the other hand, the lower bound we obtain for an $\epsilon-$approximation of a bounded function's average holds even if the graph's structure is precisely known.

Number of downloads to produce a close-to-uniform sample. We prove a lower bound of $\Omega(\mathrm{t_{mix}}\,\mathrm{d_{avg}})$, thus, showing that the rejection algorithm and the maximum degree algorithm suggested in the literature [7] can be optimal (Theorem 1). We observe that the two algorithms require some knowledge of $\mathrm{t_{mix}}$. In most scenarios, only an upper bound on $\mathrm{t_{mix}}$ is available. Thus, it is more accurate to claim that the two algorithms are optimal when some constant approximation of the mixing time is available.

Number of downloads to estimate the number of vertices. The problem of estimating the order of a graph is widely studied [9, 18]. Katzir et al. [18] (2011) propose an algorithm that, having access to an oracle that produces random vertices from the graph's stationary distribution, requires $\max\{\frac{1}{|\Pi^1|_2}, \mathrm{d_{avg}}\}(\frac{1}{\epsilon^2\delta})$ samples to obtain an ϵ approximation with probability at least $1-\delta$. It has been shown the number of samples in Katzir's algorithm is necessary ([17]). The Katzir et al. algorithm implies an upper bound of $\mathrm{t_{mix}}\max\{\frac{1}{|\Pi^1|_2}, \mathrm{d_{avg}}\}(\frac{\log(\epsilon^{-1})}{\epsilon^2\delta})$ vertex queries to obtain an ϵ approximation with probability at least $1-\delta$ in our friendship-oracle model. In Theorem 4 we present a lower bound on the number of accesses to the vertices, to get a constant approximation of the graph's order in our friendship-oracle model. Our lower bound is tight for the graphs that satisfy $\frac{1}{|\Pi^1|_2} < \mathrm{d_{avg}}$ – that is, the graphs whose variance

of the degree distribution is greater than n.[6] This class include, say, all the graphs having a power-law degree distribution with exponent smaller than 3/2 (e.g., social networks [19]).

We remark that this lower bound problem is still open for graphs with $\frac{1}{|\Pi^1|_2} > \mathrm{d_{avg}}$, for example regular sparse graphs. Recently, Ben-Hamou et al. studied the problem of estimating the size of a regular graph when having access to an oracle analogous to ours, and presented an constant approximation algorithm querying $(t_{\mathrm{unif}})^{3/4}\sqrt{n}$ vertices, where t_{unif} is the minimum integer satisfying: $\tau \geq t_{\mathrm{unif}}(\mathcal{G})$, $\max_{v\in V} |X^\tau(v)/\Pi^1(v) - 1| \leq 1/4$ [3].

Number of downloads to estimate the average degree. There are quite a few results on estimating the average degree of a graph. The first one by Feige et al. [13] introduced a sublinear algorithm of complexity $\sqrt{|V_\mathcal{G}|}$ for a 2-approximation. Goldreich et al. [16] extends Feige et al.'s result and presents an $(1 \pm \epsilon)$ approximation algorithm with running time $O(1/\epsilon)\sqrt{|V_G/\,\mathrm{d_{avg}}|}$ – they also prove a lower bound on the number of samples of $\sqrt{|V_G|/\,\mathrm{d_{avg}}}$ – both of [13] and [16] assume to have access to an oracle capable of producing a uniform at random vertex. Recently, Dasgupta et al. [10] showed that by sampling $O(\log(\mathcal{D})\log\log(\mathcal{D}))$ vertices of a graph from some weighted distribution[7] one can obtain a $(1\pm\epsilon)$ approximation of its average degree, where $\mathcal{D}$ is an upper bound on the maximum degree. By factoring in the the cost of sampling, the complexity becomes $O(\mathrm{t_{mix}}\log(\mathcal{D})\log\log(\mathcal{D}))$. Taking $\mathcal{D} = n$ and adding the cost of estimating the graph size, takes the upper bound to: $O\left(\mathrm{t_{mix}}\left((\log(n)\log\log(n)) + \mathrm{d_{avg}} + \frac{1}{|\Pi^1|_2}\right)\right)$.

In Theorem 4 of this paper we show that by downloading $o(\mathrm{t_{mix}}\,\mathrm{d_{avg}})$ vertices, it is impossible for an algorithm to have any constant approximation of the average degree $\mathrm{d_{avg}}$ with probability more than some constant.

Finally, our main result is the following lower bound – unlike the above three lower bounds, this one holds even if we know exactly the graph's structure.

Number of downloads to find an ϵ, δ approximation for the average of a bounded function. In Theorem 3, we show that an algorithm requires $\Omega\left(\mathrm{t_{mix}}\,\mathrm{d_{avg}}(1/\epsilon^2)\log(1/\delta)\right)$ vertex downloads to produce an $\epsilon-$additive approximation of f_{avg}, with probability at least $1-\delta$. This lower bound, together with Theorem 2, allows us to conclude that the "maximum degree algorithm" is an optimal algorithm for this problem. Note that this algorithm has to have some upper bound $\mathcal{D}$ on the maximum degree of the graph. In many situations, one can assume that this information is available – for instance $\mathcal{D} \leq n$ and, in many cases, one can assume to have a constant approximation to the order of the graph (for instance, in Facebook, one could claim that $\mathcal{D}$ is no larger than the world's population.) Observe that the maximum degree algorithm suffers no loss in getting a large $\mathcal{D}$, as opposed to a tighter one, since $\mathcal{D}$ does not impact the upper bound on the number of downloaded vertices.

2.1 Statement of Problems and Results

▶ **Problem 1.** *Input: A seed vertex $s \in V$ in graph $\mathcal{G} = \langle V_\mathcal{G}, E_\mathcal{G}\rangle$. Output: A random vertex $v \in V_\mathcal{G}$ whose distribution is at total variation distance at most ϵ from the uniform one on $V_\mathcal{G}$.*

---

[6] Let pr_k be the fraction of vertices with degree k. We have $\left|\Pi^1\right|_2 = n\sum_{i=1}^n \mathrm{pr}_k \frac{k^2}{4|E|^2} = \frac{1}{n\,\mathrm{d_{avg}}^2}\sum_{i=1}^n \mathrm{pr}_k k^2$. Thus, to have $1/\sqrt{|\Pi^1|_2} \leq \mathrm{d_{avg}}$, it is necessary and sufficient to have $\sum_{i=1}^n k^2\mathrm{pr}_k > n$.

[7] Dasgupta et al. use an oracle samples each $v \in V_\mathcal{G}$ proportional to $\deg(v) + c$ for some constant c. Note that for $c = 0$ this distribution will be the same as the stationarity.

Several algorithms have been proposed for Problem 1 [7, 18] – we will specifically consider the "maximum degree sampling" algorithm, the "rejection sampling" algorithm, and the "Metropolis Hasting" algorithm.

The efficiency of the three algorithms has been studied in terms of the number of their running time (or the number of steps they make on the Markov chain they are based on) and, more importantly, on the number of *queries*[8] (or downloaded vertices) that the algorithm performs. The rejection sampling and maximum degree algorithms produce a close-to-uniform random vertex by querying[9] $\tilde{O}\left(\mathrm{t_{mix}}\,\mathrm{d_{avg}}\right)$ distinct vertices from the graph, where $\mathrm{t_{mix}}$ is the mixing time of a simple random walk on $\mathcal{G}$, and $\mathrm{d_{avg}}$ is the average degree of $\mathcal{G}$. In terms of space complexity, each of these algorithms is based on a simple random walk on $\mathcal{G}$ and thus only require space to save constant number of vertices.

One of the main results of this paper is Theorem 1, which shows the optimality of the maximum degree, and of the rejection sampling, algorithms for Problem 1 – their running time. We observe that our lower bound holds regardless of the amount of space available to the algorithm.

▶ **Theorem 1.** *For any large enough constant c, and for any arbitrary n, $d = \omega(\log n)$, and $t = o(\frac{n}{d^2})$ there exists a distribution over graphs $\mathcal{G} = \langle V, E\rangle$, each having mixing time $\Theta(t)$, $\mathbb{E}(|V|) = \Theta(n)$, $\mathrm{d_{avg}} = \mathbb{E}_{v\in V}(\deg_v) = \Theta(d)$, such that any algorithm $\mathcal{A}$ that queries less than $\mathrm{d_{avg}}\,\mathrm{t_{mix}}/c$ vertices of $\mathcal{G}$, and that returns some random vertex of $\mathcal{G}$ with distribution $\Pi_{\mathcal{A}}$, is such that*[10] $\mathbb{E}\left[\left|\Pi_{\mathcal{A}} - \Pi^0\right|_1\right] \geq \frac{24}{100} - \frac{202}{c-1}$.

The same lower bounds also hold if one aims to obtain the generic Π^ζ distribution [11] *: if $\zeta > 1$, and d and t satisfy $d = o(t^{\frac{\zeta-1}{\zeta}})$, then any algorithm $\mathcal{A}$ that queries less than $\mathrm{d_{avg}}\,\mathrm{t_{mix}}/c$ vertices of $\mathcal{G}$, and that returns some random vertex of $\mathcal{G}$ with distribution $\Pi_{\mathcal{A}}$, is such that: $\mathbb{E}\left[\left|\Pi_{\mathcal{A}} - \Pi^\zeta\right|_1\right] \geq \frac{24}{100} - \frac{202}{c-1}$.*

The above theorem, and the other lower bound results that we mention in this section, will be proved in Section 3.

Then, we consider the problem of finding the average of a function $\mathcal{F}$ defined on vertices of a graph and ranging in $[0, 1]$.

▶ **Problem 2.** *Input: A seed vertex $s \in V$ in graph $\mathcal{G} = \langle V, E\rangle$ – each vertex v holds a value $0 \leq \mathcal{F}(v) \leq 1$ which we learn upon visiting it. Output: $\bar{f}$ such that $\mathbb{P}\left(|\bar{f} - f_{avg}| \leq \epsilon\right) \geq 1 - \delta$.*

Note that having a uniform sampler (the maximum degree or rejection sampling algorithm of [7]), we can have an ϵ approximation of f_{avg} with probability $1-\delta$ by taking $O(\epsilon^{-2}\log(\delta^{-1}))$ independent samples which are ϵ close to uniformity. In total, the number of queries will be $O(\mathrm{t_{mix}}\,\mathrm{d_{avg}}\log(\delta^{-1})\epsilon^{-2}\log(\epsilon^{-1}))$. Here we propose a slight variation of the "maximum degree" algorithm to obtain a tight upper bound. We improve the analysis of the "maximum degree algorithm" in Theorem 2 – its performance beats the other natural three algorithms, and the main result of this paper is that this performance is optimal (Theorem 3).

The proof of the following Theorem is omitted from this extended abstract.

---

[8] A vertex is "queried", when the set of its neighbors is obtained from the oracle for the first time – equivalently, when it is downloaded.

[9] To get ϵ close to the uniform distribution we need $O\left(\mathrm{t_{mix}}\,\mathrm{d_{avg}}\log(\epsilon^{-1})\right)$ downloads.

[10] Observe that the expected ℓ_1 distance between the distributions is over the random variable $\Pi_{\mathcal{A}}$.

[11] The Π^ζ distribution is the distribution in which the probability of a vertex $v \in V$ is proportional to $deg(v)^\zeta$.

Algorithm 1 The Maximum Degree Algorithm.

Input: Seed vertex $s \in V_{\mathcal{G}}$, $\mathrm{t}'_{\mathrm{mix}}$ a constant approximation of $\mathrm{t}_{\mathrm{mix}}$, and an upper bound $\mathcal{D}$ on d_{max}

Output: An ϵ additive approximation of f_{avg} with probability at least $1-\delta$

Consider the maximum degree Markov chain: at vertex $v \in V$ go to the generic $u \in N_v$ with probability $1/\mathcal{D}$, otherwise stay at v.
$T \leftarrow \mathrm{t}'_{\mathrm{mix}}\mathcal{D}/\mathrm{d}_{\min}$
Starting from s, run the chain for $T \cdot \left(1+\epsilon^{-2}\ln\delta^{-1}\right)$ steps – let $v_0 = s, v_1, v_2, \ldots$ be the states that are visited by the walk
$S \leftarrow 0, t \leftarrow 0, i \leftarrow 0$
while $t < \frac{\mathrm{d}_{\mathrm{avg}}}{d_{min}}(\mathrm{t}'_{\mathrm{mix}}/\epsilon^2)\log(1/\delta)$ **do**
  $i \leftarrow i+1$
  if $v_i \neq v_{i-1}$ **then**
    $t \leftarrow t+1$
  $S = S + \mathcal{F}(v_i)$
return S/i

▶ **Theorem 2.** *Consider a graph $\mathcal{G} = \langle V, E\rangle$, and a function $\mathcal{F} : V \to [0,1]$. Let $\mathrm{t}_{\mathrm{mix}}$ be the mixing time of the simple lazy random walk on $\mathcal{G}$. Let $\bar{f}$ be the value returned by Algorithm 1. We assume the algorithm knows a constant approximation to $\mathrm{t}_{\mathrm{mix}}$. i.e. $\mathrm{t}'_{\mathrm{mix}} = \Theta(\mathrm{t}_{\mathrm{mix}})$. Then,*

$$\mathbb{P}\left(|\bar{f} - f_{avg}| \geq \epsilon\right) \leq \delta \tag{1}$$

This algorithm queries $\Theta(\mathrm{t}_{\mathrm{mix}}\,\mathrm{d}_{\mathrm{avg}}\,\epsilon^{-2}\log(\delta^{-1}))$ vertices from the graph, and requires space for saving a constant number of them. The number of computational steps it performs is $\Theta(\mathcal{D}\mathrm{t}_{\mathrm{mix}}\epsilon^{-2}\log(\delta^{-1}))$.

The main result of this paper is the following lower bound which complements the upper bound given in the previous theorem:

▶ **Theorem 3.** *For any arbitrary n, $d = \omega(\log n)$, and $t = o(\frac{n}{d^2})$ there exists a distribution over graphs $\mathcal{G} = \langle V, E\rangle$ with mixing time $\Theta(t)$, $\mathbb{E}(|V|) = 4n$, $\mathrm{d}_{\mathrm{avg}} = \mathbb{E}_{v\in V}(\deg_v) = \Theta(d)$, and a function $\mathcal{F} : V \to \{0,1\}$ such that, any algorithm $\mathcal{A}$ as described above which aims to return the average of $\mathcal{F}$, with ϵ precision for arbitrary $0 < \epsilon, \delta < 1$, and queries less than $\Omega(\mathrm{t}_{\mathrm{mix}}\,\mathrm{d}_{\mathrm{avg}}\,\epsilon^{-2}\log(\delta^{-1}))$ vertices of $\mathcal{G}$ fails with probability greater than δ.*

Finally, we consider the problems of obtaining an approximation of the average degree, and the number of vertices, of a graph:

▶ **Problem 3.** *Input: A seed vertex $s \in V$ in graph $\mathcal{G} = \langle V, E\rangle$. Output: an integer $\bar{n}$ such that $\mathbb{P}\left(|\bar{n} - |V|| \leq \epsilon\right) \geq 1-\delta$.*

By a result of Katzir [18], we know by taking $\max\{\mathrm{d}_{\mathrm{avg}}, 1/\sqrt{|\Pi^2|_2}\}\epsilon^{-2}\delta^{-1}$ samples from the stationary distribution we are capable to obtain an ϵ approximation with probability at least $1-\delta$. To implement a sampling oracle using our neighborhood oracle, we can run a Markov chain for $\mathrm{t}_{\mathrm{mix}}\log(\epsilon^{-1})$ steps. Thus, the runtime will be $\mathrm{t}_{\mathrm{mix}}\max\{\mathrm{d}_{\mathrm{avg}}, 1/\sqrt{|\Pi^1|_2}\}\log(\epsilon^{-1})\epsilon^{-2}\delta^{-1}$, which for constant ϵ and δ is $\mathrm{t}_{\mathrm{mix}}\max\{\mathrm{d}_{\mathrm{avg}}, 1/\sqrt{|\Pi^1|_2}\}$. Theorem 4 provides a lower bound for a constant approximation which is as mentioned before tight when the variance of the degree distribution is greater than n.

▶ **Problem 4.** *Input: A seed vertex $s \in V$ in graph $\mathcal{G} = \langle V, E \rangle$. Output: an integer $\bar{d}$ such that $\mathbb{P}\left(|\bar{d} - \mathrm{d_{avg}}| \leq \epsilon\right) \geq 1 - \delta$.*

Normalize the function $deg : V_{\mathcal{G}} \to \mathbb{R}$ by dividing its value to $\mathcal{D}$. By Theorem 2, Algorithm 1 provides an ϵ approximation with probability at least $1 - \delta$ after downloading $O(\mathcal{D}^2\, \mathrm{t_{mix}}\, \mathrm{d_{avg}}\, \epsilon^{-2} \log(\delta^{-1}))$ many vertices – that is, $O(\mathcal{D}^2\, \mathrm{t_{mix}}\, \mathrm{d_{avg}})$ many vertices for constant ϵ and δ. With Theorem 4, we provide a lower bound for a constant approximation.

▶ **Theorem 4.** *For any arbitrary n, $d = \omega(\log n)$, and $t = o(\frac{n}{d^2})$ there exists a distribution of graphs $\mathcal{G} = \langle V, E \rangle$ with mixing time $\Theta(t)$, $\mathbb{E}(|V|) = \Theta(n)$, $\mathrm{d_{avg}} = \mathbb{E}_{v \in V}(\deg_v) = \Theta(d)$ such that, for arbitrary constants $c' > 1$ and large enough c, any algorithm that queries at most $\mathrm{d_{avg}}\, \mathrm{t_{mix}}\, /c$ vertices of the graph, and that outputs an estimation $\bar{n}$ of $n = |V|$ (resp., an estimation $\bar{d}$ of $\mathrm{d_{avg}} = 2|E|/n$), has to satisfy $\max\{\bar{n}/n, n/\bar{n}\} > c'$ (resp., $\max\{\bar{d}/\,\mathrm{d_{avg}}, \mathrm{d_{avg}}\,/\bar{d}\} > c'$), with probability at least $\frac{99}{100} - \frac{202}{c-1}$.*

3 Proof Strategy of the Main Theorems

The proof of our Lower Bounds will be based on the following high-level strategy. Nature will first randomly sample a graph $\mathcal{H}$ according to some distribution; with probability 1/2, $\mathcal{H}$ will be the unknown graph traversed by the algorithm; with the remaining probability, the algorithm will traverse a graph $\mathcal{G}$ which is obtained from $\mathcal{H}$ by means of a transformation that we call the *decoration construction*. We will prove that, for the right choice of the distribution over $\mathcal{H}$, an algorithm that performs too few queries to the unknown graph will be unable to tell with probability more than $1/2 + o(1)$, whether the unknown graph it is traversing is distributed like $\mathcal{H}$, or like $\mathcal{G}$.

The decoration construction will guarantee that the properties (e.g., number of nodes, average degree, or even the values assigned by the bounded function to the vertices) will be quite far from each other in $\mathcal{H}$ and $\mathcal{G}$. This will make it impossible for the algorithm to get good approximation of any of those properties – we will also show it impossible for the algorithm to return a close to uniform-at-random vertex (essentially because the decoration construction will add a linear number of nodes to $\mathcal{H}$, and the algorithm will be unable to visit any of them with the given budget of queries.)

We present a roadmap of our proof strategy here, and omit the detailed proofs in this extended abstract. We start by describing the *decoration construction* which, given any graph $\mathcal{H}$, produces a graph $\mathcal{G}$ with similar mixing time and average degree, but with a linear number of "hidden" new vertices. After presenting the definition for the decoration construction, in Definition 6 we introduce a class of graphs to which we apply this construction. These graphs' mixing time and average degree can be set arbitrarily. Later, in Lemma 7 we prove that if an algorithm, equipped only with the neighborhood oracle traverses a graph of this type and queries few vertices of it, it will not be capable of finding any of its hidden vertices. This is our main lemma from which Theorems 1, 3, and 4 can be concluded. We now proceed to the formal definitions:

▶ **Definition 5** (The Decoration Construction)**.** Let $\mathcal{H} = \langle V, E \rangle$ be an arbitrary graph. We construct $\mathcal{G}$ from $\mathcal{H}$ in the following way:

Take $t := \mathrm{t_{mix}}(\mathcal{H})$, and mark any vertex $v \in V$ with probability $1/t$. For any marked vertex $v \in V$, add a vertex v^* and connect it to v via an edge. For a constant c_1, attach $c_1 t - 1$ new degree one vertices to v^* – this makes the degree of v^* equal to $c_1 t$. Let this new graph be $\mathcal{G}$. We denote the set of marked vertices by MARKED and the set $\mathcal{G} \setminus \mathcal{H}$ by STARRED.

By saying a vertex v is STARRED (MARKED) we mean $v \in$ STARRED ($v \in$ MARKED), and to indicate their numbers we use a preceding #. We call the STARRED vertices with degree $c_1 t$ the STARRED centers. Note that to any STARRED vertex we can associate a unique MARKED vertex.

We now introduce the random graph to which we will apply the decoration construction, and which will be at the heart of our lower bounds.

▶ **Definition 6.** We define the graph $\mathcal{H}_{n,d,\psi}$ as follows: given arbitrary parameters n, d, and $0 < \psi < 1$, take two Erdös-Rényi graphs $H_1 = \langle V_{H_1}, E\rangle$ and $H_2 = \langle V_{H_2}, E\rangle$ with parameters $\langle n, d/n\rangle$. Choose ψn vertices uniformly at random from V_{H_1} namely $v_1, v_2, \dots v_{\psi n}$, and then ψn vertices uniformly at random from V_{H_2} namely $u_1, u_2, \dots n_{\psi n}$. Select a uniformly random permutation σ of ψn numbers and put an edge between the vertices v_i and $u_{\sigma(i)}$ for each $1 \le i \le \psi n$.

The decoration construction does not change the mixing time of $\mathcal{H}$ drastically, in fact, $\mathrm{t_{mix}}(\mathcal{H}) \le \mathrm{t_{mix}}(\mathcal{G}) \le c\,\mathrm{t_{mix}}(\mathcal{H})$ for some constant c. The $\mathcal{H}_{n,d,\psi}$s are useful in our proofs, for the reason that, by changing the parameters n, d, and ψ in certain ranges these graphs acquire arbitrary $\mathrm{t_{mix}}$ and $\mathrm{d_{avg}}$, yet their behaviour remains similar to Erdös-Rényi random graphs.

We now present the following lemma (proof ommited), which states if few queries are performed by an algorithm, then the probability of finding the STARRED vertices is tiny. Then, we conclude our main theorems; Theorem 1, 3, and 4:

▶ **Lemma 7.** *Consider arbitrary n, $d > \omega(\log n)$, $\Omega(\log n) < t < o(n/d^2)$, so that $t/d = \Omega(1)$, take $\mathcal{G}$ to be the graph obtained from the decoration construction applied to $\mathcal{H}_{n,d,d/t}$[12]. We have, $\mathrm{t_{mix}}(\mathcal{G}) = \Theta(t)$ and $\mathrm{d_{avg}} = \Theta(d)$.*

If, instead, $t = O(\log n/\log d)$, and $d = \Theta(\log^d n)$, take $\mathcal{G}$ to be the decorated version of an Erdös-Rényi graph with parameters $\langle n, d/n\rangle$.

Then,

- *if an algorithm traverses the edges of $\mathcal{G}$ and queries at most td/c vertices of $\mathcal{G}$; c being a constant, then with probability at least $99/100 - 202/(c-1)$ there is no* STARRED *vertex among its queried vertices.*
- *If an algorithm traverses the edges of $\mathcal{G}$ and queries $q \le \frac{n}{cd}$ vertices of $\mathcal{G}$; c being a constant, then with probability $1 - o(1)$ the expected number of* STARRED *centers which have been queried is less than $\frac{8c}{c-1}\left(\frac{q}{dt}\right)$.*

We can finally prove our three main Theorems:

*** Proof of Theorem 1.** Consider the two graphs $\mathcal{G}_1$ and $\mathcal{G}_2$, $\mathcal{G}_1$ being the graph of Lemma 7 with $c_1 = 1$ and $\mathcal{G}_2$ the same graph without the STARRED vertices (the graph before the decoration construction). Any algorithm which queries less than $\mathrm{t_{mix}}\,\mathrm{d_{avg}}/c$ vertices of $\mathcal{G}_1$ or $\mathcal{G}_2$ will fail to distinguish between them with probability at least $\frac{1}{100} + \frac{202}{c-1}$. Let $\Pi^0_{\mathcal{G}_i}$ be the uniform distribution on vertices of $\mathcal{G}_i$; $i = 1, 2$. In $\mathcal{G}_1$ with high probability we have at least $2|V_{\mathcal{G}_1}|$ STARRED vertices.

- *Part 1.* Note that $|\Pi^0_{\mathcal{G}_1}, \Pi^0_{\mathcal{G}_2}|_1 \ge 1/4$. Thus, if the natures selects $\mathcal{G}_1$, any algorithm $\mathcal{A}$ which aims to outputs $\Pi^0_{\mathcal{G}_1}$ will return a distribution $\Pi_{\mathcal{A}}$ satisfying $|\Pi^0_{\mathcal{G}_1}, \Pi_{\mathcal{A}}|_1 \ge 1/4 - \frac{1}{100} - \frac{202}{c-1}$.

[12] If $c > d/t \ge 1$, for constant c, let $\psi = d/tc$.

- *Part 2.* For $\zeta > 1$, let $\Pi^{\zeta}_{\mathcal{G}_i}$ be the probability distribution on vertices of $\mathcal{G}_i$; $i = 1, 2$ weighing each vertex v proportional to $deg(v)^{\zeta}$. If we take a sample from distribution $\Pi^{\zeta}_{\mathcal{G}_1}$ it will be STARRED vertex with probability $(t^{\zeta-1}+1)/2(t^{\zeta-1}+d^{\zeta}+1)$. Thus, for $t^{\zeta-1} \geq d^{\zeta}$ we have, $|\Pi^{\zeta}_{\mathcal{G}_1}, \Pi^{\zeta}_{\mathcal{A}}|_1 \geq 1/4$. Thus, $|\Pi^{0}_{\mathcal{G}_1}, \Pi_{\mathcal{A}}|_1 \geq 24/100 - 202/c$. □

* **Proof of Theorem 4.** Take the two graphs $\mathcal{G}_1$ and $\mathcal{G}_2$, $\mathcal{G}_1$ being the graph of Lemma 7, and $\mathcal{G}_2$ the same graph without the STARRED vertices (the graph before the decoration construction). We have: $\mathbb{E}(|V_{\mathcal{G}_2}|) = n$, $\mathbb{E}(|V_{\mathcal{G}_1}|) = (1+c_1)n$, and $\mathbb{E}(\mathrm{d_{avg}}(\mathcal{G}_2)|) = d$, $\mathbb{E}(|\,\mathrm{d_{avg}}(\mathcal{G}_1)|) = \frac{d+c_1}{1+c_1}$. □

* **Proof of Theorem 3.** Take $c_1 = 1$, and let $\mathcal{G} = \langle V_{\mathcal{G}}, E_{\mathcal{G}} \rangle$ be the graph constructed as in Lemma 7. Consider two functions $\mathcal{F}_1 : V_{\mathcal{G}} \to [0,1]$ and $\mathcal{F}_2 : V_{\mathcal{G}} \to [0,1]$. Let the function $\forall v \in V_{\mathcal{G}} \setminus \text{STARRED}, \mathcal{F}_1(v) = \mathcal{F}_2(v) = 0$. For any $v \in$ STARRED we set $\mathcal{F}_1(v) = 1$ with probability $1/2 + \epsilon$ and $\mathcal{F}_2(v) = 1$ with probability $1/2 - \epsilon$.

Note that $|\mathcal{F}_1 - \mathcal{F}_2|_1 \geq \epsilon$, and by employing the following classical result [6], with probability $1 - o(1)$ we will not be able to distinguish between $\mathcal{F}_1$ and $\mathcal{F}_2$.

▶ **Lemma 8** ([6]). *Consider a $\left(\frac{1}{2}-\epsilon, \frac{1}{2}+\epsilon\right)$-biased coin (that is, a coin whose most likely outcome has probability $\frac{1}{2}+\epsilon$. To determine with probability at least $1-\delta$ what is the most likely outcome of the coin, one needs at least $\Omega(1/\epsilon^2 \log(1/\delta))$ coin flips.*

By Lemma 7 with probability $1 - o(1)$, the expected number of STARRED centers will be $\frac{8q}{dt(1-o(1))}$. Let QUERIED be the set of queried vertices by the algorithm. If $q = \omega(dt)$

$$\mathbb{P}\left(\#\ \text{QUERIED} \cap \text{STARRED}_{\text{ center}} \geq 48q/dt\right) \leq e^{-16q/dt} \leq o(1).$$

Therefore, since in order to distinguish between $\mathcal{F}_1$ and $\mathcal{F}_2$ with probability at least $1-\delta$, we need at to see at least $\Omega\left(\log(1/\delta)(1/\epsilon^2)\right)$ starred centers, or equivalently $\Omega\left(dt \log(1/\delta)(1/\epsilon^2)\right)$ queries. □

4 Conclusion

In this paper we have studied the complexity of computing a number of functions of online graphs, such as online social networks, in terms of their average degree and their mixing time. We have obtained a tight bound for the problem of computing the average of a bounded function on the vertices of the graph (e.g., the average star rating of a movie), and a near-tight bound for the problem of sampling a close-to uniform-at-random vertex (many algorithms in the literature assume to have access to such an oracle), and lower bounds for the problems of estimating the order, and the average degree of the graphs.

It will be interesting to pursue the study of these online graphs problems in order to bridge the gap between theoretical algorithms, and applied ones. Besides the obvious questions (what are the optimal bounds for estimating the order and the average degree of a graph?), an interesting open problem is to understand which structural properties of online social networks could be used by algorithms to improve the complexity of the various problems that practitioners have been considering.

Abstract

We give exponential lower bounds on the Price of Stability (PoS) of weighted congestion games with polynomial cost functions. In particular, for any positive integer d we construct rather simple games with cost functions of degree at most d which have a PoS of at least $\Omega(\Phi_d)^{d+1}$, where $\Phi_d \sim d/\ln d$ is the unique positive root of equation $x^{d+1} = (x+1)^d$. This essentially closes the huge gap between $\Theta(d)$ and Φ_d^{d+1} and asymptotically matches the Price of Anarchy upper bound. We further show that the PoS remains exponential even for singleton games. More generally, we also provide a lower bound of $\Omega((1+1/\alpha)^d/d)$ on the PoS of α-approximate Nash equilibria, even for singleton games. All our lower bounds extend to network congestion games, and hold for mixed and correlated equilibria as well.

On the positive side, we give a general upper bound on the PoS of α-approximate Nash equilibria, which is sensitive to the range W of the player weights and the approximation parameter α. We do this by explicitly constructing a novel approximate potential function, based on Faulhaber's formula, that generalizes Rosenthal's potential in a continuous, analytic way. From the general theorem, we deduce two interesting corollaries. First, we derive the existence of an approximate pure Nash equilibrium with PoS at most $(d+3)/2$; the equilibrium's approximation parameter ranges from $\Theta(1)$ to $d+1$ in a smooth way with respect to W. Secondly, we show that for unweighted congestion games, the PoS of α-approximate Nash equilibria is at most $(d+1)/\alpha$.

1 Introduction

In the last 20 years, a central strand of research within Algorithmic Game Theory has focused on understanding and quantifying the inefficiency of equilibria compared to centralized, optimal solutions. There are two standard concepts that measure this inefficiency. The Price of Anarchy (PoA) [34] which takes the worst-case perspective, compares the worst-case equilibrium with the system optimum. It is a very robust measure of performance. On the other hand, the Price of Stability (PoS) [44, 5], which is also the focus of this work, takes an optimistic perspective, and uses the best-case equilibrium for this comparison. The PoS is an appropriate concept to analyse the ideal solution that we would like our protocols to produce.

The initial set of problems that arose from the Price of Anarchy theory have now been resolved. The most rich and well-studied among these models are, arguably, the atomic and non-atomic variants of congestion games (see [38, Ch. 18] for a detailed discussion). This class of games is very descriptive and captures a large variety of scenarios where users compete for resources, most prominently routing games. The seminal work of Roughgarden and Tardos [42, 43] gave the answer for the non-atomic variant, where each player controls a negligible amount of traffic. Awerbuch et al. [6], Christodoulou and Koutsoupias [17] resolved the Price of Anarchy for atomic congestion games with affine latencies, generalized by Aland et al. [3] to polynomials; this led to the development of Roughgarden's Smoothness Framework [41] which extended the bounds to general cost functions, but also distilled and formulated previous ideas to bound the Price of Anarchy in an elegant, unified framework. At the computational complexity front, we know that even for simple congestion games, finding a (pure) Nash equilibrium is a PLS-complete problem [21, 2].

Allowing the players to have different loads, gives rise to the class of *weighted* congestion games [40]; this is a natural and very important generalization of congestion games, with numerous applications in routing and scheduling. Unfortunately though, an immediate dichotomy between weighted and unweighted congestion games occurs: the former may *not* even have pure Nash equilibria [36, 25, 27, 30]; as a matter of fact, it is a strongly NP-hard problem to even determine if that's the case [20]. Moreover, in such games there does not, in general, exist a potential function [37, 31], which is the main tool for proving equilibrium existence in the unweighted case.

As a result, a sharp contrast with respect to our understanding of the two aforementioned inefficiency notions arises. The Price of Anarchy has been studied in depth and general techniques for providing tight bounds are known. Moreover, the asymptotic behaviour of weighted and unweighted congestion games with respect to the Price of Anarchy is identical; it is $\Theta(d/\log d)^d$ for both classes when latencies are polynomials of degree at most d [3].

The situation for the Price of Stability though, is completely different. For unweighted games we have a good understanding[3] and the values are much lower than the Price of

[3] Much work has been done on the PoS for network design games, which is though not so closely related to our work. This problem was first studied by Anshelevich et al. [5] who showed a tight bound of H_n, the harmonic number of the number of players n, for directed networks. Finding tight bounds on undirected networks is still a long-standing open problem (see, e.g., [23, 9, 35]). Recently, Bilò et al. [10] (asymptotically) resolved the question for broadcast networks. For the weighted variant of this problem, Albers [4] showed a lower bound of $\Omega(\log W/\log\log W)$, where W is the sum of the players'

Table 1 Previous results (*left table*) regarding the Price of Anarchy and Stability for unweighted and weighted congestion games, with polynomial latency functions of maximum degree d. Φ_d is the unique positive solution of $(x+1)^d = x^{d+1}$ and $\Phi_d = \Theta(d/\log d)$. Tight answers were known for all settings, except for the Price of Stability of the weighted case were only trivial bounds existed. In this paper (*right table*) we essentially close this gap by showing a lower bound of $\Omega(\Phi_d)^{d+1}$ (Theorem 1), even for network games, which is exponential even for singleton games Theorem 5.

	PoA	PoS
unweighted	$\lfloor\Phi_d\rfloor^{d+1}$ [3]	$\Theta(d)$ [15]
weighted	Φ_d^{d+1} [3]	$[\Theta(d), \Phi_d^{d+1}]$

	PoS lower bound
general	$\Omega(\Phi_d)^{d+1}$
singleton	$\Omega(2^d/d)$
α-approximate equilibria	$\Omega((1+1/\alpha)^d/d)$

Anarchy values, and also *tight*; approximately 1.577 for affine functions [16, 14], and $\Theta(d)$ [15] for polynomials. For weighted games though there is a huge gap; the current state of the art lower bound is $\Theta(d)$ and the upper bound is $\Theta(d/\ln d)^d$. These previous results are summarized at the left of Table 1.

The main focus of this work is precisely to deal with this lack of understanding, and to determine the Price of Stability of weighted congestion games. What makes this problem challenging is that the only general known technique for showing upper bounds for the Price of Stability is the potential method, which is applicable only to potential games. In a nutshell, the idea of this method is to use the global minimizer of Rosenthal's potential [39] as an equilibrium refinement. This equilibrium is also a pure Nash equilibrium and can serve as an upper bound of the Price of Stability. Interestingly, it turns out that, for several classes of potential games, this technique actually provides the tight answer (see for example [5, 16, 14, 15]). However, as already mentioned above, unlike their unweighted counterparts, weighted congestion games are not potential games;[4] so, a completely fresh approach is required.

One way to override the aforementioned limitations of non-existence of pure Nash equilibria, but also their computational hardness, is to consider *approximate* equilibria. In this direction, Hansknecht et al. [29] have shown that $(d+1)$-approximate pure Nash equilibria always exist in weighted congestion games with polynomial latencies of maximum degree d, while, in the negative side, there exist games that do not have 1.153-approximate pure Nash equilibria. Notice here, that these results do not take into account computational complexity considerations; if we insist in polynomial-time algorithms for actually finding those equilibria, then the currently best approximation parameter becomes $d^{O(d)}$ [12, 13, 22].

1.1 Our Results

We provide lower and upper bounds on the Price of Stability for the class of weighted congestion games with polynomial latencies with nonnegative coefficients. We consider both exact and approximate equilibria. Our lower bounds are summarized at the right of Table 1.

weights. See [10] and references therein for a thorough discussion of those results.

[4] For the special case of weighted congestion games with linear latency functions, a potential does exist [25] and this was used by [8] to provide a PoS upper bound of 2.

Lower Bound for Weighted Congestion Games. In our main result in Theorem 1, we resolve a long-standing open problem by providing almost tight bounds for the Price of Stability of weighted congestion games with polynomial latency functions. We construct an instance having a Price of Stability of $\Omega(\Phi_d)^{d+1}$, where d is the maximum degree of the latencies and $\Phi_d \sim \frac{d}{\ln d}$ is the unique positive solution of equation $(x+1)^d = x^{d+1}$.

This bound essentially closes the previously huge gap between $\Theta(d)$ and Φ_d^{d+1} for the PoS of weighted congestion games. The previously best lower and upper bounds were rather trivial: the lower bound corresponds to the PoS results of Christodoulou and Gairing [15] for the unweighted case (and thus, it is also a valid lower bound for the general weighted case as well) and the upper bound comes from the Price of Anarchy results of Aland et al. [3] (PoA, by definition, upper-bounds PoS).

We stress that, although as mentioned before, weighted congestion games do not always possess pure equilibria, our lower bound construction involves a *unique* equilibrium occurring by iteratively eliminating strongly dominated strategies. As a result, this lower bound holds not only for pure, but mixed and correlated equilibria as well.

Singleton Games. Next we switch to the class of singleton congestion games, where a pure strategy for each player is a *single* resource. This class is very well-studied as, on one hand, it abstracts scheduling environments, and on the other, it has very attractive equilibrium properties; unlike general weighted congestion games, there exists an (ordinal) lexicographic potential [24, 32], thus implying the existence of *pure* Nash equilibria. It is important to note that, the tight lower bounds for the Price of Anarchy of general weighted congestion games, hold also for the class of singleton games [14, 7, 11].

Nevertheless, even for this special class, we show in Theorem 5 an exponential lower bound of $\Omega(2^d/d)$. The previous best upper and lower bounds were the same as those of the general case, namely $\Theta(d)$ and Φ_d^{d+1}, respectively. As a matter of fact, this new lower bound comes as a corollary of a more general result that we show in Theorem 5, that extends to approximate equilibria and gives a lower bound of $\Omega((1+1/\alpha)^d/d)$ on the PoS of α-approximate equilibria, for any (multiplicative) approximation parameter $\alpha \in [1, d)$. Setting $\alpha = 1$ we recover the special case of exact equilibria and the aforementioned exponential lower bound on the standard, exact notion of the PoS. Notice here that, as we show in [26, Appendix D], the optimal solution (which, in general, is not an equilibrium) itself constitutes a $(d+1)$-approximate equilibrium with a (trivially) optimal PoS of 1.

Positive Results for Approximate Equilibria. In light of the above results, in Section 4, we turn our attention to identifying environments with more structure or flexibility with respect to the underlying solution concept, for which we can hope for improved quality of equilibria. Both our lower bound constructions discussed above use players' weights that form a geometric sequence. In particular the ratio W of the largest over the smallest weight is equal to w^n (for some $w > 1$), which grows very large as the number of players $n \to \infty$. On the other hand, for games where the players have equal weights, i.e. $W = 1$, we know that the PoS is at most $d+1$. It is therefore natural to ask how the performance of the good equilibria captured by the notion of PoS varies with respect to W. In Theorem 9, we are able to give a general upper bound for α-approximate equilibria which is sensitive to this parameter W and to α. This general theorem has two immediate, interesting corollaries.

Firstly (Corollary 10), by allowing the ratio W to range in $[1, \infty)$, we derive the existence of an α-approximate pure Nash equilibrium with PoS at most $(d+3)/2$; the equilibrium's approximation parameter α ranges from $\Theta(1)$ to $d+1$ in a smooth way with respect to W.

This is of particular importance in settings where player weights are not very far away from each other (that is, W is small). Secondly (Corollary 11), by setting $W = 1$ and allowing α to range, we get an upper bound of $\frac{d+1}{\alpha}$ for the α-approximate PoS of *unweighted* congestion games which, to the best of our knowledge, was not known before, degrading gracefully from $d + 1$ (which is the actual PoS of exact equilibria in the unweighted case [15]) down to the optimal value of 1 if we allow $(d + 1)$-approximate equilibria (which in fact can be achieved by the optimum solution itself; see [26, Appendix D]).

Our Techniques. An advantage of our main lower bound (Theorem 1) is the simplicity of the underlying construction, as well as its straightforward adaptation to network games (see Section 3.1.1)). However, fine-tuning the parameters of the game (player weights and latency functions), to ensure uniqueness of the equilibrium at the "bad" instance, was a technically involved task. This was in part due to the fact that, in order to guarantee uniqueness (via iteratively dominant strategies), each player interacts with a window of μ other players. This μ depends on d in a delicate way (see [26, Fig. 1] and Lemma 2); it has to be an integer but, at the same time, needs also to balance nicely with the algebraic properties of Φ_d. Moreover we needed to provide deeper insights on the asymptotic, analytic behaviour of Φ_d, and to explore some new algebraic characteristics of Φ_d (see, e.g., [26, Lemma 7]).

In order to derive our upper bounds, we need to define a novel *approximate potential function* [18, 29]. First, in Lemma 6, we identify clear algebraic sufficient conditions for the existence of approximate equilibria with good social-cost guarantees, and then explicitly define (see the (8) and the proof of Theorem 9 in [26]) a function that satisfies them. This continuous function, which is defined in the entire space of positive reals, essentially generalizes that of Rosenthal's in a smooth way: by setting $W = \alpha = 1$, we recover exactly the first significant terms of the well known Rosenthal potential [39] polynomial, with which one can demonstrate the usual PoS results for the unweighted case (see, e.g. [16]). The simple, analytic way in which this function is defined, is the very reason why we can handle both the approximation parameter α of the equilibrium and the ratio W of the weights in a smooth manner while at the same time providing good PoS guarantees.

It is important to stress that, by the purely analytical way in which our approximate potential function is defined, in principle it can also incorporate more general cost functions than polynomials; so, we believe that this technique may be of independent interest. We point towards that direction in [26, Appendix C].

Due to space limitations, all omitted proofs and various supplementary figures can be found in the full version of our paper [26].

2 Model and Notation

Weighted Congestion Games. A *weighted congestion game* consists of a finite, nonempty set of players N and resources (or facilities) E. Each player $i \in N$ has a real *weight* w_i 0 and a *strategy set* $S_i \subseteq 2^E$. Associated with each resource $e \in E$ is a *cost* (or *latency*) *function* $c_e : (0, \infty) \longrightarrow [0, \infty)$. In this paper we mainly focus on polynomial cost functions with maximum degree $d \geq 0$ and nonnegative coefficients; that is, every cost function is of the form $c_e(x) = \sum_{j=0}^{d} a_{e,j} \cdot x^j$, with $a_{e,j} \geq 0$ for all j. In the following, whenever we refer to polynomial cost functions we mean cost functions of this particular form.

A *pure strategy profile* is a choice of strategies $\mathbf{s} = (s_1, s_2, ...s_n) \in S = S_1 \times \cdots \times S_n$ by the players. We use the standard game-theoretic notation $\mathbf{s}_{-i} = (s_1, \ldots, s_{i-1}, s_{i+1}, \ldots s_n)$, $S_{-i} = S_1 \times \cdots \times S_{i-1} \times S_{i+1} \times \cdots \times S_n$, such that $\mathbf{s} = (s_i, \mathbf{s}_{-i})$. Given a pure strategy profile

$\mathbf{s}$, we define the *load* $x_e(\mathbf{s})$ of resource $e \in E$ as the total weight of players that use resource e on $\mathbf{s}$, i.e., $x_e(\mathbf{s}) = \sum_{i \in N : e \in s_i} w_i$. The *cost* player i is defined by $C_i(\mathbf{s}) = \sum_{e \in s_i} c_e(x_e(\mathbf{s}))$.

A *singleton* weighted congestion game is a special form of congestion games where the strategies of all players consist only of single resources; that is, for all players $i \in N$, $|s_i| = 1$ for all $s_i \in S_i$. In a weighted *network* congestion games the resources E are given as the edge set of some directed graph $G = (V, E)$, and each player $i \in N$ has a source $o_i \in V$ and destination $t_i \in V$ node; then, the strategy set S_i of each player is implicitly given as the edge sets of all directed $o_i \to t_i$ paths in G.

Nash Equilibria. A pure strategy profile $\mathbf{s}$ is a pure *Nash equilibrium* if and only if for every player $i \in N$ and for all $s'_i \in S_i$, we have $C_i(\mathbf{s}) \leq C_i(s'_i, \mathbf{s}_{-i})$. Similarly a strategy profile is an *α-approximate pure Nash equilibrium*, for $\alpha \geq 1$, if $C_i(\mathbf{s}) \leq \alpha \cdot C_i(s'_i, \mathbf{s}_{-i})$ for all players $i \in N$ and $s'_i \in S_i$. As discussed in the introduction, weighted congestion games do not always admit pure Nash equilibria. However, by Nash's theorem they have mixed Nash equilibria. A tuple $\sigma = (\sigma_1, \cdots, \sigma_N)$ of independent probability distributions over players' strategy sets is a *mixed Nash equilibrium* if

$$\mathop{\mathbb{E}}_{\mathbf{s} \sim \sigma}[C_i(\mathbf{s})] \leq \mathop{\mathbb{E}}_{\mathbf{s}_{-i} \sim \sigma_{-i}}[C_i(s'_i, \mathbf{s}_{-i})]$$

holds for every $i \in N$ and $s'_i \in S_i$. Here σ_{-i} is a product distribution of all σ_j's with $j \neq i$, and $\mathbf{s}_{-i}$ denotes a strategy profile drawn from this distribution. We use $\mathrm{NE}(G)$ to denote the set of all mixed Nash equilibria of a game G.

Social Cost and Price of Stability. Fix a weighted congestion game G. The *social cost* of a pure strategy profile $\mathbf{s}$ is the weighted sum of the players' costs

$$C(\mathbf{s}) = \sum_{i \in N} w_i \cdot C_i(\mathbf{s}) = \sum_{e \in E} x_e(\mathbf{s}) \cdot c_e(x_e(\mathbf{s})).$$

Denote by $\mathrm{OPT}(G) = \min_{\mathbf{s} \in S} C(\mathbf{s})$ the *optimum social cost* over all strategy profiles $\mathbf{s} \in S$. Then, the *Price of Stability (PoS)* of G is the social cost of the best-case Nash equilibrium over the optimum social cost:

$$\mathrm{PoS}(G) = \min_{\sigma \in \mathrm{NE}(G)} \frac{\mathbb{E}_{\mathbf{s} \sim \sigma}[C(\mathbf{s})]}{\mathrm{OPT}(G)}.$$

The Price of Stability of α-approximate Nash equilibria is defined accordingly. The PoS for a class $\mathcal{G}$ of games is the worst (i.e., largest) PoS among all games in the class, that is, $\mathrm{PoS}(\mathcal{G}) = \sup_{G \in \mathcal{G}} \mathrm{PoS}(G)$. For example, our focus in this paper is determining the Price of Stability for the class $\mathcal{G}$ of weighted congestion games with polynomial cost functions.

Finally, notice that, by using a straightforward scaling argument, it is without loss with respect to the PoS metric to analyse games with player weights in $[1, \infty)$; if not, divide all w_i's with $\min_i w_i$ and scale cost functions accordingly.

3 Lower Bounds

In this section, we present our lower bound constructions. In Section 3.1 we present the general lower bound and then in Section 3.2 the lower bound for singleton games.

3.1 General Congestion Games

The next theorem presents our main negative result on the Price of Stability of weighted congestion games with polynomial latencies of degree d, that essentially matches the Price of Anarchy upper bound of Φ_d^{d+1} from Aland et al. [3]. Our result, shows a strong separation of the Price of Stability of weighted and unweighted congestion games, where the Price of Stability is at most $d+1$ [15]. This is in sharp contrast to the Price of Anarchy of these two classes, where the respective bounds are essentially the same.

We will need to introduce some notation. Let $\Phi_d = \Theta\left(\frac{d}{\ln d}\right)$ be the unique positive root of the equation $(x+1)^d = x^{d+1}$ and let β_d be a parameter such that $\beta_d \geq 0.38$ for any d, $\lim_{d\to\infty} \beta_d = \frac{1}{2}$. A plot of its values can be seen in [26, Fig. 1].

▶ **Theorem 1.** *The Price of Stability of weighted congestion games with polynomial latency functions of degree at most $d \geq 9$ is at least $(\beta_d \Phi_d)^{d+1}$.*

▶ **Lemma 2.** *For any positive integer d define*

$$c_d = \frac{1}{d}\left\lfloor d\frac{\ln(\Phi_d^{1+2/d} - \Phi_d) - \ln(\Phi_d^{1+2/d} - \Phi_d - 1)}{\ln \Phi_d}\right\rfloor \qquad \text{and} \qquad \beta_d = 1 - \Phi_d^{-c_d}, \tag{1}$$

Then $\Phi_d^{d+2} \leq \left(\Phi_d + \frac{1}{\beta_d}\right)^d$; furthermore, for all $d \geq 9$ we have: $d \cdot c_d \geq 3$, $0.38 \leq \beta_d \leq \frac{1}{2}$ and $\lim_{d\to\infty} \beta_d = \frac{1}{2}$.

Proof of Theorem 1. We now move on to the description of our congestion game instance. Fix some integer[5] $d \geq 9$. Our instance consists of $n+\mu$ players and $n+\mu+1$ facilities, where $\mu \equiv c \cdot d$ for some real $c \geq \frac{3}{d}$ (to be specifically determined later on, see (1)) such that $\mu \geq 3$ is an integer. You can think of n as a very large integer, since at the end we will take $n \to \infty$. Every player $i = 1, 2, \ldots, n+\mu$ has a weight of $w_i = w^i$, where $w = 1 + \frac{1}{\Phi_d}$.

It will be useful for subsequent computations to notice that $w^d = \left(1 + \frac{1}{\Phi_d}\right)^d = \frac{(\Phi_d+1)^d}{\Phi_d^d} = \frac{\Phi_d^{d+1}}{\Phi_d^d} = \Phi_d$ and $w^{d+1} = w^d \cdot w = \Phi_d\left(1 + \frac{1}{\Phi_d}\right) = \Phi_d + 1$. Let also define

$$\alpha = \alpha(\mu) \equiv \sum_{j=1}^{\mu} w^{-j} = \frac{1 - w^{-\mu}}{w - 1} = \frac{1 - (w^d)^{-c}}{w - 1} = \frac{1 - \Phi_d^{-c}}{1 + \frac{1}{\Phi_d} - 1} = \Phi_d\left(1 - \Phi_d^{-c}\right) = \beta_d \Phi_d,$$

where $\beta_d \equiv 1 - \Phi_d^{-c} \in (0,1)$. Observe that

$$w^{-\mu} = 1 - \beta_d \Phi_d (w-1) = 1 - \beta_d \Phi_d \left(1 + \frac{1}{\Phi_d} - 1\right) = 1 - \beta_d$$

and furthermore, for every $i \geq \mu + 1$, $\sum_{j=i-\mu}^{i-1} w_j = \sum_{j=1}^{\mu} w^{i-j} = \alpha \cdot w^i$, $\sum_{j=i-\mu}^{i} w_j = (\alpha+1) \cdot w^i$ and $\sum_{\ell=1}^{\infty} w^{-\ell} = \frac{1}{w-1} = \frac{1}{1+\frac{1}{\Phi_d}-1} = \Phi_d$.

The facilities have latency functions

$$\begin{aligned} c_j(t) &= (\alpha+1)^d, && \text{if } j = 1, \ldots, \mu, \\ c_j(t) &= w^{-j(d+1)} t^d, && \text{if } j = \mu+1, \ldots, \mu+n, \\ c_{n+\mu+1}(t) &= 0, \end{aligned}$$

where for simplicity we use j instead e_j to refer to the j-th facility.

[5] For polynomial latencies of smaller degrees $d \leq 8$ we can instead apply the simpler lower-bound instance for singleton games given in Section 3.2.

Every player i has two available strategies, s_i^* and $\tilde{s}_i$. Eventually we will show that the profile $\mathbf{s}^*$ corresponds to the optimal solution, while $\tilde{\mathbf{s}}$ corresponds to the *unique* Nash equilibrium of the game. Informally, at the former the player chooses to stay at her "own" i-th facility, while at the latter she chooses to deviate and play the μ following facilities $i+1,\ldots,i+\mu$. However, special care shall be taken for the boundary cases of the first μ and last μ players, so for any player i we formally define $S_i = \{s_i^*, \tilde{s}_i\}$ where $s_i^* = \{i\}$ and

$$\tilde{s}_i = \begin{cases} \{\mu+1,\ldots,\mu+i\}, & \text{if } i=1,\ldots,\mu, \\ \{i+1,\ldots,i+\mu\}, & \text{if } i=\mu+1,\ldots,n, \\ \{i+1,\ldots,n+\mu+1\}, & \text{if } i=n+1,\ldots,n+\mu. \end{cases}$$

These two outcomes, $\mathbf{s}^*$ and $\tilde{\mathbf{s}}$, are shown in [26, Fig. 2].

Notice here that any facility j cannot get a load greater than the sum of the weights of the previous μ players plus the weight of the j-th player. So, for and any strategy profile $\mathbf{s}$:

$$x_j(\mathbf{s}) \leq \sum_{\ell=j-\mu}^{j} w_\ell = (\alpha+1)w^j \qquad \text{for all } j \geq \mu+1 \tag{2}$$

Next we will show that the strategy profile $\tilde{\mathbf{s}} = (\tilde{s}_1,\ldots,\tilde{s}_{n+\mu})$ is the *unique* Nash equilibrium of our congestion game. We do that by proving that

1. It is a strongly *dominant* strategy for any player $i=1,\ldots,\mu$ to play $\tilde{s}_i$.
2. For any $i=\mu+1,\ldots,n+\mu$, given that every player $k<i$ has chosen to play $\tilde{s}_k$, then it is a strongly *dominant* strategy for player i to deviate to $\tilde{s}_i$ as well.

For the first condition, fix some player $i \leq \mu$ and a strategy profile $\mathbf{s}_{-i}$ for the other players and observe that by choosing $\tilde{s}_i$, player i incurs a cost of at most

$$\begin{aligned} C_i(\tilde{s}_i,\mathbf{s}_{-i}) &= \sum_{j\in\tilde{s}_i} c_j(x_j(\tilde{s}_i)) \leq \sum_{\ell=\mu+1}^{\mu+i} c_\ell\left((\alpha+1)w^\ell\right) \\ &= \sum_{\ell=d+1}^{d+i} w^{-\ell(d+1)}(\alpha+1)^d w^{\ell d} = (\alpha+1)^d \sum_{\ell=d+1}^{d+i} w^{-\ell} \\ &< (\alpha+1)^d w^{-d} \sum_{\ell=1}^{\infty} w^{-\ell} = (\alpha+1)^d \frac{1}{\Phi_d}\Phi_d = (\alpha+1)^d = C_i(s_i^*,\mathbf{s}_{-i}), \end{aligned}$$

where in the first inequality we used the bound from (2).

For the second condition, we will consider the deviations of the remaining players.[6] Fix now some $i=\mu+1,\ldots,n$ and assume a strategy profile $\mathbf{s}_{-i} = (\tilde{s}_1,\ldots,\tilde{s}_{i-1},s_{i+1},\ldots,s_{n+\mu})$ for the remaining players. If player i chooses strategy s_i^* she will experience a cost of

$$C_i(s_i^*,\mathbf{s}_{-i}) = c_i\left(\sum_{\ell=i-\mu}^{i} w_\ell\right) = c_i\left((\alpha+1)w^i\right) = w^{-i(d+1)}(\alpha+1)^d w^{id} = (\alpha+1)^d w^{-i}.$$

It remains to show that

$$C_i(\tilde{s}_i,\mathbf{s}_{-i}) < C_i(s_i^*,\mathbf{s}_{-i}) = (\alpha+1)^d w^{-i}. \tag{3}$$

[6] For the remaining last μ players $i=n+1,\ldots,n+\mu$ the proof is similar to the text, and as a matter of fact easier, since when these players deviate to $\tilde{s}_i$ they also use the final "dummy" facility $n+\mu+1$ that has zero cost.

The cost $C_i(\tilde{s}_i, \mathbf{s}_{-i})$ is complicated to bound immediately, for any profile $\mathbf{s}_{-i}$. Instead, we will resort to the following claim which characterizes the profile $\mathbf{s}_{-i}$ where this cost is maximized. [7]

▶ **Claim 3.** *There exists a profile* $\mathbf{s}'$ *with*

1. $s'_j = s_j$ *for all* $j \leq i$ *and* $i > i + \mu$
2. $s'_{i+\mu} = s^*_{i+\mu}$
3. *there exists some* $k \in \{i+1, \ldots, i+\mu-1\}$ *such that*

$$s'_j = \tilde{s}_j \qquad \text{for all } j \in \{i+1, \ldots, i+\mu-1\} \setminus \{k\},$$

that dominates $\mathbf{s}$*, i.e.* $C_i(\tilde{s}_i, \mathbf{s}_{-i}) \leq C_i(\tilde{s}_i, \mathbf{s}'_{-i})$.

By use of Claim 3, it remains to show

$$C_i(\tilde{s}_i, \mathbf{s}'_{-i}) < (\alpha+1)^d w^{-i}, \tag{4}$$

just for the special case of profiles $\mathbf{s}'$ that are described in Claim 3. We do this in [26, Appendix A.4].

Summarizing, we proved that indeed $\tilde{\mathbf{s}}$ is the *unique* Nash equilibrium of our congestion game. Finally, to conclude with lower-bounding the Price of Stability, let us compute the social cost on profiles $\tilde{\mathbf{s}}$ and $\mathbf{s}^*$. On $\mathbf{s}^*$, any facility j (except the last one) gets a load equal to the weight of player j, so

$$\begin{aligned}
C(\mathbf{s}^*) &= \sum_{j=1}^{n+\mu} w_j c_j(w_j) \\
&= \sum_{j=1}^{\mu} w^j (\alpha+1)^d + \sum_{j=\mu+1}^{n+\mu} w^j w^{-j(d+1)} (w^j)^d \\
&= (\alpha+1)^d \sum_{j=1}^{\mu} w^j + \sum_{j=\mu+1}^{\mu+n} 1 \\
&= (\alpha+1)^d w \frac{w^\mu - 1}{w-1} + n \\
&= n + (\beta\Phi_d + 1)^d \left(1 + \frac{1}{\Phi_d}\right) \frac{\frac{1}{1-\beta} - 1}{1 + \frac{1}{\Phi_d} - 1} \\
&= n + (\beta\Phi_d + 1)^d (\Phi_d + 1) \frac{\beta}{1-\beta} \\
&\leq n + \frac{\beta}{1-\beta} (\Phi_d + 1)^{d+1}.
\end{aligned}$$

On the other hand, at the unique Nash equilibrium $\tilde{\mathbf{s}}$ each facility $j \geq \mu + 1$ receives a load equal to the sum of the weights of the previous μ players, i.e.

$$x_j(\tilde{\mathbf{s}}) = \sum_{\ell=j-\mu}^{j-1} w_\ell = \alpha w^j$$

[7] For an explanatory figure and a proof of this claim, see the full version of our paper [26, Fig. 3].

so

$$C(\tilde{\mathbf{s}}) \geq \sum_{j=\mu+1}^{n+\mu} x_j(\tilde{\mathbf{s}}) c_j(x_j(\tilde{\mathbf{s}})) = \sum_{j=\mu+1}^{n+\mu} w^{-j(d+1)} \left(\alpha w^j\right)^{d+1} = \alpha^{d+1} \sum_{j=\mu+1}^{\mu+n} 1 = \alpha^{d+1} n.$$

By taking n arbitrarily large we get a lower bound on the Price of Stability of

$$\lim_{n\to\infty} \frac{C(\tilde{\mathbf{s}})}{C(\mathbf{s}^*)} \geq \lim_{n\to\infty} \frac{\alpha^{d+1} n}{n + \frac{\beta}{1-\beta}(\Phi_d + 1)^{d+1}} = \alpha^{d+1} = (\beta \Phi_d)^{d+1},$$

where from Lemma 2 we know that $\frac{1}{3} \leq \beta = \frac{1}{2} - o(1)$. ◀

3.1.1 Network Games

Due to the rather simple structure of the players' strategy sets in the lower bound construction of Theorem 1, it can be readily extended to network games as well:

▶ **Proposition 4.** *Theorem 1 applies also to* network *weighted congestion games.*

3.2 Singleton Games

In this section we give an exponential lower bound for *singleton* weighted congestion games with polynomial latency functions. The following theorem handles also approximate equilibria and provides a lower bound on the Price of Stability in a very strong sense; even if one allows for the best approximate equilibrium with approximation factor $\alpha = o\left(\frac{d}{\ln d}\right)$, then its cost is lower-bounded by $\omega(d)$ times the optimal cost.[8] In other words, in order to achieve linear guarantees on the Price of Stability, one has to consider $\Omega\left(\frac{d}{\ln d}\right)$-approximate equilibria—almost linear in d; this shows that our positive result in Corollary 10, of the following Section 4.3, is essentially tight. This is furthermore complemented by [26, Appendix D], where we show that the socially optimum profile is a $(d+1)$-approximate equilibrium (achieving an optimal Price of Stability of 1).

▶ **Theorem 5.** *For any positive integer d and any real $\alpha \in [1, d)$, the α-approximate (mixed) Price of Stability of weighted (singleton) congestion games with polynomial latencies of degree at most d is at least $\frac{1}{e(d+1)} \left(1 + \frac{1}{\alpha}\right)^{d+1}$. In particular, for the special case of $\alpha = 1$, we derive that the Price of Stability of* exact *equilibria is $\Omega(2^d/d) = (2 - o(1))^{d+1}$.*

4 Upper Bounds

The negative results of the previous sections, involve constructions where the ratio W of the largest to smallest weight can be exponential in d. In the main theorem (Theorem 9) of this section we present an analysis which is sensitive to this parameter W, and identify conditions under which the performance of approximate equilibria can be significantly improved.

Our upper bound approach is based on the design of a suitable approximate potential function and has three main steps. First, in Section 4.1, we set up a framework for the definition of this function by identifying conditions that, on the one hand, certify the existence of an approximate equilibrium and, on the other, provide guarantees about its efficiency.

[8] To see this, just take any upper bound of $\frac{d+1}{c \ln(d+1)}$ on α, for a constant $c > 2$. Then, the lower bound in Theorem 5 becomes $\Omega(d^{c-1})$.

Then, in Section 4.2, by use of the Euler-Maclaurin summation formula we present a general form of an approximate potential function, which extends Rosenthal's potential for weighted congestion games (see also [26, Appendix C]). Finally, in Section 4.3, we deploy this potential for polynomial latencies. Due to its analytic description, our potential differs from other extensions of the Rosenthal's potential that have appeared in previous work, and we believe that this contribution might be of independent interest, and applied to other classes of latency functions.

4.1 The Potential Method

In the next lemma we lay the ground for the design and analysis of approximate potential functions, by supplying conditions that not only provide guarantees for the existence of approximate equilibria, but also for their performance with respect to the social optimum. In the premises of the lemma, we give conditions on the resource functions ϕ_e, having in mind that $\Phi(\mathbf{s}) = \sum_{e\in E} \phi_e(x_e(\mathbf{s}))$ will eventually serve as the "approximate" potential function.

▶ **Lemma 6.** *Consider a weighted congestion game with latency functions c_e, for each facility $e \in E$, and player weights w_i, for each player $i \in N$. If there exist functions $\phi_e : [0,\infty) \longrightarrow \mathbb{R}$ and parameters $\alpha_1, \alpha_2, \beta_1, \beta_2 > 0$ such that for any facility e and player weight $w \in \{w_1, \ldots, w_n\}$*

$$\alpha_1 \leq \frac{\phi_e(x+w) - \phi_e(x)}{w \cdot c_e(x+w)} \leq \alpha_2, \qquad \text{for all } x \geq 0, \tag{5}$$

and

$$\beta_1 \leq \frac{\phi_e(x)}{x \cdot c_e(x)} \leq \beta_2, \qquad \text{for all } x \geq \min_n w_n, \tag{6}$$

then our game has an $\frac{\alpha_2}{\alpha_1}$-approximate pure Nash equilibrium which, furthermore, has Price of Stability at most $\frac{\beta_2}{\beta_1}$.

4.2 Faulhaber's Potential

In this section we propose an approximate potential function, which is based on the following classic number-theoretic result, known as Faulhaber's formula[9], which states that for any positive integers n, m,

$$\begin{aligned}\sum_{k=1}^{n} k^m &= \frac{1}{m+1}\sum_{j=0}^{m}(-1)^j \binom{m+1}{j} B_j n^{m+1-j} \\ &= \frac{1}{m+1}n^{m+1} + \frac{1}{2}n^m + \frac{1}{m+1}\sum_{j=2}^{m}\binom{m+1}{j} B_j n^{m+1-j},\end{aligned} \tag{7}$$

where the coefficients B_j are the usual Bernoulli numbers.[10] In particular, this shows that the sum of the first n powers of m can be expressed as a polynomial of n with degree $m+1$. Furthermore, this sum corresponds to the well-known potential of Rosenthal [39] for *unweighted* congestion games when the latency function is the monomial $x \mapsto x^m$.

[9] See, e.g., [33, p. 287] or [19, p. 106]).

[10] See, e.g., [28, Chapter 6.5] or [1, Chapter 23]. The first Bernoulli numbers are: $B_0 = 1, B_1 = -1/2, B_2 = 1/6, B_3 = 0, B_4 = -1/30, \ldots$. Also, we know that $B_j = 0$ for all *odd* integers $j \geq 3$.

Based on the above observation, we go beyond just integer values of n, and generalize this idea to all positive reals; in that way, we design a "potential" function that can handle different player weights and, furthermore, incorporate in a more powerful, analytically smooth way, approximation factors with respect to both the Price of Stability, as well as the approximation parameter of the equilibrium (in the spirit of Lemma 6). A natural way to do that is to directly generalize (7) and simply define, for any real $x \geq 0$ and positive integer m,

$$S_m(x) \equiv \frac{1}{m+1}x^{m+1} + \frac{1}{2}x^m, \tag{8}$$

keeping just the first two significant terms.[11] For the special case of $m = 0$ we set $S_0(y) = y$.

For any nonnegative integer m we define the function $A_m : [1, \infty) \longrightarrow (0, \infty)$ with

$$A_m(x) \equiv \left[\frac{S_m(x)}{x^{m+1}}\right]^{-1} = \left(\frac{1}{m+1} + \frac{1}{2x}\right)^{-1} = \frac{2(m+1)x}{2x+m+1}. \tag{9}$$

Observe that A_m is strictly increasing (in x) for all $m \geq 1$,

$$A_m(1) = \frac{2(m+1)}{m+3} \in [1, 2), \qquad \text{and} \qquad \lim_{x\to\infty} A_m(x) = m+1. \tag{10}$$

For the special case of $m = 0$ we simply have $A_0(x) = 1$ for all $x \geq 0$. A graph of these functions can be found in [26, Fig. 6]. Since A_m is strictly increasing for $m \geq 1$, its inverse function, $A_m^{-1} : [2\frac{m+1}{m+3}, m+1] \longrightarrow [1, \infty)$, is well-defined and also strictly increasing for all $m \geq 1$.

The following two lemmas describe some useful properties regarding the algebraic behaviour, and the relation among, functions A_m and S_m:

▶ **Lemma 7.** *Fix any reals $y \geq x \geq 1$. Then the sequences $\frac{A_m(x)}{m+1}$ and $\frac{A_m(x)}{A_m(y)}$ are decreasing, and sequence $A_m(x)$ is increasing (with respect to m).*

▶ **Lemma 8.** *Fix any integer $m \geq 0$ and reals $\gamma, w \geq 1$. Then*

$$\frac{\gamma^{m+1}}{A_m(\gamma w)} \leq \frac{S_m(\gamma(x+w)) - S_m(\gamma x)}{w(x+w)^m} \leq \gamma^{m+1}, \qquad \textit{for all } x \geq 0, \tag{11}$$

and

$$\frac{\gamma^{m+1}}{m+1} \leq \frac{S_m(\gamma x)}{x^{m+1}} \leq \frac{\gamma^{m+1}}{A_m(\gamma)}, \qquad \textit{for all } x \geq 1. \tag{12}$$

4.3 The Upper Bound

Now we are ready to state our main positive result:

▶ **Theorem 9.** *At any congestion game with polynomial latency functions of degree at most $d \geq 1$ and player weights ranging in $[1, W]$, for any $\frac{2(d+1)W}{2W+d+1} \leq \alpha \leq d+1$ there exists an α-approximate pure Nash equilibrium that, furthermore, has Price of Stability at most*

$$1 + \left(\frac{d+1}{\alpha} - 1\right) W.$$

[11] See [26, Sec. 4.4] for further discussion on this choice.

Observe that, as the approximation parameter α increases, the Price of Stability decreases, in a smooth way, from $\frac{d+3}{2}$ down to the optimal value of 1. Furthermore, notice how the interval within which α ranges, shrinks as the range of player weights W grows; in particular, its left boundary $\frac{2(d+1)W}{2W+d+1}$ goes from $2\frac{d+1}{d+3}$ (for $W = 1$) up to $d + 1$ (for $W \to \infty$).

As a result, Theorem 9 has two interesting corollaries, one for $\alpha = \frac{2(d+1)W}{2W+d+1}$ and one for $W = 1$ (unweighted games):

▶ **Corollary 10.** *At any congestion game with polynomial latencies of degree at most $d \geq 1$ where player weights lie within the range $[1, W]$, there is an $\frac{2(d+1)W}{2W+d+1}$-approximate pure Nash equilibrium with Price of Stability at most $\frac{d+3}{2}$.*

It is interesting to point out here that, in light of Theorem 5, the above result of Corollary 10 is essentially asymptotically tight as far as the Price of Stability is concerned (see the discussion preceding Theorem 5).

▶ **Corollary 11.** *At any* unweighted *congestion game with polynomial latencies of degree at most $d \geq 1$, the Price of Stability of α-approximate equilibria is at most $\frac{d+1}{\alpha}$, for any $2\frac{d+1}{d+3} \leq \alpha \leq d + 1$.*

Abstract

Wardrop equilibria in nonatomic congestion games are in general inefficient as they do not induce an optimal flow that minimizes the total travel time. Network tolls are a prominent and popular way to induce an optimum flow in equilibrium. The classical approach to find such tolls is marginal cost pricing which requires the exact knowledge of the demand on the network. In this paper, we investigate under which conditions demand-independent optimum tolls exist that induce the system optimum flow for any travel demand in the network. We give several characterizations for the existence of such tolls both in terms of the cost structure and the network structure of the game. Specifically we show that demand-independent optimum tolls exist if and only if the edge cost functions are shifted monomials as used by the Bureau of Public Roads. Moreover, non-negative demand-independent optimum tolls exist when the network is a directed acyclic multi-graph. Finally, we show that any network with a single origin-destination pair admits demand-independent optimum tolls that, although not necessarily non-negative, satisfy a budget constraint.

1 Introduction

The impact of selfish behavior on the efficiency of traffic networks is a longstanding topic in the algorithmic game theory and operations research literature. Already more than half a century ago, Wardrop [41] stipulated a main principle of a traffic equilibrium that – in light of the omnipresence of modern route guidance systems – is as relevant as ever: "The

45th International Colloquium on Automata, Languages, and Programming (ICALP 2018).

journey times on all the routes actually used are equal, and less than those which would be experienced by a single vehicle on any unused route." This principle can be formalized by modeling traffic as a flow in a directed network where edges correspond to road segments and vertices correspond to crossings. Each edge is endowed with a cost function that maps the total amount of traffic on it to a congestion cost that each flow particle traversing the edge has to pay. Further, we are given a set of commodities, each specified by an origin, a destination, and a flow demand. In this setting, a Wardrop equilibrium is a multi-commodity flow such that for each commodity the total cost of any used path is not larger than the total cost of any other path linking the commodity's origin and destination. Popular cost functions, put forward for the use in traffic models by the U.S. Bureau of Public Roads [40] are of the form

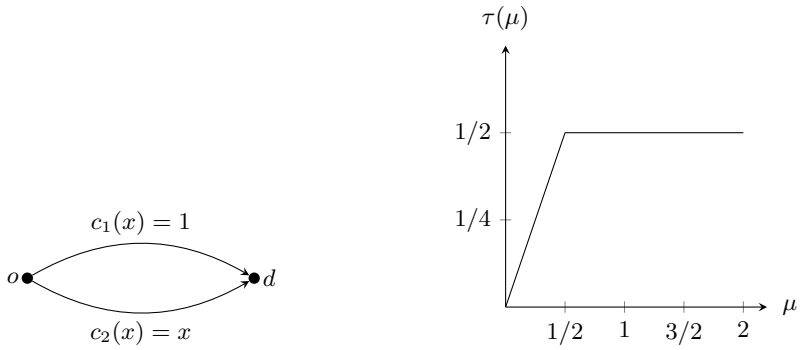
$$c_e(x_e) = t_e\left(1 + \alpha\left(\frac{x_e}{k_e}\right)^{\beta}\right), \tag{1}$$

where x_e is the traffic flow along edge e, $t_e \geq 0$ is the free-flow travel time, k_e is the capacity of edge e and α and β are parameters fitted to the model.

While Wardrop equilibria are guaranteed to exist under mild assumptions on the cost functions [4], it is well known that they are inefficient in the sense that they do not minimize the overall travel time of all commodities [34]. A popular mechanism to decrease the inefficiency of selfish routing are congestion tolls. A toll is a payment that the system designer defines for each edge of the graph and that has to be paid by each flow particle traversing the edge. By carefully choosing the edges' tolls, the system designer can steer the Wardrop equilibrium in a favorable direction. A classic approach first due to Pigou [34] is *marginal cost pricing* where the toll of each edge is equal to difference between the marginal social cost and the marginal private cost of the system optimum flow on that edge. Marginal cost pricing induces the system optimal flow – the one that minimizes the overall travel time – as a Wardrop equilibrium [4]. Congestion pricing is not only an interesting theoretical issue that links system optimal flows and traffic equilibria, but also a highly relevant tool in practice, as various cities of the world, including Stockholm, Singapore, Bergen, and London, implement congestion pricing schemes to mitigate congestion [22, 39].

The problem. Marginal cost pricing is an elegant way to induce the system optimum flow as a Wardrop equilibrium, but the concept crucially relies on the exact knowledge of the travel demand. As an example consider the Pigou network in Figure 1a for an arbitrary flow demand of $\mu > 0$ going from o to d. The optimal flow only uses the lower edge with cost function $c(x) = x$ as long as $\mu \leq 1/2$. For demands $\mu > 1/2$, a flow of $1/2$ is sent along the lower edge and the remaining flow of $\mu - 1/2$ is sent along the upper edge. Using marginal cost pricing the toll of the lower edge is $\min\{\mu, 1/2\}$ and no toll is to be payed for the upper edge, see Figure 1b.

This toll scheme is problematic as it depends on the flow demand μ in the network. In particular, when the demand is estimated incorrectly, the resulting tolls will be sub-optimal. Assume the network designer expects a flow of $\mu = 1/4$ and, thus, sets a (marginal cost) toll of $\tau_2 = 1/4$ on the lower link. When the actual total flow demand is higher than expected and equal to $\mu = 1$, a fraction $1/4$ of the flow uses the upper edge and $3/4$ of the flow uses the lower edge resulting in a cost of $1/4 + 9/16$. However, it is optimal to induce an equal split between the edge which can be achieved by a toll of $1/2$ on the lower edge. Quite strikingly, the toll of $\tau_2 = 1/2$ is optimal for all possible demand values as it always induces the optimal flow. For demands less than $1/2$, a toll of $1/2$ on the lower edge does not hinder any flow particle from using the lower edge, which is optimal. On the other hand, for any demand



(a) Pigou network. **(b)** Marginal cost toll for lower edge.

Figure 1 Dependence of the marginal cost tolls for the Pigou network.

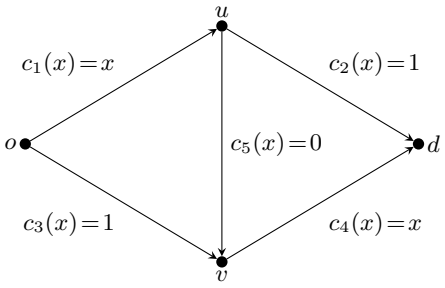


Figure 2 Braess network.

larger 1/2, the toll of 1/2 on the lower edge forces the flow on this edge to not exceed 1/2, which is optimal as well.

The situation is even more severe for the Braess network in Figure 2. When the system designer expects a traffic demand of 1 going from o to d, marginal cost pricing fixes a toll of 1 on both the upper left and the lower right edge (both with cost function $c(x) = x$). When the demand is lower than expected, say, $\mu = 1/2$, under marginal cost pricing, the flow is split equally between the lower and the upper path leading to a total cost of 5/4. The optimal flow with flow value 1/2, however, only uses the zig-zag-path $o \to u \to v \to d$ with cost 1. It is interesting to note that this flow is actually equal to the Wardrop equilibrium without any tolls. To conclude this example, marginal cost pricing may actually *increase* the total cost of the Wardrop equilibrium when the travel demand is estimated incorrectly. We note that also in the Braess graph, there is a distinct toll vector that enforces the optimum flow as a Wardop equilibrium *for any demand*. We will see that by setting a toll of 1 on the central edge from u to v, the Wardrop equilibrium for any flow demand is equal to the respective optimum flow.

We conclude that for both the Pigou network and the Braess network, marginal cost pricing is not robust with respect to changes in the demand since wrong estimates of the travel demand lead to sub-optimal tolls. Since such changes may occur frequently in road networks (e.g., due to sudden weather changes, accidents, or other unforeseen events), marginal cost pricing does not use the full potential of congestion pricing and may even be harmful for the traffic. On the other hand, for both networks, there exist tolls that enforce the optimum flow as an equilibrium for *any* flow demand. In this paper, we systematically study conditions for such demand-independent optimal tolls to exist.

Our results. In this paper we study the existence of demand-independent optimum tolls (DIOTs) that induce the optimum flow as an equilibrium for *any* flow demand. We give a precise characterization in terms of the cost structure on the edges for DIOTs to exists. Specifically, we show that DIOTs exist for any network where the cost of each edge is a BPR-type function, i.e.,

$$c_e(x) = t_e + a_e x_e^\beta \quad \text{for all } e \in \mathcal{E}, \tag{2}$$

where $t_e, a_e \in \mathbb{R}_+$ are arbitrary while $\beta \in \mathbb{R}_+$ is a common constant for all edges $e \in \mathcal{E}$. This existence result holds regardless of the topology of the network and on the number of origin-destination (O/D) pairs. On the other hand, for any cost function that is not of the form as in (2), there is a simple network consisting of two parallel edges with cost function c and cost function $c + b$ for some $b > 0$ that does not admit a DIOT. Our existence result for networks with BPR-type cost functions is proven in terms of a characterization that uniquely determines the sum of the tolls along each path that is used by the optimum flow for some demand.

In general the DIOTs used in the characterization may use negative tolls as well. We provide an example of a network with BPR-type cost functions where a non-negative DIOT does not exist. Besides conditions on the costs, conditions on the network are needed to guarantee the existence of non-negative DIOTs. We show that non-negative DIOTs exist for directed acyclic multi-graphs (DAMGs) with BPR-type cost functions, like the Pigou network and the Braess network discussed in Section 1. This condition on the network is sufficient, but not necessary for the existence of non-negative DIOTs.

Under a weaker condition than DAMG, we prove the existence of DIOTs that follow a budget constraint of non-negativity of the total amount of tolls. This condition is satisfied by networks with a single O/D pair.

Due to space constraint, some of the proofs are omitted and can be found in the arXiv version [15].

Related work. Marginal cost pricing as a means to reduce the inefficiency of selfish resource allocation was first proposed by Pigou [34] and subsequently discussed by Knight [31]. Wardrop [41] introduced the notion of a traffic equilibrium where each flow particle only uses shortest paths. Beckmann et al. [4] showed that marginal cost pricing always induces the system optimal flow as a Wardrop equilibrium. The set of feasible tolls that induce optimal flows was explored in [5, 26, 32]. They showed that the set of optimal tolls can be described by a set of linear equations and inequalities.

This characterization led to various developments regarding the optimization of secondary objectives of the edge tolls, such as the minimization of the tolls collected from the users [1, 16, 17], or the minimzation of the number of edges that have positive tolls [2, 3]. A problem closely related to the latter is to compute tolls for a given subset of edges with the objective to minimize the total travel time of the resulting equilibrium. Hoefer et al. [27] showed that this problem is NP-hard for general networks, and gave an efficient algorithm for parallel edges graphs with affine cost functions. Harks et al. [25] generalized their result to arbitrary cost functions satisfying a technical condition. Bonifaci et al. [8] studied generalizations of this problem with further restrictions on the set of feasible edge tolls.

For heterogenous flow particles that trade off money and time differently, marginal cost pricing cannot be applied to find tolls that induce the system optimum flow. In this setting, Ciole et al. [13] showed the existence of a set of tolls enforcing the system optimal flow, when there is a single commodity in the network. Similarly, Yang and Huang [42] studied how

to design toll structure when there are users with different toll sensitivity. Fleischer [18] showed that in single source series-parallel networks the tolls have to be linear in the latency of the maximum latency path. Karakostas and Kolliopoulos [28] and Fleischer et al. [19] independently generalized this result to arbitrary networks. Karakostas and Kolliopoulos [30] showed similar results for players with elastic demands. Han et al. [24] extended the previous results to different classes of cost functions.

Most of the literature assumes that the charged tolls cause no disutilty to the network users. For the case where tolls contribute to the cost, Cole et al. [14] showed that marginal cost tolls do not improve the equilibrium flow for a large class of instances, including all instances with affine costs. They further showed that for these networks it is NP-hard to approximate the minimal total cost that can be achieved as a Wardrop equilibrium with tolls. Karakostas and Kolliopoulos [29] proved that the total disutility due to taxation is bounded with respect to the social optimum for large classes of latency functions. Moreover, they showed that, if both the tolls and the latency are part of the social cost, then for some latency functions the coordination ratio improves when taxation is used. For networks of parallel edges, Christodoulou et al. [12] studied a generalization of edge tolls where cost functions are allowed to increase in an arbitrary way. They showed that for affine cost functions, the price of anarchy is strictly better than in the original network, even when the demand is not known.

Brown and Marden [9, 10] studied how marginal tolls can create perverse incentives when users have different sensitivity to the tolls and how it possible to circumvent this problem. Caragiannis et al. [11] studied the optimal toll problem for atomic congestion games. They proved that in the atomic case the optimal system performance cannot be achieved even in very simple networks. On the positive side they shown that there is a way to assign tolls to edges such that the induced social cost is within a factor of 2 to the optimal social cost. Singh [38] observed that marginal tolls weakly enforce optimal flows. Fotakis and Spirakis [21] showed that in series-parallel networks with increasing cost functions the optimal social cost can be induced with tolls. Fotakis et al. [20] were the first to consider the problem of defining tolls for heterogeneous users in atomic congestion games with unsplittable flow. In [7] the problem of defining tolls for atomic congestion games with polynomial cost functions was considered for the first time. Meir and Parkes [33] discussed how in atomic congestion games with marginal tolls multiple equilibria are near-optimal when there is a large number of players.

Sandholm [36, 37] studied tolls from a mechanism design perspective where the social planner has no information over the preferences of the users and has limited ability to observer the users' behavior. Bhaskar et al. [6] studied the problem of achieving target flows as equilibria of a nonatomic routing game without knowing the underlying latency functions and showed that a given target flow can be achieved using a polynomial number of queries to an oracle that takes tolls as input and outputs the resulting equilibrium flow. Roth et al. [35] considered the problem of finding optimal tolls in a polynomial number of rounds when latency functions are unknown. They solved the problem by embedding it in a broad class of Stackelberg game.

2 Model and preliminaries

In this section, we present some notation and basic definitions that are used in the sequel. We start with the underlying network model and will then introduce equilibria and tolls.

Network model. We consider a finite directed multi-graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ with vertex set $\mathcal{V}$ and edge set $\mathcal{E}$. We call $(v \to v')$ the set of all edges e whose tail is v and whose head is v'. We assume that there is a finite set of *origin-destination* (O/D) pairs $i \in \mathcal{I}$, each with an individual *traffic demand* $\mu^i \geq 0$ that has to be routed from an origin $o^i \in \mathcal{V}$ to a destination $d^i \in \mathcal{V}$ via $\mathcal{G}$. Denote the demand vector by $\boldsymbol{\mu} = (\mu^i)_{i\in\mathcal{I}}$. We call $\mathcal{P}^i$ the set of (simple) paths joining o^i to d^i, where each path $p \in \mathcal{P}^i$ is a finite sequence of edges such that the head of each edge meets the tail of the subsequent edge. For as long as all pairs (o^i, d^i) are different, the sets $\mathcal{P}^i$ are disjoint. Call $\mathcal{P} := \bigcup_{i\in\mathcal{I}} \mathcal{P}^i$ the union of all such paths.

Each path p is traversed by a *flow* $f_p \in \mathbb{R}_+$. Call $\boldsymbol{f} = (f_p)_{p\in\mathcal{P}}$ the vector of flows in the network. The set of feasible flows for $\boldsymbol{\mu}$ is defined as

$$\mathcal{F}(\boldsymbol{\mu}) = \Big\{ \boldsymbol{f} \in \mathbb{R}_+^{\mathcal{P}} : \textstyle\sum_{p\in\mathcal{P}^i} f_p = \mu^i \text{ for all } i \in \mathcal{I} \Big\}. \tag{3}$$

In turn, a routing flow $\boldsymbol{f} \in \mathcal{F}(\boldsymbol{\mu})$ induces a *load* on each edge $e \in \mathcal{E}$ as

$$x_e = \sum_{p\ni e} f_p. \tag{4}$$

We call $\boldsymbol{x} = (x_e)_{e\in\mathcal{E}}$ the corresponding *load profile* on the network. For each $e \in \mathcal{E}$ consider a nondecreasing, continuous *cost function* $c_e \colon \mathbb{R}_+ \to \mathbb{R}_+$. Denote $\boldsymbol{c} = (c_e)_{e\in\mathcal{E}}$. If $\boldsymbol{x}$ is the load profile induced by a feasible routing flow $\boldsymbol{f}$, then the incurred delay on edge $e \in \mathcal{E}$ is given by $c_e(x_e)$; hence, with a slight abuse of notation, the associated cost of path $p \in \mathcal{P}$ is given by the expression $c_p(\boldsymbol{f}) \equiv \sum_{e\in p} c_e(x_e)$. We call the tuple $\Gamma = (\mathcal{G}, \mathcal{I}, \boldsymbol{c})$ a (*nonatomic*) *routing game*.

Equilibrium Flows and Optimal Flows. A routing flow $\boldsymbol{f}^*$ is a *Wardrop equilibrium* (WE) of Γ if, for all $i \in \mathcal{I}$, we have:

$$c_p(\boldsymbol{f}^*) \leq c_{p'}(\boldsymbol{f^*}) \quad \text{for all } p, p' \in \mathcal{P}^i \text{ such that } f_p^* > 0.$$

This concept was introduced by Wardrop [41]. Beckmann et al. [4] showed that Wardrop equilibria are the optimal solutions to the convex optimization problem

$$\begin{aligned} \min \ & \sum_{e\in\mathcal{E}} \int_0^{x_e} c_e(s)\,\mathrm{d}s \\ \text{s.t.:} \ & x_e = \sum_{p\ni e} f_p \\ & \boldsymbol{f} \in \mathcal{F}, \end{aligned}$$

and, thus, are guaranteed to exist. A *social optimum* (SO) is a flow that minimizes the overall travel time, i.e., it solves the following total cost minimization problem:

$$\begin{aligned} \min \ & L(\boldsymbol{f}) = \sum_{p\in\mathcal{P}} f_p c_p(\boldsymbol{f}), \\ \text{s.t.:} \ & \boldsymbol{f} \in \mathcal{F}. \end{aligned} \tag{5}$$

As shown in [4], all Wardrop equilibria have the same social cost. We write $\mathrm{Eq}(\Gamma) = L(\boldsymbol{f}^*)$ and $\mathrm{Opt}(\Gamma) = \min_{\boldsymbol{f}\in\mathcal{F}} L(\boldsymbol{f})$, where $\boldsymbol{f}^*$ is a Wardrop equilibrium of Γ. The game's *price of anarchy* (PoA) is then defined as $\mathrm{PoA}(\Gamma) = \mathrm{Eq}(\Gamma)/\,\mathrm{Opt}(\Gamma)$. It is known that Wardrop equilibria need not minimize the social cost, in that case $\mathrm{PoA}(\Gamma) > 1$. For a pair $i \in \mathcal{I}$, we

denote the set of paths that are eventually used in a optimum flow for some demand vector $\boldsymbol{\mu}$ by

$$\tilde{\mathcal{P}}^i = \{p \in \mathcal{P}^i : \tilde{\boldsymbol{f}}_p(\boldsymbol{\mu}) > 0 \text{ for some demand } \boldsymbol{\mu} \text{ and corresponding social optimum } \tilde{\boldsymbol{f}}(\boldsymbol{\mu})\}.$$

Here and in the following we write $\boldsymbol{f}(\boldsymbol{\mu})$ instead of $\boldsymbol{f}$ when we want to indicate the corresponding demand vector $\boldsymbol{\mu}$.

Tolls. We want to explore the possibility of imposing tolls on the edges of the network in such a way that the equilibrium flow of the game with tolls produces a flow that is a solution of the original miminization problem (5). In other words, we want to see whether it is possible to achieve an optimum flow as an equilibrium of a modified game.

We call $\boldsymbol{\tau} = (\tau_e)_{e\in\mathcal{E}} \in \mathbb{R}^{\mathcal{E}}$ a *toll vector*. Note that we allow both for positive and negative tolls. We call c_e^τ the cost of edge e under the toll τ, i.e., $c_e^\tau(x_e) := c_e(x_e) + \tau_e$. Similarly $c_p^\tau(\boldsymbol{f}) := \sum_{e\in p} c_e^\tau(x_e)$. Define $\Gamma^{\boldsymbol{\tau}} := (\mathcal{G}, \mathcal{I}, \boldsymbol{c}^{\boldsymbol{\tau}})$. A toll vector $\boldsymbol{\tau}$ that for each demand vector $\boldsymbol{\mu} \in \mathbb{R}_+^{\mathcal{I}}$ enforces the corresponding system optimum as the equilibrium in $\Gamma^{\boldsymbol{\tau}}$ is called demand-independent optimal toll.

▶ **Definition 1** (Demand-independent optimal toll (DIOT))**.** Let $\Gamma = (\mathcal{G}, \mathcal{I}, \boldsymbol{c})$. A toll vector $\boldsymbol{\tau} \in \mathbb{R}^{\mathcal{E}}$ is called demand-independent optimal toll (DIOT) for Γ if for every demand vector $\boldsymbol{\mu} \in \mathbb{R}_+^{\mathcal{I}}$ every corresponding equilibrium with tolls $\boldsymbol{f}^{\boldsymbol{\tau}}(\boldsymbol{\mu}) \in \mathrm{Eq}(\Gamma^{\boldsymbol{\tau}})$ is optimal for Γ, i.e., $L(\boldsymbol{f}^{\boldsymbol{\tau}}(\boldsymbol{\mu})) = \sum_{p\in\mathcal{P}} f_p^{\boldsymbol{\tau}}(\boldsymbol{\mu}) c_p(\boldsymbol{f}^{\boldsymbol{\tau}}(\boldsymbol{\mu})) \le L(\boldsymbol{f}(\boldsymbol{\mu})) = \sum_{p\in\mathcal{P}} f_p c_p(\boldsymbol{f}(\boldsymbol{\mu}))$ for all $\boldsymbol{f}(\boldsymbol{\mu}) \in \mathcal{F}(\boldsymbol{\mu})$.

In Section 1 we visited two games, the Pigou networks and Braess' paradox, that admit a DIOT. The aim of this paper is to characterize the networks $\Gamma = (\mathcal{G}, \mathcal{I}, \boldsymbol{c})$ for which DIOTs exist.

3 BPR-type cost functions

In this section, we give a complete characterization of the sets of cost functions that admit a DIOT. On the positive side, we will show that any network with BPR-type cost functions admits a DIOT, independently of the number of commodities and the network topology. On the other hand, we show a strong lower bound proving that for any non-BPR cost function there is a single-commodity game on two parallel edges with costs functions c and $c + t$ for some $t \in \mathbb{R}_+$ that does not admit a DIOT. Formally, for $\beta > 0$, let

$$\mathcal{C}_{\mathrm{BPR}}(\beta) = \{c : \mathbb{R}_+ \to \mathbb{R}_+ : c(x) = t_c + a_c x^\beta \text{ for all } x \ge 0,\ a, t \in \mathbb{R}_+\}$$

be the set of BPR-type cost functions with degree β.

The following theorem gives a sufficient condition for games with BPR-type cost functions to admit a DIOT.

▶ **Theorem 2.** *Consider a game $\Gamma = (\mathcal{G}, \mathcal{I}, \boldsymbol{c})$ such that there is $\beta \in \mathbb{R}_+$ with $c_e \in \mathcal{C}_{\mathrm{BPR}}(\beta)$ for all $e \in \mathcal{E}$. Let $\boldsymbol{\tau}$ be a toll vector such that*

$$\sum_{e\in p}\left(\tau_e + \tfrac{\beta}{\beta+1} t_e\right) \le \sum_{e\in p'}\left(\tau_e + \tfrac{\beta}{\beta+1} t_e\right). \tag{6}$$

for all $i \in \mathcal{I}$ and all $p \in \tilde{\mathcal{P}}^i$ and all $p' \in \mathcal{P}^i$. Then, $\boldsymbol{\tau}$ is a DIOT.

Proof. Fix a demand vector $\boldsymbol{\mu} \in \mathbb{R}_+^{\mathcal{I}}$ and a corresponding optimum flow $\tilde{\boldsymbol{f}}(\boldsymbol{\mu})$ in Γ arbitrarily. We denote by $\tilde{x}_e = \sum_{p \in \mathcal{P}: e \in p} \tilde{f}_p(\boldsymbol{\mu})$ the load imposed on edge e by $\tilde{\boldsymbol{f}}(\boldsymbol{\mu})$. The local optimality conditions of $\tilde{\boldsymbol{f}}(\boldsymbol{\mu})$ imply that for all $i \in \mathcal{I}$ and all $p, p' \in \mathcal{P}^i$ with $\tilde{f}_p(\boldsymbol{\mu}) > 0$ we have

$$\sum_{e \in p} c_e(\tilde{x}_e) + c_e'(\tilde{x}_e)\tilde{x}_e \leq \sum_{e \in p'} c_e(\tilde{x}_e) + c_e'(\tilde{x}_e)\tilde{x}_e.$$

This implies that for all $i \in \mathcal{I}$ and all $p, p' \in \mathcal{P}^i$ with $\tilde{f}_p(\boldsymbol{\mu}) > 0$, there exists a non-negative constant $\lambda(p, p') \geq 0$ such that

$$\lambda(p, p') + \sum_{e \in p} \Big((\beta + 1) a_e \tilde{x}_e^\beta + t_e \Big) = \sum_{e \in p'} \Big((\beta + 1) a_e \tilde{x}_e^\beta + t_e \Big). \tag{7}$$

We proceed to show that when the toll vector $\boldsymbol{\tau}$ satisfies (6), then $\tilde{\boldsymbol{f}}(\boldsymbol{\mu})$ is a Wardop equilibrium of Γ^τ. To this end, consider arbitrary $p, p' \in \mathcal{P}^i$ with $\tilde{f}_p(\boldsymbol{\mu}) > 0$. We have

$$\begin{aligned}
\sum_{e \in p} \Big(c_e(\tilde{x}_e) + \tau_e \Big) &= \sum_{e \in p} \Big(a_e \tilde{x}_e^\beta + t_e + \tau_e \Big) \\
&= \sum_{e \in p} \Big((\beta + 1) a_e \tilde{x}_e^\beta + t_e \Big) - \sum_{e \in p} \Big(\beta a_e \tilde{x}_e^\beta - \tau_e \Big) \\
&= \sum_{e \in p'} \Big((\beta + 1) a_e \tilde{x}_e^\beta + t_e \Big) - \sum_{e \in p} \Big(\beta a_e \tilde{x}_e^\beta - \tau_e \Big) - \lambda(p, p'), \\
&= \sum_{e \in p'} \Big(c_e(\tilde{x}_e) + \tau_e \Big) + \sum_{e \in p'} \Big(\beta a_e \tilde{x}_e^\beta - \tau_e \Big) - \sum_{e \in p} \Big(\beta a_e \tilde{x}_e^\beta - \tau_e \Big) - \lambda(p, p'),
\end{aligned}$$

where the third equality comes from (7). By assumption, the toll vector $\boldsymbol{\tau}$ satisfies equation (6) which implies $\sum_{e \in p} \tau_e - \sum_{e \in p'} \tau_e \leq -\frac{\beta}{\beta+1} \left(\sum_{e \in p} t_e - \sum_{e \in p'} t_e \right)$. Therefore,

$$\begin{aligned}
\sum_{e \in p} \Big(c_e(\tilde{x}_e) + \tau_e \Big) &\leq \sum_{e \in p'} \Big(c_e(\tilde{x}_e) + \tau_e + \beta a_e \tilde{x}_e^\beta + \tfrac{\beta}{\beta+1} t_e \Big) - \sum_{e \in p} \Big(\beta a_e \tilde{x}_e^\beta + \tfrac{\beta}{\beta+1} t_e \Big) - \lambda(p, p') \\
&= \sum_{e \in p'} \Big(c_e(\tilde{x}_e) + \tau_e \Big) + \tfrac{\beta}{\beta+1} \lambda(p, p') - \lambda(p, p') \\
&= \sum_{e \in p'} \Big(c_e(\tilde{x}_e) + \tau_e \Big) - \tfrac{1}{\beta+1} \lambda(p, p'),
\end{aligned}$$

where the first equality stems from (7). The statement of the theorem follows from the fact that $\lambda(p, p') \geq 0$. ◀

As an immediate corollary of this theorem, we obtain the existence of DIOTs in arbitrary multi-commodity networks with BPR-type cost functions as long as negative tolls are allowed.

▶ **Corollary 3.** *Consider a game $\Gamma = (\mathcal{G}, \mathcal{I}, \boldsymbol{c})$ with BPR-type cost functions. Then there exists a DIOT for Γ.*

Proof. Setting the toll vector $\hat{\boldsymbol{\tau}} = (\hat{\tau}_e)_{e \in \mathcal{E}}$ as

$$\hat{\tau}_e = -\frac{\beta}{\beta + 1} t_e, \tag{8}$$

obviously satisfies (6), so that the claim follows from Theorem 2. ◀

In the following, we call $\hat{\boldsymbol{\tau}}$ the *trivial DIOT*. The necessary condition of Theorem 2 implies in particular that $\sum_{e\in p}\tau_e + \frac{\beta}{\beta+1}t_e$ must be equal for all paths $p \in \tilde{\mathcal{P}}^i$ and all pairs $i \in \mathcal{I}$. We proceed to show that this is actually a necessary condition for a DIOT.

▶ **Theorem 4.** *Consider a game $\Gamma = (\mathcal{G}, \mathcal{I}, \boldsymbol{c})$ with BPR-type cost functions. If $\boldsymbol{\tau}$ is a DIOT for Γ, then*

$$\sum_{e\in p}\Big(\tau_e + \tfrac{\beta}{\beta+1}t_e\Big) = \sum_{e\in p'}\Big(\tau_e + \tfrac{\beta}{\beta+1}t_e\Big).$$

for all $i \in \mathcal{I}$ and all $p, p' \in \tilde{\mathcal{P}}^i$.

Proof. Let $i \in \mathcal{I}$ and $p^*, p^{**} \in \tilde{\mathcal{P}}^i$ be arbitrary. By definition of $\tilde{\mathcal{P}}^i$ there are demands vectors $\boldsymbol{\mu}, \boldsymbol{\mu}' \in \mathbb{R}_+^{\mathcal{I}}$ such that $\tilde{f}_{p^*}(\boldsymbol{\mu}) > 0$ and $\tilde{f}_{p^{**}}(\boldsymbol{\mu}') > 0$. Before we prove that $\sum_{e\in p^*}(\frac{\beta}{\beta+1}t_e+\tau_e) = \sum_{e\in p^{**}}(\frac{\beta}{\beta+1}t_e + \tau_e)$, we need some observation regarding the continuity of the optimal path flow functions.

Hall [23] showed that the path flow functions of a Wardrop equilibrium are continuous functions in the travel demand. For $\lambda \in [0,1]$, let $\boldsymbol{\mu}(\lambda) = (1-\lambda)\boldsymbol{\mu} + \lambda\boldsymbol{\mu'}$ parametrize the travel demands on the convex combination of $\boldsymbol{\mu}$ and $\boldsymbol{\mu'}$. Then, by Hall's result, there are continuous path flow functions $f_p(\boldsymbol{\mu}(\cdot)) : [0,1] \to \mathbb{R}_+^{\mathcal{E}}$ for all $p \in \mathcal{P}$ such that $\boldsymbol{f}(\boldsymbol{\mu}(\lambda))$ is a Wardrop equilibrium for the travel demand vector $\boldsymbol{\mu}(\lambda)$ for all $\lambda \in [0,1]$. As the system optimal flow $\tilde{\boldsymbol{f}}$ is a Wardrop equilibrium with respect to the marginal cost function (cf. [4]), the same holds for the system optimum flow vector $\tilde{\boldsymbol{f}}$, i.e., there are continuous path flow functions $\tilde{f}_p(\boldsymbol{\mu}(\cdot)) : [0,1] \to \mathbb{R}_+^{\mathcal{E}}$ for all $p \in \mathcal{P}$ such that $\tilde{\boldsymbol{f}}(\boldsymbol{\mu}(\lambda))$ is an optimal flow for the travel demand vector $\boldsymbol{\mu}(\lambda)$ for all $\lambda \in [0,1]$.

For a flow vector $\boldsymbol{f}$, let $\mathcal{S}^i(\boldsymbol{f}) = \{p \in \mathcal{P}^i : f_p > 0\}$ denote the support of $\boldsymbol{f}$ for $i \in \mathcal{I}$. For a possible support set $S \in 2^{\mathcal{P}^i}$, let

$$L^i(S) = \big\{\lambda \in [0,1] : S = \mathcal{S}^i(\tilde{\boldsymbol{f}}(\boldsymbol{\mu}(\lambda))\big\}$$

denote the (possibly empty) set of values of λ for which the optimal flow $\tilde{\boldsymbol{f}}(\boldsymbol{\mu}(\lambda))$ has support S for i.

Consider an arbitrary support set S with $L^i(S) \neq \emptyset$ and an arbitrary $\lambda \in L^i(S)$. Since $\boldsymbol{\tau}$ is a DIOT for Γ, the optimal flow $\tilde{\boldsymbol{f}}(\boldsymbol{\mu}(\lambda))$ is a Wardrop equilibrium with respect to $\boldsymbol{\tau}$, i.e., $\sum_{e\in p}(c_e(\tilde{x}_e(\boldsymbol{\mu}(\lambda))) + \tau_e) = \sum_{e\in p'}(c_e(\tilde{x}_e(\boldsymbol{\mu}(\lambda))) + \tau_e)$ for all $p, p' \in S$ which implies

$$\sum_{e\in p}\left(a_e\tilde{x}_e(\boldsymbol{\mu}(\lambda))^\beta + t_e + \tau_e\right) = \sum_{e\in p'}\left(a_e\tilde{x}_e(\boldsymbol{\mu}(\lambda))^\beta + t_e + \tau_e\right). \tag{9}$$

for all $p, p' \in S$. By the local optimality conditions of $\tilde{\boldsymbol{f}}(\boldsymbol{\mu}(\lambda)))$, we further have

$$\sum_{e\in p} c_e(\tilde{x}_e(\boldsymbol{\mu}(\lambda))) + c_e'(\tilde{x}_e(\boldsymbol{\mu}(\lambda)))\tilde{x}_e(\boldsymbol{\mu}(\lambda)) = \sum_{e\in p'} c_e(\tilde{x}_e(\boldsymbol{\mu}(\lambda))) + c_e'(\tilde{x}_e(\boldsymbol{\mu}(\lambda)))\tilde{x}_e(\boldsymbol{\mu}(\lambda)), \tag{10}$$

which is equivalent to

$$\sum_{e\in p}\Big((\beta+1)a_e\tilde{x}_e(\boldsymbol{\mu}(\lambda))^\beta + t_e\Big) = \sum_{e\in p'}\Big((\beta+1)a_e\tilde{x}_e(\boldsymbol{\mu}(\lambda))^\beta + t_e\Big) \tag{11}$$

for all $p, p' \in S$. Subtracting (11) from $(\beta+1)$ times (9) and dividing by $\beta+1$ we obtain

$$\sum_{e\in p}\left(\tfrac{\beta}{\beta+1}t_e + \tau_e\right) = \sum_{e\in p'}\left(\tfrac{\beta}{\beta+1}t_e + \tau_e\right) \tag{12}$$

for all $p, p' \in S$.

By the continuity of the path flow functions $\tilde{f}_p(\boldsymbol{\mu}(\cdot))$, for each path $p \in \mathcal{P}$ the set $L^i(p) = \bigcup_{S \in 2^{\mathcal{P}^i} : p \in S} L^i(S)$ is open in $[0,1]$, i.e., it is an open set in the relativ topology of $[0,1]$. In addition, we have that neither $\mu_i(0)$ nor $\mu_i(1)$ are zero, so that for all $\lambda \in [0,1]$ there is a path $p \in \mathcal{P}^i$ such that $\tilde{f}_p(\boldsymbol{\mu}(\lambda)) > 0$. We conclude that $\bigcup_{p \in \mathcal{P}} L^i(p) = [0,1]$. Since the sets $L^i(p)$, $p \in \mathcal{P}^i$ are open and cover the compact $[0,1]$, there is a finite set $\{p_1, \dots, p_t\} \subseteq \mathcal{P}^i$ such that $0 \in L^i(p_1)$, $1 \in L^i(p_t)$, $L^i(p_1) \cup \dots \cup L^i(p_t) = [0,1]$ and $L^i(p_j) \cap L^i(p_{j+1}) \neq \emptyset$ for all $j \in \{1, \dots, t-1\}$. The latter condition implies that for $\lambda \in L^i(p_j) \cap L^i(p_{j+1})$ we have $p_j, p_{j+1} \in \mathcal{S}^i(\tilde{\boldsymbol{f}}(\boldsymbol{\mu}(\lambda))$. Equation (12) then implies $\sum_{e \in p_j} (\frac{\beta}{\beta+1} t_e + \tau_e) = \sum_{e \in p_{j+1}} (\frac{\beta}{\beta+1} t_e + \tau_e)$. Iterating this argument shows $\sum_{e \in p_1} (\frac{\beta}{\beta+1} t_e + \tau_e) = \sum_{e \in p_t} (\frac{\beta}{\beta+1} t_e + \tau_e)$. Finally using that $p_1, p^* \in \mathcal{S}^i(\tilde{\boldsymbol{f}}(\boldsymbol{\mu}(0))$ and $p_t, p^{**} \in \mathcal{S}^i(\tilde{\boldsymbol{f}}(\boldsymbol{\mu}(1))$ gives the claimed result. ◀

We proceed to show that the set of BPR-type cost functions is the largest set of cost functions that guarantee the existence of a DIOT, even for single-commodity networks consisting of two parallel edges. The proof can be found in the arXiv version.

▶ **Theorem 5.** *Let c be twice continuously differentiable, strictly semi-convex and strictly increasing, but not of BPR-type. Then there is a congestion game $\Gamma = (\mathcal{G}, \mathcal{I}, \boldsymbol{c})$ with two parallel edges and cost functions $c(x)$ and $c(x) + t$ for some $t \in \mathbb{R}_+$ that does not have a DIOT.*

A similar construction as in the proof of Theorem 5 shows also that a network with two parallel edges with cost functions $c_1 \in \mathcal{C}_{\mathrm{BPR}}(\beta_1)$ and $c_2 \in \mathcal{C}_{\mathrm{BPR}}(\beta_2)$ does not admit a DIOT if $\beta_1 \neq \beta_2$.

4 Nonnegative tolls

The trivial DIOT toll $\hat{\boldsymbol{\tau}}$ is the trivial solution for both the sufficient condition for a DIOT imposed by Theorem 2 and the necessary condition for a DIOT shown in Theorem 4. However, the trivial DIOT is always negative so that the system designer needs to subsidize the traffic in order to enforce the optimum flow. One may wonder whether the conditions imposed by Theorems 2 and 4 admit also a non-negative solution. Our next result shows that, for games played on a *directed acyclic multi-graph* (DAMG), a non-negative DIOT can always be found. The proof can be found in the arXiv version.

▶ **Theorem 6.** *Consider a game $\Gamma = (\mathcal{G}, \mathcal{I}, \boldsymbol{c})$ with BPR-type cost functions where $\mathcal{G}$ is a DAMG. Then there exists a non-negative DIOT for Γ.*

Proof. Given a DAMG there exists a topological sort, namely a linear ordering $\prec$ of its vertices such that, if $v \prec v'$, then there is no path from v' to v in the DAMG. Notice that, in general the topological sort of a DAMG is not unique. Let $|\mathcal{V}| = n$ and call $\boldsymbol{v}^{\prec} = (v_{(1)}, \dots, v_{(n)})$ the vector of ordered vertices. For each edge $e \in (v_{(i)} \to v_{(j)})$, define

$$\delta_e := j - i. \tag{13}$$

Let $\hat{\boldsymbol{\tau}}$ be the trivial DIOT of the game Γ and let

$$\xi := \min_{e \in \mathcal{E}} \frac{\hat{\tau}_e}{\delta_e} \quad \text{and} \quad \chi := \xi_-, \tag{14}$$

where $\xi_- = \max\{-\xi, 0\}$ is the negative part of ξ. Define now

$$\tau_e = \hat{\tau}_e + \delta_e \chi. \tag{15}$$

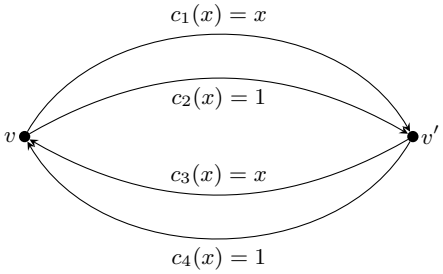

Figure 3 A cyclic network with positive tolls.

We first prove that the toll vector $\boldsymbol{\tau}$ is non-negative. Notice that χ, defined as in (14) is non-negative and $\chi = 0$ only if $\hat{\tau}_e \geq 0$ for all $e \in \mathcal{E}$. Assume that there exists a $\hat{\tau}_e < 0$ and let $e^* \in \arg\min_{e \in \mathcal{E}} \hat{\tau}_e/\delta_e$. Then

$$\tau_{e^*} = \hat{\tau}_{e^*} + \delta_{e^*}\chi = \hat{\tau}_{e^*} - \delta_{e^*}\frac{\hat{\tau_{e^*}}}{\delta_{e^*}} = 0.$$

In general, whenever $\tau_e < 0$, we have

$$\tau_e = \hat{\tau}_e + \delta_e\chi = \hat{\tau}_e - \delta_e\frac{\hat{\tau_{e^*}}}{\delta_{e^*}} \geq \hat{\tau}_e - \delta_e\frac{\hat{\tau}_e}{\delta_e} = 0.$$

Now we prove that the toll vector $\boldsymbol{\tau}$ is a DIOT. By Theorem 2, this means that it satisfies equation (6). First, notice that, by construction of the δ_e, for any $i \in \mathcal{I}$, we have

$$\sum_{e \in p} \delta_e = \sum_{e \in p'} \delta_e \quad \text{for all } p, p' \in \mathcal{P}^i. \tag{16}$$

By (6) we have

$$\sum_{e \in p}\Big((\beta+1)\hat{\tau}_e + \beta t_e\Big) = \sum_{e \in p'}\Big((\beta+1)\hat{\tau}_e + \beta t_e\Big),$$

hence, by (16),

$$\sum_{e \in p}\Big((\beta+1)(\hat{\tau}_e + \delta_e\chi) + \beta t_e\Big) = \sum_{e \in p'}\Big((\beta+1)(\hat{\tau}_e + \delta_e\chi) + \beta t_e\Big),$$

that is

$$\sum_{e \in p}\left((\beta+1)\tau_e + \beta t_e\right) = \sum_{e \in p'}\left((\beta+1)\tau_e + \beta t_e\right),$$

which finishes the proof. ◀

The condition that the graph $\mathcal{G}$ is a DAMG is sufficient for the existence of a non-negative DIOT. It is not necessary, as the following counterexample shows.

▶ **Example 7.** Let $\Gamma = (\mathcal{G}, \mathcal{I}, \boldsymbol{c})$ with $\mathcal{I} = \{1, 2\}$, $\mathcal{V} = \{v, v'\}$, $o_1 = d_2 = v$, $o_2 = d_1 = v'$, $e_1, e_2 \in (o_1 \to d_1)$, $e_3, e_4 \in (o_2 \to d_2)$, and the costs are as in Figure 3. The graph $\mathcal{G}$ is not a DAMG, but the following non-negative toll is a DIOT:

$$\tau_1 = \frac{1}{2} \quad \tau_2 = 0, \quad \tau_3 = \frac{1}{2}, \quad \tau_4 = 0.$$

We proceed to show that for graphs that contain a directed cycle, non-negative DIOTs need not exist, even in networks with affine costs.

▶ **Proposition 8.** *There are networks with affine costs that do not admit a non-negative DIOT.*

5 Aggregatively non-negative Tolls

When nonnegative DIOTs do not exist, it is conceivable that a social planner may sometime want to use negative tolls in order to achieve her goal. Nevertheless, the planner may be subject to budget constraints and not be able to afford a toll system that implies a global loss. Therefore it is interesting to study the existence of conditions for a DIOT $\boldsymbol{\tau}$ such that the following budget constraint is satisfied:

$$\sum_{e\in\mathcal{E}} \tau_e x_e \geq 0, \quad \text{for any feasible flow } \boldsymbol{f}. \tag{17}$$

Intuitively, (17) requires that the social planner does not loose money for any feasible flow. In this section, we show that when the origin-destination pairs (o^i, d^i) satisfy a order condition, then a DIOT satisfying the budget constraint exists.

▶ **Theorem 9.** *Consider a game $\Gamma = (\mathcal{G}, \mathcal{I}, \boldsymbol{c})$ with BPR-type cost functions. If there exists an order $\prec$ on $\mathcal{V}$ such that for all $i \in \mathcal{I}$ we have $o^i \prec d^i$, then there exists a DIOT $\boldsymbol{\tau}$ that satisfies* (17)*.*

We obtain the existence the budget feasible DIOTs for single commodity networks as a direct corollary of Theorem 9.

▶ **Corollary 10.** *Consider a game $\Gamma = (\mathcal{G}, \mathcal{I}, \boldsymbol{c})$ with BPR-type cost and a single O/D pair. Then, there exists a DIOT $\boldsymbol{\tau}$ that satisfies* (17)*.*

Example 7 shows that the condition of Theorem 9 is only sufficient for the existence of a DIOT that satisfies (17).

Abstract

In an instance of the *network design* problem, we are given a graph $G = (V, E)$, an edge-cost function $c : E \to \mathbb{R}^{\geq 0}$, and a connectivity criterion. The goal is to find a minimum-cost subgraph H of G that meets the connectivity requirements. An important family of this class is the *survivable network design problem* (SNDP): given non-negative integers r_{uv} for each pair $u, v \in V$, the solution subgraph H should contain r_{uv} edge-disjoint paths for each pair u and v.

While this problem is known to admit good approximation algorithms in the offline case, the problem is much harder in the online setting. Gupta, Krishnaswamy, and Ravi [14] (STOC'09) are the first to consider the online survivable network design problem. They demonstrate an algorithm with competitive ratio of $O(k \log^3 n)$, where $k = \max_{u,v} r_{uv}$. Note that the competitive ratio of the algorithm by Gupta *et al.* grows linearly in k. Since then, an important open problem in the online community [22, 14] is whether the linear dependence on k can be reduced to a logarithmic dependency.

Consider an online greedy algorithm that connects every demand by adding a minimum cost set of edges to H. Surprisingly, we show that this greedy algorithm significantly improves the competitive ratio when a congestion of 2 is allowed on the edges or when the model is stochastic. While our algorithm is fairly simple, our analysis requires a deep understanding of k-connected graphs. In particular, we prove that the greedy algorithm is $O(\log^2 n \log k)$-competitive if one satisfies every demand between u and v by $r_{uv}/2$ edge-disjoint paths. The spirit of our result is similar to the work of Chuzhoy and Li [7] (FOCS'12), in which the authors give a polylogarithmic approximation algorithm for edge-disjoint paths with congestion 2.

Moreover, we study the greedy algorithm in the online stochastic setting. We consider the i.i.d. model, where each online demand is drawn from a single probability distribution, the unknown i.i.d. model, where every demand is drawn from a single but unknown probability distribution, and the *prophet* model in which online demands are drawn from (possibly) different probability distributions. Through a different analysis, we prove that a similar greedy algorithm is constant competitive for the i.i.d. and the prophet models. Also, the greedy algorithm is $O(\log n)$-competitive for the unknown i.i.d. model, which is almost tight due to the lower bound of [9] for single connectivity.

1 Introduction

In an instance of the *network design* problem, we are given a graph $G = (V, E)$, an edge-cost function $c : E \to \mathbb{R}^{\geq 0}$, and a connectivity criteria. The goal is to find a minimum-cost subgraph H of G that satisfies the connectivity requirements. An important family of this class is the *survivable network design problem* (SNDP): Given non-negative integers r_{uv} for each pair $u, v \in V$, the solution subgraph H should contain r_{uv} edge-disjoint paths for each pair u and v. SNDP arises in fault tolerance management and thus is of much interest in design community: the connectivity of nodes u and v in H is resilient to even $(r_{uv} - 1)$ edge failures. This problem clearly generalizes the *Steiner tree*[1] and *Steiner forest*[2] problems.

For a non-empty cut $S \subset V$, let $\delta(S)$ denote the set of edges with exactly one endpoint in S. SNDP falls in the general class of network design problems that can be characterized by *proper cut functions*. A function $f : 2^V \to \mathbb{Z}^{\geq 0}$ defined over cuts in the graph is *proper*, if it is symmetric ($f(S) = f(V \setminus S)$ for all $S \subset V$) and it satisfies maximality ($f(S \cup T) \leq \max\{f(S), f(T)\}$ for all $S \cap T = \phi$). For SNDP, one can choose $f(S) = \max_{u \in S, v \notin S} r_{uv}$ for every cut S. Given a proper function f over cuts in the graph, the goal is to find a minimum-cost subgraph H such that

$$|E(H) \cap \delta(S)| \geq f(S) \qquad \forall \textit{non-empty } S \subset V \ .$$

Over the past decades, the offline SNDP and proper cut functions have been extensively studied especially as an important testbed for primal-dual and iterative rounding methods (see e.g. [10, 11, 13, 18, 26, 27]). In this paper, we consider SNDP in the *online* setting: we are given a graph $G = (V, E)$ and an edge-cost function c in advance. We receive an online sequence of demands in the form of tuples $(u, v, r_{uv}) \in V \times V \times \mathbb{Z}^{\geq 0}$. We start with an empty subgraph H. Upon the arrival of a demand (u, v, r_{uv}), we need to immediately *augment* H such that there exist at least r_{uv} edge-disjoint paths between u and v in H. The goal is to minimize the cost of H. The *competitive ratio* of an algorithm is defined as the maximum ratio of the cost of its output and that of an optimal offline solution, over all possible input instances.

The online 1-connectivity problems, in which $r_{uv} \in \{0, 1\}$ for all pairs, have been extensively studied in the last decades. Imase and Waxman [17] (SIAM'91) were first to consider the edge-weighted Steiner tree problem. They used a dual-fitting argument to show that the natural greedy algorithm is $O(\log n)$-competitive where n denotes the number of vertices[3]. Their result is asymptotically tight. Later, Berman and Coulston [3] (STOC'97) and Awerbuch, Azar, and Bartal [2] (TCS'04) demonstrated an $O(\log n)$-competitive algorithm for

[1] In the Steiner tree problem, given a set of terminal nodes $T \subset V$, the goal is to find a minimum-cost subgraph connecting all terminals.

[2] In the Steiner forest problem, given a set of pairs of vertices $s_i, t_i \in V$, the goal is to find a minimum-cost subgraph in which every pair is connected.

[3] In fact, the competitive ratio is $O(\log \min\{n, \mathcal{D}\})$ where $\mathcal{D}$ is the number of demand requests. However,

the more general Steiner forest problem by designing an elegant online primal-dual technique. The latter also shows that the greedy algorithm achieves the competitive ratio of $O(\log^2 n)$ for Steiner forest. Indeed, due to the simplicity of greedy approaches, an important open problem is to settle the competitiveness of the greedy algorithm for Steiner forest. In the recent years, several primal-dual techniques are developed for solving node-weighted variants [1, 15, 22], and prize-collecting variants [25, 16] of 1-connectivity problems.

Gupta, Krishnaswamy, and Ravi [14] (SIAM'12) were first to consider the online survivable network design problem. They demonstrate an elegant algorithm with competitive ratio of $\tilde{O}(k \log^3 n)$, where $k = \max_{u,v} r_{uv}$. The crux of their analysis is to use distance-preserving tree-embeddings in an online setting. More precisely, they first pick a random distance-preserving spanning subtree $T \subseteq G$. They satisfy a connectivity demand r_{uv} by iteratively increasing the connectivity of u and v. In each iteration, they show that it is sufficient to use cycles that are formed by an edge $e = (a, b) \notin T$ and the $\{a, b\}$-path in T; hence, reducing the number of *options* for satisfying a connectivity demand. This would enable them to use a set cover approach to solve the problem in an online manner and achieve the first competitive algorithm for online SNDP.

Single-source SNDP is a variant of SNDP where all demands share the same endpoint. Naor, Panigrahi, and Singh [22] (FOCS'11) partially improve the results of Gupta et al. [14] by demonstrating a *bi-criteria* competitive algorithm for single-source SNDP using structural properties of a single-source optimal solution. A bi-criteria competitive ratio of (α, β) for SNDP implies that the solution produced by the online algorithm achieves a connectivity of $\lfloor \frac{r_i}{\beta} \rfloor$ for every demand σ_i and is at most a factor of α more expensive than the optimal offline solution for connectivity of r_i. The algorithm by Naor et al. achieves the competitive ratio of $(O(\frac{k \log n}{\epsilon}), 2 + \epsilon)$ for any $\epsilon > 0$. They also study and give bi-criteria algorithms for the vertex-connectivity problem.

The competitive ratio of algorithms by Gupta et al. and Naor et al. grow linearly in k. This seems to be inherent to their methods since they may need to solve a set-cover-like problem in each iteration of incrementing the connectivity of a demand; hence, losing a polylogarithmic factor in each iteration. One would need a new approach to break the linear dependency on k. Indeed, both factors of $O(\log^3 n)$ and $O(k)$ are not plausible in practice, and an important open problem in the online community [22, 14] is whether the linear dependency on k can be reduced to a logarithmic dependency.

We circumvent this problem within the class of greedy algorithms. This class has been a center of attention in many applications due to its simplicity. We would like to note that the previous algorithms for the problem are based on fairly complex techniques such tree-embedding and reductions to online set cover. Despite their theoretical provable guarantees, these approaches are not efficiently implementable for large networks and become extremely harder to analyze when more parameters of the system are involved, e.g. degree constraints. For these reasons, we are interested in the theory behind simple algorithms for the online SNDP. In this paper, we study both the cases with and without the presence of priori information about connectivity demands.

No Information Setting: for this traditional online setting, we show that the greedy approach is promising although the *classic greedy algorithm*[4] fails to give a competitive

to simplify the comparison with results for SNDP, in this paper we ignore the distinction between this factor and $O(\log n)$.

[4] Which augments the solution with the cheapest set of edges that satisfy full connectivity demands.

solution. In Section 2, we give a hardness instance for the classic greedy algorithm and present our modified versions of it which have polylogarithmic competitive ratio. In particular, we demonstrate a deterministic algorithm with a bi-criteria competitive ratio of $(O(\log^2 n \log_{1+\epsilon} k), 2+\epsilon)$ for any constant $\epsilon > 0$. For the single-rooted variant, the competitive ratio is $(O(\log n \log_{1+\epsilon} k), 2+\epsilon)$. Besides, our hardness instance shows a loss of $\Omega(n)$ on the weight criterion if satisfying full connectivities greedily.

Partial Information Setting: one of the recent trends in the study of online problems is to consider a stochastic model for the online demands. This, in particular, is to model the scenarios in which the algorithm designer has sufficient data available in hand to be able to make predictions, i.e. fit distributions, for future requests. In this paper, we consider an online stochastic model inspired by the well-known *prophet inequality* problem[5] in which different demands are drawn independently from different distributions. We call it the *prophet setting* not only to highlight the similarity between this online stochastic model and prophet inequalities but also to distinguish it from other online stochastic models[6].

In the second half of this paper, we study online SNDP in the prophet setting for both cases of known and unknown distributions. For the most general case in prophet setting in which the distributions are known and (possibly) different, we show that the classic greedy algorithm that satisfies full connectivity results in a constant approximation solution. Furthermore, we explore the connection between the *known i.i.d.* case and the general case and present a framework that transforms an algorithm for the former into one for the latter by loosing only a constant factor on the approximation ratio. Lastly but more interestingly, we prove that the classic greedy algorithm is $O(\log n)$ approximation[7] for the *unknown i.i.d.* case[8]. This result shows that a simple algorithm can significantly outperform the previous complex algorithms when the demands are drawn from the same distribution without even learning the underlying distribution!

1.1 Our Results and Techniques

Let $\sigma_i = (u_i, v_i, r_i)$ denote the i-th connectivity demand. Consider the following intuitive greedy approach. Upon the arrival of σ_i, we augment the solution subgraph H, by finding the minimum-cost set of edges whose addition to H creates r_i edge-disjoint paths between u_i and v_i. Awerbuch et al. [2] (TCS'04) show that if all the demands require 1-connectivity (i.e., $r_i = 1$ for every i), this algorithm achieves a competitive ratio of $O(\log^2 n)$. This leads to a natural question that whether greedy works for higher connectivity problems as well. However, we show an instance of online SND in Section 2, for which the greedy algorithm has a competitive ratio of $\Omega(n)$. Indeed, the connectivity demands in the instance are either zero or two, hence greedy is not competitive even for low connectivity demands. However, on the positive side, we show that *greedy-like* algorithms do surprisingly well in both the stochastic version of the problem and the case when a small congestion on the edges is acceptable.

---

[5] Given n distributions $D_1, \ldots, D_n$ on real numbers and an online sequence of random draws $X_i \sim D_i$, we have to make an immediate and irrevocable selection X_τ that maximizes the ratio $\mathbb{E}[X_\tau]/\mathbb{E}[\max_{1 \le i \le n} X_i]$.

[6] Such as "the (two stage) stochastic version" of Gupta et al [14].

[7] Which is almost tight

[8] When unknown, it is natural to assume the distributions are i.i.d. Otherwise, the algorithm can be easily tricked.

1.1.1 Allowing Small Congestion

We show that a greedy algorithm does surprisingly well, if we relax the connectivity requirements by a constant factor. Let α denote an arbitrary scale factor. We define an *α-scaled* variant of the greedy algorithm in which the goal is to find only $\lfloor \frac{r_i}{\alpha} \rfloor$ disjoint paths between the endpoints of σ_i. Our main result states that the scaled greedy algorithm is polylogarithmic competitive.

▶ **Theorem 1.** *For any constant $\epsilon > 0$, the $(2+\epsilon)$-scaled greedy algorithm is $(O(\log^2 n \log_{1+\epsilon} k), 2+\epsilon)$-competitive. For the single-source variant, the competitive ratio is $(O(\log n \log_{1+\epsilon} k), 2+\epsilon)$.*
Furthermore, for uniform SNDP, 2-scaled greedy is $(O(\log^2 n), 2)$-competitive.

We start by demonstrating a deep connection between the greedy method for SNDP and the *Steiner packing problems*. The Steiner packing problems are motivated by vast applications in VLSI-layout and have been used as an algorithmic toolkit in computer science. In the *Steiner tree packing* problem, we are given a graph $G = (V, E)$ and a set S of vertices and the goal is to find the *Steiner decomposition number* (SDN), the maximum number of edge-disjoint subgraphs that each connects the vertices of S. We note that a minimal connecting subgraph is a *Steiner tree* with respect to S. In the *Steiner forest packing* problem, we are given a set of demand pairs $u_i, v_i \in V$ and the goal is to find SDN, the maximum number of edge-disjoint subgraphs that in each the demand pairs are connected.

For simplicity, let us assume we have a *uniform* instance. In a uniform instance, we are given an integer k in advance and for any demand (u, v) we must k-connect u to v. Let opt denote the optimal SNDP solution, with the Steiner decomposition number q. In Section 2, we show that the $(\frac{k}{q})$-scaled greedy algorithm approximates opt up to logarithmic factors. Intuitively, every forest in the Steiner forest decomposition, gives us a path to satisfy a demand. Hence, we need to bound the overall cost of satisfying demands in all the q forests. The crux of our analysis is then to charge the cost of the scaled greedy to that of a parallel set of greedy algorithms that solve 1-connectivity instances on every forest. Finally, to get a polylogarithmic competitive algorithm, we need to find a universal lower bound on the SDN number q with respect to k.

It is shown that finding SDN is NP-hard and cannot be computed in polynomial time unless P=NP[6] (Algorithmica'06). Given that there exist q disjoint Steiner forests connecting a set of demands, it is straight forward to show the graph is q-connected on the demands. Therefore, a natural upper bound on SDN is the minimum connectivity of the endpoints of demands. For the case of spanning trees (Steiner tree with $S = V(G)$), it is proven that the above upper bound also provides a good approximation guarantee for the problem. In other words, any k-connected graph can be decomposed into $k/2$ edge-disjoint spanning trees[23]. This is also followed by a matching upper bound. The problem is much subtler when S does not encompass all vertices of the graph. The first lower bound for the Steiner tree packing problem was achieved by Petingi and Rodriguez[24] (CON'03) who proved every S-k-connected[9] has $\lfloor (2/3)^{(|V(G)-|S|)} k/2 \rfloor$ disjoint Steiner trees. This was later improved by Kriesell [20] (JCT'03), Jain, Mahdian, and Salavatipour [19] (SODA'03), Lau [21] (FOCS'04), and DeVos, McDonald, and Pivotto [8] (Man'13), the most recent of which shows for every S-$(5k+4)$-connected graph, we can find k edge-disjoint Steiner trees. However, the main conjecture is that, similar to the case of spanning trees, every S-k-connected graph admits a $k/2$-disjoint Steiner tree decomposition [20].

[9] A graph which is k-connected on a set of vertices S

For a set of demand pairs (u_i, v_i)'s, let $\mathcal{T}$ denote the set of Steiner forests that satisfy all the demands. In the *fractional Steiner forest packing* problem, the output is a fractional assignment x over $\mathcal{T}$ such that for every edge e, $\sum_{T\in\mathcal{T}:e\in T} x_T$ is not more than one. The goal is to find a fractional Steiner forest decomposition with the maximum total sum of weights in x. While the term fractional Steiner forest packing is not explicitly used in the previous work, it follows from the arguments of [4, 8] that the conjecture of Kriesell holds for the fractional variant.

▶ **Theorem 2** (proven in [4]). *Given a set of demand pairs (u_i, v_i), if G is k-connected for every demand pair, then the fractional Steiner decomposition number is at least $k/2$.*

Indeed, in Section 2, we use a dependent rounding method to show that the connection between SDN and the competitiveness of the greedy approach holds even for the stronger fractional variant of SDN. Hence, Theorem 2 implies that the 2-scaled greedy algorithm, achieves a polylogarithmic competitive ratio for the uniform SNDP. Finally, we prove that the scaled greedy is also competitive for the non-uniform variant if one is willing to lose an extra $O(\log k)$ factor in the competitive ratio (Theorem 1).

1.1.2 Online Stochastic SNDP

A single-source *uniform* instance of online SNDP is an instance in which for every demand σ_i, $u_i = u$, $r_i = k$ for some vertex $u \in V$ and integer k. For a non-uniform variant, let $k = \max_i r_i$. Let D be a given probability distribution over V. In i.i.d. SNDP, at each online step i, a random connectivity demand $\sigma_i = (u, v_i, k)$ arrives, where v_i is drawn independently at random from distribution D. We call the problem unknown distribution SNDP if the probability distribution D is not given in advance. Another interesting generalization of the i.i.d. model, which we call the prophet SNDP is defined as follows. In prophet SNDP, instead of only a single probability distribution D, we are given T probability distributions $D_1, \ldots, D_T$, such that the i-th demand is $\sigma_i = (u, v_i, k)$, where v_i is drawn independently at random from distribution D_i. In all three variants of the stochastic SNDP, the competitive-ratio is defined as the expected cost of an algorithm $\mathcal{A}$ over the expected cost of an optimal offline algorithm while the distributions are chosen by an adversary. More precisely let $E[A(\omega)]$ and $E[opt(\omega)]$ denote the expected cost of an algorithm $\mathcal{A}$ and the expected cost of an optimal offline algorithm for an online scenario ω, respectively. Thus the competitive-ratio of algorithm $\mathcal{A}$ is defined as follows.

$$cr(\mathcal{A}) := \max_{D} \frac{E_{\omega\sim D}[\mathcal{A}(\omega)]}{E_{\omega\sim D}[opt(\omega)]}.$$

We first provide an oblivious[10] greedy algorithm for the i.i.d. SNDP. This algorithm starts with a sampling of the demands and finding a 2-approximation solution for them using the algorithm of Jain [18]. Let us call this the backbone solution. Then, to satisfy each demand v, we simply connect it to the backbone using the cheapest set of edges and show that this greedy approach leads to a 4-competitive solution. The oblivious algorithm for the i.i.d. case is in fact a stepping stone that enables us to further analyze the greedy algorithm in the unknown distribution and different known distributions (prophet) cases.

▶ **Theorem 3.** *The oblivious greedy is 4-competitive algorithm for i.i.d. SNDP.*

[10] An oblivious algorithm connects a demand through a path which is independent of the rest of the demands

A similar result to Theorem 3 is also given in [5].

1.1.2.1 Unknown i.i.d.

Although computing the backbone solution is impossible for the unknown i.i.d. case, we take advantage of our analysis of the oblivious i.i.d. algorithm and show that the classic greedy algorithm is $O(\log n)$-approximation for unknown i.i.d. SNDP. The main idea is simple but tricky: due to the sampling nature of the backbone solution, for every $1 \leq k \leq T/2$ we can think of a solution for the first k demands as a backbone solution for the next k demands. Hence, we can exploit our analysis for the known i.i.d. case. This in conjunction with the submodularity of Steiner networks results in the desired competitive ratio. We note that the factor $O(\log n)$ is almost tight given the $\Omega(\frac{\log n}{\log \log n})$ lower bound of [9] for the 1-connectivity case.

▶ **Theorem 4.** *The classic greedy algorithm is $O(\log n)$-competitive for unknown i.i.d. SNDP.*

1.1.2.2 From Oblivious i.i.d. to Prophet

We show if there exists a competitive oblivious algorithm for an online problem in i.i.d. setting, we can obtain a competitive algorithm for the same problem in prophet setting. Roughly speaking, we show that we can combine different distributions in the prophet setting to obtain a single average distribution. Therefore, the i.i.d. oblivious algorithm for the average distribution does not incur more than a constant factor to the competitive ratio.

▶ **Theorem 5** (restated informally). *Given an oblivious α-competitive online algorithm for problem $\mathcal{P}$ in the i.i.d. setting, there exists an $\alpha\frac{2e}{e-1}(1+o(1))$-competitive online algorithm for $\mathcal{P}$ in prophet setting.*

▶ **Corollary 6.** *There exists a constant competitive algorithm for prophet SNDP.*

Using our framework, we can obtain competitive algorithms for many fundamental and classical problems in prophet setting. For instance, define $D_1, \ldots, D_T$ be T probability distributions over the elements of a set cover instance. Now let i-th demand of a set cover problem be an element randomly and independently drawn from distribution D_i. We call this problem the prophet set cover problem. Similarly one may define prophet facility location the same as the classical facility location problem, with the difference that the i-th demand is randomly drawn from a known distribution D_i. Garg et al. [9] provide oblivious online algorithms for i.i.d. facility location and i.i.d. vertex cover. Applying the above framework directly results in the following corollary.

▶ **Corollary 7.** *There exist constant competitive algorithms for prophet vertex cover and prophet facility location problems.*

Also, Grandoni et al. [12] provide an oblivious online algorithm for i.i.d. set cover. Hence, we have the following corollary.

▶ **Corollary 8.** *There exists an $O(\log n)$-competitive algorithm for prophet set cover.*

1.2 Further Related Work

Over the past decades, SNDP and proper cut functions have been an important testbed for primal-dual and iterative rounding methods. Goemans and Williamson [11] (SIAM'95) were first to consider the case of $\{0,1\}$-proper functions. They used a primal-dual method to obtain a 2-approximation algorithm for the problem; which later on got generalized to the celebrated moat-growing framework for solving connectivity problems. Klein and Ravi [26] (IPCO'93) considered the two-connectivity problem and the case of $\{0,2\}$-proper functions. They gave a primal-dual 3-approximation algorithm for the problem. Williamson, Goemans, Mihail, and Vazirani [27] (Combinatorica'95) were first to consider general proper functions. They too developed a primal-dual algorithm with approximation ratio $2k$, where $k = \max_S f(S)$. Subsequently, Goemans, Goldberg, Plotkin, Shmoys, Tardos, and Williamson [10] (SODA'94) presented a primal-dual $2H(k)$-approximation algorithm, where $H(k)$ is the k^{th} harmonic number. Finally, in his seminal work [18] (Combinatorica'01), Jain introduced the *iterative rounding* method by developing a 2-approximation algorithm for network design problems characterized by proper cut functions[11]. We refer the reader to [13] for a survey of results for (offline) network design problems.

2 Uniform SNDP

In this section we consider the uniform-connectivity version of the online survivable Steiner network design problem, in which all connectivity requirements are equal to a given number. For this problem we first give a very simple algorithm and then analyze it using Steiner packing tools. Further in the paper, we explain how to generalize our algorithm to make it work for inputs with non-uniform connectivity requirements.

In the online uniform-connectivity survivable Steiner forest problem we are given an offline graph $G = \langle V(G), E(G)\rangle$, an integer k, and an online stream of demands $S = (s_1,t_1),(s_2,t_2),\ldots$. Every time a demand (s_i,t_i) arrives we have to add some of the edges of G to our current solution H in order to make k edge-disjoint paths between s_i and t_i in H. The online uniform-connectivity survivable Steiner tree problem is a special case of the forest problem in which the second endpoints of all demands are fixed at some vertex *root*. The objective of the problems is to minimize the cost of the selected subgraph H according to a given cost function.

A simple approach to solve these problems is to choose edges based on the following greedy method: for every demand add a minimum-cost subset of edges that satisfies the k-connectivity between its endpoints. In this section we show that this algorithm is not competitive to the optimum offline solution. This is shown by Lemma 14 in which we give an instance graph and a series of demands for which the greedy algorithm gives a solution of cost $\Omega(n)$ times the cost of the optimum offline solution.

However, we show a modified version of the greedy algorithm can be a viable approach for these problems if we lose some factor on the connectivity requirement. This can be done by satisfying half of the required connectivity. In particular, for every demand we add a minimum-cost subset of the edges that makes the current solution $(k/2)$-connected between the endpoints of that demand. Let us call this algorithm *GA*. In this section we show the cost of the edges GA selects is poly-logarithmically competitive to the optimum offline solution that satisfies k-connectivity for every demand.

[11] Indeed, the results in [10] and [18] applies to the more general class of weakly or skew supermodular cut functions.

Algorithm 1: 2-scaled Greedy

Input: A graph G, an integer k, and an online stream of demands $(s_1, t_1), (s_2, t_2), \ldots$.

Output: A set H of edges such that every given demand (s_i, t_i) is connected through k edge-disjoint paths in H.

Offline Process:

1: Initialize $H = \varnothing$.

Online Scheme; assuming a demand (s_i, t_i) is arrived:

1: $P_i =$ A minimum-cost subset of edges, such that s_i is $k/2$-connected to t_i in $H \cup P_i$.

2: Update $H = H \cup P_i$.

▶ **Theorem 9.** *For the online survivable Steiner forest problem, the output of GA satisfies $(k/2)$-connectivity for every demand and its cost is $O(\log^2 n)$-competitive.*

▶ **Theorem 10.** *For the online survivable Steiner tree problem, the output of GA satisfies $(k/2)$-connectivity for every demand and its cost is $O(\log n)$-competitive.*

As a direct consequence of adding edges according to GA, the $(k/2)$-connectivity is guaranteed for every demand. To complete the proof of the theorems, we need to show that the cost of the solution produced by GA is upper bounded by a factor of $O(\log^2 n)$ for forests, and $O(\log n)$ for trees.

Let $c : E(G) \to \mathbb{R}^{\geq 0}$ be the cost function on the edges. With some abuse of notation, we also use $c(Y)$ for a subset of edges $Y \subseteq E(G)$ as the sum of the cost of the edges in Y. With this notation we can say at every step i GA chooses a subset of edges P_i that satisfies $(k/2)$-connectivity and minimizes $c(P_i)$.

The overall idea of the proofs is as follows. We take an optimum solution and charge every $c(P_i)$ to $c(L_i)$, where L_i is a set of edges chosen from the optimum solution. The way we define L_i's allows them to have overlapping edges, but we show that their total cost is limited by the desired poly-logarithmic factor of the cost of the optimum solution. More specifically, we charge $c(L_i)$ to the cost of a fractional routing Q_i between s_i and t_i. Every Q_i is itself a linear combination of routes on different Steiner forests of the optimum solution. The coefficients of this linear combination are achieved from an Steiner forest packing of the optimum solution. In this fashion, the problem boils down to finding an upper bound for the total cost of routings on each Steiner forest. In the following we formally prove every step in detail.

Let OPT be an optimum offline solution of the survivable Steiner forest problem on graph G, a stream of demands S, and the connectivity requirement k. Now we define L_i for every demand i as a minimum-cost set of edges in OPT that is $(k/2)$-connected between s_i and t_i assuming the endpoints of every previous demand are contracted. In particular, we call a set of edges a *pseudo-path* between s_i and t_i if there is a path between these vertices using those edges and the edges in $\{(s_j, t_j) | \forall j < i\}$. A *pseudo-routing* between s_i and t_i is hence a set of pseudo-paths between s_i and t_i. With these definitions, L_i is a minimum-cost pseudo-routing between s_i and t_i in OPT that consists of $k/2$ pseudo-paths. The following lemma shows the relation between the costs of L_i and P_i.

▶ **Lemma 11.** *For every demand i, $c(P_i) \leq c(L_i)$.*

Proof. Every time a demand i arrives, GA finds a set P_i with the minimum cost and adds it to H in order to satisfy $(k/2)$-connectivity between s_i and t_i. Note that the endpoints

of every demand $j < i$ are already connected with $k/2$ disjoint paths in H. Besides, L_i is a pseudo-routing between s_i and t_i which is $(k/2)$-connected between s_i and t_i if we contract the two endpoints of every previous demand. Therefore adding L_i to H makes H $(k/2)$-connected between s_i and t_i. Since GA finds a minimum-cost set of edges that satisfies $(k/2)$-connectivity in H, $c(P_i)$ never exceeds $c(L_i)$. ◀

In the remaining we show how to charge the total cost of L_i's to $c(OPT)$. As a property of an optimum solution, OPT contains k edge-disjoint paths between the endpoints of every demand $(s_i, t_i) \in S$. Therefore, according to Theorem 2 there exists a solution for the fractional Steiner forest packing of OPT and demand set S with value at least $k/2$. Let $\mathbf{z}$ be a Steiner forest packing of OPT with value $k/2$. In the following we use $\mathcal{F}_S(OPT)$ to denote the collection of all Steiner forests of OPT with respect to demand set S. The theorem states there exists a vector $\mathbf{z}$ such that

$$\sum_{F \in \mathcal{F}_S(OPT)} z_F = k/2 \tag{1}$$

$$\sum_{F \in \mathcal{F}_S(OPT): e \in F} z_F \leq 1 \qquad \forall e \in OPT \ . \tag{2}$$

Moreover, the following inequality holds for the summation of the costs of these forests.

▶ **Lemma 12.** $\sum_{F \in \mathcal{F}_S(OPT)} z_F.c(F) \leq c(OPT)$.

Proof. For each forest we replace its cost with the sum of the cost of its edges.

$$\begin{aligned}
\sum_{F \in \mathcal{F}_S(OPT)} z_F.c(F) &= \sum_{F \in \mathcal{F}_S(OPT)} z_F \sum_{e \in F} c(e) \\
&= \sum_{e \in OPT} \sum_{F \in \mathcal{F}_S(OPT): e \in F} z_F c(e) \\
&= \sum_{e \in OPT} c(e) \Big(\sum_{F \in \mathcal{F}_S(OPT): e \in F} z_F \Big) \ .
\end{aligned}$$

Now we use the fact that the load on every edge in the fractional Steiner forest packing is no more than 1.

$$\begin{aligned}
\sum_{F \in \mathcal{F}_S(OPT)} z_F.c(F) &\leq \sum_{e \in OPT} c(e) \qquad \textit{Inequality} \quad (2) \\
&= c(OPT) \ .
\end{aligned}$$

◀

Now for every forest $F \in \mathcal{F}_S(OPT)$ and every demand i we define $Q_i(F)$ as a minimum-cost pseudo-path between s_i to t_i in F. This definition allows using an edge $e \in F$ multiple times in $Q_i(F)$ of different demands. Note that $Q_i(F)$ can be considered as a fractional pseudo-routing between s_i and t_i with value z_F. Considering this for all forests in $\mathcal{F}_S(OPT)$, we achieve a fractional pseudo-routing between s_i and t_i that has a value of $k/2$. We use Q_i to refer to this fractional pseudo-routing and $c(Q_i) = \sum_{F \in \mathcal{F}_S(OPT)} z_F.c(Q_i(F))$ to refer to its cost.

For every demand i we have mentioned two different pseudo-routings between s_i and t_i in OPT with value $k/2$: an integral pseudo-routing L_i, and a fractional pseudo-routing Q_i. The following lemma shows the relation between the costs of these two.

▶ **Lemma 13.** *For every L_i and Q_i pseudo-paths defined as above, we have:*

$$c(L_i) \leq c(Q_i)$$

In the interest of space, we defer the proof of Lemma 13 to the full-version of the paper.

Finally for a particular $F \in \mathcal{F}_S(OPT)$ we show an upper bound for the sum of $c(Q_i(F))$ over all demands. First let us take a closer look at every $Q_i(F)$ on a particular F. Every time a new demand (s_i, t_i) arrives $Q_i(F)$ connects its endpoints through a pseudo-path in F. This can be generalized to an algorithm for the online single-connectivity Steiner forest problem that greedily connects the endpoints of every demand by fully buying a minimum-cost pseudo-path between s_i and t_i. This is very similar to the greedy algorithm proposed in [2]. Theorem 2.1 of that paper states that their greedy algorithm is $O(\log^2 n)$-competitive. The statement of that theorem is slightly different than Claim 2.1, but the same proof verifies the correctness of the claim.

▶ **Claim 2.1.** *For the online Steiner forest problem, the algorithm that connects every demand with a minimum-cost pseudo-path is $O(\log^2 n)$-competitive.*

Now we are ready to wrap up the proof of Theorem 9.

Proof of Theorem 9. Let ALG denote the output of GA. The cost of ALG is the sum of the cost of P_i's over all demands. Therefore, by applying lemmas 11 and 13 we have

$$\begin{aligned} c(ALG) &= \sum_{(s_i,t_i)\in S} c(P_i) \\ &\leq \sum_{(s_i,t_i)\in S} c(L_i) && \textit{Lemma } 11 \\ &\leq \sum_{(s_i,t_i)\in S} c(Q_i) && \textit{Lemma } 13 \end{aligned}$$

Now we replace $c(Q_i)$ with the weighted sum of $c(Q_i(F))$'s with respect to $\mathbf{z}$.

$$\begin{aligned} c(ALG) &\leq \sum_{(s_i,t_i)\in S} \sum_{F\in\mathcal{F}_S(OPT)} z_F.c(Q_i(F)) \\ &= \sum_{F\in\mathcal{F}_S(OPT)} z_F \sum_{(s_i,t_i)\in S} c(Q_i(F)) \qquad (3) \end{aligned}$$

By applying Claim 2.1 to Inequality (3) we achieve an $O(\log^2 n)$-competitive ratio for GA.

$$\begin{aligned} c(ALG) &\leq \sum_{F\in\mathcal{F}_S(OPT)} z_F \Big(O(\log^2 n) c(F) \Big) && \textit{Claim } 2.1 \\ &\leq O(\log^2 n) \sum_{F\in\mathcal{F}_S(OPT)} z_F.c(F) \\ &\leq O(\log^2 n) c(OPT) \ . && \textit{Lemma } 12 \end{aligned}$$

◀

Finally, for the survivable Steiner tree problem we show that GA is $O(\log n)$-competitive. In other words, if one endpoint of every demand is fixed at the root, then the output of GA is at most $O(\log n)$ times the optimum offline solution. To complete the proof of Theorem 10 we use a result from [22]. In that paper the authors prove a competitive ratio of $O(\log n)$ for the algorithm which satisfies every demand using a minimum-cost pseudo-path. The following claim is a restatement of their result.

▶ **Claim 2.2.** *For the online Steiner tree problem, the algorithm that satisfies each demand with a minimum-cost pseudo-path is $O(\log n)$-competitive.*

of Theorem 10. Note that the tree problem is a special case of the forest problem, hence Inequality (3) also holds for it. By applying Claim 2.2 to that inequality the proof is complete.

$$\begin{aligned} c(ALG) &\leq \sum_{F \in \mathcal{F}_S(OPT)} z_F \Big(O(\log n) c(F) \Big) && \textit{Claim} \quad 2.2 \\ &\leq O(\log n) \sum_{F \in \mathcal{F}_S(OPT)} z_F . c(F) \\ &\leq O(\log n) c(OPT) \ . && \textit{Lemma} \quad 12 \end{aligned}$$

◀

The following Lemma shows that there exists a graph G and a sequence of demands σ such that Greedy algorithm performs $\Omega(n)$ times worse than the optimal solution.

▶ **Lemma 14.** *The competitive ratio of the greedy algorithm for survivable Steiner network design is $\Omega(n)$, even if every connectivity requirement is exactly 2.*

Proof. First we provide an online instance of the survivable network design problem where every connectivity requirement is exactly 2 and show the greedy algorithm performs poorly in comparison with the optimal solution. We construct a graph G of size n as follows. For each $1 \leq i \leq n-1$, there exist two undirected edges from node i to node $i+1$ of weights 1 and $n - i - \epsilon$ for some small $\epsilon > 0$. There exist two undirected edges from node n to node 1 with weights 1 and $n - \epsilon$. Thus G is the union of two cycles of size n. We construct a set of demands S as follows. For each $1 \leq i \leq n-1$, let $(i, i+1)$ be the i'th demand in S.

Now we analyze the output of the greedy algorithm for the input instance. We claim that after satisfying demand i the greedy algorithm has selected both edges between j and $j+1$ for every $j \leq i$. We prove this claim by induction. For the base case, when the first demand arrives the greedy algorithm chooses both edges between nodes 1 and 2 which costs $n - \epsilon$. Now assume the greedy algorithm has selected every edge between j and $j+1$ for every $j < i$ before the arrival of the i'th demand. When the i'th demand arrives, the set of edges with minimum cost that provides two edge-disjoint paths from i to $i+1$ is the two edges between i and $i+1$ which costs $n - i - \epsilon$. Thus the total cost of the greedy algorithm at the end is $\frac{n(n-1)}{2} - \epsilon n$. However, the optimum offline solution chooses the cycle containing all edges of weight 1. Thus the competitive ratio of the greedy algorithm is $\Omega(n)$. ◀

Abstract

The noisy broadcast model was first studied by [10] where an n-character input is distributed among n processors, so that each processor receives one input bit. Computation proceeds in rounds, where in each round each processor broadcasts a single character, and each reception is corrupted independently at random with some probability p. [10] gave an algorithm for all processors to learn the input in $O(\log \log n)$ rounds with high probability. Later, a matching lower bound of $\Omega(\log \log n)$ was given by [11].

We study a relaxed version of this model where each reception is erased and replaced with a '?' independently with probability p, so the processors have knowledge of whether a bit has been corrupted. In this relaxed model, we break past the lower bound of [11] and obtain an $O(\log^* n)$-round algorithm for all processors to learn the input with high probability. We also show an $O(1)$-round algorithm for the same problem when the alphabet size is $\Omega(\text{poly}(n))$.

1 Introduction

In recent years, it is becoming increasingly common for computational tasks to be performed by multiple processors in a distributed fashion. The communication channels of these networks may have imperfections, which introduces noise to the system.

A formal version of a noise model was proposed by [7]: There are n processors: $1, 2, \ldots, n$ and each processor is given a bit. In each round, every processor broadcasts a bit to all other processors. Every processor will receive the correct message with some probability, and may receive a different (corrupted) message independently with probability $p < 1/2$ (i.e., each reception gets corrupted with probability p). The goal is for the processors to collectively compute the XOR of all their inputs. An algorithm that takes $O(\log \log n)$ rounds for all processors to learn the full input (and hence the XOR as well) was found by [10]. A matching lower bound of $\Omega(\log \log n)$ rounds was proven by [11].

All of the prior works were concerned with *substitution errors*. In this paper, we study such networks in the presence of *erasure errors*, where instead of messages getting corrupted into other messages, instead messages may get dropped. Specifically, we study the following model: in a single round each processor can broadcast a single bit b to all other processors. For each ordered pair (i, j), independently with some probability p, the character that i

transmitted is not received by j and a '?' is received instead. In other words, there is a string $X \in \{0,1\}^n$ and processor i is given the ith bit of X, called x_i, and the goal is for each processor to learn X using as few rounds of communication as possible. We call our noise model the *erasure model*.

1.1 Our results

We show that for any alphabet, each processor can learn the inputs of all other processors with high probability within $O(\log^* n)$ rounds. At the high level, the algorithm involves recursively running the protocol on groups of size $\log n$, and having each group encode its input using a constant rate and constant relative distance error correcting code. Then, the group collectively transmits this encoded string within a constant number of rounds. It can be shown that with high probability every processor receives enough bits to decode the group's input. There are groups for which not enough processors learn the full string (i.e., the recursive call fails), and some technical steps are needed to handle these 'failed groups'. The protocol is described in full detail in section 2.

We note that in the presence of *substitution errors*, it was proven in [11] that $\Omega(\log \log n)$ rounds are required for all processors to learn the whole input. Since we show a $O(\log^*(n))$ algorithm for the problem in the presence of *erasure errors*, this shows a fundamental difference between substitution errors and erasure errros in the broadcast model.

We then show that when the alphabet is of polynomial size, there is an $O(1)$ round algorithm for every processor to learn the full input. The algorithm involves treating the alphabets as elements of a finite field $\mathbb{F}_q$, and simulating multiplying the input vector with an appropriate random matrix. Then , the processors receive a random system of linear equations which one can show has a unique solution with high probability.

We then show that any symmetric function of the input can be computed within a constant number of rounds via computing the Hamming weight.

1.2 Related Work

A related problem was studied in [10] where the broadcast model assumed was sequential, where in one round only one processor can broadcast a bit. Additionally, the noise model assumed was that of bit flips instead of erasures. That is, each transmitted bit is independently flipped with probability p on the receiving end. In their model, [10] shows that all the processors can learn the entire input within $O(\log \log n)$ rounds. However, it left open the question of whether a faster protocol was possible.

The model of [10] was studied further in [11] where a lower bound of $\Omega(n \log \log n)$ was proven for the total number of broadcasts, thereby establishing that Gallager's protocol is optimal up to constant factors. The lower bound is proved via a reduction to another model called the generalized noisy decision tree, which is a variant of the noisy decision tree model introduced in [9]. [11] also studies whether more efficient protocols exist when the processors only want to compute some specific function on the entire input and shows that the Hamming weight can be computed with constant probability within $O(n)$ broadcasts.

We note that it follows from the lower bound in [11] that in a variant of our model where one considers substitution errors instead of erasure errors, any protocol from which all the processors learn the entire input must take $\Omega(\log \log n)$ rounds. In light of this lower bound, our result of an $O(\log^* n)$ protocol is interesting, as it shows a fundamental difference between substitution and erasure errors in this broadcast model.

Recently, a work by Efremenko, Kol, and Saxena [6] showed that under a model where the processors can adaptively choose which processor will speak in each round, the lower bound of [11] breaks down.

Note that the work of Gallager [10] shows that in the substitution model where a single processor broadcasts to the rest in a round, any function can be computed within $O(n \log \log n)$ rounds. A work by Kushilevitz and Mansour [14] studies the question of which Boolean functions can be computed within $O(n \log \log n)$ broadcasts. They determine that threshold functions can be computed with constant probability within $O(n)$ broacasts.

A paper by Feige and Killian [8] studied a harsher noise model than [10], where an adversary can arbitrarily 'uncorrupt' arbitrary corrupted bits, causing the noise to lose structure. In this harsher model, they show an $O(\log^* n)$ round protocol to compute the OR of all input bits. Newman [16] studies another noise model where each bit transmitted is independently flipped with an unknown probability that is at most p and gives algorithms that use $O(n)$ broadcasts and $O(\log^* n)$ rounds for certain classes of Boolean functions, including OR, AND, and functions with linear size AC_0 formulas.

In [1], the authors show efficient protocols to handle errors in the UCAST model, in which instead of broadcasting bits, a processor can send a different message to each other processor. They also show efficient protocols to handle errors when the communication network has certain expansion properties. For general graphs of low degree, a protocol for handling errors was found in [17], which was later shown to be optimal in [3].

Our model in the absence of errors is known as the Broadcast Congested Clique, which is a computational model often studied in distributed computing (see for example, [5, 15, 4, 2, 12]. In this model, n processors each get a piece of the input, and they work together to compute some function of this shared input. Computation proceeds in rounds, where in each round each processor can broadcast a short message to all other processors. Our work can be interpreted as showing that when using messages of constant size, every protocol in the Broadcast Congested Clique can be made resilient to erasure errors with a blowup of only $O(\log^*(n))$. In the case where messages are of logarithmic size, we show the Broadcast Congested Clique can be made resilient to erasure errors with only a constant blowup.

1.3 Notation and conventions

In this section, we state some notational conventions we use. First, we describe the computational model (without erasures), and then we formally define the model we consider with erasures.

The Computational Model: In a setting with n processors, each processor is identified with a distinct number in $[n]$. Given a string X, which we denote using an upper case character, we write the ith bit as x_i, using the corresponding lower case character. To denote the substring of X starting at position i and ending in position j we write $X_{[i,j]}$. When we wish to compute some function of a n-bit string X using n processors, assume x_i is provided as input to processor i. In the description of algorithms, $\textsc{Algo}(x_1, \ldots, x_n)$ refers to an algorithm that runs on n processors where the ith processor is given x_i as input.

In all our algorithms, we assume that each broadcast is repeated γ times where γ is some appropriately chosen constant.

Formally, we have:

▶ **Definition 1.** We let the *noisy parallel broadcast model* be a model of computation where there are n processors $P_1, \ldots, P_n$, and P_i receives input bit x_i. In each round of computation, each processor can broadcast one bit to all other processors. Each reception is corrupted

with some constant probability $0 \leq p < 1$, in which case the character '?' is received instead of the bit which was sent.

In this paper, we study the complexity of computing certain functions in the above model. Specifically, for constant erasure probability p we show a bound of $O(\log^*(n))$ for computing any function, and a bound of $O(1)$ for symmetric functions.

As part of our algorithm we use error correcting codes, so we include standard results and notations for codes below: **Error Correcting Codes:** An error correcting code is described by functions $\mathsf{Enc} : \{0,1\}^n \to \{0,1\}^k$ and $\mathsf{Dec} : \{0,1\}^k \to \{0,1\}^n$ with the property that $\mathsf{Dec}(x)$ maps to the string y for which $\mathsf{Enc}(y)$ is the closest string to x in $\mathcal{C} = \text{Image}(\mathsf{Enc})$.

The *rate* of an error correcting code is defined as $\frac{k}{n}$ and the *relative distance* is defined as $\frac{\min_{x,y \in \mathcal{C}} d(x,y)}{k}$. The quantity $\frac{d(x,y)}{2}$ is referred to as the *decoding radius*.

We use the result of [13] that error correcting code families of constant rate and constant relative distance exist. In particular, for the sake of this paper, we assume the existence of an error correcting code family E with relative distance 0.25 and rate some absolute constant K.

2 An $O(\log^* n)$ algorithm for computing any function

We consider the following message-passing model. There are n processors, and in each round, every processor transmits a single bit b to all other processors. Each processor receives each bit independently and at random with probability $1 - p$. With probability p, the character '?' is received instead. If each processor starts with a single input bit, we ask how many rounds are required so that every processor knows all input bits with high probability. We show a bound of $O(\log^*(n))$ for this problem. Specifically, we will show:

▶ **Theorem 2.** *For every $0 \leq p < 1$, there is an algorithm in the noisy broadcast parallel erasure model that computes ID_n with high probability within $O(\log^*(n) \log \frac{1}{1-p})$ rounds.*

Without loss of generality, we assume that $p \leq 0.01$, since for any erasure probability $p < 1$, repeating each message $O(\log \frac{1}{1-p})$ times can be used to effectively lower the probability of receiving '?'. We describe our algorithm for the case where the alphabet $\Sigma = \{0,1\}$. The protocol generalizes to larger alphabets in a straightforward manner.

We describe a protocol for n processors with the guarantees: at the end of the protocol, all n processors can output the full string C with probability at least $1 - \frac{1}{n^5}$, and if the protocol fails (that is, there is some processor who cannot output the full string C), then all n processors can output '$\perp$' with probability at least $1 - \frac{1}{2^{7n}}$. For the rest of this section, we assume $n \geq n_0$ for a sufficiently large n_0.

We begin by describing algorithms for simpler subproblems.

▶ **Lemma 3.** *Let b_i be the input to processor i, and let the erasure probability p be .01. Then there is an $O(1)$-round algorithm and an absolute constant α such that all processors output the AND of all b_i with probability at least $1 - 2^{-\alpha n}$.*

Proof. **Algorithm:** The algorithm is as follows: in each round, a processor i broadcasts '0' either if $x_i = 0$ or if processor i has received at least one '0' in at least one of the previous rounds. Otherwise, processor i boradcasts 1. This is repeated for 100 rounds.

Processor j's output is the AND of all bits it received.

Analysis: First, note that if all of the $b_i = 1$, then all processors must output 1, no matter what messages were corrupted, since all received bits of all processors must be 1.

Algorithm 1: EQUALITYTEST$(S_1, \ldots, S_n)$.

Enc is the encoding function of a code $\mathcal{C}$ with relative distance 0.25 and constant rate K.

1. Transmit $(\mathsf{Enc}(S_i))_{[(i-1)K+1,iK]}$ over K rounds
2. Let $A_{t,i}$ be the K-bit string received from processor t and $A_i = A_{1,i}A_{2,i}\ldots A_{n,i}$. Set c_i to 1 if Hamming distance between A_i and $\mathsf{Enc}(S_i)$ is at most $0.06Kn$ and 0 otherwise
3. The processors run the AND protocol from Lemma 3 and output the AND of all c_i

Now, suppose there is an i for which $b_i = 0$. Let t be the number of processors that received the transmission of i in the first round. The probability that processor j receives only 1s in the second round is at most p^t.

We can use Hoeffding's inequality to obtain

$$\mathbf{Pr}\left[t < \frac{n}{2}\right] \leq e^{-\alpha' n}$$

for some constant α'. Thus, the probability that there is some j that received only 1's even if there is a processor with a 0 is at most $n(e^{-\alpha' n} + p^{n/2})$, bounded above by $e^{-\alpha n}$ for a constant α. ◀

We note that the above protocol does not work in the substitution model (the model where a message may be flipped with small probability, as opposed to being corrupted to a '?'). In fact, in [11] it was proven that computing the AND function with high probability in the substitution model requires $\Omega(\log \log n)$ rounds.

We next show an $O(1)$ round algorithm for EQUALITY TESTING. Each processor is given an n-bit string S_i as input, and the goal is for all processors to output 1 if all their inputs are equal and 0 otherwise with probability at least $1 - 2^{-\Omega(n)}$. Unless otherwise specified, each step of the algorithm is from the view of processor i. Roughly speaking, this step will be used in the main algorithm to verify that all processors end up with the same output string S.

▶ **Lemma 4.** *When the erasure probability $p \leq .01$, Algorithm 1 correctly solves* EQUALITY TESTING *with probability at least $1 - 2^{-\beta n}$ for some absolute constant β.*

Proof. Let A be the string collectively transmitted by all processors in Step 1. We know

$$\begin{aligned} d(\mathsf{Enc}(S_i), \mathsf{Enc}(S_j)) &\leq d(\mathsf{Enc}(S_i), A_i) + d(A_i, A) + d(A, A_j) + d(A_j, \mathsf{Enc}(S_j)) \\ &\leq 2(d(\mathsf{Enc}(S_i), A_i) + d(\mathsf{Enc}(S_j), A_j)) \end{aligned}$$

where the second inequality is because $d(A, A_i)$ is the number of '?'s received, and lower bounds $d(\mathsf{Enc}(S_i), A_i)$.

If both $d(\mathsf{Enc}(S_i), A_i)$ and $d(\mathsf{Enc}(S_j), A_j)$ are at most $0.06Kn$, then $d(\mathsf{Enc}(S_i), \mathsf{Enc}(S_j))$ is at most $0.24Kn$, but since they are codewords of a code with relative distance 0.25, $\mathsf{Enc}(S_i) = \mathsf{Enc}(S_j)$, implying $S_i = S_j$. So if there is a pair i, j with $S_i \neq S_j$, then either c_i or c_j must be 0. And then from Lemma 3, with probability at least $1 - e^{-\alpha n}$, the processors correctly detect that there is a c_i equal to 0.

On the other hand, if all the strings are indeed equal, then c_j is 0 only if processor j receives fewer than $0.94Kn$ bits. We upper bound the probability that this happens by using Chernoff bound along with a union bound over all processors.

$$n\mathbf{Pr}[\text{processor } i \text{ receives fewer than } 0.88Kn \text{ bits}] \leq ne^{-\alpha'' n} \leq e^{-\alpha' n}$$

where α' is some constant. We let $\beta = \min\{\alpha, \alpha'\}$. ◀

Let $X = x_1x_2 \dots x_n$ be the input string and processor i is given x_i and is required to output a tuple (X_i, s_i), where X_i an n-bit string and s either 1, indicating success or 0, indicating failure, with the goal of having all $X_i = X$ and all $s_i = 1$. We say that an algorithm on a group of processors **succeeded** if $X_i = X$ and $s_i = 1$ for all i, **failed with knowledge** if $r_i = 0$ for all i, and **failed without knowledge** otherwise. We describe an algorithm for this problem where each step is from the view of processor i unless otherwise specified. Recall that each broadcast is repeated γ times to effectively reduce the erasure probability p to be at most .01. For simplicity, we assume that n is a power of 2, and so $\log n$ is an integer. It is easy to generalize the algorithm to all values of n.

At the high level, the algorithm proceeds as follows. We partition the processors into $n/\log n$ sets of size $\log n$ each (Step 2a). Then, we recursively compute the input on each of these subsets. Now, some of these subsets will have succeeded, and some will have failed. For the ones that failed, we now recompute the input, but this time we add more processors to be "helper processors". That is, the processors which succeeded in the recursive calls will now be used to aid the processors who failed in the recursive call by sending messages on their behalf. This can be seen in Step 2g, where the processor sends x_{ℓ_i}, which is the input to a processor which failed on the recursive call. This idea of using successful processors to help others who failed helps ensure that within a constant number of tries, with high probability all input bits will be known.

We now prove the following proposition, from which Theorem 2 immediately follows.

▶ **Proposition 5.** *Algorithm 2 runs in $O(\log^* n)$ rounds, succeeds (i.e., each processor outputs $(X, 1)$, where X is the input to all processors) with probability at least $1 - \frac{1}{n^5}$ and fails without knowledge with probability at most $\frac{1}{2^{7n}}$.*

Proof. We list conditions under which the protocol definitely succeeds, and show all these conditions hold with probability at least $1 - \frac{1}{n^5}$. Define R as $r'_1r'_2 \dots r'_n$ from the output of Step 2a. Define M_s as all j such that $\frac{n(s-1)}{z} < j \leq \frac{ns}{z}$ where z is the number of 0's in R.

The protocol definitely succeeds if the following conditions hold:

1. All but at most $\frac{n}{\log^3 n}$ groups succeed in the recursive call of Step 2a.
2. No group fails without knowledge in the recursive call of Step 2a, and $R_i = R$ for all i.
3. For all j such that $(R)_j = 0$, for all i, processor i receives at least one transmission from a processor in $M_{\ell_j,i}$ in Step 2g where the ℓ_jth 0 in R occurs at $(R)_j$.
4. Each processor receives at least $0.88K \log n$ bits from each successful group in at least one transmission in Step 2d of the algorithm.

Indeed, for any j in a successful group, all processors correctly learn the input to processor j because Condition 4 is met. By Condition 2, for fixed s, $M_{s,i}$ is the same for all i since $M_{s,i}$ depends on R_i. For any j in a failed group, by Condition 2, $(R)_j = (R_i)_j = 0$, and by Condition 3, each processor receives at least one transmission of processor j's input in Step 2g and so all processors correctly learn the input to processor j.

We now proceed with showing a lower bound on the probability that all of these conditions hold.

We can see that Condition 1 holds with probability at least $1 - \frac{1}{n^6}$ since by Chernoff bounds, the number of failed groups exceeds $\frac{n}{\log^3 n}$ with probability at most $\frac{1}{n^6}$.

Now suppose Condition 1 holds. A group fails without knowledge with probability at most $\frac{1}{n^7}$ by the guarantees of the protocol. The probability that there exists a group that failed without knowledge, by the union bound, is therefore at most $\frac{1}{n^6}$. If no group failed without knowledge, the only way R_i cannot equal R is if there is a group $M_{j,i}$ that processor i did not receive a single bit from. The probability that processor i does not receive a single

Algorithm 2: LearnInput$(x_1, \ldots, x_n)$.

Enc is the encoding function of a code $\mathcal{C}$ with relative distance 0.25 and constant rate K

1. **Base Case:** If $n < 100$
   a. Transmit x_i repeatedly 100 times, and set string S_i as per

$$(S_i)_j = \begin{cases} b & \text{if } b \text{ was received in any transmission from } j \\ \text{random bit} & \text{if all transmissions from } j \text{ are `?'} \end{cases}$$

   and go to Step 3a.
2. **Recursive Step:**
   a. Recursively obtain $(X'_i, r'_i) = \text{LearnInput}\left(x_{\lfloor \frac{i}{\log n} \rfloor \log n+1}, \ldots, x_{\lfloor \frac{i}{\log n} \rfloor \log n+\log n}\right)$. We call this set of processors the *group* of i.
   b. Broadcast r'_i
   c. Set R_i by setting $(R_i)_j$ to 1 if only 1's were received from j's group (i.e., from the processors which j computed the recursive call with) and 0 otherwise, for each $j \in [n]$.
   d. Let $i' = i \bmod \log n$ and transmit $\mathsf{Enc}(X'_i)_{[(i'-1)K+1, i'K]}$ over the next K rounds.
   e. Let z_i be the number of zeros in R_i and let $j = \left\lceil \frac{iz_i}{n} \right\rceil$ and let ℓ_i be the index of the jth zero in R_i. Create set $M_{s,i}$ to be all t such that

$$\frac{n(s-1)}{z_i} < t \leq \frac{ns}{z_i}$$

   f. Transmit x_i.
   g. Broadcast what was received from ℓ_i, which is either '?' or x_{ℓ_i}. Let $M'_{j,i}$ be the set of characters received from $M_{j,i}$.
   h. Set X_i by setting $(X_i)_j$ to x_i if $j = i$, by decoding the bits received in Step 2d if $(R_i)_j = 1$ and at least $0.88K \log n$ bits were received from the group of j, to a random bit if $(R_i)_j = 1$ and fewer than $0.88K \log n$ bits were received from group j in Step 2d, and to $\mathbf{1}_{1 \in M'_{j,i}}$ if $(R_i)_j = 0$. Proceed to Step 3a.
3. **Verification of output**
   a. Obtain $v_i = \text{EqualityTest}(X_1, \ldots, X_n)$ and output (X_i, v_i).

bit from this group is $p^{\gamma \log n}$, which for appropriate γ is at most $\frac{1}{n^8}$. Thus, the probability that there is some i, j pair such that processor i does not receive a single bit from group j is at most $\frac{1}{n^6}$ by a union bound. So the probability that Condition 2 is not met (given that Condition 1 is met) is at most $\frac{2}{n^6}$.

Note that $R_i = R$ means $M_s = M_{s,i}$ for all i. It follows from Chernoff bounds that the number of processors in M_s that receive the bit transmitted by processor s is at least $\log n$ with probability at least $1 - \frac{1}{n^6}$. The probability that processor i does not receive any bits from processors in M_s in any of the repetitions of Step 2g is at most $p^{\gamma \log n}$, which can be made smaller than $\frac{1}{n^8}$ by setting γ to be large enough. Now by taking a union bound over all pairs (i, s) we can conclude that Condition 3 does not hold with probability at most $\frac{1}{n^6}$.

The probability that processor i receives fewer than $0.88K \log n$ bits from group j in all repetitions of Step 2d is at most $\frac{1}{n^{c\gamma}}$ for some constant c by Chernoff bounds. A union bound across all processor-group pairs tells us that Condition 4 does not hold with probability at most $\frac{1}{n^{c\gamma-2}}$ which can be made smaller than $\frac{1}{n^6}$ with large enough γ.

Algorithm 3: LearnInputLargeAlphabet$(x_1, \ldots, x_n)$.

Let F be a function that encodes subsets of $[6 \log n]$ as elements of $\mathbb{F}_q$

1. Let $k = \lfloor 6 \log n \rfloor$ and determine $B_i = \{\frac{nj}{k} + 1, \ldots, \frac{n(j+1)}{k}\}$, where j is chosen such that $i \in B_i$
2. Broadcast x_i for 10 rounds
3. For each t from 1 to 10 and for each processor in B_i from which an entry was received in round t of Step 2, choose the processor with probability $\frac{1}{2(1-p)}$ and choose i with probability $\frac{1}{2}$. Let $T_{t,i}$ be the set of chosen elements.
4. For the next 20 rounds, processor i transmits all the $\sum_{b \in T_{t,i}} x_b$ (where the x_b are added as elements of $\mathbb{F}_q$) and $F(T_{t,i})$
5. Output X_i consistent with all received pairs $\left(\sum_{b \in T_{t,i}} x_b, F(T_{t,i})\right)$. If there is more than one possibility for such an X_i, pick one at random.

Based on the bounds we obtained on the probability that each of Conditions 1, 2, 3, 4 don't hold, we can conclude that the probability that all the conditions hold is at least $1 - \frac{1}{n^5}$.

It remains to show that the probability that the processors failed without knowledge is at most 2^{-7n}. If there is X_i such that $X_i \neq X$, then it differs from X in some index j, which means $(X_i)_j \neq (X_j)_j$ by construction of X_j implying $X_i \neq X_j$. Thus, a failure without knowledge happens only if Step 3a fails, which happens with probabilty at most $e^{-\beta n}$, which can be made smaller than 2^{-7n} by choosing the number of repetitions γ to be a large enough constant.

The number of rounds this algorithm takes is given by $T(n)$, which satisfies the recurrence relation $T(n) = T(\log n) + L$ where L is a constant and with base case $T(100) = O(1)$, which solves to $T(n) = O(\log^* n)$. ◀

3 An $O(1)$ algorithm for large alphabets

For large alphabets, in the regime where the alphabet Σ is $\mathbb{F}_q$ and $q = \text{poly}(n)$, we give a constant round algorithm to have all processors learn the input X with probability at least $1 - \frac{1}{\text{poly}(n)}$. Unless otherwise specified, the algorithm is from the view of processor i. While our algorithm works for any q that is polynomial in n, for simplicity of exposition we assume $q \geq n^6$ and that q is a prime.

▶ **Theorem 6.** *With probability at least $1 - \frac{1}{\text{poly}(n)}$, after running Algorithm 3, all processors will know all other processors' inputs. Furthermore, the algorithm terminates within $O(1)$ rounds.*

As a first ingredient towards proving Theorem 6, we prove the following lemma.

▶ **Lemma 7.** *If A is a $5k \times k$ random binary matrix where each entry is i.i.d. generated by flipping a fair coin, then with probability at least $1 - e^{-0.4k}$, A is full rank.*

Proof. Suppose V is a subspace of $\mathbb{F}_q^k$ that is not equal to all of $\mathbb{F}_q^k$, then we can find standard basis vector e_i that is not in V. Then for any binary vector v, consider v' with the bit at the i-th coordinate flipped. Either v or v' is not in V, which means at least half of the binary vectors are not in V, which means each new vector has probability at least $\frac{1}{2}$ of not being in

V. If we let $V = \mathsf{span}\{\text{vectors drawn so far}\}$, then each draw has a probability at least $\frac{1}{2}$ of increasing the dimension. Suppose we flip $5k$ coins, the probability that the number of heads is at most k is an upper bound on the probability of the span of $5k$ randomly drawn vectors not being the whole space.

By Chernoff bounds, this probability is at most $e^{-0.4k}$. ◀

Proof of Theorem 6. Each $T_{t,i}$ is a uniformly random subset of input bits of set B_i. Let x_{B_i} be a k-dimensional vector of the inputs to processors in B_i, then the transmitted characters in Round 5 are of the form $(\langle a_{B_i}, x_{B_i}\rangle, F(T_{t,i}))$ where a_{B_i} is a random binary vector, and $F(T_{t,i})$ is an encoding of a_{B_i}. The transmitted characters can be viewed as elements in the vector Ax_{B_i}, where A is a matrix whose rows are the a_{B_i}. A single processor's output of x_{B_i} is given by sampling rows of the equation $Ay_{B_i} = Ax_{B_i}$ where y_{B_i} is indeterminate and solving for y_{B_i}. If the number of sampled rows is at least $5k$, then from Lemma 7 the probability that the sampled rows span $\mathbb{F}_q^k$ and hence give a unique solution to y_{B_i} is at least $1 - \frac{1}{n^{2.4}}$.

The probability that the number of sampled rows for a group is less than $5k$ can be upper bounded by $\frac{1}{n^5}$ using Chernoff bounds.

So by union bound over all group-processor pairs (i.e., all pairs (i, B_j)), we get a $\frac{1}{\mathrm{poly}(n)}$ upper bound on the failure probability. ◀

A An $O(1)$ protocol for computing any symmetric function

We show that any symmetric function can be computed within $O(1)$ rounds in the model. Symmetric functions are functions whose value doesn't change under permutation of the input bits. In other words, these functions only depend on the Hamming weight of the input string. Hence, an algorithm for every processor to learn the Hamming weight of the string leads to an algorithm to compute any symmetric function. Our algorithm is inspired by a similar algorithm (for a different model) of [11].

▶ **Theorem 8.** *There is an $O(1)$ round algorithm in the noisy broadcast parallel erasure model that computes Hamming Weight(X) with probability at least 0.75.*

Our algorithm proceeds in two phases:

1. Divide the interval $[0, n]$ into subintervals of length $c\sqrt{n}$ and find which interval the Hamming weight belongs to.
2. Figure out exactly which integer in the interval is the Hamming weight.

More precisely, the first step will give us three intervals, and we will show for at least two of these intervals, with high probability all processors will end up with the same interval. Then, we will run the second step (where we pinpoint the exact Hamming weight) on each of the three intervals, and take a majority vote to compute the final output.

We describe the first step below:

▶ **Lemma 9.** *With probability at least $1 - \exp(-\Omega(n))$, for at least two t in $\{1, 2, 3\}$, all $C_{i,t}$ outputted in Step 4 of Algorithm 4 are equal and correspond to an interval containing Hamming Weight(X).*

Proof. By Chernoff bounds, the probability that h_i deviates from the truth by $t\sqrt{n}$ is at most e^{-Ct^2} for an absolute constant C. This can be made smaller than 0.01 with appropriate choice of a constant t. Then for at least two values of s, h_i lies in the correct interval in $\mathcal{B}_s$ with probability at least 0.99. Without loss of generality, say this happens for $s = 0$ and $s = 1$. Using Chernoff bounds, we can show that for some constant c, with probability at least $1 - \exp(-\Omega(n))$, at least 0.95 fraction of the processors decode the correct interval in $\mathcal{B}_0$ and $\mathcal{B}_1$.

Algorithm 4: DETERMINEINTERVAL$(x_1, \ldots, x_n)$.

$A_1, A_2, \ldots, A_k$ are disjoint intervals of size $\approx 2t\sqrt{n}$ covering $[0, n]$, with t chosen later.
Let A_i be $\varnothing$ if $i < 1$ or $i > k$.
$B_i := A_i \cup A_{i+1} \cup A_{i+2}$.
$\mathcal{B}_s := \{B_i : i \equiv s \bmod 3\}$.
Enc is the encoding function of a code with relative distance 0.25 and constant rate K.

---

1. Transmit x_i
2. Compute $h_i := \frac{\text{number of 1's received}}{1-p}$
3. For $s = 0, 1, 2$:
   a. Find interval in $\mathcal{B}_s$ containing h_i, called I. I is encoded as a string s_I (of size $O(\log n)$).
   b. Let $i' = i \bmod \log n$ and transmit $\mathsf{Enc}(s_I)_{[K(i'-1)+1, Ki']}$ over K rounds
   c. $C_{i,s} := \begin{cases} s_I & \text{if at least } .88K \log n \text{ bits were received in Step 3b} \\ \text{decoded string} & \text{if fewer than } .88K \log n \text{ bits were received in Step 3b} \end{cases}$
4. Return $C_{i,0}, C_{i,1}$ and $C_{i,2}$.

And assuming at least 0.95 fraction of the processors decode the correct intervals in $\mathcal{B}_0$ and $\mathcal{B}_1$, we can show once again using Chernoff bounds and union bound, that the number of bits from the encoded string of the correct interval received by each processor is more than $0.9Kn$ with probability at least $1 - \exp(-\Omega(n))$, which means with exponentially high probability, every processor decodes the correct interval in $\mathcal{B}_0$ and $\mathcal{B}_1$. ◀

For the second step, our goal is the following: given that every processor knows an interval $[a, b]$ in which the Hamming weight of the input string lies, it can recover the value of the Hamming weight in $O(1)$ rounds.

▶ **Lemma 10.** *On running Algorithm 5, all processors return the Hamming weight s of X with probability at least* 0.9.

Proof. Define $\widehat{\theta}_s$ to be the fraction of β_i transmitted in Step 3 that are 1.

We can lower bound $\theta_{\ell+1} - \theta_\ell$ for $x \leq \ell < y$ by $\frac{c}{\sqrt{n}}$ where c is some constant [11, Lemma 41]. The probability that $|\theta_s - \widehat{\theta}_s|$ is at most $\frac{c}{8\sqrt{n}}$ can be made at least 0.99 with an appropriate choice of the number of repetitions γ. Similarly, we can ensure that $|\widehat{\theta}_s - \widehat{\theta}_{s,i}|$ is at most $\frac{c}{8\sqrt{n}}$ with probability at least 0.99.

By Chernoff bounds, the fraction of processors for which $|\widehat{\theta}_s - \widehat{\theta}_{s,i}| < \frac{c}{8\sqrt{n}}$ is at least 0.95 with probability at least $1 - \exp(-\Omega(n))$. Thus, conditioned on $|\theta_s - \widehat{\theta}_s| < \frac{c}{8\sqrt{n}}$, we have that for at least 0.95 of the processors, $|\theta_s - \widehat{\theta}_{s,i}| < \frac{c}{4\sqrt{n}}$. Further, the string $S_1 S_2 \ldots S_n$ transmitted in Step 6 with random erasures has distance less than the decoding radius of $\mathcal{C}$ of $\mathsf{Enc}(s)$ with probability at least $1 - \exp(-\Omega(n))$, in which case all processors can correctly output s.

Since the condition $|\theta_s - \widehat{\theta}_s| < \frac{c}{8\sqrt{n}}$ holds with probability at least 0.99, the required guarantees of the Lemma hold. ◀

Proof of Theorem 8. The processors run Algorithm 4 to obtain 3 candidate intervals I_1, I_2 and I_3, and with exponentially high probability, at least two of these candidate intervals

Algorithm 5: PINPOINTWEIGHT$(x_1, x_2, \ldots, x_n; [a, b])$.

$[a, b]$ is the interval of length up to $3\sqrt{n}$ where the Hamming weight is promised to lie
Enc is the encoding function of a code $\mathcal{C}$ with relative distance 0.25 that maps $\log n$ bit strings to $K \log n$ bit strings
Let θ_s be defined as the probability that when flipping s coins, each coming up heads with probability $1 - p$, at least $(1 - p)\left(\frac{a+b}{2}\right)$ come up heads.

---

1. Transmit x_i
   Let Y be the number of 1's received.
2. $\beta_i := \begin{cases} 1 & \text{if number of 1's received is greater than } (1-p)\left(\frac{a+b}{2}\right) \\ 0 & \text{otherwise} \end{cases}$
3. Transmit β_i
4. Let $\widehat{\theta}_{s,i}$ be the fraction of received bits from Step 3 that are 1 (i.e., the total number of 1's received, divided by the total number of 1's or 0's received).
5. $\widehat{s}_i = \arg\min_\ell |\theta_\ell - \widehat{\theta}_{s,i}|$
6. Let $i' = i \bmod \log n$ and transmit $\mathsf{Enc}(\widehat{s}_i)_{[K(i'-1)+1, Ki']}$ over K rounds
7. $\tilde{s}_i = \begin{cases} \text{decoded string} & \text{if at least } .88K \log n \text{ bits were received in Step 6} \\ \widehat{s}_i & \text{if fewer than } .88K \log n \text{ bits were received in Step 6} \end{cases}$

contain the Hamming weight. The processors run Algorithm 5 on each of the three intervals and processor i obtains outputs n_0, n_1 and n_2 respectively. With constant probability, at least two of n_0, n_1 and n_2 are the same and equal to the correct Hamming weight, and hence outputting the majority of the three matches the guarantee. ◀

Efficient Black-Box Reductions for Separable Cost Sharing

Abstract

In *cost sharing games with delays,* a set of agents jointly uses a finite subset of resources. Each resource has a fixed cost that has to be shared by the players, and each agent has a non-shareable player-specific delay for each resource. A prominent example is uncapacitated facility location (UFL), where facilities need to be opened (at a shareable cost) and clients want to connect to opened facilities. Each client pays a cost share and his non-shareable physical connection cost. Given any profile of subsets used by the agents, a *separable cost sharing protocol* determines cost shares that satisfy budget balance on every resource and separability over the resources. Moreover, a separable protocol guarantees existence of pure Nash equilibria in the induced strategic game for the agents.

In this paper, we study separable cost sharing protocols in several general combinatorial domains. We provide black-box reductions to reduce the design of a separable cost sharing protocol to the design of an approximation algorithm for the underlying cost minimization problem. In this way, we obtain new separable cost sharing protocols in games based on arbitrary player-specific matroids, single-source connection games without delays, and connection games on n-series-parallel graphs with delays. All these reductions are efficiently computable – given an initial allocation profile, we obtain a profile of no larger cost and separable cost shares turning the profile into a pure Nash equilibrium. Hence, in these domains any approximation algorithm can be used to obtain a separable cost sharing protocol with a price of stability bounded by the approximation factor.

1 Introduction

Cost sharing is a fundamental task in networks with strategic agents and has attracted a large amount of interest in algorithmic game theory. Traditionally, cost sharing has been studied in a cooperative sense, i.e., in the form of cooperative games or mechanism design. Many of these approaches treat cost in a *non-separable* way and return a single, global cost share for each agent. In contrast, when agents jointly design a resource infrastructure in large networks, it is much more desirable to provide algorithms and protocols for *separable* cost sharing that specify which agent needs to pay how much to each resource. Here the natural approach are strategic cost sharing games with n players that use subsets of m resources. Each resource generates a cost depending on the subset of players allocating it. A protocol determines a cost share for each resource and each player using it. In addition to separability, there are further natural desiderata for such protocols, such as budget-balance (distribute exactly the arising cost of each resource) and existence of a pure Nash equilibrium (PNE), i.e., allow the resulting game to stabilize.

Perhaps the most prominent such protocol is the fair share protocol, in which the cost of each resource is allocated in equal shares to the players using it. This approach has been studied intensively (see our discussion below), but there are several significant drawbacks. Even in connection games on undirected networks, it can be PLS-hard to find a PNE [51] and the PoS (the total cost of the best Nash equilibrium compared to the cost of the optimal allocation) is not known to be constant. This contrasts the fact that there are polynomial time approximation algorithms with low approximation factors, see, e.g. [12]. For directed networks the PoS can even be as large as $\Omega(\log n)$ [4, 17].

In this paper, we study a slight generalization of cost sharing games, where every resource has a shareable cost component and a non-shareable player-specific delay component. The shareable cost needs to be shared by the players using it, the non-shareable player-specific delay represents, e.g., a physical delay and is thus unavoidable. This setting arises in several relevant scenarios, such as uncapacitated facility location (UFL) [37]. Here players share the monetary cost of opened facilities but additionally experience delays measured by the distance to the closest open facility. Another important example appears in network design, where players jointly buy edges of a graph to connect their terminals. Besides the monetary cost for buying edges, each player experiences player-specific delays on the chosen paths. In such a distributed network environment, it is not clear a priori if an optimal solution can be stable – i.e., if the shareable costs can be distributed among the players in a separable way so that players do not want to deviate from it. This question leads directly to the design of protocols that distribute the costs in order to induce stable and good-quality solutions of the resulting strategic game.

Our results are three polynomial-time black-box reductions for the price of stability (PoS) of separable cost sharing protocols in combinatorial resource allocation problems. Our domains represent broad generalizations of UFL – arbitrary, player-specific matroids, single-source connection games without delays, and connection games on undirected n-series-parallel graphs with delays. In each of these domains, we take as input an arbitrary profile and efficiently turn it into a profile having no larger cost and a sharing of the shareable costs such that it is a Nash equilibrium. Our protocols are polynomial-time in several ways. Firstly, the games we study are succinctly represented. In matroids, we assume that strategies

are represented implicitly via an independence oracle. For connection games on graphs, the strategies of each player are a set of paths, which is implicitly specified by terminal vertices of the player and the graph structure. The cost sharing protocol is represented by a strategy profile S and a sharing of the shareable costs arising in S on each resource. While in principle the protocol must specify a sharing of the costs for all of the other (possibly exponentially many) strategy profiles, one can do so implicitly by a simple lexicographic assignment rule. It guarantees that the profile S becomes a PNE. As such, starting from an arbitrary initial profile S', we can give in polynomial time the Nash equilibrium profile S, the cost shares for S, and the assignment rule for cost shares in the other profiles. Hence, if S' is polynomial-time computable, then both protocol and Nash equilibrium S are both polynomial-time computable and polynomial-space representable.

1.1 Our Results

We present several new polynomial-time black-box reductions for separable cost sharing protocols with small PoS. We study three domains that represent broad generalizations of the uncapacitated facility location problem. In each domain, we devise an efficient black-box reduction that takes as input an arbitrary strategy profile and computes a new profile of no larger cost together with a separable cost sharing protocol inducing the new profile as a PNE. Thus, *any* polynomial-time α-approximation of the social cost can be turned into a separable cost sharing protocol with PoS at most α.

Matroidal Set Systems. In Section 3 we provide a black-box reduction for matroidal set systems. Our results even apply to the broad class of *subadditive* cost functions that include fixed costs and discrete concave costs even with weighted players as a special case. Here we assume access to a value oracle for the subadditive cost function for each resource. Matroidal set systems with player-specific delays include uncapacitated facility location as a special case, since these correspond to matroid games, where each player has a uniform rank 1 matroid. For *metric* UFL, there is for instance a 1.488-approximation algorithm [45] using ideas of a previous 1.5-approximation algorithm [11]. This leads to a separable cost sharing protocol with PoS equal 1.488. Also, the existing hardness results for UFL carry over, meaning that for any polynomial-time computable, separable cost sharing protocol, the cost of an equilibrium that can be computed in polynomial time is bounded from below by the inapproximability bound. For metric UFL there is a lower bound of 1.46 [31].

Single-Source Connection Games with Fixed Costs. In Section 4 we consider cost sharing games on graphs, where the set systems correspond to paths connecting a global source with a player-specific terminal. We again provide a polynomial-time black-box reduction. Our result improves significantly over the existing Prim-Sharing [17] with a PoS of 2. We obtain separable protocols based on any approximation algorithm for Steiner tree, such as, e.g., the classic 1.55-approximation algorithm [49], or the celebrated recent 1.39-approximation algorithm [12]. Our black-box reduction continues to hold even for directed graphs, where we can use any algorithm for the Directed Steiner Tree problem [15], or games based on the (directed or undirected) Group Steiner Tree problem [16, 26]. All lower bounds on approximation hardness translate to the quality of polynomial-time computable equilibria of polynomial-time computable separable protocols.

Connection Games With Delays. Finally, in Section 5 we study multi-terminal connection games with delays and fixed costs. For directed graphs, an optimal Steiner forest is not enforceable by a separable cost sharing protocol, even for two players [17]. Very recently,

a similar result was shown even for two-player games on undirected graphs [35]. Thus, for general graphs, we cannot expect separable protocols with optimal or close-to-optimal equilibria, or (efficient) black-box reductions. We introduce a class of so-called n-series-parallel graphs, which allows to obtain a black-box reduction in polynomial time. The transformation directly implies that the n-series-parallel graphs always admit a separable cost sharing protocol inducing an optimal Steiner forest as an equilibrium.

The reduction also applies to discrete-concave cost functions and player-specific delays, however, we do not know if polynomial running time is guaranteed. n-series-parallel graphs have treewidth at most 2, thus, for fixed edge costs and no delays, it is possible to compute efficiently even an optimal Steiner forest [7]. Hence, in this case we obtain a separable protocol with PoS of 1 in polynomial time. We finally demonstrate that the specific setting of n-series-parallel graphs is in some sense necessary: Even for generalized series-parallel graphs we give a counterexample showing that a black-box reduction is impossible to achieve.

1.2 Preliminaries and Related Work

Cooperative cost sharing games have been studied over the last decades for a variety of combinatorial optimization problems, such as minimum spanning tree [10], Steiner tree [29,30, 46,52], facility location [28], vertex cover [22], and many more. Cooperative cost sharing games have interesting implications for (group-)strategyproof cost sharing mechanisms [41,42,47,48]. For Bayesian cost-sharing mechanisms there even exist efficient black-box reductions from algorithm to mechanism design [27]. A major difference to our work is that cooperative cost sharing is *not separable*.

The most prominent example of a *separable* cost sharing protocol is the *fair share protocol*, in which the cost of each resource is divided in equal shares among the players that use it. This protocol is also anonymous, and it implies that the resulting game is a congestion game [50]. It guarantees the smallest PoS within a class of anonymous protocols [17]. The fair share protocol has attracted a serious amount of research interest over the last decade [1, 4, 8, 33], especially the notorious open problem of a constant PoS for connection games in undirected graphs [9, 23, 25, 43, 44]. However, as a significant drawback - outside of the domain of undirected connection games - the PoS is often as large as $\Omega(\log n)$, e.g. [17, 32].

More general separable protocols have been studied mostly in terms of the price of anarchy, e.g., for scheduling (or matroid games) [6, 13, 19, 24, 53] or single-source network design with [20, 21] and without uncertainty [17]. The best result here is a price of anarchy (and stability) of 2 via Prim-Sharing [17], a protocol inspired by Prim's MST algorithm. A protocol with logarithmic PoS was shown for capacitated UFL games [37].

We observe that separable protocols with low PoS can be obtained using results for cost sharing games with so-called "arbitrary sharing", where effectively players pay the cost increment when changing their strategy (see [36] for a formal definition). A PNE for arbitrary sharing can be translated directly into a PNE for a suitable separable cost sharing protocol. A simple proof of Proposition 1 can be found in the full version of this paper [34].

▶ **Proposition 1.** *If for a cost sharing model, the non-cooperative game with arbitrary sharing has a PNE, then there is a separable cost sharing protocol with the same PNE.*

This implies existence of separable protocols with optimal PNE and PoS 1 for a variety of classes of games, including matroid games with uniform discrete-concave costs [36], uncapacitated facility location with fixed [14] and discrete-concave costs [39], connection games (single-source [5, 38] and other classes [2, 3, 40]) with fixed costs, and more. However, the large majority of these results are *inefficient*, i.e., there is no polynomial-time algorithm that computes the required optimal equilibrium.

Alternatively, one may resort to approximate equilibria in games with arbitrary sharing that are efficiently computable. The most prominent technique works via reducing costs by an additive value ε to ensure polynomial running time (put forward for single-source connection games in [5] and used in much of the follow-up work [2, 3, 14, 38]). This approach *does not translate* to separable protocols, since a player must eventually contribute to *all resources*. This is impossible for the model we consider here.

2 Separable Cost Sharing Protocols

We are given a finite set N of players and a finite set E of resources. Each player $i \in N$ is associated with a predefined family of subsets $\mathcal{S}_i \subseteq 2^E$ from which player i needs to pick at least one. The space of strategy profiles is denoted by $\mathcal{S} := \times_{i \in N} \mathcal{S}_i$. For $S \in \mathcal{S}$ we denote by $N_e(S) = \{i \in N : e \in S_i\}$ the set of players that use resource e. Every resource $e \in E$ has a fixed cost $c_e \geq 0, e \in E$ that is assumed to be *shareable* by the players. In addition to the shareable costs, there are *player-specific constant costs* $d_{i,e} \geq 0, i \in N, e \in E$ that are not shareable. If player i chooses subset S_i, then the player-specific costs $\sum_{e \in S_i} d_{i,e}$ must be paid completely by player i. The total cost of a profile S is defined as $C(S) = \sum_{e \in \cup_{i \in N} S_i} c_e + \sum_{i \in N} \sum_{e \in S_i} d_{i,e}$.

A *cost sharing protocol* assigns cost share functions $\xi_{i,e} : \mathcal{S} \to \mathbb{R}_{\geq 0}$ for all $i \in N$ and $e \in E$ and thus induces the strategic game $(N, \mathcal{S}, \xi)$. For a player i, her total private cost of strategy S_i in profile S is $\pi_i(S) := \sum_{e \in S_i} (\xi_{i,e}(S) + d_{i,e})$. We assume that every player picks a strategy in order to minimize her private cost. A prominent solution concept in non-cooperative game theory are pure Nash equilibria. Using standard notation in game theory, for a strategy profile $S \in \mathcal{S}$ we denote by $(S'_i, S_{-i}) := (S_1, \ldots, S_{i-1}, S'_i, S_{i+1}, \ldots, S_n) \in \mathcal{S}$ the profile that arises if only player i deviates to strategy $S'_i \in \mathcal{S}_i$. A profile is a *pure Nash equilibrium (PNE)* if for all $i \in N$ it holds $\pi_i(S) \leq \pi_i(S'_i, S_{-i})$ for all $S'_i \in \mathcal{S}_i$.

In order to be practically relevant, cost sharing protocols need to satisfy several desiderata. In this regard, *separable* cost sharing protocols are defined as follows [17].

▶ **Definition 2** (Cost Sharing Protocols and Enforceability)**.** A cost sharing protocol is

1. *stable* if it induces only games that admit at least one pure Nash equilibrium.
2. *budget balanced,* if for all $e \in E$ with $N_e(S) \neq \emptyset$

$$c_e = \sum_{i \in N_e(S)} \xi_{i,e}(S) \text{ and } \xi_{i,e}(S) = 0 \text{ for all } i \notin N_e(S).$$

3. *separable* if it is stable, budget-balanced and induces only games for which in any two profiles $S, S' \in \mathcal{S}$ for every resource $e \in E$,

$$N_e(S) = N_e(S') \Rightarrow \xi_{i,e}(S) = \xi_{i,e}(S') \text{ for all } i \in N_e(S).$$

4. *polynomial time computable,* if the cost sharing functions ξ can be computed in polynomial time in the encoding length of the cost sharing game.

We call a strategy profile S *enforceable*, if there is a separable protocol inducing S as a PNE.

Separability means that for any two profiles S, S' the cost shares on e are the same if the set of players using e remains unchanged. Still, separable protocols can assign cost share functions that are specifically tailored to a given congestion model, for example based on an optimal profile. In this paper, we are additionally interested in *polynomial-time computable protocols* that we introduce here.

3 Matroid Games

In this section, we consider matroid games. As usual in matroid theory, we will write $\mathcal{B}_i$ instead of $\mathcal{S}_i$, and $\mathcal{B}$ instead of $\mathcal{S}$, when considering matroid games. The tuple $\mathcal{M} = (N, E, \mathcal{B}, (c_e)_{e\in E}, (d_{i,e})_{e\in E, i\in N})$ is called a *matroid game* if $E = \bigcup_{i\in N} E_i$, and each set system $\mathcal{B}_i \subseteq 2^{E_i}$ forms the base set of some matroid $\mathcal{M}_i = (E_i, \mathcal{B}_i)$. While seemingly abstract, the class includes several prominent application domains, such as UFL games. In a UFL game, the resources are facilities (e.g. common transport hubs) and the players incur delay $d_{i,e}$ in addition to their cost shares for opening used facilities. Every player i chooses exactly one resource, that is $|B_i| = 1$ for all $B_i \in \mathcal{B}_i$ and $i \in N$ and hence $\mathcal{B}_i$ corresponds to a *uniform matroid of rank one*. Recall that every base B of a matroid $\mathcal{M}_i = (E_i, \mathcal{B}_i)$ has the same cardinality which we denote with rk_i (the rank of $\mathcal{M}_i$).

In the following, instead of fixed costs on the resources, we allow for *subadditive* cost functions $c_e : 2^N \to \mathbb{R}_{\geq 0}, e \in E$. c_e is called *subadditive*, if it satisfies (1) $c_e(S) \leq c_e(T)$ for all $S \subseteq T \subseteq N$, and (2) $c_e(S + \{i\}) \leq c_e(S) + c_e(\{i\})$ for all $S \subset N, i \in N$. Note that subadditive functions include fixed costs, but also discrete concave costs, where the nondecreasing cost $c_e : \mathbb{N} \to \mathbb{R}_{\geq 0}$ depends on the number of players using e and satisfies $c_e(x + \delta) - c_e(x) \geq c_e(y + \delta) - c_e(y) \forall x \leq y;\ x, y, \delta \in \mathbb{N}$. As such, in the discrete concave setting, all players have the same weight of 1, whereas subadditive costs also allow for different weights (as in weighted congestion games). We furthermore assume $c_e(\emptyset) = 0, e \in E$.

Let us denote the cost of the cheapest alternative of player i to resource e for profile $B \in \mathcal{B}$ by $\Delta_i^e(B) := \min_{f\in E, B_i+f-e\in\mathcal{B}_i} (c_e(B_i + f - e, B_{-i}) + d_{i,f})$. Here we use the simplified notations $B_i + f - e := B_i \cup \{f\} \setminus \{e\}$ and $c_e(B) := c_e(N_e(B))$. We recapitulate the following characterization of enforceable strategy profiles (obtained in [37], where also a cost sharing protocol inducing the enforceable profile as a PNE is given).[1]

▶ **Lemma 3.** *A profile $B = (B_1, \ldots, B_n)$ is enforceable iff the following two properties are satisfied. Note that* (D1) *implies that each summand $\Delta_i^e(B) - d_{i,e}$ in* (D2) *is nonnegative.*

$$d_{i,e} \leq \Delta_i^e(B) \text{ for all } i \in N, e \in B_i \tag{D1}$$

$$c_e(B) \leq \sum_{i\in N_e(B)} (\Delta_i^e(B) - d_{i,e}) \text{ for all } e \in E. \tag{D2}$$

▶ Remark. The characterization was used in [37] to prove that an optimal collection of bases is enforceable. This implies a PoS of 1 for a separable cost sharing protocol that relies on the optimal profile. As such, the protocol is not efficiently computable (unless $P = NP$).

In the following, we devise a black-box reduction in Algorithm 1. It takes as input an arbitrary collection of bases B and transforms them *in polynomial time* into an enforceable set of bases B' of no larger cost. We define for each $i \in N, e \in E$ a *virtual cost value* $v_i^e := c_e(\{i\}) + d_{i,e}$, and for each $B \in \mathcal{B}, i \in N, e \in E$ a *virtual deviation cost* $\bar{\Delta}_i^e(B) := \min_{f\in E, B_i+f-e\in\mathcal{B}_i} v_i^f$. The algorithm now iteratively checks whether (D1) and (D2) from Lemma 3 hold true (in fact it checks this condition for smaller values on the right hand side given by the virtual values), and if not, exchanges one element of some player. We show that the algorithm terminates with an enforceable profile after polynomially many steps.

▶ **Theorem 4.** *Let B be a strategy profile for a matroid congestion model with subadditive costs. There is an enforceable profile B' with $C(B') \leq C(B)$ that can be computed in at most*

[1] The original characterization in [37] was proven for weighted players and load-dependent non-decreasing cost functions but the proof also works for subadditive cost functions.

Algorithm 1: Transforming any profile B into an enforceable profile B'

Input: Congestion model $(N, \mathcal{B}, c, d)$ and profile $B \in \mathcal{B}$
Output: Enforceable profile B' with $C(B') \leq C(B)$.

1 Set $B' \leftarrow B$
2 **while** *there is* $e \in E$ *that satisfies at least one of the following conditions:*

$$d_{i,e} > \bar{\Delta}_i^e(B') \text{ for some } i \in N_e(B') \quad (1) \text{ or}$$

$$c_e(B') > \sum_{i \in N_e(B')} \left(\bar{\Delta}_i^e(B') - d_{i,e}\right) \quad (2) \textbf{ do}$$

3 **if** (1) *holds true for some* $i \in N_e(B')$ **then**
4 Let $f_i \in \arg \min_{\substack{f \in E \\ B_i' + f - e \in \mathcal{B}_i}} v_i^f$
5 Update $B_i' \leftarrow B_i' + f_i - e$
6 **else if** (2) *holds true* **then**
7 **while** (2) *holds true on* e **do**
8 Pick $i \in N_e(B')$ with $v_i^e > \bar{\Delta}_i^e(B')$
9 Let $f_i \in \arg \min_{\substack{f \in E \\ B_i' + f - e \in \mathcal{B}_i}} v_i^f$
10 Update $B_i' \leftarrow B_i' + f_i - e$

$n \cdot m \cdot rk(\mathcal{B})$ iterations of the outer while-loop in Algorithm 1, where $rk(\mathcal{B}) = \max_{i \in N} rk_i$. Furthermore, each such iteration needs $\mathcal{O}(n \cdot m \cdot rk(\mathcal{B}) \cdot Q + (m+n) \cdot Q')$ time, where Q and Q' denote the maximum complexities of the independence oracles for the players' strategies, and of the value oracles for the subadditive cost functions of the resources, respectively.

Proof. First, observe that if (D1) and (D2) from Lemma 3 hold true for smaller values $0 \leq \bar{\Delta}_i^e(B) \leq \Delta_i^e(B), i \in N, e \in E$, then the profile B is also enforceable. Hence, if the algorithm terminates, the resulting strategy profile B' will be enforceable.

To show that the algorithm is well-defined, we only need to check Line 8. By subadditivity we get $\sum_{i \in N_e(B')} c_e(\{i\}) > c_e(B')$. Thus, whenever $c_e(B') > \sum_{i \in N_e(B')} \left(\bar{\Delta}_i^e(B') - d_{i,e}\right)$, there is an $i \in N_e(B')$ with $c_e(\{i\}) + d_{i,e} > \bar{\Delta}_i^e(B')$.

We now bound the running time. Consider player i and the matroid bases $\mathcal{B}_i$. We interpret a basis $B_i \in \mathcal{B}_i$ as distributing exactly rk_i unit sized packets over the resources in E. This way, we can interpret the algorithm as iteratively moving packets away from those resources $e \in E$ for which either (1) or (2) holds true. We give each packet a unique ID $i_k, k = 1, \ldots, \mathrm{rk}_i$. For $B_i \in \mathcal{B}_i$, let e_{i_k} denote the resource on which packet i_k is located. We now analyse the two types of packet movements during the execution of the algorithm. For a packet movement executed in Line 5 of Algorithm 1, we have $d_{i,e} > \bar{\Delta}_i^e(B')$, thus, when packet i_k located on $e = e_{i_k}$ is moved to f_i, it holds that $v_i^{e_{i_k}} = v_i^e \geq d_{i,e} > \bar{\Delta}_i^e(B') = v_i^{f_i}$. For packet movements executed in Line 10, then by the choice of player $i \in N_e(B')$ (see Line 8) for the corresponding packet i_k it holds $v_i^{e_{i_k}} = v_i^e > \bar{\Delta}_i^e(B') = v_i^{f_i}$. In both cases we obtain $v_i^e > v_i^{f_i}$. Hence, every movement of a single packet i_k is in strictly decreasing order of virtual value of the resource. Note that the virtual cost value v_i^e does not depend on profile B. Thus, there are at most m different virtual cost values that a packet i_k of player i can experience, and thus packet i_k can move at most $m - 1$ times. The following is an upper bound on the

total number of packet movements for all players $\sum_{i \in N} \mathrm{rk}_i \cdot (m-1) \leq n \cdot m \cdot \mathrm{rk}(\mathcal{B})$. Thus, the number of iterations of the outer while-loop can be at most that value. It is straightforward to observe the stated complexity of one iteration of the while-loop.

It is left to argue that the final output B' has cost at most $C(B)$. We prove this inductively by the different types of packet movements. Consider first a packet movement of type (1). Let B and B' be the profiles before and after packet i_k has been moved from e to f_i, respectively. We obtain (by using subadditivity and assumption (1))

$$\begin{aligned} C(B') - C(B) &= (c_{f_i}(B') - c_{f_i}(B) + d_{i,f_i}) - (c_e(B) - c_e(B') + d_{i,e}) \\ &\leq c_{f_i}(\{i\}) + d_{i,f_i} - (c_e(B) - c_e(B') + d_{i,e}) \\ &= \bar{\Delta}_i^e(B) - d_{i,e} + (c_e(B') - c_e(B)) \leq \bar{\Delta}_i^e(B) - d_{i,e} \quad < \quad 0. \end{aligned}$$

Now consider packet movements of type (2). We treat all movements occurring in one run of the while loop in Line 7. Let B denote the profile before and B' after all these movements. Let $T_e(B) \subseteq N_e(B)$ denote the set of those players whose packet i_k on e is moved to f_i for $i \in T_e(B)$ during the while loop. Let $F_e(B) = \bigcup_{i \in T_e(B)} \{f_i\}$ and for $i \in T_e(B)$ define $T_{f_i}(B) = \{j \in T_e(B) \mid f_j = f_i\}$. We derive some useful observations. Before entering the while loop, it holds

$$c_e(B) > \sum_{i \in N_e(B)} \left(\bar{\Delta}_i^e(B) - d_{i,e}\right) = \sum_{i \in N_e(B) \setminus T_e(B)} \left(\bar{\Delta}_i^e(B) - d_{i,e}\right) + \sum_{i \in T_e(B)} \left(\bar{\Delta}_i^e(B) - d_{i,e}\right). \quad (3)$$

Moreover, after exiting the while loop it holds

$$c_e(B') \leq \sum_{i \in N_e(B) \setminus T_e(B)} \left(\bar{\Delta}_i^e(B) - d_{i,e}\right). \quad (4)$$

Thus, combining (3) and (4) we get

$$c_e(B) - c_e(B') > \sum_{i \in T_e(B)} \left(\bar{\Delta}_i^e(B) - d_{i,e}\right). \quad (5)$$

Putting everything together, we obtain

$$\begin{aligned} C(B') - C(B) &= \sum_{f_i \in F_e(B)} \left(c_{f_i}(B') - c_{f_i}(B)\right) + \sum_{i \in T_e(B)} d_{i,f_i} - \left(c_e(B) - c_e(B') + \sum_{i \in T_e(B)} d_{i,e}\right) \\ &\leq \sum_{f_i \in F_e(B)} \sum_{j \in T_{f_i}(B)} c_{f_i}(\{i\}) + \sum_{i \in T_e(B)} d_{i,f_i} - \left(c_e(B) - c_e(B') + \sum_{i \in T_e(B)} d_{i,e}\right) \\ &= \sum_{i \in T_e(B)} \bar{\Delta}_i^e(B) - \left(c_e(B) - c_e(B') + \sum_{i \in T_e(B)} d_{i,e}\right) \quad < \quad 0, \end{aligned}$$

where the first inequality follows from subadditivity, and the last inequality from (5). ◀

4 Single-Source Connection Games without Delays

In this section, we study connection games in an undirected graph $G = (V, E)$ with a common source vertex $s \in V$. Every player i wants to connect a player-specific terminal node $t_i \in V$ to s. Consequently, every strategy P_i of player i is an (s, t_i)-path in G. We denote the set of paths for player i by $\mathcal{P}_i$ and the set of profiles by $\mathcal{P}$. Furthermore we focus on fixed shareable costs $c_e \geq 0$ and no player-specific delays $d_{i,e} = 0$, for all $i \in N$, $e \in E$.

For single-source games with delays, a black-box reduction is impossible to achieve, since one can construct instances where no optimal solution is enforceable. To see this, take any

multi-source multi-terminal connection game and introduce a new auxiliary source vertex s. Then connect s to each s_i with an auxiliary edge e_i, which has cost $c_{e_i} = 0$ and delays $d_{i,e_i} = 0$, $d_{j,e_i} = M$ for all other players j (for some prohibitively large constant M). Now in any equilibrium and any optimal state of the resulting game, player i will choose an (s, t_i)-path which begins with edge e_i. Moreover, e_i does not generate additional cost for player i. As such, the optimal solutions, the Nash equilibria, and their total costs correspond exactly to the ones of the original multi-source game. For the general multi-source case, there are instances with no enforceable optimal solution (even for only two players, see [35]).

For connection games with fixed shareable costs and no delays, the state of the art for polynomial-time cost sharing protocols is the Prim-Sharing protocol with a PoS of 2 [17]. Moreover, it is known that an optimal *tree* profile (a profile in which the union of player paths constitute a tree) is always enforceable [5,17]. Our result for polynomial-time computation of cheap enforceable profiles, stated in Theorem 5, represents a significant generalization – for any (possibly non-enforceable) tree profile, Algorithm 2 (given in detail in [34]) computes an enforceable profile that can only be cheaper in terms of total cost. Moreover, by combining the result with existing approximation algorithms, we obtain a protocol with PoS of 1.39.

▶ **Theorem 5.** *Let P be a strategy profile for a single-source connection game with fixed costs. There is an enforceable profile P' with $C(P') \leq C(P)$ that can be computed by Algorithm 2 in polynomial time.*

It is straightforward that for fixed costs we can transform each profile P into a tree profile $\hat{P}$, in which the union of player paths constitute a tree T, without increasing the cost. Over the course of the algorithm, we adjust this tree and construct a cost sharing for it in a bottom-up fashion. The approach has similarities to an approach for obtaining approximate equilibria for single-source cost sharing games with arbitrary sharing [5]. However, our algorithm exploits crucial properties of separable protocols, thereby providing an exact Nash equilibrium and polynomial running time.

When designing a separable protocol based on a state $\hat{P}$, we can always assume that when a player i deviates unilaterally to one or more edges $e \in G \setminus \hat{P}_i$, she needs to pay all of c_e. As such, player i always picks a collection of shortest paths with respect to c_e between pairs of nodes on her current path $\hat{P}_i$. All these paths in G are concisely represented in the algorithm as "auxiliary edges". The algorithm initially sets up an auxiliary graph $\hat{G}$ given by T and the set of auxiliary edges based on $\hat{P}$. It adjusts the tree T by removing edges of T and adding auxiliary edges in a structured fashion.

We first show in the following Lemma 6 (for a proof see [34]) that this adjustment procedure improves the total cost of the tree, and that the final tree $\hat{T}$ is enforceable in $\hat{G}$. In the corresponding cost sharing, every auxiliary edge contained in $\hat{T}$ is completely paid for by a single player that uses it. In the subsequent proof of Theorem 5, we only need to show that for the auxiliary edges in $\hat{T}$, the edge costs of the corresponding shortest paths in G can be assigned to the players such that we obtain an equilibrium in G. The proof shows that the profile P' evolving in this way is enforceable in G and has cost no larger than P.

▶ **Lemma 6.** *Algorithm 2 computes a cost sharing of a feasible tree $\hat{T}$ in the graph $\hat{G}$. The total cost $C(\hat{T}) \leq C(T)$, every auxiliary edge in $\hat{T}$ is paid for by a single player, and the corresponding profile $\hat{P}$ is enforceable in $\hat{G}$.*

Proof of Theorem 5. The previous lemma shows that the algorithm computes a cost sharing of a tree $\hat{T}$ in $\hat{G}$, such that every player is happy with the path $\hat{P}_i$ and every auxiliary edge in $\hat{T}$ is paid for completely by a single player. We now transform $\hat{P}$ into P' by replacing each

auxiliary edge $e = (u, v) \in \hat{P}_i$ by the corresponding shortest path $P(u, v)$ in G. We denote by E_i the set of edges introduced in the shortest paths for auxiliary edges in $\hat{P}_i$. For the total cost of the resulting profile we have that $C(P') \leq C(\hat{P}) \leq C(P)$, since the sets E_i can overlap with each other or the non-auxiliary edges of $\hat{T}$.

We show that P' is enforceable by transforming the cost sharing constructed in function $\hat{c}$ into separable cost sharing functions as follows. Initially, set $\xi_{i,e}(P') = 0$ for all $e \in E$ and $i \in N$. Then, for each non-auxiliary edge $e \in \hat{T}$ we assign $\xi_{i,e}(P') = \hat{c}_e(i)$ if $e \in \hat{P}_i$ and $\xi_{i,e}(P') = 0$ otherwise. Finally, number players arbitrarily from 1 to n and proceed in that order. For player i, consider the edges in E_i. For every $e \in E_i$, if $\sum_{j<i} \xi_{j,e}(P') = 0$, then set $\xi_{i,e}(P') = c_e$.

This yields a budget-balanced assignment for state P'. As usual, if a player i deviates in P' from P'_i to P''_i, we can assume player i is assigned to pay the full cost c_e for every edge $e \in P''_i \setminus P'_i$. To show that there is no profitable deviation from P', we first consider a thought experiment, where every edge in E_i comes as a separate edge bought by player i. Then, clearly P' is enforceable – the cost of P'_i with ξ is exactly the same as the cost of $\hat{P}$ with $\hat{c}$ in $\hat{G}$. Moreover, any deviation P''_i can be interpreted as an (s, t_i)-path in $\hat{G}$ by replacing all subpaths consisting of non-auxiliary edges in P'' by the corresponding auxiliary edge of $\hat{G}$. As such, the cost of P''_i is exactly the same as the cost of the corresponding deviation in $\hat{G}$. Now, there is not a separate copy for every edge in E_i. The set E_i can overlap with other sets E_j and/or non-auxiliary edges. Then player i might not need to pay the full cost on some $e \in E_i$. Note, however, every edge for which player i pays less than c_e is present in P'_i as well. Hence, P''_i cannot improve over P'_i due to this property. ◀

The result continues to hold for various generalizations. For example, we can immediately apply the arguments in directed graphs, where every player i seeks to establish a directed path between t_i and s. Moreover, the proof can also be applied readily for a group-connection game, where each player wants to establish a directed path to s from *at least one node of a set* $V_i \subset V$. For this game, we simply add a separate super-terminal t_i for every player i and draw a directed edge of cost 0 from t_i to every node in V_i.

▶ **Corollary 7.** *Let P be a strategy profile for a single-source group-connection game in directed graphs with fixed costs. There is an enforceable profile P' with $C(P') \leq C(P)$ that can be computed by Algorithm 2 in polynomial time.*

5 Connection Games and Graph Structure

In this section, we consider connection games played in undirected graphs $G = (V, E)$ with player-specific source-terminal pairs. Each player $i \in N$ has a source-terminal-pair (s_i, t_i). Consequently, every strategy P_i of player i is an (s_i, t_i)-path in G. We denote the set of paths for player i by $\mathcal{P}_i$.

Note that we can assume w.l.o.g. that $(G, (s_1, t_1), \ldots, (s_n, t_n))$ is *irredundant*, meaning that each edge and each vertex of G is contained in at least one (s_i, t_i)-path for some player $i \in N$ (nodes and edges not used by any player can easily be recognized (and then deleted) by Algorithm Irredundant in [34]; adapted from Algorithm 1 in [18]).
For the special case without delays, enforceability was characterized via an LP in [35]. We

can directly adapt this characterization as follows. For a strategy profile $P = (P_1, \dots, P_n)$:

$$\text{LP}(P) \quad \max \sum_{i \in N, e \in P_i} \xi_{i,e} \text{ s.t.: } \sum_{i \in N_e(P)} \xi_{i,e} \leq c_e \forall e \in E \text{ with } N_e(P) \neq \emptyset,$$
$$\sum_{e \in P_i \setminus P_i'} (\xi_{i,e} + d_{i,e}) \leq \sum_{e \in P_i' \setminus P_i} (c_e + d_{i,e}) \ \forall P_i' \in \mathcal{P}_i \ \forall i \in N \qquad \text{(NE)}$$
$$\xi_{i,e} \geq 0 \ \forall e \in P_i \ \forall i \in N$$

▶ **Theorem 8.** *P is enforceable iff there is an optimal solution $(\xi_{i,e})_{i \in N, e \in P_i}$ for LP(P) with*
$$\textstyle\sum_{i \in N_e(P)} \xi_{i,e} = c_e \ \forall e \in E \text{ with } N_e(P) \neq \emptyset. \qquad \text{(BB)}$$

Given an optimal solution $(\xi_{i,e})_{i \in N, e \in P_i}$ for LP(P) with the property (BB), the profile P becomes a PNE in the game induced by ξ, which assigns for each $i \in N$ and $e \in E$ and each strategy profile $P' = (P_1', \dots, P_n')$ the following cost shares (these cost shares resemble those introduced in [53]; the proof that P is a PNE can be directly adapted from [35]):

$$\xi_{i,e}(P') = \begin{cases} \xi_{i,e}, & \text{if } i \in S_e(P') = S_e(P), \\ c_e, & \text{if } i \in (S_e(P') \setminus S_e(P)) \text{ and } i = \min(S_e(P') \setminus S_e(P)), \\ c_e, & \text{if } i \in S_e(P') \subsetneq S_e(P) \text{ and } i = \min S_e(P'), \\ 0, & \text{else.} \end{cases}$$

We now introduce a subclass of generalized series-parallel graphs for which we design a polynomial time black-box reduction.

▶ **Definition 9** (*n*-series-parallel graph)**.** An irredundant graph $(G, (s_1, t_1), \dots, (s_n, t_n))$ is *n-series-parallel* if, for all $i \in N$, the subgraph G_i (induced by $\mathcal{P}_i$) is created by a sequence of series and/or parallel operations starting from the edge $s_i - t_i$. For an edge $e = u - v$, a series operation replaces it by a new vertex w and two edges $u - w, w - v$; a parallel operation adds to $e = u - v$ a parallel edge $e' = u - v$.

▶ **Theorem 10.** *If $(G, (s_1, t_1), \dots, (s_n, t_n))$ is n-series-parallel, the following holds:*

(1) *Given an arbitrary strategy profile P, an enforceable strategy profile P' with cost $C(P') \leq C(P)$, and corresponding cost share functions ξ, can be computed in polynomial time.*

(2) *For all cost functions c, d, every optimal strategy profile of $(G, (s_1, t_1), \dots, (s_n, t_n), c, d)$ is enforceable.*

(3) *For all edge costs c, an optimal Steiner forest of $(G, (s_1, t_1), \dots, (s_n, t_n), c)$ can be computed in polynomial time.*

Proof Sketch for Theorem 10. We first describe how to compute, given an arbitrary profile $P = (P_1, \dots, P_n)$, an enforceable strategy profile with cost at most $C(P)$. Assume that P is not enforceable, and let $(\xi_{i,e})_{i \in N, e \in P_i}$ be an optimal solution for LP(P). In the following, we denote the variables $(\xi_{i,e})_{i \in N, e \in P_i}$ as *cost shares*, although they do not correspond to a budget-balanced cost sharing protocol (since P is not enforceable). There is at least one edge f which is not completely paid, i.e. $\sum_{i \in N_f(P)} \xi_{i,f} < c_f$ holds. The optimality of the cost shares implies that each player $i \in N_f(P)$ has an alternative path P_i' with $f \notin P_i'$ and equality in the corresponding LP(P)-inequality (so-called *tight alternative* of player i that substitutes f). Furthermore, if the path P_i of player i contains more than one edge which is not completely paid, there is a tight alternative P_i' for player i which substitutes all non-paid edges. Figure 1 illustrates this for the case that P_i (straight edges) contains the three non-paid edges f, g, h, and player i substitutes them by using P_i' (thick edges).

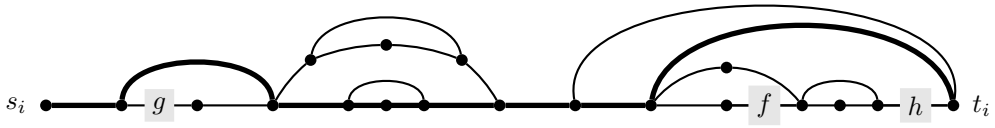

Figure 1 Illustration for substitution of nonpaid edges.

The high-level idea of the algorithm now is that all players with unpaid edges in their paths deviate from those edges by using tight alternatives until we reach a strategy profile in which all edges are completely paid. This strategy profile will then be enforceable and cheaper than P. In the following we explain this in more detail. Let $P' = (P'_1, \dots, P'_n)$ be the strategy profile which results from P if all players with unpaid edges in their paths substitute all these edges by a tight alternative path (as described above). Furthermore we define cost shares (again not nec. budget-balanced) for P' (for each player $i \in N, e \in P'_i$):

$$\xi_{i,e}(P') = \begin{cases} \xi_{i,e}, & \text{for } e \in P'_i \cap P_i, \\ c_e, & \text{for } e \in P'_i \setminus P_i. \end{cases}$$

If $\sum_{i \in N_e(P')} \xi_{i,e}(P') \geq c_e$ holds for all edges e with $N_e(P') \neq \emptyset$, the profile P' has the desired properties: The cost of P' is strictly smaller than P since the private costs of the players remain unchanged if they use tight alternatives. Furthermore the cost shares $(\xi_{i,e}(P'))_{i \in N, e \in P'_i}$ induce a feasible solution of $\mathrm{LP}(P')$ with (BB); thus P' is enforceable (we possibly need to decrease some cost shares to get a feasible solution of $\mathrm{LP}(P')$).

It remains to consider the case that there is at least one edge f which is not completely paid, i.e. for which $\sum_{i \in N_f(P')} \xi_{i,f}(P') < c_f$ holds. We can show that all users of nonpaid edges again have tight alternatives which substitute those edges, therefore we can again update the strategy profile (resulting in P'') and the corresponding cost shares. If now all edges are completely paid, P'' has the desired properties. Proceeding in this manner, we can show that one finally reaches a strategy profile for which all edges are completely paid; thus it is enforceable and cheaper than the profile P. Algorithm n-SePa in [34] summarizes the described procedure. To complete the proof of the first statement of Theorem 10, it remains to show that P' and ξ can be computed in polynomial time, i.e. Algorithm n-SePa has polynomial running time. This follows from two facts. First, the number of strategy profiles that we have to consider until we reach the desired strategy profile is bounded by $|P|$, the number of edges in the union of the paths $P_1, \dots, P_n$. Second, we can solve $\mathrm{LP}(P)$ in polynomial time. To this end we show that, for every player i, we do not need to consider all paths $P'_i \in \mathcal{P}_i$ in (NE) of $\mathrm{LP}(P)$, which can be exponentially many paths, but only a set of *alternatives* $\mathcal{A}_i$ of polynomial cardinality. Algorithm Alternatives(i) in [34] computes this set of alternatives. This completes the proof sketch for the first statement of Theorem 10.

Our analysis of the cost of P' immediately implies that every optimal strategy profile has to be enforceable: Otherwise Algorithm n-SePa computes a strategy profile with strictly smaller cost; contradiction. Thus the second statement of Theorem 10 holds.

The third statement follows from [7] where it is shown that an optimal Steiner forest can be computed in polynomial time if the underlying graph has treewidth at most 2. We show that every n-series-parallel graph is generalized series-parallel, and since these graphs have treewidth at most 2, the desired result follows. For a full proof of Theorem 10, see [34]. ◀

▶ Remark. The first two results of Theorem 10 can be generalized to nonnegative, nondecreasing and discrete-concave shareable edge cost functions. However, we do not know whether or not polynomial running time can be guaranteed.

We now demonstrate in Theorem 11 (for a proof see [34]) that the assumption of n-series-parallel graphs is in some sense well justified. Recall that a *generalized series-parallel graph* is created by a sequence of series, parallel, and/or add operations starting from a single edge, where an *add* operation adds a new vertex w and connects it to an existing vertex v by the edge $w - v$. The proofs of Theorem 10 and Theorem 11 show that the n-series-parallel graphs form a proper subclass of the generalized series-parallel graphs.

▶ **Theorem 11.** *For $n \geq 3$ players, there is a generalized series-parallel graph with fixed edge costs and no player-specific delays, so that the unique optimal Steiner forest is not enforceable. Therefore, a black-box reduction as for n-series-parallel graphs is impossible for generalized series-parallel graphs (even without player-specific delays).*

Abstract

We study the price of anarchy of mechanisms in the presence of risk-averse agents. Previous work has focused on agents with quasilinear utilities, possibly with a budget. Our model subsumes this as a special case but also captures that agents might be less sensitive to payments than in the risk-neutral model. We show that many positive price-of-anarchy results proved in the smoothness framework continue to hold in the more general risk-averse setting. A sufficient condition is that agents can never end up with negative quasilinear utility after playing an undominated strategy. This is true, e.g., for first-price and second-price auctions. For all-pay auctions, similar results do not hold: We show that there are Bayes-Nash equilibria with arbitrarily bad social welfare compared to the optimum.

1 Introduction

Many practical, "simple" auction mechanisms are not incentive compatible, making it beneficial for agents to behave strategically. A standard example is the first-price auction, in which one item is sold to one of n agents. Each of these agents is asked to report a valuation; the item is given to the agent reporting the highest value, who then has to pay what he/she reported. A common way to understand the effects of strategic behavior is to study resulting equilibria and to bound the *price of anarchy*. That is, one compares the social welfare that is achieved at the (worst) equilibrium of the induced game to the maximum possible welfare. Typical equilibrium concepts are Bayes-Nash equilibria and (coarse) correlated equilibria, which extend mixed Nash equilibria toward incomplete information or learning settings respectively. A key assumption in these analyses is that agents are *risk neutral*: Agents are assumed to maximize their expected quasilinear utility, which is defined to be the difference of the value associated to the outcome and payment imposed to the agent. So, an agent having a value of 1 for an item would be indifferent between getting this item with probability 10% for free and getting it all the time, paying 0.9.

However, there are many reasons to believe that agents are not risk neutral. For instance, in the above example the agent might favor the certain outcome to the uncertain one. Therefore, in this paper, we ask the question: *What "simple" auction mechanisms preserve good performance guarantees in the presence of risk-averse agents?*

The standard model of risk aversion in economics (see, e.g., [16]) is to apply a (weakly) concave function to the quasilinear term. That is, if agent i's outcome is x_i and his payment is p_i, his utility is given as $u_i(x_i, p_i) = h_i(v_i(x_i) - p_i)$, where $h_i \colon \mathbb{R} \to \mathbb{R}$ is a weakly concave, monotone function. That is, for $y, y' \in \mathbb{R}$ and for all $\lambda \in [0, 1]$, it holds that $h_i(\lambda y + (1-\lambda)y') \geq \lambda h_i(y) + (1-\lambda)h_i(y')$. Agent i is risk neutral if and only if h_i is a linear function. If the function is strictly concave, this has the effect that, by Jensen's inequality, the utility for fixed x_i and p_i is higher than for a randomized x_i and p_i with the same expected $v_i(x_i) - p_i$.

We compare outcomes based on their social welfare, which is defined to be the sum of utilities of all involved parties including the auctioneer. That is, it is the sum of agents' utilities and their payments $\mathrm{SW}(\mathbf{x}, \mathbf{p}) = \sum_i u_i(x_i, p_i) + \sum_i p_i$. In the quasilinear setting this definition of social welfare coincides with the sum of values $\sum_i v_i(x_i)$. With risk-averse utilities they usually differ. However, all our results bound the sum of values and therefore also hold for this benchmark.

We assume that the mechanisms are oblivious to the h_i-functions and work like in the quasilinear model. Only the individual agent's perception changes. This makes it necessary to normalize the h_i-functions because otherwise they could be on different scales, e.g., if $h_1(y) = y$ and $h_2(y) = 1000 \cdot y$, which would be impossible for the mechanism to cope with without additional information. Therefore, we will assume that $u_i(\mathbf{x}, p_i) = v_i(\mathbf{x})$ if $p_i = 0$ and that $u_i(\mathbf{x}, p_i) = 0$ if $p_i = v_i$. That is, for the two cases that p_i is either 0 or the full value, the utility matches exactly the quasilinear one. However, due to risk aversion, the agents might be less sensitive to payments.[1]

1.1 Our Contribution

We give bounds on the price of anarchy for Bayes-Nash and (coarse) correlated equilibria of mechanisms in the presence of risk-averse agents. Our positive results are stated within the smoothness framework, which was introduced by [24]. We use the version that is tailored to quasilinear utilities by [26], which we extend to mechanism settings with general utilities (for a formal definition see Section 4). Our main positive result states that the loss of performance compared to the quasilinear setting is bounded by a constant if a slightly stronger smoothness condition is fulfilled.

▶ **Main Result 1.** *Given a mechanism with price of anarchy α in the quasilinear model provable via smoothness such that the deviation guarantees non-negative utility, then this mechanism has price of anarchy at most 2α in the risk-averse model.*

This result relies on the fact that the deviation action to establish smoothness guarantees agents non-negative utility. A sufficient condition is that all undominated strategies never have negative utility. First-price and second-price auctions satisfy this condition, we thus get constant price-of-anarchy bounds for both of these auction formats.

[1] We note here that this will not in turn allow the mechanism to arrive at huge utility gains, as compared to the quasilinear model, for example, by increasing payments arbitrarily. Indeed, Lemma 1 in Section 3 will show that the difference between the two optima is bounded by at most a multiplicative factor of 2.

In an all-pay auction every positive bid can lead to negative utility. Therefore, the positive result does not apply. As a matter of fact, this is not a coincidence because, as we show, equilibria can be arbitrarily bad.

▶ **Main Result 2.** *The single-item all-pay auction has unbounded price of anarchy for Bayes-Nash equilibria, even with only three agents.*

This means that although equilibria of first-price and all-pay auctions have very similar properties with quasilinear utilities, in the risk-averse setting they differ a lot. We feel that this to some extent matches the intuition that agents should be more reluctant to participate in an all-pay auction compared to a first-price auction.

In our construction for proving Main Result 2, we give a symmetric Bayes-Nash equilibrium for two agents. The equilibrium is designed in such a way that a third agent of much higher value would lose with some probability with every possible bid. Losing in an all-pay auction means that the agent has to pay without getting anything, resulting in negative utility. In the quasilinear setting, this negative contribution to the utility would be compensated by respective positive amounts when winning. For the risk-averse agent in our example, this is not true. Because of the risk of negative utility, he prefers to opt out of the auction entirely.

We also consider a different model of aversion to uncertainty, in which solution concepts are modified. Instead of evaluating a distribution over utilities in terms of their expectation, agents evaluate them based on the expectation minus a second-order term. We find that this model has entirely different consequences on the price of anarchy. For example, the all-pay auction has a constant price of anarchy in correlated and Bayes-Nash equilibria, whereas the second-price auction can have an unbounded price of anarchy in correlated equilibria.

1.2 Related Work

Studying the impact of risk-averseness is a regularly reoccurring theme in the literature. A proposal to distinguish between money and the utility of money, and to model risk aversion by a utility function that is concave first appeared in [1]. The expected utility theory, which basically states that the agent's behavior can be captured by a utility function and the agent behaves as a maximizer of the expectation of his utility, was postulated in [27]. This theory does not capture models that are standardly used in portfolio theory, "expectation minus variance" or "expectation minus standard deviation" [14], the latter of which we also consider in Section 7.

In the context of mechanisms, one usually models risk aversion by concave utility functions. One research direction in this area is to understand the effects of risk aversion on a given mechanism. For example, [6] studies symmetric equilibria in all-pay auctions with a homogenous population of risk-averse players. Due to symmetry and homogeneity, in this case, equilibria are fully efficient, that is, the price of anarchy is 1. In [18] a similar analysis for auctions with a buyout option is performed; [10] considers customers with heterogeneous risk attitudes in mechanisms for cloud resources. In [4] it is shown that for certain classes of mechanisms the correlated equilibrium is unique and has a specific structure depending on the respective valuations but independent of the actual utility function. One consequence of this result is that risk aversion does not influence the allocation outcome or the revenue.

Another direction is to design mechanisms for the risk-averse setting. For example, the optimal revenue is higher because buyers are less sensitive to payments. In a number of papers, mechanisms for revenue maximization are proposed [19, 17, 25, 11, 2, 7]. Furthermore, randomized mechanisms that are *truthful in expectation* lose their incentive properties if agents

are not risk neutral. Black-box transformations from truthful-in-expectation mechanisms into ones that fulfill stronger properties are given in [3] and [8].

Studying the effects of risk aversion also has a long history in game theory, where different models of agents' attitudes towards risk are analyzed. One major question is, for example, if equilibria still exist and if they can be computed [5, 9]. Price of anarchy analyses have so far only been carried out for congestion games. Tight bounds on the price of anarchy for atomic congestion games with affine cost functions under a range of risk-averse decision models are given in [23].

The smoothness framework was introduced by [24]. Among others, [26] tailored it to the quasilinear case of mechanisms. It is important to remark here that our approach is different from the one taken by [20]. They use the smoothness framework to prove generalized price of anarchy bounds for nonatomic congestion games in which players have biased utility functions. They assume that players are playing the "wrong game" and their point of comparison is the "true" optimal social welfare, meaning that the biases only determine the equilibira but do not affect the social welfare. We take the utility functions as they are, including the risk aversion, to evaluate social welfare in equilibria and also to determine the optimum, which makes our models incomparable.

For precise relation of von Neumann-Morgenstern preferences to mean-variance preferences, see for instance [15]. Mean-variance preferences were explored for congestion games in [21, 22], while [13] studies the bidding behavior in an all-pay auction depending on the level of variance-averseness.

2 Preliminaries

2.1 Setting

We consider the following setting: There is a set N of n players and $\mathcal{X}$ is the set of possible outcomes. Each player i has a utility function $u_i^{\theta_i}$, which is parameterized by her type $\theta_i \in \Theta_i$. Given a type θ_i, an outcome $\mathbf{x} \in \mathcal{X}$, and a payment $p_i \geq 0$, her utility is $u_i^{\theta_i}(\mathbf{x}, p_i)$. The traditionally most studied case are quasilinear utilities, in which types are valuation functions $v_i \in \mathcal{V}_i$, $v_i \colon \mathcal{X} \to \mathbb{R}$ and $u_i^{v_i}(\mathbf{x}, p_i) = v_i(\mathbf{x}) - p_i$. Throughout this paper, we will refer to quasilinear utilities by $\hat{u}_i^{v_i}$.

For fixed utility functions and types, the social welfare of an outcome $\mathbf{x} \in \mathcal{X}$ and payments $(p_i)_{i \in N}$ is defined as $\mathrm{SW}^{\boldsymbol{\theta}}(\mathbf{x}, \mathbf{p}) := \sum_{i \in N} u_i^{\theta_i}(\mathbf{x}, p_i) + \sum_{i \in N} p_i$. In the quasilinear case, this simplifies to $\sum_{i \in N} v_i(\mathbf{x})$. Unless noted otherwise, by $\mathrm{OPT}(\boldsymbol{\theta})$, we will refer to the optimal social welfare under type profile $\boldsymbol{\theta}$, i.e., $\max_{\mathbf{x},\mathbf{p}} \mathrm{SW}^{\boldsymbol{\theta}}(\mathbf{x}, \mathbf{p})$.

A *mechanism* is a triple $(\mathcal{A}, X, P)$, where for each player i, there is a set of actions $\mathcal{A}_i$ and $\mathcal{A} = \times_i \mathcal{A}_i$ is the set of action profiles, $X \colon \mathcal{A} \to \mathcal{X}$ is an allocation function that maps actions to outcomes and $P \colon \mathcal{A} \to \mathbb{R}_+^n$ is a payment function that maps actions to payments p_i for each player i. Given an action profile $\mathbf{a} \in \mathcal{A}$, we will use the short-hand notation $u_i^{\theta_i}(\mathbf{a})$ to denote $u_i^{\theta_i}(X(\mathbf{a}), p_i)$.

2.2 Solution Concepts

In the setting of *complete information*, the type profile $\boldsymbol{\theta}$ is fixed. We consider (coarse) correlated equilibria, which generalize Nash equilibria and are the outcome of (no-regret) learning dynamics. A *correlated equilibrium (CE)* is a distribution $\mathbf{a}$ over action profiles from $\mathcal{A}$ such that for every player i and every strategy a_i in the support of $\mathbf{a}$ and every action

$a_i' \in \mathcal{A}_i$, player i does not benefit from switching to a_i' whenever he was playing a_i. Formally,

$$\mathbb{E}_{\mathbf{a}_{-i}|a_i}[u_i(\mathbf{a})] \geq \mathbb{E}_{\mathbf{a}_{-i}|a_i}[u_i(a_i', \mathbf{a}_{-i})], \forall a_i' \in \mathcal{A}_i, \forall i \ .$$

In *incomplete information*, the type of each player is drawn from a distribution F_i over her type space Θ_i. The distributions are common knowledge and the draws are independent among players. The solution concept we consider in this setting is the *Bayes-Nash Equilibrium*. Here, the strategy of each player is now a (possibly randomized) function $s_i \colon \Theta_i \to \mathcal{A}_i$. The equilibrium is a distribution over these functions s_i such that each player maximizes her expected utility conditional on her private information. Formally,

$$\mathbb{E}_{\boldsymbol{\theta}_{-i}|\theta_i}[u_i^{\theta_i}(\mathbf{s}(\boldsymbol{\theta}))] \geq \mathbb{E}_{\boldsymbol{\theta}_{-i}|\theta_i}[u_i^{\theta_i}(a_i, \mathbf{s}_{-i}(\boldsymbol{\theta}_{-i}))], \forall a_i \in \mathcal{A}_i, \forall \theta_i \in \Theta_i, \forall i \ .$$

The measure of efficiency is the expected social welfare over the types of the players: given a strategy profile $\mathbf{s} \colon \times_i \Theta_i \to \times_i \mathcal{A}_i$, we consider $\mathbb{E}_{\boldsymbol{\theta}}[\mathrm{SW}^{\boldsymbol{\theta}}(\mathbf{s}(\boldsymbol{\theta}))]$. We compare the efficiency of our solution concept with respect to the expected optimal social welfare $\mathbb{E}_{\boldsymbol{\theta}}[\mathrm{OPT}(\boldsymbol{\theta})]$.

The *price of anarchy (PoA)* with respect to an equilibrium concept is the worst possible ratio between the optimal expected welfare and the expected welfare at equilibrium, that is

$$\mathrm{PoA} = \max_{F} \max_{D \in EQ(F)} \frac{\mathbb{E}_{\boldsymbol{\theta} \sim F}[\mathrm{OPT}(\boldsymbol{\theta})]}{\mathbb{E}_{\boldsymbol{\theta} \sim F, \mathbf{a} \sim D}[\mathrm{SW}^{\boldsymbol{\theta}}(\mathbf{a})]} \ ,$$

where by $F = F_1 \times \cdots \times F_n$ we denote the product distribution of the players' type distributions and by $EQ(F)$ the set of all equilibria, which are probability distributions over action profiles.

We assume that players always have the possibility of not participating, hence any rational outcome has non-negative utility in expectation over the non-available information and the randomness of other players and the mechanism.

3 Modeling Risk Aversion

When modeling risk aversion, one wants to capture the fact that a random payoff (lottery) X is less preferred than a deterministic one of value $\mathbf{E}[X]$. The standard approach is, therefore, to apply a concave non-decreasing function $h \colon \mathbb{R} \to \mathbb{R}$ to X and consider $h(X)$ instead. By Jensen's inequality, we now know $\mathbf{E}[h(X)] \leq h(\mathbf{E}[X])$.

In the case of mechanism design, the utility of a risk-neutral agent is defined as the quasilinear utility $v_i(\mathbf{x}) - p_i$. That is, if an agent has a value of 1 for an item and has to pay 0.9 for it, then the resulting utility is 0.1. The expected utility is identical if the agent only gets the item with probability 0.1 for free. To capture the effect that the agent prefers the certain outcome to the uncertain one, we again apply a concave function $h_i \colon \mathbb{R} \to \mathbb{R}$ to the quasilinear term $v_i(\mathbf{x}) - p_i$. We then consider utility functions $u_i(\mathbf{x}, p_i) = h_i(v_i(\mathbf{x}) - p_i)$ in the setting described in Section 2. Note that the mechanisms we consider do not know the h_i-functions. They work as if all utility functions were quasilinear.

We want to compare outcomes based on their social welfare. We use the definition of social welfare being the sum of utilities of all involved parties including the auctioneer. That is, $\mathrm{SW}(\mathbf{x}, \mathbf{p}) = \sum_{i \in N} u_i(\mathbf{x}, p_i) + \sum_{i \in N} p_i$. It is impossible for any mechanism to choose good outcomes for this benchmark if the h_i-function are arbitrary and unknown. Therefore, we assume that utility functions are normalized so that the utility matches the quasilinear one for $p_i = 0$ and $p_i = v_i(\mathbf{x})$ (see Figure 1). In more detail, we assume the following *normalized risk-averse utilities*:

1. $u_i^{v_i}(\mathbf{x}, p_i) \geq u_i^{v_i}(\mathbf{x}, p_i')$ if $p_i \leq p_i'$ (monotonicity)
2. $u_i^{v_i}(\mathbf{x}, p_i) = 0$ if $p_i = v_i(\mathbf{x})$ (normalization at $p_i = v_i(\mathbf{x})$)

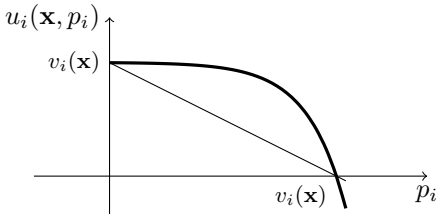

Figure 1 Normalized risk-averse utility function (bold) and quasilinear utility function for a fixed allocation $\mathbf{x}$ and varying payment p_i.

3. $u_i^{v_i}(\mathbf{x}, p_i) = v_i(\mathbf{x})$ if $p_i = 0$ (normalization at $p_i = 0$)
4. $u_i^{v_i}(\mathbf{x}, p_i) \geq v_i(\mathbf{x}) - p_i$ if $0 \leq p_i \leq v_i(\mathbf{x})$ and $u_i^{v_i}(\mathbf{x}, p_i) \leq v_i(\mathbf{x}) - p_i$ otherwise (relaxed concavity)

Assumption 4 is a relaxed version of concavity that suffices our needs for the positive results. Our negative results always fulfill concavity.

As an effect of normalization, the optimal social welfare of the risk-averse setting can be bounded in terms of the optimal sum of values, which coincides with the social welfare for quasilinear utilities.

▶ **Lemma 1.** *Given valuation functions $(v_i)_{i\in N}$ and normalized risk-averse utilities $(u_i^{v_i})_{i\in N}$, let OPT denote the optimal social welfare with respect to utilities $(u_i^{v_i})_{i\in N}$ and $\widehat{OPT}$ denote the optimal social welfare with respect to quasilinear utilities $(\hat{u}_i^{v_i})_{i\in N}$. Then, $OPT \leq 2\widehat{OPT}$.*

Proof. Let $\mathbf{x}$, $\mathbf{p}$ denote the outcome and payment profile that maximizes the social welfare $\sum_{i\in N} u_i^{v_i}(\mathbf{x}, p_i) + \sum_{i\in N} p_i$. Consider a fixed player i. If $0 \leq p_i \leq v_i(\mathbf{x})$, then by monotonicity of $u_i^{v_i}(\mathbf{x}, \cdot)$ and Assumption 3, $u_i^{v_i}(\mathbf{x}, p_i) + p_i \leq u_i^{v_i}(\mathbf{x}, 0) + p_i \leq 2v_i(\mathbf{x})$. If $p_i > v_i(\mathbf{x})$, then we know from Assumption 4 that $u_i^{v_i}(\mathbf{x}, p_i) + p_i \leq v_i(\mathbf{x})$. So, always, $u_i^{v_i}(\mathbf{x}, p_i) + p_i \leq 2v_i(\mathbf{x})$.

By taking the sum over all players, we get $\mathrm{OPT} = \sum_{i\in N} u_i^{v_i}(\mathbf{x}, p_i) + \sum_{i\in N} p_i \leq \sum_{i\in N} 2v_i(\mathbf{x}) \leq 2\widehat{\mathrm{OPT}}$. ◀

As a consequence, the optimal social welfare changes only within a factor of 2 by risk aversion and we may as well take $\widehat{\mathrm{OPT}}$ as our point of comparison. A VCG mechanism, for example, is still incentive compatible under risk-averse utilities but optimizes the wrong objective function. Lemma 1 shows that it is still a constant-factor approximation to optimal social welfare. However, in simple mechanisms, the agents' strategic behavior may or may not change drastically under risk aversion, depending on the mechanism. This way, equilbria and outcomes can possibly be very different.

4 Smoothness Beyond Quasilinear Utilities

Most of our positive results rely on the *smoothness* framework. It was introduced by [24] for general games. There are multiple adaptations to the quasilinear mechanism-design setting. We will use the one by [26]. As our utility functions will not be quasilinear, in this section we first observe that the framework can be extended to general utility functions. Note that throughout this section, the exact definition of $\mathrm{OPT}(\boldsymbol{\theta})$ is irrelevant. Therefore, it can be set to the optimal social welfare but also to weaker benchmarks depending on the setting.

▶ **Definition 2** (Smooth Mechanism)**.** A mechanism M is (λ, μ)-smooth with respect to utility functions $(u_i^{\theta_i})_{\theta_i\in\Theta_i, i\in N}$ for $\lambda, \mu \geq 0$, if for any type profile $\boldsymbol{\theta} \in \times_i \Theta_i$ and for any

action profile $\mathbf{a}$ there exists a randomized action $a_i^*(\boldsymbol{\theta}, a_i)$ for each player i, such that $\sum_i u_i^{\theta_i}(a_i^*(\boldsymbol{\theta}, a_i), \mathbf{a}_{-i}) \geq \lambda \mathrm{OPT}(\boldsymbol{\theta}) - \mu \sum_i p_i(\mathbf{a})$. We denote by $u_i^{\theta_i}(\mathbf{a})$ the expected utility of a player if $\mathbf{a}$ is a vector of randomized strategies.

Mechanism smoothness implies bounds on the price of anarchy. The following theorem and its proof are analogous to the theorems in [26], the proof is therefore deferred to the full version [12]. In cases where the deviation required by smoothness does not depend on a_i, the results extend to coarse correlated equilibria. The important point is that the respective bounds mostly do not depend on the assumption of quasilinearity.

▶ **Theorem 3.** *If a mechanism M is (λ, μ)-smooth w.r.t. utility functions $(u_i^{\theta_i})_{\theta_i \in \Theta_i, i \in N}$, then any Correlated Equilibrium in the full information setting and any Bayes-Nash Equilibrium in the Bayesian setting achieves efficiency of at least $\frac{\lambda}{\max\{1,\mu\}}$ of $OPT(\boldsymbol{\theta})$ or of $\mathbb{E}_{\boldsymbol{\theta}}[OPT(\boldsymbol{\theta})]$, respectively.*

In the standard single-item setting, one item is auctioned among n players, with their valuations and actions (bids) both being real numbers. In the common auction formats, the item is given to the bidder with the highest bid.

In a *first-price auction*, the winner has to pay her bid; the other players do not pay anything. It is $(1 - 1/e, 1)$-smooth w.r.t. quasilinear utility functions. In an *all-pay auction*, all players have to pay their bid. It is $(1/2, 1)$-smooth w.r.t. quasilinear utility functions. These smoothness results were given by [26]. They also show that simultaneous and sequential compositions of smooth mechanisms are again smooth.

What is remarkable here is that first-price and all-pay auctions achieve nearly the same welfare guarantees. We will show that in the risk-averse setting this is not true. While the first-price auction almost preserves its constant price of anarchy, the all-pay auction has an unbounded price of anarchy, even with only three players.

5 Quasilinear Smoothness Often Implies Risk-Averse Smoothness (Main Result 1)

Our main positive result is that many price-of-anarchy guarantees that are proved via smoothness in the quasilinear setting transfer to the risk-averse one. First, we consider mechanisms that are (λ, μ)-smooth with respect to quasilinear utility functions. We show that if the deviation strategy $\mathbf{a}^*$ that is used to establish smoothness ensures non-negative utility, then the price-of-anarchy bound extends to risk-averse settings at a multiplicative constant loss.

▶ **Theorem 4.** *If a mechanism is (λ, μ)-smooth w.r.t. quasilinear utility functions $(\hat{u}_i^{v_i})_{i \in N, v_i \in \mathcal{V}_i}$ and the actions in the support of the smoothness deviations satisfy $\hat{u}_i(a_i^*, \mathbf{a}_{-i}) \geq 0, \forall \mathbf{a}_{-i}, \forall i$, then any Correlated Equilibrium in the full information setting and any Bayes-Nash Equilibrium in the Bayesian setting achieves efficiency at least $\frac{\lambda}{2 \cdot \max\{1,\mu\}}$ of the expected optimal even in the presence of risk averse bidders.*

Using Theorem 3, it suffices to prove the following lemma.

▶ **Lemma 5.** *If a mechanism is (λ, μ)-smooth w.r.t. quasilinear utility functions $(\hat{u}_i^{v_i})_{i \in N, v_i \in \mathcal{V}_i}$ and the actions in the support of the smoothness deviations satisfy*

$$\hat{u}_i(a_i^*, \mathbf{a}_{-i}) \geq 0, \forall \mathbf{a}_{-i}, \forall i \ , \tag{1}$$

then the mechanism is $(\lambda/2, \mu)$-smooth with respect to any normalized risk-averse utility functions $(u_i^{v_i})_{i \in N, v_i \in \mathcal{V}_i}$.

Proof. We start from an arbitrary action profile $\mathbf{a}$ and want to satisfy Definition 2. Since there exist smoothness deviations s.t. $\hat{u}_i(a_i^*, \mathbf{a}_{-i}) = v_i(\mathbf{x}(a_i^*, \mathbf{a}_{-i})) - p_i \geq 0, \forall \mathbf{a}_{-i}, \forall i$, we know from property 4 of the risk aversion definition that $u_i^{v_i}(a_i^*, \mathbf{a}_{-i}) \geq \hat{u}_i^{v_i}(a_i^*, \mathbf{a}_{-i})$. Therefore,

$$\sum_i u_i^{v_i}(a_i^*, \mathbf{a}_{-i}) \geq \sum_i \hat{u}_i^{v_i}(a_i^*, \mathbf{a}_{-i}) \geq \lambda \widehat{\mathrm{OPT}} - \mu \sum_i p_i(\mathbf{a}) \geq \frac{\lambda}{2}\mathrm{OPT} - \mu \sum_i p_i(\mathbf{a}) \ ,$$

where the last inequality follows from Lemma 1. ◀

Note that in order for (1) to hold, it is sufficient if all undominated strategies guarantee non-negative quasilinear utility. For example, in a first-price auction, the only undominated bids are the ones from 0 to v_i. Regardless of the other players' bids, these can never result in negative utilities.

▶ **Corollary 6.** *Under normalized risk-averse utilities, the first-price auction has a constant price of anarchy for correlated and Bayes-Nash equilibria.*

We in addition note here that the first part of Property 4 of the normalization assumption, $u_i^{v_i}(\mathbf{x}, p_i) \geq v_i(\mathbf{x}) - p_i, 0 \leq p_i \leq v_i(\mathbf{x})$, is not crucial for obtaining a result similar to Theorem 4. Indeed, a relaxation of the form $u_i^{v_i}(\mathbf{x}, p_i) \geq C \cdot (v_i(\mathbf{x}) - p_i), 0 \leq p_i \leq v_i(\mathbf{x})$ for $0 < C < 1$, C constant, would incur a loss of at most a factor of C in the efficiency bound of Theorem 4. More details can be found in the full version [12].

For second-price auctions and their generalizations, for example, the just stated theorems do not suffice to prove guarantees on the quality of equilibria. One in addition needs a no-overbidding assumption and this is further taken care of in the framework of *weak smoothness*, also introduced in [26]. We defer all definitions and results that deal with weak smoothness, including the extension from quasilinear to general utility functions and risk-averse utilities yielding a constant loss as compared to the quasilinear case, to the full version [12].

We also consider the setting where players have hard *budget constraints*. Note that in this case the players' preferences are not quasilinear already in the risk neutral case. Informally, we show that if a mechanism is (λ, μ)-smooth w.r.t. quasilinear utility functions, then the loss of performance in the budgeted setting is bounded by a constant, even in the presence of risk-averse agents. All details can be found in the full version [12].

6 Unbounded Price of Anarchy for All-Pay Auctions (Main Result 2)

From the previous section, we infer that the constant price-of-anarchy bounds for first-price and second-price auctions immediately extend to the risk-averse setting. This is not true for all-pay auctions; by definition there is no non-trivial bid that always ensures non-negative utility. Indeed, as we show in this section, the price of anarchy is unbounded in the presence of risk-averse players. Missing calculation details can be found in the full version [12].

▶ **Theorem 7.** *In an all-pay auction with risk-averse players, the PoA is unbounded.*

The general idea is to construct a Bayes-Nash equilibrium with two players that very rarely have high values and only then bid high values. We then add a third player who always has a high value. However, as the first two players bid high values occasionally, there is no possible bid that ensures he will surely win. This means, any bid has a small probability of not getting the item but having to pay. Risk-averse players are more inclined to avoid this kind of lotteries. In particular, making our third player risk-averse enough, he prefers the sure zero utility of not participating to any way of bidding that always comes with a small probability of negative utility.

Proof of Theorem 7. We consider two (mildly) risk-averse players who both have the same valuation distributions and a third (very) risk-averse player with a constant value. For a large number $M > 5$, the first two players have values v_1 and v_2 drawn independently from distributions with density functions of value $2 \cdot (1 - (M-1) \cdot \varepsilon)$ on the interval $[1/2, 1)$ and value ε on the interval $[1, M]$, where $\varepsilon = 1/M^2$. The third player always has value $1/3 \cdot \ln(M/2)$ for winning.

We will construct a symmetric pure Bayes-Nash equilibrium involving only the first two players. It will be designed such that for the third player it is a best response to always bid 0, i.e., to opt out of the mechanism and never win the item. So, the combination of these strategies will be a pure Bayes-Nash equilibrium for all three players.

Note that the social welfare of any equilibrium of this form is upper-bounded by the optimal social welfare that can be achieved by the first two bidders. By Lemma 1, it is bounded by

$$\mathbb{E}[\mathrm{SW}] \leq 2 \cdot \mathbb{E}[\max\{v_1, v_2\}] \leq 2 \cdot \mathbb{E}[v_1 + v_2] = 2 \cdot (\mathbb{E}[v_1] + \mathbb{E}[v_2]) = 4 \cdot \mathbb{E}[v_1] \leq 4 \ .$$

Furthermore, the third player's value $v_3 = 1/3 \cdot \ln(M/2)$ is a lower bound to the optimal social welfare in the construction containing all three players. So, as pointwise $\mathrm{OPT}(v) \geq 1/3 \cdot \ln(M/2)$, where $v = (v_1, v_2, v_3) \in \mathcal{V}$ denotes the valuation profile, this implies that the price of anarchy can be arbitrarily high.

We define the utility functions by setting

$$u_i^{v_i}(b_i) = \begin{cases} \frac{h_i(v_i - b_i)}{h(v_i)} \cdot v_i & \text{if } b_i \text{ is the winning bid} \\ \frac{h_i(-b_i)}{h(v_i)} \cdot v_i & \text{otherwise} \end{cases} \tag{2}$$

For the first two players, we use $h_i(x) := 1 - e^{-x}$, $i \in \{1, 2\}$, so in particular increasing and concave. For the third player, we set $h_i(x) = x$ for $x \geq 0$ and $h_i(x) = C \cdot x$ for $x < 0$, where $C = (16 \cdot \frac{1}{3} \cdot \ln M/2) \cdot M^2 \geq 1$. Again this function is increasing and concave[2]. Note that the utility functions also satisfy normalizations at $p_i = v_i(\mathbf{x})$ and at $p_i = 0$. We see that in this example risk aversion has the effect of heavily penalizing payments without winning the auction.

▶ **Claim 8.** *With the third player not participating, it is a symmetric pure Bayes-Nash equilibrium for the first two players to play according to bidding function* $\beta \colon \mathcal{V}_i \to \mathbb{R}_+, i \in \{1, 2\}$, *such that*

$$\beta(x) = \int_{\frac{1}{2}}^{x} \frac{f(t)(e^t - 1)}{F(t) + (1 - F(t))e^t} dt \ , \tag{3}$$

where F *denotes the cumulative distribution function of the value and* f *denotes its density.*

Proof. We will argue that playing according to β is always the unique best response if the other player is playing according to β, too. Due to symmetry reasons, it is enough to argue about the first player.

Let us fix player 1's value $v_1 = x$ and consider the function $g \colon \mathbb{R}_{\geq 0} \to \mathbb{R}$ that is defined by $g(y) = \mathbf{E}[u_1^x(b_1 = y, b_2 = \beta(v_2), b_3 = 0)]$. We claim that g is indeed maximized at $y = \beta(x)$.

[2] Its slope is not an absolute constant. This is indeed necessary because the price of anarchy can be bounded in terms of the slopes of the h_i-functions as we show in the full version [12].

We have[3]

$$\begin{aligned} g(y) &= \Pr[\beta(v_2) \le y] \cdot \frac{h_1(x-y)}{h_1(x)} \cdot x + (1 - \Pr[\beta(v_2) \le y]) \cdot \frac{h_1(-y)}{h_1(x)} \cdot x \\ &= \frac{x}{h_1(x)} \left[F(\beta^{-1}(y)) \Big(h_1(x-y) - h_1(-y) \Big) + h_1(-y) \right] \\ &= x e^y F(\beta^{-1}(y)) + \frac{x(1-e^y)}{1-e^{-x}} \ . \end{aligned}$$

The first derivative of this function is given by

$$g'(y) = x e^y F(\beta^{-1}(y)) + x e^y \frac{d}{dy} F(\beta^{-1}(y)) - \frac{x}{1-e^{-x}} e^y \ .$$

The inverse function theorem implies $\frac{d}{dy} F(\beta^{-1}(y)) = \frac{f(\beta^{-1}(y))}{\beta'(\beta^{-1}(y))}$. Furthermore, as $\beta'(t) = \frac{f(t)(e^t-1)}{F(t)+(1-F(t))e^t}$, we get for all t that $\frac{f(t)}{\beta'(t)} = \frac{F(t)+(1-F(t))e^t}{e^t-1} = (1-F(t)) + \frac{1}{e^t-1}$. This simplifies $g'(y)$ to

$$g'(y) = x e^y + \frac{x e^y}{e^{\beta^{-1}(y)} - 1} - \frac{x e^y}{1-e^{-x}} = \frac{x e^y}{(1-e^{-x})(e^{\beta^{-1}(y)}-1)} \left(1 - e^{-x+\beta^{-1}(y)} \right) \ .$$

Notice that the factor $\frac{x e^y}{(1-e^{-x})(e^{\beta^{-1}(y)}-1)}$ is always positive. Therefore, we observe that $g'(y) = 0$ if and only if $e^{-x+\beta^{-1}(y)} = 1$, which is equivalent to $y = \beta(x)$. Furthermore, $g'(y) > 0$ for $y < \beta(x)$ and $g'(y) < 0$ for $y > \beta(x)$. This means that $y = \beta(x)$ has to be the (unique) global maximum of $g(y)$. ◀

▶ **Claim 9.** *If the first two players are bidding according to (3), then it is a best response for the third player to always bid* 0*.*

Proof. We now show that the very risk-averse third player with valuation $1/3 \cdot \ln(M/2)$ will indeed bid 0 because every bid $b_3' > 0$ will cause negative expected utility.

We distinguish two cases. For values of $b_3' > \frac{1}{16}$, we use that with a small probability one of the two remaining players has a valuation of at least $M-1$, which leads to negative utility. For $b_3' \le \frac{1}{16}$ on the other hand, he loses so often that his expected utility is again negative.

Let us first assume that the third player bids b_3' with $\frac{1}{16} < b_3' \le v_3$. In this case, with probability more than ε one of the first two players has value of at least $M-1$. The bid of this player with $v_i \ge M-1$ can be estimated as follows

$$\begin{aligned} \beta(v_i) \ge \beta(M-1) &\ge \int_{M/2}^{M-1} \frac{f(t)(e^t-1)}{1+(1-F(t))e^t} dt = \int_{M/2}^{M-1} \frac{\varepsilon(e^t-1)}{1+\varepsilon(M-t)e^t} dt \\ &\ge \frac{1}{2}(1-e^{-\frac{M}{2}}) \int_{M/2}^{M-1} \frac{\varepsilon e^t}{\varepsilon(M-t)e^t} dt = \frac{1}{2}(1-e^{-\frac{M}{2}}) \ln(M/2) > \frac{1}{3}\ln(M/2) \ , \end{aligned}$$

which means that by bidding b_3' the third player loses with probability of at least $\varepsilon = 1/M^2$. For the expected utility, this implies

$$\mathbb{E}[u_3(b_3', \mathbf{b}_{-3})] \le (1-\varepsilon)(v_3 - b_3') + \varepsilon(-C \cdot b_3') < \frac{1}{3}\ln\frac{M}{2} - \frac{1}{16} \cdot 16 \cdot \frac{1}{3}\ln\frac{M}{2} = 0 \ .$$

[3] Note that the first step assumes tie breaking in favor of player 1. This is irrelevant for the future steps as the involved probability distributions are continuous.

In the case where the third player bids b'_3, $0 < b'_3 \leq \frac{1}{16}$, we need to be a bit more careful with estimating the winning probability. We first give a lower bound on the bidding function of the first player for $v_1 < 1$

$$\beta(v_1) \geq \int_{1/2}^{v_1} \frac{2(1-\frac{M-1}{M^2})(e^t-1)}{2(t-\frac{1}{2})(1-\frac{M-1}{M^2})+(1-2(t-\frac{1}{2})(1-\frac{M-1}{M^2}))\cdot e^t} dt > \frac{1}{4}\left(v_1 - \frac{1}{2}\right) \ .$$

Since for $v_1 \geq 1$, $\beta(v_1) > \frac{1}{16}$ with probability 1, this implies that with b'_3, the third player has a winning probability of at most

$$\Pr[\beta(v_1) \leq b'_3] \leq \Pr\left[\frac{1}{4}\left(v_1 - \frac{1}{2}\right) \leq b'_3\right] = \Pr\left[v_1 \leq 4b'_3 + \frac{1}{2}\right] < 2 \cdot 4b'_3 \ .$$

Now, having in mind that $C = (16v_3) \cdot M^2 \geq 32 \cdot v_3$, the utility can be estimated as follows

$$\begin{aligned}\mathbb{E}[u_3(b'_3, \mathbf{b}_{-3})] &\leq \Pr[\beta(v_1) \leq b'_3] \cdot (v_3 - b'_3) - \Pr[\beta(v_1) > b'_3] \cdot 32 \cdot v_3 \cdot b'_3 \\ &< 8b'_3\left(-v_3 - \frac{1}{16}\right) < 0 \ .\end{aligned}$$

So also in this case, the expected utility is negative. ◀

Combining the two claims, we have constructed a class of distributions and Bayes-Nash equilibria with unbounded price of anarchy. ◀

As a final remark, we note that the first two bidders occasionally bid high only due to risk aversion. In a symmetric Bayes-Nash equilibrium of the all-pay auction in the quasilinear setting, all bids are always bounded by the expected value of a player (see full version [12]). Therefore, such an equilibrium would not work as a point of departure.

7 Variance-Aversion Model

In this section, we consider a different model that tries to capture the effect that agents prefer certain outcomes to uncertain ones. It is inspired by similar models in game theory and penalizes variance of random variables. Rather than reflecting the aversion in the utility functions, it is modeled by adapting the solution concept.

In the usual definition of equilibria involving randomization, the utility of a randomized strategy profile is set to be the expectation over the pure strategies. The definition we consider here is modified by subtracting the respective standard deviation. For a player i, the utility of a randomized strategy profile $\mathbf{a}$ is given as $u_i^{v_i}(\mathbf{a}) = \mathbb{E}_{\mathbf{b}\sim\mathbf{a}}[\hat{u}_i^{v_i}(\mathbf{b})] - \gamma\sqrt{\mathrm{Var}[\hat{u}_i^{v_i}(\mathbf{b})]}$, so a player's utility for an action profile is his expected quasilinear utility for this profile minus the standard deviation multiplied by a parameter γ that determines the degree of variance-averseness, $0 \leq \gamma \leq 1$. As already mentioned, $\hat{u}_i(\mathbf{a})$ denotes the quasilinear utility of player i for the action profile $\mathbf{a}$.

Bayes-Nash Equilibria and correlated equilibria can be defined the same way as before, always replacing expectations by the difference of expectation and standard deviation. The formal definition for $s(\mathbf{v})$ being a Bayes-Nash equilibrium in this setting is that $\forall i \in N$, $\forall v_i \in \Theta_i$, $a_i \in \mathcal{A}_i$,

$$\begin{aligned}&\mathbb{E}_{\mathbf{v}_{-i}}[\hat{u}_i^{v_i}(s(\mathbf{v})) \mid v_i] - \gamma\sqrt{\mathrm{Var}[\hat{u}_i^{v_i}(s(\mathbf{v})) \mid v_i]} \\ &\qquad \geq \mathbb{E}_{\mathbf{v}_{-i}}[\hat{u}_i^{v_i}(a_i, s_{-i}(\mathbf{v}_{-i})) \mid v_i] - \gamma\sqrt{\mathrm{Var}[\hat{u}_i^{v_i}(a_i, s_{-i}(\mathbf{v}_{-i})) \mid v_i]} \ .\end{aligned}$$

Note that we again evaluate social welfare as agents perceive it. That is, for a randomized strategy profile $\mathbf{a}$, we set $\mathrm{SW}^{\mathbf{v}}(\mathbf{a}) = \sum_i u_i^{v_i}(\mathbf{a}) + \sum_i p_i(\mathbf{a})$.

Our first result shows that first-price and notably also all-pay auctions have a constant price of anarchy in this setting. Note that even though the proof looks a lot like smoothness proofs, it is not possible to phrase it within the smoothness framework, since here we are dealing with a different solution concept.

▶ **Theorem 10.** *Bayes-Nash Equilibria and Correlated Equilibria of the first-price and all-pay auction have a constant price of anarchy in this model.*

Proof. For simplicity, we will show the claim only for Bayes-Nash equilibria. The proof for correlated equilibria works the same way with minor modifications to the notation.

Assume $\mathbf{b}$ is a Bayes-Nash equilibrium. We claim that $\mathbb{E}_{\mathbf{v}}[\mathrm{SW}^{\mathbf{v}}(\mathbf{b})] \geq \frac{1}{16} \cdot \mathbb{E}_{\mathbf{v}}[\mathrm{OPT}]$, where OPT denotes the value of social welfare in the allocation that maximizes it, i.e. maximized sum of utility and payments of the agents.

Consider a fixed player j and a fixed valuation v_j. Let $q = \Pr[\max_{i \neq j} b_i \leq \frac{1}{4} \cdot v_j]$ denote the probability that no other player's bid exceeds $\frac{1}{4} \cdot v_j$.

Assume first that $q \leq \frac{3}{4}$. Then, because the total social welfare lower bounded by the payments $\mathbb{E}_{\mathbf{v}_{-j}|v_j}[\mathrm{SW}^{\mathbf{v}}(\mathbf{b})] \geq (1-q)\frac{1}{4}v_j \geq \frac{1}{16}v_j$.

On the other hand, if $q \geq \frac{3}{4}$, since $\mathbb{E}_{\mathbf{v}_{-j}|v_j}[\mathrm{SW}^{\mathbf{v}}(\mathbf{b})] \geq \mathbb{E}_{\mathbf{v}_{-j}|v_j}\left[u_j^{v_j}(\frac{v_j}{4}, b_{-j})\right]$,

$$\mathbb{E}_{\mathbf{v}_{-j}|v_j}[\mathrm{SW}^{\mathbf{v}}(\mathbf{b})] \geq v_j q - \frac{1}{4}v_j - \gamma v_j \sqrt{q(1-q)} \geq \left(\frac{2-\gamma\sqrt{3}}{4}\right) v_j \geq \frac{1}{16}v_j \ ,$$

where the first inequality is in fact an equality for the all-pay auction.

From here, by taking the expectation over v_j and by weighing the right hand side by the probability that OPT takes a particular agent, the theorem follows. ◀

This is contrasted by a correlated equilibrium with 0 social welfare in a setting with positive values. Indeed, for the special case of $\lambda = 1$, we see that the variance-averse model further differs from the risk-averse model described in previous sections.

▶ **Observation 1.** *The PoA for CE of second price auctions is unbounded if $\gamma = 1$.*

The proof can be found in the full version [12]. This is not only a difference between smoothness and weak smoothness. Our final result is a mechanism that is (λ, μ)-smooth for constant λ and μ but has unbounded price of anarchy.

▶ **Theorem 11.** *For any constant $\gamma > 0$ there is a mechanism that is (λ, μ)-smooth with respect to quasilinear utility functions for constant λ and μ but has unbounded price of anarchy in the variance-aversion model.*

Proof. Consider a setting with two items and two players, who have unit-demand valuation functions such that $\frac{1}{c}v_{i,1} \leq v_{i,2} \leq cv_{i,1}$ for constant $c \geq 1$. The players' possible actions are to either report one of the two items as preferred or to opt out entirely. Our mechanism first assigns player 1 her (claimed) favorite item, then assigns player 2 the remaining one unless she opts out. There are no payments. Obviously, this mechanism is $(\frac{1}{c}, 0)$-smooth because the allocation is within a $\frac{1}{c}$-factor of the optimal allocation by construction.

We will now construct a mixed Nash equilibrium of bad welfare. To this end, let $v_{1,1} = v_{1,2} = \varepsilon$ for some small $\varepsilon > 0$. This makes player 1 indifferent between items 1 and 2. In particular, it is a best response to ask for item 1 with probability $\frac{q-1}{q}$ and for item 2 with

probability $\frac{1}{q}$. We note at this point that in a Bayes-Nash equilibrium we could make this respective action the unique best response by having random types.

For player 2, we set $v_{2,1} = c$, $v_{2,2} = 1$. She has the choice of participating or opting out. Opting out implies utility 0, whereas participating implies

$$u_2(\mathbf{a}) = \frac{c+q-1}{q} - \gamma\sqrt{\frac{(c-1)^2(q-1)}{q^2}} = \frac{(c-1)(1-\gamma\sqrt{q-1})}{q} + 1$$

Now, if we set $q = c-1$, then $u_2(\mathbf{a}) = 2 - \gamma\sqrt{c-2}$ which is negative for $c > \frac{4}{\gamma^2} + 2$. We further set $c = \frac{4}{\gamma^2} + 3$. That is, player 2 prefers to opt out. This outcome has social welfare ε whereas the optimal social welfare is c. ◀

Note that this last example shows that variance-averseness yields very strange preferences for lotteries. In our example, the variance-averse player prefers not to participate although any outcome in the (free) lottery has positive value.

Abstract

Starting with Michail, Chatzigiannakis, and Spirakis work [20], the problem of *Counting* the number of nodes in Anonymous Dynamic Networks has attracted a lot of attention. The problem is challenging because nodes are indistinguishable (they lack identifiers and execute the same program) and the topology may change arbitrarily from round to round of communication, as long as the network is connected in each round. The problem is central in distributed computing as the number of participants is frequently needed to make important decisions, such as termination, agreement, synchronization, and many others. A variety of algorithms built on top of *mass-distribution* techniques have been presented, analyzed, and also experimentally evaluated; some of them assumed additional knowledge of network characteristics, such as bounded degree or given upper bound on the network size. However, the question of whether Counting can be solved deterministically in sub-exponential time remained open. In this work, we answer this question positively by presenting Methodical Counting, which runs in polynomial time and requires no knowledge of network characteristics. Moreover, we also show how to extend Methodical Counting to compute the sum of input values and more complex functions without extra cost. Our analysis leverages previous work on random walks in evolving graphs, combined with carefully chosen alarms in the algorithm that control the process and its parameters. To the best of our knowledge, our Counting algorithm and its extensions to other algebraic and Boolean functions are the first that can be implemented in practice with worst-case guarantees.

1 Introduction

How much information can one derive deterministically and distributedly from an arbitrarily evolving connected graph in polynomial time? Can we learn its size, or compute some simple Boolean functions, on its (distributed) input? In this work, we answer this question, posed in [20], in the affirmative. Specifically, we address first the problem of *Counting* the number of nodes of an Anonymous Dynamic Network (ADN) (and later extend to other algebraic functions) with a distributed and deterministic protocol. After a polynomial number of rounds of communication all nodes running our protocols obtain the result and stop. Our protocols resemble mass-distribution algorithms, however, our method is novel and quite complex as it has to deal with lack of node identities, lack of knowledge of network parameters, and adversarial topology changes.

The problem has been thoroughly studied [20, 10, 11, 12, 9, 21, 6] because Counting is central for distributed computing. Indeed, more complex tasks need the network size to make various decisions on state agreement, synchronization, termination, and others (e.g. [14, 15]). However, Anonymous Dynamic Networks pose a particularly challenging scenario. On one hand, nodes are indistinguishable from each other. For instance, they may lack identifiers or their number may be so massive that keeping record of them is not feasible. On the other hand, the topology of the network is highly dynamic. Indeed, the subsets of nodes that may communicate with each other may change all the time. All these features make ADN a valid model for anonymous ad hoc communication and computation.

In such a restrictive scenario, finding a way of providing theoretical guarantees of deterministic polynomial time has been elusive. Previous papers have either weaken the objective (e.g., computing only upper bound, only stochastic guarantees, etc.), assumed availability of network information (e.g., maximum number of neighbors, size upper bound, etc.), relied on a stronger model of communication, or provided only superpolynomial time guarantees.

Methodical Counting uses no information about the network. After completing its execution, all nodes obtain the exact size of the network and stop. Moreover, they stop all at the same time, allowing the algorithm to be concatenated with other computations.

Our algorithm is based on nodes continuously sharing some magnitude, which we call *potential*,[3] resembling *mass-distribution* and *push-pull* algorithms. Unlike previous algorithms, in Methodical Counting carefully and periodically (i.e. , "methodically") some potential is removed from the network, rather than greedily doing so continuously. This approach is combined with another methodological innovation testing whether the candidate value (for the network size) is within some polynomial range of the actual network size. This complex strategy yields an algorithm in which the progress in mass-distribution can be analyzed as a sequence of parametrized Markov chains (even though the algorithm itself is purely deterministic) enhanced by mass drift and alarms controlling the process and its parameters. Our analysis approach opens the path to study more complex tasks in Anonymous Dynamic Networks applying similar techniques.

Finally, we also present a variety of extensions of Methodical Counting to compute more complex functions. Most notably, we present an extension that, concurrently with finding the network size, computes the sum of input values held at each node without asymptotic time overhead. Having a method to compute the sum and network size, more complex computations are possible in polynomial time as well. Indeed, we also describe how to compute a variety of algebraic and Boolean functions.

[3] In previous related works this quantity, used in a different way, was termed *energy*. We steer away from such denomination to avoid confusion with node energy supply.

To the best of our knowledge, ours are the first algorithms for anonymous dynamic Counting and other algebraic computations that can be implemented in practice with worst-case polynomial-time guarantees.

Roadmap. The rest of the paper is organized as follows. Model and notation are detailed in Section 2. We overview previous work in Section 3 and present our results in Section 4. Section 5 includes the details of Methodical Counting, and we prove its correctness and running time in Section 6. Extensions to other functions are presented in Section 7.

2 Model, Problem, and Notation

The Counting Problem

The definition of the problem is simple. An algorithm solves the Counting Problem if, after completing its execution, all nodes have obtained the exact size of the network and stop.

Anonymous Dynamic Networks

The following model is customary in the Anonymous Dynamic Networks literature. We consider a network composed by a set V of $n > 1$ network *nodes* with processing and communication capabilities. It was shown in [20] that Counting cannot be solved in Anonymous Networks without the availability of at least one distinguished node in the network. Thus, we assume the presence of such node called *leader*. Aside from the leader, we assume that all other nodes are indistinguishable from each other. That is, we do not assume the availability of labels or identifiers, and all non-leader nodes execute exactly the same program.

Each pair of nodes that are able to communicate define a communication *link*, and the set of links is called the *topology* of the network. The nodes in a communication link are called *neighbors*. The event of sending a message to neighbors is called a *broadcast* or *transmission*. Nodes and links are reliable, in the sense that no communication or node failures occur. Hence, a broadcasted message is received by all neighbors. Moreover, links are *symmetric*, that is, if node a is able to send a message to node b, then b is able to send a message to a.

Without loss of generality, we discretize time in *rounds*. In any given round, a node may broadcast a message, receive all messages from broadcasting neighbors, and carry out some computations, in that order. Time needed for computations is assumed negligible.

The set of links among nodes may change from round to round, and nodes have no way of knowing which were the neighbors they had before. These topology changes are arbitrary, limited only to maintain the network connected in each round. That is, at any given round the topology is such that there is a *path*, i.e., a sequence of links, between each pair of nodes, but the set of links may change arbitrarily from round to round. This adversarial model of dynamics was called 1-*interval connectivity* in [19].

The following notation will be used. The maximum number of neighbors that any node may have at any given time, called the *dynamic maximum degree*, is denoted as Δ. An upper bound on Δ is denoted as $d_{\max}$. The maximum length of a shortest path between any pair of nodes at any given time is called the *dynamic diameter* and it is denoted as D. The maximum length of an opportunistic shortest path between any pair of nodes over many time slots is called the *chronopath* [13] and it is denoted as $\mathcal{D}$.

Table 1 Comparison of Counting protocols for Anonymous Dynamic Networks.

algorithm	needs		computes	stops?	complexity	
	size upper bound N	dynamic maximum degree u.b. $d_{\max}$			time	space
Degree Counting [20]		✓	$O(d_{\max}^n)$	✓	$O(n)$	
Conscious [10]	✓	✓	n	✓	$O(e^{N^2}N^3) \Rightarrow$ $O(e^{d_{\max}^{2n}} d_{\max}^{3n})$ using [20]	
Unconscious [10]			n	No	No theoretical bounds	
$\mathcal{A}_{\mathcal{O}^P}$ [11]		Oracle for each node	n	Eventually	Unknown	
EXT [9]			n	✓	$O(n^{n+4})$	EXPSPACE
Incremental Counting [21]		✓	n	✓	$O\left(n\,(2d_{\max})^{n+1}\,\frac{\ln n}{\ln d_{\max}}\right)$	
Methodical Counting [This work]			n	✓	$O(n^5 \ln^2 n)$	PSPACE

3 Previous Work

A comprehensive overview of work related to Anonymous Dynamic Networks can be found in a survey by Casteigts et al. [5] and references in the papers cited here. The directly related work overviewed in comparison with our results is summarized in Table 1.

With respect to lower bounds, it was proved in [8] that at least $\Omega(\log n)$ rounds are needed, even if D is constant. Also, $\Omega(\mathcal{D})$ is a lower bound since at least one node needs to hear about all other nodes to obtain the right count.

Counting and *Naming* was already studied in [20] for dynamic and static networks, showing that it is impossible to solve Counting without the presence of a distinguished node, even if the network is static. The Counting protocol requires knowledge of an upper bound on Δ, and obtains only an upper bound, which may be as bad as exponential.

Conscious Counting [10] computes the exact count, but it needs to start from an upper bound, and it takes exponential time only if the size upper bound is tight. In the same work and follow-up papers [11, 12], more challenging scenarios where Δ is unknown are studied, but protocols either do not terminate [10], or the protocol is terminated heuristically [12]. In experiments [12], such heuristic was found to perform well on dense topologies, but for other topologies the error rate was high. Another protocol in [11] is shown to terminate eventually, without running-time guarantees and under the assumption of having for each node an estimate of the number of neighbors in each round. In [20] it was conjectured that some knowledge of the network such as the latter would be necessary, but the conjecture was disproved later in [9]. On the other hand the protocol in [9] requires exponential space.

Incremental Counting, presented recently in [21], reduced exponentially the best-known running time guarantees. The protocol obtains the exact count, all nodes terminate simultaneously, the topology dynamics is only limited to 1-interval connectivity, it only requires polynomial space, and it only requires knowledge of of an upper bound ($d_{\max}$) on the dynamic maximum degree. The running time is still exponential, but reducing from doubly-exponential was an important step towards understanding the complexity of Counting.

In a follow-up paper [6], Incremental Counting was tested experimentally showing a promising polynomial behavior. The study was conducted on pessimistic inputs designed to slow the convergence, such as bounded-degree trees rooted at the leader uniformly chosen at random for each round, and a single path starting at the leader with non-leader nodes permuted uniformly at random for each round. The protocol was also tested on static versions of the inputs mentioned, classic random graphs, and networks where some disconnection is allowed. The results exposed important observations. Indeed, even for topologies that stretch the dynamic diameter, the running times obtained are below Δn^3. It was also observed that random graphs, as used in previous experimental studies [12], reduce the convergence time, and therefore are not a good choice to indicate worst-case behavior. These experiments showed good behavior even for networks that sometimes are disconnected, indicating that more relaxed models of dynamics, such as (α, β)-connectivity [13, 16], are worth to study. All in all, the experiments in [6] showed that Incremental Counting behaves well in a variety of pessimistic inputs, but not having a proof of what a worst-case input looks like, and being the experiments restricted to a range of values of n far from the expected massive size of an Anonymous Dynamic Network, a theoretical proof of polynomial time remained an open problem even from a practical perspective.

In a recent manuscript [2] a polynomial Counting algorithm is presented relying on the availability of an algorithm to compute average with polynomial convergence time. Such average computation is modeled as a Markov chain with underlying doubly-stochastic matrix, which requires topology information within two hops (cf. [23]). In our model of Anonymous Dynamic Network, such information is not available, and gathering it may not be possible due to possible topology changes from round to round.

Other studies also dealing with the time complexity of information gathering exist [7, 3, 24, 4, 22], but include in their model additional assumptions, such as the network having the same topology frequently enough.

4 Our Contributions

We present a deterministic distributed algorithm, which we call Methodical Counting, to compute the number of nodes in an Anonymous Dynamic Network. As opposed to previous works, our algorithm does not require any knowledge of network characteristics, such as dynamic maximum degree or an upper bound on the size. After $O(n^5 \ln^2 n)$ communication rounds of running Methodical Counting, all nodes obtain the network size and stop at the same round. To the best of our knowledge, this is the first polynomial deterministic Counting algorithm in the pure model of Anonymous Dynamic Network.

Our algorithm distributes potential in a mass-distribution fashion resembling previous works for Counting. The main novelty in our approach is that the leader participates in the process as any other node, removing potential only after it has accumulated enough. This approach allowed us to leverage previous work on random walks in evolving graphs. For this approach to work, we combine it with testing whether the candidate value for the network size is polynomially close to the actual value. Our approach also opens the path to study more complex computations in Anonymous Dynamic Networks using the same analysis.

Finally, we also present extensions of Methodical Counting to compute more complex functions. Most notably, we show how to modify Methodical Counting to compute the sum of input values held by nodes at the same time than counting. Having an algorithm to compute the network size and the sum of input values, we also show how to compute other algebraic and Boolean functions.

Algorithm 1 METHODICAL COUNTING algorithm for the leader. N is the set of neighbors of the leader in the current round. The parameters d, p, r and τ are as defined in Theorem 6.

```

29:             Broadcast ⟨status⟩ and Receive ⟨status_i⟩, ∀i ∈ N
            /* epoch completed */
30:     return k
```

5 Methodical Counting

In this section we present METHODICAL COUNTING. First, we give the intuition of the algorithm, the details can be found in Algorithms 1 and 2. (References to algorithm lines are given as $\langle algorithm\#\rangle.\langle line\#\rangle$.)

Initially, the leader is assigned a potential of 0 and all the other nodes are assigned a potential of 1. Then, the algorithm is composed by epochs, each of which is divided into phases composed by rounds of communication. Epoch k corresponds to a size estimate k that is iteratively increased from epoch to epoch until the correct value n is found. Each epoch is divided into p phases. The purpose of each phase is for the leader to collect as much potential as possible from the other nodes in a mass-distribution fashion as follows.

Algorithm 2 METHODICAL COUNTING algorithm for each non-leader node i. N is the set of neighbors of i in the current round. The parameters d, p, r and τ are as defined in Theorem 6.

```
1:  procedure COUNT
2:      Φ ← 1                                                    // current potential
3:      k ← 2                                                    // current estimate
4:      status ← normal                                          // status=normal|alarm|done
5:      while status ≠ done do                                   // iterating epochs
6:          for phase = 1 to p do                                // iterating phases
7:              for round = 1 to r do                            // iterating rounds
8:                  Broadcast ⟨Φ, status⟩ and Receive ⟨Φ_i, status_i⟩, ∀i ∈ N
9:                  if status = normal and |N| ≤ d−1 and ∀i ∈ N : status_i = normal then
10:                     Φ ← Φ + Σ_{i∈N} Φ_i/d − |N|Φ/d           // update potential
11:                 else                                         // k is wrong
12:                     status ← alarm
13:                     Φ ← 1
               /* r rounds completed */
14:             if phase = 1 and Φ > τ then                      // k is wrong
15:                 status ← alarm
16:                 Φ ← 1
           /* p phases completed */
17:         for round = 1 to k do                                // disseminate termination
18:             Broadcast ⟨status⟩ and Receive ⟨status_i⟩, ∀i ∈ N
19:             if ∃i ∈ N : status_i = done then
20:                 status ← done
21:         if status ≠ done then
22:             k ← k + 1
23:             status ← normal
           /* epoch completed */
24:     return k
```

Each phase is composed by r rounds of communication. In each round, each node[4] broadcasts its potential and receives the potential of all its neighbors. Each node keeps only a fraction $1/d$ of the potentials received. The parameters p, r, and d are functions of k. The specific functions needed to guarantee correctness and saught efficiency are defined in Theorem 6. This varying way of distributing potential is different from previous approaches using mass distribution. After communication, each node updates its own potential accordingly (cf. Lines 1.11 and 2.10). That is, it adds a fraction $1/d$ of the potentials received, and subtracts a fraction $1/d$ of the potential broadcasted times the number of potentials received. Then, a new round starts.

At the end of each phase the leader "consumes" its potential. That is, it increases an internal accumulator ρ with its current potential, which is zeroed for starting the next phase (cf. Lines 1.19 and 1.20). A node stops the update of potential described, raises its potential to 1, and broadcasts an alarm in each round until the end of the epoch if any of the following happens: 1) at the end of the first phase its potential is above some threshold τ as defined in

[4] As opposed to previous work, in METHODICAL COUNTING the leader also follows this procedure.

Theorem 6 (cf. Lines 1.15 and 2.14), 2) at any round it receives more than $d-1$ messages (cf. Lines 1.12 and 2.11), or 3) at any round it receives an alarm (cf. Lines 1.12 and 2.11). The alarm for case 1) allows the leader to detect that the estimate is wrong when $k^{1+\epsilon} < n$ for some $\epsilon > 0$ (Lemmas 4 and 5), the alarm for case 2) allows the leader to detect that d is too small and hence the estimate is wrong, and the alarm for case 3) allows dissemination of all alarms. In the alarm status the potential is set to 1 to facilitate the analysis, but it is not strictly needed by the algorithm.

At the end of each epoch, the leader checks the value of ρ. If $k - 1 - 1/k \leq \rho \leq k - 1$ the current estimate is correct and the leader changes its status to "done" (cf. Line 1.21). Otherwise, all its variables are reset to start a new epoch with the next estimate (cf. Line 1.23). Before starting a new epoch the network is flooded with the status of the leader for k rounds (cf. Lines 1.28 and 2.17). If $k = n$, the leader initiates message "done" and the k rounds are enough for all the nodes to receive the "done" status and after completing the k rounds stop. Otherwise, nodes will not receive the "done" status and after completing the k rounds they start a new epoch.

6 Analysis

In this section we analyze Methodical Counting. References to algorithm lines are given as $\langle algorithm\# \rangle.\langle line\# \rangle$. We use standard notations $\mathbf{I}$ for the unit vector, and L_p for the norm of vector $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ as $||\mathbf{x}||_p = \left(\sum_{i=1}^{n} |x_i|^p\right)^{1/p}$, for any $p \geq 1$. Only for the analysis, nodes are labeled as $0, 1, 2, \ldots, n-1$, where the leader has label 0. The potential of a node i at the beginning of round s of phase t is denoted as $\Phi_{s,t}[i]$, the potential of all nodes is denoted as a vector $\mathbf{\Phi}_{s,t}$, and the aggregated potential is then $||\mathbf{\Phi}_{s,t}||_1$. The subindices s, t, or both are omitted sometimes for clarity. We will refer to the potential right after the last round of a phase as $\mathbf{\Phi}_{r+1}$. Round $r+1$ does not exist in the algorithm, but we use this notation to distinguish between the potential right before the leader consumes its own potential (cf. Line 1.23) and the potential at the beginning of the first round of the next phase.

First, we provide a broad description of our analysis of Methodical Counting. Consider the vector of potentials $\mathbf{\Phi}_i$ held by nodes at the beginning of any given phase i. The way that potentials are updated in each round (cf. Lines 1.11 and 2.10) is equivalent to the progression of a d-lazy random walk on the evolving graph underlying the network topology [1], where the initial vector of potentials is equivalent to an initial distribution $\mathbf{\Pi}_i$ on the overall potential $||\mathbf{\Phi}_i||_1$ and the probability of choosing a specific neighbor is $1/d$. For instance, the initial vector of potentials $\mathbf{\Phi}_0 = \langle 0, 1, 1, \ldots \rangle$, corresponds to a distribution $\mathbf{\Pi}_0 = \langle 0, 1/(n-1), 1/(n-1), \ldots \rangle$ on the initial $||\mathbf{\Phi}_0||_1 = n - 1$.

Note that our Methodical Counting is not a simple "derandomization" of the lazy random walk on evolving graphs. First, in the Anonymous Dynamic Network model neighbors cannot be distinguished, and even their number is unknown at transmission time (only at receiving time the node learns the number of its neighbors). Second, due to unknown network parameters, it may happen in an execution of Methodical Counting that the total potential received could be bigger than 1. Third, our algorithm does not know a priori when to terminate and provide result even with some reasonable accuracy, as the formulas on mixing and cover time of lazy random walks depend on (a priori unknown) number of nodes n. Nevertheless, we can still use some results obtained in the context of analogous lazy random walks in order to prove useful properties of parts of algorithm Methodical Counting, namely, some parts in which parameters are temporarily fixed and the number of received messages does not exceed parameter d.

It was shown in [1] that random walks on d-regular explorable evolving graphs have a uniform stationary distribution, and bounds on the mixing and cover time were proved as well. Moreover, it was observed that those properties hold even if the graph is not regular and d is only an upper bound on the degree.[5]

Thus, for the cases where d is an upper bound on the number of neighboring nodes, we analyze the evolution of potentials within each phase leveraging previous work on random walks on evolving graphs. Specifically, we use the following result which is an extension of Corollary 14 in [1].

▶ **Theorem 1.** *(Corollary 14 in [1].) After t rounds of a $d_{\max}$-lazy random walk on an evolving graph with n nodes, dynamic diameter D, upper bound on maximum degree $d_{\max}$, and initial distribution $\mathbf{\Pi}_0$, the following holds:*

$$\left|\left|\mathbf{\Pi}_t - \frac{\mathbf{I}}{n}\right|\right|_2^2 \leq \left(1 - \frac{1}{d_{\max} D n}\right)^t \left|\left|\mathbf{\Pi}_0 - \frac{\mathbf{I}}{n}\right|\right|_2^2 .$$

In between phases the leader "consumes" its potential, effectively changing the distribution at that point. Then, a new phase starts.

In Methodical Counting, given that d is a function of the estimate k, if the estimate is low, there may be inputs for which d is not an upper bound on the number of neighbors. We show in our analysis that in those cases the leader detects the error and after some time all nodes increase the estimate.

First, we prove correctness when $k = n$ in the following lemma. The proof, left to the full version of this paper, is based on upper bounding the potential left in the system after running the algorithm.

▶ **Lemma 2.** *If $d \geq k$ and $k = n$, after running the* Methodical Counting *protocol for $p \geq \frac{k}{1-1/k} \ln(k(k-1))$ phases, each of $r \geq 4dk^2 \ln k$ rounds, the potential ρ consumed by the leader is $k - 1 - 1/k \leq \rho \leq k - 1$.*

Lemma 2 shows that if $\rho > k-1$ or $\rho < k-1-1/k$ we know that the estimate k is wrong, but the complementary case, that is, $k-1-1/k \leq \rho \leq k-1$, may occur even if the estimate is $k < n$ and hence the error has to be detected by other means. To prove correctness in that case, we show first that if $k < n \leq k^{1+\epsilon}$ for some $\epsilon > 0$ the leader must consume $\rho > k-1$ potential if the protocol is run long enough. To ensure that $d \geq \Delta + 1$, we restrict $d \geq k^{1+\epsilon}$. The proof of the following lemma, based again on upper bounding the potential left in the system after running the algorithm, is left to the full version of this paper.

▶ **Lemma 3.** *If $1 < k < n \leq k^{1+\epsilon} \leq d$, $\epsilon > 0$, after running the* Methodical Counting *protocol for $p \geq \frac{(2+\epsilon)k^{1+\epsilon}}{1-1/k} \ln k$ phases, each of $r \geq (4+2\epsilon)dk^{2+2\epsilon} \ln k$ rounds, the potential ρ consumed by the leader is $\rho > k-1$.*

It remains to show that even if $n > k^{1+\epsilon}$ Methodical Counting still detects that the estimate is low. First, we prove the following two claims that establish properties of the potential during the execution of Methodical Counting. (Recall that we use round $r+1$ to refer to potentials at the end of the phase right before the leader consumes its potential in Line 1.23.) The proofs of both claims, based on observing the mass-distribution properties and the alarms in the algorithm, are left to the full version of this paper.

[5] Their analysis relies on Lemma 12, which bounds the eigenvalues of the transition matrix as long as it is stochastic, connected, symmetric, and non-zero entries lower bounded by $1/d$. Those conditions hold for all the transition matrices, even if the evolving graph is not regular.

▶ **Claim 1.** *Given an Anonymous Dynamic Network of n nodes running* Methodical Counting *with parameter d, for any round t of the first phase, such that $1 \leq t \leq r+1$, if d was larger than the number of neighbors of each node x for every round $t' < t$, then $||\mathbf{\Phi}_{1,t}||_1 = n-1$.*

▶ **Claim 2.** *Given an Anonymous Dynamic Network of n nodes running* Methodical Counting*, for any round t of any phase and any node x, it is $0 \leq \Phi_t[x] \leq 1$.*

It remains to show that even if $n > k^{1+\epsilon}$ Methodical Counting still detects that the estimate is low. We focus on the first phase. We define a threshold τ such that, after the phase is completed, all nodes that have potential above τ can send an alarm to the leader, as such potential indicates that the estimate is low. We show that the alarm must be received after $k^{1+\epsilon}$ further rounds of communication in the following lemma. The proof, based on bounding the "room" that nodes have up to the maximum potential, is left to the full version of this paper.

▶ **Lemma 4.** *For $\epsilon > 0$, after running the first phase of the* Methodical Counting *protocol, there are at most $k^{1+\epsilon}$ nodes that have potential at most $\tau = 1 - 1/k^{1+\epsilon}$.*

In our last lemma, we show that if $k^{1+\epsilon} < n$ the leader detects the error. The proof, based on bounding the number of nodes with low potential at the end of the first phase, is left to the full version of this paper.

▶ **Lemma 5.** *If $k^{1+\epsilon} < n$, $\epsilon > 0$, and $r \geq (4 + 2\epsilon - 2\ln(k^\epsilon - 1)/\ln k)dk^2 \ln k$, within the following $k^{1+\epsilon}$ rounds after the first phase of the* Methodical Counting *protocol, the leader has received an alarm message.*

Based on the above lemmata, we establish our main result in the following theorem.

▶ **Theorem 6.** *Given an Anonymous Dynamic Network with n nodes, after running* Methodical Counting *for each estimate $k = 2, 3, \ldots, n$ with parameters*

$$
\begin{aligned}
d &= k^{1+\epsilon}, \\
p &= \left\lceil \frac{(2+\epsilon)k^{1+\epsilon}}{1-1/k} \ln k \right\rceil, \\
r &= \left\lceil \left(4 + 2\epsilon + \max\left\{0, -\frac{2\ln(k^\epsilon - 1)}{\ln k}\right\}\right) dk^{2+2\epsilon} \ln k \right\rceil, \\
\tau &= 1 - 1/k^{1+\epsilon},
\end{aligned}
$$

where $\epsilon > 0$, all nodes stop after $\sum_{k=2}^{n}(pr + k)$ rounds of communication and output n.

Proof. Notice that the above parameters fulfill the conditions of the previous lemmas. First, we prove that Methodical Counting is correct. To do so, it is enough to show that for each estimate $k < n$ the algorithm detects the error and moves to the next estimate, and that if otherwise $k = n$ the algorithm stops and outputs k. We consider three cases: $k = n$, $k < n \leq k^{1+\epsilon}$, and $k^{1+\epsilon} < n$, for a chosen value of $\epsilon > 0$.

Assume first that $k < n \leq k^{1+\epsilon}$. Then, even if the leader does not receive an alarm during the execution, as shown in Lemma 3, at the end of the epoch in Line 1.21 the leader will detect that ρ is out of range and will not change its status to done. Therefore, no other node will receive a termination message (loop in Line 1.28), and all nodes will continue to the next epoch.

Assume now that $k^{1+\epsilon} < n$. Lemma 5 shows that within the following $k^{1+\epsilon}$ rounds after the first phase the leader has received an alarm message, even if no node has more than $d-1$ neighbors during the execution and alarms due to this are not triggered. For the given value of p and $k \geq 2$, the epoch has more than one phase. Therefore, within $k^{1+\epsilon}$ rounds into the second phase the leader will change to alarm status in Line 1.13, will not change its status to done later in this epoch, and no other node will receive a termination message. Hence, all nodes will continue to the next epoch.

Finally, if $k = n$, Lemma 2 shows that the accumulated potential ρ will be $k - 1 - 1/k \leq \rho \leq k - 1$. Thus, in Line 1.21 the leader will change its status to done, and in the loop of Line 1.28 will inform all other nodes that the current estimate is correct. The number of iterations of such loop are enough due to 1-interval connectivity.

The claimed running time can be obtained by inspection of the algorithm, either for the leader or non-leader since they are synchronized. Refer for instance to the leader algorithm in Algorithm 1. The outer loop in Line 1.6 corresponds to each epoch with estimates $k = 2, 3, \ldots, n$. For each epoch, Line 1.7 starts a loop of p phases followed by k rounds in Line 1.28. Each of the p phases has r rounds. Thus, the overal number of rounds is $\sum_{k=2}^{n}(pr + k)$. ◀

Choosing $\epsilon = \log_k 2$ and replacing in Theorem 6 yields the following corollary.

▶ **Corollary 7.** *The time complexity of* Methodical Counting *is* $O(n^5 \log^2 n)$.

7 Extensions

We argue that Methodical Counting can be extended to compute the sum of values stored in the nodes, and thus also the average (as it computes the number of nodes n), and other functions. Given that our Counting algorithm is based on mass-distribution, the standard approach could be to compute the average (by sharing the input values repeatedly until convergence to average) at the same time we compute the count. Then, the sum would be simply the average times the count. However, mass-distribution algorithms only converge to the result. That is, we may not get the exact sum with the procedure described. Then, a more careful method is needed.

Assume that each node of the Anonymous Dynamic Network initially stores a value, represented as a sequence of bits. Without loss of generality, we could assume that the value stored at the leader is zero; otherwise, the nodes could compute the sum of other initial values (with the leader value set up to 0), and later the leader could propagate its actual initial value appended to the message "done" at the end of the execution to be added to the computed sum of other nodes.

The modified Methodical Counting prepends the potential to the sequence. Instead of sending potential by the original Methodical Counting, each node transmits its current sequence (in which the potential stands in the first location). Changes at each position of the sequence are done independly by the same algorithm as used for the potential, cf. Algorithms 1 and 2. Re-setting the values, in the beginning of each epoch, means putting back the initial values of the sequence. It means that the modified algorithm maintains potential in exactly the same way as the original Methodical Counting, regardless of the initial values. At the end of some epoch, with number corresponding to the number of nodes n, all nodes terminate. When it happens, each node recalls the sequence stored in it at the end of the first phase of the epoch, multiplies the values stored at each position of the sequence by the epoch number n, and rounds each of the results to the closest integer;

then it sums up the subsequent values multiplied by corresponding (consecutive) powers of 2. Note that such "recalling" could be easily implemented by storing and maintaining the sequence after the first phase of each epoch.

We argue that the computed value is the sum of the initial values. It is enough to analyze how the modified algorithm processes values at one position of the sequence, as positions are treated independently; therefore, w.l.o.g. we assume that each node has value 0 or 1 in the beginning. Consider the last epoch before the leader sends the final sequence (in our case, representing one value). In the beginning of the epoch, the values are re-set to the original one, and manipulated independently according to the rules in Algorithms 1 and 2. Therefore, let us focus on the first phase of this epoch. Since we already proved that the estimate of the last epoch is equal to the number of nodes, the value of d in this epoch (and thus also in its first phase) is an upper bound on the node degree. Thus, the mass distribution scaled down by the sum of the initial values behaves exactly the same as the probabilities of being at nodes in the corresponding round of the lazy random walk, with parameter d and starting from initial distribution equal to the initial values divided by the sum. Since the length of the phase is set up to guarantee that the distribution is close to the stationary uniform within error $1/n$, and the sum of bits is not bigger than n, at the end of the phase the value stored by each node is close to the sum (i.e., scaling factor) divided by n by at most $1/n^4$ (cf. proof of Lemma 2). Therefore, after multiplying it by n, each node gets value of sum within error of at most $1/n^3$, which after rounding will give the integer equal to the value of the sum.

Once having the number n and the sum, each node can compute the average. As argued in [17], the capacity of computing the sum of the input values makes possible the computation of more complex functions. As opposed to [17] where the computation only converges, our approach outputs the exact sum. Therefore, the extension to database queries that can be approximated using *linear synopses*[6] is straightforward. Boolean functions $f : \{0,1\}^n \to \{0,1\}$, such as AND (sum $= n$), OR (sum > 0), and XOR (sum $= 1$), as well as their complementaries NAND (sum $\neq n$), NOR (sum $= 0$), and XNOR (sum $\neq 1$), can also be implemented having n and the sum. This applies also to other "symmetric" (i.e., do not depend on the order of variables) Boolean functions, as they could be computed based on computed sum of ones and n [18]. Maximum (L_∞ norm) and minimum can be computed subsequently by flooding. That is, each node broadcasts the maximum and minimum input values seen so far. Due to 1-interval connectivity within n rounds all nodes have the answers.

Note that all these computations, including the Methodical Counting, could be done using only polynomial estimates of values, that is, with messages of length $O(\log n)$, multiplied by the maximum number of coordinates of any of the initial values. This could be also traded for time: we could use only messages of length $O(\log n)$ with time increased by the maximum number of coordinates of any initial value (which is still polynomial in the size of the input,[7] which in this case is at least n plus the maximum number of coordinates).

8 Open Directions

Straightway questions emerging from our work include existence of polynomial (in n) lower bound and improvement of our upper bound. One of the potential ways could be through investigating bi-directional relationships between random processes and computing algebraic functions in Anonymous Dynamic Network. Extending the range of polynomially computable

[6] Additive functions on multisets, e.g. $f(A \cup B) = f(A) + f(B)$.
[7] The input in this case is distributed among the nodes, and each node possesses at least one bit

functions is another intriguing future direction. Finally, generalizing the model by not assuming connectivity in every round or dropping assumption on synchrony could introduce even more challenging aspects of communication and computation, including group communication and its impact on the common knowledge about the system parameters.

The Unfortunate-Flow Problem

Abstract

In the traditional maximum-flow problem, the goal is to transfer maximum flow in a network by directing, in each vertex in the network, incoming flow into outgoing edges. The problem is one of the most fundamental problems in TCS, with application in numerous domains. The fact a maximal-flow algorithm directs the flow in all the vertices of the network corresponds to a setting in which the authority has control in all vertices. Many applications in which the maximal-flow problem is applied involve an adversarial setting, where the authority does not have such a control.

We introduce and study the *unfortunate flow problem*, which studies the flow that is guaranteed to reach the target when the edges that leave the source are saturated, yet the most unfortunate decisions are taken in the vertices. When the incoming flow to a vertex is greater than the outgoing capacity, flow is lost. The problem models evacuation scenarios where traffic is stuck due to jams in junctions and communication networks where packets are dropped in overloaded routers.

We study the theoretical properties of unfortunate flows, show that the unfortunate-flow problem is co-NP-complete and point to polynomial fragments. We introduce and study interesting variants of the problem: *integral unfortunate flow*, where the flow along edges must be integral, *controlled unfortunate flow*, where the edges from the source need not be saturated and may be controlled, and *no-loss controlled unfortunate flow*, where the controlled flow must not be lost.

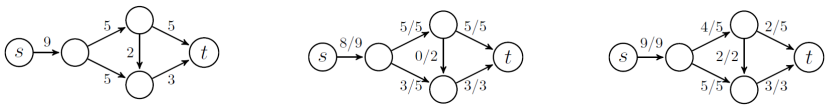
1 Introduction

A *flow network* is a directed graph in which each edge has a capacity, bounding the amount of flow that can travel through it. The amount of flow that enters a vertex equals the amount of flow that leaves it, unless the vertex is a *source*, which has only outgoing flow, or a *target*, which has only incoming flow. The fundamental *maximum-flow problem* gets as input a flow network and searches for a maximal flow from the source to the target [4, 10]. The problem was first formulated and solved in the 1950's [8, 9]. It has attracted much research on improved algorithms, variants, and applications [6, 5, 11, 15].

The maximum-flow problem can be applied in many settings in which something travels along a network. This covers numerous application domains, including traffic in road or rail systems, fluids in pipes, packets in a communication network, and many more [1]. Less obvious applications involve flow networks that are constructed in order to model settings with an abstract network, as in the case of scheduling with constraints [1]. In addition, several



(a) (b) (c)

Figure 1 A flow network $\mathcal{G}$, and preflows that attain its maximum-flow and unfortunate-flow values.

classical graph-theory problems can be reduced to the maximum-flow problem. This includes the problem of finding a maximum bipartite matching, minimum path cover, maximum edge-disjoint or vertex-disjoint path, and many more [4, 1]. Variants of the maximum-flow problem can accommodate further settings, like circulation problems [18], multiple source and target vertices, costs for unit flows, multiple commodities, and more [7].

Studies of flow networks so far assume that the vertices in the network are controlled by a central authority. Indeed, maximum-flow algorithms directs the flow in all vertices of the network. In many applications of flow networks, however, vertices of the network may not be controlled. Thus, every vertex may make autonomous and independent decisions regarding how to direct incoming flow to outgoing edges.

Consider, for example, a road network of a city, where the source s models the center of the city and the target t models the area outside the city. In order to *evacuate* the center of the city, drivers navigate from s to t. In each vertex, every incoming driver chooses an arbitrary outgoing edge with free capacity. If the outgoing capacity from a vertex is less than the incoming flow, then a traffic jam occurs, and flow is lost. As another example, consider a communication network in which packets are sent from a source router s and should reach a target router t. Whenever an internal router receives a packet it forwards it to an arbitrary neighbor router. If the outgoing capacity from a vertex is less than the incoming flow, then packets are dropped, and flow is lost.

In both examples, we want to find the flow that is guaranteed to reach the target in the worst scenario. We now formalize this intuition. Let $\mathcal{G} = \langle V, E, c, s, t\rangle$ be a flow network, where $\langle V, E\rangle$ is a directed graph, $c : E \to \mathbb{N}$ assigns a capacity for each edge, and s, t are the source and target vertices. A *preflow* is a function $f : E \to \mathbb{R}$ that assigns to each edge $e \in E$, a flow in $[0, c(e)]$ such that the incoming flow to each vertex is greater or equal to its outgoing flow. A *saturating preflow* is a preflow in which all outgoing edges from s are saturated, and for every vertex $v \in V \setminus \{s, t\}$, the outgoing flow from v is the minimum between the incoming flow to v and the outgoing capacity from v. That is, in a saturating preflow, flow loss occurs in a vertex v if and only if the incoming flow to v is greater than the capacity of the edges outgoing from v. The *unfortunate flow value* of $\mathcal{G}$ is the minimal flow that reaches t in a saturating preflow. Thus, it is the flow that is guaranteed to reach t when the edges that leave s are saturated, yet the most unfortunate routing decisions are taken in junctions. In the *unfortunate-flow problem*, we want to find the unfortunate flow value of $\mathcal{G}$.

▶ **Example 1.** Consider the flow network $\mathcal{G}$ appearing in Figure 1 (a). A maximum flow in $\mathcal{G}$ has value 8, attained, for example, with the preflow in (b). A saturating preflow in $\mathcal{G}$ appears in (c), and has value 5. While the edges leaving s are saturated, the routing of 7 flow units to the vertex at the bottom leads to a loss of 4 flow units in this vertex. ◀

We introduce the unfortunate-flow problem, study the theoretical properties of saturating preflows, and study the complexity of the problem. We also introduce and study interesting variants of the problem: *integral unfortunate flow*, where the flow along edges must be

integral, *controlled unfortunate flow*, where the edges from the source need not be saturated and may be controlled, and *no-loss controlled unfortunate flow*, where the controlled flow must avoid loss.

Before we describe our contribution, let us review *flow games* and their connection to our contribution here. In flow games [14], the vertices of a flow network are partitioned between two players. Each player controls how incoming flow is partitioned among edges outgoing from her vertices. Then, one player aims at maximizing the flow that reaches t and the other player aims at minimizing it. It is shown in [14] that when the players are restricted to *integral strategies*, thus when the flows along the edges are integers, then the problem of finding the maximal flow that the maximizer player can guarantee is Σ_2^P-complete. The restriction to integral strategies is crucial. Indeed, unlike the case of the traditional maximum-flow problem, non-integral strategies may be better than integral ones. In fact, the problem of finding a maximal flow for the maximizer in a setting with non-integral strategies was left open in [14]. The unfortunate-flow problem can be viewed as a special case of flow games, in which the maximizer player controls no vertex.

We start with the complexity of the unfortunate-flow problem. We consider the decision-problem variant, where we are given a threshold $\gamma > 0$ and decide whether the unfortunate flow value is at least γ. In the case of maximal flow, the problem can be solved in polynomial time [9], and so are many variants of it. We first show that, quite surprisingly, the unfortunate-flow problem is co-NP-hard and that it is NP-hard to approximate within any multiplicative factor. We then point to a polynomial fragment. Intuitively, the fragment restricts the number of vertices in which flow may be lost, which we pinpoint as the computational bottleneck. Formally, we say that a vertex is a *funnel* if its incoming capacity is greater than its outgoing capacity. We show that the unfortunate-flow problem can be solved in time $O(2^{|H|} \cdot (|E|^2 log|V| + |E||V|log^2|V|))$, where $H \subseteq V$ is the set of funnels in $\mathcal{G}$. In particular, the problem can be solved in strongly-polynomial time if the network has a logarithmic number of funnels. Our solution reduces the problem to a sequence of *min-cost max-flow* problems [1], implying the desirable *integral flow property*: the unfortunate-flow value can always be attained by an integral flow. The integral flow property implies a matching co-NP upper bound, thus the unfortunate-flow problem is co-NP-complete.

In some scenarios, we have some initial control on the flow. For example, in evacuation scenarios, as in the example of traffic leaving the city, police may direct cars at the center of the city, but has no control on them once they leave the center. Likewise, when entering or evacuating stadiums, police may direct the crowd to different gates, but has no control on how people proceed once they pass the gates [13]. We study the *controlled unfortunate-flow problem*, where the outgoing flow from s is bounded and controlled. Formally, there is an integer $\alpha \geq 0$ such that the total outgoing flow from s is bounded by α, and it is possible to control how this outgoing flow is partitioned among the edges that leave s. Our goal is to control this flow so that the flow that reaches t in the most unfortunate case is maximized. [1] We show that the integral-flow property no longer holds in this setting. Thus, there are networks in which an optimal strategy is to partition the α units of flow that leave s into non-integers. A troublesome implication of this is that an algorithm that guesses the strategy has to go over unboundedly many possibilities. This challenge is what has left flow games undecidable [14]. We show that we can still reduce the controlled unfortunate-flow problem into the second alternation level of the theory of real numbers under addition and order [17].

[1] We note that this is different from work done in *evacuation planning*, where the goal is to find routes and schedules of evacuees (for a survey, see [16]).

The reduction implies membership in Σ_2^P, and we show a matching lower bound. Thus, the controlled unfortunate-flow problem is Σ_2^P-complete. We also study a generalization of the problem, where control can be placed in a subset of the vertices.[2]

Finally, in some scenarios it is crucial for flow not to get lost. For example, in evacuation scenarios, we may prefer to give up an evacuation attempt under a loss risk, and in communication networks, we may tolerate low traffic and not tolerate dropping of packets. We say that a flow network $\mathcal{G}$ is *safe* if all saturating preflows have no loss. For example, networks with no funnels are clearly safe. It is easy to see that $\mathcal{G}$ is safe if its unfortunate flow value is equal to the maximal flow the source can generate, thus to the capacity of the edges outgoing from the source. This gives a co-NP algorithm for deciding the safety of a network. We show one can do better and reduce the safety problem to a maximum weighted flow problem, which can be solved in polynomial time. We then turn to study the *no-loss controlled unfortunate-flow problem*, where we control the flow in edges from s, and we want to maximize the flow to t but in a way that flow loss is impossible. We show that the problem is NP-complete.

Due to space limitations, some examples and proofs are omitted and can be found in the full version, in the authors' URLs.

2 Preliminaries

A *flow network* is $\mathcal{G} = \langle V, E, c, s, t\rangle$, where V is a set of vertices, $E \subseteq V \times V$ is a set of directed edges, $c : E \to \mathbb{N}$ is a capacity function, and $s, t \in V$ are source and target vertices. The capacity function assigns to each edge $e \in E$ a nonnegative capacity $c(e) \geq 0$. We define the *size* of $\mathcal{G}$, denoted $|\mathcal{G}|$ by $|V| + |E| + |c|$, where $|c|$ is the size required for encoding the capacity function c, thus assuming the capacities are given in binary. For a vertex $v \in V$, let $E^{\to v}$ and $E^{v\to}$ be the sets of incoming and outgoing edges to and from v, respectively. That is, $E^{\to v} = (V \times \{v\}) \cap E$ and $E^{v\to} = (\{v\} \times V) \cap E$. A *sink* is a vertex v with no outgoing edges, thus $E^{v\to} = \emptyset$. We assume that t is a sink, it is reachable from s, and $E^{\to s} = \emptyset$. We also assume that $\langle V, E\rangle$ does not contain parallel edges and self loops. For a vertex $v \in V$, let $c(\to v) = \sum_{e\in E^{\to v}} c(e)$ and $c(v\to) = \sum_{e\in E^{v\to}} c(e)$ be the sums of capacities of edges that enter and leave v, respectively. We say that a vertex $v \in V$ is a *funnel* if $c(v\to) < c(\to v)$. We use C_s to denote the total capacity of edges outgoing from the source, thus $C_s = c(s\to)$.

A *preflow* in $\mathcal{G}$ is a function $f : E \to \mathbb{R}$ that satisfies the following two properties:

- For every $e \in E$, we have that $0 \leq f(e) \leq c(e)$.
- For every vertex $v \in V \setminus \{s\}$, the incoming flow to v is greater or equal to its outgoing flow. Formally, $\sum_{e\in E^{\to v}} f(e) \geq \sum_{e\in E^{v\to}} f(e)$.

For a preflow f and an edge $e \in E$, we say that e is *saturated* if $f(e) = c(e)$. We extend f to vertices: for every vertex $v \in V$, let $f(\to v) = \sum_{e\in E^{\to v}} f(e)$ and $f(v\to) = \sum_{e\in E^{v\to}} f(e)$. For a vertex $v \in V \setminus \{s, t\}$, the *flow loss of f in v*, denoted $l_f(v)$, is the quantity that enters v and does not leave v. Formally, $l_f(v) = f(\to v) - f(v\to)$. Then, $L_f = \sum_{v\in V\setminus\{s,t\}} l_f(v)$ is the *flow loss of f*. The value of a preflow f, denoted $val(f)$, is $f(\to t)$; that is, the incoming flow to t. Note that $val(f) = f(s\to) - L_f$. A *flow* is a preflow f with $L_f = 0$. A *maximum flow* is a flow with a maximal value.

[2] Not to confuse with the problem of finding critical nodes for firefighters [2, 3]. While there the firefighters block the fire, in our setting they direct the evacuation. Thus, there, the goal is to block undesired vulnerabilities in the network, and here the goal is maximize desired traffic.

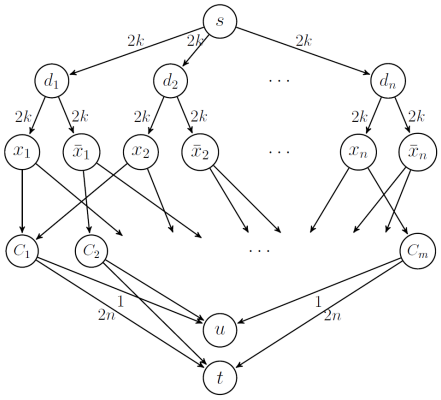


Figure 2 The flow network $\mathcal{G}$. The capacities of the edges entering $C_1, \ldots, C_m$ are 1.

A *saturating preflow* is a preflow in which all edge in $E^{s\rightarrow}$ are saturated, and for every $v \in V \setminus \{s, t\}$, we have $f(v\rightarrow) = \min\{f(\rightarrow v), c(v\rightarrow)\}$. That is, in a saturating preflow, flow loss may occur in a vertex v only if the incoming flow to v is bigger than the capacities of the edges outgoing from v.

The *unfortunate value* of a flow network $\mathcal{G}$, denoted $uval(\mathcal{G})$, is the minimal value of a saturating preflow in $\mathcal{G}$. That is, it is the value that is guaranteed to reach t when the edges that leave s are saturated, yet the most unfortunate routing decisions are taken in junctions. An *unfortunate saturating preflow* is a saturating preflow that attains the network's unfortunate value. The *unfortunate flow* problem (UF problem, in short) is to decide, given a flow network $\mathcal{G}$ and a threshold $\gamma > 0$, whether $uval(\mathcal{G}) \geq \gamma$.

3 The Complexity of the Unfortunate-Flow Problem

In this section we study the complexity of the unfortunate-flow problem. We start with bad news and show that the problem is co-NP-hard, and in fact is NP-hard to approximate within any multiplicative factor. A more precise analysis of the complexity then enables us to point to a polynomial fragment and to prove an integral-flow property, which implies a matching co-NP upper bound.

▶ **Theorem 2.** *The UF problem is co-NP-hard.*

Proof. We show a reduction from CNF-SAT to the complement problem, namely deciding whether $uval(\mathcal{G}) < \gamma$ for some $\gamma \in \mathbb{N}$. Let $\psi = C_1 \wedge \ldots \wedge C_m$ be a CNF formula over the variables $x_1 \ldots x_n$. We assume that every literal in $x_1, \ldots, x_n, \bar{x}_1, \ldots, \bar{x}_n$ appears in exactly k clauses in ψ. Indeed, every CNF formula can be converted to such a formula in polynomial time and with a polynomial blowup. We construct a flow network $\mathcal{G} = \langle V, E, c, s, t\rangle$ as demonstrated in Figure 2. Let $Z = \{x_1, \ldots, x_n, \bar{x}_1, \ldots, \bar{x}_n\}$. For a literal $z \in Z$ and a clause C_i, the network $\mathcal{G}$ contains an edge $\langle z, C_i\rangle$ iff C_i contains z. Thus, each vertex in Z has exactly k outgoing edges. The capacities of these edges are 1. Each vertex C_i has two outgoing edges – to t and to the sink u. In the full version, we prove that ψ is satisfiable iff $uval(\mathcal{G}) < kn - m + 1$. ◀

By a simple manipulation of the network $\mathcal{G}$ constructed in the reduction in the proof of Theorem 2, we can obtain, given a CNF-SAT formula ψ, a network $\mathcal{G}'$ such that if ψ is

satisfiable, then $uval(\mathcal{G}') = 0$, and otherwise, $uval(\mathcal{G}') \geq 1$. Hence the following (a detailed proof can be found in the full version.

▶ **Theorem 3.** *It is NP-hard to approximate the UF problem within any multiplicative factor.*

Following the hardness of the problem, we turn to analyze its complexity in terms of the different parameters of the flow network. Our analysis points to a class of networks for which the UF problem can be solved in polynomial time.

Consider a flow network $\mathcal{G} = \langle V, E, c, s, t\rangle$. Let $H \subseteq V \setminus \{s, t\}$ be the set of funnels in $\mathcal{G}$. Thus, $H = \{v : c(\rightarrow v) > c(v\rightarrow)\}$. For $L \subseteq V$, let $\mathcal{F}_L$ be a set of saturating preflows in which edges outgoing from vertices in L are saturated, and flow loss may occur only in vertices in L. Thus, $f \in \mathcal{F}_L$ iff f is a saturating preflow in $\mathcal{G}$ such that for every $u \in L$, we have $f(u\rightarrow) = c(u\rightarrow)$, and for every $u \in V \setminus L$, we have $l_f(u) = 0$. By the definition of a saturating flow, flow loss in $\mathcal{G}$ may occur only in vertices in H. Accordingly, we have the following.

▶ **Lemma 4.** $\bigcup_{L\subseteq H} \mathcal{F}_L$ *contains all the saturating preflows in* $\mathcal{G}$.

By Lemma 4, a search for the unfortunate value of $\mathcal{G}$ can be restricted to preflows in $\mathcal{F}_L$, for $L \subseteq H$. Accordingly, the UF problem can be solved by solving $2^{|H|}$ optimization problems, solvable by either linear programming (Theorem 5) or a reduction to the min-cost max-flow problem (Theorem 6).

▶ **Theorem 5.** *Consider a flow network* $\mathcal{G}$ *and let* H *be the set of funnels in* $\mathcal{G}$. *The UF problem for* $\mathcal{G}$ *can be solved in time* $2^{|H|} \cdot poly(|\mathcal{G}|)$.

Proof. The algorithm goes over all the subsets of H and for each subset $L \subseteq H$, finds a minimum-value preflow in $\mathcal{F}_L$. The latter is done by linear programming. Given L, the linear program for $\mathcal{F}_L$ is described below. The variable x_e, for every $e \in E$, stands for $f(e)$. The program is of size linear in $|\mathcal{G}|$, thus the overall complexity is $2^{|H|} \cdot poly(|\mathcal{G}|)$.

minimize	$\sum_{e\in E^{\rightarrow t}} x_e$	
subject to	$0 \leq x_e \leq c(e)$	for each $e \in E$
	$x_e = c(e)$	for each $u \in L \cup \{s\}, e \in E^{u\rightarrow}$
	$\sum_{e\in E^{u\rightarrow}} x_e \leq \sum_{e\in E^{\rightarrow u}} x_e$	for each $u \in L$
	$\sum_{e\in E^{u\rightarrow}} x_e = \sum_{e\in E^{\rightarrow u}} x_e$	for each $u \notin L \cup \{s, t\}$

◀

The complexity of solving each linear program in the algorithm described in the proof of Theorem 5 is polynomial in $|\mathcal{G}|$, but not *strongly polynomial*. Thus its running time depends (polynomially) on the number of bits required for representing the capacities in $\mathcal{G}$. We now describe an alternative algorithm whose complexity depends only on the number of vertices and edges in the network.

Our algorithm reduces the problem of finding a minimal-value preflow in $\mathcal{F}_L$ to the *min-cost max-flow* problem in flow networks with costs [1]. A flow network with costs is $\mathcal{G} = \langle V, E, a, c, s, t\rangle$, where $\langle V, E, c, s, t\rangle$ is a flow network and $a : E \rightarrow \mathbb{R}$ is a cost function. The cost of a flow f in $\mathcal{G}$, denoted $cost(f)$, is $\sum_{e\in E} a(e) \cdot f(e)$. In the min-cost max-flow problem we are given a flow network with costs, and find a maximum flow with a minimum cost. By [1], this problem can be solved in time $O(|E|^2 log|V| + |E||V|log^2|V|)$.

▶ **Theorem 6.** *Consider a flow network* $\mathcal{G} = \langle V, E, c, s, t\rangle$ *and let* H *be the set of funnels in* $\mathcal{G}$. *The UF problem for* $\mathcal{G}$ *can be solved in time* $O(2^{|H|} \cdot (|E|^2 log|V| + |E||V|log^2|V|))$.

Proof. The algorithm finds, for each subset $L \subseteq H$, a minimum-value preflow in $\mathcal{F}_L$ by a reduction to the min-cost max-flow problem. By Lemma 4, the minimum value found for some $L \subseteq H$ is $uval(\mathcal{G})$.

Consider the flow network with costs $\mathcal{G}' = \langle V', E', a, c', s, t' \rangle$ that is obtained from $\mathcal{G}$ as follows. We add a new vertex t' and edges $\langle u, t' \rangle$ for every $u \in L \cup \{t\}$, thus $V' = V \cup \{t'\}$ and $E' = E \cup (L \cup \{t\}) \times \{t'\}$. The capacity $c'(e)$ for every new edge $e \in E' \setminus E$ is large (for example, it may be C_s), and for every $e \in E$, we have $c'(e) = c(e)$. Let $C = \max\{c(e) : e \in E\}$ denote the maximal capacity in $\mathcal{G}$. For edges $e \in L \times \{t'\}$, we define $a(e) = -1$; for edges $e \in L \times V$, we define $a(e) = -C \cdot |V|^2$; and for all the other edges, we define $a(e) = 0$. Intuitively, the costs of the edges in $L \times V$ are negative and small enough, so that a min-cost max-flow in $\mathcal{G}'$ would have to saturate them first, and only then try to direct flow to edges in $L \times \{t'\}$.

In the full version, we prove the correctness of the following algorithm: First, find a min-cost max-flow f' in $\mathcal{G}'$. If $val(f') < C_s$ or $cost(f') > -C \cdot |V|^2 \cdot \sum_{e \in L \times V} c(e)$, then $\mathcal{F}_L = \emptyset$. Otherwise, the minimal value of a preflow in $\mathcal{F}_L$ is $C_s + cost(f') + C \cdot |V|^2 \cdot \sum_{e \in L \times V} c(e)$. Since the min-cost max-flow problem can be solved in time $O(|E|^2 log|V| + |E||V|log^2|V|)$ [1] and there are $2^{|H|}$ subsets of funnels to check, the required complexity follows. ◀

▶ **Corollary 7.** *The UF problems for networks with a logarithmic number of funnels can be solved in strongly-polynomial time.*

We say that a preflow $f : E \to \mathbb{R}$ is *integral* if $f(e) \in \mathbb{N}$ for all $e \in E$. It is sometimes desirable to restrict the flow to an integral one, for example in settings in which the objects we transfer along the network cannot be partitioned into fractions. We now show that the UF problem always has an integral-flow solution, and that such a solution can be obtained by the algorithm shown in the proof of Theorem 6. Essentially (see proof in the full version), it follows from the fact that the min-cost max-flow problem has an integral solution. As we show in Section 4, this *integral flow property* is not maintained in variants of the UF problem.

▶ **Theorem 8.** *The UF problem has an integral-flow solution: for every flow network, there exists an integral unfortunate saturating preflow. Moreover, such integral preflow can be found by the algorithm described in the proof of Theorem 6.*

The integral-flow property suggests an optimal algorithm for solving the UF problem:

▶ **Theorem 9.** *The UF problem is co-NP-complete.*

Proof. Hardness in co-NP is proven in Theorem 2. We prove membership in NP for the complementary problem: given $\gamma > 0$ and a flow network $\mathcal{G}$, we need to decide whether $uval(\mathcal{G}) < \gamma$. According to Theorem 8, it is enough to decide whether there is a saturating preflow f in which for every $e \in E$, the value $f(e)$ is an integer, and $val(f) < \gamma$. Given a function $f : E \to \mathbb{N}$, checking whether f satisfies these requirements can be done in polynomial time, implying membership in NP. ◀

4 The Controlled Unfortunate-Flow Problem

In this section we study the controlled unfortunate-flow problem, where the outgoing flow from s is bounded and controlled. That is, there is $0 \leq \alpha \leq C_s$ such that the total outgoing flow from s is bounded by α, and it is possible to control how this outgoing flow is partitioned among the edges that leave s. Our goal is to control this flow so that the flow that reaches t in the worst case is maximized. As discussed in Section 1, this problem is motivated by scenarios where we have an initial control on the flow, say by positioning police at the entrance to a stadium or at the center of a city we need to evacuate, or by transmitting messages we want to send from a router we own.

For $\alpha \geq 0$, a *regulator with bound* α is a function $g : E^{s\rightarrow} \rightarrow \mathbb{R}$ that directs α flow units from s. Formally, for every $e \in E^{s\rightarrow}$, we have $0 \leq g(e) \leq c(e)$, and $\sum_{e \in E^{s\rightarrow}} g(e) \leq \alpha$. A *controlled saturating preflow that respects a regulator* g is a preflow $f : E \rightarrow \mathbb{R}$ such that for every $e \in E^{s\rightarrow}$, we have $f(e) = g(e)$, and for every $v \in V \setminus \{s, t\}$, we have $f(v\rightarrow) = \min\{f(\rightarrow v), c(v\rightarrow)\}$. Thus, unlike saturating preflow, here the edges in $E^{s\rightarrow}$ need not be saturated and the flow in them is induced by g. The *unfortunate g-controlled value* of $\mathcal{G}$, denoted $cuval(\mathcal{G}, g)$, is the minimal value of a controlled saturating preflow that respects g. Then, the *unfortunate α-controlled value* of $\mathcal{G}$, denoted $cuval(\mathcal{G}, \alpha)$ is the maximal unfortunate g-controlled value of $\mathcal{G}$ for some regulator g with bound α. In the *controlled unfortunate flow* problem (CUF problem, for short), we are given a flow network $\mathcal{G}$, a bound $\alpha \geq 0$, and a threshold $\gamma > 0$, and we need to decide whether $cuval(\mathcal{G}, \alpha) \geq \gamma$. Thus, in the CUF problem we need to decide whether there is a regulator g with bound α that ensures a value of at least γ.

For two regulators g and g', we denote $g \geq g'$ if for every $e \in E^{s\rightarrow}$, we have $g(e) \geq g'(e)$. In the following theorem we show that the g-controlled unfortunate value is monotonic with respect to g. Thus, increasing g can only increase the value. In particular, it follows that a maximal $cuval(\mathcal{G}, \alpha)$ is obtained with $\alpha = C_s$ and a regulator g in which $g(e) = c(e)$ for every $e \in E^{s\rightarrow}$. Thus, if the outgoing flow from s is not bounded, then the optimal behavior is to saturate the edges in $E^{s\rightarrow}$. Essentially (see full proof in the full version of the paper), it follows from the fact that given g and g' such that $g \geq g'$, and a minimum-value controlled saturating preflow f that respects g, we can construct a controlled saturating preflow f' that respects g' and such that $val(f) \geq val(f')$.

▶ **Theorem 10.** *Consider a flow network $\mathcal{G}$, and let g, g' be two regulators such that $g \geq g'$. Then, $cuval(\mathcal{G}, g) \geq cuval(\mathcal{G}, g')$.*

We now turn to study the complexity of the CUF problem. We first explain why the problem is challenging. One could expect an algorithm in which, given $\mathcal{G}$, α, and γ, we guess an *integral regulator* $g : E^{s\rightarrow} \rightarrow \mathbb{N}$ with bound α, and then use an NP oracle in order to check whether $cuval(\mathcal{G}, g) \geq \gamma$. The problem with the above idea is that it restricts the regulators to integral ones. In Theorem 11 below we show that in some cases, an optimal regulator must use non-integral values. Accordingly, an algorithm that guesses a regulator, as has been the case with the guessed flows in Theorem 9, has to go over unboundedly many possibilities. In fact, when an arbitrary set of vertices (rather than the source only) may be controlled, the problem is not known to be decidable [14].

▶ **Theorem 11.** *Integral regulators are not optimal: There is a flow network $\mathcal{G}$ such that for every integral regulator $g : E^{s\rightarrow} \rightarrow \mathbb{N}$ with bound 2 we have $cuval(\mathcal{G}, g) = 1$, but there is a regulator $g' : E^{s\rightarrow} \rightarrow \mathbb{R}$ with bound 2 such that $cuval(\mathcal{G}, g') = 2$.*

Proof. Consider the flow network $\mathcal{G}$ appearing in Figure 3. For every pair $\langle u_i, u_j \rangle$ for $1 \leq i < j \leq 4$, the network $\mathcal{G}$ contains a vertex v_{ij} with incoming edges from u_i and u_j. The capacities of the edges in $\mathcal{G}$ are all 1. It is not hard to see that for every integral regulator g with bound 2 we have $cuval(\mathcal{G}, g) = 1$. Indeed, for such g there is a controlled saturating preflow that respects g, which directs a flow of 2 to some vertex v_{ij}, causing a loss of 1 in v_{ij}. Consider now the regulator g' that assigns a flow of 0.5 to every edge in $E^{s\rightarrow}$. In this case, a flow of more than 1 cannot be directed to any vertex v_{ij} and therefore $cuval(\mathcal{G}, g') = 2$. ◀

We turn to solve the CUF problem. Theorem 11 forces us to consider non-integral regulators. We do this by a reduction to a problem with a similar challenge, namely *the second alternation level of the theory of real numbers under addition and order*. There, we are given a

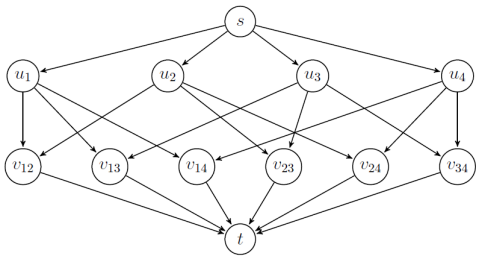

Figure 3 The flow network $\mathcal{G}$. All capacities are 1.

formula of the form $\exists x_1 \ldots x_n \forall y_1 \ldots y_m F(x_1, \ldots, x_n, y_1, \ldots, y_m)$, where F is a propositional combination of linear inequalities of the form $a_1 x_1 + \ldots a_n x_n + b_1 y_1 + \ldots + b_m y_m \leq d$, for constant integers $a_1, \ldots, a_n$, $b_1, \ldots, b_m$, and d, and we have to decide whether there is an assignment of $x_1, \ldots, x_n$ to real numbers so that F is satisfied for every assignment of $y_1, \ldots, y_m$ to real numbers. Even though the domain of possible solutions is infinite, It is shown in [17] that the problem can be solved in Σ_2^P, namely the class of problems that can be solved by a nondeterministic polynomial Turing machine that has an oracle to some NP-complete problem. In [14], a Σ_2^P lower bound is proven for the problem of finding the value of a flow game, where the outgoing flow of a subset of the vertices can be controlled. Recall that in the CUF problem, only the flow from the source vertex can be controlled. While this corresponds to the "exists-forall" nesting of quantifiers that characterizes reasoning in Σ_2^P, it not clear how to reduce Boolean formulas to unfortunate flows. Indeed, in the reduction in [14], control in intermediate vertices is used in order to model disjunctions in the formulas. In the CUF problem, such a control is impossible, as all vertices in the network except for the source are treated in a conjunctive manner.

▶ **Theorem 12.** *The CUF problem is Σ_2^P-complete.*

Proof. We first prove membership in Σ_2^P by a reduction to the second alternation level of the theory of real numbers under addition and order. Given G, α, and γ, we construct a propositional combination F of linear inequalities over the variables x_e for every $e \in E^{s\rightarrow}$, and variables y_e, for every $e \in E$. The formula F states that the values of the variables x_e corresponds to a regulator g with bound α, and that if the values of the variables y_e correspond to a controlled saturating preflow f that respects g then $val(f) \geq \gamma$. Then, our problem amounts to deciding whether there are real values x_e such that for every real values y_e the formula F holds.

For the lower bound, we describe a reduction from QBF_2, namely satisfiability for quantified Boolean formulas with one alternation of quantifiers, where the external quantifier is "exists". Let ψ be a propositional formula over the variables $x_1, \ldots, x_n, y_1, \ldots, y_m$, and let $\theta = \exists x_1 \ldots \exists x_n \forall y_1 \ldots \forall y_m \psi$. Also, let $X = \{x_1, \ldots, x_n\}$, $\bar{X} = \{\bar{x}_1, \ldots, \bar{x}_n\}$, $Y = \{y_1, \ldots, y_m\}$, $\bar{Y} = \{\bar{y}_1, \ldots, \bar{y}_m\}$, $Z = X \cup Y$, and $\bar{Z} = \bar{X} \cup \bar{Y}$. We construct a flow network $\mathcal{G}_\theta$ and define α and γ, such that θ holds iff there is a regulator g with bound α such that $cuval(\mathcal{G}_\theta, g) \geq \gamma$.

We assume that ψ is given in a positive normal form; that is, ψ is constructed from the literals in $Z \cup \bar{Z}$ using the Boolean operators $\vee$ and $\wedge$, and that there is $k \geq 1$ such that every literal in $Z \cup \bar{Z}$ appears in ψ exactly k times. Clearly, every Boolean propositional formula can be converted with only a quadratic blow-up to an equivalent one that satisfies these conditions.

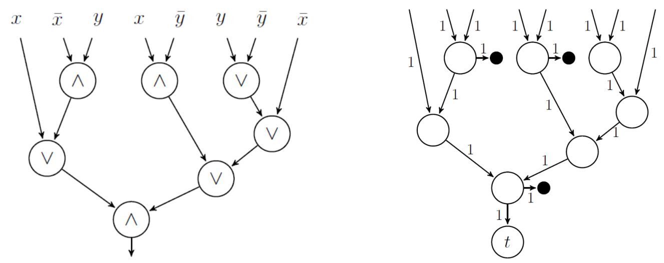

Figure 4 The Boolean circuit $\mathcal{C}_\psi$ and the external-source flow network G_ψ.

We first translate ψ into a Boolean circuit $\mathcal{C}_\psi$ with $k(2n+2m)$ inputs – one for each occurrence of a literal in ψ. For example, in Figure 4, on the left, we describe C_ψ for $\psi = x \vee (\bar{x} \wedge y) \wedge ((x \wedge \bar{y}) \vee (y \vee \bar{y} \vee \bar{x}))$. Each gate in $\mathcal{C}_\psi$ has fan-in 2 and fan-out 1. We say that an input assignment to $\mathcal{C}_\psi$ is consistent if it corresponds to an assignment to the variables in Z. That is, for each variable $z \in Z$, there is a value $b \in \{0,1\}$ such that all the k inputs that correspond to the literal z have value b and all the k inputs that correspond to the literal $\bar{z}$ have value $1-b$. If the input to $\mathcal{C}_\psi$ is consistent then $\mathcal{C}_\psi$ computes the value of ψ for the corresponding assignment.

Now, we translate $\mathcal{C}_\psi$ to an *external-source flow network* $\mathcal{G}_\psi = \langle V, E, c, t\rangle$: a flow network in which there is no source vertex, and an input flow is given externally. Formally, some of the edges in E have an unspecified source, to be later connected to edges with an unspecified target. The idea behind the translation is as follows: The capacities in $\mathcal{G}_\psi$ are all 1. Each OR gate in $\mathcal{C}_\psi$ induces a vertex v that has in-degree 2 and out-degree 1. Thus, if the incoming flow in each incoming edge to v is 0 or 1, then its outgoing flow is 1 iff at least one of its incoming edges has flow 1. Then, each AND gate in $\mathcal{C}_\psi$ induces a vertex v that has in-degree 2 and out-degree 2, yet, one of the two edges that leaves v leads to a sink. Accordingly, if the incoming flow in each incoming edge to v is 0 or 1, then the outgoing flow in the edge that does not lead to the sink must be 1 iff both incoming edges have flow 1. For example, the Boolean circuit $\mathcal{C}_\psi$ from Figure 4 is translated to the external-source flow network $\mathcal{G}_\psi$ to its right.

Given a flow from the external source, we define the unfortunate value of $\mathcal{G}_\psi$ as the minimal value of a controlled saturating preflow that respects the external flow. The following lemma can be easily proved by induction on the structure of ψ.

▶ **Lemma 13.** *Consider a Boolean formula ψ and its corresponding external-source flow network $\mathcal{G}_\psi$.*

1. *Given input flows to $\mathcal{G}_\psi$, if we increase some input flow, then the new unfortunate value of $\mathcal{G}_\psi$ is greater than or equal to the original unfortunate value.*
2. *Given input flows in $\{0,1\}$ to $\mathcal{G}_\psi$, the unfortunate value of $\mathcal{G}_\psi$ is equal to the output of $\mathcal{C}_\psi$ with the same input. Thus, if the input flow to $\mathcal{G}_\psi$ corresponds to a consistent input to $\mathcal{C}_\psi$, then the unfortunate value of $\mathcal{G}_\psi$ is the value of ψ for the corresponding assignment.*

We complete the reduction by constructing the flow network $\mathcal{G}_\theta$ that uses $\mathcal{G}_\psi$ as a subnetwork as shown in Figure 5 The vertices $d_{y_1}, \ldots, d_{y_m}$ are associated with the variables in Y. The vertices $x_i, \bar{x}_i, y_i, \bar{y}_i$ for every i are associated with the literals in $Z \cup \bar{Z}$. Each outgoing edge from a literal vertex that enters $\mathcal{G}_\psi$ is connected to an input of $\mathcal{G}_\psi$ that corresponds to this literal. The outgoing edge from the subnetwork $\mathcal{G}_\psi$ corresponds to an edge from the target vertex of $\mathcal{G}_\psi$. In the full version we describe the network $\mathcal{G}_\theta$ for the case $\psi = (x \vee y) \wedge (\bar{x} \vee \bar{y})$.

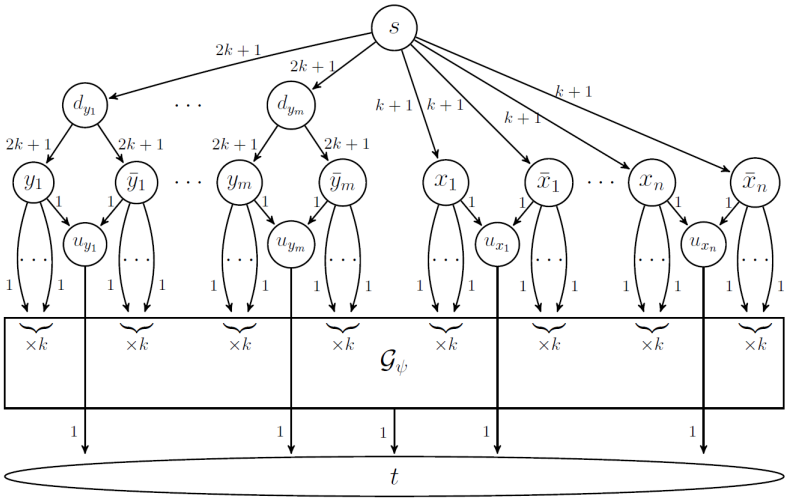

Figure 5 The flow network $\mathcal{G}_\theta$.

In the full version we prove that θ holds iff there is a regulator g with bound $(2k+1)m + (k+1)n$ such that for every controlled saturating preflow f that respects g we have $val(f) \geq m + n + 1$.

◀

In Theorem 11 we showed that in some cases an optimal regulator must use non-integral values. Sometimes, however, it is desirable to restrict attention to integral regulators. In the following theorem (see proof in the full version) we show that the Σ_2^P-completeness stays valid also for integral regulators.

▶ **Theorem 14.** *Let $\mathcal{G}$ be a flow network and let α, γ be integral constants. Deciding whether there exists an integral regulator $g : E^{s\rightarrow} \to \mathbb{N}$ with bound α such that $cuval(\mathcal{G}, g) \geq \gamma$, is Σ_2^P-complete.*

▶ Remark. **[Bounded Global Control]** In the CUF problem, it is possible to control the flow leaving the source. This could be generalized by letting an authority control also internal vertices in the network. In the *bounded global control* problem, we get as input a flow network $\mathcal{G}$, a number $k \geq 0$, and a threshold $\gamma > 0$, and we need to decide whether we can guarantee an unfortunate flow of at least γ by controlling the outgoing flow in at most k vertices. Note that while in the problem of finding critical nodes for firefighters [2, 3], a firefighter blocks the fire, in our setting the firefighters direct the evacuation. Thus, there, the goal is to block undesired vulnerabilities in the network, and here the goal is maximize desired traffic in the network. The formal definition of the bounded global control problem goes through the flow games of [14], which includes the notion of strategies for controlling flow. The Σ_2^P algorithm for solving flow games with integral flows can be extended to solve the bounded global control problem. By making the control on the source vertex essential (say, by adding a transition with a large capacity to a sink), the CUF problem can be reduced to the global control problem with $k = 1$, implying Σ_2^P completeness.

5 Safe Networks and No-Loss Unfortunate Flow

In this section we consider settings in which loss must be avoided. We say that a flow network $\mathcal{G}$ is *safe* if $L_f = 0$ for every saturating preflow f. For example, networks with no funnels are clearly safe. It is easy to see that $\mathcal{G}$ is safe iff $uval(\mathcal{G}) = C_s$. Together with Theorem 9, this gives a co-NP algorithm for deciding the safety of a network. We first show that by reducing the safety problem to the maximum weighted flow problem, we can decide safety in polynomial time. Essentially, the reduction checks, for every vertex $v \in V$, whether it is possible to direct to v flow that is greater than its outgoing capacity, and the weights are used in order to filter flow incoming to v. For details, see the full version.

▶ **Theorem 15.** *Deciding whether a flow network is safe can be done in polynomial time.*

We now consider the case where the total outgoing flow from s is controlled, and we need to find an optimal regulator that guarantees no flow loss. Formally, in the *no-loss controlled unfortunate-flow problem* (NLCUF problem, for short), we are given a flow network $\mathcal{G}$ and an integer $\gamma > 0$, and we need to decide whether there exists a regulator g such that $\sum_{e \in E^{s\rightarrow}} g(e) \geq \gamma$, and for every controlled saturating preflow that respects g the flow loss is 0 (equivalently, $cuval(\mathcal{G}, g) = \gamma$). That is, decide whether there is a regulator that ensures no loss and a value of at least γ. We show that the NLCUF problem is NP-complete. For the upper bound one could expect an algorithm in which we guess an integral regulator $g : E^{s\rightarrow} \rightarrow \mathbb{N}$ in which the total flow is at least γ, and then use Theorem 15 in order to check in polynomial time whether flow loss is possible. However, Theorem 11 shows that in some cases a regulator must use non-integral values in order to ensure that flow loss is impossible. Consequently, our algorithm is more complicated and uses a result from the theory of real numbers with addition.

▶ **Theorem 16.** *The NLCUF problem is NP-complete.*

Proof. We start with the upper bound. For a rational number q we denote by $\#(q)$ the *length* of q, namely, if $q = a/b$ with a, b relatively prime, then $\#(q)$ is the sum of the number of bits in the binary representations of a and b. Consider a formula $\varphi = \exists x_1, ..., x_n \forall y_1, ..., y_m F(x_1, ..., x_n, y_1, ..., y_m)$, where F is a propositional combination of linear inequalities of the form $a_1x_1 + ... + a_nx_n + b_1y_1 + ... + b_my_m \leq d$ for integral constants $a_1, ..., a_n$, $b_1, ..., b_m$, and d. The variables $x_1, ..., x_n, y_1, ..., y_m$ are real. In [17] (in the proof of Theorem 3.1 there) it is shown that φ holds iff there exists rational values $x_1, ..., x_n$ such that for every i the length $\#(x_i)$ is polynomial in the size of φ and for every real values $y_1, ..., y_m$ the formula F holds.

We construct a propositional combination F of linear inequalities over the variables x_e, for every $e \in E^{s\rightarrow}$, and y_e, for every $e \in E$. The formula F states that the values of the variables x_e correspond to a regulator g with bound γ, and that if the values of the variables y_e correspond to a controlled saturating preflow f that respects g, then $L_f = 0$. Then, our problem amounts to deciding whether there are real values x_e such that for every real values y_e, the formula F holds. By [17], it is enough to check whether there are rational values x_e for $e \in E^{s\rightarrow}$ with polynomial lengths such that for every real values y_e for $e \in E$, the formula F holds. Given values for the variables x_e, checking whether for every real values y_e the formula F holds can be done in polynomial time with the algorithm shown in the proof of Theorem 15. Hence the membership in NP.

We proceed to the lower bound. We show a reduction from CNF-SAT. Let $\psi = C_1 \wedge ... \wedge C_m$ be a CNF formula over the variables $x_1 \dots x_n$. We denote $Z = \{x_1, \dots, x_n, \bar{x}_1, \dots, \bar{x}_n\}$. We assume that for every literal $z \in Z$ there is at least one clause in ψ that does not contain

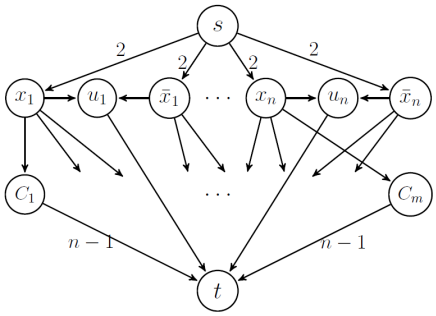

Figure 6 The flow network $\mathcal{G}$. Unless stated otherwise, the capacities are 1.

z. We construct a flow network $\mathcal{G} = \langle V, E, c, s, t\rangle$ as demonstrated in Figure 6. For a literal $z \in Z$ and a clause C_i, the network $\mathcal{G}$ contains an edge $\langle z, C_i\rangle$ iff the clause C_i does not contain the literal z. Let $\gamma = 2n$. In the full version, we show that ψ is satisfiable iff there is a regulator that ensures no loss and a value of at least γ. ◀

Sometimes it is desirable to restrict attention to integral regulators. As we show below, NP-completeness applies for them too (see the full version for proof).

▶ **Theorem 17.** *Let $\mathcal{G}$ be a flow network and let $\gamma > 0$ be an integer. Deciding whether there exists an integral regulator $g : E^{s\to} \to \mathbb{N}$ in $\mathcal{G}$ such that $\sum_{e\in E^{s\to}} g(e) \geq \gamma$, and for every controlled saturating preflow that respects g the flow loss is 0, is NP-complete.*

6 Discussion

The unfortunate-flow problem captures settings in which the authority has no control on how flow is directed in the vertices of a flow network. For many problems, a transition from a cooperative setting to an adversarial one dualizes the complexity class to which the problem belongs, as in NP for satisfiability vs. co-NP for validity. In the case of flow, the polynomial complexity of the maximum-flow problem is not preserved when we move to the dual unfortunate-flow problem, and we prove that the problem is co-NP-complete.

On the positive side, the integral-flow property of maximal flow is preserved in unfortunate flows. This property, however, is lost once we move to controlled unfortunate flows, where non-integral regulators may be more optimal than integral ones. The need to consider real-valued flows questions the decidability of the controlled unfortunate-flow problem. As we show, the problem is decidable, by a reduction to the second alternation level of the theory of real numbers under addition and order [17]. There, the infinite domain of the real numbers is reduced to a finite one, namely rational numbers of length polynomial in the input. A direct algorithm for the controlled unfortunate-flow problem, thus one that does not rely on [17], is still open. Such a direct algorithm would reduce the real-number domain to a finite one in a tighter manner – one that depends on the network. We see several interesting problems in this direction, in particular finding a *sufficient granularity* that a regulator may need, and *bounding the non-optimality* caused by integral regulators. Similar problems are open in the settings of flow games with two or more players [14, 12].

Finally, the unfortunate-flow problem sets the stage to problems around network design, where the goal is to design networks with maximal unfortunate flows. In particular, in *network repair*, we are given a network and we are asked to modify it in order to increase its unfortunate flow value. Different algorithms correspond to different types of allowed

modifications. For example, we may be allowed to change the capacity of a fixed number of edges. Note that unlike the case of maximal flow, here a repair may reduce the capacity of edges. Also, unlike the case of maximal flow, there is no clear theory of minimal cuts that may assist us in such a repair.

Abstract

We introduce the problem of finding a spanning tree along with a partition of the tree edges into fewest number of feasible sets, where constraints on the edges define feasibility. The motivation comes from wireless networking, where we seek to model the irregularities seen in actual wireless environments. Not all node pairs may be able to communicate, even if geographically close – thus, the available pairs are specified with a link graph $\mathcal{L} = (V, E)$. Also, signal attenuation need not follow a nice geometric formula – hence, interference is modeled by a conflict (hyper)graph $\mathcal{C} = (E, F)$ on the links. The objective is to maximize the efficiency of the communication, or equivalently, to minimize the length of a schedule of the tree edges in the form of a coloring.

We find that in spite of all this generality, the problem can be approximated linearly in terms of a versatile parameter, the inductive independence of the interference graph. Specifically, we give a simple algorithm that attains a $O(\rho \log n)$-approximation, where n is the number of nodes and ρ is the inductive independence, and show that near-linear dependence on ρ is also necessary. We also treat an extension to Steiner trees, modeling multicasting, and obtain a comparable result.

Our results suggest that several canonical assumptions of geometry, regularity and "niceness" in wireless settings can sometimes be relaxed without a significant hit in algorithm performance.

1 Introduction

We introduce the problem of finding a spanning tree along with a partition of the tree edges into fewest number of feasible sets, which are independent sets in a given conflict (hyper)graph. The motivation comes from wireless networking, where we seek a basic communication structure while capturing the irregularities seen in actual wireless environments.

A spanning tree is the minimal structure for connecting the given set of nodes into a mutually communicable network. The *cost* of a communication spanning tree is the *time* required to *schedule* all the tree edges – the transmission *links* – while obeying the *interference* caused by simultaneous transmissions. The *scheduling complexity* of the tree represents its throughput capacity: how much communication can be sustained in the long run. The task might be to *aggregate* the data measured at the sensor nodes, or to *broadcast* using one-to-one communication to all nodes of the network.

Algorithmic studies of wireless connectivity to date have generally involved strong "niceness" assumptions. One core assumption is that points are located in the Euclidean plane and *all (close enough) pairs of nodes are available as links* for use in the spanning tree. Interference modeling has become progressively more realistic, starting with range-based graph models to the fractional *SINR* model of interference, but the common thread is that *interference is a direct function of the geometry.* While natural, these assumptions depend on a simplified view of the nature of wireless communication.

Wireless networking in the real world behaves quite different from these theoretical models [10, 32, 38] and typically displays a high degree of irregularity. This manifests in how the strength of signals (and the corresponding interference) often varies greatly within the same region, and is often poorly correlated with distance [2]. This behavior holds even in simple outdoor environments, but is magnified inside buildings. It is also evidenced by fluctuations, sensitivity to environmental changes (even levels of humidity), and hard-to-explain unreliability.

There has been increased emphasis for greater robustness in the design and analysis of wireless algorithms to address the observed irregularities. In the world of communications engineering, the default is to introduce stochastic distributions, e.g., on signal strengths. The algorithms world prefers more adversarial effects, but that can easily lead to intractability.

The objective of this work is to embrace this irregularity in connectivity problems. We replace the previous assumptions by the opposite premises:

A link may not be usable even if it should be.

and

Interference need not follow (or even relate to) the underlying geometry.

Technically, the former premise means that the set of usable or *available links* is now given as a link graph $\mathcal{L} = (V, L)$. We place no restrictions on the structure of this graph. The second premise implies another graph, this time on top of the *links*. Namely, the conflict (hyper)graph $\mathcal{C} = (L, F)$ specifies whether a given pair of links in L can coexist in the same color (of a spanning tree). In the Connectivity Scheduling problem, we seek a spanning tree T of $\mathcal{L}$ and a coloring of the links of T minimizing the number of colors used.

These formulations naturally raise a number of questions: Can arbitrary sets of available/usable links actually be handled effectively? Can we disconnect the conflicts/interference from the geometry? Since the ugly specter of intractability is bound to raise its head somewhere, what are minimal restrictions that keep these problems well-approximable?

Our Results. Given the generality of the ConnectivityScheduling problem, it is unsurprising that it is very hard even to approximate. We show that strong $n^{1-\epsilon}$-approximation hardness holds, even for the natural special case of 2-hop interference. Instead, we aim to obtain approximations in terms of natural instance parameters.

We show that the problem is approximable within $O(\rho \log n)$-factor, where ρ is the *inductive independence* of the (fractional) conflict graph. This is particularly relevant since ρ is known to be constant in both of the predominant interference models: the physical (or SINR) model, and the protocol model. This is attained by a simple greedy algorithm that can be viewed as a combination of Kruskal's MST algorithm and a link scheduling algorithm for the physical model. In contrast, we find that the (perhaps more natural) approach of selecting and coloring an MST fails badly.

We also generalize the problem to Steiner trees and obtain a similar logarithmic approximation. The results carry over to the SINR model, where we obtain the first results that hold for general metric spaces. We also give a supplementary result in the full version (for space reasons), involving natural geometric interference assumptions, namely that all links of length smaller than a threshold are available.

Definitions. In line with a modern view of wireless interference, we represent the interference conflicts by a fractional conflict graph $\mathcal{C} = (L, W)$. Here L is the set of communication links and $W : L \times L \to \mathbb{R}^+$ is a function on ordered pairs of links, where $W(e, f)$ represents (or approximates) the degree to which a transmission on link e interferes with a transmission on link f. Of particular interest are functions W in terms of geometric relationships involving link lengths and distances between links. Note that W may be asymmetric. For convenience, let $W(e, e) = 0$. We shall write $W(S, e) = \sum_{f \in S} W(f, e)$ and $W(f, S) = \sum_{e \in S} W(f, e)$. Let $\mathcal{C}[Y] = (Y, W\restriction_Y)$ denotes the subgraph induced by a given subset $Y \subseteq L$.

A set S of links is an independent or a feasible set if $W(S, e) \leq 1$, for all $e \in S$. A coloring of $\mathcal{C} = (L, W)$ is a partition of L into independent sets. Observe that when W is a 0-1 function, we have the usual independent sets and colorings of graphs. Also, the formulation with fractional conflicts corresponds to hypergraphs that contain a hyperedge for each minimal set S' where $W(S', e) \geq 1$ holds for some $e \in S'$.

We can now state our Connectivity Scheduling problem formally:

> Given a link graph $\mathcal{L} = (V, L)$ and a fractional conflict graph $\mathcal{C} = (L, W)$, we seek a spanning tree T of $\mathcal{L}$ and a coloring of $\mathcal{C}[T]$, using the fewest number of colors.

A fractional conflict graph $\mathcal{C} = (L, W)$ is said to be ρ-inductive independent, w.r.t. an ordering $\prec$ of the links, if for every link e and every feasible set I with $e \prec I$, $W(I, e) + W(e, I) \leq \rho$, where $e \prec I$ means that e precedes each link in I. Here, "inductive" refers to how the interference is measured only towards later links, and "independence" that it is towards independent sets. In geometric settings (including range-based and SINR models), $\prec$ corresponds to a non-decreasing ordering by link length.

For a fractional conflict graph $\mathcal{C} = (L, W)$, let $\chi(\mathcal{C})$ denote the smallest number of independent sets into which L can be partitioned; when $\mathcal{C}$ is an ordinary graph, $\chi(\mathcal{C})$ is the chromatic number of $\mathcal{C}$. We view a coloring of $\mathcal{C}$ also as a schedule and refer to the colors also as slots (which could be time slots or frequency bands).

Notable Instantiations. Connectivity Scheduling has a number of special cases of independent interest, both graph-based and geometric:

- A well-studied setting is where two links conflict if they are incident on a common link, i.e., when $\mathcal{C}$ is the square of the line graph of the link graph $\mathcal{L}$. This case corresponds to bidirectional version of the classic *radio network* model. The directed version of Connectivity Scheduling was treated in [9] as the *radio aggregation scheduling problem*.
- In *range-based or disk models*, nodes are embedded in the plane and two links are adjacent if the distance between (the closest points on) them is less than K times the length of the longer link, where K is some fixed constant. In a variant, the condition is on distances between particular nodes on the links. Also, in the the related *protocol* model, adjacency occurs if the distance is less than K_1 times the length of the longer link plus K_2 times the length of the shorter link, for some constants K_1, K_2.
- The original driving motivation is when nodes and links are embedded in a metric space and the fractional conflicts follow the *geometric SINR model* of interference in terms of the lengths and distances between links. Before this work, only the case when $\mathcal{L}$ is the complete graph over a set of points in a Euclidean metric was considered.
- A different geometric version is when we view that no signal gets transmitted between nodes on unavailable links, perhaps due to an obstacle. The links are then unavailable, but the nodes also don't interfere with each other. We refer to this as the Missing Links version.
- A natural special case occurs when link unreliability is restricted by link length, so that only reasonably long links are unavailable or attenuated, but short links follow the normal SINR laws (short links are reliable). This is treated in the full version of this paper.
- Finally, when the conflict graph $\mathcal{C}$ is the *line graph* of the link graph $\mathcal{L}$, i.e., $\mathcal{C} = L(\mathcal{L})$, we obtain the well-known *minimum degree spanning tree* (MDST) problem, where given a graph $\mathcal{L}$, the goal is to find a spanning tree of smallest maximum degree. By König's theorem, the chromatic number of the line graph of a tree (in fact, of any bipartite graph) is equal to the maximum degree of the tree. This problem has more structure that allows for better solution: while it is NP-hard, it can be approximated within an additive one [8]. In particular, $L(\mathcal{L})$ is claw-free (does not contain an induced star graph $K_{1,3}$), which is stronger than being 2-inductive independent), and is intimately related to $\mathcal{L}$.

Related Work. The connectivity problem in the geometric SINR model was first considered by Moscibroda and Wattenhofer [35]. It was, in fact, the first work on worst-case analysis in the SINR model. They show that unlike in random networks, the worst-case connectivity depends crucially on the use of power control, and with optimal power control, $O(\log^4 n)$ slots suffice to connect the nodes. They soon improved this to $O(\log^2 n)$ [36, 34]. Currently, the best upper bounds known are $O(\log n)$ [17] and $O(\log^* \Lambda)$ [23], where Λ is the ratio between the longest to the shortest length of a link in a minimum spanning tree (MST), a structural parameter that is independent of n. Both of these results hold for the MST of the pointset; there are pointsets where $\Omega(\log^* \Lambda)$ slots are necessary for scheduling an MST [21].

The scheduling complexity of connectivity relates closely to the efficiency of *aggregation*, a key primitive for wireless sensor networks. We refer the reader to [26] for bibliography on aggregation/collection problems.

There are many approaches that have been proposed to model irregularity in wireless networks. We first examine static cases, or the modeling of non-geometric behavior. The basic SINR model allows the pathloss constant α to be adjusted [13], giving a first-order approximation of the signal gain. In the engineering community, it is most common to assume that the deviations are drawn from a particular stochastic distribution, typically

assuming independence of events. In the TCS camp, the prevailing approach is to view the variations as conforming the plane into a non-Euclidean metric space [7, 16], while retaining some tractable characteristics. This can also entail identifying appropriate parameters [4].

For frequent temporal changes, the standard engineering assumption is Rayleigh fading. Dams et al. [6] (see also [22]) showed that link scheduling algorithms are not significantly affected by such variation, assuming independence across time.

For unpredictably changing behavior, there is much research on adapting to new conditions, particularly with exponential backoff. A theoretic model proposed to specifically capture unreliability is the *dual graph model* [33], which extends the radio network model to a pair of graphs, the reliable and the unreliable links, where the latter are under adversarial control. The focus there is on distributed algorithms for one-shot problems, like global and local broadcast problems, where the nodes do not know which links are reliable. As far as we know, it has not been considered in settings involving a long-term communication structure.

Inductive independence was first defined by [1] and studied by [37] in the graph setting, while the weighted version was introduced by Hoefer and Kesselheim [25]. It has been used as a performance measure for various problems related to wireless networks, including admission control [11], dynamic packet scheduling [31, 15], and spectrum auctions [25, 24, 15].

Outline of the paper. We first examine, in Sec. 2, how the standard approach – finding a minimum spanning tree – fares for our problem, and show that it can give poor solutions in every known interference model when there are missing or unreliable links. We then give in Sec. 3 a greedy algorithm for Connectivity Scheduling achieving $O(\rho \log n)$-approximation, where ρ is the inductive independence number of the conflict graph. This dependence on ρ is shown to be essentially tight in Sec. 5. We also obtain a similar approximation of a *Steiner or multicast* version of the problem in Sec. 4. Implications of our results to the SINR (or physical) model are given in Sec. 6. The rest of the paper can safely be read without any background in that model. We then close with open problems. Missing proofs, as well as a brief primer on SINR concepts, are given in the full version of the paper.

2 MST Fails

In a basic setting, the nodes are located on the plane, and the interference between two links is a function of the lengths of links (distance between the two end-nodes), and the distance between the (endpoints of) links. For instance, in the SINR model, the interference between two links is a decreasing function of their distance, and an increasing function of the length of the interfered link. In this setting, the Euclidean minimum spanning tree (MST) over the set of nodes is a natural candidate for connectivity, since it favors short links and has low degree (or, more generally, contains few links in the vicinity of any node). Indeed, the MST of n nodes can be scheduled in $O(\log n)$ slots in the Euclidean SINR model [17].

Somewhat surprisingly, we find that when the set of possible links is restricted, the MST can actually fail quite badly. This holds in every reasonable model of interference.

▶ **Interference Assumption 1.** *We say that an interference model is reasonable if: a) incident links cannot be scheduled together, while b) sparse instances of equal length links can be scheduled in $O(1)$ slots, where a set of length ℓ links is sparse if any ball of radius ℓ contains $O(1)$ endpoints of those links.*

Every geometrically-defined wireless interference model known satisfies this reasonableness property. In particular, this holds in the protocol and Euclidean SINR models.

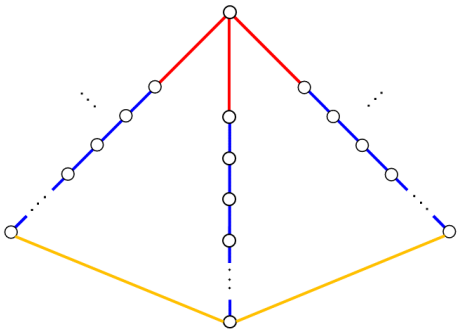

Figure 1 The construction from Thm. 1

▶ **Theorem 1.** *For any n, there is an instance of n nodes embedded on the plane together with a spanning tree that is schedulable in $O(1)$ slots while scheduling the MST requires $\Omega(n^{1/3})$ slots, in every reasonable interference model.*

Proof. Let $k \geq 1$ be a number and $K = 2k^2$. Let $V = \{o\} \cup \{v_{i,j} : i = 0, 1, \ldots, k-1, j = 0, 1, \ldots, K-1\}$ denote the set of $n = kK + 1 = 2k^3 + 1$ nodes. We position the nodes in the plane using polar coordinates, with the node o as the origin. For node $v_{i,j}$, angular coordinate $r_{i,j}$ is $2\pi \cdot i/k$, while its radial coordinate is $k + j$.

The links are given by $L = O \cup T \cup Y$, where $O = \{(o, v_{i,1}) : i = 0, \ldots, k-1\}$, $T = \{(v_{i,j}, v_{i,j+1}) : i = 0, \ldots, k-1, j = 0, \ldots, K-2\}$, $Y = \{(v_{i,K-1}, v_{i+1 \bmod k,K-1}) : i = 0, \ldots, k-1\}$, or the *ordinary*, the *tiny* and the *yuge* links. That is, the link graph is in the form of a wheel, centered at origin, with k spokes, and K nodes on each spoke (see Fig. 1). Ordinary links are incident with the origin, while the yuge links form the tire of the wheel.

We observe that $d(v_{i,K-1}, v_{i+1 \bmod k,K-1}) > k = d(o, v_{i',1})$, for any i, i'. Thus, the MST consists of the ordinary and tiny links, $S \cup L$. Since all the ordinary links have an endpoint in the origin, they must all be scheduled in different slots, implying that the MST requires $k = \Theta(n^{1/3})$ slots. On the other hand, a more efficient solution is to use the set Q, consisting of T, Y and one (arbitrary) link from O. This set Q is a union of three sparse subsets, and therefore can be scheduled in $O(1)$ slots. ◀

This same example shows why the known results for Euclidean SINR do not carry over to general metric spaces (even without missing links). Namely, one could simply form a metric space on the n nodes by shortest-path distances in the link graph.

3 Greedy Algorithm

A natural greedy approach is to find a large feasible subset of edges, assign it a fresh color, contract it, and iterate on the contracted graph. The key step is obtaining a constant-approximation for a maximum feasible subset. A logarithmic approximation then follows from a set cover argument.

We assume in this section that $\mathcal{L}$ can have parallel edges but no loops. We assume that the conflict graph $\mathcal{C}$ is ρ-inductive independent for a number $\rho > 0$, and the corresponding conflict function W and ordering of edges $\prec$ are given. In the maximum feasible forest problem, the goal is to find a maximum cardinality subset of edges of $\mathcal{L}$, which is both independent in $\mathcal{C}$ and acyclic in $\mathcal{L}$.

The algorithm, given as Alg. 1, is a greedy Kruskal-like algorithm that mixes the edge selection criteria of wireless capacity algorithms [16, 29] with the classic MST algorithm of

Kruskal, thus the name CapKruskal. It processes the edges in order of precedence $\prec$ and adds an edge to the forest if: a) the interference on that edge from previously selected edges is small, and b) the edge does not induce a cycle (as per Kruskal). We state it in terms of the classic union-find operations of MakeSet, Connected, and Union.

Algorithm 1 CapKruskal$(\mathcal{L}, \mathcal{C})$

MakeSet(v), for each $v \in V(\mathcal{L})$
$S \leftarrow \emptyset$
for $e = (u, v)$ in L in $\prec$ order **do**
  if $W(S, e) + W(e, S) \leq 1/2$ and **not** Connected(u, v) **then**
    $S \leftarrow S \cup \{e\}$
    Union(u, v)
  end if
end for
return $S' = \{e \in S : W(S, e) \leq 1\}$

Algorithm 2 Conn$(\mathcal{L}, \mathcal{C})$

$i \leftarrow 0$
$\mathcal{L}_0 \leftarrow \mathcal{L}$
while $\mathcal{L}_i$ has an edge **do**
  $S_i \leftarrow$ CapKruskal$(\mathcal{L}_i, \mathcal{C}[\mathcal{L}_i])$
  $\mathcal{L}_{i+1} \leftarrow Contract(\mathcal{L}_i, S_i)$
  $i \leftarrow i + 1$
end while
return $S_0, S_1, \ldots, S_{i-1}$

Recall that a subset S of edges in $\mathcal{L}$ is feasible if $W(S, e) = \sum_{f \in S} W(f, e) \leq 1$, for all $e \in S$. Define the ordered weight function W^+ as $W^+(e, f) = W(e, f)$ if $e \prec f$, and $W^+(e, f) = 0$, otherwise. Similarly, define W^- as $W^-(e, f) = W(e, f)$ if $f \prec e$, and $W^-(e, f) = 0$, otherwise. Also define the cumulative versions $W^+(S, e)$, $W^+(e, S)$ as before.

We say that a set S is semi-feasible if for each $e \in S$, $W^+(S, e) + W^-(e, S) \leq 1/2$. Namely, the weighted indegree from shorter nodes and to longer nodes is bounded, but the total indegree of e may not be. By an averaging argument, a semi-feasible set I contains a feasible subset of at least half its size. Indeed, using semi-feasibility and sum rearrangements, we have,

$$\sum_{e \in S} W(S, e) = \sum_{e \in S} \left(W^+(S, e) + W^-(e, S) \right) \leq \frac{|S|}{2} \tag{1}$$

so for at least half of the links $e \in S$ it holds that $W(S, e) \leq 1$.

▶ **Theorem 2.** *Let F be a maximum feasible forest of $\mathcal{L}$. Then* CapKruskal$(\mathcal{L}, \mathcal{C})$ *outputs a feasible forest of size $\Omega(|F|/\rho)$.*

Proof. Let S and S' be the sets computed in CapKruskal$(\mathcal{L}, \mathcal{C})$. By definition, S' is feasible. To argue that S' is large, we examine an arbitrary feasible forest, break it into three parts, and show that none of the parts can be too large compared to S'. This will hold, in particular, for the optimal feasible forest. By (1), we can focus on bounding $|S|$, as $|S'| \geq |S|/2$.

Let I be a feasible forest. Observe that the selection condition of the algorithm is equivalent to $W^+(S, e) + W^-(e, S) \leq 1/2$, since the edges are considered in the order of $\prec$. Let I_R be those edges e in I that failed the degree condition ($W^+(S, e) + W^-(e, S) > 1/2$), and I_T those edges $e = (u, v)$ in I that failed the connectivity condition (Connected(u, v)). The rest, $I_S = I \setminus (I_R \cup I_T)$ are contained in S. We bound these sets in terms of S.

Since I_T contains only edges inside components that S also connects (recalling that I induces a forest), $|I_T| \leq |S|$. Also, clearly $I_S \subseteq I \cap S \subseteq S$, so $|I_S| \leq |S|$. To bound the size of I_R, observe first that by the definition of ρ-inductive independence, $W^-(I_R, f) + W^+(f, I_R) \leq$

ρ, for every edge $f \in S$. This implies that

$$W^-(I_R, S) + W^+(S, I_R) = \sum_{f \in S} \left[W^-(I_R, f) + W^+(f, I_R)\right] \leq \rho \cdot |S|.$$

On the other hand, by the selection criteria,

$$W^+(S, I_R) + W^-(I_R, S) = \sum_{e \in I_R} \left[W^+(S, e) + W^-(e, S)\right] > \sum_{e \in I_R} \frac{1}{2} = \frac{|I_R|}{2}.$$

Thus, $|I_R| \leq 2\rho \cdot |S|$ and $|I| \leq (2\rho + 2)|S| \leq 4(\rho + 1)|S'|$. ◀

Connectivity Scheduling Algorithm. The algorithm Conn repeatedly calls CapKruskal to obtain a large independent set of links and assigns it to a new color class. These links are then contracted and the process repeated until we have obtained a spanning tree.

The contraction of an edge is defined in the standard way, except we discard loops. Note that *contraction leaves the conflict graph $\mathcal{C}$ intact.* The operation $Contract(\mathcal{L}, S)$ contracts all edges in S of a link graph $\mathcal{L}$ and outputs the resulting graph.

The pseudocode of the algorithm is given in Alg. 2. The proof of the following theorem, which is relegated to the full version, follows the classic set cover argument [27].

▶ **Theorem 3.** Conn *terminates in $O(\rho \log n) \cdot \chi$ rounds, where χ is the number of colors needed for coloring an optimum spanning tree.*

4 Multicast Tree Schedules

A natural generalization of Connectivity Scheduling is to allow for a set of optional nodes that can be used in the tree construction but need not. Formally, the node set V contains a subset X of terminals and we seek a Steiner tree that spans all the terminals. As before, we ask also for the shortest schedule of the tree links. We refer to this as the Steiner Connectivity Scheduling.

It is not hard to construct examples for which optimal multicast trees are arbitrarily better than trees that use only the terminals, even in a geometric setting. One instance can be obtained from the example of Sec. 2 by restricting the terminals to only the origin and the nodes incident on yuge links.

We give an algorithm for Steiner Connectivity Scheduling with *unweighted* conflict graph $\mathcal{C}$, and analyse it in terms of a parameter similar to ρ but involving clique covers rather than independence (this setting is also applicable to the SINR model, see Sec. 6). An unweighted graph $\mathcal{C} = (L, E)$ is η-simplicial if there is an ordering $\prec$ of L such that for each link $v \in L$, the subgraph induced by v's neighbors that are later in the ordering can be covered with η cliques. We refer to neighbors later in the ordering as post-neighbors. As before, in the geometric setting, the ordering is given by link length. Observe that $\rho \leq \eta$, while the best bound in the other direction is $\eta \leq \rho \log n$.

Our algorithm is a reduction to a multi-dimensional version of the Steiner tree (MMST) problem, recently treated by Bilò et al. [3]. In MMST, each edge of the input graph has an associated d-dimensional weight vector, where the weight of edge e along dimension i indicates how much of the i-th *resource* is required by e. The objective is to find a tree that minimizes the ℓ_p-norm of its load vector, where the load vector of a Steiner tree is the sum of the weight vectors of its edges. We use the ℓ_∞-norm, as we want to minimize the maximum use of a resource. They give a greedy $O(\log d)$-approximation algorithm for that case.

Given an instance of Steiner Connectivity Scheduling with link graph $\mathcal{L}$ and conflict graph $\mathcal{C}$, our reduction is as follows. Each link e in $\mathcal{L}$ is itself (or corresponds to) a resource, so there are n (=number of edges) resources. The weight of link f along dimension e is 1 if f is a post-neighbor of e in the conflict graph $\mathcal{C}$, and 0 otherwise.

Suppose now that the MMST algorithm of [3] returns a tree T with ℓ_∞-norm Z. Then, the sum of the tree edges along each dimension is at most Z, namely, each link (whether in T or not) has at most Z post-neighbors in T. In particular, $\mathcal{C}[T]$ is Z-inductive, and can then be colored greedily using $Z+1$ colors.

On the other hand, consider an optimal tree T^* and let Z^* denote the infinity norm of its load vector. From [3], we know that $Z = O(\log n) \cdot Z^*$. Let f be a link with Z^* post-neighbors in T^*, and let N_f be its set of post-neighbors in T^*. By assumption, $\mathcal{C}[N_f]$ can be covered with η cliques, and thus N_f contains a clique of size at least $|N_f|/\eta = Z^*/\eta$. It follows that the length of the schedule of the optimal tree is at least the chromatic number of $\mathcal{C}[N_f]$, which is at least Z^*/η. Thus, our solution yields a $O(\eta \log n)$-approximation.

▶ **Theorem 4.** *There is a $O(\eta \log n)$-approximation algorithm for* Steiner Connectivity Scheduling*, where conflicts are given by a η-simplicial graph.*

It is a folklore that $\eta \leq 6$ in disk graphs.

▶ **Corollary 5.** *There is a $O(\log n)$-approximation algorithm for* Steiner Connectivity Scheduling*, where conflicts are given by a disk graph.*

5 Hardness of Approximation

It is easy to see that with an arbitrary conflict graph $\mathcal{C}$, the problem is hard to approximate. For instance, if the link graph $\mathcal{L}$ is already a spanning tree, Connectivity Scheduling becomes simply the classical graph coloring problem (of $\mathcal{C}$). We show below that the hardness extends to other more restricted settings. These results also show that near-linear dependence on ρ, the inductive independence, is unavoidable.

We first show that hardness holds when $\mathcal{C}$ is the square of the line graph of $\mathcal{L}$ (for general $\mathcal{L}$), $\mathcal{C} = L^2(\mathcal{L})$, then extend the construction to the case when $\mathcal{L}$ is a complete graph and $\mathcal{C}$ is general (Thm. 7), and to signal strength models (Sec. 6). This corresponds to (bidirectional) 2-hop interferences: two transmission links conflict if they are incident on a common edge. The reduction is from the Distance-2 Edge Coloring problem in general graphs, also known as Strong Edge Coloring: Given a graph $\mathcal{L}$, find a partition of the edge set into induced matchings, i.e., induced subgraphs where every vertex is of degree 1.

▶ **Theorem 6.** *The* Connectivity Scheduling *problem is hard to approximate within a $n^{1-\epsilon}$-factor, for any $\epsilon > 0$, even when $\mathcal{C} = L^2(\mathcal{L})$.*

Proof. Given an instance of Strong Edge Coloring with graph $G' = (V', E')$, we construct an instance of Connectivity Scheduling problem with the graph $\mathcal{L}$ constructed as follows. Consider a bipartite graph $G'' = (V_1, V_2, E)$, as follows. For each vertex v in V', there are two vertices v_1, v_2 in $V = V_1 \cup V_2$, where $v_i \in V_i$, $i = 1, 2$. If $uv \in E'$ then v_1u_2 and v_2u_1 are in E. Link graph $\mathcal{L}$ is obtained from G'' by taking a complete binary tree with $|V_2|$ leaves and identifying each leaf with a vertex of V_2. The conflict graph is given by a simple graph $\mathcal{C}$ with vertex set E, where $e_1, e_2 \in E$ are adjacent in $\mathcal{C}$ if and only if they form an induced matching in G', i.e., there is no edge in G' connecting an endpoint of e_1 to an endpoint of e_2. This completes the construction.

First, let us show that a strong edge coloring of G' can be used to construct a spanning tree in $\mathcal{L}$ with a similar coloring number. Consider a strong coloring that partitions the edges of G' into c color classes $E_1, E_2, \ldots, E_c$. Each class E_i induces a pair of feasible slots S_i, S'_i in $\mathcal{L}$, where $S_i = \{v_1u_2 : uv \in E_i\}$ and $S'_i = \{u_1v_2 : uv \in E_i\}$. Indeed, since E_i is an induced matching in G', each of the slots S_i, S'_i is also an induced matching in $\mathcal{L}$ (and hence independent in $\mathcal{C}$). Note that the edges in these slots cover all vertices of $\mathcal{L}$, except for the binary tree. We also add $O(\log n)$ slots to the schedule, two for each layer in the binary tree. The number of slots used then is $O(c + \log n)$. This gives us a connected subgraph of $\mathcal{L}$ that can be scheduled in $O(c + \log n)$ slots.

Next, consider a spanning tree of $\mathcal{L}$ with a corresponding schedule of the edges in slots $S_1, S_2, \ldots, S_t$. Ignoring all edges within the binary tree, we obtain a partition of the edges of the bipartite graph G'' between V_1 and V_2. We claim that each class corresponds to an induced matching in G', leading to a strong edge coloring of G' with t colors.

Consider a pair of edges v_1u_2 and w_1x_2 in the same feasible slot. Since they are feasible, there are no edges v_1x_2 nor w_1u_2 in $\mathcal{L}$, and thus no edges vx nor wu in E. Then vu and wx form an induced matching in G'.

Hence, the optimum number of colors in strong edge coloring of G' is within a constant factor plus a logarithmic term of the optimal number of slots needed for scheduling a spanning tree in $\mathcal{L}$. Since the former is hard to approximate within $n^{1-\epsilon}$-factor [5], so is the latter. ◀

▶ **Theorem 7.** *For general graphs $\mathcal{C}$, the* Connectivity Scheduling *problem is hard to approximate within a $n^{1-\epsilon}$-factor, for any $\epsilon > 0$, even if the link graph $\mathcal{L}$ is complete.*

Proof. We modify the instance of Thm. 6, by adding to $\mathcal{L}$ all edges that were not there and make them adjacent (in $\mathcal{C}$) to *all* other edges in the graph. If these new edges are used in a spanning tree, they have to be scheduled separately in individual time slots. Thus, using them can only increase the length of any schedule. ◀

6 Implications to Signal Strength Models

We consider in this section the implementation and implication of our results to signal strength models, most importantly metric SINR model.

SINR-feasibility, besides the underlying metric, also depends on the *transmission power control* regime. Different power control methods give different notions of feasibility. Nevertheless, it is known that for most interesting cases, SINR-feasibility has constant-inductive independence property. In particular, power control is usually split into two modes: fixed monotone power schemes, where links use only local information, such as the link length, to define the power level, and global power control, where all power levels are controlled simultaneously to give larger independent sets. The former includes the uniform power mode, where all links use equal power. Another technical issue is *directionality* of links, which is not explicitly addressed by our general results, but will be addressed below.

Let us start the discussion from Euclidean metrics (or more generally doubling metrics). For the global power control mode, [29] introduced a weight function W and proved that with this function, the conflict graph of any set of links is constant-inductive independent (see [29, Thm. 1]), so our results apply here directly (except for directionality issues, addressed below). Similarly, for fixed monotone power schemes (excluding uniform power), [15] showed that in order to get constant-inductive independence, one may take the natural weight function, affectance (also called *relative* or normalized interference) [15, Thm.3.3]. In all cases, the ordering $\prec$ corresponds to a non-decreasing order of links by length.

For general metric spaces, a slightly more technical definition of inductive independence is used, where a fractional conflict graph $\mathcal{C} = (L, W)$ is (ρ, γ)-inductive independent, w.r.t. an ordering $\prec$ of the links, if for every link e and every feasible set $I \in \mathcal{F}$ with $e \prec I$, there is a subset $I' \subseteq I$ of size $|I'| \geq |I|/\gamma$, such that $W(I, e) + W(e, I) \leq \rho$. The old definition corresponds to the setting $\gamma = 1$. It is easily verified that Thms. 2 and 3 extend to cover this new definition, with approximation ratios multiplied by a factor of γ. Now, the counterparts of the results from the previous paragraph in general metrics can be found in [18, Lemmas 2,4] and [30, Thm. 1, Lemma 3], where it is shown that with appropriate weight functions, feasibility for any fixed monotone power scheme (including uniform power), as well as feasibility with global power control, can be expressed by a fractional conflict graph, which is $(O(1), O(1))$-inductive independent.

The claims above concern settings where the links have fixed directions. In particular, if we apply Thm. 3 to the weighted functions from the previous paragraph, then we should add "there exists a direction of links, such that..." to the claim. This issue is easily resolved for the global power control mode, where the weight function of [29] does not depend on directions. Namely, it gives a schedule, such that whatever direction is assigned to the links, one can find a power assignment that makes it work (the power assignment could be different for different orientations of links).

For oblivious powers, the following trick applies. It is known that for a set of links with some direction and an oblivious power assignment, and with the weight function W defined in terms of the affectances, if $W(e, S) \leq 1/2$ for all $e \in S$ (call this dual-feasibility), then there is another oblivious power assignment (called the *dual* of the original one) that makes S feasible with the reversed directions of links [28]. Thus, we would like to have schedules with slots S being also dual-feasible. To this end, it is enough to modify CapKruskal, so that the threshold $1/2$ in the acceptance condition is replaced with $1/4$, and the output set S' is given by $S' = \{e \in S : (W(S, e) \leq 1) \wedge (W(e, S) \leq 1/2)\}$. Very similar methods then show that this again gives an $O(\rho)$-approximation to the maximum feasible forest problem. The rest of the analysis is left intact, so we obtain an $O(\log n)$-approximation as before, but with schedule slots that are both feasible and dual-feasible. Then we can replace each slot with its two copies and revert the directions of links in one of the copies. Every link thus gets scheduled in both directions, while the schedule length increases by a factor of two.

Summarizing the observations above, we state the following theorem.

▶ **Theorem 8.** *There is an $O(\log n)$-approximation to* Connectivity Scheduling *problem in the SINR model in arbitrary metric spaces. This holds both in the case of fixed monotone power assignments, and for arbitrary power control. It holds even when only a subset of the node-pairs are available as links (but interferences follow the metric SINR definitions).*

These are the first results that hold in general metrics. They are necessarily relative approximations, since in general metric spaces, there is no good upper bound on the connectivity number, even for complete graphs. Two simple examples are the metric induced by the star $K_{1,t}$ with unit-length edges, and the unit metric formed by distances on the unit-length clique metric.

For the case of points in the plane (i.e., a complete link graph with conflicts induced by distances), connectivity can be achieved in $O(\log n)$ slots [17]. Since it is not known if $O(1)$ slots always suffice, this result is not directly implied by Thm. 3. However, it was also shown in [17] that the MST contains a feasible forest of $\Omega(n)$ edges. The rest of our analysis (using constant-inductive independence) then implies a result matching [17].

▶ **Corollary 9.** *Let P be a set of points in the plane. Then,* Conn *finds and schedules a spanning tree of P in $O(\log n)$ slots.*

Steiner trees. In the geometric SINR model with a fixed monotone power scheme (with not all links available), we reduce the problem to a graph question as follows. It was observed in [14] that links of the same length class behave approximately like unit-disk graphs, where a length class refers to links whose lengths differ by at most a factor of 2. Namely, there are constants c_1 and c_2 such that for a set S of links of length approximately ℓ, if all links are of mutual distance greater than $c_2\ell$, then they form a feasible set, whereas any pair of links in S of distance at most $c_1\ell$ must be scheduled separately.

We modify the reduction to MMST to that of the graph construction so that weight of link f along dimension e is 1 only if f is a post-neighbor of e in $\mathcal{C}$ *and* f and e are of the same length class. We then take the resulting tree and schedule the length classes separately, at an extra cost of $O(\log \Lambda)$ (the number of length classes).

▶ **Corollary 10.** *There is a $O(\log \Lambda \log n)$-approximation algorithm for* Steiner Connectivity Scheduling *in the geometric SINR model, under any fixed monotone power scheme.*

Using power control, we can do considerably better. The main result of [19] shows that for any set L of links, there is an unweighted conflict graph $\mathcal{C}(L)$, such that every independent set in $\mathcal{C}$ is feasible, and the chromatic number of $\mathcal{C}$ is at most $O(\log^* \Delta)$ factor away from the optimum schedule length of L (using global power control). Moreover, $\mathcal{C}$ is constant-simplicial [19, Prop. 1].

▶ **Corollary 11.** *There is a $O(\log n \log^* \Lambda)$-approximation algorithm for* Steiner Connectivity Scheduling *in the geometric SINR model with global power control.*

A similar result with $O(\log \log \Lambda)$-factor holds also for certain monotone power schemes (but not, for instance, uniform power) [20].

Hardness. A special Missing Links variant of the geometric case is where the nodes/links are embedded in the plane and all interferences are either zero or follow the SINR model (with either fixed power or global power control).

▶ **Theorem 12.** *The geometric Missing Links variant is $n^{1-\epsilon}$-hard to approximate, for any $\epsilon > 0$. It is also $\Lambda^{2-\epsilon}$-hard, where Λ is the ratio between the longest to the shortest node distance. This holds even if all unavailable links are missing links.*

Proof. We embed the instance of Thm. 6 in the plane. The nodes of V_1 are located in a unit square in a mesh pattern, $1/\sqrt{n}$ apart in $\sqrt{n}$ columns $\sqrt{n}$ abreast. At a unit distance, a similar unit square holds the nodes of V_2. The length of an edge in $\mathcal{L}$ (in distance in the plane) is then between 1 and 4.

An induced matching in $\mathcal{L}$ corresponds to a set of links with no mutual interference. On the other hand, a pair of links that are incident on a common edge or share a vertex, will receive interference from each other according to the SINR formula (using the shared edge or each other). Given that distances along available edges vary only by a constant factor, the interference between the links is a constant (specifically, at least $1/4^\alpha$, where α is the "pathloss" constant of the SINR model). Thus, in the setting where the SINR threshold is at least the reciprocal of that constant (i.e., $\beta \geq 4^\alpha$), feasible sets are necessarily induced matchings in $\mathcal{L}$. We can then conclude by recalling a "signal-strengthening" result [12] that shows that varying the threshold by a constant factor only affects the schedule length by a constant factor.

The longest node distance is at most $\log n$, which is from the root of the binary tree to its leaves, while the shortest distance is $1/\sqrt{n}$. Thus, $\Lambda \leq 4\sqrt{n}\log n$, and $n^{1-\epsilon} \geq \Lambda^{2-\epsilon'}$, for some $\epsilon' \geq \epsilon/3$.

We can restrict the available edges incident to (non-leaf) nodes on the binary tree to the tree edges alone. Thus, non-leaf nodes in the tree must be connected via the tree edges. Then, all unavailable edges are missing edges. ◀

7 Open Issues

Many related problems are left addressing; we list the most prominent ones.

- Latency minimization: Bounding the time it takes for a packet to filter through the tree from a leaf to a root (and back). This requires optimizing both the height of the tree as well as the ordering of the links in the schedule.
- Directed case: Finding an arborescence. This requires new techniques, as our argument crucially depends on the graph being undirected.
- Distributed algorithms: This relates also to the issue of detecting or learning whether a link is usable/reliable or not.

Abstract

We give a simple distributed algorithm for computing adjacency matrix eigenvectors for the communication graph in an asynchronous gossip model. We show how to use this algorithm to give state-of-the-art asynchronous community detection algorithms when the communication graph is drawn from the well-studied *stochastic block model*. Our methods also apply to a natural alternative model of randomized communication, where nodes within a community communicate more frequently than nodes in different communities.

Our analysis simplifies and generalizes prior work by forging a connection between asynchronous eigenvector computation and Oja's algorithm for streaming principal component analysis. We hope that our work serves as a starting point for building further connections between the analysis of stochastic iterative methods, like Oja's algorithm, and work on asynchronous and gossip-type algorithms for distributed computation.

1 Introduction

Motivated by the desire to process and analyze increasingly large networks – in particular social networks – considerable research has focused on finding efficient distributed protocols for problems like triangle counting, community detection, PageRank computation, and node centrality estimation. Many of the most popular systems for massive-scale graph processing, including Google's Pregel [19] and Apache Giraph [29] (used by Facebook), employ programming models based on the simulation of distributed message passing algorithms, in which each node is viewed as a processor that can send messages to its neighbors.

Apart from computational benefits, distributed graph processing can also be required when privacy constraints apply: for example, EU regulations restrict the personal data sent to countries outside of the EU [8]. Distributed algorithms avoid possibly problematic aggregation of network information, allowing each node to compute a local output based on their own neighborhood and messages received from their neighbors.

One of the main problems of interest in network analysis is the computation of the eigenvectors of a networks' adjacency matrix (or related incidence matrices, such as the graph Laplacian). The extremal eigenvectors have many important applications – from graph partitioning and community detection [13, 23], to embedding in graph-based machine learning [5, 26], to measuring node centrality and computing importance scores like PageRank [6].

Due to their importance, there has been significant work on distributed eigenvector approximation. In *synchronous* message passing systems, it is possible to simulate the well-known power method for iterative eigenvector approximation [17]. However, this algorithm requires that each node communicates synchronously with all of its neighbors in each round.

In an attempt to relax this requirement, models in which a subset of neighbors are sampled in each communication round [18] have been studied. However, the computation of graph eigenvectors in fully asynchronous and gossip-based message passing systems, in which nodes communicate with a single neighbor at a time in an asynchronous fashion, is not well-understood. While a number of algorithms have been proposed, which give convergence to the true eigenvectors as the number of iterations goes to infinity, strong finite iteration approximation bounds are not known [14, 24].

Our contributions

In this work, we give state-of-the-art algorithms for graph eigenvector computation in asynchronous systems with randomized schedulers, including the classic gossip model [7, 12] and population protocol model [2]. We show that in these models, communication graph eigenvectors can be computed via a very simple adaption of Oja's classic iterative algorithm for principal components analysis [27]. Our analysis leverages recent work studing Oja's algorithm for streaming covariance matrix eigenvector estimation [1, 16].

By making an explicit connection between work on streaming eigenvector estimation and asynchronous computation, we hope to generally expand the toolkit of techniques that can be applied to analyzing graph algorithms in asynchronous systems.

As a motivating application, we use our results to give state-of-the-art distributed community detection protocols, significantly improving upon prior work for the well-studied stochastic-block model and related models where nodes communicate more frequently within their community than outside of it. We summarize our results below.

Asynchronous eigenvector computation. First, we provide an algorithm (Algorithm 2) that approximates the k largest eigenvectors $\mathbf{v}_1, ..., \mathbf{v}_k$ for an arbitrary communication matrix (essentially a normalized adjacency matrix, defined formally in Theorem 1).

For an n-node network, the algorithm ensures, with good probability, that each node $u \in [n]$ computes the u^{th} entries of vectors $\tilde{\mathbf{v}}_1, ..., \tilde{\mathbf{v}}_k$ such that for all $i \in [k]$, $\|\tilde{\mathbf{v}}_i - \mathbf{v}_i\|_2^2 \leq \epsilon$. Each message sent by the algorithm requires communicating just $O(k)$ numbers, and the global time complexity is $\tilde{O}(\frac{\Lambda k^3}{\text{gap} \cdot \min(\text{gap}, \gamma_{mix})\epsilon^3})$ local rounds, where gap is the minimal gap between the k largest eigenvalues, γ_{mix} is roughly speaking the spectral gap, i.e., the difference between the largest and second-largest eigenvalue, and Λ is the sum of the k largest eigenvalues. We note that we use $\tilde{O}(\cdot)$ to suppress logarithmic terms, and in particular, factors of $\text{poly}\log n$. See Theorem 6 for a more precise statement.

For illustration, consider a communication graph generated via the stochastic block model – $G(n, p, q)$, which has n nodes, partitioned into two equal-sized clusters. Each intracluster edge added independently with probability p and each intercluster edge is added with probability $q < p$. If, for example, $p = \Omega\left(\frac{\log n}{n}\right)$ and $q = p/2$, and $k = 2$, we can bound with high probability $\Lambda = \Theta(1/n)$, gap $= \Theta(1/n)$, and $\gamma_{mix} = \Theta(1/n)$, which yields an eigenvector approximation algorithm running in $\tilde{O}(\frac{n}{\epsilon^3})$ global rounds, or $\tilde{O}(\frac{1}{\epsilon^3})$ local rounds.

Approximate community detection. Second, we harness our eigenvector approximation routine for community detection in the stochastic block model with connection probabilities p, q (we give two natural definitions of this model in an asynchronous distributed system with a random scheduler; see Theorem 2 and Theorem 3). After executing our protocol (Algorithm 5), with good probability, all but an ϵ fraction of the nodes output a correct community label in $\tilde{O}\left(1/\epsilon^3\rho^2\right)$ local rounds, where $\rho = \min\left(\frac{q}{p+q}, \frac{p-q}{p+q}\right)$. For example, when $q = p/2$, this complexity is $\tilde{O}\left(1/\epsilon^3\right)$. See Theorem 8 and Theorem 9 for precise bounds.

Exact community detection. Finally, we show how to produce an exact community labeling, via a simple gossip-based error correction scheme. For ease of presentation, here we just state our results in the case when $q = p/2$ and we refer to section 5 (Theorem 10 and Theorem 11) for general results. Starting from an approximate labeling in which only a small constant fraction of the nodes are incorrectly labeled, we show that, with high probability, after $O(\log n)$ local rounds, all nodes are labeled correctly.

Related work

Community detection via graph eigenvector computation and other spectral methods has received ample attention in centralized setting [22, 9, 32]. Such methods are known to recover communities in the stochastic block model close to the information theoretic limit. Interestingly, many state-of-the-art community detection algorithms in this model, which improve upon spectral techniques, are based on message passing (belief propagation) algorithms [11, 25]. However, these algorithms are not known to work in asynchronous contexts.

Community detection in asynchronous distributed systems has received less attention. It has recently been tackled in a beautiful paper by Becchetti et al. [3]. The algorithm studied in this paper is a very simple averaging protocol, originally considered by the authors in a synchronous setting [4]. Each node starts with a random value chosen uniformly in $\{-1, 1\}$. Each time two nodes communicate, they update their values to the average of their previous values. After each round of communication, a node's estimated community is given by the *sign* of the change of its value due to the averaging update in that round.

Beccheti et al. analyze their algorithm for *regular* clustered graphs, including regular stochastic block model graphs, where all nodes have exactly a edges to (randomly selected) nodes in their cluster and exactly $b < a$ edges to nodes outside their cluster. As discussed in [3], for regular graphs their protocol can be viewed as estimating the sign of entries in the second largest adjacency matrix eigenvector. Thus, it has close connections with our protocols, which explicitly estimate this eigenvector and label communitues using the signs of its entries.

The results of Becchetti et al. apply with $O(\text{polylog}\, n)$ local rounds of communication when either $\frac{a}{b} = \Omega(\log^2 n)$, or when $a - b = \Omega(\sqrt{a+b})$. In contrast, our results for the (non-regular) stochastic block model give $O(\text{polylog}\, n)$ local runtime when $\frac{p}{q} = \Omega(1)$ or $n(p-q) = \Omega(\sqrt{n(p+q)\log n})$. Here we assume that q is not too small – see Theorem 9 for

details. Note that $n \cdot p$ and $n \cdot q$ can be compared to a and b, since they are the expected number of intra- and inter-cluster edges respectively. Thus, our results give comparable bounds, tightening those of Becchetti et al. in some regimes and holding in the most commonly studied family of stochastic block model graphs, without any assumption of regularity[1].

Outside of community detection, our approach to asynchronous eigenvector approximation is related to work on asynchronous distributed stochastic optimization [31, 10, 28]. Often, it is assumed that many processors update some decision variable in parallel. If these updates are sufficiently sparse, overwrites are rare and the algorithm converges as if it were run in a synchronous manner. Our implementation of Oja's algorithm falls under this paradigm. Each update to our eigenvector estimates is sparse – requiring a modification just by the two nodes that communicate at a given time. In this way, we can fully parallelize the algorithm, even in an asynchronous system.

2 Preliminaries

2.1 Notation

For integer $n > 0$, let $[n] \stackrel{\text{def}}{=} \{1, \ldots, n\}$. Let $\mathbf{1}_{n,m}$ be an $n \times m$ all-ones matrix and $\mathbf{I}_{n \times n}$ be an $n \times n$ identity. Let $\mathbf{e}_i$ be the i^{th} standard basis vector, with length apparent from context. Let V denote a set of nodes with cardinality $|V| = n$. Let $\mathcal{P}$ be the set of all unordered node pairs (u, v) with $u \neq v$. $|\mathcal{P}| = \binom{n}{2}$.

For vector $\mathbf{x} \in \mathbb{R}^n$, $\|\mathbf{x}\|_2$ is the Euclidean norm. For matrix $\mathbf{M} \in \mathbb{R}^{n \times m}$, $\|\mathbf{M}\|_2 = \max_{\mathbf{x}} \frac{\|\mathbf{M}\mathbf{x}\|_2}{\|\mathbf{x}\|_2}$ is the spectral norm. $\|\mathbf{M}\|_F = \sqrt{\sum_{i=1}^{n} \sum_{j=1}^{m} \mathbf{M}_{i,j}^2}$ denotes the Frobenius norm. $\mathbf{M}^T$ is the matrix transpose of $\mathbf{M}$. When $\mathbf{M} \in \mathbb{R}^{n \times n}$ is symmetric we let $\lambda_1(\mathbf{M}) \geq \lambda_2(\mathbf{M}) \geq \ldots \geq \lambda_n(\mathbf{M})$ denote its eigenvalues. $\mathbf{M}$ is positive semidefinite (PSD) if $\lambda_i(\mathbf{M}) \geq 0$ for all i. For symmetric $\mathbf{M}, \mathbf{N} \in \mathbb{R}^{n \times n}$ we use $\mathbf{M} \preceq \mathbf{N}$ to indicate that $\mathbf{N} - \mathbf{M}$ is PSD.

2.2 Computational model

We define an asynchronous distributed computation model that encompasses both the well-studied population protocol [2] and asynchronous gossip models [7]. Computation proceeds in rounds and a random scheduler chooses a single pair of nodes to communicate in each round. The choice is independent across rounds, but may be nonuniform across node pairs.

▶ **Definition 1** (Asynchronous communication model)**.** Let V be a set of nodes with $|V| = n$. Computation proceeds in rounds, with every node $v \in V$ having some state $s(v, t)$ in round t.

Recall that $\mathcal{P}$ denotes all unordered pairs of nodes in V. Let $w : \mathcal{P} \to \mathbb{R}^+$ be a nonnegative weight function. In each round, a random scheduler chooses exactly one $(u, v) \in \mathcal{P}$ with probability $w(u, v) / \left[\sum_{(i,j) \in \mathcal{P}} w(i, j)\right]$ and u, v both update their states according to some common (possibly randomized) transition function σ. Specifically, they set $s(v, t+1) = \sigma(s(v, t), s(u, t))$ and $s(u, t+1) = \sigma(s(u, t), s(v, t))$.

Note that in our analysis we often identify the weight function w with a symmetric weight matrix $\mathbf{W} \in \mathbb{R}^{n \times n}$ where $\mathbf{W}_{u,u} = 0$ and $\mathbf{W}_{u,v} = \mathbf{W}_{v,u} = w(u, v) / \left[\sum_{(i,j) \in \mathcal{P}} w(i, j)\right]$. Let $\mathbf{D}$ be a diagonal matrix with $\mathbf{D}_{u,u} = \sum_{v \in V} \mathbf{W}_{u,v}$. $\mathbf{D}_{u,u}$ is the probability that node u

[1] We note that the analysis of Bechitti et al. seems likely to extend to our alternative communication model (Theorem 2), where the communication graph is weighted and regular

communicates in any given round. Since two nodes are chosen in each round, $\sum_u \mathbf{D}_{u,u} = 2$. We will refer to $\mathbf{D} + \mathbf{W}$ as the *communication matrix* of the communication model.

▶ Remark (Asynchronous algorithms). Since the transition function σ in Theorem 1 is universal, nodes can be seen as identical processes, with no knowledge of w or unique ids. We do assume that nodes can initiate and terminate a protocol synchronously. That is, nodes interact from round 0 up to some round T, after which they cease to interact, or begin a new protocol. This assumption is satisfied if each node has knowledge of the global round number but, in general, is much weaker. For example, in the asynchronous gossip model discussed below, it is sufficient for nodes to have access to a synchronized clock.

We use *algorithm* to refer to a sequence of transition functions, each corresponding to a subroutine run for specified number of rounds. Subroutines are run sequentially. The first has input nodes with identical starting states (as prescribed by Theorem 1) but later subroutines start once nodes have updated their states and thus have distinguished inputs.

▶ Remark (Simulation of existing models). The standard *population protocol model* [2] is recovered from Theorem 1 by setting $w(u, v) = 1$ for all (u, v) – i.e., pairs of nodes communicate uniformly at random. A similar model over a fixed communication graph $G = (E, V)$ is recovered by setting $w(u, v) = 1$ for all $(u, v) \in E$ and $w(u, v) = 0$ for $(u, v) \notin E$.

Theorem 1 also encompasses the *asynchronous gossip model* [7, 12], where each node holds an independent Poisson clock and contacts a random neighbor when the clock ticks. If we identify rounds with clock ticks, let λ_u be the rate of node u's clock, and let $p(u, v)$ be the probability that u contacts v when its clock ticks. Then the probability that nodes u and v interact in a given round is $\frac{1}{2}\left[\frac{\lambda_u}{\sum_{z\in V}\lambda_z} \cdot p(u, v) + \frac{\lambda_v}{\sum_{z\in V}\lambda_z} \cdot p(v, u)\right]$. With $w(u, v)$ set to this value, Theorem 1 corresponds exactly to the asynchronous gossip model.

2.3 Distributed community detection problem

This paper studies the very general problem of computing communication matrix eigenvectors with asynchronous protocols run by the nodes in V. One primary application of computing eigenvectors is to detect community structure in G. Below we formalize this application as the *distributed community detection problem* and introduce two specific cases of interest.

In the distributed community detection problem, the weight function w and corresponding weight matrix $\mathbf{W}$ of Theorem 1 are clustered: nodes in the same cluster are more likely to communicate than nodes in different clusters. The goal is for each node to independently identify what cluster it belongs to (up to a permutation of the cluster labels).

We consider two models of clustering. In the first (n, p, q)-*weighted communication model*, the weight function directly reflects the increased likelihood of intracluster communication. In the second, $G(n, p, q)$-*communication model*, weights are uniform on a graph sampled from the well-studied planted-partition or *stochastic block model* [15]. For simplicity, we focus on the setting in which there are two equal sized clusters, but believe that our techniques can be extended to handle a larger number of clusters, potentially with unbalanced sizes.

▶ **Definition 2** ((n, p, q)-weighted communication model)**.** An asynchronous model (Theorem 1), where node set V is partitioned into disjoint sets V_1, V_2 with $|V_1| = |V_2| = n/2$. For values $q < p$, $w(u, v) = p$ if $u, v \in V_i$ for some i and $w(u, v) = q$ if $u \in V_i$ and $v \in V_j$ for $i \neq j$.

▶ **Definition 3** ($G(n, p, q)$-communication model)**.** An asynchronous model (Theorem 1), where node set V is partitioned into disjoint sets V_1, V_2 with $|V_1| = |V_2| = n/2$. The weight matrix $\mathbf{W}$ is a normalized adjacency matrix of a random graph $G(V, E)$ generated as follows:

for each pair of nodes $u, v \in V$, add edge (u, v) to edge set E with probability p if u and v are in the same partition V_i and probability $q < p$ if u and v are in different partitions.

Analysis of community detection in the (n, p, q)-weighted communication model is more elegant, and will form the basis of our analysis for the $G(n, p, q)$-communication model, which more closely matches models considered in prior work on in both distributed and centralized settings. Formally, we define the distributed community detection problem as follows:

▶ **Definition 4** (Distributed community detection problem)**.** An algorithm executing in the communication models of Theorem 2 and Theorem 3 solves community detection in T rounds if for every $t \geq T$, all nodes in V_1 hold some integer state $s_1 \in \{-1, 1\}$, while all nodes in V_2 hold state $s_2 = -s_1$. An algorithm solves the community detection problem in L *local rounds* if every node's state remains fixed after L local interactions with other nodes.

3 Asynchronous Oja's algorithm

Our main contribution is a distributed algorithm for computing eigenvectors of the communication matrix $\mathbf{D} + \mathbf{W}$. These eigenvectors can be used to solve the distributed community detection problem or in other applications. Our main algorithm is a distributed, asynchronous adaptation of Oja's classic iterative eigenvector algorithm [27], described below:

Algorithm 1 Oja's method (centralized)

Input: $\mathbf{x}_0, ..., \mathbf{x}_{T-1} \in \mathbb{R}^n$ drawn i.i.d. from some distribution $\mathcal{D}$ such that for some constant C, $\mathbb{P}_{\mathbf{x}\sim\mathcal{D}}[\|\mathbf{x}\|_2^2 \leq C] = 1$ and $\mathbb{E}_{\mathbf{x}\sim\mathcal{D}}[\mathbf{x}\mathbf{x}^T] = \mathbf{M}$. Rank parameter k and step size η.
Output: Orthonormal $\tilde{\mathbf{V}} \in \mathbb{R}^{n\times k}$ whose columns approximate $\mathbf{M}$'s k top eigenvectors.

1: Choose $\mathbf{Q}_0$ with entries drawn i.i.d. from the standard normal distribution $\mathcal{N}(0, 1)$.
2: **for** $t = 0, ..., T-1$ **do**
3: $\quad \mathbf{Q}_{t+1} := (\mathbf{I} + \eta \mathbf{x}_t \mathbf{x}_t^T)\mathbf{Q}_t$.
4: **end for**
5: **return** $\tilde{\mathbf{V}}_T := \text{orth}(\mathbf{Q}_T)$. ▷ Orthonormalizes the columns of $\mathbf{Q}_T$.

3.1 Approximation bounds for Oja's method

A number of recent papers have provided strong convergence bounds for the *centralized* version of Oja's method [1, 16]. We will rely on the following theorem, which we prove in full verison using a straightforward application of the arguments in [1].

▶ **Theorem 5.** *Let* $\mathbf{M} \in \mathbb{R}^{n\times n}$ *be a PSD matrix with* $\frac{\sum_{i=1}^{k}\lambda_i(\mathbf{M})}{C} \leq \Lambda$ *and* $\frac{\lambda_k(\mathbf{M})-\lambda_{k+1}(\mathbf{M})}{C} \geq \text{gap}$ *for some values* Λ, gap*. For any* $\epsilon, \delta \in (0, 1)$*, let* $\xi = \frac{n}{\delta\epsilon\cdot\text{gap}}$*,* $\eta = \frac{c_1\epsilon^2\cdot\text{gap}\cdot\delta^2}{C\Lambda k\log^3\xi}$ *for some sufficiently small constant* c_1*, and* $T = \frac{c_2\cdot(\log\xi+1/\epsilon)}{C\cdot\text{gap}\cdot\eta}$ *for sufficiently large* c_2*. Then with probability* $\geq 1-\delta$*, Algorithm 1 run with step size* η *returns* $\tilde{\mathbf{V}}_T$ *satisfying,*

$$\|\mathbf{Z}^T\tilde{\mathbf{V}}_T\|_F^2 \leq \epsilon.$$

where $\mathbf{Z}$ *is an orthonormal basis for the bottom* $n-k$ *eigenvectors of* $\mathbf{M}$*.*

If $\tilde{\mathbf{V}}_T$ exactly spanned $\mathbf{M}$'s top k eigenvectors, $\|\mathbf{Z}^T\tilde{\mathbf{V}}_T\|_F^2$ would equal 0. To obtain an approximation of ϵ, the number of iterations required by Oja's method naturally depends inversely on ϵ, the failure probability δ, and the gap between eigenvalues $\lambda_k(\mathbf{M})$ and $\lambda_{k+1}(\mathbf{M})$.

3.2 Distributed Oja's method via random edge sampling

Oja's method can be implemented in the asynchronous communication model (Theorem 1) to compute top eigenvectors of the communication matrix $\mathbf{D}+\mathbf{W}$, defined in subsection 2.2.

For any pair of nodes (u,v), let $\mathbf{e}_{u,v}=\mathbf{e}_u+\mathbf{e}_v$ be the vector with all zero entries except 1's in its u^{th} and v^{th} positions. Given weight function w and associated matrix $\mathbf{W}$, let $\mathcal{D}_{\mathbf{W}}$ be the distribution in which each $\mathbf{e}_{u,v}$ is selected with probability $\mathbf{W}_{u,v}$. That is, the same distribution by which edges are selected to be active by the scheduler in Theorem 1. Noting that $\mathbf{e}_{u,v}\mathbf{e}_{u,v}^T$ is all zero except at its (u,u), (v,v), (u,v), and (v,u) entries, we can see that

$$\mathop{\mathbb{E}}_{\mathbf{e}_{u,v}\sim\mathcal{D}_{\mathbf{W}}}\left[\mathbf{e}_{u,v}\mathbf{e}_{u,v}^T\right]=\sum_{(u,v)\in\mathcal{P}}\mathbf{W}_{u,v}\cdot\mathbf{e}_{u,v}\mathbf{e}_{u,v}^T=\mathbf{D}+\mathbf{W}, \tag{1}$$

where $\mathcal{P}$ denotes the set of unordered node pairs (u,v) with $u\neq v$. So if we run Oja's algorithm with $\mathbf{e}_{u,v}$ sampled according to $\mathcal{D}_{\mathbf{W}}$, we will obtain an approximation to the top eigenvectors of $\mathbf{D}+\mathbf{W}$. Note that this matrix is PSD, by the fact that each $\mathbf{e}_{u,v}\mathbf{e}_{u,v}^T$ is PSD.

Furthermore, the algorithm can be implemented in our communication model as an *extremely simple averaging protocol.* Each iteration of Algorithm 1 requires computing $\mathbf{Q}_{t+1}=(\mathbf{I}+\eta\mathbf{x}_t\mathbf{x}_t^T)\mathbf{Q}_t$. If $\mathbf{x}_t=\mathbf{e}_{u,v}$ for $\mathbf{e}_{u,v}\sim\mathcal{D}_{\mathbf{W}}$, we can see that computing $\mathbf{Q}_{t+1}$ just requires updating the u^{th} and v^{th} rows of $\mathbf{Q}_t$. Thus, if the n rows of $\mathbf{Q}_t$ are distributed across n nodes, this update can be done locally by nodes u and v when they are chosen to interact by the randomized scheduler. Specifically, letting $[q_u^{(1)},...,q_u^{(k)}]$ be the u^{th} row of $\mathbf{Q}_t$, stored as the state at node u, applying $(\mathbf{I}+\eta\mathbf{e}_{u,v}\mathbf{e}_{u,v}^T)$ just requires setting for all $i\in[k]$:

$$q_u^{(i)}:=(1+\eta)q_u^{(i)}+\eta q_v^{(i)}. \tag{2}$$

Node v makes a symmetric update, and all other entries of $\mathbf{Q}_t$ remain fixed.

We give the pseudocode for this protocol in Algorithm 2. Along with the main iteration based on the simple update in (2), the nodes need to implement Step 5 of Algorithm 1, where $\mathbf{Q}_T$ is orthogonalized. This can be done with a gossip-based protocol, which we abstract as the routine `AsynchOrth`. We give an implementation of `AsynchOrth` in subsection 3.3.

▶ Remark (Choice of communication matrix). While, as we will show, the eigenvectors of $\mathbf{D}+\mathbf{W}$ are naturally useful in our applications to community detection, the above techniques easily extend to computing eigenvectors of other matrices. For example, if we set $\mathbf{e}_{u,v}=\mathbf{e}_u-\mathbf{e}_v$, $\mathbb{E}_{\mathbf{e}_{u,v}\sim\mathcal{D}_{\mathbf{W}}}[\mathbf{e}_{u,v}\mathbf{e}_{u,v}^T]=\mathbf{D}-\mathbf{W}=\mathbf{L}$, a scaled Laplacian of the communication graph.

Algorithm 2 Asynchronous Oja's (`AsynchOja`(T,T',η))

Input: Time bounds T,T', step size η.
Initialization: $\forall u$, chose $[q_u^{(1)},...,q_u^{(k)}]$ independently from standard Gaussian $\mathcal{N}(0,1)$.

1: **if** $t<T$ **then**
2: (u,v) is chosen by the randomized scheduler.
3: For all $i\in[k]$, $q_u^{(i)}:=(1+\eta)q_u^{(i)}+\eta q_v^{(i)}$. ▷ Computes of $(\mathbf{I}+\eta\mathbf{e}_{u,v}\mathbf{e}_{u,v}^T)\mathbf{Q}_t$.
4: **else**
5: $[\hat{v}_u^{(1)},...,\hat{v}_u^{(k)}]=$ `AsynchOrth`$([q_u^{(1)},...,q_u^{(k)}],T')$. ▷ Implements of $\tilde{\mathbf{V}}_T=\text{orth}(\mathbf{Q}_T)$.
6: **end if**

Note that in the pseudocode above, when nodes u,v interact in the asynchronous model, they only need to share their respective values of $q_u^{(i)}$ and $q_v^{(i)}$ for $i\in[k]$.

Up to the orthogonalization step, we see that Algorithm 2 *exactly simulates* Algorithm 1 on input $\mathbf{M}=\mathbf{D}+\mathbf{W}$. Thus, assuming that `AsynchOrth`$([q_u^{(1)},...,q_u^{(k)}])$ exactly computes

$\tilde{\mathbf{V}}_T = \text{orth}(\mathbf{Q}_T)$ as in Step 5 of Algorithm 1, the error bound of Theorem 5 applies directly. Specifically, if we let the local states, $[q_1^{(1)}, \ldots, q_n^{(1)}], \ldots, [q_1^{(k)}, \ldots, q_n^{(k)}]$ correspond to the k length-n vectors in $\tilde{\mathbf{V}}_T$, Theorem 5 shows that $\|\mathbf{Z}^T\tilde{\mathbf{V}}_T\|_F^2 \leq \epsilon$. In subsection 3.3 we show that this bound still holds when `AsynchOrth` computes an approximate orthogonalization.

3.3 Distributed orthogonalization and eigenvector guarantees

In fact, a specific orthogonalization strategy yields a stronger bound, which is desirable in many applications, including community detection: Algorithm 2 can actually well approximate *each* of $\mathbf{D} + \mathbf{W}$'s top k eigenvectors, instead of just the subspace they span.

Specifically, let $\tilde{\mathbf{v}}_i$ denote the i^{th} column of $\tilde{\mathbf{V}}_T$ and $\mathbf{v}_i$ denote the i^{th} eigenvector of $\mathbf{D} + \mathbf{W}$. We want $(\tilde{\mathbf{v}}_i^T\mathbf{v}_i)^2 \geq 1 - \epsilon$ for all i. Such a guarantee requires sufficiently large gaps between the top k eigenvalues, so that their corresponding eigenvectors are identifiable. If these gaps exist, the guarantee can by using the following orthogonalization procedure:

Algorithm 3 Orthogonalization via Cholesky Factorization (centralized)

Input: $\mathbf{Q} \in \mathbb{R}^{n\times k}$ with full column rank. **Output**: Orthonormal span for $\mathbf{Q}$, $\tilde{\mathbf{V}} \in \mathbb{R}^{n\times k}$.

1: $\mathbf{L} := \text{chol}(\mathbf{Q}^T\mathbf{Q})$ ▷ Cholesky decomp. returns lower triangular $\mathbf{L}$ with $\mathbf{L}\mathbf{L}^T = \mathbf{Q}^T\mathbf{Q}$.
2: **return** $\tilde{\mathbf{V}} := \mathbf{Q}(\mathbf{L}^T)^{-1}$ ▷ Orthonormalize $\mathbf{Q}_T$'s columns using the Cholesky factor.

▶ Remark. Algorithm 3 requires an input that is *full-rank*, which always includes $\mathbf{Q}_T$ in Algorithms 1 and 2: $\mathbf{Q}_0$'s entries are random Gaussians so it is full-rank with probability 1 and each $(\mathbf{I} + \eta\mathbf{x}_t^T\mathbf{x}_t)$ is full-rank since $\eta < \|\mathbf{x}_t\|$. Thus, $\mathbf{Q}_T = \prod_{t=0}^{T-1}(\mathbf{I} + \eta\mathbf{x}_t^T\mathbf{x}_t)\mathbf{Q}_0$ is too.

Ultimately, our `AsynchOrth` is an asynchronous distributed implementation of Algorithm 3. We first prove an eigenvector approximation bound under the assumption that this implementation is exact and then adapt that result to account for the fact that `AsynchOrth` only outputs an approximate solution.

Pseudocode for `AsynchOrth` is included below. Each node first computes a (scaled) approximation to every entry of $\mathbf{Q}^T\mathbf{Q}$ using a simple averaging technique. Nodes then locally compute $\mathbf{L} = \text{chol}\left(\mathbf{Q}^T\mathbf{Q}\right)$ and the u^{th} row of $\tilde{\mathbf{V}}_T = \mathbf{Q}(\mathbf{L}^T)^{-1}$. In the full version of this paper [20] we argue that, due to numerical stability of Cholesky decomposition, each node's output is close to the u^{th} row of an exactly computed $\tilde{\mathbf{V}}_T$, despite the error in constructing $\mathbf{Q}^T\mathbf{Q}$.

Algorithm 4 Asynchronous Cholesky Orthogonalization (`AsynchOrth`(T))

Input: Time bound T.
Initialization: Each node holds $[q_u^{(1)}, ..., q_u^{(k)}]$. For all $i, j \in [k]$, let $r_u^{(i,j)} := q_u^{(i)} \cdot q_u^{(j)}$.

1: **if** $t < T$ **then**
2: (u, v) is chosen by the randomized scheduler.
3: for all $i, j \in [k]$, $r_u^{(i,j)} := \frac{r_u^{(i,j)} + r_v^{(i,j)}}{2}$. ▷ Estimation of $\frac{1}{n}\mathbf{q}_i^T\mathbf{q}_j$ via averaging.
4: **else**
5: Form $\mathbf{R}_u \in \mathbb{R}^{k\times k}$ with $(\mathbf{R}_u)_{i,j} = (\mathbf{R}_u)_{j,i} := n \cdot r_u^{(i,j)}$. ▷ Approximation of $\mathbf{Q}^T\mathbf{Q}$.
6: $\mathbf{L}_u := \text{chol}(\mathbf{R}_u)$.
7: $[\hat{v}_u^{(1)}, ..., \hat{v}_u^{(k)}] := [q_u^{(1)}, ..., q_u^{(k)}] \cdot (\mathbf{L}_u^T)^{-1}$. ▷ Approximation of u^{th} row of $\mathbf{Q}(\mathbf{L}_u^T)^{-1}$.
8: **end if**

Ultimately in [20] we prove the following result when Algorithm 4 is used to implement `AsynchOrth` as a subroutine for Algorithm 2, `AsynchOja`(T, T', η):

▶ **Theorem 6** (Asynchronous eigenvector approximation). *Let $\mathbf{v}_1, ..., \mathbf{v}_k$ be the top k eigenvectors of the communication matrix $\mathbf{D}+\mathbf{W}$ in an asynchronous communication model, and let $\Lambda, \overline{\text{gap}}, \gamma_{mix}$ be bounds satisfying: $\Lambda \geq \sum_{j=1}^{k} \lambda_j(\mathbf{D}+\mathbf{W})$, $\overline{\text{gap}} \leq \min_{j\in[k]}[\lambda_j(\mathbf{D}+\mathbf{W}) - \lambda_{j+1}(\mathbf{D}+\mathbf{W})]$, and $\gamma_{mix} \leq \min\left[\frac{1}{n}, \log\left(\lambda_2^{-1}(\mathbf{I} - \frac{1}{2}\mathbf{D} + \frac{1}{2}\mathbf{W})\right)\right]$.*

For any $\epsilon, \delta \in (0,1)$, let $\xi = \frac{n}{\delta\epsilon\cdot\overline{\text{gap}}}$. Let $\eta = \frac{c_1\epsilon^2\cdot\overline{\text{gap}}\cdot\delta^2}{\Lambda k^3 \log^3 \xi}$ for sufficiently small c_1, and $T = \frac{c_2\cdot(\log\xi + 1/\epsilon)}{\overline{\text{gap}}\cdot\eta}$, $T' = \frac{c_3(\log\xi+1/\epsilon)\cdot\lambda_1(\mathbf{D}+\mathbf{W})}{\overline{\text{gap}}\cdot\gamma_{mix}}$ for sufficiently large c_2, c_3. For all $u \in [n], i \in [k]$, let $\hat{v}_u^{(j)}$ be the local state computed by Algorithm 2. If $\hat{\mathbf{V}} \in \mathbb{R}^{n\times k}$ is given by $(\hat{\mathbf{V}})_{u,j} = \hat{v}_u^{(j)}$ and $\hat{\mathbf{v}}_i$ is the i^{th} column of $\hat{\mathbf{V}}$, then with probability $\geq 1 - \delta - e^{-\Theta(n)}$, for all $i \in [k]$:

$$\left|\hat{\mathbf{v}}_i^T \mathbf{v}_i\right| \geq 1 - \epsilon \quad \text{and} \quad \|\hat{\mathbf{v}}_i\|_2 \leq 1 + \epsilon.$$

4 Distributed community detection

From the results of section 3, we obtain a simple population protocol for distributed community detection that works for many clustered communication models, including the (n,p,q)-weighted communication and $G(n,p,q)$-communication models of Definitions 2 and 3.

In particular, we show that if each node $u \in V$ can locally compute the u^{th} entry of an approximation $\hat{\mathbf{v}}_2$ to the second eigenvector of the communication matrix $\mathbf{D}+\mathbf{W}$, then it can solve the community detection problem locally: u just sets its state to the sign of this entry.

Algorithm 5 Asynchronous Community Detection (`AsynchCD`(T, T', η))

Input: Time bounds T, T', step size η.

1: Run `AsynchOja`(T, T', η) (Algorithm 2) with $k = 2$.
2: Set $\hat{\chi}_u := \text{sign}(\hat{v}_u^{(2)})$.

Here $\hat{\chi}_u \in \{-1, 1\}$ is the final state of node u. We will claim that this state solves the community detection problem of Theorem 4. We use the notation $\hat{\chi}_u$ because we will use $\boldsymbol{\chi}$ to denote the true *cluster indicator vector* for communities V_1 and V_2 in a given communication model: $\boldsymbol{\chi}_u = 1$ for $u \in V_1$ and $\boldsymbol{\chi}_u = -1$ for $u \in V_2$.

In particular, we will show that if η is set so that `AsynchOja` outputs eigenvectors with accuracy ϵ, then a $1 - O(\epsilon)$ fraction of nodes will correctly identify their clusters. In section 5 we show how to implement a 'cleanup phase' where, starting with ϵ set to a small constant (e.g. $\epsilon = .1$), the nodes can converge to a state with *all* cluster labels correct with high probability.

4.1 Community detection in the (n,p,q)-weighted communication model

We start with an analysis for the (n,p,q)-weighted communication model. Recall that in this model the nodes are partitioned into two sets, V_1 and V_2, each with $n/2$ elements. Without loss of generality we can identify the nodes with integer labels such that $1, \ldots, n/2 \in V_1$ and $n/2+1, \ldots, n \in V_2$. We define the weighted cluster indicator matrix, $\mathbf{C}^{(p,q)} \in \mathbb{R}^{n\times n}$:

$$\mathbf{C}^{(p,q)} \stackrel{\text{def}}{=} \begin{bmatrix} p\cdot\mathbf{1}_{\frac{n}{2}\times\frac{n}{2}} & q\cdot\mathbf{1}_{\frac{n}{2}\times\frac{n}{2}} \\ q\cdot\mathbf{1}_{\frac{n}{2}\times\frac{n}{2}} & p\cdot\mathbf{1}_{\frac{n}{2}\times\frac{n}{2}} \end{bmatrix}. \tag{3}$$

p and q can be arbitrary, but we will always take $p > q > 0$. It is easy to check that $\mathbf{C}^{(p,q)}$ is a rank two matrix with eigendecomposition:

$$\mathbf{C}^{(p,q)} = \frac{n}{2}\begin{bmatrix}\mathbf{v}_1 & \mathbf{v}_2\end{bmatrix}\begin{bmatrix}p+q & 0\\ 0 & p-q\end{bmatrix}\begin{bmatrix}\mathbf{v}_1^T\\ \mathbf{v}_2^T\end{bmatrix} \quad \text{where} \quad \mathbf{v}_1 = \frac{\mathbf{1}_{n\times 1}}{\sqrt{n}},\ \mathbf{v}_2 = \frac{\boldsymbol{\chi}}{\sqrt{n}}. \tag{4}$$

So, if all nodes could compute their corresponding entry in the *second eigenvector* of $\mathbf{C}^{(p,q)}$, then by simply returning the sign of this entry, they would solve the distributed community detection problem (Theorem 4). If they compute this eigenvector approximately, then we can still show that a large fraction of them correctly solve community detection. Specifically:

▶ **Lemma 7.** *Let $\mathbf{v}_2$ be the second eigenvector of $\mathbf{C}^{(p,q)}$ for any $p > q > 0$. If $\tilde{\mathbf{v}}_2$ satisfies:*

$$\left|\tilde{\mathbf{v}}_2^T\mathbf{v}_2\right| \geq 1-\epsilon \quad \textit{and} \quad \|\tilde{\mathbf{v}}_2\|_2 \leq 1+\epsilon. \tag{5}$$

for $\epsilon \leq 1$, then $\operatorname{sign}(\tilde{\mathbf{v}}_2)$ gives a labeling such that, after ignoring at most $5\epsilon n$ nodes, all remaining nodes in V_1 have the same labeling, and all in V_2 have the opposite.

A proof can be found in [20]. With Theorem 7 in place, we can then apply Theorem 6 to prove the correctness of `AsynchCD` (Algorithm 5) for the (n,p,q)-weighted communication model

▶ **Theorem 8** (ϵ-approximate community detection: (n,p,q)-weighted communication model)**.** *Consider Algorithm 5 in the (n,p,q)-weighted communication model. Let $\rho = \min\left(\frac{q}{p+q}, \frac{p-q}{p+q}\right)$. For sufficiently small constant c_1 and sufficiently large c_2 and c_3, let*

$$\eta = \frac{c_1\epsilon^2\delta^2\rho}{\log^3\left(\frac{n}{\epsilon\delta\rho}\right)},\ T = \frac{c_2 n\left(\log^3\left(\frac{n}{\epsilon\delta\rho}\right) + \frac{\log\left(\frac{n}{\epsilon\delta\rho}\right)}{\epsilon}\right)}{\epsilon^2\delta^2\rho^2},\ T' = \frac{c_3 n\left(\log\left(\frac{n}{\epsilon\delta\rho}\right) + \frac{1}{\epsilon}\right)}{\rho^2}.$$

With probability $1-\delta$, after ignoring ϵn nodes, all remaining nodes in V_1 terminate in some state $s_1 \in \{-1,1\}$, and all nodes in V_2 terminate in state $s_2 = -s_1$. Suppressing polylogarithmic factors in the parameters, the total number of global rounds and local rounds required are: $T + T' = \tilde{O}\left(\frac{n}{\epsilon^3\delta^2\rho^2}\right)$ and $L = \tilde{O}\left(\frac{1}{\epsilon^3\delta^3\rho^2}\right)$.

Proof. In the (n,p,q)-weighted communication model the weight and degree matrices are:

$$\mathbf{W} = \frac{4}{n^2(p+q)-2np}\cdot(\mathbf{C}^{(p,q)} - p\cdot\mathbf{I}_{n\times n}) \quad \text{and} \quad \mathbf{D} = \frac{2}{n}\cdot\mathbf{I}_{n\times n}.$$

Thus, referring to the eigendecomposition of $\mathbf{C}^{(p,q)}$ shown in (4), the top eigenvector of $\mathbf{D}+\mathbf{W}$ is $\mathbf{v}_1 = \mathbf{1}_{n\times 1}/\sqrt{n}$ with corresponding eigenvalue: $\lambda_1 = \frac{4}{n^2(p+q)-2np}\cdot\left(\frac{n(p+q)}{2} - p\right) + \frac{2}{n} = \frac{4}{n}$. The second eigenvector is the scaled cluster indicator vector $\mathbf{v}_2 = \boldsymbol{\chi}/\sqrt{n}$ with eigenvalue

$$\lambda_2 = \frac{4}{n^2(p+q)-2np}\cdot\left(\frac{n(p-q)}{2} - p\right) + \frac{2}{n} = \frac{4}{n}\cdot\frac{p}{p + \frac{n}{n-2}\cdot q}.$$

Finally, for all remaining eigenvalues of $\mathbf{D}+\mathbf{W}$, $\{\lambda_3, ..., \lambda_n\}$, $\lambda_i = \frac{2}{n} - \frac{4p}{n^2(p+q)-2np}$. We can bound the eigenvalue gaps:

$$\lambda_1 - \lambda_2 \geq \frac{4}{n} - \frac{4}{n}\cdot\frac{p}{p+q} = \frac{4q}{n(p+q)} \qquad \lambda_2 - \lambda_3 = \frac{2(p-q)}{n(p+q)-2p} \geq \frac{2(p-q)}{n(p+q)}$$

Let $\rho = \min\left(\frac{q}{p+q}, \frac{p-q}{(p+q)}\right)$. We bound the mixing time of $\mathbf{W}+\mathbf{D}$ by noting that $\lambda_2(\mathbf{I} - 1/2\mathbf{D} + 1/2\mathbf{W}) \leq 1 - \frac{2q}{n(p+q)}$. Then using that $\log(1/x) \geq 1-x$ for all $x \in (0,1]$, $\log(\lambda_2^{-1}(\mathbf{I} - 1/2\mathbf{D} + 1/2\mathbf{W}) \geq \frac{2q}{n(p+q)} \geq \frac{2\rho}{n}$. We then apply Theorem 6 with $k=2$, $\Lambda = \frac{4}{n} + \frac{4}{n}\frac{p}{p+\frac{n}{n-2}q} \leq \frac{8}{n}$, $\overline{\text{gap}} = \frac{4}{n} \cdot \min\left(\frac{q}{p+q}, \frac{p-q}{2(p+q)}\right) \geq \frac{2\rho}{n}$, and $\gamma_{mix} = \frac{2\rho}{n}$. With these parameters we set, for sufficiently small c_1 and large c_2, c_3,

$$\eta = \frac{c_1\epsilon^2\delta^2 \cdot \rho}{\log^3\left(\frac{n}{\epsilon\delta\rho}\right)}, \quad T = \frac{c_2 \cdot n \cdot \left(\log^3\left(\frac{n}{\epsilon\delta\rho}\right) + \frac{\log\left(\frac{n}{\epsilon\delta\rho}\right)}{\epsilon}\right)}{\epsilon^2\delta^2\rho^2}, \quad T' = \frac{c_3 \cdot n \cdot \left(\log\left(\frac{n}{\epsilon\delta\rho}\right) + \frac{1}{\epsilon}\right)}{\rho^2}$$

where to bound T' we use that $\frac{\lambda_1(\mathbf{D}+\mathbf{W})}{\overline{\text{gap}}} \leq \frac{2}{\rho}$. Let $\hat{\mathbf{V}} \in \mathbb{R}^{n\times k}$ be given by $(\hat{\mathbf{V}})_{u,j} = \hat{v}_u^{(j)}$ where $\hat{v}_u^{(j)}$ are the states of $\texttt{AsynchOja}(T, T', \eta)$ and let $\hat{\mathbf{v}}_2$ be the second column of $\hat{\mathbf{V}}$. With these parameters, Theorem 6 gives with probability $\geq 1-\delta$ that $\left|\hat{\mathbf{v}}_2^T\mathbf{v}_2\right| \geq 1-\epsilon$ and $\|\hat{\mathbf{v}}_2\|_2 \leq 1+\epsilon$.

Applying Theorem 7 then gives the theorem if we adjust ϵ by a factor of $1/5$. Recall that the second eigenvector of $\mathbf{D}+\mathbf{W}$ is identical to that of $\mathbf{C}^{(p,q)}$. Additionally, in expectation, each node is involved in $L = \frac{2(T+T')}{n}$ interactions. This bound holds for all nodes within a factor 2 with probability $1-\delta$ by a Chernoff bound, since $L = \Omega(\log(n/\delta))$. We can union bound over our two failure probabilities and adjust δ by $1/2$ to obtain overall failure probability $\leq \delta$. ◀

4.2 Community Detection in the $G(n,p,q)$-communication model

In the $G(n,p,q)$-communication model, nodes communicate using a random graph which is equal to the communication graph in the (n,p,q)-weighted communication model *in expectation*. Using an approach similar to [30], which is a simplifies the perturbation method used in [21], we can prove that in the $G(n,p,q)$-communication model $\mathbf{W}$ is a small perturbation of $\mathbf{C}^{(p,q)}$ and so the second eigenvector of $\mathbf{D}+\mathbf{W}$ approximates that of $\mathbf{C}^{(p,q)}$ – i.e., the cluster indicator vector $\boldsymbol{\chi}$. We defer this analysis to the full version [20], stating the main result here:

▶ **Theorem 9** (ϵ-approximate community detection: $G(n,p,q)$-communication model)**.** *Consider Algorithm 5 in the $G(n,p,q)$-communication model. Let $\rho = \min\left(\frac{q}{p+q}, \frac{p-q}{p+q}\right)$. For sufficiently small constant c_1 and sufficiently large c_2 and c_3 let*

$$\eta = \frac{c_1\epsilon^2\delta^2\rho}{\log^3\left(\frac{n}{\epsilon\delta\rho}\right)}, \quad T = \frac{c_2 n \left(\log^3\left(\frac{n}{\epsilon\delta\rho}\right) + \frac{\log\left(\frac{n}{\epsilon\delta\rho}\right)}{\epsilon}\right)}{\epsilon^2\delta^2\rho^2}, \quad T' = \frac{c_3 n \left(\log\left(\frac{n}{\epsilon\delta\rho}\right) + \frac{1}{\epsilon}\right)}{\rho^2}.$$

If $\frac{\min[q,p-q]}{\sqrt{p+q}} \geq \frac{c_4\sqrt{\log(n/\delta)}}{\epsilon\sqrt{n}}$ for large enough constant c_4, then, with probability $1-\delta$, after ignoring ϵn nodes, all remaining nodes in V_1 terminate in some state $s_1 \in \{-1,1\}$, and all nodes in V_2 terminate in state $s_2 = -s_1$. Supressing polylogarithmic factors, the total number of global rounds and local rounds required are: $T+T' = \tilde{O}\left(\frac{n}{\epsilon^3\delta^2\rho^2}\right)$ and $L = \tilde{O}\left(\frac{1}{\epsilon^3\delta^3\rho^2}\right)$.

If for example, $p, q = \Theta(1)$ and thus the $G(n,p,q)$ graph is dense, we can recover the communities with probability $1-\delta$ up to $O(1)$ error as long as $q \leq p - c\sqrt{\log(n/\delta)/n}$ for sufficiently large constant c. Alternatively, if $p, q = \Theta\left(\log(n/\delta)/n\right)$, so the $G(n,p,q)$ graph is sparse, we require $q \leq cp$ for sufficiently small c.

5 Cleanup Phase

After we apply Theorem 9 (respectively, Theorem 8) an ϵ-fraction of nodes are incorrectly clustered. The goal of this section is to provide a simple algorithm that improves this clustering so that *all nodes* are labeled correctly after a small number of rounds.

For the (n, p, q)-weighted communication model, doing so is straightforward. After running Algorithm 2 and selecting a label, each time a node communicates in the future it records the chosen label of the node it communicates with. Ultimately, it changes its label to the majority of labels encountered. If ϵ is small enough so $p(1-\epsilon) > q + \epsilon p$, this majority tends towards the node's correct label. The number of required rounds for the majority to be correct, with good probability for all nodes, is a simple a function of p, q, and ϵ.

The $G(n, p, q)$-communication model is more difficult. Theorem 9 does not guarantee how incorrectly labeled nodes are distributed: it is possible that a majority of a node's neighbors fall into the set of ϵn "bad nodes". In that case, even after infinitely many rounds of communication, the majority label encountered will not tend towards the node's correct identity.

As a remedy, we introduce a phased algorithm (Algorithm 6) where each node updates its label to the majority of labels seen during a phase. We show that in each phase the fraction of incorrectly labeled nodes decreases by a constant factor. Our analysis establishes a graph theoretic bound on the external edge density of most subsets of nodes. Specifically, for all subsets S below a certain size, we show that, with high probability, there are at most $|S|/3$ nodes which have enough connections to S so that if an adversary gave all nodes in S incorrect labels, it could cause these nodes to have an incorrect majority label. This bound guarantees that at most $|S|/3$ bad labels 'propagate' to the next phase of the algorithm.

Algorithm 6 Cleanup phase (pseudocode for node u)
Input: Number of phases k and number of rounds per phase r.
Output: Label $\hat{\chi}_u \in \{-1, 1\}$

```
for Phase 1 to k do
    for Round i = 1 to r do
        S_i := χ̂_v, where χ̂_v denotes the i^th sample of node u.
    end for
    χ̂_u := 1 if Σ_i^r S_i ≥ 0, χ̂_u := −1 otherwise.
end for
```

▶ **Theorem 10.** *Consider the (n, p, q)-weighted communication model. Assume that a fraction of at most $\epsilon \leq 1/64$ of the nodes are incorrectly clustered after Algorithm 2. As long as $p' = (1-\epsilon)p$ and $q' = q + \epsilon p$ satisfy $p' > q'$, Algorithm 6 ensures that all nodes are correctly labeled with high probability after $O(\frac{p \ln n}{(\sqrt{p'} - \sqrt{q'})^2})$ local rounds. In particular, for $q \leq p/2$ and $\epsilon < 1/8$, the number of local rounds required is $O(\log n)$.*

▶ **Theorem 11.** *Consider the $G(n, p, q)$-communication model. Let $\Delta = \frac{p}{2} - \frac{q}{2} - \sqrt{12p \ln n/n} - \sqrt{12q \ln n/n}$. Assume that $\Delta = \Omega(\ln n/n)$ and at most $\epsilon \leq \Delta/24p$ nodes are incorrectly clustered after Algorithm 2. As long as $p'' = \frac{p}{2} - \sqrt{\frac{6p \ln n}{n}} - \frac{\Delta}{12}$ and $q'' = \frac{q}{2} + \sqrt{\frac{6q \ln n}{n}} + \frac{\Delta}{12}$ satisfy $p'' > q''$, Algorithm 6 ensures that all nodes are correctly labeled with high probability after $O(\frac{p \ln^2 n}{(\sqrt{p''} - \sqrt{q''})^2})$ local rounds. In particular, for $q \leq p/2$ the number of local rounds required is $O(\log^2 n)$.*

Note that if $p - q = \Omega(\sqrt{\log n/n})$, then Δ simplifies to $\Delta = \Theta(p - q)$. Incidentally, $p - q = \Omega(\sqrt{\log n/n})$ is sometimes tight because, in this regime, clustering correctly can be infeasible: some nodes will simply have more neighbors in the opposite cluster. Consider for example when $p = 1/2 + \sqrt{\ln n/(10n)}$ and $q = 1/2$.

$(\Delta + 1)$ Coloring in the Congested Clique Model

Merav Parter
Weizmann IS, Rehovot, Israel
merav.parter@weizmann.ac.il

Abstract

In this paper, we present improved algorithms for the $(\Delta + 1)$ (vertex) coloring problem in the *Congested Clique* model of distributed computing. In this model, the input is a graph on n nodes, initially each node knows only its incident edges, and per round each two nodes can exchange $O(\log n)$ bits of information.

Our key result is a randomized $(\Delta + 1)$ vertex coloring algorithm that works in $O(\log\log\Delta \cdot \log^*\Delta)$-rounds. This is achieved by combining the recent breakthrough result of [Chang-Li-Pettie, STOC'18] in the LOCAL model and a degree reduction technique. We also get the following results with high probability: (1) $(\Delta + 1)$-coloring for $\Delta = O((n/\log n)^{1-\epsilon})$ for any $\epsilon \in (0, 1)$, within $O(\log(1/\epsilon)\log^*\Delta)$ rounds, and (2) $(\Delta + \Delta^{1/2+o(1)})$-coloring within $O(\log^*\Delta)$ rounds.
Turning to *deterministic* algorithms, we show a $(\Delta+1)$-coloring algorithm that works in $O(\log\Delta)$ rounds. Our new bounds provide *exponential* improvements over the state of the art.

1 Introduction & Related Work

Graph coloring is one of the most central symmetry breaking problems, with a wide range of applications to distributed systems and wireless networks. The most studied coloring problem is the $(\Delta + 1)$ *vertex* coloring in which all nodes are given the *same* palette of $\Delta + 1$ colors, where Δ is the maximum degree in the graph. Vertex coloring among other LCL problems[1] (e.g., MIS, matching) are traditionally studied in the LOCAL model in which any two neighboring vertices in the input graph can exchange arbitrarily long messages.

In recent years there has been a tremendous progress in the understanding of the randomized and the deterministic complexities of many LCL problems in the LOCAL model [6, 20, 8, 9, 1]. Putting our focus on the $(\Delta + 1)$ coloring problem, in a seminal work, Schneider and Wattenhofer [23] showed that increasing the number of colors from $\Delta + 1$ to $(1 + \epsilon)\Delta$ has a dramatic effect on the round complexity and coloring can be computed in just $O(\log^* n)$ rounds when $\epsilon = \Omega(1)$ and $\Delta > \mathsf{poly}\log n$. This has led to two recent breakthroughs. Harris, Schneider and Su [13] showed an $O(\sqrt{\log\Delta})$-round algorithm for $(\Delta + 1)$ coloring, providing a separation for the first time between MIS and coloring (due to the MIS lower bound of [17]). In a recent follow-up breakthrough, Chang, Li and Pettie [7] extended the

technique of [13] to obtain the remarkable and quite extraordinary round complexity of $O(\log^* n + \mathsf{Det}_{\deg}(\mathsf{polylog} n))$ for the $(\Delta+1)$-list coloring problem where $\mathsf{Det}_{\deg}(n')$ is the deterministic round complexity of $(\deg+1)$ list coloring algorithm[2] in n'-vertex graph. Both of these recent breakthroughs use messages of large size, potentially of $\Omega(n)$ bits.

In view of these recent advances, the understanding of LCL problems in bandwidth-restricted models is much more lacking. Among these models, the congested clique model [19], which allows all-to-all communication has attracted a lot of attention in the last decade and more recently, in the context of LCL problems [4, 15, 14, 5, 12, 24]. In the congested clique model, each node can send $O(\log n)$ bits of information to any node in the network (i.e., even if they are not connected in the input graph). The ubiquitous of overlay networks and large scale distributed networks make the congested clique model far more relevant (compared to the LOCAL and the CONGEST models) in certain settings.

Randomized LCL in the Congested Clique Model. Starting with Barenboim et al. [2], currently, all efficient randomized algorithms for classical LCL problems have the following structure: an initial randomized phase and a *post-shattering* deterministic phase. The shattering effect of the randomized phase which dates back to Beck [3], breaks the graph into subproblems of $\mathsf{poly}\log n$ size to be solved deterministically. In the congested-clique model, the shattering effect has an even more dramatic effect. Usually, a node survives (i.e., remained undecided) the randomized phase with probability of $1/\mathsf{poly}(\Delta)$. Hence, in expectation the size of the remaining unsolved graph is[3] $O(n)$. At that point, the entire unsolved subgraph can be solved in $O(1)$ rounds, using standard congested clique tools (e.g., the routing algorithm by Lenzen [18]). Thus, as long as the main randomized part uses short messages, the congested clique model "immediately" enjoys an improved round complexity compared to that of the LOCAL model.

In a recent work [12], Ghaffari took it few steps farther and showed an $\widetilde{O}(\sqrt{\log\Delta})$-round randomized algorithm for MIS in the congested clique model, improving upon the state-of-the-art complexity of $O(\log\Delta + 2^{O(\sqrt{\log\log n})})$ rounds in the LOCAL model, also by Ghaffari [11]. When considering the $(\Delta+1)$ coloring problem, the picture is somewhat puzzling. On the one hand, in the LOCAL model, $(\Delta+1)$ coloring is provably simpler then MIS. However, since all existing $o(\log\Delta)$-round algorithms for $(\Delta+1)$ coloring in the LOCAL model, use large messages, it is not even clear if the power of all-to-all communication in the congested clique model can compensate for its bandwidth limitation and outperform the LOCAL round complexity, not to say, even just match it. We note that on hind-sight, the situation for MIS in the congested clique was somewhat more hopeful (compared to coloring), for the following reason. The randomized phase of Ghaffari's MIS algorithm although being in the LOCAL model [11], used *small* messages and hence could be implemented in the CONGEST model with the same round complexity. To sum up, currently, there is no $o(\log\Delta)$-round algorithm for $(\Delta+1)$ coloring in any bandwidth restricted model, not even in the congested-clique.

Derandomization of LCL in the Congested-Clique Model. There exists a curious gap between the known complexities of randomized and deterministic solutions for local problems in the LOCAL model ([6, 20]). Censor et al. [5] initiated the study of *deterministic* LCL algorithms in the congested clique model by means of derandomization. The main take home message of [5] is as follows: for most of the classical LCL problems there are $\mathsf{poly}\log n$ round

[2] In the $(\deg+1)$ list coloring problem, each vertex v is given a palette with $\deg(v,G)+1$ colors.
[3] Using the bounded dependencies between decisions, this holds also with high probability.

randomized algorithms (even in the CONGEST model). For these algorithms, it is usually sufficient that the random choices made by vertices are *almost* independent. This implies that each round of the randomized algorithm can be simulated by giving all nodes a shared random seed of $\mathsf{poly}\log n$ bits. To dernadomize a single round of the randomized algorithm, nodes should compute (deterministically) a seed which is at least as "good"[4] as a random seed would be. To compute this seed, they need to estimate their "local progress" when simulating the random choices using that seed. Combining the techniques of conditional expectation, pessimistic estimators and bounded independence leads to a simple "voting"-like algorithm in which the bits of the seed are computed *bit-by-bit*. Once all bits of the seed are computed, it is used to simulate the random choices of that round. For a recent work on other complexity aspects in the congested clique, see [16].

1.1 Main Results and Our Approach

In this paper, we show that the power of all-to-all communication compensates for the bandwidth restriction of the model:

▶ **Theorem 1.** *There is a randomized algorithm that computes a* $(\Delta+1)$ *coloring in* $O(\log\log\Delta\cdot\log^* n)$ *rounds of the congested clique model, with high probability*[5]*.*

This significantly improves over the state-of-the-art of $O(\log\Delta)$-round algorithm for $(\Delta+1)$ in the congested clique model. It should also be compared with the round complexity of $(2^{O(\sqrt{\log\log n})})$ in the LOCAL model, due to [7]. As noted by the authors, reducing the LOCAL complexity to below $O((\log\log n)^2)$ requires a radically new approach.

Our $O(\log\log\Delta\cdot\log^* n)$ round algorithm is based on a recursive degree reduction technique which can be used to color any almost-clique graph with $\Delta=\widetilde{O}(n^{1-o(1)})$ in essentially $O(\log^* n)$ rounds.

▶ **Theorem 2.** *(i) For every* $\epsilon\in(0,1)$*, there is a randomized algorithm that computes a* $(\Delta+1)$ *coloring in* $O(\log(1/\epsilon)\cdot\log^* n)$ *rounds for graphs with* $\Delta=O((n/\log n)^{1-\epsilon})$*, (ii) This also yields a* $(\Delta+\Delta^{1/2+o(1)})$ *coloring in* $O(\log^* n)$ *rounds, with high probability.*

Claim (ii) improves over the $O(\Delta)$-coloring algorithm of [14] that takes $O(\log\log\log n)$ rounds in *expectation*. We also provide fast *deterministic* algorithms for $(\Delta+1)$ list coloring. The stat-of-the-art in the LOCAL model is $\widetilde{O}(\sqrt{\Delta})+\log^* n$ rounds due to Fraigniaud, Heinrich, Marc and Kosowski [10].

▶ **Theorem 3.** *There is a deterministic algorithm that computes a* $(\Delta+1)$ *coloring in* $O(\log\Delta)$ *rounds of the congested clique model and an* $O(\Delta^2)$ *coloring in* $O(1)$ *rounds.*

In [5], a deterministic algorithm for $(\Delta+1)$ coloring in $O(\log\Delta)$ round was shown only for the case where $\Delta=O(n^{1/3})$. Here it is extended for $\Delta=\Omega(n^{1/3})$. This is done by derandomizing an $(\Delta+1)$-list coloring algorithm which runs in $O(\log n)$ rounds. Similarly to [5], we first show that this algorithm can be simulated when the random choices made by the nodes are pairwise independent. Then, we enjoy the small search space and employ the method of conditional expectations. Instead of computing the seed bit by bit, we compute it in chunks of $\lfloor\log n\rfloor$ bits at a time, by fully exploiting the all-to-all power of the model.

[4] The random seed is usually shown provide a large progress in expectation. The deterministically computed seed should provide a progress at least as large as the expected progress of a random seed.

[5] As usual, by high probability we mean $1-1/n^c$ for some constant $c\geq 1$.

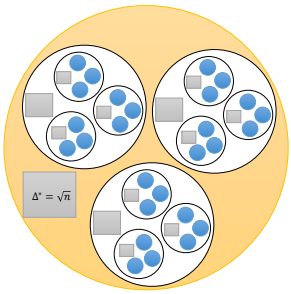

Figure 1 Illustration of the recursive sparsification. Gray boxes correspond to subgraphs with maximum degree $O(\sqrt{\Delta})$.

The Challenges and the Degree Reduction Technique. Our starting observation is that the CLP algorithm [7] can be implemented in $O(\log^* n)$ rounds in congested clique model for $\Delta = O(\sqrt{n})$. When $\Delta = O(\sqrt{n})$, using Lenzen's routing algorithm [18], each node can learn in $O(1)$ rounds, the palettes of all its neighbors along with the neighbors of its neighbors. Such knowledge is mostly sufficient for the CLP algorithm to go through.

To handle large degree graphs, we design a graph sparsification technique that essentially reduces the problem of $(\Delta+1)$ coloring for an arbitrarily large $\Delta = \widetilde{O}(n^{1-\epsilon})$ into $\ell = O(\log(1/\epsilon))$ (non-independent) subproblems. In each subproblem, one has to compute a $(\Delta'+1)$ coloring for a subgraph with $\Delta' = O(\sqrt{n})$, which can be done in $O(\log^* n)$ rounds, using a modification of the CLP algorithm, that we describe later on. Since there many dependencies between these ℓ sub-problems, it is required by our algorithm to solve them one-by-one, leading to a round complexity of $O(\log(1/\epsilon)\log^* n)$. See Figure 1 for an illustration of the recursion levels. To get an intuition into our approach and the challenges involved, consider an input graph G with maximum degree $\Delta = (n/\log n)^{1-\epsilon}$ and a palette $\mathsf{Pal}(G) = \{1,\ldots,\Delta+1\}$ given to each node in G. A natural approach (also taken in [14]) for handling a large degree graph is to decompose it (say, randomly) into k vertex disjoint graphs $G_1, G_2, \ldots, G_k$, allocate a *distinct* set of colors for each of the subgraphs taken from $\mathsf{Pal}(G)$ and solve the problem recursively on each of them, enjoying (hopefully) smaller degrees in each G_i. Intuitively, assigning a *disjoint* set of colors to each G_i has the effect of *removing* all edges connecting nodes in different subgraphs. Thus, the input graph G is sparsified into a graph $G' = \bigcup G_i$ such that a legal coloring of G' (with the corresponding palettes given to the nodes) is a legal coloring for G. The main obstacle in implementing this approach is that assigning a distinct set of $\Delta(G_i)+1$ colors to each of the G_i subgraph might be beyond the budget of $\Delta+1$ colors. Indeed in [14] this approach led to $O(\Delta)$ coloring rather than $(\Delta+1)$. To reduce the number of colors allocated to each subgraph G_i, it is desirable that the maximum degree $\Delta(G_i)$ would be as small as possible, for each G_i. This is exactly the problem of (k,p) *defective coloring* where one needs to color the graph with k colors such that the number of neighbors with the same color is at most p. To this point, the best defective coloring algorithm for large degrees is the randomized one: let each node pick a subgraph G_i (i.e., a color in the defective coloring language) uniformly at random. By a simple application of Chernoff bound, it is easy to see that the partitioning is "almost" perfect: w.h.p., for every i, $\Delta(G_i) \leq \Delta/k + \sqrt{\log n \cdot \Delta/k}$. Hence, allocating $\Delta(G_i)+1$ colors to each subgraphs consumes $\Delta + \widetilde{O}(\sqrt{\Delta k})$ colors. To add insult to injury, this additive penalty of $\widetilde{O}(\sqrt{\Delta k})$ is only for one recursion call!

It is interesting to note that the parameter k – number of subgraphs (colors) – plays a key role here. Having a large k has the benefit of sharply decreasing the degree (i.e., from Δ

to Δ/k). However, it has the drawback of increasing the standard deviation and hence the total number of colors used. Despite these opposing effects, it seems that for whatever value of k chosen, increasing the number of colors to $\Delta + \Delta^{\epsilon}$ is unavoidable.

Our approach bypasses this obstacle by partitioning only a large fraction of the vertices into small-degree subgraphs *but not all of them*. Keeping in mind that we can handle efficiently graphs with maximum degree $\sqrt{n}$, in every level of the recursion, roughly $1-1/\sqrt{\Delta}$ of the vertices are partitioned into subgraphs $G_1, \ldots, G_k$. Let $\Delta(G_i)$ be the maximum degree of G_i. The remaining vertices join a left-over subgraph G^*. The number of subgraphs, k, is chosen carefully so that allocating $\Delta(G_i)+1$ colors to each of the k subgraphs, consumes at most Δ colors, on the one hand; and that the degree reduction in each recursion level is large enough on the other hand. These subgraphs are then colored recursively, until all remaining subgraphs have degree of $O(\sqrt{n})$. Once all vertices in these subgraphs are colored, the algorithm turns to color the left-over subgraph G^*. Since the maximum degree in G^* is $O(\sqrt{n})$, it is tempting to use the CLP algorithm to complete the coloring, as this can be done in $O(\log^* n)$ rounds for such bound on the maximum degree. This is not so immediate for the following reasons. Although the degree of v in G^* is $O(\sqrt{n})$, the graph G^* cannot be colored independently (as at that point, we ran out of colors to be solely allocate to G^*). Instead, the coloring of G^* should agree with the coloring of the rest of the graph and each v might have $\Omega(\Delta) = n^{1-\epsilon}$ neighbors in G. At first glance, it seems that this obstacle is easily solved by letting each $v \in G^*$ pick a subset of $\deg(v, G^*) = O(\sqrt{n})$ colors from its palette (i.e., removing the colors taken by its neighbors in $G \setminus G^*$). Now, one can consider only the graph G^* with maximum degree $\sqrt{n}$, where each vertex has a palette of $\deg(v, G^*)+1$ colors. Unfortunately, this seemingly plausible approach has a subtle flaw: for the CLP algorithm it is essential that each vertex receives a palette with *exactly* $\Delta(G^*)+1$ colors. This is indeed crucial and as noted by the authors adopting their algorithm to a $(\deg+1)$ coloring algorithm is highly non-trivial and probably calls for a different approach.

In our setting, allocating each vertex $v \in G$ the exact same number of colors seems to be impossible as the number of available colors of each v depends on the number of its neighbors in $G \setminus G^*$, and this number has some fluctuations due to the random partitioning of the vertices. To get out of this impasse, we show that after coloring all vertices in $G \setminus G^*$, every vertex $v \in G^*$ has $r_v \in [\Delta(G^*) \pm (\Delta(G^*))^{3/5}]$ available colors in its palette where $r_v \geq \deg(v, G^*)$. In other words, all vertices can be allocated "almost" the same number of colors, but not exactly the same. We then carefully revise the basic definitions of the CLP algorithm and show that the analysis still goes through (upon minor changes) for this narrow range of variation in the size of the palettes.

Paper Organization. In Section 2, we explain how the CLP algorithm of [7] can be simulated in $O(\log^* n)$ congested-clique rounds when $\Delta = O(\sqrt{n})$. In Section 3.1, we illustrate the degree-reduction technique on the case where $\Delta = O((n/\log n)^{3/4})$. Section 3.2 extends this approach for $\Delta = O((n/\log n)^{1-\epsilon})$ for any $\epsilon \in (0,1)$, and Section 3.3 handles the general case and provides the complete algorithm. Finally, Section 4 discusses deterministic coloring algorithms. Missing proofs are deferred to the full version.

2 The Chang-Li-Pettie (CLP) Alg. in the Congested Clique

High-level Description of the CLP Alg. in the LOCAL Model. In the description below, we focus on the main randomized part of the CLP algorithm [13].

Harris-Schneider-Su algorithm is based on partitioning the graph into an ϵ-sparse subgraph and a collection of vertex-disjoint ϵ-dense components, for a given input parameter ϵ. Since

the CLP algorithm extends this partitioning, we next formally provide the basic definitions from [13]. For an $\epsilon \in (0,1)$, an edge $e=(u,v)$ is an ϵ-friend if $|N(u) \cap N(v)| \geq (1-\epsilon)\cdot\Delta$. The endpoints of an ϵ-friend edge are ϵ-friends. A vertex v is ϵ-dense if v has at least $(1-\epsilon)\Delta$ ϵ-friends, otherwise it is ϵ-sparse. A key structure that arises from the definition of ϵ dense vertices is that of ϵ-*almost clique* which is a connected component of the subgraph induced by the ϵ-dense vertices and ϵ-friend edges. The dense components, ϵ-*almost* cliques, have some nice properties: each component C has at most $(1+\epsilon)\Delta$ many vertices, each vertex $v \in C$ has $O(\epsilon\Delta)$ neighbors outside C (called *external* neighbors) and $O(\epsilon\Delta)$ vertices in C which are not its neighbors. In addition, C has weak diameter at most 2. Coloring the dense vertices consists of $O(\log_{1/\epsilon}\Delta)$ phases. The efficient coloring of dense regions is made possible by generating a random proper coloring inside each clique so that each vertex has a small probability of receiving the same color as one of its external neighbors. To do that, in each cluster a random permutation is computed and each vertex selects a tentative color from its palette excluding the colors selected by lower rank vertices. Since each component has weak diameter at most 2, this process is implemented in 2 rounds of the LOCAL model. The remaining *sparse* subgraph is colored using a Schneider-Wattenhofer style algorithm [23] within $O(\log(1/\epsilon))$ rounds.

In Chang-Li-Pettie algorithm the vertices are partitioned into $\ell = \lceil \log\log\Delta \rceil$ layers in decreasing level of density. This hierarchical partitioning is based on a sequence of ℓ sparsity thresholds $\epsilon_1,\ldots,\epsilon_\ell$ where $\epsilon_i = \sqrt{\epsilon_{i-1}}$. Roughly speaking, level i consists of the vertices which are ϵ_i-dense but ϵ_{i-1}-sparse. Instead of coloring the vertices layer by layer, the algorithm partitions the vertices in level i into large and small components and partitions the layers into $O(\log^*\Delta)$ strata. It then colors the vertices in $O(\log^*\Delta)$ phases, giving priority to vertices in small components. The algorithms used to color these vertices are of the same flavor of the dense-coloring procedure of Harris-Schneider-Su. The key benefit in having the hierarchical structure is that the dense-coloring procedure is applied for $O(1)$ many phases on each stratum, rather than applying it for $O(\log_{1/\epsilon}\Delta)$ phases as in [13].

An $O(\log^*\Delta)$-Round Alg. for $\Delta = O(\sqrt{n})$ in the Congested Clique. We next observe that the randomized part of the CLP algorithm [7] can be implemented in the congested clique model when $\Delta = O(\sqrt{n})$ within $O(\log^*\Delta)$ rounds. We note that we obtain a round complexity of $O(\log\Delta^*)$ rather than $O(\log^* n)$ as in [7], due to the fact that the only part of the CLP algorithm that requires $O(\log^* n)$ rounds was for coloring a subgraph with maximum constant degree. In the congested-clique model such a step can be implemented in $O(1)$ rounds using Lenzen's routing algorithm. We show:

▶ **Theorem 4.** *For every graph with maximum degree $\Delta = O(\sqrt{n})$, there is an $O(\log^*\Delta)$-round randomized algorithm that computes $(\Delta+1)$-list coloring in the congested clique model.*

The main advantage of having small degrees is that it is possible for each node to collect its 2-neighborhood in $O(1)$ rounds (i.e., using Lenzen's routing [18]). As we will see, this is sufficient in order to simulate the CLP algorithm in $O(\log^*\Delta)$ rounds. The hierarchical decomposition of the vertices depends on the computation of ϵ-dense vertices. By collecting the neighbors of its neighbors, every vertex can learn its ϵ-dense friends and based on that deduce if it is an ϵ-dense vertex for every ϵ. In particular, for every edge (u,v), v can learn the minimum i such that u and v are ϵ_i-friends. To allow each vertex v compute the ϵ-almost cliques to which it belongs, we do as follows. Each vertex v sends to each of its neighbors $N(v)$, the minimum ϵ_i such that u,v are ϵ_i-friends, for every $u \in N(v)$. Since the

weak diameter of each almost-clique is at most 2, each vertex has collected all the required information from its 2^{nd} neighborhood to locally compute its ϵ_i-almost cliques for every ϵ_i. Overall, each vertex sends $O(\Delta)$ messages and receives $O(\Delta^2) = O(n)$ messages, collection this information can be done in $O(1)$ rounds for all nodes, using Lenzen's routing algorithm. The next obstacle is the simulation of the algorithm that colors the ϵ-dense vertices. Since each ϵ-almost clique C has $(1+\epsilon)\Delta = O(\sqrt{n})$ vertices, we can make the leader of each such C learn the palettes of all the vertices in its clique as well as their neighbors in $O(1)$ rounds. The leader can then locally simulate the dense-coloring procedure and notify the output color to each of its almost-clique vertices. Finally, coloring the sparse regions in a Schneider-Wattenhofer style uses messages of size $O(\Delta)$ and hence each vertex is the target of $O(\Delta^2) = O(n)$ messages which again can be implemented in $O(1)$ many rounds. A more detailed description appears in the full version [22]. By the above description, we also have:

▶ **Corollary 5.** *Given q vertex-disjoint subgraphs $G_1, \ldots, G_q$ each with maximum degree $\Delta = O(\sqrt{n})$, a $(\Delta+1)$ coloring can be computed in $O(\log^* \Delta)$ rounds, for all subgraphs simultaneously.*

Handling Non-Equal Palette Size for $\Delta = O(\sqrt{n})$. The CLP algorithm assumes that each vertex is given a list of *exactly* $(\Delta+1)$ colors. Our coloring algorithms requires a more relaxed setting where each vertex v is allowed to be given a list of $r_v \in [\Delta - \Delta^{3/5}, \Delta+1]$ colors where $r_v \geq \deg(v,G)+1$. In this subsection we show:

▶ **Lemma 6.** *Given a graph G with $\Delta = O(\sqrt{n})$, if every vertex v has a palette with $r_v \geq \deg(v,G)+1$ colors and $r_v \in [\Delta - \Delta^{3/5}, \Delta+1]$ then a list coloring can be computed in $O(\log^* \Delta)$ rounds in the congested clique model.*

The key modification for handling non-equal palette sizes is in definition of ϵ-friend (which affects the entire decomposition of the graph). Throughout, let $q = \Delta^{3/5}$ and say[6] that u, v are (ϵ, q)-friends if $|N(u) \cap N(v)| \geq (1-\epsilon)\cdot(\Delta - q)$. Clearly, if u, v are ϵ-friends, they are also (ϵ, q)-friends. A vertex v is an (ϵ, q)-*dense* if it has at least $(1-\epsilon)\cdot(\Delta - q)$ neighbors which are (ϵ, q)-friends. An (ϵ, q)-almost clique is a connected component of the subgraph induced by (ϵ, q)-dense vertices and their (ϵ, q) friends edges. We next observe that for the ϵ-values used in the CLP algorithm, the converse is also true up to some constant. The full proof of Theorem 6 is in the full version.

▶ **Observation 7.** *For any $\epsilon \in [\Delta^{-10}, K^{-1}]$, where K is a large constant, and for $q = \Delta^{3/5}$, it holds that if u, v are (ϵ, q) friends, they are (2ϵ)-friends. Also, if v is an (ϵ, q)-dense, then it is 2ϵ-dense.*

3 $(\Delta+1)$-Coloring for $\Delta = \Omega(\sqrt{n})$

In this section, we describe a new recursive degree-reduction technique. As a warm-up, we start with $\Delta = O((n/\log n)^{3/4})$. We make use of the following fact.

▶ **Theorem 8** (Simple Corollary of Chernoff Bound). *Suppose $X_1, X_2, \ldots, X_\ell \in [0,1]$ are independent random variables, and let $X = \sum_{i=1}^{\ell} X_i$ and $\mu = \mathbb{E}[X]$. If $\mu \geq 5\log n$, then w.h.p. $X \in \mu \pm \sqrt{5\mu \log n}$, and if $\mu < 5\log n$, then w.h.p. $X \leq \mu + 5\log n$.*

[6] The value of q is chosen to be a bit above the standard deviation of $\sqrt{\Delta \log n}$ that will occur in our algorithm.

3.1 An $O(\log^* \Delta)$-round algorithm for $\Delta = O((n/\log n)^{3/4})$

The algorithm partitions G into $O(\Delta^{1/3})$ subgraphs as follows. Let $\ell = \lceil \Delta^{1/3} \rceil$. We define $\ell + 1$ subsets of vertices $V_1, \ldots, V_\ell, V^*$. A vertex joins each V_i with probability

$$p_i = 1/\ell - 2\sqrt{5 \log n}/(\Delta^{1/3} \cdot \ell),$$

for every $i \in \{1, \ldots, \ell\}$, and it joins V^* with the remaining probability of $p^* = 2\sqrt{5 \log n}/\Delta^{1/3}$.

Let $G_i = G[V_i]$ be the induced subgraph for every $i \in \{1, \ldots, \ell, *\}$. Using Chernoff bound of Theorem 8, the maximum degree Δ' in each subgraph G_i, $i \in \{1, \ldots, \ell\}$ is w.h.p.:

$$\Delta' \leq \Delta/\ell - 2\Delta^{2/3}\sqrt{5 \log n}/\ell + \sqrt{5\Delta \log n/\ell} \leq \Delta/\ell - 1$$

In the first phase, all subgraphs $G_1, \ldots, G_\ell$ are colored independently and simultaneously. This is done by allocating a distinct set of $(\Delta' + 1)$ colors for each of these subgraphs. Overall, we allocate $\ell \cdot (\Delta' + 1) \leq \Delta$ colors. Since $\Delta' = O(\Delta^{2/3}) = O(\sqrt{n})$, we can apply the $(\Delta' + 1)$-coloring algorithm of Theorem 5 on all the graphs $G_1, \ldots, G_\ell$ simultaneously. Hence, all the subgraphs $G_1, \ldots, G_\ell$ are colored in $O(\log^* \Delta)$ rounds.

Coloring the remaining left-over subgraph G^*. The second phase of the algorithm completes the coloring for the graph G^*. This coloring should agree with the colors computed for $G \setminus G^*$ computed in the previous phase. Hence, we need to color G^* using a *list* coloring algorithm. We first show that w.h.p. the maximum degree Δ^* in G^* is $O(\sqrt{n})$. The probability of vertex to be in G^* is $p^* = 2\sqrt{5 \log n}/\Delta^{1/3}$. By Chernoff bound of 8, w.h.p., $\Delta^* \leq p^* \cdot \Delta + \sqrt{5p^* \cdot \Delta \cdot \log n}$. Since $\Delta \leq (n/\log n)^{3/4}$, $\Delta^* = O(\sqrt{n})$. To be able to apply the modified CLP of Theorem 6, we show:

▶ **Lemma 9.** *Every $v \in G^*$ has at least $\Delta^* - (\Delta^*)^{3/5}$ available colors in its palette after coloring all its neighbors in $G \setminus G^*$.*

Proof. First, consider the case where $\deg(v, G) \leq \Delta - (\Delta^* - \sqrt{5\Delta^* \cdot \log n})$. In such case, even after coloring all neighbors of v, it still has an access of $\Delta^* - \sqrt{5\Delta^* \cdot \log n} \geq \Delta^* - (\Delta^*)^{3/5}$ colors in its palette after coloring $G \setminus G^*$ in the first phase. Now, consider a vertex v with $\deg(v, G) \geq \Delta - (\Delta^* - \sqrt{5\Delta^* \cdot \log n})$. Using Chernoff bound, w.h.p., $\deg(v, G^*) > (\Delta - (\Delta^* - \sqrt{\Delta^* \cdot 5 \log n})) \cdot p^* - \sqrt{5 \log n \Delta p^*} \geq \Delta^* - (\Delta^*)^{3/5}$. ◀

Also note that a vertex $v \in G^*$ has at least $\deg(v, G^*) + 1$ available colors, since all its neighbors in G^* are uncolored at the beginning of the second phase and initially it was given $(\Delta + 1)$ colors. Eventhough, $v \in G^*$ might have $\Omega(\Delta)$ neighbors not in G^*, to complete the coloring of G^*, by Theorem 9, after the first phase, each v can find in its palette $r \in [\Delta^* - (\Delta^*)^{3/5}, \Delta^* + 1]$ available colors and this sub-palette is sufficient for its coloring in G^*. Since $\Delta^* = O(\sqrt{n})$, to color G^* (using these small palettes), one can apply the $O(\log^* \Delta)$ round list-coloring algorithm of Theorem 6.

3.2 An $O(\log(1/\epsilon) \cdot \log^* \Delta)$-round algorithm for $\Delta = O((n/\log n)^{1-\epsilon})$

Let $N = n/(5 \log n)$. First assume that $\Delta \leq N/2$ and partitions the range of relevant degrees $[\sqrt{n}, N/2]$ into $\ell = \Theta(\log \log \Delta)$ classes. The y^{th} range contains all degrees in $[N^{1-1/2^y}, N^{1-1/(2^{y+1})}]$ for every $y \in \{1, \ldots, \ell\}$. Given a graph G with maximum degree $\Delta = O(N^{1-1/(2^{y+1})})$, Algorithm RecursiveColoring colors G in $y \cdot O(\log^* \Delta)$ rounds, w.h.p.

Step (I): Partitioning (Defective-Coloring). For $i \in \{0, \ldots, y-1\}$, in every level i of the recursion, we are given a graph G', with maximum degree $\Delta_i = O(N^{1-1/2^{y-i+1}})$, and a palette Pal_i of $(\Delta_i + 1)$ colors. For $i = 0$, $\Delta_0 = \Delta$ and the palette $\mathsf{Pal}_0 = \{1, \ldots, \Delta + 1\}$.

The algorithm partitions the vertices of G' into $q_i + 1$ subsets: $V'_1, \ldots, V'_{q_i}$ and a special left-over set V^*. The partitioning is based on the following parameters. Set $x = 2^{y-i}$ and

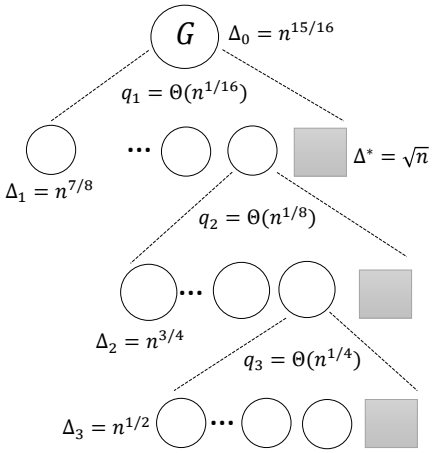
$$q_i = \lceil \Delta_i^{1/(2x-1)} \rceil \quad \text{and} \quad \delta_i = 2\sqrt{5 \log n} \cdot q_i^{3/2} / \sqrt{\Delta_i}.$$

Each vertex $v \in V(G')$ joins V'_j with probability $p_j = 1/q_i - \delta_i/(q_i)^2$ for every $j \in \{1, \ldots, q_i\}$, and it joins V^* with probability $p^* = \delta_i/q_i$. Note that $p^* \in (0, 1)$ as $x \geq 2$. For every $j \in \{1, \ldots, q_i\}$, let $G'_j = G'[V'_j]$ and let $G^* = G'[V^*]$.

Step (II): Recursive coloring of $G'_1, \ldots, G'_{q_i}$. Denote by $\widetilde{\Delta}_j$ to be the maximum degree in G'_j for every $j \in \{1, \ldots, q_i\}$ and by Δ^*, the maximum degree in G^*. The algorithm allocates a distinct subset of $(\widetilde{\Delta}_j + 1)$ colors from Pal_i for every $j \in \{1, \ldots, q_i\}$. In the analysis, we show that w.h.p. Pal_i contains sufficiently many colors for that allocation. The subgraphs $G'_1, \ldots, G'_{q_i}$ are colored recursively and simultaneously, each using its own palette. It is easy to see that the maximum degree of each G'_j is $O(N^{1-1/2^{y-i}})$ (which is indeed the desire degree for the subgraphs colored in level $i+1$ of the recursion).

Step (III): Coloring the left-over graph G^*. Since the algorithm already allocated at most Δ_i colors for coloring the G'_j subgraphs, it might run out of colors to allocate for G^*. This last subgraph is colored using a list-coloring algorithm only after all vertices of $G'_1, \ldots, G'_{q_i}$ are colored. Recall that Δ^* is the maximum degree of G^*. In the analysis, we show that w.h.p. $\Delta^* = O(\sqrt{n})$. For every $v \in G^*$, let $\mathsf{Pal}(v) \subseteq \mathsf{Pal}_i$ be the remaining set of available colors after coloring all the vertices in $V'_1, \ldots, V'_{q_i}$. Each vertex $v \in G^*$ computes a new palette $\mathsf{Pal}^*(v) \subseteq \mathsf{Pal}(v)$ such that: (i) $|\mathsf{Pal}^*(v)| \geq \deg(v, G^*) + 1$, and (ii) $|\mathsf{Pal}^*(v)| \in [\Delta^* - \Delta^{3/5}, \Delta^* + 1]$. In the analysis section, we show that w.h.p. this is indeed possible for every $v \in G^*$. The algorithm then applies the modified CLP algorithm, and G^* gets colored within $O(\log^* \Delta)$ rounds.

Example:



Assume that input graph G has maximum degree $\Delta_0 = n^{15/16}$. The algorithm partitions G into $k_0 = n^{1/15}$ subgraphs in the following manner. For sake of clarity, we omit logarithmic

factors in the explanation. With probability $1/(\Delta_0)^{1/2+o(1)}$, v joins a left-over subgraph G^*, and with the remaining probability it picks a subgraph $[1, k_0]$ uniformly at random. It is easy to see that the maximum degree in each of these subgraphs is at most $\Delta_1 = n^{7/8} + n^{7/16}$. A distinct set of Δ_1 colors from $[1, \Delta_0 + 1]$ is allocated to each of the k subgraphs. Each such subgraph is now partitioned into $k_1 = n^{1/8}$ subgraphs plus a left-over subgraph. This continues until all subgraphs have their degrees sharply concentrated around $\sqrt{n}$. At that point, the modified CLP algorithm can be applied on all the subgraphs in the last level ℓ. Once these subgraphs are colored, the left-over subgraphs in level $\ell - 1$ are colored, this continues until the final left-over subgraph of the first level is colored. We next provide a compact and high level description of the algorithm.

Algorithm 1 RecursiveColoring(G', Pal_i)

Input: Graph G' with maximum degree $\Delta_i = O(N^{1-1/2^{y-i+1}})$.
A palette Pal_i of $(\Delta_i + 1)$ colors (same for all nodes).

- Partitions G' into $q_i + 1$ vertex-disjoint subgraphs:
  - q_i vertex-subgraphs $G'_1, \ldots, G'_{q_i}$ with maximum degree $\Delta_{i+1} = O(N^{1-1/2^{y-i}})$.
  - Left-over subgraph G^* with maximum degree $\Delta^* = O(\sqrt{n})$.
- Allocate a distinct palette $\mathsf{Pal}_j \subset \mathsf{Pal}_i$ of $(\Delta_{i+1} + 1)$ colors for each $j \leq q_i$.
- Apply RecursiveColoring(G_j, Pal_j) for every $j \leq q_i$ simultaneously.
- Apply a $(\Delta_i + 1)$-list coloring restricted to Pal_i, to complete the coloring of $G[V^*]$.

Analysis.

▶ **Lemma 10.** *(i) For every $j \in \{1, \ldots, q_i\}$, w.h.p., $\widetilde{\Delta}_j = O(N^{1-1/2^{y-i}})$. (ii) One can allocate $(\widetilde{\Delta}_j + 1)$ distinct colors from Pal_i for each G'_j, $j \in \{1, \ldots, q_i\}$.*

Proof. Using Chernoff bound of Theorem 8, w.h.p., for every $j \in \{1, \ldots, q_i - 1\}$, the maximum degree $\widetilde{\Delta}_j$ in G'_j is at most $\widetilde{\Delta}_j = O(\Delta_i/q_i)$. Since $\Delta_i = O(N^{1-2^{y-i+1}})$, claim (i) follows. We now bound the sum of all colors allocated to these subgraphs:

$$\widetilde{\Delta}_j \leq \Delta_i/q_i - (\Delta_i \cdot \delta_i)/(q_i)^2 + \sqrt{5 \log n \cdot \Delta_i/q_i} \leq \Delta_i/q_i - 1 \ .$$

where the last inequality follows by the value of δ_i. We get that $\sum_{j=1}^{q_i}(\widetilde{\Delta}_j + 1) \leq \Delta_i$ and since Pal_i contains $\Delta_i + 1$ colors, claim (ii) follows. ◀

We next analyze the final step of the algorithm and begin by showing that, w.h.p., the maximum degree in the left-over graph G^* is $O(\sqrt{n})$. By Chernoff bound of Theorem 8, w.h.p., the maximum degree $\Delta^* \leq \Delta_i \cdot \delta_i/q_i + \sqrt{\log n \cdot \Delta_i \cdot \delta_i/q_i}$. Since $\Delta_i = O(N^{1-1/2^{y-i+1}})$, we get that $\Delta^* = O(\sqrt{n})$. We now claim:

▶ **Lemma 11.** *After coloring for all the vertices in $G'_1, \ldots, G'_{q_i}$, each vertex $v \in G^*$ has a palette $\mathsf{Pal}^*(v)$ of free colors such that (i) $|\mathsf{Pal}^*(v)| \geq \deg(u, G^*) + 1$, and (ii) $|\mathsf{Pal}^*(v)| \in [\Delta^* - (\Delta^*)^{3/5}), \Delta^* + 1]$.*

Proof. Since each vertex $v \in G'$ has a palette of size $(\Delta_i + 1) \geq \deg(v, G')$, after coloring all its neighbors in $G'_1, \ldots, G'_{q_i}$, it has at least $\deg(v, G^*) + 1$ free colors in its palette. Claim (ii) follows the same argument as in Theorem 9. We show that the palette of v has at least $\Delta^* - O(\sqrt{\Delta^* \cdot 5 \log n}) \geq (\Delta^* - (\Delta^*)^{3/5})$ available colors after coloring all the vertices in

$G \setminus G^*$. First, when $\deg(v, G') \leq \Delta_i - (\Delta^* - \sqrt{\Delta^* \cdot 5 \log n})$, then even after coloring all neighbors of v in G', it still has an access of $\Delta^* - \sqrt{\Delta^* \cdot 5 \log n}$ colors in its palette. Consider a vertex v with $\deg(v, G') \geq \Delta_i - (\Delta^* - \sqrt{\Delta^* \cdot 5 \log n})$. By Chernoff, w.h.p. it holds that:

$$\begin{aligned} \deg(v, G^*) &\geq (\Delta_i - (\Delta^* - \sqrt{\Delta^* \cdot 5 \log n})) \cdot p^* - \sqrt{5 \log n \cdot \Delta_i \cdot p^*} \\ &\geq \Delta_i \cdot \delta_i / q_i - O(\sqrt{\Delta_i \cdot \delta_i \log n / q_i}) \geq \Delta^* - (\Delta^*)^{3/5} \ . \end{aligned}$$

Hence, by combining with claim (i), the lemma follows. ◀

This completes the proof of Theorem 2(i).

$(\Delta + \Delta^{1/2+\epsilon})$ Coloring in Log-Star Rounds

▶ **Lemma 12.** *For any fixed $\epsilon \in (0, 1)$, one can color, w.h.p., a graph with $(\Delta + \Delta^{1/2+\epsilon})$ colors in $O(\log(1/\epsilon) \cdot \log^* \Delta)$ rounds.*

Proof. Due to Theorem 4, it is sufficient to consider the case where $\Delta = \Omega(\sqrt{n})$. Partition the graph into $k = \lfloor \Delta^\epsilon \rfloor$ subgraphs $G_1, \ldots, G_k$, by letting each vertex independently pick a subgraph uniformly at random. By Chernoff bound of Theorem 8, the maximum degree Δ_i in each subgraph G_i is at most $\Delta_i \leq \Delta^{1-\epsilon} + \Delta^{1/2-\epsilon/2} \cdot \sqrt{5 \log n}$. Allocate a distinct set of $\Delta_i + 1$ colors Pal_i to each subgraph G_i. Since $\Delta^{1-\epsilon} = O((n/\log n)^{1-\epsilon/2})$, we can apply Alg. RecursiveColoring on each of these subgraphs which takes $O(\log(1/\epsilon) \cdot \log^* \Delta)$ rounds. It is easy to see, that since the subgraphs are vertex disjoint, Alg. RecursiveColoring can be applied on all k subgraphs simultaneously with the same round complexity. Overall, the algorithm uses $\Delta + \Delta^{1/2+\epsilon}$ colors. ◀

3.3 $(\Delta + 1)$ Coloring Algorithm for General Graphs

For graphs G with $\Delta \leq n/(10 \log n)$, we simply apply Alg. RecursiveColoring. Plugging $\epsilon = 1/\log n$ in Theorem 2, we get that this is done in $O(\log \log \Delta \cdot \log^* \Delta)$ rounds. It remains to handle graphs with with $\Delta \in [n/(10 \log n), n]$. We partition the graph into $\ell = \lceil 5 \log n \rceil$ subgraphs $G_1, G_2, \ldots, G_\ell$ and a left-over graph G^* in the following manner. Each $v \in V$ joins G_i with probability $p = 1/\ell - 2\sqrt{5 \log n/(\Delta \cdot \ell)}$ for every $i \in \{1, \ldots, \ell\}$, and it joins G^* with probability $p^* = 1 - \ell \cdot p = \Theta(\log n/\sqrt{\Delta})$. By Chernoff bound, the maximum degree in G_i for $i \in \{1, 2, \ldots, \ell\}$ is $\Delta_i \leq \Delta/\ell - 2\sqrt{(\Delta \cdot 5 \log n)/\ell} + \sqrt{\Delta \cdot 5 \log n/\ell} \leq \Delta/\ell - 1$. Hence, we have the budget to allocate a distinct set Pal_i of Δ_i colors for each G_i.

The first phase applies Algorithm RecursiveColoring on each (G_i, Pal_i) simultaneously for every i. Since $\Delta_i = O(n/\log n)$, and the subgraphs are vertex-disjoint, this can be done in $O(\log \log \Delta \cdot \log^* \Delta)$ rounds for all subgraphs simultaneously (see Theorem 2(i)).

After all the vertices of $G \setminus G^*$ get colored, the second phase colors the left-over subgraph G^*. The probability of a vertex v to be in G^* is $O(\log n/\sqrt{\Delta}) = O(\log^2 n/\sqrt{n})$. Hence, G^* contains $O(\log^2 n \cdot \sqrt{n})$ vertices with high probability. We color G^* in two steps. First, we use the deg $+1$ list coloring Algorithm OneShotColoring from [2] to reduce the uncolored-degree of each vertex to be $O(\sqrt{n}/\log^2 n)$ with high probability. This can be done in $O(\log \log n)$ rounds. In the second step, the entire uncolored subgraph $G'' \subset G^*$ has $O(n)$ edges and can be solved locally in $O(1)$ rounds. Note that for each $v \in G''$, it is sufficient to consider a palette with $\deg(v, G'') + 1$ colors, and hence sending all these palettes can be done in $O(1)$ rounds as well. The complete proof of Theorem 1 is in the full-version.

Algorithm 2 FastColoring(G)

- If $\Delta \leq n/(10\log n)$, call RecursiveColoring$(G, [1, \Delta+1])$.
- Else, partition G into vertex-subgraphs as follows:
  - $G'_1, \ldots, G'_q$ with the maximum degree $\Theta(\Delta/\log n)$, and
  - a left-over subgraph G^* with maximum degree $\Delta^* = O(\sqrt{n})$.
- Allocate a distinct palette $\mathsf{Pal}_j \subset [1, \Delta+1]$ of $(\Delta(G_j)+1)$ colors for each $j \leq q_i$.
- Apply RecursiveColoring(G_j, Pal_j) for all $G_1, \ldots, G_q$ simultaneously.
- Apply a (deg +1)-list coloring algorithm on G^* for $O(\log\log n)$ rounds.
- Solve the remaining uncolored subgraph locally.

4 Deterministic Coloring Algorithms

In this section, we provide deterministic coloring algorithms using the tools of bounded inpdendent and conditional expectation introduced in [5].

▶ **Theorem 13.** *There is a deterministic $(\Delta+1)$ list coloring using $O(\log\Delta)$ rounds, in the congested clique model.*

In [5], a deterministic $(\Delta+1)$ coloring was presented only for graphs with maximum degree $\Delta = O(n^{1/3})$. Here, we handle the case of $\Delta = \Omega(n^{1/3})$. We derandomize the following simple $(\Delta+1)$-algorithm that runs in $O(\log n)$ rounds.

Algorithm 3 Round $\boldsymbol{i}$ of Algorithm **SimpleRandColor** (for node $\boldsymbol{v}$ with palette $\mathbf{Pal}_{\boldsymbol{v}}$)

- Let F_v be the set of colors taken by the colored neighbors of v.
- Pick a color c_v uniformly at random from $\mathsf{Pal}_v \setminus F_v$.
- Send colors to neighbors and if $c_v \neq 0$ and legal, halt.

▶ **Observation 14.** *The correctness of Algorithm* SimpleRandColor *is preserved, even if the coin flips are* pairwise-*independent.*

The goal of *phase* i in our algorithm is to compute a seed that would be used to simulate the random color choices of *round* i of Alg. SimpleRandColor. This seed will be shown to be good enough so that at least $1/4$ of the currently uncolored vertices, get colored when picking their color using that seed. Let V_i be the set of uncolored vertices at the beginning of phase i. We need the following construction of bounded independent hash functions:

▶ **Lemma 15.** *[25] For every $\gamma, \beta, d \in \mathbb{N}$, there is a family of d-wise independent functions $\mathcal{H}_{\gamma,\beta} = \left\{h : \{0,1\}^\gamma \to \{0,1\}^\beta\right\}$ such that choosing a random function from $\mathcal{H}_{\gamma,\beta}$ takes $d \cdot \max\{\gamma, \beta\}$ random bits, and evaluating a function from $\mathcal{H}_{\gamma,\beta}$ takes time poly(γ, β, d).*

For our purposes, we use Theorem 15 with $d = 2, \gamma = \log n, \beta = \log\Delta$ and hence the size of the random seed is $\alpha \cdot \log n$ bits for some constant α. Instead of revealing the seed bit by bit using the conditional expectation method, we reveal the assignment for a *chunk* of $z = \lfloor \log n \rfloor$ variables at a time. To do so, consider the i'th chunk of the seed $Y'_i = (y'_1, \ldots, y'_z)$. For each of the n possible assignments $(b'_1, \ldots, b'_z) \in \{0,1\}^z$ to the z variables in Y', we assign a leader u that represent that assignment and receives the conditional expectation values from

all the uncolored nodes V_i, where the conditional expectation is computed based on assigning $y'_1 = b'_1, \ldots, y'_z = b'_z$. Unlike the MIS problem, here the vertex's success depends only on its neighbors (i.e., and does not depend on its second neighborhood). Using the partial seed and the IDs of its neighbors, every vertex v can compute the probability that it gets colored based on the partial seed. It then sends its probability of being colored using a particular assignment $y'_1 = b'_1, \ldots, y'_z = b'_z$ to the leader u responsible for that assignment. The leader node u of each assignment $y'_1 = b'_1, \ldots, y'_z = b'_z$ sums up all the values and obtains the expected number of colored nodes conditioned on the assignment. Finally, all nodes send to the leader their computed sum and the leader selects the assignment $(b^*_1, \ldots, b^*_z) \in \{0,1\}^z$ of largest value. After $O(1)$ many rounds, the entire assignment of the $O(\log n)$ bits of the seed are revealed. Every yet uncolored vertex $v \in V_i$ uses this seed to simulate the random choice of Alg. SimpleRandColor, that is selecting a color in $\{0, 1, 2, \ldots, \Delta + 1\} \setminus F_v$ and broadcasts its decision to its neighbors. If the color $c_v \neq 0$ is legal, v is finally colored and it notifies its neighbors. By the correctness of the conditional expectation approach, we have that least $1/4 \cdot |V_i|$ vertices got colored. Hence, after $O(\log n) = O(\log \Delta)$ rounds, all vertices are colored. In the full version, we also show a deterministic $O(\Delta^2)$ coloring in $O(1)$ rounds.

Abstract

We consider *oblivious* two-party protocols where a *client* outsources N blocks of private data to a *server*. The client wishes to access the data to perform operations in such a way that the access pattern does not leak information about the data and the operations. In this context, we consider *oblivious shuffling* with a focus on bandwidth efficient protocols for clients with small local memory. In the shuffling problem, the N outsourced blocks, $B_1, \ldots, B_N$, are stored on the server according to an initial permutation π. The client wishes to reshuffle the blocks according to permutation σ. Oblivious shuffling is a building block in several applications that hide patterns of data access. In this paper, we introduce a generalization of the oblivious shuffling problem, the K-*oblivious shuffling* problem, and provide bandwidth efficient algorithms for a wide range of client storage requirements. The task of a K-oblivious shuffling algorithm is to shuffle N encrypted blocks that were previously randomly allocated on the server in such a way that an adversarial server learns nothing about either the new allocation of blocks or the block contents. The security guarantee must hold when an adversary has partial information on the initial placement of a subset of $K \leq N$ *revealed* blocks. The notion of oblivious shuffling is obtained for $K = N$.

We first study the N-oblivious shuffling problem and start by presenting CacheShuffleRoot, that is tailored for clients with $O(\sqrt{N})$ blocks of memory and uses approximately $4N$ blocks of bandwidth. CacheShuffleRoot is a 4x improvement over the previous best known N-oblivious shuffle for practical sizes of N. We then generalize CacheShuffleRoot to CacheShuffle that can be instantiated for any client memory size S and requires $O(N \log_S N)$ blocks of bandwidth. Next, we present K-oblivious shuffling algorithms that require $2N + f(K, S)$ blocks of bandwidth for all K and a wide range of S. Any extra bandwidth above the $2N$ lower bound depends solely on K and S. Specifically, for clients with $O(K)$ blocks of memory, we present KCacheShuffleBasic that uses exactly $2N$ blocks of bandwidth. For clients with memory $S \leq K$, we present KCacheShuffle, that requires $2N + O(K \log_S K)$ blocks of bandwidth. Finally, motivated by applications to ORAMs, we consider the case where the server stores D dummy blocks whose contents are irrelevant in addition to the N real blocks. For this case, we design algorithm KCacheShuffleDummy that shuffles $N + D$ blocks with K revealed blocks using $O(K)$ blocks of client storage and approximately $D + 2N$ blocks of bandwidth.

1 Introduction

In recent years, cloud storage has increased in popularity due to the great benefits available to users. Outsourcing files to the cloud allows users to share documents conveniently. Users are able to access documents from many different machines without transferring data. The burden of data replication for recovery is placed on the storage provider. For many corporations, cloud storage is cost efficient compared to maintaining their own internal storage systems. With the widespread use of cloud storage, providing privacy for outsourced data becomes crucial. Unfortunately, encrypting outsourced data is not sufficient. Previous works [8, 9] show that learning the patterns of data access may leak information about the contents of encrypted data. This scenario provides motivation towards the study of *oblivious algorithms*.

In this paper, we focus on oblivious algorithms for *shuffling* data stored on a server. The ability to obliviously move blocks of encrypted data is an important primitive for privacy-conscious users of cloud storage. We consider the scenario where a client has outsourced the encryptions of N identically-sized blocks, $B_1, \ldots, B_N$, to a server. The N blocks are stored by the server on an array Source according to a permutation π. That is, an encryption of B_i is stored as $\mathsf{Source}[\pi(i)]$, for all $i = 1, \ldots, N$. The client wishes to shuffle the blocks into a server-stored destination array, Dest, according to a permutation σ.

An *oblivious shuffle* is an algorithm whose pattern of block movement and operations involving the server does not leak information about either σ or the contents of $B_1, \ldots, B_N$. If the client has N blocks of client memory available, oblivious shuffling is trivial. All N blocks are downloaded, decrypted, re-encrypted and re-uploaded to their correct location in Dest according to σ. Similarly, if bandwidth is unlimited, then oblivious shuffling is also trivial. The client streams all N blocks and keeps block $B_{\sigma^{-1}(1)}$ to be be placed into $\mathsf{Dest}[1]$ after all blocks have been streamed. The client repeats this algorithm for all $i = 2, \ldots, N$, which costs N^2 blocks of bandwidth. Our work focuses on oblivious shuffles that minimize bandwidth while the client has only a sublinear number of blocks of memory available.

Our Contributions. Our contribution is two-fold. We propose an obliviousness notion that abstracts the initial knowledge of π given to the adversarial server. Then, we present bandwidth efficient oblivious shuffles for any possible initial knowledge of π by the adversary and a wide range of client memory requirements.

Our work generalizes the notion of obliviousness studied in previous work by presenting the notion of *K-oblivious shuffling* that takes into account the knowledge of the adversary on the initial positioning of the blocks (that is, π). In the K-oblivious shuffling problem, the adversary fixes the position of $K \leq N$ blocks, which we denote as the *revealed* blocks. The client wishes to shuffle the N blocks into the server-stored destination array, Dest, without revealing information about σ or the contents of $B_1, \ldots, B_N$ to the adversarial server. The parameter K describes the difficulty of the problem. Intuitively, as K decreases, K-obliviously shuffling should be more efficient. In our work, we present algorithms whose bandwidth above inherent lower bounds depend only on K. For $K = N$, the notion of K-oblivious shuffling coincides with the original notion of a oblivious shuffling by Ohrimenko *et al.* [10], which assumes that the adversary has initial knowledge about all N input blocks.

The notion of K-oblivious shuffling is suitable in the context of Oblivious RAMs. Oblivious RAM (or ORAM) is a storage primitive introduced by Goldreich [4] that allows random

access to N encrypted blocks that are stored by an adversarial server. Many ORAMs use oblivious shuffling as a building block to move blocks without revealing information about the final positions of blocks as well as the contents of the blocks. In the majority of ORAM constructions, the adversary does not learn the position of all blocks that are going to be shuffled. By incorporating the initial amount of knowledge available to the adversary about the N input blocks, we can improve the bandwidth efficiency of ORAM constructions such as the Square Root ORAM [4, 5].

Before designing efficient K-oblivious shuffling algorithms, we revisit the original oblivious shuffling (that is, N-oblivious shuffling) problem and present new oblivious shuffling algorithms with improved bandwidth efficiency. Our algorithms use a client-stored *cache* to store blocks. The main technical difficulty in our algorithms is showing that the size of the cache remains small. We first apply this design principle in Section 3 by presenting an oblivious shuffling algorithm, CacheShuffleRoot, that uses approximately $4N$ blocks of bandwidth and $O(\sqrt{N})$ block of client storage. For similar client memory usage, the previous, state-of-the-art algorithm, the Melbourne Shuffle [10], uses about 4 times more bandwidth. We present a generalization of CacheShuffleRoot, $\mathsf{CacheShuffle}_S$, in Section 4 when the client has $S = \omega(\log N)$ blocks of available client storage. $\mathsf{CacheShuffle}_S$ uses $O(N \log_S N)$ blocks of bandwidth.

Next, we focus on designing K-oblivious shuffling algorithms when $K < N$. All previous oblivious shuffling algorithms have always considered the most difficult scenario when $K = N$. To our knowledge, our work is the first to separate the two problems. In Section 5, we present a simple K-oblivious shuffling algorithm, KCacheShuffleBasic, when the client has $O(K)$ blocks of available client storage. KCacheShuffleBasic uses exactly $2N$ blocks of bandwidth. In Section 6, we present $\mathsf{KCacheShuffle}_S$ for clients with only $O(S)$ blocks of client storage available. KCacheShuffle uses $2N + O(K \log_S K)$ blocks of bandwidth. For the case of $S = \sqrt{K}$, we present KCacheShuffleRoot, which uses approximately $2N + 4K$ blocks of bandwidth. In general, any K-oblivious shuffling algorithm must upload and download each block at least once meaning a lower bound of $2N$ blocks of bandwidth when $K > 0$. The amount of bandwidth used by all our K-oblivious shuffling algorithms beyond the lower bound only depends on K.

In many ORAM schemes, encryptions of dummy blocks are also outsourced to the server. The contents of a dummy block is irrelevant. However, it is important that an adversarial server cannot learn whether a block is dummy or not. In the full version [11], we consider a scenario where the client has outsourced the encryptions of D *dummy* blocks and N *real* blocks inspired by the work of Stefanov *et al.* [12]. Any K-oblivious shuffling algorithm could be used to perform shuffling by treating dummy blocks as real blocks. By using the fact that the contents of dummy blocks are irrelevant, we present KCacheShuffleDummy that uses approximately $D + 2N$ blocks of bandwidth when the client has $O(K)$ blocks of available client storage. Applying directly KCacheShuffleBasic would require $2(N + D)$ blocks of bandwidth. Therefore, KCacheShuffleDummy saves D blocks of bandwidth. The bandwidth savings come at the cost of a small amount of server computation.

We complement our theoretical analysis with experiments to show that our algorithms are of practical interest in the full version.

Previous works. The early approach to oblivious shuffling was based on oblivious sorting algorithms which could be immediately derived from any sorting circuit. To evaluate a compare-exchange gate of a sorting circuit, the client downloads the two input encrypted blocks, decrypts and re-encrypts both blocks and uploads them in the correct order. Batcher's

sort [2] is considered the most practical sorting circuit even though it has asymptotic cost of $O(N \log^2 N)$. Sorting networks such as AKS [1] and Zig-Zag [7] have $O(N \log N)$ size but large hidden constants. Randomized Shellsort [6] is another $O(N \log N)$ oblivious sort with smaller hidden constants but larger depth. Waksman [13] presents a circuit for oblivious shuffling of size $O(N \log N)$. Oblivious shuffling based on sorting circuits is interesting because the client only needs to store $O(1)$ blocks at any point. However, sorting circuits incur a large $\Omega(N \log N)$ blocks of bandwidth cost. The first oblivious shuffling algorithm not based on sorting circuits, the *Melbourne Shuffle*, was introduced by Ohrimenko *et al.* [10]. The Melbourne Shuffle uses $O(N)$ bandwidth while only requiring $O(\sqrt{N})$ blocks to be stored on the client at any time.

In the table below, we compare our algorithms with the Melbourne Shuffle [10].

Table 1 N denotes the number of blocks. Algorithm KCacheShuffleDummy receives D additional dummy blocks, for a total of $N + D$ blocks. Algorithm KCacheShuffleRoot is obtained from algorithm KCacheShuffle by setting $S = \sqrt{N}$. For all algorithms, server storage is cN, for a small constant c.

		Client Storage	Bandwidth
$K = N$	Melbourne Shuffle [10]	$O(\sqrt{N})$	$\approx 18N$
	CacheShuffleRoot	$O(\sqrt{N})$	$(4+\epsilon)N$
	CacheShuffle	$O(S)$	$O(N \log_S N)$
General K	KCacheShuffleBasic	$O(K)$	$2N$
	KCacheShuffleRoot	$O(\sqrt{K})$	$2N + (4+\epsilon)K$
	KCacheShuffle	$O(S)$	$2N + O(K \log_S K)$
	KCacheShuffleDummy	$O(K)$	$D + (2+\epsilon)N$

An algorithm similar to CacheShuffleRoot was developed in parallel and independent work in [3] for the context of privacy-preserving software monitoring.

2 Definitions

In this section, we give formal definition for *shuffling algorithms* and *oblivious shuffling algorithms*. Our reference scenario is a cloud storage model where a *client* outsources the storage of N identically-sized data blocks to a *server* with the capacity to store $M \geq N$ blocks.

We assume the N data blocks are uploaded by the Setup algorithm. As input, Setup receives N data blocks, $\mathbb{B} = (B_1, \ldots, B_N)$, each of size B and a *permutation* $\pi : [N] \to [N]$. Setup randomly selects an encryption key, `key`, whose length is determined by the security parameter λ, for a symmetric encryption scheme and uploads an encryption of each of the N data blocks to the server according to π. Formally, an encryption of B_i under `key` will be stored at server location $\pi(i)$, for all $i \in [N]$. Once Setup has uploaded all N blocks, an adversary $\mathcal{A}$ is allowed to learn the initial position of a subset of the data blocks, which we denote Revealed $\subseteq [N]$. For each index $i \in$ Revealed, $\pi(i)$ is revealed to $\mathcal{A}$. We call the data blocks in Revealed, the *revealed* data blocks.

The shuffling algorithm takes as input the encryption key `key`, the permutation map π, the set of revealed data blocks Revealed, and a new permutation σ. The task of the shuffling algorithm is to re-permute the N data blocks stored on the server according to the new permutation map σ. In particular, we are interested in *oblivious shuffling* algorithms. Roughly speaking, oblivious shuffles hide information about both the contents of $B_1, \ldots, B_N$

and σ even when the adversary has partial information on π (restricted to the input set Revealed) and observes the blocks movements performed by the shuffling algorithm.

For convenience, we will abuse the notation of array indexing and function evaluation throughout our work. For any array A and index i, $A[i]$ refers to the element stored at location i in A. For a set of indices S, we define $A[S] := \{A[s] : s \in S\}$. Similarly for any function f and input set S, we define $f(S) := \{f(s) : s \in S\}$.

2.1 Mechanics of the Shuffling Algorithm

A shuffling algorithm receives as input the initial permutation π, the final permutation σ and the set Revealed. A shuffling algorithm proceeds in steps. The state after the q-th step is described by a *server allocation map* $\rho_q : [M] \to [N] \cup \{\perp\}$ and by a *client allocation map* $L_q : [S] \to [N] \cup \{\perp\}$. Each allocation map specifies the block currently occupying each of the M server locations and S client locations, respectively. More precisely, $\rho_q(j) = i$ means that, after the q-th step is performed, the j-th server location contains an encryption of the B_i. If instead $\rho_q(j) = \perp$, then an encryption of a dummy block is stored at location j. Similar statements are true for the client allocation map, L_q.

When a shuffling algorithm starts, the server allocation map ρ_0 coincides with permutation map π on the first N storage location of the M server memory locations. That is, $\rho_0(i) = \pi^{-1}(i)$ for all $i = 1, \ldots, N$. The remaining $N - M$ locations contain encryptions of dummy blocks. All S client block locations initially contain dummy blocks. That is, $L_0(i) = \perp$ for all $i = 1, \ldots, S$. During each step, a shuffling algorithm can perform either a *move* operation or a *server computation* operation. A move operation can be either a *download* or an *upload* move and they modify the state as follows. All download and upload operations are associated with a *source* and a *destination*. Suppose the q-th operation is a download with source s_q and destination d_q. Then, an encryption of block $B_{\rho_{q-1}(s_q)}$ stored at server location s_q is copied to location d_q of client storage. Before storing in client storage, the block is decrypted and re-encrypted. As a consequence, the ρ_q is identical to ρ_{q-1}. On the other hand, L_q is identical to L_{q-1} except that $L_q(d_q) = \rho_{q-1}(s_q)$. If the q-th operation was an upload with source s_q and destination d_q, then the encryption of block $B_{L_{q-1}(s_q)}$ stored at client location s_q is copied to location d_q of server storage. In this case, L_q is identical to L_{q-1}. However, S_q is obtained by modifying S_{q-1} such that $S_q(d_q) = L_{q-1}(s_q)$. Shuffle algorithms may perform upload moves with the source as $\perp$. In this case, an encryption of a dummy block is uploaded to the destination location of server storage.

A server computation operation is specified by the server performing a circuit that uses a subset of the blocks as input and copies the circuit's output to a subset of server storage locations. In our shuffling algorithms, server computation operations consist of homomorphic operations on block ciphertexts, which reduce bandwidth by using small amounts of server computation. The circuit description sent by the client must be considered as bandwidth.

2.2 Efficiency Measures

In our work, we consider three measures of efficiency for a shuffling algorithm: bandwidth, client memory and server memory. Our work focuses on minimizing bandwidth for a given amount of client memory, which is typically sublinear. While we do not prioritize optimizing server storage, all our shuffling algorithms use server storage that is linear with small constants in the number N of blocks. For shuffling algorithms with small client storage, we assume that the input permutations π and σ are space-efficient pseudorandom permutations.

Throughout this work, we consider blocks as our unit of measure. For example, if a shuffling algorithm uses T bandwidth, it means the shuffling algorithm uses T blocks of bandwidth.

2.3 Obliviousness

We define a *transcript* produced an execution of a shuffling algorithm Sh as the information seen by the adversarial server. The transcript consists of the initial encryptions of the data blocks as stored in server memory, the ordered list of the sources of all download moves, the ordered list of the destinations of all upload moves as well as the encryptions of the uploaded block and the list of circuits uploaded by the client. We stress that a transcript only contains the server locations that are involved in each move. That is, the transcript only contains the source for downloads and the destination for uploads. The transcript does not contain the involved client locations in each upload and download. The transcript models that an adversarial server $\mathcal{A}$ cannot observe information about the client's storage such as the destination of a download and the source of an upload.

Using the definition of a transcript, we now formally define an oblivious shuffling algorithm. For every sequence of N blocks $\mathbb{B} = (B_1, \ldots, B_N)$, every subset $\mathsf{Revealed}$ of revealed blocks, and every pair of permutations (π, σ), a shuffling algorithm Sh naturally induces a probability distribution $\mathcal{T}_{\mathsf{Sh}}(\mathbb{B}, \pi, \sigma, \mathsf{Revealed})$ over all possible transcripts. We capture the notion of a *K-oblivious shuffling* algorithm by the following game $\mathsf{OSGame}^{\mathcal{A}}_{\mathsf{Sh}}$ for a shuffling algorithm Sh between an adversary $\mathcal{A}$ and a challenger $\mathcal{C}$. In the formalization of our security notion, the adversary $\mathcal{A}$ receives partial information on the starting permutation map π to reflect the fact that the shuffling algorithm Sh might be part of a larger protocol whose execution leaks information about π. More precisely, $\mathcal{A}$ chooses the initial server locations of a subset of the N data blocks, $\mathsf{Revealed}$. We parametrize the security notion by the cardinality of the set $\mathsf{Revealed}$, which we denote as K. We say that an adversary $\mathcal{A}$ is *K-restricted* if it specifies the location of at most K blocks. That is, $|\mathsf{Revealed}| \leq K$. $\mathcal{C}$ fills in the remaining $N - |\mathsf{Revealed}|$ locations randomly under the constraint that each of the N blocks appears in exactly one location on the server. Then, $\mathcal{A}$ proposes two sequences of N blocks, $\mathbb{B}_0$ and $\mathbb{B}_1$, and two permutations, σ_0 and σ_1. $\mathcal{C}$ randomly picks $b \in \{0, 1\}$ and samples a transcript $\texttt{trans}$ according to $\mathcal{T}_{\mathsf{Sh}}(\mathbb{B}_b, \pi, \sigma_b, \mathsf{Revealed})$. On input $\texttt{trans}$, $\mathcal{A}$ outputs its guess b' for b. We present the formal definition below.

▶ **Definition 1.** For a shuffle algorithm Sh, we define the game $\mathsf{OSGame}^{\mathcal{A}}_{\mathsf{Sh}}(N, \lambda)$ between an adversary $\mathcal{A}$ and a challenger $\mathcal{C}$ for N data blocks and security parameter λ as follows:

1. $\mathcal{A}$ chooses a subset $\mathsf{Revealed} \subseteq [N]$, specifies $\pi(i)$ for each $i \in \mathsf{Revealed}$, and sends $(\mathsf{Revealed}, \pi(\mathsf{Revealed})$ to $\mathcal{C}$;
2. $\mathcal{A}$ chooses two pairs $(\mathbb{B}_0, \sigma_0)$ and $(\mathbb{B}_1, \sigma_1)$ and sends them to $\mathcal{C}$;
3. $\mathcal{C}$ completes the permutation π by randomly choosing the values at the point left unspecified by $\mathcal{A}$;
4. $\mathcal{C}$ randomly selects $b \leftarrow \{0, 1\}$ and sends $\mathcal{A}$ transcript $\texttt{trans}$ drawn according to $\mathcal{T}_{\mathsf{Sh}}(\mathbb{B}_b, \pi, \sigma_b, \mathsf{Revealed})$;
5. $\mathcal{A}$ on input $\texttt{trans}$ outputs b';

The game outputs 1 iff $b = b'$.

▶ **Definition 2** (K-oblivious shuffling)**.** We say that shuffling algorithm Sh is a *K-oblivious shuffling* algorithm if for all K-restricted probabilistically polynomial time adversaries $\mathcal{A}$,

and for all $N = \text{poly}(\lambda)$

$$\Pr[\mathsf{OSGame}^{\mathcal{A}}_{\mathsf{Sh}}(N, \lambda) = 1] \leq \frac{1}{2} + \text{negl}(\lambda).$$

We refer to N-oblivious shuffling algorithms as just *oblivious shuffling* algorithms.

2.4 Move-Based shuffling Algorithms

Move-based algorithms are shuffling algorithm that only perform move operations between client and server storage; that is, the server does not perform any computation on the stored encrypted blocks. To prove K-obliviousness for move-based algorithms, it suffices to show that for every random π and for every subset $\mathsf{Revealed} \subseteq [N]$ containing at most K indices, the probability distribution consisting of both the sources of downloads and the destinations of uploads are independent of σ conditioned on $\mathsf{Revealed}$ and $\pi(\mathsf{Revealed})$. More precisely, we define $\mathcal{M}_{\mathsf{Sh}}(\mathbb{B}, \pi, \sigma, \mathsf{Revealed})$ as the distribution of the move transcript $\mathtt{Mtrans}$ obtained from a transcript $\mathtt{trans}$ drawn from $\mathcal{T}_{\mathsf{Sh}}(\mathbb{B}, \pi, \sigma, \mathsf{Revealed})$ by removing the encryption of server-stored blocks and the encrypted blocks associated with upload moves. This is equivalent to considering the blocks as opaque indistinguishable balls. It is straightforward to prove that if the encryption scheme is IND-CPA and $\mathcal{T}_{\mathsf{Sh}}(\mathbb{B}, \pi, \sigma, \mathsf{Revealed})$ is independent of σ conditioned on $\mathsf{Revealed}$ and $\pi(\mathsf{Revealed})$, then Sh is a K-oblivious shuffling algorithm.

In the full version, we show that move-based K-oblivious shuffles have an inherent lower bound of $2N$ blocks of bandwidth when $K \geq 1$.

3 Oblivious Shuffling with $O(\sqrt{N})$ Client Memory

In this section, we describe $\mathsf{CacheShuffleRoot}$, which is an oblivious shuffling algorithm that uses $O(\sqrt{N})$ blocks of client storage except with negligible probability. For every $\epsilon > 0$, we describe an algorithm $\mathsf{CacheShuffleRoot}_\epsilon$ that uses $(3 + \epsilon/2)N$ blocks of server storage, $(4 + \epsilon)N$ blocks of bandwidth and $\delta_\epsilon\sqrt{N}$ blocks of client storage except with negligible probability in N. The value δ_ϵ is a constant that depends solely on ϵ and not from N. Whenever ϵ is clear from the context, we will just call the algorithm $\mathsf{CacheShuffleRoot}$.

3.1 Intuition

We start by describing a simple algorithm, which is insufficient to perform oblivious shuffling. However, the algorithm provides a general idea of our techniques.

Let us recall the inputs to oblivious shuffling. The client is provided permutations π and σ. Note that in our security model, σ is provided privately to the client and hidden from the adversarial server. On the server, N block ciphertexts are stored in the array Source. An encryption of block B_i is stored at $\mathsf{Source}[\pi(i)]$, for all $i = 1, \ldots, N$. At the termination of an oblivious shuffling, an encryption of block B_i should appear at $\mathsf{Dest}[\sigma(i)]$, for all $i = 1, \ldots, N$.

We now describe a simple, but incorrect, algorithm to provide intuition of our techniques. The N indices of Dest are randomly partitioned into $q := \sqrt{N}$ *destination buckets*, $\mathsf{destInd}_1, \ldots, \mathsf{destInd}_q$. Each $i \in [N]$ is assigned to a uniformly and independently chosen destination bucket. The indices of Source are partitioned into $s := \sqrt{N}$ *source groups*, $\mathsf{srcInd}_1, \ldots, \mathsf{srcInd}_s$, of exactly $N/s = \sqrt{N}$ blocks. The j-th source group consists of blocks located in $\mathsf{Source}[(j-1)N/s + 1, \ldots, j \cdot N/s]$, for all $j = 1, \ldots, s$. Finally, there will be q temporary server-stored arrays, $\mathsf{temp}_1, \ldots, \mathsf{temp}_q$, each of size s and initially empty.

On average, each destination bucket will contain $N/q = \sqrt{N}$ indices. Furthermore, each destination bucket will receive one block from each of the s source groups according to σ

in expectation. For now, let us suppose that each destination bucket receives exactly one block from each of the s source groups. In this case, we show that oblivious shuffling can be easily performed. Our algorithm would process each of the s source groups one at a time. When processing srcInd_j, the algorithm downloads all $\sqrt{N}$ blocks of $\mathsf{Source}[\mathsf{srcInd}_j]$. Then, exactly one block is uploaded to each of $\mathsf{temp}_1, \ldots, \mathsf{temp}_q$ from srcInd_j. In particular, the block to temp_k is the only block from srcInd_j that will be placed to $\mathsf{Dest}[\mathsf{destInd}_k]$ according to σ. After all s source groups have been processed, each temp_k contains all the blocks that are to be placed in a location of $\mathsf{Dest}[\mathsf{destInd}_k]$ but in the incorrect order. The algorithm performs another q phases to process each of $\mathsf{temp}_1, \ldots, \mathsf{temp}_q$. When processing temp_k, all s blocks of temp_k are downloaded and re-uploaded to their correct locations in $\mathsf{Dest}[\mathsf{destInd}_k]$ in any arbitrary order (such as as increasing order of $\mathsf{destInd}_k$).

This algorithm is easily seen to be oblivious but, unfortunately, it is unlikely that each destination bucket receives exactly the expected number blocks from each group. We thus present algorithm CacheShuffleRoot, which modifies the above algorithm to handle variances in expectation. CacheShuffleRoot does not expect each source group to contain exactly one block that should be uploaded to each destination bucket. Any time more than one block from a source group should be uploaded to a destination bucket, the extra blocks will be stored in a cache in the client's private storage. To ensure that the client's cache does not grow too large, we slightly increase the number of destination buckets from $\sqrt{N}$ to $(1 + \epsilon/2)\sqrt{N}$, for any constant $\epsilon > 0$. Let us now proceed more formally.

3.2 CacheShuffleRoot Description

For any constant $\epsilon > 0$, we describe algorithm CacheShuffleRoot. As input, the client receives permutations π and σ. On the server, the N blocks are stored in the *source array* Source according to π. That is, a ciphertext of block B_i appears in $\mathsf{Source}[\pi(i)]$, for all $i = 1, \ldots, N$. CacheShuffleRoot will output a server-stored *destination array*, Dest, such that an encryption of block B_i is stored as $\mathsf{Dest}[\sigma(l)]$, for all $l = i, \ldots, N$.

CacheShuffleRoot proceeds by partitioning the indices of Source into $s := \sqrt{N}$ *source groups* $\mathsf{srcInd}_1, \ldots, \mathsf{srcInd}_s$. For all $j = 1, \ldots, s$, srcInd_j consists of blocks stored at locations $\mathsf{Source}[(j-1)s + 1, \ldots, js]$. The N indices of the destination array Dest are randomly partitioned into $q := (1 + \epsilon/2)\sqrt{N}$ *destination buckets*, $\mathsf{destInd}_1, \ldots, \mathsf{destInd}_q$. Formally, index $i \in [N]$ is assigned to uniformly and independently chosen destination bucket. CacheShuffleRoot also initializes q server-stored *temporary arrays*, $\mathsf{temp}_1, \ldots, \mathsf{temp}_q$ and q client-stored *caches*, $\mathsf{Q}_1, \ldots, Q_q$. Each temporary array initially contains s empty block locations and each cache is initially empty.

CacheShuffleRoot consists of two phases: Spray and Recalibrate. The Spray phase consists of s rounds, one for each of the s source groups. In the j-th Spray round, the algorithm downloads all blocks in $\mathsf{Source}[\mathsf{srcInd}_j]$. Each downloaded ciphertext is decrypted and re-encrypted with fresh randomness. Each downloaded block is placed into one of the q caches according to their placement by σ. If block B_i is downloaded, then the re-encryption of B_i is placed into Q_k such that $\sigma(i) \in \mathsf{destInd}_k$. After all blocks of $\mathsf{Source}[\mathsf{srcInd}_j]$ are placed into their respective queues, exactly one block from each of $\mathsf{Q}_1, \ldots, Q_q$ is uploaded to the server. In particular, one block from Q_k is uploaded to temp_k. If any Q_k is empty, a *dummy* block containing an encryption of any arbitrary block is uploaded instead. After all s rounds of the Spray phase are completed, each of $\mathsf{temp}_1, \ldots, \mathsf{temp}_q$ contains exactly s blocks. Furthermore, there might be some blocks remaining in $\mathsf{Q}_1, \ldots, \mathsf{Q}_q$. Every block that is assigned to a location of $\mathsf{Dest}[\mathsf{destInd}_k]$ according to σ appears in either Q_k or temp_k.

The Recalibrate phase will simply rearrange all non-dummy blocks of Q_k and temp_k into the correct locations of $\mathsf{Dest}[\mathsf{destInd}_k]$. Formally, Recalibrate operates in q rounds, one round for each pair of $(\mathsf{Q}_1, \mathsf{temp}_1), \ldots, (\mathsf{Q}_q, \mathsf{temp}_q)$. In the k-th round, all s blocks of temp_k are

downloaded. All non-dummy blocks of temp_k are decrypted and re-encrypted before being placed into Q_k. At this point, all blocks assigned to $\mathsf{Dest}[\mathsf{destInd}_k]$ according to σ appear in Q_k. All blocks are simply uploaded to $\mathsf{Dest}[\mathsf{destInd}_k]$ in any arbitrary order (such as increasing order of $\mathsf{destInd}_k$). After all q rounds of Recalibrate, CacheShuffleRoot finishes executing.

The proof of the following theorem can be found in the full version.

▶ **Theorem 3.** CacheShuffleRoot *is an oblivious shuffle algorithm that uses* $(4+\epsilon)N$ *blocks of bandwidth,* $(3+\epsilon/2)N$ *blocks of server memory and* $O(\sqrt{N})$ *blocks of client memory except with probability negligible in* N*.*

4 Oblivious Shuffling with Smaller Client Memory

In this section, we generalize algorithm CacheShuffleRoot from Section 3. For any $S = \omega(\log N)$, we provide an oblivious shuffling algorithm that uses $O(S)$ blocks of client memory and $O(N \log_S N)$ blocks of bandwidth.

Let us take another look at CacheShuffleRoot. Once CacheShuffleRoot completes the Spray phase, all the blocks that should be placed into $\mathsf{Dest}[\mathsf{destInd}_k]$ according to σ are stored either in temp_k or Q_k. Afterwards the k-th round of Recalibrate arranges all non-dummy blocks in temp_k and Q_k into their correct location in $\mathsf{Dest}[\mathsf{destInd}_k]$. Each round of Recalibrate requires $|\mathsf{temp}_k| + |\mathsf{Q}_k|$ blocks of client memory. Therefore, the key to a oblivious shuffling using less blocks of client memory requires a modification to the Spray phase so that less blocks are placed into each temp_k and Q_k. We present RSpray, a modification of Spray, to achieve smaller server-stored temporary arrays and client-stored caches. Additionally, the output of RSpray is structured such that RSpray may be recursively applied.

4.1 RSpray Description

First, we abstract the input to RSpray to handle recursive applications. As input, RSpray receives a server-stored *source array*, RSource, of n block ciphertexts. In addition, the client privately receives, $\mathsf{destInd} \subseteq [N]$, of d *destination indices*. For every i such that $\sigma(i) \in \mathsf{destInd}$, an encryption of block B_i appears in RSource. The remaining $n - d$ ciphertexts of RSource are dummy blocks.

RSpray is parameterized by the number of blocks of client storage available, which we denote by S. As output, RSpray outputs S *temporary arrays*, $\mathsf{temp}_1, \ldots, \mathsf{temp}_S$, which contain block ciphertexts as well as a partition of destInd into S *destination buckets*, $\mathsf{destInd}_1, \ldots, \mathsf{destInd}_S \subset \mathsf{destInd}$. Furthermore, RSpray guarantees that if $\sigma(i) \in \mathsf{destInd}_k$, then an encryption of B_i will appear in temp_k. To keep the same notation as Section 3, we set $q = S$.

We now formally describe RSpray. RSpray partitions destInd into q destination buckets, $\mathsf{destInd}_1, \ldots, \mathsf{destInd}_q$. Each index $d \in \mathsf{destInd}$ is assigned to one of the q subsets uniformly and independently at random. RSpray will initialize q server-stored temporary arrays, $\mathsf{temp}_1, \ldots, \mathsf{temp}_q$. Each temp_k will contain $s := n/q$ empty block locations. RSpray also initializes q client-stored caches, $\mathsf{Q}_1, \ldots, \mathsf{Q}_q$. All q caches are initially empty. Finally, RSpray partitions RSource into s server-stored *source buckets*, $\mathsf{srcInd}_1, \ldots, \mathsf{srcInd}_s$. Each block ciphertext in RSource is assigned to one of the s source buckets uniformly and independently at random. Unlike Spray, RSpray initializes the s source buckets randomly.

RSpray performs s rounds, one for each of $\mathsf{srcInd}_1, \ldots, \mathsf{srcInd}_s$. In the j-th round, RSpray downloads all blocks of srcInd_j. All non-dummy blocks are decrypted and re-encrypted.

If block B_i is downloaded, then the new encryption of B_i is placed into Q_k such that $\sigma(i) \in \mathsf{destInd}_k$. After all blocks in srcInd_j are placed into their corresponding cache, exactly one block ciphertext is uploaded from each $\mathsf{Q}_1, \ldots, \mathsf{Q}_q$ to the server. In particular, a block from Q_k is uploaded to temp_k, for all $k = 1, \ldots, q$. If Q_k is empty, a dummy block is uploaded instead.

After all s rounds complete, each temp_k contains exactly s block ciphertexts. Furthermore, RSpray guarantees that if $\sigma(i) \in \mathsf{destInd}_k$, then an encryption of B_i appears in either temp_k or Q_k. RSpray performs another q *adjustment rounds* to move all client-stored blocks in Q_k to the server-stored temp_k. In the k-th adjustment round, RSpray downloads all s blocks of temp_k. All dummy blocks of temp_k are discarded. The non-dummy blocks of temp_k are decrypted and re-encrypted. Now, all blocks of Q_k are combined with the non-dummy downloaded blocks of temp_k. If more than s non-dummy blocks remain, then RSpray fails. If there are less than s non-dummy blocks, dummy blocks are added until exactly s blocks remain. Finally, all s blocks are uploaded back to temp_k. RSpray terminates upon completion of the s rounds.

4.2 CacheShuffle Description

We now describe CacheShuffle, which uses RSpray and Spray as subroutines. CacheShuffle starts by running the Spray algorithm of CacheShuffleRoot with parameters $s := N/S$ and $q := (1 + \epsilon)S$. Under these parameters, Spray uses $O(S)$ client memory and outputs the following:

1. q caches $\mathsf{Q}_1, \ldots, \mathsf{Q}_q$ on the client;
2. q temporary arrays $\mathsf{temp}_1, \ldots, \mathsf{temp}_q$ on the server;
3. q destination buckets $\mathsf{destInd}_1, \ldots, \mathsf{destInd}_q$ on the client such that if $\sigma(i) \in \mathsf{destInd}_k$ then Q_k or temp_k contain an encryption of B_i;

For $j = 1, \ldots, q$, we perform the *adjustment round* of RSpray for each pair of $(\mathsf{Q}_k, \mathsf{temp}_k)$ outputted by Spray. In particular, all blocks of Q_k are placed into temp_k. After all q adjustment rounds, we have the property that if $\sigma(i) \in \mathsf{destInd}_k$, then temp_k contains an encryption of B_i.

Next, CacheShuffle recursively calls RSpray on each $\mathsf{temp}_1, \ldots, \mathsf{temp}_q$ exactly $l = O(\log_S N)$ times. Formally, each application of RSpray will produce q pairs of temporary arrays and destination buckets. RSpray will be applied to each of the q pairs independently. After l recursive applications of RSpray, we will receive q^l temporary arrays and destination buckets, $(\mathsf{temp}_{l,1}, \mathsf{destInd}_{l,1}), \ldots, (\mathsf{temp}_{l,q^l}, \mathsf{destInd}_{l,q^l})$. Furthermore, all temporary arrays and destination buckets will contain less than S^2 elements. Each $\mathsf{temp}_{l,k}$ is obliviously shuffled into $\mathsf{Dest}[\mathsf{destInd}_{l,k}]$ using CacheShuffleRoot, for all $k = 1, \ldots, q^l$. CacheShuffleRoot may be applied since the client has at least S blocks of client memory.

The proof of the following theorem can be found in the full version.

▶ **Theorem 4.** CacheShuffle *is an Oblivious Shuffle algorithm that uses $O(N \log_S N)$ blocks of bandwidth, $O(N)$ blocks of server memory and $O(S)$ blocks of client memory except with probability negligible in N.*

5 K-Oblivious Shuffling with $O(K)$ Client Memory

In this section, we present an K-oblivious shuffling algorithm, KCacheShuffleBasic, for clients with at least K blocks of client memory. The algorithm uses $2N$ blocks of bandwidth to shuffle N data blocks We remind the reader that the client of a K-oblivious shuffling receives

two permutations (π, σ) as well as a subset of indices $\mathsf{Revealed} \subseteq [N]$. Identical to Oblivious Shuffling, KCacheShuffleBasic also receives ciphertexts of the N blocks in Source according to π and must place the N blocks in Dest according to σ.

KCacheShuffleBasic starts by downloading the ciphertexts from locations $\mathsf{Source}[\pi(\mathsf{Revealed})]$. That is, the encryption of every block whose index belongs to Revealed is downloaded. Each block is decrypted and re-encrypted. Then, KCacheShuffleBasic initializes $\mathsf{tbDown} = [N] \setminus \mathsf{Revealed}$, which is the set of indices of blocks that have not been downloaded yet.

Then, KCacheShuffleBasic runs N rounds. The goal of the i-th round is to place a ciphertext of $B_{\sigma^{-1}(i)}$ into $\mathsf{Dest}[i]$. If $\sigma^{-1}(i) \in \mathsf{tbDown}$, and thus the ciphertext of $B_{\sigma^{-1}(i)}$ has not been downloaded yet, KCacheShuffleBasic simply downloads $B_{\sigma^{-1}(i)}$ from $\mathsf{Source}[\pi(\sigma^{-1}(i))]$ and removes $\sigma^{-1}(i)$ from tbDown. If $\sigma^{-1}(i) \notin \mathsf{tbDown}$, then $B_{\sigma^{-1}(i)}$ has already been downloaded from $\mathsf{Source}[\pi(\sigma^{-1}(i))]$. If $\mathsf{tbDown} \neq \emptyset$, any arbitrary index $i' \in \mathsf{tbDown}$ is removed and $B_{i'}$ is downloaded from $\mathsf{Source}[\pi(i')]$. In any of the above cases, the downloaded block is decrypted and re-encrypted. Finally, $B_{\sigma^{-1}(i)}$ is placed into $\mathsf{Dest}[i]$.

From first look, it seems that KCacheShuffleBasic requires $O(N)$ roundtrips of client-server communication. However, the number of roundtrips may be reduced by grouping indexes of Dest together. Specifically, we can group indexes of Dest into groups of size $O(K)$ and perform the required downloads and uploads in $O(N/K)$ roundtrips.

The proof of the following theorem can be found in the full version.

▶ **Theorem 5.** KCacheShuffleBasic *is a K-Oblivious Shuffle that uses $2N$ blocks of bandwidth, $2N$ blocks of server storage and $O(K)$ blocks of client storage.*

6 K-Oblivious Shuffling with Smaller Client Memory

In this section, for any constant $\epsilon > 0$, we describe $\mathsf{KCacheShuffle}_{\epsilon,S}$, a K-oblivious shuffling that uses $O(S)$ blocks of client memory. For convenience, we fix ϵ and S and refer to $\mathsf{KCacheShuffle}_{\epsilon,S}$ as simply KCacheShuffle.

KCacheShuffle will invoke a modification of CacheShuffle (using the same value of ϵ). Recall that CacheShuffle invokes CacheShuffleRoot before completion. KCacheShuffle invokes CacheShuffle such that the last Recalibrate phase of CacheShuffleRoot is skipped. Note, only the last Recalibrate phase of CacheShuffleRoot actually places ciphertexts of blocks into the destination array Dest. Therefore, the modified CacheShuffle does not actually use Dest at all. Formally, CacheShuffle invokes KCacheShuffle using Source[Revealed] as the source array and (π, σ) restricted to the input set Revealed as the input permutations. The output of the modified CacheShuffle is:

1. q client-stored *destination buckets* $\mathsf{destInd}_1, \ldots, \mathsf{destInd}_q$, which is a partition of Revealed;
2. q server-stored *temporary arrays* $\mathsf{temp}_1, \ldots, \mathsf{temp}_q$ containing exactly S block ciphertexts such that if $i \in \mathsf{Revealed}$ and $\sigma(i) \in \mathsf{destInd}_k$ then temp_k contains an encryption of B_i;

In the next step, KCacheShuffle merges the revealed and unrevealed blocks. KCacheShuffle will extend $\mathsf{destInd}_1, \ldots, \mathsf{destInd}_q$ from a partition of Revealed to a partition of $[N]$. That is, each index of $[N] \setminus \sigma(\mathsf{Revealed})$ is assigned uniformly and independent at random to one of $\mathsf{destInd}_1, \ldots, \mathsf{destInd}_q$. KCacheShuffle initializes $\mathsf{tbDown}_k = \sigma^{-1}(\mathsf{destInd}_k \setminus \sigma(\mathsf{Revealed}))$, which is all unrevealed blocks assigned to $\mathsf{Dest}[\mathsf{destInd}_k]$ by σ, for all $k = 1, \ldots, q$. Then, KCacheShuffle will run up to q rounds, one for each of $\mathsf{destInd}_1, \ldots, \mathsf{destInd}_q$. In the k-th round, KCacheShuffle downloads all S ciphertexts of temp_k.

We quickly diverge by mentioning an obvious, but incorrect, next step. In particular, it might be tempting to just download all of $\mathsf{Source}[\pi(\mathsf{tbDown}_k)]$ to upload into $\mathsf{Dest}[\mathsf{destInd}_k]$.

However, this step would reveal to the adversary the number of revealed (as well as unrevealed blocks) that are placed into $\mathsf{Dest}[\mathsf{destInd}_k]$ according to σ. This possible next step would cause our algorithm to lose K-obliviousness. In particular, our algorithm cannot leak knowledge about the number of revealed (and unrevealed) blocks that belong in the set $\mathsf{Dest}[\mathsf{destInd}_k]$.

Instead, KCacheShuffle downloads exactly $u_k := |\mathsf{destInd}_k| - (1-\epsilon)K/q$ unrevealed blocks in the k-th round. If $|\mathsf{tbDown}_k| > u_k$, then KCacheShuffle will fail and abort (in Theorem 6 we shall prove that this happens with negligible probability). On the other hand, suppose that $|\mathsf{tbDown}_k| \leq u_k$. In this case, the algorithm will download all blocks in $\mathsf{Source}[\pi(\mathsf{tbDown}_k)]$ and if more are needed, that is if $|\mathsf{tbDown}_k| < u_k$, then extra unrevealed blocks that are not assigned to $\mathsf{Source}[\mathsf{destInd}_k]$ are downloaded from the destination array with the largest index that has not been used yet. Formally, KCacheShuffle initializes $\mathsf{leftover} = q$ before any of the q rounds begins. The $|\mathsf{tbDown}_k| - u_k$ extra blocks are chosen arbitrarily from the set $\mathsf{Source}[\pi(\mathsf{tbDown}_{\mathsf{leftover}})]$, which have not been downloaded yet. If all blocks of $\mathsf{Source}[\pi(\mathsf{tbDown}_{\mathsf{leftover}})]$ have been been downloaded, then leftover is decremented.

All u_k blocks downloaded by KCacheShuffle in the k-th round will be decrypted and re-encrypted. Then, KCacheShuffle will upload all blocks belonging to $\mathsf{Dest}[\mathsf{destInd}_k]$ in any arbitrary order such as increasing in $\mathsf{destInd}_k$. Furthermore, KCacheShuffle has a set of extra unrevealed blocks, which we denote Rem_k, that are not assigned to $\mathsf{Dest}[\mathsf{destInd}_k]$ by σ. If $|\mathsf{Rem}_k| > 2\epsilon K/q$, then KCacheShuffle fails and aborts Otherwise, KCacheShuffle pads Rem_k to contain exactly $2\epsilon K/q$ ciphertexts by adding encryptions of dummy blocks. Afterwards, Rem_k is uploaded to the server.

At some point, leftover and k will be equal. Once leftover and k are the same, KCacheShuffle will stop running these rounds. However, KCacheShuffle still has to place blocks into $\mathsf{Dest}[\mathsf{destInd}_{\mathsf{leftover}}], \ldots, \mathsf{Dest}[\mathsf{destInd}_q]$ from $\mathsf{temp}_{\mathsf{leftover}}, \ldots, \mathsf{temp}_q$ and $\mathsf{Rem}_1, \ldots, \mathsf{Rem}_{\mathsf{leftover}-1}$. To achieve this, KCacheShuffle invokes CacheShuffle using $\mathsf{temp}_{\mathsf{leftover}} \cup \ldots \cup \mathsf{temp}_q \cup \mathsf{Rem}_1 \cup \ldots \mathsf{Rem}_{\mathsf{leftover}-1}$ as the source array, $\mathsf{Dest}[\mathsf{destInd}_{\mathsf{leftover}} \cup \ldots \cup \mathsf{destInd}_q]$ as the destination array and (π, σ) restricted to $\sigma^{-1}(\mathsf{destInd}_{\mathsf{leftover}}) \cup \ldots \cup \sigma^{-1}(\mathsf{destInd}_q)$ as the permutations. In the full version, we show that $\mathsf{destInd}_{\mathsf{leftover}} \cup \ldots \cup \mathsf{destInd}_q$ contains $O(K)$ indices.

If the client has $O(\sqrt{K})$ blocks of client storage, then we may replace CacheShuffle with CacheShuffleRoot above. We refer to this construction as KCacheShuffleRoot.

The proof of the following theorem can be found in the full version.

▶ **Theorem 6.** *For every $S = \omega(\log N)$ and for every ϵ, $\mathsf{KCacheShuffle}_{\epsilon,S}$ is a K-oblivious shuffling algorithm that uses $2N + O(K \log_S K)$ blocks of bandwidth, $O(N)$ blocks of server storage, $O(S)$ blocks of client storage and fails with probability negligible in N.*

7 Conclusions

In this paper, we studied the notion of *oblivious* algorithms for the problem of shuffling data. We introduce the notion of K-oblivious shuffling, a fine-grained notion of obliviousness, which accurately describes the adversary's knowledge about the initial position of the N blocks. In particular, we assume the adversary gains information about the initial position of exactly K blocks. This notion has direct application to the design of Oblivious RAMs. Previous notions only considered the extreme case where the adversary has complete knowledge about the initial positioning of all N input blocks (that is, $K = N$).

We present bandwidth efficient moved-based K-oblivious shuffling algorithms for any K and for any client with $S = \omega(\log N)$ blocks of available storage. The bandwidth required by our algorithms is of the form $2N + f(K, S)$. We also look at the previous considered the case of $K = N$ corresponding to previous oblivious shuffling notions. We present an oblivious

shuffle using essentially $4N$ blocks of bandwidth. The previous, state-of-the-art oblivious shuffle [10] required approximately $18N$ blocks of bandwidth for similar failure probabilities.

We also consider the case where we shuffle N *real* blocks along with D *dummy* blocks. In this case, the contents of dummy blocks are irrelevant. By utilizing server-side computation, we shuffle using essentially $D + (2 + \epsilon)N$ blocks of bandwidth. Thus, our algorithm uses less bandwidth than any move-based algorithm uses at least $2(N + D)$ blocks of bandwidth.

Abstract

Solving large-scale graph problems is a fundamental task in many real-world applications, and it is an increasingly important problem in data analysis. Despite the large effort in designing scalable graph algorithms, many classic graph problems lack algorithms that require only a sublinear number of machines and space in the input size. Specifically when the input graph is large and sparse, which is indeed the case for many real-world graphs, it becomes impossible to store and access all the vertices in one machine – something that is often taken for granted in designing algorithms for massive graphs. The theoretical model that we consider is the *Massively Parallel Communications* (MPC) model which is a popular theoretical model of MapReduce-like systems. In this paper, we give an algorithmic framework to adapt a large family of dynamic programs on MPC. We start by introducing two classes of dynamic programming problems, namely "(poly log)-expressible" and "linear-expressible" problems. We show that both classes can be solved efficiently using a sublinear number of machines and a sublinear memory per machine. To achieve this result, we introduce a series of techniques that can be plugged together. To illustrate the generality of our framework, we implement in $O(\log n)$ rounds of MPC, the dynamic programming solution of fundamental problems such as minimum bisection, k-spanning tree, maximum independent set, longest path, etc., when the input graph is a tree.

nowadays. The past decade has seen a lot of progress in studying important computer science problems in the large-scale setting, which led to either adapting the sequential algorithms to modern parallel settings or at times designing from scratch algorithms for these problems [1, 2, 4, 7, 5]. Despite this trend, we still have limited theoretical understanding of the status of several fundamental problems when it comes to designing large-scale algorithms. In fact, even simple and widely used techniques such as the greedy approach or dynamic programming seem to suffer from an inherent sequentiality that makes them difficult to adapt in parallel or distributed settings on the aforementioned platforms. Finding methods to run generic greedy algorithms or dynamic programming algorithms on MapReduce, for instance, has broad applications. This is the main goal of this paper.

We consider the Massively Parallel Communication ($\mathcal{MPC}$) model among previously studied MapReduce-like models [9, 8, 3]. Let n denote the input size and let m denote the number of available machines which is given in the input. At each round, every machine can use a space of size $s = \tilde{\mathrm{O}}(n/m)$ and run an algorithm that is preferably linear time (but at most polynomial time) in the size of its memory. Machines may only communicate between the rounds, and no machine can receive or send more data than its memory.

In this paper, we give an algorithmic framework that could be used to simulate many natural dynamic programs on trees. Indeed we formulate the properties that make a dynamic program (on trees) amenable to our techniques. These properties, we show, are natural and are satisfied by many known algorithms for fundamental optimization problems. To illustrate the generality of our framework, we design $\mathrm{O}(\log n)$ round algorithms for well-studied graph problems on trees, such as, minimum bisection, minimum k-spanning tree, maximum weighted matching, etc.

2 Main Results

We introduce a class of dynamic programming problems which we call f-expressible problems. Here, f is a function and we get classes such as (poly log)-expressible problems or linear-expressible problems. Roughly speaking, f is proportional to the amount of data that each node of the tree stores in the dynamic program. Thus, linear-expressible problems are generally harder to solve than (poly log)-expressible problems.

(poly log)-Expressible Problems. Many natural problems can be shown to be (poly log)-expressible. For example, the following graph problems are all (poly log)-expressible if defined on trees: maximum (weighted) matching, vertex cover, maximum independent set, dominating set, longest path, etc. Intuitively, the dynamic programming solution of each of these problems, for any vertex v, computes at most a constant number of values. Our first result is to show that every (poly log)-expressible problem can be efficiently solved in $\mathcal{MPC}$. As a corollary of that, all the aforementioned problems can be solved efficiently on trees using the optimal total space of $\tilde{\mathrm{O}}(n)$.

▶ **Theorem 1.** *For any given m, there exists an algorithm that w.h.p. solves any* (poly log)*-expressible problem in* $\mathrm{O}(\log n)$ *rounds of $\mathcal{MPC}$ using m machines while each machine uses a space of size at most* $\tilde{\mathrm{O}}(n/m)$.

Proof sketch. The first problem in solving dynamic programs on trees is that there is no guarantee on the depth of the tree. If the given tree has only logarithmic depth one can obtain a logarithmic round algorithm by simulating a bottom-up dynamic program in parallel, where nodes at the same level are handled in the same round simultaneously. This is

reminiscent of certain parallel algorithms whose number of rounds depends on the diameter of the graph. Unfortunately the input tree might be quite unbalanced, with superlogarithmic depth. An extreme case is a path of length n. In this case we can partition the path into equal pieces (despite not knowing a priori the depth of each particular node), handling each piece independently, and then stitching the results together. Complications arise, because the subproblems are not completely independent. Things become more nuanced when the input tree is not simply a path. To resolve this issue, we adopt a celebrated *tree contraction* method of parallel computing to our model. Roughly speaking, the algorithm decomposes the tree into pieces of size at most $\tilde{O}(m)$ (i.e., we can fit each component completely on one machine), with small interdependence. Omitting minor technical details, the latter property allows us to almost independently solve the subproblems on different machines. This results in a partial solution that is significantly smaller than the whole subtree; therefore, we can send all these partial solutions to a master machine in the next round and merge them.

Linear-Expressible Problems. Although many natural problems are indeed (poly log)-expressible, there are instances that are not. Consider for example the *minimum bisection problem*. In the natural dynamic programming solution of this problem, for a subtree T of size n_T, we store $O(n_T)$ different values. That is, for any $i \in [n_T]$, the dynamic program stores the weight of the optimal coloring that assigns blue to i vertices and red to the rest of $n_T - i$ vertices. This problem is not necessarily (poly log)-expressible unless we find another problem specific dynamic programming solution for it. However, it can be shown that minimum bisection, as well as many other natural problems, including k-spanning-tree, k-center, k-median, etc., are linear-expressible. It is notoriously more difficult to solve linear-expressible problems. However, using a slightly more total memory, we show that it is still possible to obtain the same result.

▶ **Theorem 2** (Main Result). *For any given m, there exists an algorithm that w.h.p. solves any linear-expressible problem that is splittable in $O(\log n)$ rounds of $\mathcal{MPC}$ using m machines that each uses a space of size $\tilde{O}(n^{4/3}/m)$*

Proof sketch. Recall that linear-expressibility implies that the dynamic programming data on each node, can be as large as the size of its subtree (i.e., even up to $O(n)$). Therefore, even by using the tree decomposition technique, the partial solution that is computed for each component of the tree can be linear in its size. This means that the idea of sending all these partial data to one master machine, which worked for (poly log)-expressible problems, does not work here since when aggregated, they take as much space as the original input. Therefore we have to distribute the merging step among the machines.

Assume for now that each component that is obtained by the tree decomposition algorithm is contracted into a node and call this *contracted tree*. The tree decomposition algorithm has no guarantee on the depth of the contracted tree and it can be super-logarithmic; therefore a simple bottom-up merging procedure does not work. However, it is guaranteed that the contracted tree itself (i.e., when the components are contracted) can be stored in one machine. Using this, we send the contracted tree to a machine and design a *merging schedule* that informs each component about the round at which it has to be merged with each of its neighbours. The merging schedule ensures that after $O(\log n)$ phases, all the components are merged together. The merging schedule also guarantees that the number of neighbours of the components, after any number of merging phases, remains constant. This is essential to allow (almost) independent merging for many linear-expressible problems such as minimum bisection. Observe that after a few rounds, the merged components grow to have up to

$\Omega(n)$ nodes and even the partial data of one component cannot be stored in one machine. Therefore, even merging the partial data of two components has to be distributed among the machines. For this to be possible, we use a *splitting* technique of independent interest that requires a further *splittability* property on linear-expressible problems. Indeed we show that the aforementioned linear-expressible problems have the splittability property, and therefore Theorem 2 implies they can also be solved in $O(\log n)$ rounds of $\mathcal{MPC}$.

Abstract

Many networking applications require timely access to recent network measurements, which can be captured using a sliding window model. Maintaining such measurements is a challenging task due to the fast line speed and scarcity of fast memory in routers. In this work, we study the impact of allowing *slack* in the window size on the asymptotic requirements of sliding window problems. That is, the algorithm can dynamically adjust the window size between W and $W(1+\tau)$ where τ is a small positive parameter. We demonstrate this model's attractiveness by showing that it enables efficient algorithms to problems such as Maximum and General-Summing that require $\Omega(W)$ bits even for constant factor approximations in the exact sliding window model. Additionally, for problems that admit sub-linear approximation algorithms such as Basic-Summing and Count-Distinct, the slack model enables a further asymptotic improvement.

The main focus of our paper [4] is on the widely studied Basic-Summing problem of computing the sum of the last W integers from $\{0, 1 \ldots, R\}$ in a stream. While it is known that $\Omega(W \log R)$ bits are needed in the exact window model, we show that approximate windows allow an *exponential* space reduction for constant τ.

Specifically, for $\tau = \Theta(1)$, we present a space lower bound of $\Omega(\log(RW))$ bits. Additionally, we show an $\Omega(\log(W/\epsilon))$ lower bound for $RW\epsilon$ additive approximations and a $\Omega(\log(W/\epsilon) + \log\log R)$ bits lower bound for $(1+\epsilon)$ multiplicative approximations. Our work is the first to study this problem in the exact and additive approximation settings. For all settings, we provide memory optimal algorithms that operate in *worst case* constant time. This strictly improves on the work of [12] for $(1+\epsilon)$-multiplicative approximation that requires $O(\epsilon^{-1}\log(RW)\log\log(RW))$ space and performs updates in $O(\log(RW))$ worst case time. Finally, we show asymptotic improvements for the Count-Distinct, General-Summing and Maximum problems.

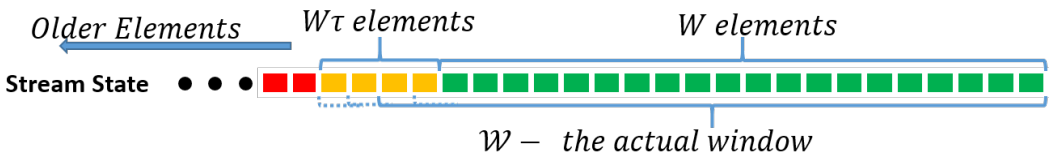

Figure 1 We need to answer each query with respect to a τ-slack window that must include the last W items, but may or may not consider a suffix of the previous $W\tau$ elements.

1 Introduction

Network algorithms in diverse areas such as traffic engineering, load balancing and quality of service [1, 8, 17, 20, 27] rely on timely link measurements. In such applications recent data is often more relevant than older data, motivating the notions of *aging* and *sliding window* [5, 10, 13, 21, 23]. For example, a sudden decrease in the average packet size on a link may indicate a SYN attack [22]. Additionally, a load balancer may benefit from knowing the current utilization of a link to avoid congestion [1].

While conceptually simple, conveying the necessary information to network algorithms is a difficult challenge due to current memory technology limitations. Specifically, DRAM memory is abundant but too slow to cope with the line rate while SRAM memory is fast enough but has a limited capacity [9, 11, 25]. Online decisions are therefore realized through space efficient data structures [6, 7, 14, 15, 3, 19, 24, 26] that store measurement statistics in a concise manner. For example, [14, 24] utilize probabilistic counters that only require $O(\log\log N)$ bits to approximately represent numbers up to N. Others conserve space using variable sized counter encoding [15, 19] and monitoring only the frequent elements [5].

Basic-Summing is one of the most basic textbook examples of such approximated sliding window stream processing problems [12]. In this problem, one is required to keep track of the sum of the last W elements, when all elements are non-negative integers in the range $\{0, 1, \ldots, R\}$. The work in [12] provides a $(1+\epsilon)$-multiplicative approximation of this problem using $O\left(\frac{1}{\epsilon}\cdot\left(\log^2 W + \log R\cdot(\log W + \log\log R)\right)\right)$ bits. The amortized time complexity is $O(\frac{\log R}{\log W})$ and the worst case is $O(\log W + \log R)$. In contrast, we previously showed an $RW\epsilon$-additive approximation with $\Theta\left(\frac{1}{\epsilon} + \log W\epsilon\right)$ bits [2].

Sliding window counters (approximated or accurate) require asymptotically more space than plain stream counters. Such window counters are prohibitively large for networking devices which already optimize the space consumption of plain counters.

This paper explores the concept of *slack*, or approximated sliding window, bridging this gap. Figure 1 illustrates a "window" in this model. Here, each query may select a *τ-slack window* whose size is between W (the green elements) and $W(1+\tau)$ (the green plus yellow elements). The goal is to compute the sum with respect to this chosen window.

Slack windows were also considered in previous works [12, 23] and we call the problem of maintaining the sum over a slack window Slack Summing. Datar et al. [12] showed that constant slack reduces the required memory from $O(\frac{1}{\epsilon}\cdot\left(\log^2 W + \log R\cdot(\log W + \log\log R)\right))$ to $O(\epsilon^{-1}\log(RW)\log\log(RW))$. For τ-slack windows they provide a $(1+\epsilon)$-multiplicative approximation using $O(\epsilon^{-1}\log(RW)(\log\log(RW) + \log\tau^{-1}))$ bits.

Our Contributions

Our paper [4] studies the space and time complexity reductions that can be attained by allowing *slack* – an error in the window size. Our results demonstrate exponentially smaller and asymptotically faster data structures compared to various problems over exact windows.

Table 1 Comparison of Basic-Summing algorithms. Our contributions are in bold. All algorithms process elements in constant time except for the rightmost column where both update in $O(\log(RW))$ time. We present matching lower bounds to all our algorithms.

	Exact Sum	Additive Error	Multiplicative Error	
$\tau = \Theta(1)$	$\mathbf{\Theta(\log(RW))}$	$\mathbf{\Theta(\log(W/\epsilon))}$	$\mathbf{\Theta(\log(W/\epsilon) + \log\log R)}$	$O(\epsilon^{-1}\log(RW)\log\log(RW))$ [12]
Exact Window	$\Theta(W \log R)$	$\Theta(\epsilon^{-1} + \log W)$ [2]	$O(\epsilon^{-1}\log^2(RW))$ [18]	$O(\epsilon^{-1}\log RW \log(W \log R))$ [12]

We start with deriving lower bounds for three variants of the Basic-Summing problem – when computing an exact sum over a slack window, or when combined with an additive and a multiplicative error in the sum. We present algorithms that are based on dividing the stream into $W\tau$-sized blocks. Our algorithms sum the elements within each block and represent each block's sum in a cyclic array of size τ^{-1}. We use multiple compression techniques during different stages to drive down the space complexity. The resulting algorithms are space optimal, substantially simpler than previous work, and reduce update time to $O(1)$.

For exact Slack Summing, we present a lower bound of $\Omega(\tau^{-1}\log(RW\tau))$ bits. For $(1+\epsilon)$ multiplicative approximations we prove an $\Omega\big(\log(W/\epsilon) + \tau^{-1}(\log(\tau/\epsilon) + \log\log(RW))\big)$ bits bound when $\tau = \Omega\left(\frac{1}{\log RW}\right)$. We show that $\Omega(\tau^{-1}\log\lfloor 1+\tau/\epsilon\rfloor + \log(W/\epsilon))$ bits are required for $RW\epsilon$ additive approximations.

Next, we introduce algorithms for the Slack Summing problem, which asymptotically reduce the required memory compared to the sliding window model. For the exact and additive error versions of the problem, we provide memory optimal algorithms. In the multiplicative error setting, we provide an $O\big(\tau^{-1}\left(\log\epsilon^{-1} + \log\log(RW\tau)\right) + \log(RW)\big)$ space algorithm. This is asymptotically optimal when $\tau = \Omega(\log^{-1} W)$ and $R = \text{poly}(W)$. It also asymptotically improves [12] when $\tau^{-1} = o(\epsilon^{-1}\log(RW))$. We further provide an asymptotically optimal solution for constant τ, even when $R = W^{\omega(1)}$. All our algorithms are deterministic and operate in worst case constant time. In contrast, the algorithm of [12] works in $O(\log RW)$ worst case time.

To exemplify our results, consider monitoring the average bandwidth (in bytes per second) passed through a router in a 24 hours window, i.e., $W \triangleq 86400$ seconds. Assuming we use a 100GbE fiber transceiver, our stream values are bounded by $R \approx 2^{34}$ bytes. If we are willing to withstand an error of $\epsilon = 2^{-20}$ (i.e., about $16KBps$), the work of [2] provides an additive approximation over the sliding window and requires about 120KB. In contrast, using a 10 minutes slack ($\tau \triangleq \frac{1}{144}$), our algorithm for **exact** Slack Summing requires only 800 bytes, 99% less than approximate summing over exact sliding window. For the same slack size, the algorithm of [12] requires more space than our **exact** algorithm even for a large 3% error. Further, if we also allow the same additive error ($\epsilon = 2^{-20}$), we provide an algorithm that requires only 240 bytes - a reduction of more than 99.8% !

Table 1 compares our results for the important case of constant slack with [12]. As depicted, our *exact* algorithm is faster and more space efficient than the multiplicative approximation of [12]. Comparing our multiplicative approximation algorithm to that of [12], we present *exponential* space reductions in the dependencies on ϵ^{-1} and R, with an asymptotic reduction in W as well. We also improve the update time from $O(\log(RW))$ to $O(1)$.

Finally, we apply the slack window approach to multiple streaming problems, including Maximum, General-Summing, Count-Distinct and Standard-Deviation. We show that, while some of these problems cannot be approximated on an exact window in sub-linear space (e.g. Maximum and General-Summing), we can easily do so for slack windows. In the count distinct problem, a constant slack yields an asymptotic space reduction over [10, 16]. The full version of our paper appears in [4].

Abstract

A theoretical model is suggested for abstracting the interaction between an expert system and its users, with a focus on reputation and incentive compatibility. The model assumes users interact with the system while keeping in mind a single *"retention parameter"* that measures the strength of their belief in its predictive power, and the system's objective is to reinforce and maximize this parameter through "informative" and "correct" predictions.

We define a natural class of *retentive scoring rules* to model the way users update their retention parameter and thus evaluate the experts they interact with. Assuming agents in the model have an incentive to report their true belief, these rules are shown to be tightly connected to truth-eliciting "proper scoring rules" studied in Decision Theory.

The difference between users and experts is modeled by imposing different limits on their predictive abilities, characterized by a parameter called *memory span*. We prove the *monotonicity theorem* ("more knowledge is better"), which shows that experts with larger memory span retain better in expectation.

Finally, we focus on the intrinsic properties of phenomena that are amenable to collaborative discovery with a an expert system. Assuming user types (or "identities") are sampled from a distribution D, the *retention complexity* of D is the minimal initial retention value (or "strength of faith") that a user must have before approaching the expert, in order for the expert to retain that user throughout the collaborative discovery, during which the user "discovers" his true "identity". We then take a first step towards relating retention complexity to other established computational complexity measures by studying retention dynamics when D is a uniform distribution over a linear space.

1 Motivation

Aspiring gurus face the problem of attracting new followers, and *retaining* existing ones, as they journey together to a better future. This is an old problem. Moses, for instance, raised it before The Lord before assuming leadership of the Israelite Exodus from Egypt, asking: *"What if they won't believe me or listen to me?" [Exodus 4:1]*. Many gurus resolve the problem by *predicting unlikely events* as a demonstration of their powers; the Biblical Exodus story contains several such events (culminating with the crossing of the Red Sea), all of which were predicted correctly by Moses.

In today's information society, crowd-based automated gurus gather data from users on a voluntary basis in order to produce meaningful insights. The quality of insights greatly depends on the amount and quality of data provided by the users, but those users have limited attention, giving rise to the study of *attention economy* [2, 4], and the design of interactive systems taking limited attention span into account. By asking *"interesting questions"* and making *"meaningful predictions"*, an automated interactive system can retain users, but only if it "knows" how to ask "interesting" questions and provide "meaningful" feedback.

The phenomenon that motivated this research is that of *early child development*; the gurus are experts in this field and the followers are parents of newborn babies [1]. For the sake of concreteness we shall continue using this particular setting to describe our model but it may be conveniently replaced by the reader with physicians or psychologists playing the gurus as they interact with patients (followers) regarding a complex medical or mental problem, or with financial advisors as gurus and their follower clientele. In these and similar settings, gurus and followers discuss a complex phenomenon that evolves over time, which the followers wish to understand, and about which the guru claims to have an advantage of *"wisdom"* over them.

The main goal of this work is the development of a clean mathematical model which mimics the retention dynamics of interactive systems, and can be used to explain why "smarter" gurus tend to retain a larger following. A clean mathematical model often sheds light on the studied phenomena, and may facilitate the future design of more efficient and successful automated gurus.

2 The Collaborative Discovery Model

The *phenomenon* about which the guru and her followers interact is modeled by a *distribution* $\mathcal{T}$ over $\mathcal{X}^\Gamma$, where Γ is the set of properties manifested by the phenomenon and $\mathcal{X}$ is an arbitrary input space. In the context of childhood development, Γ is the set of developmental milestones (like *"first smile"*), and each follower is represented by a sample $u \in \mathcal{X}^\Gamma$ that describes the ages at which that child achieved each milestone.

The guru and follower interact over a number of *rounds*: At the start of each round of interaction, the guru picks an undisclosed property $\gamma_t \in \Gamma$, and makes a prediction by announcing a distribution P_{γ_t} over $\mathcal{X}$ that she claims is the true one for a latent attribute $\gamma_t \notin \Gamma_t$; the follower has a distribution Q_{γ_t} that he believes corresponds to γ_t. After announcing both distributions, the true value $u_{\gamma_t} \in \mathcal{X}$ is revealed.

After each round, the follower updates the strength of his *retention* by the guru. We assume this strength is given by a *retention parameter* r_t that starts with a fixed value r_0 and varies with time; once r_t turns negative, the follower will be said to have lost all faith in the guru and therefore terminate the interaction. The main objective of the guru is to maintain $r_t \geq 0$ for all $t \geq 0$.

3 Main Contributions

Retentive Scoring Rules

The retention parameter r_t mentioned above and the dynamics that form around it are the key ingredients that give the model its expressive strength. Defining the retention parameter update rules, and the surprising corollaries of the chosen definitions, are what dominates the first part of our study.

We assume the retention parameter changes in an additive manner after each round, according to a function $\mathcal{S}(\cdot,\cdot,\cdot)$ that is real-valued and takes three inputs: (i) the guru's predicted distribution P_{γ_t}; (ii) the follower's assessment of that distribution Q_{γ_t}; and (iii) the value u_{γ_t} that materialized, picked by Nature. Analysis is further facilitated by assuming that $\mathcal{S}$ belongs to a class of functions that *elicit* the true beliefs of both guru and follower regarding the distribution of the attribute γ_t. Truth eliciting rules are ones that incentivize rational players to supply the rule with what they believe to be the truth.

Truthfulness under rationality is a powerful assumption which often leads to non-trivial corollaries. We characterize the functions that can act as retentive scoring rules, showing that such rules can take a surprisingly simple form.

Memory Span and Monotonicity

To model the different predictive capacities of gurus and followers, we characterize the forecasting abilities of agents in the Collaborative Discovery model by a parameter called *memory span*.

A variety of psychological studies could be summarized by saying that the human short-term memory has a capacity of about "seven, plus-or-minus two" *chunks*, where each chunk can be roughly defined as a collection of elementary information relating to a single concept [5, 6], where the "information capacity" of a chunk depends on the knowledge of the person being tested.

We model the discrepancy between users and experts by imposing the different limits on their memory spans. In this context, we show that the definition of memory span is *monotone*, verifying that experts with larger memory span retain followers longer in expectation.

Retention Complexity and Linear Codes

A distribution $\mathcal{T}$ for which there exists a guru that, in expectation, manages to retain followers to eternity (or until $t = |\Gamma|$ for finite Γ) will be said to be r_0-*retainable* and the *retention complexity* of $\mathcal{T}$ will be the minimal r_0 such that $\mathcal{T}$ is r_0-retainable.

To initiate the study of the retention complexity of specific distribution, a class of simple-to-understand, but non-trivial distributions, is needed. Inspired by other initial works, like that of Valiant which studied machine learning in the "restricted, but nontrivial context" of boolean functions [7] and that of Goldreich, Goldwasser and Ron that studied property testing in the context of graph properties [3], we begin by studying retention complexity of uniform distributions over linear spaces.

Uniform distributions over linear spaces are such a family and our final object of discussion. While such distributions are far from ones appearing in the "real world", studying them in this context provide convenient tools and insights about the Collaborative Discovery model, and the intuition and techniques we develop here will be generalized as we move to more "applied" settings.

Abstract

Depth first search is a natural algorithmic technique for constructing a closed route that visits all vertices of a graph. The length of such route equals, in an edge-weighted tree, twice the total weight of all edges of the tree and this is asymptotically optimal over all exploration strategies. This paper considers a variant of such search strategies where the length of each route is bounded by a positive integer B (e.g. due to limited energy resources of the searcher). The objective is to cover all the edges of a tree T using the minimum number of routes, each starting and ending at the root and each being of length at most B. To this end, we analyze the following natural greedy tree traversal process that is based on decomposing a depth first search traversal into a sequence of limited length routes. Given any arbitrary depth first search traversal R of the tree T, we cover R with routes $R_1, \ldots, R_l$, each of length at most B such that: R_i starts at the root, reaches directly the farthest point of R visited by R_{i-1}, then R_i continues along the path R as far as possible, and finally R_i returns to the root. We call the above algorithm *piecemeal-DFS* and we prove that it achieves the asymptotically minimal number of routes l, regardless of the choice of R. Our analysis also shows that the total length of the traversal (and thus the traversal time) of piecemeal-DFS is asymptotically minimum over all energy-constrained exploration strategies. The fact that R can be chosen arbitrarily means that the exploration strategy can be constructed in an online fashion when the input tree T is not known in advance. Each route R_i can be constructed without any knowledge of the yet unvisited part of T. Surprisingly, our results show that depth first search is efficient for energy constrained exploration of trees, even though it is known that the same does not hold for energy constrained exploration of arbitrary graphs.

1 Introduction

Consider a mobile robot (also called an *agent*) that needs to explore an initially unknown edge-weighted tree, where the weight of each edge is its length. Starting from a single vertex (the root), the robot must traverse all edges of and return to its initial location. Upon visiting a vertex v for the first time, the robot discovers the edges incident to v and can choose one of them to continue the exploration. Provided that the robot can remember the visited vertices and edges, a simple depth first search (DFS) is an efficient algorithm for exploring the tree, achieving the optimal cost of twice the sum of the lengths of edges in the tree. In a more interesting scenario, the robot has a limited source of energy (e.g. a battery) which allows it to traverse a path of length at most B (we say such a robot is *energy constrained*). Naturally, we assume that each vertex of the tree is at distance at most $B/2$ from the root, otherwise the tree cannot be fully explored. In this case, exploration is possible if the robot can recharge its battery whenever it returns back to the initial location. Thus, the exploration is a collection of routes of the robot, each of which starts and ends at the root, and has length at most B. We are interested in minimizing the number of such routes (i.e. the number of times the robot has to recharge) to completely explore the tree.

Related work. There exists extensive literature on graph traversal and exploration. We refer interested reader to works on several models that do not consider any energy limitation for the agents, including results on general graphs [22], trees [9, 17, 18, 19], lower bounds on exploration time [9, 13, 14, 20, 21], or exploration with little memory [1, 12].

The energy constrained exploration problem was first studied under the name of *Piecemeal Graph Exploration* [8], with the assumption that the route length $B \geq 2(1+\beta)r$, where r is the furthest distance from the starting vertex to other vertices, and $0 < \beta < 1$. That paper provided exploration algorithms for a special class of grid graphs with 'rectangular obstacles'. Awerbuch et al. [4] showed that, for general graphs, there exists an energy constrained exploration algorithm with a total cost of $O(m + n^{1+o(1)})$. This has been further improved (by an algorithm that is a combination of DFS and BFS) to $O(m + n\log^2 n)$ in [5]. Finally [15] provided an exploration algorithm for general unknown weighted graphs with total cost asymptotic to the sum of edge weights of the graph. Note that, as mentioned, all the above strategies require the length of each route to be strictly larger than the shortest path from the starting vertex to the farthest vertex. In other words, these algorithms fail in the extreme cases when the height of the explored tree (or the diameter of the graph) is equal to half of the energy budget, which seem to be the most challenging ones. The off-line version of the problem is NP-hard, see e.g. [18].

See [6, 11, 16] for works on the tree exploration model we consider, with one difference: each route, also of length at most B, starts at the root but may end at any vertex of the tree. Distributed algorithms for energy constrained agents have been a subject of recent investigation, see e.g. [2, 3, 7, 10].

2 Problem statement and DFS exploration

Let $T = (V(T), E(T), \omega\colon E(T) \to \mathbb{R}_+)$ be an edge-weighted tree with root r. We define a *route* $R = (v_0, v_1, \ldots, v_l)$ as a sequence of vertices that satisfies: (i) $\{v_i, v_{i+1}\} \in E(T)$ for each $i \in \{0, \ldots, l-1\}$, and (ii) $v_0 = v_l$ is the root r of T. Informally speaking, a route is a sequence of vertices forming a walk in T that starts and ends at the root. We define the *length* of R to be $\ell(R) = \sum_{i=1}^{l} \omega(\{v_{i-1}, v_i\})$. We say that a vertex v is *visited* by the route if $v = v_i$ for some $i \in \{1, \ldots, l\}$.

Given a tree T and a real number B, we say that $\mathcal{S} = (R_1, \ldots, R_k)$ is a *B-exploration strategy* for T if for each $i \in \{1, \ldots, k\}$, R_i is a route in T of length at most B, and each vertex of T is visited by some route in $\mathcal{S}$. We write $|\mathcal{S}|$ to refer to the number of routes in $\mathcal{S}$, $k = |\mathcal{S}|$. We formulate the combinatorial problem we study in this work as follows.

Energy Constrained Tree Exploration problem (ECTE)

Given a real number $B > 1$ and an edge-weighted rooted tree T of height at most $B/2$ what is the minimum integer k such that there exists a B-exploration strategy that consists of k routes?

Our goal is to analyze a particular type of solution to this problem, namely, an exploration strategy that behaves like a depth first search traversal but adopted to the fact that route lengths are bounded by B. Let $R_{\mathrm{DFS}} = (v_0, v_1, \ldots, v_l)$ be a route in T that covers the tree T and performs a depth first search traversal of T. (Note that R_{DFS} is a route and thus we consider a depth first search traversal to have vertex repetitions.) For two vertices u and v of T, $d(u, v)$ denotes the distance between u and v understood as the sum of weights of the edges of the path connecting these vertices. We refer by $\mathrm{PDFS}(T) = (R_1, \ldots, R_k)$ (*Piecemeal Depth First Search*) to the following B-exploration strategy constructed iteratively for $i := 1, \ldots, k$:

- **(i)** let $j_0 = 0$ i.e. $v_{j_0} = v_0 = r$,
- **(ii)** R_i continues DFS exploration from where R_{i-1} *stopped making progress* (from the vertex $v_{j_{i-1}}$) as long as for currently visited v_p: $d(r, v_{j_{i-1}}) + \ell((v_{j_{i-1}}, v_{j_{i-1}+1}, \ldots, v_p)) + d(v_p, r) \leq B$,
- **(iii)** furthest v_p (for $p \leq l$) that satisfies condition from ii is denoted as v_{j_i}, the vertex where R_i stopped making progress,
- **(iv)** let $R_i = P_{i-1} \circ (v_{j_{i-1}}, v_{j_{i-1}+1}, \ldots, v_{j_i-1}, v_{j_i}) \circ P_i^R$, where P_{i-1} is the path from r to $v_{j_{i-1}}$, and P_i^R is the path from v_{j_i} to r.

Such a strategy $\mathrm{PDFS}(T)$ is called a *DFS B-exploration*.

We remark that different depth first search traversals R_{DFS} may result in different values of k (different number of routes) in the resulting DFS B-exploration, although for a particular choice of R_{DFS} the corresponding $\mathrm{PDFS}(T)$ is unique. We point out that our results stated below hold for an *arbitrary* choice of R_{DFS}.

3 Our results

The following theorem provides the first main result of this work.

▶ **Theorem 1.** *Let T be a tree and let the longest path from the root to a leaf in T be at most $B/2$. It holds $|\mathrm{PDFS}(T)| \leq 10\,|\mathcal{R}|$, where $\mathcal{R}$ is a B-exploration strategy that consists of the minimum number of routes.*

The theorem refers to the number of routes in an exploration strategy. However, in order to analyze the behavior of $\mathrm{PDFS}(T)$, we introduce another parameter which turns out to be simpler to analyze. For any B-exploration strategy $\mathcal{S} = (R_1, \ldots, R_k)$ of T we will denote by $\xi(\mathcal{S})$ the *cost* of $\mathcal{S}$ defined as $\xi(\mathcal{S}) = \sum_{i=1}^{k} \ell(R_i)$. Then, $\mathrm{COPT}(T)$ is an optimal solution with respect to the cost, that is, a B-exploration strategy whose cost is minimum over all B-exploration strategies. Thus, in order to prove Theorem 1, we obtain, on route, the following second main result of our work.

▶ **Theorem 2.** *Let T be a tree and let $B/2$ be greater than or equal to the longest path from the root to a leaf in T. It holds $\xi(\mathrm{PDFS}(T)) \leq 10 \cdot \xi(\mathrm{COPT}(T))$.*
