As the inner **while**-loop of Algorithm 1 executes, we can view l as being divided into three sets: the set containing just the *active* element, $l[j]$ (which we view as moving to the left, starting from position i, as it is participating in comparisons and swaps), the *semi-sorted* portion, $l[0 : i]$, not including $l[j]$, and the *unsorted* portion, $l[i + 1 : n - 1]$. Note that if no random adjacent swaps were occurring in l' (that is, if we were executing insertion-sort in the classical algorithmic model), then the semi-sorted portion would be in sorted order.

To understand the nature of the inversions in the semi-sorted portion, we will use the *Cartesian tree* [17]. Given a list, L, of m numbers with no two equal numbers, the Cartesian tree of L is a binary rooted tree on the numbers where the root is the minimum element $L[k]$, the left subtree of the root is the Cartesian tree of $L[0 : k - 1]$, and the right subtree of the root is the Cartesian tree of $L[k + 1 : m]$. In our analysis, we will primarily consider the Cartesian tree of the simulated final state at time t where $L[k] = \hat{\sigma}_t(k)$ in the frozen-state

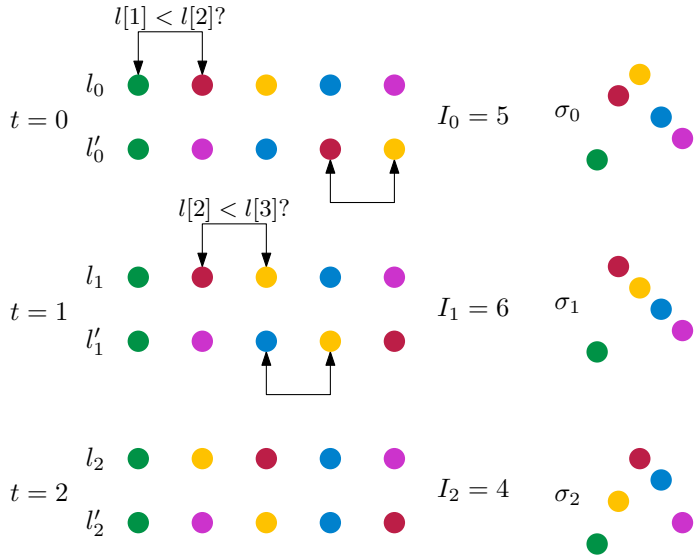

Figure 1 Examples of l, l', I, and σ over two steps of an algorithm. In the first step the green and red elements are compared in l and the red and yellow elements are swapped in l'. In the second step the red and yellow elements are compared and swapped in l and the blue and yellow elements are swapped in l'.

permutation $\hat{\sigma}_t$. We also choose to include two additional elements, $L[-1] = -1$ and $L[n] = n$, for boundary cases.

We call the path from the root to the rightmost leaf of the Cartesian tree the (right-to-left) minima path as the elements on this path are the right-to-left minima in the list. For a minimum, $l[k]$, denote with $M(k)$ the index of the element in the left subtree of $l[k]$ that maximizes $\hat{\sigma}(k)$, i.e., the index of the largest element in the left subtree.

We use the phrase *with high probability* to indicate when an event occurs with probability that tends towards 1 as $n \to \infty$. When an event occurs with probability of the form $1 - e^{-poly(n)}$, we say it occurs with *exponentially high probability*. During our analysis, we will make use of the following facts.

▶ **Lemma 2** (Poisson approximation (Corollary 5.9 in [16])). *Let $X_1^{(m)}, \ldots, X_n^{(m)}$ be the number of balls in each bin when m balls are thrown uniformly at random into n bins. Let $Y_1^{(m)}, \ldots, Y_n^{(m)}$ be independent Poisson random variables with $\lambda = m/n$. Then for any event $\varepsilon(x_1, \ldots, x_n)$:*

$$\Pr\left[\varepsilon\left(X_1^{(m)}, \ldots, X_n^{(m)}\right)\right] \leq e\sqrt{m}\Pr\left[\varepsilon\left(Y_1^{(m)}, \ldots, Y_n^{(m)}\right)\right].$$

▶ **Lemma 3** (Hoeffding's inequality (Theorem 2 in [11])). *If $X_1, \ldots, X_n$ are independent random variables and $a_k \leq X_k \leq b_k$ for $k = 1, \ldots, n$, then for $t > 0$:*

$$\Pr\left[\sum_k X_k - E\left[\sum_k X_k\right] \geq tn\right] \leq e^{-2n^2t^2/(\sum_k (b_k - a_k)^2)}.$$

3 Sorting Evolving Data with Repeated Insertion Sort

Let us begin with some simple bounds with respect to a single round of insertion sort.

▶ **Lemma 4.** *If a round of insertion sort starts at time t_s and finishes at time t_e, then*

1. *$t_e - t_s = F + n - 1$, where F is the number of inversions fixed (at the time of a comparison in the inner **while**-loop) by this round of insertion sort.*
2. *$t_e - t_s < n^2/2$*
3. *for any $t_s \leq t \leq t_e$, $I_t - I_{t_s} < n$.*

Proof. (1): For each iteration of the outer **for**-loop, each comparison in the inner **while**-loop either fixes an inversion (at the time of that comparison) or fails to fix an inversion and completes the inner **while**-loop. Note that this "failed" comparison may not have compared elements of l, but may have short circuited due to $j \leq 0$. Nevertheless, every comparison that doesn't fail fixes an inversion (at the time of that comparison); hence, each non-failing comparison is counted in F.

(2): In any round, there are at most $n(n-1)/2$ comparisons, by the formulations of the outer **for**-loop and inner **while**-loop.

(3): At time t, the round of insertion sort will have executed $t - t_s$ steps. Of those steps, at least $t - t_s - (n-1)$ comparisons resulted in a swap that removed an inversion and at most $n-1$ comparisons did not result in a change to l. The random swaps occurring during these comparisons introduced at most $t - t_s$ inversions. So $I_t - I_{t_s} \leq t - t_s - \big(t - t_s - (n-1)\big) = n - 1$. ◀

We next assert the following two lemmas, which are used in the next section.

▶ **Lemma 5.** *There exists a constant, $0 < \epsilon < 1$, such that, for a round of insertion sort that takes time t^*, at least ϵt^* of the random adjacent swaps in l' decrease I during the round, with exponentially high probability.*

Proof. Proof omitted due to space requirements. ◀

▶ **Lemma 6.** *If a round of insertion sort starts at time t_s with $I_{t_s} \geq (12c^2 + 2c)n$ and finishes at time t_e, then, with exponentially high probability, $t_e - t_s \geq cn$, i.e., the insertion sort round takes at least cn steps.*

Proof. See Section 4. ◀

3.1 Proof of Theorem 1

Armed with the above lemmas (albeit postponing the proofs of Lemma 5 and Lemma 6), let us prove our main theorem.

Theorem 1. *There exists a constant, $0 < \epsilon < 1$, such that, when running the repeated insertion-sort algorithm, for every step $t > (1 + 1/\epsilon)n^2$, the Kendall tau distance between the maintained list, l_t, and the underlying ordered list, l'_t, is $O(n)$, with exponentially high probability.*

Proof. By Lemma 5, there exists a constant $0 < \epsilon < 1$ such that at least an ϵ fraction of all of the random swaps during a round of insertion sort fix inversions. Consider an epoch of the last $(1 + 1/\epsilon)n^2$ steps of the repeated insertion-sort algorithm, that is, from time $t' = t - (1 + 1/\epsilon)n^2$ to t. During this epoch, some number, $m \geq 1$, of complete rounds of insertion sort are performed from start to end (by Lemma 4). Denote with t_k the time at which insertion-sort round k ends (and round $k+1$ begins), and let t_m denote the end time of the final complete round, during this epoch. By construction, observe that $t' \leq t_0$ and

$t_m \leq t$. Furthermore, because the insertion-sort rounds running before t_0 and after t_m take fewer than $n^2/2$ steps (by Lemma 4), $t_m - t_0 \geq n^2/\epsilon$.

The remainder of the proof consists of two parts. In the first part, we show that for some complete round of insertion sort ending at time $t_k \leq t$, I_{t_k} is $O(n)$, with exponentially high probability. In the second part, we show that once we achieve I_{t_k} being $O(n)$, for $t_k \leq t$, then I_t is $O(n)$, with exponentially high probability.

For the first part, suppose, for the sake of a contradiction, $I_{t_k} > \left(12(\frac{1}{\epsilon})^2 + \frac{2}{\epsilon}\right)n$, for all $0 \leq k \leq m$. Then, by a union bound over the polynomial number of rounds, Lemma 6 applies to every such round of insertion sort. So, with exponentially high probability, each round takes at least n/ϵ steps. Moreover, by Lemma 5, with exponential probability, an ϵ fraction of the random swaps from t_m to t_0 will decrease the number of inversions. That is, these random swaps increase the number of inversions by at most

$$(1-\epsilon)(t_m - t_0) - \epsilon(t_m - t_0) = (1-2\epsilon)(t_m - t_0),$$

with exponentially high probability. Furthermore, by Lemma 4, at least a $\frac{(1/\epsilon)-1}{1/\epsilon} = 1-\epsilon$ fraction of the insertion-sort steps fix inversions (at the time of a comparison). Therefore, with exponentially high probability, we have the following:

$$\begin{aligned} I_{t_m} &\leq I_{t_0} - (1-\epsilon)(t_m - t_0) + (1-2\epsilon)(t_m - t_0) \\ &= I_{t_0} - \epsilon(t_m - t_0) \\ &\leq I_{t_0} - n^2. \end{aligned}$$

But, since $I_{t_0} < n^2$, the above bound implies that $I_{t_m} < 0$, which is a contradiction. Therefore, with exponentially high probability, there is a $k \leq m$ such that $I_{t_k} \leq (12(\frac{1}{\epsilon})^2 + \frac{2}{\epsilon})n$.

For the second part, we show that the probability for a round $\ell > k$ to have $I_{t_\ell} > (12(\frac{1}{\epsilon})^2 + \frac{2}{\epsilon} + 1)n$ is exponentially small, by considering two cases (and their implied union-bound argument):

- If $I_{t_{\ell-1}} \leq (12(\frac{1}{\epsilon})^2 + \frac{2}{\epsilon})n$, then Lemma 4 implies $I_{t_\ell} \leq (12(\frac{1}{\epsilon})^2 + \frac{2}{\epsilon} + 1)n$.
- If $(12(\frac{1}{\epsilon})^2 + \frac{2}{\epsilon})n \leq I_{t_{\ell-1}} \leq (12(\frac{1}{\epsilon})^2 + \frac{2}{\epsilon} + 1)n$, then, similar to the argument given above, during a round of insertion sort, ℓ, at least a $1-\epsilon$ fraction of the steps fix an inversion, and an ϵ fraction of the steps do nothing. Also at least an ϵ fraction of the random swaps fix inversions, while a $1-\epsilon$ fraction add inversions. Finally, the total length of the round is $t_\ell - t_{\ell-1}$. Thus, with exponentially high probability, the total change in inversions is at most $-\epsilon(t_\ell - t_{\ell-1})$ and $I_{t_\ell} < I_{t_{\ell-1}}$.

Therefore, by a union bound over the polynomial number of insertion-sort rounds, the probability that any $I_{t_\ell} > (12(\frac{1}{\epsilon})^2 + \frac{2}{\epsilon} + 1)n$ for $k < \ell \leq m$ is exponentially small. By Lemma 4, $I_t \leq I_{t_m} + n$. So, with exponentially high probability, $I_{t_m} \leq (12(\frac{1}{\epsilon})^2 + \frac{2}{\epsilon} + 1)n = O(n)$ and $I_t = O(n)$, completing the proof. ◀

3.2 Improved Convergence Rate

In this subsection, we provide an algorithm that converges to $O(n)$ inversions more quickly. To achieve the steady state of $O(n)$ inversions, repeated insertion sort performs $\Theta(n^2)$ comparisons. But this running time to reach a steady state is a worst-case based on the fact that the running time of insertion sort is $O(n+I)$, where I is the number of initial inversions in the list, and, in the worst case, I is $\Theta(n^2)$. By simply running a round of quicksort on l first, we can achieve a steady state of $O(n)$ inversions after just $\Theta(n \log n)$ comparisons. See Algorithm 2. That is, we have the following.

Algorithm 2 Quicksort followed by repeated insertion sort pseudocode

```
function QUICK_THEN_INSERTION_SORT(l)
    quicksort(l)
    while true do
        for i ← 1 to n − 1 do
            j ← i
            while j > 0 and l[j] < l[j − 1] do
                swap l[j] and l[j − 1]
                j ← j − 1
```

▶ **Theorem 7.** *When running Algorithm 2, for every $t = \Omega(n \log n)$, I_t is $O(n)$ with high probability.*

Proof. By the results of Anagnostopoulos *et al.* [1], the initial round of quicksort takes $\Theta(n \log n)$ comparisons and afterwards the number of inversions (that is, the Kendall tau distance between the maintained list and the true total order) is $O(n \log n)$, with high probability. Using a nearly identical argument to the proof of Theorem 1, and the fact that an insertion-sort round takes $O(I + n)$ time to resolve I inversions, the repeated insertion-sort algorithm will, with high probability, achieve $O(n)$ inversions in an additional $O(n \log n)$ steps. From that point on, it will maintain a Kendall tau distance of $O(n)$, with high probability. ◀

4 Proof of Lemma 6

Recall Lemma 6, which establishes a lower bound for the running time of an insertion-sort round, given a sufficiently large amount of inversions relative to the underlying total order.

Lemma 6. *If a round of insertion sort starts at time t_s with $I_{t_s} \geq (12c^2 + 2c)n$ and finishes at time t_e, then, with exponentially high probability, $t_e - t_s \geq cn$, i.e., the insertion sort round takes at least cn steps.*

The main difficulty in proving Lemma 6 is understanding how the adjacent random swaps in l' affect the runtime of the current round of insertion sort on l. Let S_t be the number of steps left to perform in the current round of insertion sort if there were no more random adjacent swaps in l'. In essence, S can be thought of as an estimate of the remaining time in the current insertion sort round. If a new round of insertion sort is started at time t_s, then $S_{t_s - 1} = 1$ and $I_{t_s} \leq S_{t_s} \leq I_{t_s} + n - 1$. Each step of an insertion sort round decreases S by one and the following random swap may increase or decrease S by some amount. Figure 2 illustrates an example where one random adjacent swap in l' decreases S by a non-constant amount (relative to n).

A random adjacent swap in l' involving two elements in the unsorted portion of l will either increase or decrease S by one depending on whether it introduces or removes an inversion. Random adjacent swaps involving elements in the semi-sorted portion have more complex effects on S.

An inversion currently in the list $\big(l[a], l[b]\big)$ will be fixed by insertion sort if $l[a]$ and $l[b]$ will be compared and the two are swapped. Because $a < b$, $l[b]$ must be the active element during this comparison. An inversion $\big(l[a], l[b]\big)$ will not be fixed by insertion sort if $l[b]$ was already inserted into the semi-sorted portion or there is some element $l[c]$ in the semi-sorted portion with $a < c < b$ and $\sigma(c) < \sigma(b)$. We call an inversion with $l[b]$ in the semi-sorted

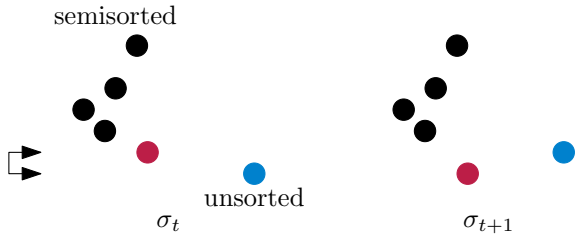

Figure 2 An example where swapping the ordering of the red and blue elements in l' creates multiple blocked inversions between the blue element and the black elements. Recall that our list is partitioned into the semisorted region, which contains elements that have already been compared in this round, and the unsorted region.

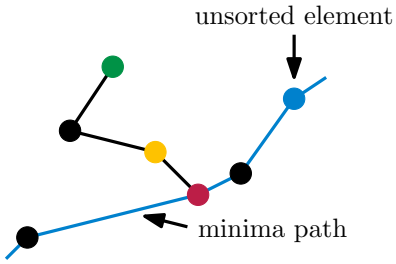

Figure 3 In this Cartesian tree, the green-blue pair is a blocked inversion and the green-yellow pair is a stuck inversion. Both pairs of inversions blame the red element.

portion a *stuck* inversion and an inversion with a smaller semi-sorted element between the pair a *blocked* inversion. We say an element $l[c]$ in the semi-sorted portion of l *blocks* an inversion $\big(l[a], l[b]\big)$ with $a \leq i$ and $l[b]$ either the active element or in the unsorted portion of l, if $l[c]$ is in the semi-sorted portion of l with $a < c < b$ and $\sigma(c) < \sigma(b)$. Note that there may be multiple elements blocking a particular inversion. Figure 3 shows examples of these two types of inversions.

We denote the number of "bad" inversions at time t that will not be fixed with B_t. That is, B_t is the sum of the blocked and stuck inversions. At the end of an insertion-sort round every inversion present at the start was either fixed by the insertion sort, fixed by a random adjacent swap in l', or is currently stuck. No elements can be blocked at the end of an insertion-sort round, because the semi-sorted portion is the entire list. Stuck inversions are either created by random adjacent swaps in l' or were blocked inversions and insertion sort finished inserting the right element of the pair. Blocked inversions are only introduced by the random adjacent swaps in l'. Thus B_t is unaffected by the steps of insertion sort.

Every inversion present at the start must be fixed by a step of insertion sort, be fixed by a random swap, or it will end up "bad". Therefore, for any given time, t, by using naive upper bounds based on the facts that every insertion sort step can fix an inversion and every random adjacent swap can remove an inversion, we can immediately derive the following:

▶ **Lemma 8.** *For an insertion sort round that starts at time t_s and ends at time t_e, if $t_s \leq t \leq t_e$, then $S_t \geq I_{t_s} - 2(t - t_s) - B_t$.*

Since, when an insertion sort round finishes, $S_{t_e - 1} = 1$, Lemma 8 implies $2(t_e - t_s - 1) + B_{t_e} + 1 \geq I_{t_s}$. If we understand how B changes with each random adjacent swap in l', then we can bound how long insertion sort needs to run for this inequality to be true.

We associate the blocked and stuck inversions with elements that we say are *blamed* for the inversions. A blocked inversion $\big(l[a], l[b]\big)$ blames the element $l[c]$ with $a < c < b$ and minimum $\sigma(c)$. Note than $l[c]$ is on the minima path of the modified Cartesian tree, and $l[a]$ is in the left subtree of $l[c]$. A stuck inversion either blames the element on the minima path whose subtree contains both $l[a]$ and $l[b]$ or if they appear in different subtrees, the inversion blames the element $l[c]$ with $a < c < b$ and minimum $\sigma(c)$. Again note that the blamed element is on the minima path and $l[a]$ is in the blamed element's left subtree. The bad inversions in Figure 3 blame the red element.

Whether stuck or blocked, every inversion blames an element on the minima path and the left element of the inverted pair appears in that minimum's subtree. If $l[k]$ is on the minima path, $M(k)$ is the index of the element in $l[k]$'s subtree with maximum $\sigma(M(k))$, and an inversion $\big(l[a], l[b]\big)$ has $l[a]$ in $l[k]$'s subtree, then both $l[a]$ and $l[b]$ are in the range $\sigma(k)$ to $\sigma(M(k))$. So we can upper bound B_t by $\sum_{k=0}^{n-1}(\sigma(M(k)) - \sigma(k))^2$, where we extend M to non-minima indices with $M(k) = k$ if k is not the index of a minima in l.

4.1 Bounding the Number of Blocked and Stuck Inversions with Counters

For the purposes of bounding B_t, we conceptually associate two counters, $Inc(x)$ and $Dec(x)$, with each element, x. The counters are initialized to zero at the start of an insertion sort round. When an element x is increased by a random swap in l', we increment $Inc(x)$ and when x is decreased by a random swap in l', we increment $Dec(x)$. After the random swap occurs, we may choose to exchange some of the counters between pairs of elements, but we will always maintain the following invariant:

Invariant 1. *For an element, $l[k]$, on the minima path,*

$$Inc\big(l[M(k)]\big) + Dec\big(l[k]\big) \geq \sigma\big(M(k)\big) - \sigma(k).$$

This invariant allows us to prove the following Lemma:

▶ **Lemma 9.** *If $\sum_{k=0}^{n-1} Inc\big(l[k]\big)^2 < \kappa$ and $\sum_{k=0}^{n-1} Dec\big(l[k]\big)^2 < \kappa$, then $B_t \leq 4\kappa$.*

Proof.

$$\begin{aligned} B_t &\leq \sum_{k=0}^{n-1} \Big(\sigma(M(k)) - \sigma(k)\Big)^2 \\ &\leq \sum_{k=0}^{n-1} \Big(Inc\big(M(k)\big) + Dec(k)\Big)^2 \qquad \text{By Invariant 1} \qquad (1) \end{aligned}$$

By the assumptions of this lemma, interpreting Inc and Dec as two n-dimensional vectors, we know their lengths are both less than $\sqrt{\kappa}$. Equation 1 is the squared length of the sum of the Dec and Inc vectors with the entries of Inc permuted by the function M. By the triangle inequality, the length of their sum is at most $2\sqrt{\kappa}$ and so the squared length of their sum is at most 4κ.

Therefore, $B_t \leq 4\kappa$. ◀

▶ **Lemma 10.** *There is a counter maintenance strategy that maintains Invariant 1 such that after each random adjacent swap in l', the corresponding counters are incremented and then some counters are exchanged between pairs of elements.*

Proof. Proof omitted due to space requirements. ◀

4.2 Bounding the Counters with Balls and Bins

We model the *Inc* and *Dec* counters each with a balls and bins process and analyze the sum of squares of balls in each bin. Each element in l is associated with one of n bins. When an element's *Inc* counter is increased, throw a ball into the corresponding bin. If a pair of *Inc* counters are exchanged, exchange the set of balls in the two corresponding bins. The *Dec* counters can be modeled similarly.

This process is almost identical to throwing balls into n bins uniformly at random. Note that the exchanging of balls in pairs of bins takes place after a ball has been placed in a chosen bin, effectively permuting two bin labels in between steps. If every bin was equally likely to be hit at each time step, then permuting the bin labels in this way would not change the final sum of squares and the exchanging of counters could be ignored entirely. Unfortunately the bin for the element at $l[n-1]$ in the case of *Inc* counters or $l[0]$ in the case of *Dec* counters cannot be hit, i.e., there is a forbidden bin controlled by the counter swapping strategy. However, even when in each round the forbidden bin is adversarially chosen, the sum of squares of the number of balls in each bin will be stochastically dominated by a strategy of always forbidding the bin with the lowest number of balls. Therefore, the sum of squares of m balls being thrown uniformly at random into $n-1$ bins stochastically dominates the sum of squares of the *Inc* (or *Dec*) counters after m steps.

▶ **Theorem 11.** *If cn balls are each thrown uniformly at random into n bins with $c > e$, then the sum over the bins of the square of the number of balls in each bin is at most $3c^2n$ with exponentially high probability.*

Proof. Let $X_1, \ldots, X_n$ be random variables where X_k is the number of balls in bin k and let $Y_1, \ldots, Y_n$ be independent Poisson random variables with $\lambda = c$.

By the Poisson approximation, Lemma 2,

$$\Pr\left[\sum_k X_k^2 \geq 3c^2n\right] \leq e\sqrt{cn}\Pr\left[\sum_k Y_k^2 \geq 3c^2n\right].$$

Let Z_k be the event that $Y_k \geq ecn^{1/6}$ and Z be the event that at least one Z_k occurs.

$$\Pr[Z] \leq n\Pr[Z_1] \quad \text{by a union bound.}$$

$$\begin{aligned}\Pr[Z_1] &= e^{-c}\sum_{k=ecn^{1/6}}^{\infty}\frac{c^k}{k!} \leq e^{-c}\sum_{k=ecn^{1/6}}^{\infty}\frac{c^k}{e\left(\frac{k}{e}\right)^k}\\ &= e^{-c-1}\sum_{k=ecn^{1/6}}^{\infty}\left(\frac{ec}{k}\right)^k \leq e^{-c-1}\sum_{k=ecn^{1/6}}^{\infty}\left(\frac{1}{n^{1/6}}\right)^k\\ &= e^{-c-1}(n^{1/6})^{-ecn^{1/6}}\sum_{k=0}^{\infty}\frac{1}{n^{1/6}}^k \leq e^{-c}n^{-\frac{ec}{6}n^{1/6}}.\end{aligned}$$

$$\Rightarrow \Pr[Z] \leq \frac{n}{e^c n^{\frac{ec}{6}n^{1/6}}} \leq e^{-\Omega(n^{1/6})}.$$

Letting $Y = \sum_k Y_k^2$:

$$E[Y|\neg Z] \leq E[Y] = nE[Y_1^2] = n\left(c + c^2\right) \leq 2c^2n.$$

Given $\neg Z$, $(Y_k)^2 \in [0, ecn^{1/3}]$. So we can apply Hoeffding's inequality, Lemma 3, to get:

$$\Pr\left[Y - E\left[Y|\neg Z\right] \geq tn|\neg Z\right] \leq e^{-2t^2n^2/\left(n\left(ecn^{1/3}\right)^2\right)}.$$

Setting $t = c^2$, we have:

$$\begin{aligned}\Pr\left[Y - E\left[Y|\neg Z\right] \geq c^2 n|\neg Z\right] &\leq e^{\left(-2c^4n^2\right)/\left(n\left(ecn^{1/3}\right)^2\right)} \\ &\leq e^{-2n^{1/3}}.\end{aligned}$$

Because $E\left[Y|\neg Z\right] \leq 2c^2 n$, we have $\Pr[Y \geq 3c^2 n|\neg Z] \leq e^{-\Omega(n^{1/3})}$.

$$\begin{aligned}\Pr\left[Y \geq 3c^2 n\right] &= \Pr\left[Y \leq 3c^2 n \text{ and } Z\right] + \Pr\left[Y \leq c^2 n \text{ and } \neg Z\right] \\ &\leq \Pr[Z] + \Pr\left[Y \leq 3c^2 n|\neg Z\right] \\ &\leq e^{-\Omega(n^{1/6})} + \Pr[Y - E[Y|\neg Z] \geq c^2 n|\neg Z] \\ &\leq e^{-\Omega(n^{1/6})} + e^{-\Omega(n^{1/3})} \leq 2e^{-\Omega(n^{1/6})}.\end{aligned}$$

Thus, we can conclude $\Pr[\sum_k X_k^2 \geq 3c^2 n] \leq \frac{2e\sqrt{cn}}{e^{\Omega(n^{1/6})}} \leq e^{-\,poly(n)}$. ◀

Recall that by Lemma 8, if an insertion-sort round ends at time t, then $I_{t_s} \leq 2(t - t_s) + B_t + 1$. Theorem 11 and a simple union bound tell us that if $t \leq t_s + cn$, then $\sum_{k=0}^{n-1} Inc\big(l[k]\big)^2 \leq 3c^2(n-1)$ and $\sum_{k=0}^{n-1} Dec\big(l[k]\big)^2 \leq 3c^2(n-1)$ with exponentially high probability. So by Lemma 9, $B_t \leq 12c^2 n$.

Recall that when the insertion sort round finishes, $2(t_e - t_s - 1) + B_{t_e} + 1 \geq I_{t_s}$. If fewer than cn steps have been performed, the left hand side of this inequality is less than $(12c^2+2c)n$ with exponentially high probability. Therefore, if we started with $(12c^2 + 2c)n$ inversions, the current round of insertion sort must perform at least cn steps with exponentially high probability; otherwise, there are unfixed but still "good" inversions. This completes the proof of Lemma 6.

5 Conclusion

We have shown that, although it is much simpler than quicksort and only fixes at most one inversion in each step, repeated insertion sort leads to the asymptotically optimal number of inversions in the evolving data model. We have also shown that by using a single round of quicksort before our repeated insertion sort, we can get to this steady state after an initial phase of $O(n \log n)$ steps, which is also asymptotically optimal.

For future work, it would be interesting to explore whether our results can be composed with other problems involving algorithms for evolving data, where sorting is a subcomponent. In addition, our analysis in this paper is specific to insertion sort, and only applies when exactly one random swap is performed after each comparison. We would like to extend this to other sorting algorithms that have been shown to perform well in practice and to the case in which the number of random swaps per comparison is a larger constant. Finally, it would also be interesting to explore whether one can derive a much better ϵ value than we derived in the proof of Lemma 5.

Abstract

Let H be an arbitrary family of hyper-planes in d-dimensions. We show that the point-location problem for H can be solved by a linear decision tree that only uses a special type of queries called *generalized comparison queries*. These queries correspond to hyperplanes that can be written as a linear combination of two hyperplanes from H; in particular, if all hyperplanes in H are k-sparse then generalized comparisons are $2k$-sparse. The depth of the obtained linear decision tree is polynomial in d and logarithmic in $|H|$, which is comparable to previous results in the literature that use general linear queries.

This extends the study of comparison trees from a previous work by the authors [Kane et al., FOCS 2017]. The main benefit is that using generalized comparison queries allows to overcome limitations that apply for the more restricted type of comparison queries.

Our analysis combines a seminal result of Forster regarding sets in isotropic position [Forster, JCSS 2002], the margin-based inference dimension analysis for comparison queries from [Kane et al., FOCS 2017], and compactness arguments.

1 Introduction

Let $H \subset \mathbb{R}^d$ be a family of $|H| = n$ hyper-planes. H partitions $\mathbb{R}^d$ into $O(n^d)$ cells. The *point-location* problem is to decide, given an input point $x \in \mathbb{R}^d$, to which cell it belongs. That is, to compute the function

$$\mathcal{A}_H(x) := (\text{sign}(\langle x, h\rangle) : h \in H) \in \{-1, 0, 1\}^n.$$

A well-studied computation model for this problem is a *linear decision tree* (LDT): this is a ternary decision tree whose input is $x \in \mathbb{R}^d$ and its internal nodes v make linear/threshold queries of the form $\text{sign}(\langle x, q\rangle)$ for some $q = q(v) \in \mathbb{R}^d$. The three children of v correspond to the three possible outputs of the query : "$-$","0","$+$". The leaves of the tree are labeled with $\{-1, 0, 1\}^n$ with correspondence to the cell in the arrangement that contains x. The complexity of a linear decision tree is its depth, which corresponds to the maximal number of linear queries made on any input.

Comparison queries

A *comparison decision tree* is a special type of an LDT, in which all queries are of one of two types:

- Label query: "sign $(\langle x, h\rangle) = ?$" for $h \in H$.
- Comparison query: "sign $(\langle x, h' - h''\rangle) = ?$" for $h', h'' \in H$.

In [6] it is shown that when H is "nice" then there exist comparison decision trees that computed $\mathcal{A}_H(\cdot)$ and has nearly optimal depth (up to logarithmic factors). For example, for any $H \subset \{-1, 0, 1\}^d$ there is a comparison decision tree with depth $O(d \log d \log|H|)$. This is off by a $\log d$ factor from the basic information theoretical lower bound of $\Omega(d \log|H|)$. Moreover, it is shown there that certain niceness conditions are necessary. Concretely, they give an example of $H \subset \mathbb{R}^3$ such that any comparison decision tree that computes $\mathcal{A}_H(\cdot)$ requires depth $\Omega(|H|)$. This raises the following natural problem: can comparison decision trees be generalized in a way that allows to handle arbitrary point-location problems?

Generalized comparisons

This paper addresses the above question by considering generalized comparison queries. A generalized comparison query allows to re-weight its terms: namely, it is query of the form

"sign $(\langle x, \alpha h' - \beta h''\rangle) =?$"

for $h', h'' \in H$ and some $\alpha, \beta \in \mathbb{R}$. Note that it may be assumed without loss of generality that $|\alpha| + |\beta| = 1$. A generalized comparison decision tree, naturally, is a linear decision tree whose internal linear queries are restricted to be generalized comparisons. Note that generalized comparison queries include as special cases both label queries (setting $\alpha = 1, \beta = 0$) and comparison queries (setting $\alpha = \beta = 1/2$).

Geometrically, generalized comparisons are 1-dimensional in the following sense: let $q = \alpha h' - \beta h''$, with $\alpha, \beta \geq 0$ then q lies on the interval connecting h' and $-h''$. If α and β have different signs, q lies on an interval between some other $\pm h'$ and $\pm h''$. So comparison queries are linear queries that lies on the projective lines intervals spanned by $\{\pm h : h \in H\}$. In particular, if each $h \in H$ has sparsity at most k (namely, at most k nonzero coordinates) then each generalized comparison has sparsity at most $2k$.

Our main result is:

▶ **Theorem 1** (Main theorem). *Let $H \subset \mathbb{R}^d$. Then there exists a generalized comparison decision tree of depth $O(d^4 \log d \log |H|)$ that computes $\mathcal{A}_H(x)$ for every input $x \in \mathbb{R}^d$.*

Why consider generalized comparisons?

We consider generalized comparisons for a number of reasons:

- The lower bound against comparison queries in [6] was achieved by essentially scaling different elements of $H \subset \mathbb{R}^3$ with exponentially different scales. Allowing for re-scaling (which is what generalized comparisons allow to do) solves this problem.
- Generalized comparisons may be natural from a machine learning perspective, in particular in the context of active learning. A common type of queries used in practice it to give a score to an example (say 1-10), and not just label it as positive (+) or negative (-). Comparing the scores for different examples can be viewed as a "coarse" type of generalized comparisons.
- If the set of original hyperplanes H is "nice", then generalized comparisons maintain some aspects of niceness in the queries performed. As an example that was already mentioned, if all hyperplanes in H are k-sparse then generalized comparisons are $2k$-sparse. This is part of a more general line of research, studying what types of "simple queries" are sufficient to obtain efficient active learning algorithms, or equivalently efficient linear decision trees for point-location problems.

1.1 Proof outline

Our proof consists of two parts. First, we focus on the case when $H \subset \mathbb{R}^d$ is in *general position*, namely, every d vectors in it are linearly independent. Then, we extend the construction to arbitrary H. The second part is derived via standard compactness arguments; it is omitted from here and appears in the full version [8]. The technical crux lies in the first part: let $H \subseteq \mathbb{R}^d$ be in general position; we first construct a randomized generalized comparison decision tree for H, and then derandomize it. The randomized tree is simple to describe: it proceeds by steps, where in each step about d^2 elements from H are drawn, labelled, and sorted using generalized comparisons. Then, it is shown that the labels of some $1/d$-fraction of the remaining elements in H are inferred, on average. The inferred vectors are then removed from H and this step is repeated until all labels in H are inferred.

A central technical challenge lies in the analysis of a single step. It hinges on a result by Forster [4] that transforms a general-positioned H to an *isotropic-positioned* H' (see formal definition below) in a way that comparison queries on H' correspond to generalized comparison queries on H. Then, since H' is in isotropic position, it follows that a significant fraction of H' has a large margin with respect to the input x. This allows us to employ a variant of the margin-based inference analysis by [6] on H' to derive the desired inference of some $\Omega(\frac{1}{d})$-fraction of the remaining labels in each step.

1.2 Related work

The point-location problem has been studied since the 1980s, starting from the pioneering work of Meyer auf der Heide [10], Meiser [9], Cardinal et al. [2] and most recently Ezra and Sharir [3]. This last work, although not formally stated as such, solves the point-location problem for an arbitrary $H \subset \mathbb{R}^d$ by a linear decision tree whose depth is $O(d^2 \log d \log |H|)$. However, in order to do so, the linear queries used by the linear decision tree could be arbitrary, even when the original family H is very simple (say 3-sparse). This is true for all previous works, as they are all based on various geometric partitioning ideas, which may

require the use of quite generic hyperplanes. This should be compared with our results (Theorem 1). We obtain a linear decision tree of a bigger depth (by a factor of d^2), however the type of linear queries we use remain relatively simple; e.g., as discussed earlier, they are 1-dimensional and preserve sparseness.

1.3 Open problems

Our work addresses a problem raised in [7], of whether "simple queries" can be sufficient to solve the point-location problem for general hyperplanes H, without making any "niceness" assumptions on H. The solution explored here is to allow for generalized comparisons, which are a 1-dimensional set of allowed queries. An intriguing question is whether this is necessary, or whether there are some 0-dimensional gadgets that would be sufficient.

In order to formally define the problem, we need the notion of *gadgets*. A t-ary gadget in $\mathbb{R}^d$ is a function $g : (\mathbb{R}^d)^t \to \mathbb{R}^d$. Let $G = \{g_1, \ldots, g_r\}$ be a finite collection of gadgets in $\mathbb{R}^d$. Given a set of hyperplanes $H \subset \mathbb{R}^d$, a G-LDT that solves $\mathcal{A}_H(\cdot)$ is a LDT where any linear query is of the form $\text{sign}(\langle q, \cdot \rangle)$ for $q = g(h_1, \ldots, h_t)$ for some $g \in G$ and $h_1, \ldots, h_t \in H$. For example, a comparison decision tree corresponds to the gadgets $g_1(h) = h$ (label queries) and $g_2(h_1, h_2) = h_1 - h_2$ (comparison queries). A generalized comparison decision tree corresponds to the 1-dimensional (infinite) family of gadgets $\{g_\alpha(h_1, h_2) = \alpha h_1 - (1-\alpha)h_2 : \alpha \in [0, 1]\}$. It was shown in [6] that comparison decision trees are sufficient to efficiently solve the point-location problem in 2 dimensions, but not in 3 dimensions. So, the problem is already open in $\mathbb{R}^3$.

▶ **Open problem 1.** *Fix $d \geq 3$. Is there a finite set of gadgets G in $\mathbb{R}^d$, such that for every $H \subset \mathbb{R}^d$ there exists a G-LDT which computes $\mathcal{A}_H(\cdot)$, whose depth is logarithmic in $|H|$? Can one hope to get to the information theoretic lower bound, namely to $O(d \log |H|)$?*

Another open problem is whether randomized LDT can always be derandomized, without losing too much in the depth. To recall, a randomized (zero-error) LDT is a distribution over (deterministic) LDTs which each computes $\mathcal{A}_H(\cdot)$. The measure of complexity for a randomized LDT is the expected number of queries performed, for the worst-case input x. The derandomization technique we apply in this work (see Lemma 16 and its proof for details) loses a factor of d, but it is not clear whether this loss is necessary.

▶ **Open problem 2.** *Let $H \subset \mathbb{R}^d$. Assume that there exists a randomized LDT which computes $\mathcal{A}_H(\cdot)$, whose expected query complexity is at most D for any input. Does there always exist a (deterministic) LDT which computes $\mathcal{A}_H(\cdot)$, whose depth is $O(D)$?*

2 Preliminaries and some basic technical lemmas

2.1 Inferring from comparisons

Let $x, h \in \mathbb{R}^d$ and let $S \subseteq \mathbb{R}^d$.

▶ **Definition 2** (Inference)**.** We say that S infers h at x if $\text{sign}(\langle h, x \rangle)$ is determined by the linear queries $\text{sign}(\langle h', x \rangle)$ for $h' \in S$. That is, if for any point y in the set

$$\left\{ y \in \mathbb{R}^d : \text{sign}(\langle h', y \rangle) = \text{sign}(\langle h', x \rangle) \quad \forall h' \in S \right\}$$

it holds that $\text{sign}(\langle h, y \rangle) = \text{sign}(\langle h, x \rangle)$. Define

$$\mathsf{infer}(S; x) := \{h \in \mathbb{R}^d : h \text{ is inferred from } S \text{ at } x\}.$$

The notion of inference has a natural geometric perspective. Consider the partition of $\mathbb{R}^d$ induced by S. Then, S infers h at x if the cell in this partition that contains x is either disjoint from h or otherwise is contained in h (so in either case, the value of $\text{sign}(\langle h, \cdot \rangle)$ is constant on the cell).

Our algorithms and analysis are based on inferences from comparisons. Let $S - S$ denote the set $\{h' - h'' : h', h'' \in S\}$.

▶ **Definition 3** (Inference by comparisons)**.** We say that *comparisons on* S infer h at x if $S \cup (S - S)$ infers h at x. Define

$$\mathsf{InferComp}(S; x) := \mathsf{infer}\big(S \cup (S - S); x\big).$$

Thus, $\mathsf{InferComp}(S; x)$ is determined by querying $\text{sign}(\langle h', x \rangle)$ and $\text{sign}(\langle h' - h'', x \rangle)$ for all $h', h'' \in S$. Naively, this requires some $O(|S|^2)$ linear queries. However, using efficient sorting algorithm (e.g. merge-sort) achieves it with just $O(|S| \log |S|)$ comparison queries. A further improvement, when $|S| > d$, is obtained by Fredman's sorting algorithm that uses just $O(|S| + d \log |S|)$ comparison queries [5].

2.2 Vectors in isotropic position

Vectors $h_1, \ldots, h_m \in \mathbb{R}^d$ are said to be in *general position* if any d of them are linearly independent. They are said to be in *isotropic position* if for any unit vectors $v \in S^d$,

$$\frac{1}{m} \sum_{i=1}^{m} \langle h_i, v \rangle^2 = \frac{1}{d}.$$

Equivalently, if $\frac{1}{m} \sum h_i h_i^T$ is $\frac{1}{d}$ times the $d \times d$ identity matrix. An important theorem of Forster [4] (see also Barthe [1] for a more general statement) states that any set of vectors in general position can be scaled to be in isotropic position.

▶ **Theorem 4** ([4])**.** *Let $H \subset \mathbb{R}^d$ be a finite set in general position. Then there exists an invertible linear transformation T such that the set*

$$H' := \left\{ \frac{Th}{\|Th\|_2} : h \in H \right\}$$

is in isotropic position. We refer to such a T as a Forster transformation *for H.*

We will also need a relaxed notion of isotropic position. Given vectors $h_1, \ldots, h_m \in \mathbb{R}^d$ and some $0 < c < 1$, we say that the vectors are in *c-approximate isotropic position*, if for all unit vectors $v \in S^d$ it holds that

$$\frac{1}{m} \sum_{i=1}^{m} \langle h_i, v \rangle^2 \geq \frac{c}{d}.$$

We note that this condition is easy to test algorithmically, as it is equivalent to the statement that the smallest eigenvalue of the positive semi-definite $d \times d$ matrix $\frac{1}{m} \sum_{i=1}^{m} h_i h_i^T$ is at least $\frac{c}{d}$.

We summarize it in the following lemma, which follows from basic real linear algebra.

▶ **Claim 5.** *Let $h_1, \ldots, h_m \in \mathbb{R}^d$ be unit vectors. Then the following are equivalent.*

- *$h_1, \ldots, h_m$ are in c-approximate isotropic position.*
- *$\lambda_1 \left(\frac{1}{m} \sum_{i=1}^{m} h_i h_i^T \right) \geq c/d$,*

where $\lambda_1(M)$ denotes the minimal eigenvalue of a positive semidefinite matrix M.

We will need the following basic claims. The first claim shows that a set of unit vectors in an approximate isotropic position has many vectors with non-negligible inner product with any unit vector.

▶ **Claim 6.** *Let $h_1, \ldots, h_m \in \mathbb{R}^d$ be unit vectors in a c-approximate isotropic position, and let $x \in \mathbb{R}^d$ be a unit vector. Then, at least a $\frac{c}{2d}$-fraction of the h_i's satisfy $|\langle h_i, x\rangle| > \sqrt{\frac{c}{2d}}$.*

Proof. Assume otherwise. It follows that

$$\frac{1}{m}\sum_{i=1}^{m}|\langle h, x_i\rangle|^2 \leq \frac{c}{2d}\cdot 1 + \left(1-\frac{c}{2d}\right)\frac{c}{2d} < \frac{c}{2d}+\frac{c}{2d} = \frac{c}{d}.$$

This contradicts the assumption that the h_i's are in c-approximate isotropic position. ◀

The second claim shows that a random subset of a set of unit vectors in an approximate isotropic position is also in approximate isotropic position, with good probability.

▶ **Claim 7.** *Let $h_1, \ldots, h_m$ be unit vectors in c-approximate isotropic position. Let $i_1, \ldots, i_k \in [m]$ be independently and uniformly sampled. Then for any $\delta > 0$, the vectors $h_{i_1}, \ldots, h_{i_k}$ are in $((1-\delta)c)$-approximate isotropic position with probability at least*

$$1 - d\cdot\left[\frac{e^{-\delta}}{(1-\delta)^{1-\delta}}\right]^{ck/d}.$$

Proof. This is an immediate corollary of Matrix Chernoff bounds [11]. By Claim 5 the above event is equivalent to that $\lambda_1\left(\frac{1}{k}\sum_{i=1}^{k} h_i h_i^T\right) \geq (1-\delta)\frac{c}{d}$. By assumption, $\lambda_1\left(\frac{1}{m}\sum_{i=1}^{m} h_i h_i^T\right) \geq \frac{c}{d}$. Now, by the Matrix Chernoff bound, for any $\delta \in [0,1]$ it holds that

$$\Pr\left[\lambda_1\left(\frac{1}{k}\sum_{i=1}^{k} h_i h_i^T\right) \leq (1-\delta)\cdot\frac{c}{d}\right] \leq d\cdot\left[\frac{e^{-\delta}}{(1-\delta)^{1-\delta}}\right]^{ck/d}. \qquad ◀$$

We will use two instantiations of Claim 7: (i) $c \geq 3/4$, and $(1-\delta)c = 1/2$, and (ii) $c = 1$ and $(1-\delta)c = 3/4$. In both cases the bound simplifies to

$$1 - d\cdot\left(\frac{99}{100}\right)^{k/d}. \tag{1}$$

3 Proof of main theorem

Let $H \subset \mathbb{R}^d$. Theorem 1 is proved in three steps.

1. First, we assume that H is in general position. In this case, we construct a randomized generalized comparison LDT which computes $\mathcal{A}_H(\cdot)$, whose expected depth is $O(d^3 \log d \log |H|)$ for any input. This is achieved in Section 3.1, see Lemma 8.
2. Next, we derandomize the construction. This gives for any H in general position a (deterministic) generalized comparison LDT which computes $\mathcal{A}_H(\cdot)$, whose depth is $O(d^4 \log d \log |H|)$. This is achieved in Section 3.2, see Lemma 16.
3. Finally, we handle an arbitrary H (not necessarily in general position), and construct by a compactness argument a generalized comparisons LDT of depth $O(d^4 \log d \log |H|)$ which computes $\mathcal{A}_H(\cdot)$. This step is omitted from this exposition and appears in the full version [8].

3.1 A randomized LDT for H in general position

In this section we construct a randomized generalized comparison LDT for H in general position. Here, by a randomized LDT we mean a distribution over (deterministic) LDT which compute $\mathcal{A}_H(\cdot)$. The corresponding complexity measure is the expected number of queries it makes, for the worst-case input x.

▶ **Lemma 8.** *Let $H \subseteq \mathbb{R}^d$ be a finite set in general position. Then there exists a randomized LDT that computes $\mathcal{A}_H(\cdot)$, which makes $O\left(d^3 \log d \log|H|\right)$ generalized comparison queries on expectation, for any input.*

The proof of Lemma 8 is based on a variant of the margin-based analysis of the inference dimension with respect to comparison queries as in [6] (The analysis in [6] assumed that all vectors have large margin, where here we need to work under the weaker assumption that only a noticeable fraction of the vectors have large margin). The crux of the proof relies on scaling every $h \in H$ by a carefully chosen scalar α_h such that drawing a sufficiently large random subset of H, and sorting the values $\langle \alpha_h h, x\rangle$ using comparison queries (which correspond to generalized comparisons on the h's) allows to infer, on average, at least $\Omega(1/d)$ of the labels of H. The scalars α_h are derived via Forster's theorem (Theorem 4). More specifically, $\alpha_h = \frac{1}{\|Th\|_2}$, where T is a Forster transformation for H.

Randomized generalized-comparisons tree for H in general position

Let $H \subseteq \mathbb{R}^d$ in general position.

Input: $x \in \mathbb{R}^d$, given by oracle access for $\text{sign}(\langle \cdot, x\rangle)$
Output: $\mathcal{A}_H(x) = (\text{sign}(\langle h, x\rangle))_{h\in H}$
(1) Initialize: $H_0 = H$, $i = 0$, $v(h) =?$ for all $h \in H$. Set $k = \Theta(d^2 \log(d))$.
(2) Repeat while $|H_i| \geq k$:
  (2.1) Let T_i be the Forster transformation for H_i. Define $H_i' = \left\{\frac{h}{\|T_i h\|_2} : h \in H_i\right\}$.
  (2.2) Sample uniformly $S_i \subset H_i'$ of size $|S_i| = k$.
  (2.3) Query $\text{sign}(\langle h, x\rangle)$ for $h \in S_i$ (using label queries).
  (2.4) Sort $\langle h, x\rangle$ and $\langle -h, x\rangle$ for $h \in S_i$ (using generalized comparison queries).
  (2.5) For all $h \in H_i$, check if $h \in \mathsf{InferComp}(\pm S_i; x)$, and in case it is, set $v(h) \in \{-, 0, +\}$ to be the inferred value of h.
  (2.6) Remove all $h \in H_i$ for which $\text{sign}(\langle h, x\rangle)$ was inferred, set H_{i+1} to be the resulting set and go to step (2).
(3) Query $\text{sign}(\langle h, x\rangle)$ for all $h \in H_i$, and set $v(h)$ accordingly.
(4) Return v as the value of $\mathcal{A}_H(x)$.

In order to understand the intuition behind the main iteration (2) of the algorithm, define $x' = (T_i^{-1})^{\mathrm{T}} x$ and for each $h \in H_i$ let $h' = \frac{T_i h}{\|T_i h\|}$. Then $\text{sign}(\langle h, x\rangle) = \text{sign}(\langle h', x'\rangle)$, and so it suffices to infer the sign for many $h' \in H_i$ with respect to x'. The main benefit is that we may assume in the analysis that the set of vectors H_i' is in isotropic position; and reduce the analysis to that of using (standard) comparisons on H_i' and x'. These then translate to performing generalized comparison queries on H_i and the original input x. The following lemma captures the analysis of the main iteration of the algorithm. Below, we denote by $\pm S := S \cup (-S)$.

▶ **Lemma 9.** *Let $x \in \mathbb{R}^d$, let $H \subseteq \mathbb{R}^d$ be a finite set of unit vectors in c-approximate isotropic position with $c \geq 3/4$, and let $S \subset H$ be a uniformly chosen subset of size $k = \Omega\left(d^2 \log d\right)$. Then*

$$\mathbb{E}_S\left[\left|\mathsf{InferComp}(\pm S; x) \cap H\right|\right] \geq \frac{|H|}{40d}.$$

Let us first argue how Lemma 8 follows from Lemma 9, and then proceed to prove Lemma 9.

Proof of Lemma 8 given Lemma 9. By Lemma 9, in each iteration (2) of the algorithm, we infer on expectation at least $\Omega(1/d)$ fraction of the $h \in H'_i$ with respect to $x' = T_i^{-1}x$. By the discussion above, this is the same as inferring an $\Omega(1/d)$ fraction of the $h_i \in H_i$ with respect to x. So, the total expected number of iterations needed is $O(d \log |H|)$. Next, we calculate the number of linear queries performed at each iteration. The number of label queries is $O(k)$ and the number of comparison queries on H'_i (which translate to generalized comparison queries on H_i) is $O(k \log k)$ if we use merge-sort, and can be improved to $O(k + d \log k)$ by using Fredman's sorting algorithm [5]. So, in each iteration we perform $O(d^2 \log d)$ queries, and the expected number of iterations is $O(d \log |H|)$. So the expected total number of queries by the algorithm is $O(d^3 \log d \log |H|)$. ◀

From now on, we focus on proving Lemma 9. To this end, we assume from now that $H \subset \mathbb{R}^d$ is in c-isotropic position for $c \geq 3/4$. Note that h is inferred from comparisons on $\pm S$ if and only if $-h$ is, and that replacing an element of S with its negation does not affect $\pm S$. Therefore, negating elements of H does not change the expected number of elements inferred from comparisons on $\pm S$. Therefore, we may assume in the analysis that $\langle h, x \rangle \geq 0$ for all $h \in H$. Under this assumption, we will show that

$$\mathbb{E}_S\left[\left|\mathsf{InferComp}(S; x) \cap H\right|\right] \geq \frac{|H|}{40d}.$$

It is convenient to analyze the following procedure for sampling S:

- Sample $h_1, \ldots h_{k+1}$ random points in H, and $r \in [k+1]$ uniformly at random.
- Set $S = \{h_j : j \in [k+1] \setminus \{r\}\}$.

We will analyze the probability that comparisons on S infer h_r at x. Our proof relies on the following observation.

▶ **Observation 10.** *The probability, according to the above process, that $h_r \in \mathsf{InferComp}(S; x)$ is equal to the expected fraction of $h \in H$ whose label is inferred. That is,*

$$\Pr\left[h_r \in \mathsf{InferComp}(S; x)\right] = \mathbb{E}\left[\frac{\left|\mathsf{InferComp}(S; x) \cap H\right|}{|H|}\right].$$

Thus, it suffices to show that $\Pr\left[h_r \in \mathsf{InferComp}(S; x)\right] \geq 1/40d$. This is achieved by the next two propositions as follows. Proposition 11 shows that S is in a $(1/2)$-approximate isotropic position with probability at least $1/2$, and Proposition 12 shows that whenever S is in $(1/2)$-approximate isotropic position then $h_r \in \mathsf{InferComp}(S; x)$ with probability at least $1/20d$. Combining these two propositions together yields that $\Pr\left[h_r \in \mathsf{InferComp}(S; x)\right] \geq 1/40d$ and finishes the proof of Lemma 9.

▶ **Proposition 11.** *Let $H \subset \mathbb{R}^d$ be a set of unit vectors in c-approximate isotropic position for $c \geq 3/4$. Let $S \subset H$ be a uniformly sampled subset of size $|S| \geq \Omega(d \log d)$. Then S is in $(1/2)$-approximate isotropic position with probability at least $1/2$.*

Proof. The proof follows from Claim 7 by plugging $k = \Omega(d \log d)$ in Equation 1 and calculating that the bound on the right hand side becomes at least $1/2$. ◀

▶ **Proposition 12.** *Let $x \in \mathbb{R}^d$, $S \subset \mathbb{R}^d$ be in (1/2)-approximate isotropic position, where $|S| \geq \Omega\left(d^2 \log d\right)$. Let $h \in S$ be sampled uniformly. Then*

$$\Pr_{h \in S}\left[h \in \mathsf{InferComp}\left(S \setminus \{h\}; x\right)\right] \geq \frac{1}{20d}.$$

Proof. We may assume that x is a unit vector, namely $\|x\|_2 = 1$. Let $s = |S|$ and assume that $S = \{h_1, \ldots, h_s\}$ with

$$\langle h_1, x\rangle \geq \langle h_2, x\rangle \geq \ldots \geq \langle h_s, x\rangle \geq 0.$$

Set $\varepsilon = \frac{1}{2\sqrt{d}}$. As S is in $(1/2)$-approximate isotropic position, Claim 6 gives that $\langle h_i, x\rangle \geq \varepsilon$ for at least $|S|/4d$ many $h_i \in S$. Set $t = |S|/8d$ and define

$$T = \{h_1, \ldots, h_t\},$$

where by out assumption $\langle h_t, x\rangle \geq \varepsilon$. Note that in this case, we can compute T from comparison queries on S. We will show that

$$\Pr_{h \in T}\left[h \in \mathsf{InferComp}\left(S \setminus \{h\}; x\right)\right] \geq \frac{1}{2},$$

from which the proposition follows. This in turn follows by the following two claims, whose proof we present shortly.

▶ **Claim 13.** *Let $h_a \in T$. Assume that there exists a non-negative linear combination v of $\{h_i - h_{i+1} : i = 1, \ldots, a-2\}$ such that*

$$\|h_a - (h_1 + v)\|_2 \leq \varepsilon/4.$$

Then $h_a \in \mathsf{InferComp}\left(S \setminus \{h_a\}; x\right)$.

▶ **Claim 14.** *The assumption in Claim 13 holds for at least half the vectors in T.*

Clearly, Claim 13 and Claim 14 together imply that for at least half of $h_a \in T$, it holds that $h_a \in \mathsf{InferComp}\left(S \setminus \{h_a\}; x\right)$. This concludes the proof of the proposition. ◀

Next we prove Claim 13 and Claim 14.

Proof of Claim 13. Let $S' = S \setminus \{h_a\}$ and $T' = T \setminus \{h_a\}$. As S is in $(1/2)$-approximate isotropic position then S' is in c-approximate isotropic position for $c = 1/2 - d/|S|$. In particular, as $|S| \geq 4d$ we have $c \geq 1/4$. By applying comparison queries to S' we can sort $\{\langle h_i, x\rangle : h_i \in S'\}$. Then T' can be computed as the set of the $t-1$ elements with the largest inner product. Claim 6 applied to S' then implies that $\langle h_i, x\rangle \geq \varepsilon/2$ for all $h_i \in T'$. Crucially, we can deduce this just from the comparison queries on S', together with our initial assumption that S is in $(1/2)$-approximate isotropic position. Thus we deduced from our queries that:

- $\langle h_1, x\rangle \geq \varepsilon/2$.
- $\langle v, x\rangle \geq 0$.

In addition, from our assumption it follows that $|\langle h_a - (h_1 + v), x\rangle| \leq \varepsilon/4$. These together infer that $\langle h_a, x\rangle > 0$. ◀

The proof of Claim 14 follows from the applying the following claim iteratively. We note that this claim appears in [6] implicitly, but we repeat it here for clarity.

▶ **Claim 15.** *Let $h_1, \ldots, h_t \in \mathbb{R}^d$ be unit vectors. For any $\varepsilon > 0$, if $t \geq 16d\ln(2d/\varepsilon)$ then there exist $a \in [t]$ and $\alpha_1, \ldots, \alpha_{a-2} \in \{0,1,2\}$ such that*

$$h_a = h_1 + \sum_{j=1}^{i-2} \alpha_j (h_{j+1} - h_j) + e,$$

where $\|e\|_2 \leq \varepsilon$.

In order to derive Claim 14 from Claim 15, we assume that $|T| \geq 32d\ln((2d)/(\varepsilon/4)) = \Omega(d\log d)$. Then we can apply Claim 15 iteratively $|T|/2$ times with parameter $\varepsilon/4$, at each step identify the required h_a, remove it from T and continue. Next we prove Claim 15.

Proof of Claim 15. Let $\mathbb{B} := \{h \in \mathbb{R}^d : \|h\|_2 \leq 1\}$ denote the Euclidean ball of radius 1, and let C denote the convex hull of $\{h_2 - h_1, \ldots, h_t - h_{t-1}\}$. Observe that $C \subset 2\mathbb{B}$, as each h_i is a unit vector. For $\beta \in \{0,1\}^{t-1}$ define

$$h_\beta = \sum \beta_j (h_{j+1} - h_j).$$

We claim that having $t \geq 16d\ln(2d/\varepsilon)$ guarantees that there exist distinct β', β'' for which

$$h_{\beta'} - h_{\beta''} \in \frac{\varepsilon}{4}(C - C).$$

This follows by a packing argument: if not, then the sets $h_\beta + \frac{\varepsilon}{4}C$ for $\beta \in \{0,1\}^{t-1}$ are mutually disjoint. Each has volume $(\varepsilon/4)^d \mathrm{vol}(C)$, and they are all contained in tC which has volume $t^d \mathrm{vol}(C)$. As the number of distinct β is 2^{t-1} we obtain that $2^{t-1}(\varepsilon/4)^d \leq t^d$, which contradicts our assumption on t.

Let $i \in [t]$ be maximal such that $\beta'_{i-1} \neq \beta''_{i-1}$. We may assume without loss of generality that $\beta'_{i-1} = 0, \beta''_{i-1} = 1$, as otherwise we can swap the roles of β' and β''. Thus we have

$$\sum_{j=1}^{i-1} (\beta'_j - \beta''_j)(h_{j+1} - h_j) \in \frac{\varepsilon}{4}(C - C) \subset \varepsilon\mathbb{B}.$$

Adding $h_i - h_1 = \sum_{j=1}^{i-1}(h_{j+1} - h_j)$ to both sides gives

$$\sum_{j=1}^{i-1} (\beta'_j - \beta''_j + 1)(h_{j+1} - h_j) \in h_i - h_1 + \varepsilon\mathbb{B},$$

which is equivalent to

$$h_i - h_1 \in \sum_{j=1}^{i-1} (\beta'_j - \beta''_j + 1)(h_{j+1} - h_j) + \varepsilon\mathbb{B}.$$

The claim follows by setting $\alpha_j = \beta'_j - \beta''_j + 1$ and noting that by our construction $\alpha_{i-1} = 0$, and hence the sum terminates at $i - 2$. ◀

3.2 A deterministic LDT for H in general position

In this section, we derandomize the algorithm from the previous section.

▶ **Lemma 16.** *Let $H \subseteq \mathbb{R}^d$ be a finite set in general position. Then there exists an LDT that computes $\mathcal{A}_H(\cdot)$ with $O\left(d^4 \log d \log|H|\right)$ generalized comparison queries.*

Note that the this bound is worse by a factor of d than the one in Lemma 8. In Open Question 2 we ask whether this loss is necessary, or whether it can be avoided by a different derandomization technique.

Lemma 16 follows by derandomizing the algorithm from Lemma 8. Recall that Lemma 8 boils down to showing that $h \in \mathsf{InferComp}(S_i; x)$ for an $\Omega(1/d)$ fraction of $h \in H_i$ on average. In other words, for every input vector x, *most of the subsets* $S_i \subseteq H_i'$ of size $\Omega(d^2 \log d)$ allow to infer from comparisons the labels of some $\Omega(1/d)$-fraction of the points in H_i. We derandomize this step by showing that *there exists a universal set* $S_i \subseteq H_i'$ of size $O(d^3 \log d)$ that allows to infer the labels of some $\Omega(1/d)$-fraction of the points in H_i, with respect to *any* x. This is achieved by the next lemma.

▶ **Lemma 17.** *Let $H \subseteq \mathbb{R}^d$ be a set of unit vectors in isotropic position. Then there exists $S \subseteq H$ of size $O(d^3 \log d)$ such that*

$$\left(\forall x \in \mathbb{R}^d\right) : |\mathsf{InferComp}(S; x) \cap H| \geq \frac{|H|}{100d}.$$

Proof. We use a variant of the double-sampling argument due to [12] to show that a random $S \subseteq H$ of size $s = O(d^3 \log d)$ satisfies the requirements. Let $S = \{h_1, \ldots, h_s\}$ be a random (multi-)subset of size s, and let $E = E(S)$ denote the event

$$E(S) := \left[\exists x \in \mathbb{R}^d : |\mathsf{InferComp}(S; x) \cap H| < |H|/100d\right].$$

Our goal is showing that $\Pr[E] < 1$. To this end we introduce an auxiliary event F. Let $t = \Theta(d^2 \log d)$, and let $T = \{h_1, \ldots, h_t\} \subseteq S$ be a subsample of S, where each h_i is drawn uniformly from S and independently of the others. Define $F = F(S, T)$ to be the event

$$F(S,T) := \Big[\exists x \in \mathbb{R}^d : |\mathsf{InferComp}(T; x) \cap H| < |H|/100d \text{ and } |\mathsf{InferComp}(T; x) \cap S| \geq |S|/50d\Big].$$

The following claims conclude the proof of Lemma 17.

▶ **Claim 18.** *If $\Pr[E] \geq 9/10$ then $\Pr[F] \geq 1/200d$.*

▶ **Claim 19.** $\Pr[F] \leq 1/250d$.

This concludes the proof, as it shows that $\Pr[E] < 9/10$. We next move to prove Claim 18 and Claim 19.

Proof of Claim 18. Assume that $\Pr[E] \geq 9/10$. Define another auxiliary event $G = G(S)$ as

$$G(S) := [S \text{ is in } (3/4)\text{-approximate isotropic position}].$$

Applying Claim 7 by plugging $m \geq 100d \ln(10d)$ in Equation 1 gives that $\Pr[G] \geq 9/10$, which implies that $\Pr[E \wedge G] \geq 8/10$. Next, we analyze $\Pr[F|E \wedge G]$.

To this end, fix S such that both $E(S)$ and $G(S)$ hold. That is: S is in $(3/4)$-approximate isotropic position, and there exists $x = x(S) \in \mathbb{R}^d$ such that $|\mathsf{InferComp}(S; x) \cap H| < |H|/100d$.

If we now sample $T \subset S$, in order for $F(S,T)$ to hold, we need that (i) $|\mathsf{InferComp}(T;x) \cap H| < |H|/100d$, which holds with probability one, as $|\mathsf{InferComp}(S;x) \cap H| < |H|/100d$; and (ii) that $|\mathsf{InferComp}(T;x) \cap S| \geq |S|/50d$. So, we analyze this event next.

Applying Lemma 9 to the subsample T with respect to S gives that

$$\mathbb{E}_T\left[|\mathsf{InferComp}(T;x) \cap S|\right] \geq |S|/40d.$$

This then implies that

$$\Pr\left[|\mathsf{InferComp}(T;x) \cap S| \geq |S|/100d\right] \geq 1/100d.$$

To conclude: we proved under the assumptions of the lemma that $\Pr_S[E(S) \wedge G(S)] \geq 8/10$; and that for every S which satisfies $E(S) \wedge G(S)$ it holds that $\Pr_T[F(S,T)|S] \geq 1/100d$. Together these give that $\Pr[F(S,T)] \geq 1/200d$. ◀

Proof of Claim 19. We can model the choice of (S,T) as first sampling $T \subset H$ of size t, and then sampling $S \setminus T \subset H$ of size $s - t$. We will prove the following (stronger) statement: for any choice of T,

$$\Pr\left[F(S,T)|T\right] < 1/250d.$$

So from now on, fix T and consider the random choice of $T' = S \setminus T$. We want to show that:

$$\Pr_{T'}\Big[(\exists x \in \mathbb{R}^d) : |\mathsf{InferComp}(T;x) \cap H| < |H|/100d \text{ and } |\mathsf{InferComp}(T;x) \cap S| \geq |S|/50d.\Big] \leq 1/250d.$$

We would like to prove this statement by applying a union bound over all $x \in \mathbb{R}^d$. However, $\mathbb{R}^d$ is an infinite set and therefore a naive union seems problematic. To this end we introduce a suitable equivalence relation that is based on the following observation.

▶ **Observation 20.** $\mathsf{InferComp}(T;x)$ *is determined by sign*$(\langle h, x\rangle)$ *for* $h \in T \cup (T-T)$.

We thus define an equivalence relation on $\mathbb{R}^d$ where $x \sim y$ if and only if $\text{sign}(\langle h, x\rangle) = \text{sign}(\langle h, y\rangle)$ for all $h \in T \cup (T-T)$. Let C be a set of representatives for this relation. Thus, it suffices to show that

$$\Pr_{T'}\Big[(\exists x \in C) : |\mathsf{InferComp}(T;x) \cap H| < |H|/100d \text{ and } |\mathsf{InferComp}(T;x) \cap S| \geq |S|/50d.\Big] \leq 1/250d.$$

Since C is finite, a union bound is now applicable. Sepcifically, it is enough to show that

$$(\forall x \in C) : \Pr_{T'}\Big[\, |\mathsf{InferComp}(T;x) \cap H| < |H|/100d \text{ and } |\mathsf{InferComp}(T;x) \cap S| \geq |S|/50d.\Big] \leq \frac{1}{250d|C|}.$$

Now, (a variant of) Sauer's Lemma (see e.g. Lemma 2.1 in [7]) implies that

$$|C| \leq \left(2e \cdot |T \cup (T-T)|\right)^d \leq \left(2e \cdot t^2\right)^d \leq (20t)^{2d}. \tag{2}$$

Fix $x \in C$. If $|\mathsf{InferComp}(T;x) \cap H| \geq \frac{|H|}{100d}$ then we are done (note that $\mathsf{InferComp}(T;x)$ is fixed since it depends only on T and x and not on T'). So, we may assume that $|\mathsf{InferComp}(T;x) \cap H| < \frac{|H|}{100d}$. Then we need to bound

$$\Pr\left[|\mathsf{InferComp}(T;x) \cap S| \geq \frac{|S|}{50d}\right] \leq \Pr\left[|\mathsf{InferComp}(T;x) \cap T'| \geq \frac{|T'|}{75d}\right],$$

where the inequality follows if $t \leq \frac{s}{150d}$, which can be satisfied since $t = \Theta(d^2 \log d)$ and $s = \Theta(d^3 \log d)$. To bound this probability we use the Chernoff bound: let $p = \frac{|\mathsf{InferComp}(T;x) \cap H|}{|H|}$; note that $|\mathsf{InferComp}(T;x) \cap T'|$ is distributed like $\mathsf{Bin}(s-t,p)$. By assumption, $p \leq \frac{1}{100d}$, and therefore:

$$\begin{aligned}\Pr\left[|\mathsf{InferComp}(T;x) \cap T'| \geq \frac{|T'|}{75d}\right] &\leq \exp\left(-\frac{(1/3)^2 \cdot (t/100d)}{3}\right) \\ &\leq \frac{1}{250d \cdot (20t)^{2d}} \leq \frac{1}{250d \cdot |C|},\end{aligned}$$

where the second inequality follows because $t = \Theta(d^2 \ln(d))$ with a large enough constant, and the last inequality follows by Equation 3.2. ◀

Abstract

An edge-weighted graph $G = (V, E)$ is called *stable* if the value of a maximum-weight matching equals the value of a maximum-weight *fractional* matching. Stable graphs play an important role in some interesting game theory problems, such as *network bargaining* games and *cooperative matching* games, because they characterize instances which admit stable outcomes. Motivated by this, in the last few years many researchers have investigated the algorithmic problem of turning a given graph into a stable one, via edge- and vertex-removal operations. However, all the algorithmic results developed in the literature so far only hold for *unweighted* instances, i.e., assuming unit weights on the edges of G.

We give the first polynomial-time algorithm to find a minimum cardinality subset of vertices whose removal from G yields a stable graph, for any weighted graph G. The algorithm is combinatorial and exploits new structural properties of basic fractional matchings, which are of independent interest. In particular, one of the main ingredients of our result is the development of a polynomial-time algorithm to compute a basic maximum-weight fractional matching with minimum number of *odd cycles* in its support. This generalizes a fundamental and classical result on unweighted matchings given by Balas more than 30 years ago, which we expect to prove useful beyond this particular application.

In contrast, we show that the problem of finding a minimum cardinality subset of edges whose removal from a weighted graph G yields a stable graph, does not admit any constant-factor approximation algorithm, unless $P = NP$. In this setting, we develop an $O(\Delta)$-approximation algorithm for the problem, where Δ is the maximum degree of a node in G.

1 Introduction

Several interesting game theory problems are defined on networks, where the vertices represent players and the edges model the way players can interact with each other. In many such games, the structure of the underlying graph that describes the interactions among players is essential in determining the existence of stable outcomes for the corresponding games, i.e., outcomes where players have no incentive to deviate. Popular examples are *cooperative matching* games, introduced by Shapley and Shubik [17], and *network bargaining* games, defined by Kleinberg and Tardos [13], both extensively studied in the game theory community. Instances of such games are described by a graph $G = (V, E)$ with edge weights $w \in \mathbb{R}^E_{\geq 0}$, where V represents a set of players, and the value of a *maximum-weight matching*, denoted as $\nu(G)$, is the total value that the players could get by interacting with each other.

An important role in such games is played by so-called *stable* graphs. An edge-weighted graph $G = (V, E)$ is called stable if the value $\nu(G)$ of a maximum-weight matching equals the value of a maximum-weight *fractional* matching, denoted as $\nu_f(G)$. Formally, $\nu_f(G)$ is given by the optimal value of the standard linear programming relaxation of the matching problem, defined as

$$\nu_f(G) := \max \left\{ w^\top x : x(\delta(v)) \leq 1 \; \forall v \in V, x \geq 0 \right\} \tag{P}$$

Here x is a vector in $\mathbb{R}^E$, $\delta(v)$ denotes the set of edges incident to the node v, and for a set $F \subseteq E$, $x(F) = \sum_{e \in F} x_e$. Feasible solutions of the above LP are called *fractional matchings*.

The relation that interplays between stable graphs and network games is as follows. In cooperative matching games [17], the goal is to find an allocation of the value $\nu(G)$ among the vertices, given as a vector $y \in \mathbb{R}^V_{\geq 0}$, such that no subset $S \subseteq V$ has an incentive to form a *coalition* to deviate. This condition is formally defined by the constraints $\sum_{v \in S} y_v \geq \nu(G[S]) \; \forall S \subseteq V$, where $G[S]$ denotes the subgraph induced by S, and an allocation y that satisfies the above set of constraints is called *stable*. Deng et al. [8] proved that a stable allocation exists if and only if the graph describing the game is a stable graph. This is an easy consequence from LP duality. If y is a stable allocation, then y is a feasible solution to the dual of (P) and has value $\nu(G)$, showing that $\nu_f(G) = \nu(G)$. Conversely, if $\nu_f(G) = \nu(G)$, then an optimal dual solution yields a stable allocation of $\nu(G)$.

In network bargaining games [13], each edge e represents a deal of value w_e. A player can enter in a deal with at most one neighbor, and when a deal is made, the players have to agree on how to split the value of the deal between them. An outcome of the game is given by a pair (M, y), where M is a matching of G and stands for the set of deals made by the players, and $y \in \mathbb{R}^V_{\geq 0}$ is an allocation vector representing how the deal values have been split. Kleinberg and Tardos have defined a notion of *stable* outcome for such games, as well as a notion of *balanced* outcome, that are outcomes where players have no incentive to deviate, and in addition the deal values are "fairly" split among players. They proved that a balanced outcome exists if and only if a stable outcome exists, and this happens if and only if the graph G describing the game is stable.

Motivated by the above connection, in the last few years many researchers have investigated the algorithmic problem of turning a given graph into a stable one, by performing a minimum number of modifications on the input graph [6, 1, 10, 7, 14, 4, 5]. Two natural operations which have a nice network game interpretation, are vertex-deletion and edge-deletion. They correspond to *blocking players* and *blocking deals*, respectively, in order to achieve stability in the corresponding games. Formally, a subset of vertices $S \subseteq V$ is called a *vertex-stabilizer* if the graph $G \setminus S := G[V \setminus S]$ is stable. Similarly, a subset of edges $F \subseteq E$

is called an *edge-stabilizer* if the graph $G \setminus F := (V, E \setminus F)$ is stable. The corresponding optimization problems, which are the focus of this paper, are:

Minimum Vertex-stabilizer: *Given an edge-weighted graph $G = (V, E)$, find a minimum-cardinality vertex-stabilizer.*
Minimum Edge-stabilizer: *Given an edge-weighted graph $G = (V, E)$, find a minimum-cardinality edge-stabilizer.*

The above problems have been studied quite intensively in the last few years on unweighted graphs. In particular, Bock et al. [6] have showed that finding a minimum-cardinality edge-stabilizer is hard to approximate within a factor of $(2-\varepsilon)$, assuming Unique Game Conjecture (UGC) [11]. On the positive side, they have given an approximation algorithm for the edge-stabilizer problem, whose approximation factor depends on the sparsity of the input graph G. In other work, Ahmadian et al. [1] and Ito et al. [10] have shown independently that finding a minimum-cardinality vertex-stabilizer is a polynomial-time solvable problem. These (exact and approximate) algorithmic results, developed for unweighted instances, do not easily generalize when dealing with arbitrary edge-weights, since they heavily rely on the structure of maximum matchings in unweighted graphs. In fact, unweighted instances of the above problems exhibit a very nice property, as shown in [6, 1]: the removal of any inclusion-wise minimal edge-stabilizer (resp. vertex-stabilizer) from a graph G *does not decrease* the cardinality of a maximum matching in the resulting graph. This property ensures that there is at least one maximum-cardinality matching that survives in the modified graph, and this insight can be successfully exploited when designing (exact and approximate) algorithms. Unfortunately, it is not difficult to realize that this crucial property does not hold anymore when dealing with edge-weighted graphs, and in fact, the development of algorithmic results for weighted graphs requires substantial new ideas.

Our results and techniques

Vertex-stabilizers. We give the first polynomial-time algorithm to find a minimum-cardinality vertex-stabilizer S, in any weighted graph G. Our algorithm also ensures that $\nu(G \setminus S) \geq \frac{2}{3}\nu(G)$, i.e., the value of a maximum-weight matching is preserved up to a factor of $\frac{2}{3}$, and we show that this factor is tight in general. Specifically, as previously mentioned, a minimum-cardinality vertex-stabilizer for a weighted graph might decrease the value of a maximum-weight matching in the resulting graph. From a network bargaining perspective, this means we are decreasing the total value which the players are able to get, which is of course undesirable. However, we can show this is inevitable, since deciding whether there exists *any* vertex-stabilizer S that preserves the value of a maximum-weight matching (i.e., such that $\nu(G \setminus S) = \nu(G)$) is an NP-complete problem. Furthermore, we give an example of a graph G where *any* vertex-stabilizer S decreases the value of a maximum-weight matching by a factor of essentially $\frac{1}{3}$, i.e. $\nu(G \setminus S) \leq \left(\frac{2}{3} + \varepsilon\right) \nu(G)$ (for an arbitrary small $\varepsilon > 0$). This shows that the bounds of our algorithm are essentially best possible: the algorithm finds a vertex-stabilizer S whose cardinality is the *smallest* possible, and preserves the value of a maximum-weight matching up to a factor of $\frac{2}{3}$, that is the tightest factor that holds for all instances.

The above result is based on two main ingredients. The first one is giving a lower bound on the cardinality of a minimum vertex-stabilizer, which generalizes the lower bound used in the unweighted setting, and is based on the structure of optimal basic solutions of (P). In particular, it was shown in [1] that a lower bound on the cardinality of a vertex-stabilizer for unweighted graphs is given by the minimum number of *odd-cycles* in the support of an optimal

basic solution to (P). We show that this lower bound holds also for weighted graphs, though this generalization is not obvious (in fact, as we will show later, the same generalization does *not* hold for edge-stabilizers). Consequently, our proof is much more involved, and requires different ideas. The second main ingredient is giving a polynomial-time algorithm for computing an optimal basic solution to (P) with the smallest number of odd-cycles in its support, which is of independent interest, as highlighted in the next paragraph.

Computing maximum fractional matchings with minimum cycle support. The fractional matching polytope given by (P) has been extensively studied in the literature, and characterizing instances for which a maximum fractional matching equals an integral one is a natural graph theory question (see [6, 1]). It is well-known that basic solutions of (P) are half-integral, and the support of a basic solution is a disjoint union of a matching (given by 1-valued entries) and a set of odd-cycles (given by half-valued entries). Balas [2] gave a polynomial-time algorithm to compute a basic maximum fractional matching in an unweighted graph, with minimum number of odd-cycles in its support. This is a classical result on matching theory, which has been known for more than 30 years. In this paper, we generalize this result to arbitrary weighted instances, exploiting structural properties of basic fractional matchings. Our algorithm is based on combinatorial techniques, and we expect that this result will prove useful beyond this particular application.

Edge-stabilizers. When dealing with edge-removal operations, the stabilizer problem becomes harder, already in the unweighted setting. It is shown in [6] that finding a minimum edge-stabilizer is as hard as vertex cover, and whether the problem admits a constant factor approximation algorithm is an interesting open question. We here show that the answer to this question is negative for weighted graphs, since we prove that the minimum edge-stabilizer problem for a weighted graph G does not admit any constant-factor approximation algorithm, unless $P = NP$. From an approximation point of view, we show that the algorithm we developed for the vertex-stabilizer problem translates into a $O(\Delta)$-approximation algorithm for the edge-stabilizer problem, where Δ is the maximum degree of a node in G.

Once again, the analysis relies on proving a lower bound on the cardinality of a minimum edge-stabilizer. It was shown in [6] that a lower-bound on the cardinality of a minimum edge-stabilizer for unweighted graphs is again given by the minimum number of odd-cycles in the support of an optimal solution to (P) (called $\gamma(G)$). Interestingly, we show that, differently from the vertex-stabilizer setting, here this lower bound does not generalize, and $\gamma(G)$ *is not* a lower bound on the cardinality of an edge-stabilizer for arbitrary weighted graphs. However, we are able to show that $\lceil \gamma(G)/2 \rceil$ *is* a lower bound on the cardinality of a minimum edge-stabilizer, and this is enough for our approximation purposes.

Additional results. Lastly, we also generalize a result given in [1] on finding a minimum vertex-stabilizer which avoids a fixed maximum matching M, on unweighted graphs. We prove that if M is a maximum-weight matching of a weighted graph G, then finding a minimum vertex-stabilizer that is element-disjoint from M is a polynomial-time solvable problem. Otherwise, if M is not a maximum-weight matching, the problem is at least as hard as vertex cover. We supplement this result with a 2-approximation algorithm for this case, that is best possible assuming UGC [12].

Related work. Biró et al. [4] were the first to consider the edge-stabilizer problem in weighted graphs, and they showed NP-hardness for this case. Stabilizing a graph via different operations on the input graph (other than removing edges/vertices) has also been studied. In

particular, Ito et al. [10] have given polynomial-time algorithms to stabilize an unweighted graph by adding edges and by adding vertices. Chandrasekaran et al. [7] have recently studied the problem of stabilizing unweighted graphs by fractionally increasing edge weights. Ahmadian et al. [1] have also studied the vertex-stabilizer problem on unweighted graphs, but in the more-general setting where there are (non-uniform) costs for removing vertices, and gave approximation algorithms for this case.

Biró et al. [5] and Könemann et al. [14] studied a variant of the problem where the goal is to compute a minimum-cardinality set of *blocking pairs*, that are edges whose removal from the graph yield the existence of a fractional vertex cover of size at most $\nu(G)$ (but note that the resulting graph might not be stable). Mishra et al. [15] studied the problem of converting a graph into a *König-Egerváry graph*, via vertex-deletion and edge-deletion operations. A König-Egerváry graph is a graph where the size of a maximum matching equals the size of an (integral) minimum vertex cover. They gave an $O(\log n \log\log n)$-approximation algorithm for the vertex-removal setting in unweighted graphs, and showed constant-factor hardness of approximation (assuming UGC) for both the minimum vertex-removal and edge-removal problem.

Paper Organization. In Section 2, we give some preliminaries and discuss notation. In Section 3, we give a polynomial-time algorithm to compute an optimal basic solution to (P) with minimum number of odd cycles in its support. This algorithm will be crucially used in Section 4, where we give our results on vertex-stabilizers. The sections on edge-stabilizers and additional results can be found in the full version of this paper. All missing proofs also appear in the full version.

2 Preliminaries and notation

A key concept that we will use is LP duality. The dual of (P) is given by

$$\tau_f(G) := \min\left\{\mathbb{1}^\top y : y_u + y_v \geq w_{uv}\ \forall uv \in E, y \geq 0\right\}. \tag{D}$$

As feasible solutions to (P) are called fractional matchings, we call feasible solutions to (D) *fractional w-vertex covers*. In fact, (D) is the standard LP-relaxation of the problem of finding a minimum w-vertex cover, obtained by adding integrality constraints on (D). We also call basic feasible solutions to (P) as *basic fractional matchings*. An application of duality theory yields the following relationship $\nu(G) \leq \nu_f(G) = \tau_f(G)$. Recall that a graph G is *stable* if $\nu(G) = \nu_f(G) = \tau_f(G)$.

For a vector $x \in \mathbb{R}^E$ and any subset $F \subseteq E$, we denote $x_{-F} \in \mathbb{R}^{E-F}$ as the subvector obtained by dropping the entries corresponding to F. For any multisubset $F \subseteq E$, we define $x(F) := \sum_{e\in F} x_e$. Note that an element may be accounted for multiple times in the sum if it appears more than once in F. We denote $\mathrm{supp}(x) := \{e \in E : x_e \neq 0\}$ as the support of x. For any positive integer k, $[k]$ represents the set $\{1, 2, \ldots, k\}$.

Given an undirected graph G, we denote by n the number of vertices and by m the number of edges. For a matching M in G, a path is called *M-alternating* if its edges alternately belong to M and $E \setminus M$. We say that an M-alternating path is *valid* if it starts with an M-exposed vertex or an edge in M, and ends with an M-exposed vertex or an edge in M. For edge weights $w \in \mathbb{R}^m_+$, a valid M-alternating path P is called *M-augmenting* if $w(P \setminus M) > w(P \cap M)$. We will need the following classical result on the structure of basic fractional matchings:

▶ **Theorem 1** ([3]). *A fractional matching x in $G = (V, E)$ is basic if and only if $x_e = \{0, \frac{1}{2}, 1\}$ for all $e \in E$ and the edges e having $x_e = \frac{1}{2}$ induce vertex-disjoint odd cycles in G.*

Let $\hat{x}$ be a basic fractional matching in G. We partition the support of $\hat{x}$ into two parts. Define

$$\mathcal{C}(\hat{x}) := \{C_1, \ldots, C_q\} \quad \text{and} \quad M(\hat{x}) := \{e \in E : \hat{x}_e = 1\}$$

as the set of odd cycles such that $\hat{x}_e = \frac{1}{2}$ for all $e \in E(C_i)$ and the set of matched edges in $\hat{x}$ respectively. For ease of notation, we use $V(\mathcal{C}(\hat{x})) = \cup_{C \in \mathcal{C}(\hat{x})} V(C)$ and $E(\mathcal{C}(\hat{x})) = \cup_{C \in \mathcal{C}(\hat{x})} E(C)$ to denote the vertex set and edge set of $\mathcal{C}(\hat{x})$ respectively. We define two operations on the entries of $\hat{x}$ associated with certain edge sets of G:

▶ **Definition 2.** By *complementing* on $E' \subseteq E$, we mean replacing $\hat{x}_e$ by $\bar{x}_e = 1 - \hat{x}_e$ for all $e \in E'$.

▶ **Definition 3.** By *alternate rounding* on $C \in \mathcal{C}(\hat{x})$ at v where $C = \{e_1, \ldots, e_{2k+1}\}$ and $v = e_1 \cap e_{2k+1}$, we mean replacing $\hat{x}_e$ by $\bar{x}_e = 0$ for all $e \in \{e_1, e_3, \ldots, e_{2k+1}\}$ and $\bar{x}_e = 1$ for all $e \in \{e_2, e_4, \ldots, e_{2k}\}$. When v is clear from the context, we just say alternate rounding on C.

Let $\mathcal{X}$ be the set of basic maximum-weight fractional matchings in G. Define $\gamma(G) := \min_{\hat{x} \in \mathcal{X}} |\mathcal{C}(\hat{x})|$. Note that G is stable if and only if $\gamma(G) = 0$.

3 Maximum fractional matching with minimum support

In this section, we give a polynomial-time algorithm to compute a basic maximum-weight fractional matching $\hat{x}$ for a weighted graph G with minimum number of odd cycles in its support, i.e., satisfying $|\mathcal{C}(\hat{x})| = \gamma(G)$. This algorithm will be used as a subroutine by our vertex-stabilizer algorithm, which we will develop in Section 4.

Our first step is to characterize basic maximum-weight fractional matchings which have more than $\gamma(G)$ odd cycles. Balas [2] considered this problem on unweighted graphs, and gave the following characterization:

▶ **Theorem 4** ([2]). *Let $\hat{x}$ be a basic maximum fractional matching in an unweighted graph G. If $|\mathcal{C}(\hat{x})| > \gamma(G)$, then there exists an $M(\hat{x})$-alternating path which connects two odd cycles $C_i, C_j \in \mathcal{C}(\hat{x})$. Furthermore, alternate rounding on the odd cycles and complementing on the path produces a basic maximum fractional matching $\bar{x}$ such that $\mathcal{C}(\bar{x}) \subset \mathcal{C}(\hat{x})$.*

We generalize this to weighted graphs. Before stating the theorem, we need to introduce the concept of *connector* (see Figure 1 for some examples):

▶ **Definition 5.** Let C be a cycle and $S_0, S_1, \ldots, S_k$ be a partition of $V(C)$ such that $|S_0|$ is even and $k \geq 2$, where S_0 is allowed to be empty and $S_1, \ldots, S_k$ are non-empty. Let M be a perfect matching on the vertex set S_0. We call the graph $C \cup M$ a *connector*. Each S_i is called a *terminal set* for $i \geq 1$. An edge $e \in M$ is called a *chord* if $e \notin E(C)$.

Connectors are useful because of the following property:

▶ **Lemma 6.** *Let $C \cup M$ be a connector. For every terminal set S_i, there exists an M-alternating path in the connector from a vertex $v \in S_i$ to a vertex $u \in S_j$, for some $j \notin \{0, i\}$.*

Let y be a minimum fractional w-vertex cover in G. We say that an edge uv is *tight* if $y_u + y_v = w_{uv}$. Similarly, we say that a path is tight if all of its edges are tight.

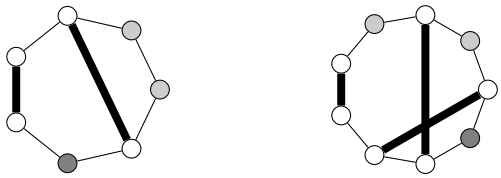

Figure 1 Two examples of connectors. Bold edges indicate M. Vertices of the same color belong to the same terminal set. White vertices are the ones in S_0.

▶ **Theorem 7.** *Let $\hat{x}$ be a basic maximum-weight fractional matching and y be a minimum fractional w-vertex cover in G. If $|\mathcal{C}(\hat{x})| > \gamma(G)$, then there exists*

(i) *a vertex $v \in V(C_i)$ for some odd cycle $C_i \in \mathcal{C}(\hat{x})$ such that $y_v = 0$; or*

(ii) *a tight $M(\hat{x})$-alternating path P which connects two odd cycles $C_i, C_j \in \mathcal{C}(\hat{x})$; or*

(iii) *a tight and valid $M(\hat{x})$-alternating path P which connects an odd cycle $C_i \in \mathcal{C}(\hat{x})$ and a vertex $v \notin V(\mathcal{C}(\hat{x}))$ such that $y_v = 0$.*

Furthermore, alternate rounding on the odd cycles and complementing on the path produces a basic maximum-weight fractional matching $\bar{x}$ such that $\mathcal{C}(\bar{x}) \subset \mathcal{C}(\hat{x})$.

Proof. We will start by proving the second part of the theorem, namely that alternate rounding and complementing produces a basic maximum-weight fractional matching with lesser odd cycles. For Case (i), let $\bar{x}$ be the basic fractional matching obtained by alternate rounding on C_i at v. Since $y_v = 0$, both $\bar{x}$ and y satisfy complementary slackness. Hence, $\bar{x}$ is optimal to (P) and $\mathcal{C}(\bar{x}) = \mathcal{C}(\hat{x}) \setminus C_i$. For Case (ii), denote $u = V(P) \cap V(C_i)$ and $v = V(P) \cap V(C_j)$ as the endpoints of P. Let $\bar{x}$ be the basic fractional matching obtained by alternate rounding on C_i, C_j at u, v respectively and complementing on P. Note that u and v are exposed after the alternate rounding, and covered after complementing. Since $\bar{x}$ and y satisfy complementary slackness, $\bar{x}$ is optimal to (P) and $\mathcal{C}(\bar{x}) = \mathcal{C}(\hat{x}) \setminus \{C_i, C_j\}$. For Case (iii), denote $u = V(P) \cap V(C_i)$ and $v \notin V(\mathcal{C}(\hat{x}))$ as the endpoints of P. Let $\bar{x}$ be the basic fractional matching obtained by alternate rounding on C_i at u and complementing on P. Since $y_v = 0$, both $\bar{x}$ and y satisfy complementary slackness. Thus, $\bar{x}$ is optimal to (P) and $\mathcal{C}(\bar{x}) = \mathcal{C}(\hat{x}) \setminus C_i$.

Next, we prove the first part of the theorem. We may assume $y_v > 0$ for every vertex $v \in V(\mathcal{C}(\hat{x}))$. Let x^* be a basic maximum-weight fractional matching in G such that $|\mathcal{C}(x^*)| = \gamma(G)$. Define $N(\hat{x}) := M(\hat{x}) \setminus E(\mathcal{C}(x^*))$ and $N(x^*) := M(x^*) \setminus E(\mathcal{C}(\hat{x}))$. Consider the following subgraph

$$J = (V, N(\hat{x}) \triangle N(x^*)).$$

Since $N(\hat{x})$ and $N(x^*)$ are matchings in G, J is made up of vertex-disjoint paths and cycles of G. For each such path or cycle, its edges alternately belong to $N(\hat{x})$ or $N(x^*)$. Moreover, its intermediate vertices are disjoint from $\mathcal{C}(\hat{x})$ and $\mathcal{C}(x^*)$. Since $\hat{x}$ and x^* are maximum-weight fractional matchings in G, every path in J is tight by complementary slackness. If there exists a path in J which connects two odd cycles from $\mathcal{C}(\hat{x})$, then we are done. If there exists a path in J which connects an odd cycle from $\mathcal{C}(\hat{x})$ and a vertex $v \notin V(\mathcal{C}(\hat{x}) \cup \mathcal{C}(x^*))$, then $y_v = 0$ because v is either exposed by $M(\hat{x})$ or $M(x^*)$. Hence, we are also done. So we may assume every path in J belongs to one of the following three categories:

(a) Vertex disjoint from $\mathcal{C}(\hat{x})$ and $\mathcal{C}(x^*)$.

(b) Starts and ends at the same cycle of $\mathcal{C}(\hat{x}) \cup \mathcal{C}(x^*)$.

(c) Connects an odd cycle from $\mathcal{C}(\hat{x})$ and an odd cycle from $\mathcal{C}(x^*)$.

Note that by the second part of the theorem, there is no path in J which connects two odd cycles from $\mathcal{C}(x^*)$ or an odd cycle from $\mathcal{C}(x^*)$ and a vertex $v \notin V(\mathcal{C}(\hat{x}) \cup \mathcal{C}(x^*))$. We say that two odd cycles C_i and C_j are *adjacent* if $V(C_i) \cap V(C_j) \neq \emptyset$ or if they are connected by a path in J.

▶ **Claim 1.** *Every cycle in $\mathcal{C}(\hat{x})$ is adjacent to a cycle in $\mathcal{C}(x^*)$.*

Proof. Let C be an odd cycle in $\mathcal{C}(\hat{x})$. For every vertex $v \in V(C)$, since we assumed $y_v > 0$, by complementary slackness it is either $M(x^*)$-covered or belongs to $V(\mathcal{C}(x^*))$. If $v \in V(\mathcal{C}(x^*))$, then we are done. So we may assume that every vertex in C is $M(x^*)$-covered. Let $uv \in M(x^*)$ where $u \in V(C)$ and $v \notin V(C)$. Observe that uv is the first edge of a path in J, so it either ends at an odd cycle in $\mathcal{C}(x^*)$ or C. Since C has an odd number of vertices, by the pigeonhole principle there exists a path in J which connects C and an odd cycle in $\mathcal{C}(x^*)$. ◀

Recall that we assumed no two cycles in $\mathcal{C}(\hat{x})$ are adjacent. We also know that no two cycles in $\mathcal{C}(x^*)$ are adjacent. Since $|\mathcal{C}(\hat{x})| > |\mathcal{C}(x^*)|$, by the previous claim there exists an odd cycle in $\mathcal{C}(x^*)$ which is adjacent to at least two odd cycles in $\mathcal{C}(\hat{x})$. Let $C^* \in \mathcal{C}(x^*)$ be adjacent to $C_1, \ldots, C_k \in \mathcal{C}(\hat{x})$ for some $k \geq 2$. For every $i \in [k]$, define

$$S_i := \{v \in V(C^*) : v \in V(C_i) \text{ or } \exists \text{ a path in } J \text{ from } v \text{ to } C_i\}$$

and $S_0 := V(C^*) \setminus \cup_{i=1}^{k} S_i$. Note that $y_v > 0$ for every vertex $v \in V(C^*)$. Hence, by complementary slackness every vertex in S_0 is $M(\hat{x})$-covered. Let $v \in S_0$. It is either matched to another vertex in S_0 or is an endpoint of a path in J whose other endpoint is also a vertex in S_0. Hence, $|S_0|$ is even. Moreover, $S_i \neq \emptyset$ for all $i \geq 1$, and the sets $S_0, \ldots, S_k$ partition $V(C^*)$. Let $\mathcal{P}$ be the set of paths in J that start and end at C^*, and consider the subgraph $C^* \cup \mathcal{P}$. We claim that there exists an $M(\hat{x})$-alternating path from S_i to S_j in $C^* \cup \mathcal{P}$ where $i \neq j$ and $i, j \neq 0$. Since every path in $\mathcal{P}$ starts and ends with an edge in $M(\hat{x})$, we can perform the following reduction: contract every path in $\mathcal{P}$ into a single edge in $M(\hat{x})$. It is easy to see that an $M(\hat{x})$-alternating path from S_i to S_j in $C^* \cup \mathcal{P}$ corresponds to an $M(\hat{x})$-alternating path from S_i to S_j in the reduced graph. Then, observe that the reduced graph along with the matching $M(\hat{x})$ forms a connector. By Lemma 6, there exists an $M(\hat{x})$-alternating path P from S_i to S_j in $C^* \cup \mathcal{P}$.

Let $v_i \in S_i$ and $v_j \in S_j$ be the endpoints of P. Let P_i and P_j be the paths in J connecting v_i to C_i and v_j to C_j respectively. If $v_i \in V(C_i)$, set $P_i = \emptyset$. Similarly if $v_j \in V(C_j)$, set $P_j = \emptyset$. Then, $P_i \cup P \cup P_j$ forms a tight $M(\hat{x})$-alternating path which connects C_i and C_j. ◀

Given a basic maximum-weight fractional matching $\hat{x}$ in G, we would like to reduce the number of odd cycles in $\mathcal{C}(\hat{x})$ to $\gamma(G)$. One way to accomplish this is to search for the structures described in Theorem 7. Fix a minimum fractional w-vertex cover y in G. Let G' be the unweighted graph obtained by applying the following operations to G (see Figure 2):

1. Delete all non-tight edges.
2. Add a vertex z.
3. For every vertex $v \in V$ where $\hat{x}(\delta(v)) = 1$ and $y_v = 0$, add the edge vz.
4. For every vertex $v \in V$ where $\hat{x}(\delta(v)) = 0$ and $y_v = 0$, add the vertex v' and the edges $vv', v'z$.
5. Shrink every odd cycle $C_i \in \mathcal{C}(\hat{x})$ into a pseudonode i.

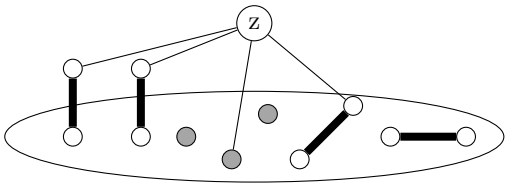

Figure 2 The auxiliary graph G' and the matching M'. Vertices in the ellipse are from the original graph G. Gray vertices represent pseudonodes.

Note that none of the edges in $M(\hat{x})$ and $\mathcal{C}(\hat{x})$ were deleted because they are tight. Consider the edge set $M' := M(\hat{x}) \cup \{vv' : v \in V\}$. It is easy to see that M' is a matching in G'. The significance of the auxiliary graph G' is given by the following lemma:

▶ **Lemma 8.** *M' is a maximum matching in G' if and only if $|\mathcal{C}(\hat{x})| = \gamma(G)$.*

Thus, searching for the structures in Theorem 7 is equivalent to searching for an M'-augmenting path in G'. This immediately gives us the following algorithm.

Algorithm 1: Minimize number of odd cycles.

```
1  Compute a basic maximum-weight fractional matching x̂ in G
2  Compute a minimum fractional w-vertex cover y in G
3  Construct G′ and M′
4  while ∃ an M′-exposed pseudonode r in G′ do
5      Grow an M′-alternating tree T rooted at r using Edmonds' algorithm [9]
6      if an M′-augmenting r-s path P′ is found in G′ then
7          Let P be the corresponding tight M(x̂)-alternating path in G
8          if s is a pseudonode then
9              Alternate round on C_r, C_s and complement on P
10         else
11             Alternate round on C_r and complement on P
12         Update G′ and M′
13     else
14         G′ ← G′ \ V(T)
15 return x̂
```

After an M'-augmenting path P' is found, let $\bar{x}$ denote the new basic maximum-weight fractional matching in G obtained by alternate rounding and complementing $\hat{x}$. We can update G' as follows. If s is a pseudonode, we unshrink C_r and C_s in G' because $\mathcal{C}(\bar{x}) = \mathcal{C}(\hat{x}) \setminus \{C_r, C_s\}$. Otherwise, $s = z$ and we only unshrink C_r. Then, there are two cases. In the first case, we have $vz \in E(P')$ for some $v \in V$. Observe that $\hat{x}(\delta(v)) = 1$ but $\bar{x}(\delta(v)) = 0$. Hence we replace the edge vz with edges $vv', v'z$. In the second case, we have $v'z \in E(P')$ for some $v \in V$. This implies $\hat{x}(\delta(v)) = 0$ but $\bar{x}(\delta(v)) = 1$. So we replace edges $vv', v'z$ with the edge vz.

▶ **Theorem 9.** *Algorithm 1 computes a basic maximum-weight fractional matching with $\gamma(G)$ odd cycles in polynomial time.*

We remark here that in Algorithm 1, we can avoid solving linear programs to obtain $\hat{x}$ and y in Steps 1 and 2. They can be computed using a simple duplication technique by Nemhauser and Trotter [16], which involves solving the problem on a suitable bipartite graph.

4 Computing vertex-stabilizers

The goal of this section is to prove the following theorem:

▶ **Theorem 10.** *There exists a polynomial-time algorithm that computes a minimum vertex-stabilizer S for a weighted graph G. Moreover, $\nu(G \setminus S) \geq \frac{2}{3}\nu(G)$.*

Let us start with discussing a lower bound on the size of a minimum vertex-stabilizer.

Lower bound. We will here prove that $\gamma(G)$ is a lower bound on the number of vertices to remove in order to stabilize a graph. Recall that a graph is stable if and only if $\gamma(G) = 0$. One strategy to achieve this is by showing that $\gamma(G)$ drops by at most 1 when a vertex is deleted (Lemma 12). We first develop a couple of claims.

▶ **Claim 2.** *Let $\hat{x}$ be a basic maximum-weight fractional matching and y be a minimum fractional w-vertex cover in G. Pick a vertex s from any odd cycle $C \in \mathcal{C}(\hat{x})$. If $\bar{x}$ is the fractional matching obtained by alternate rounding on C at s, then $\bar{x}_{-\delta(s)}$ is a basic maximum-weight fractional matching and y_{-s} is a minimum fractional w-vertex cover in $G \setminus s$.*

The following operation allows us to switch between fractional matchings on a set of edges:

▶ **Definition 11.** Let x and x' be fractional matchings in G. By *switching* on $E' \subseteq E$ from x to x', we mean replacing x_e by x'_e for all $e \in E'$.

Switching does not necessarily yield a feasible fractional matching. Hence, we will only use it on the components of a specific subgraph of G:

▶ **Claim 3.** *Given two basic fractional matchings x and x', let H be the subgraph of G induced by* $\operatorname{supp}(x + x')$*. For any component K in H, switching on $E(K)$ from x to x' yields a basic fractional matching in G.*

▶ **Lemma 12.** *For every vertex $v \in V$, $\gamma(G \setminus v) \geq \gamma(G) - 1$.*

Proof. Let x^* be a basic maximum-weight fractional matching in G such that $|\mathcal{C}(x^*)| = \gamma(G)$. Let y be a minimum fractional w-vertex cover in G. For the purpose of contradiction, suppose there exists a vertex $u \in V$ such that $\gamma(G \setminus u) < \gamma(G) - 1$. There are two cases:

Case 1: $u \in V(C)$ for some odd cycle $C \in \mathcal{C}(x^*)$. Let $\bar{x}$ be the fractional matching obtained from x^* by alternate rounding on C at u. By Claim 2, we know that $\bar{x}_{-\delta(u)}$ is a basic maximum-weight fractional matching and y_{-u} is a minimum fractional w-vertex cover in $G \setminus u$. We first give a proof sketch for this case. If $\bar{x}_{-\delta(u)}$ is not an optimal basic solution yielding $\gamma(G \setminus u)$ odd cycles, then one of the structures given by Theorem 7 must exist. This same structure would be a structure corresponding to the basic solution x^*, but this yields a contradiction since x^* is an optimal basic solution with $\gamma(G)$ odd cycles.

For notational convenience, we can use $\mathcal{C}(\bar{x})$ and $M(\bar{x})$ to refer to the odd cycles and matched edges of $\bar{x}_{-\delta(u)}$ respectively because $\mathcal{C}(\bar{x}) = \mathcal{C}\left(\bar{x}_{-\delta(u)}\right)$ and $M(\bar{x}) = M\left(\bar{x}_{-\delta(u)}\right)$. Since $|\mathcal{C}(\bar{x})| = |\mathcal{C}(x^*)| - 1 = \gamma(G) - 1 > \gamma(G \setminus u)$, Theorem 7 tells us that $G \setminus u$ contains one of the following structures. The first structure is a vertex $v \in V(C_i)$ for some odd cycle $C_i \in \mathcal{C}(\bar{x})$ such that $y_v = 0$. However, since $C_i \in \mathcal{C}(x^*)$, by Theorem 7 we arrive at the contradiction $|\mathcal{C}(x^*)| > \gamma(G)$. The second structure is a tight and valid $M(\bar{x})$-alternating path P which connects two odd cycles $C_i, C_j \in \mathcal{C}(\bar{x})$, or an odd cycle $C_i \in \mathcal{C}(\bar{x})$ and a vertex

$v \notin V(\mathcal{C}(\bar{x}))$ such that $y_v = 0$. Note that $C_i, C_j \in \mathcal{C}(x^*)$. If $V(P) \cap V(C) = \emptyset$, then P is also a tight and valid $M(x^*)$-alternating path in G which connects C_i and C_j, or C_i and v. So, let $s = V(C_i) \cap V(P)$ and t denote the first vertex of C encountered while traversing along P from s. Then, the s-t subpath of P is a tight $M(x^*)$-alternating path which connects $C_i, C \in \mathcal{C}(x^*)$. We again obtain the contradiction $|\mathcal{C}(x^*)| > \gamma(G)$ by Theorem 7.

Case 2: $u \notin V(\mathcal{C}(x^*))$. If u is $M(x^*)$-exposed, then $\nu_f(G \setminus u) = \nu_f(G)$ and $\gamma(G \setminus u) = \gamma(G)$. So we may assume u is $M(x^*)$-covered. Let $\hat{x}$ be a basic maximum-weight fractional matching in $G \setminus u$ such that $|\mathcal{C}(\hat{x})| < \gamma(G) - 1$. Define $N(\hat{x}) := M(\hat{x}) \setminus E(\mathcal{C}(x^*))$ and $N(x^*) := M(x^*) \setminus E(\mathcal{C}(\hat{x}))$. Consider the subgraph $J = (V, N(x^*) \triangle N(\hat{x}))$. Note that u is covered by $N(x^*)$ and exposed by $N(\hat{x})$. Let P be the component in J which contains u. We know that P is a path with u as an endpoint. Let v be the other endpoint of P. There are 3 subcases, but before jumping into them, we first give an overview of how we arrive at a contradiction in each subcase. We show that one can move from x^* to a new solution $\tilde{x}$ such that:

- **(i)** $\tilde{x}$ is a basic maximum-weight fractional matching for a subgraph G' obtained by deleting at most 1 vertex from a cycle of $\mathcal{C}(x^*)$; and
- **(ii)** $|\mathcal{C}(\tilde{x})| < \gamma(G')$.

Clearly, both of the above properties cannot hold, so this yields a contradiction.

Subcase 2.1: $v \in C$ for some odd cycle $C \in \mathcal{C}(x^*)$. In this subcase, the path P has even length. Let $\bar{x}$ be the fractional matching obtained from x^* by alternate rounding on C at v. By Claim 2, $\bar{x}_{-\delta(v)}$ is a basic maximum-weight fractional matching in $G \setminus v$. Let H be the subgraph of G induced by $\text{supp}(\hat{x} + \bar{x})$. Note that $\hat{x}_e + \bar{x}_e = 0$ for every edge $e \notin E(P)$ which is incident to a vertex in P. Thus, P is a component in H. Since $|\mathcal{C}(\bar{x})| = \gamma(G) - 1 > |\mathcal{C}(\hat{x})|$, there exists a component K in H which has more odd cycles from $\mathcal{C}(\bar{x})$ than $\mathcal{C}(\hat{x})$. Switching on K from $\bar{x}_{-\delta(v)}$ to $\hat{x}$ yields a basic fractional matching in $G \setminus v$ with less than $\gamma(G) - 1$ odd cycles. To yield a contradiction to Case 1, it is left to show that it is maximum-weight. This is because we are deleting a vertex v from an odd cycle of $\mathcal{C}(x^*)$, but $\gamma(G \setminus v)$ decreases by more than 1. Now, since $\hat{x}$ and $\bar{x}_{-\delta(v)}$ are maximum-weight fractional matchings in $G \setminus u$ and $G \setminus v$ respectively, we have $\sum_{e \in E(K)} w_e \hat{x}_e = \sum_{e \in E(K)} w_e \bar{x}_e$ because $u, v \notin V(K)$. Thus, the resulting matching is indeed maximum-weight in $G \setminus v$.

Subcase 2.2: $v \in C$ for some odd cycle $C \in \mathcal{C}(\hat{x})$. In this subcase, the path P has odd length. Let $\bar{x}$ be the fractional matching obtained from $\hat{x}$ by alternate rounding on C at v. By Claim 2, $\bar{x}_{-\delta(v)}$ is a basic maximum-weight fractional matching in $G \setminus \{u, v\}$. Let H be the subgraph of G induced by $\text{supp}(x^* + \bar{x})$. Note that $x^*_e + \bar{x}_e = 0$ for every edge $e \notin E(P)$ incident to a vertex in P. Thus, P is a component in H. Since $|\mathcal{C}(\bar{x})| = |\mathcal{C}(\hat{x})| - 1 < \gamma(G) - 2 < |\mathcal{C}(x^*)|$, there exists a component K in H which has more odd cycles from $\mathcal{C}(x^*)$ than $\mathcal{C}(\bar{x})$. Switching on K from x^* to $\bar{x}$ yields a basic fractional matching in G with less than $\gamma(G)$ odd cycles. To yield a contradiction, it is left to show that it is maximum-weight. Since x^* and $\bar{x}_{-\delta(v)}$ are maximum-weight fractional matchings in G and $G \setminus \{u, v\}$ respectively, we have $\sum_{e \in E(K)} w_e x^*_e = \sum_{e \in E(K)} w_e \bar{x}_e$ because $u, v \notin V(K)$. Thus, the resulting basic fractional matching is maximum-weight in G.

Subcase 2.3: $v \notin V(\mathcal{C}(x^*) \cup \mathcal{C}(\hat{x}))$. Let H be the subgraph of G induced by $\text{supp}(x^* + \hat{x})$. Note that $x^*_e + \hat{x}_e = 0$ for every edge $e \notin E(P)$ which is incident to a vertex in P. Thus, the path P is a component in H. Since $|\mathcal{C}(x^*)| > \gamma(G) - 1 > |\mathcal{C}(\hat{x})|$, there exists a component K in H which has more odd cycles from $\mathcal{C}(x^*)$ than $\mathcal{C}(\hat{x})$. Switching on K from x^* to $\hat{x}$ yields a basic fractional matching in G with less than $\gamma(G)$ odd cycles. To yield a contradiction, it is left to show that it is maximum-weight. Since x^* and $\hat{x}$ are maximum-weight fractional

matchings in G and $G \setminus u$ respectively, we have $\sum_{e \in E(K)} w_e x^*_e = \sum_{e \in E(K)} w_e \hat{x}_e$ because $u \notin V(K)$. Hence, the resulting basic fractional matching is maximum-weight in G. ◀

As a corollary to the above lemma, we obtain the claimed lower bound.

▶ **Lemma 13.** *For every vertex-stabilizer S of G, $|S| \geq \gamma(G)$.*

The algorithm. The algorithm we use to stabilize a graph is very simple: it computes a basic maximum-weight fractional matching $\hat{x}$ in G with $\gamma(G)$ odd cycles (this can be done using Algorithm 1) and a minimum fractional w-vertex cover y in G, and then removes *one* vertex from every cycle in $\mathcal{C}(\hat{x})$, namely, the vertex with the least y-value in the cycle. Algorithm 2 formalizes this.

Algorithm 2: Minimum vertex-stabilizer

```
Initialize S ← ∅
Compute a minimum fractional w-vertex cover y in G
Compute a basic maximum-weight fractional matching x̂ in G with γ(G) odd cycles
Let 𝒞(x̂) = {C_1, C_2, ..., C_γ(G)}
for i = 1 to γ(G) do
    Let v_i = arg min_{v ∈ V(C_i)} y_v
    S ← S + v_i
return S
```

We are now ready to prove the main theorem stated at the beginning of the section, Theorem 10.

Proof of Theorem 10. Let $S = \{v_1, v_2, \ldots, v_{\gamma(G)}\}$ be the set of vertices returned by the algorithm. Let $\bar{x}$ be the vector obtained from $\hat{x}$ by alternate rounding on C_i at v_i for all i respectively. By Lemma 2, $\bar{x}_{-\bigcup_{i=1}^{\gamma(G)} \delta(v_i)}$ is a basic maximum-weight fractional matching in $G \setminus S$. Note that it is also a maximum-weight integral matching in $G \setminus S$. Thus, $\nu(G \setminus S) = \nu_f(G \setminus S)$ and $G \setminus S$ is stable. Moreover, S is minimum by Lemma 13. It is left to show that $\nu(G \setminus S) \geq \frac{2}{3}\nu(G)$. For every odd cycle $C_i \in \mathcal{C}(\hat{x})$, we have

$$y_{v_i} \leq \frac{y(V(C_i))}{|V(C_i)|} \leq \frac{y(V(C_i))}{3}$$

because v_i has the smallest fractional w-vertex cover in C_i. From Lemma 2, we also know that y_{-S} is a minimum fractional w-vertex cover in $G \setminus S$. Then,

$$\nu(G \setminus S) = \tau_f(G \setminus S) = \mathbb{1}^\top y - \sum_{i=1}^{\gamma(G)} y_{v_i} \geq \mathbb{1}^\top y - \frac{1}{3}\sum_{i=1}^{\gamma(G)} y(C_i) \geq \mathbb{1}^\top y - \frac{1}{3}\mathbb{1}^\top y = \frac{2}{3}\tau_f(G) \geq \frac{2}{3}\nu(G) \blacktriangleleft$$

Note that removing any single vertex from each cycle of $\mathcal{C}(\hat{x})$ yields a minimum-cardinality vertex stabilizer. The reason we chose the vertex with the smallest y_v is to preserve the value of the original maximum-weight matching by a factor of $\frac{2}{3}$.

Tightness of the matching bound. A natural question is whether it is possible to design an algorithm that always returns a vertex-stabilizer S satisfying $\nu(G \setminus S) \geq \alpha\nu(G)$, for some $\alpha > \frac{2}{3}$. We report an example in the full version of this paper showing that, in general, this is not possible since the bound of $\frac{2}{3}$ can be asymptotically tight.

Another natural question is whether one can at least distinguish if, for a specific instance, there exists a vertex-stabilizer S such that $\nu(G \setminus S) = \nu(G)$. Once again, we show that the answer is negative. Specifically, let us call a vertex-stabilizer S *weight-preserving* if

$\nu(G \setminus S) = \nu(G)$. We show that finding such a vertex-stabilizer is hard in general. The proof is based on a reduction from the independent set problem, similar to the one given by Biró et al. [4].

▶ **Theorem 14.** *Deciding whether a graph has a weight-preserving vertex-stabilizer is NP-complete.*

Abstract

We initiate the study of spectral generalizations of the graph isomorphism problem.

(a) The *Spectral Graph Dominance (SGD)* problem:
On input of two graphs G and H does there exist a permutation π such that $G \preceq \pi(H)$?

(b) The *Spectrally Robust Graph Isomorphism (κ-SRGI)* problem:
On input of two graphs G and H, find the smallest number κ over all permutations π such that $\pi(H) \preceq G \preceq \kappa c \pi(H)$ for some c. SRGI is a natural formulation of the network alignment problem that has various applications, most notably in computational biology.

$G \preceq cH$ means that for all vectors x we have $x^T L_G x \leq c x^T L_H x$, where L_G is the Laplacian G.

We prove NP-hardness for SGD. We also present a κ^3-approximation algorithm for SRGI for the case when both G and H are bounded-degree trees. The algorithm runs in polynomial time when κ is a constant.

1 Introduction

Network alignment, a problem loosely defined as the comparison of graphs under permutations, has a very long history of applications in disparate fields [5]. Notably, alignment of protein and other biological networks are among the most recent and popular applications [18, 6]. There are several heuristic algorithms for the problem; naturally some of them are based on generalizations of the graph isomorphism problem, mostly including variants of the robust

graph isomorphism problem which asks for a permutation that minimizes the number of 'mismatched' edges [16].

Robust graph isomorphism may not be always an appropriate problem for applications where one wants to certify the 'functional' equivalence of two graphs. Consider for example the case when G and H are two random constant-degree expanders. While they can be arguably functionally equivalent (e.g. as information dispersers), all permutations will incur a large number of edge mismatches, deeming the two graphs very unsimilar. Functional equivalence is of course an application-dependent notion. In the case of protein networks, it is understood that proteins act as electron carriers [9]. Thus it is reasonable to model them as electrical resistive networks that are algebraically captured by graph Laplacian matrices [4]. Going back to the graph isomorphism problem, we note the simple fact that the Laplacian matrices of two isomorphic graphs share the same eigenvalues, with the corresponding eigenspaces being identical up to the isomorphism. We can them aim for a **spectrally robust** version of graph isomorphism (SRGI) which allows for similar eigenvalues and approximately aligned eigenspaces, up to a permutation.

In lieu of using directly the eigenvalues and eigenspaces to define SRGI, we will rely on the much cleaner notion of spectral graph similarity, which underlies spectral sparsification of graphs, a notion that has been proven extremely fruitful in algorithm design [2, 14]. More concretely, let us introduce the precise notion of similarity we will be using.

▶ **Definition 1** (dominance)**.** We say that graph G dominates graph H ($G \preceq H$), when for all vectors x, we have $x^T L_G x \leq x^T L_H x$, where L_G is the standard Laplacian matrix for G.

▶ **Definition 2** (κ-similarity)**.** We say that graphs G and H are κ-similar, when when there exist numbers β and γ, such that $\kappa = \gamma/\beta$ and $\beta H \preceq G \leq \gamma H$.[3]

We are now ready to introduce our main problem.

Spectrally Robust Graph Isomorphism (κ-SRGI): Given two graphs G, H, does there exist a permutation π on $V(G)$ such that G and $\pi(H)$ are κ-similar?

It can been shown that this definition does imply approximately equal eigenvalues and aligned eigenspaces [13], thus testing for κ-similarity under permutations is indeed a spectrally robust version of graph isomorphism. Going back to our example with the two random expanders, it is well-understood that G and $\pi(H)$ will be κ-similar for a constant κ and for all permutations π, which is what we intuitively expect.

We view spectrally robust graph isomorphism as an interesting theoretical problem due to its close relationship with other fundamental algorithmic questions. In particular, it can be easily seen that κ-SRGI is equivalent to the graph isomorphism problem when $\kappa = 1$. As we will discuss in more detail, SRGI can also be viewed as a natural generalization of the minimum distortion problem [10]. Up to our knowledge, the spectral-similarity approach to network alignment has been mentioned earlier only in [20]. In view of the vast number of works on GI ([11, 7, 21, 19, 3, 15, 1] to mention a few) as well as the works on the robust graph isomorphism problem [16] and the minimum distortion problem [10], we find it surprising that SRGI has not received a wider attention.

The goal of this work is to prove some initial results on SRGI and stimulate further research. Towards that end, we provide the first algorithm for this problem, for the case when both graphs are trees.

[3] Graphs are weighted and cG is graph G with its edge weights multiplied by c.

▶ **Theorem 3.** *Given two κ-similar trees G and H of maximum degree d, there exists an algorithm running in time $O(n^{O(k^2 d)})$ which finds a mapping certifying that the they are at most κ^4-similar.*

The algorithm for trees is already highly involved, which gives grounds for speculating that the problem is NP-hard. We give evidence that this may be indeed true by turning our attention to the one-sided version of the problem.

Spectral Graph Dominance (SGD): Given two graphs G, H, does there exist a permutation π such that G dominates $\pi(H)$?

Given two graphs G and H that have the same eigenvalues, it is not hard to prove that if G and H are not isomorphic, then G cannot dominate H (and vice-versa). Combining this with the fact that isomorphic graphs have the same eigenvalues, we infer that SGD is at least graph isomorphism-hard. The second contribution of this work is the following theorem.

▶ **Theorem 4.** *The* Spectral Graph Dominance *problem is NP-hard.*

Theorem 4 is proved in Section 2. We can actually prove a slightly stronger theorem that restricts one of the input graphs to be a tree.

1.1 Related Work

The Robust Graph Isomorphism problem (RGI) asks for a permutation that minimizes the number of mismatched edges. O'Donnell *et al.* [16] gave a constant factor hardness for RGI . The Minimum Distortion problem (MD) views graphs as distance metrics, using the shortest path metric. The goal is to find a mapping between the two metrics so as to minimize the maximum distortion. The connection between SRGI and MD stems from the observation that if two tree graphs G and H are κ-similar up to a permutation π, then the distortion between the induced graph distances of G and $\pi(H)$ is at most κ. For the MD problem, Kenyon *et al.* [10] gave an algorithm which finds a solution with distortion at most α (provided that it exists) in time $\text{poly}(n)\exp(d^{O(\alpha^3)})$, for a tree of degree at most g and an arbitrary weighted graph. They also prove that this problem is NP-hard to approximate within a constant factor.

The term 'spectral alignment' has been used before in [6] in the context of spectral relaxation of the graph matching function. The algorithm in [18] is more spectral 'in spirit' because it uses directly the spectral of the normalized Laplacians of several subgraphs to construct complicated 'graph signatures' that are then compared for similarity. There is no underlying objective function that drives the computation of these signatures, but we imagine that the proposed algorithm or some variant of it, may be a reasonably good practical candidate for SRGI. The work by Tsourakakis [20] proposes an algorithm that searches for the optimal permutation via a sequence of transpositions; however the running time of the algorithm does not have any non-trivial sub-exponential upper bound.

2 Graph Dominance

Preliminaries. Given a weighted graph $G = (V, E, w)$ we denote by E_G its edges. The Laplacian L_G of G is the matrix defined by $L(i,j) = -w_{ij}$ and $L(i,i) = \sum_{i \neq j} w_{ij}$. The quadratic form $\mathcal{R}(G, x)$ of G is the function defined as:

$$\mathcal{R}(G, x) = x^T L_G x = \sum_{i,j} w_{ij}(x_i - x_j)^2. \tag{1}$$

Let G^∞ be the infinite graph with vertex set equal to all points on the plane with integer coordinates. There is an edge between two points of G^∞ if they have Euclidean distance one. A *cubic subgrid* is a finite subgraph of G^∞ such that all of its nodes have degree at most 3.

The main ingredient of the proof is the following theorem.

▶ **Theorem 5.** *Let G be a cubic subgrid and C be the cycle graph, both on n vertices. There exists a permutation π such that $\pi(C) \preceq G$ if and only if G contains a Hamiltonian cycle.*

Proof. If G contains a Hamiltonian cycle $\pi(C)$, then equation 1 directly implies that $\pi(C) \preceq G$. To prove the converse assume that G does not contain a Hamiltonian cycle and let H be a permutation of C such that $|E_G \cap E_H|$ is maximized. We prove a number of claims and lemmas.

▶ **Claim 1.** *Let G', H' be the graphs obtained by deleting the common edges between G and H respectively. Then, $\mathcal{R}(G,x) < \mathcal{R}(H,x)$ if and only if $\mathcal{R}(G',x) < \mathcal{R}(H',x)$.*

Proof. Let F be the graph induced by the edges shared by G and H. By equation 1 we have $\mathcal{R}(G,x) = \mathcal{R}(G',x) + \mathcal{R}(F,x)$ and $\mathcal{R}(H,x) = \mathcal{R}(H',x) + \mathcal{R}(F,x)$. The claim follows. ◀

▶ **Claim 2.** *Let v be a vertex with $deg_{G'}(v) = 1$, $deg_{H'}(v) = 0$ and let G'' be the graph obtained from G' after deleting the edge incident to v, and set $H'' = H'$. Then, there exists a vector x s.t. $\mathcal{R}(H',x) > \mathcal{R}(G',x)$ iff there exists a vector y s.t. $\mathcal{R}(H'',y) > \mathcal{R}(G'',y)$.*

Proof. Let x be a vector such that $\mathcal{R}(H',x) > \mathcal{R}(G',x)$. Since G'' is a subgraph of G', we have $\mathcal{R}(G'',x) \leq \mathcal{R}(G',x) < \mathcal{R}(H',x) = \mathcal{R}(H'',x)$, and we can take $y = x$. For the converse, assume that there is a vector y such that $\mathcal{R}(H'',y) > \mathcal{R}(G'',y)$. Let (v,w) be the edge incident to v in G'. We define a vector x as follows: $x_u = y_u$ for all $u \neq v$ and $x_v = y_w$. Since, $deg_{H''}(v) = 0$, we have $\mathcal{R}(H'',y) = \mathcal{R}(H'',x)$. On the other hand, G' and G'' agree on all the edges except (v,w). Hence, $\mathcal{R}(G',x) = \mathcal{R}(G'',x) + (x_v - x_w)^2 = \mathcal{R}(G'',x)$. The two vectors x and y agree on all the entries except at v, and the degree of v in G'' is zero. Hence, $\mathcal{R}(G'',x) = \mathcal{R}(G'',y)$. Combining all the inequalities, we get:
$\mathcal{R}(G',x) = \mathcal{R}(G'',x) = \mathcal{R}(G'',x) < \mathcal{R}(H'',y) = \mathcal{R}(H'',x) = \mathcal{R}(H',x)$. ◀

▶ **Claim 3.** *Let G' and H' be the graphs obtained by deleting the shared edges between G and H as in Claim 1. Let $\tilde{G}$ and $\tilde{H}$ be the graphs obtained starting from G' and H' and repeatedly applying the edge deletion operation of Claim 2. Then, for any vertex u, $deg_{\tilde{G}}(u) \leq deg_{\tilde{H}}(u) + 1$.*

Proof. Since G is a cubic subgrid graph and H is a cycle, $deg_G(u) \leq 3$, $deg_H(u) = 2$, for all vertices u. Deleting edges shared between G and H decreases the degree of any given vertex by the same amount in G and H. Moreover, at any given step, we only delete edges from G'. Hence, $deg_{\tilde{G}}(u) \leq deg_{\tilde{H}}(u) + 1$. ◀

▶ **Claim 4.** *Let G' and H' be the graphs obtained by deleting the shared edges between G and H as in Claim 1. If there exists a vertex v such that $deg_{G'}(v) = 1, deg_{H'}(v) \geq 1$. Then, there exists a vector x such that $\mathcal{R}(H',x) > \mathcal{R}(G',x)$.*

Proof. Let the edge incident to v in G' be (v,w) and an edge incident to v in H' be (v,u). Since, H' and G' do not share any edge, we have $u \neq w$. Let $x \in \mathbb{R}^n$ be a vector defined as follows: $x_v = 0, x_w = \frac{1}{2}$ and $x_t = 1$ otherwise. We have $\mathcal{R}(H',x) > (x_v - x_u)^2 = 1$, and

$$\mathcal{R}(G',x) = (x_v - x_w)^2 + \sum_{(w,a)\in E'_G, a\neq v} (x_w - x_a)^2$$

Vertex w has at most two neighbors other than v in G, since $deg_{G'}(v) \leq 3$ and for any such neighbor a, we have $(x_a - x_w)^2 = (\frac{1}{2} - 1)^2 = 1/4$. Hence $\mathcal{R}(G', x) \leq 3/4 < 1 \leq \mathcal{R}(H', x)$. ◀

Let G' and H' be the graphs obtained by deleting the shared edges between G and H as in Claim 1. Claims 3 and 4 allow us to assume without loss of generality that there is no degree one vertex in G' and for all vertices u, $deg_{G'}(u) \leq deg_{H'}(u) + 1$. For convenience, we will refer to the edges of G' as **black edges** and edges of H' as **blue edges**.

▶ **Lemma 6.** *If there exist five vertices u, v, w_1, w_2, w_3 such that*
- *$(u, w_1), (w_1, w_2), (w_2, w_3)$ are black edges and $(v, w_1), (v, w_2)$ are **not** black edges.*
- *(u, v) is a blue edge and (u, w_2) is **not** a blue edge.*

Then, there exists a vector x such that $\mathcal{R}(H', x) > \mathcal{R}(G', x)$.

Proof. Let x be the vector with $x_u = 0$, x_v=2, $x_{w_1} = \frac{1}{3}$ and $x_{w_2} = \frac{2}{3}$, and $x_t = 1$ otherwise. We have

$$\begin{aligned}
\mathcal{R}(H', x) &\geq (x_u - x_v)^2 + \sum_{\substack{(u,a)\in E_{H'} \\ a \neq v}} (x_u - x_a)^2 + \sum_{\substack{(v,b)\in E_{H'} \\ b \neq u}} (x_v - x_b)^2 \\
&= 4 + (deg_{H'}(u) - 1) \cdot (0 - 1)^2 + (deg_{H'}(v) - 1) \cdot (2 - 1)^2 \\
&= deg_{H'}(u) + deg_{H'}(v) + 2 \geq deg_{G'}(u) + deg_{G'}(v) \qquad \text{(Claim 3)}
\end{aligned}$$

and

$$\begin{aligned}
\mathcal{R}(G', x) &= (x_u - x_{w_1})^2 + (x_{w_1} - x_{w_2})^2 + (x_{w_2} - x_{w_3})^2 + \sum_{\substack{(u,a)\in E_{G'} \\ a \neq w_1}} (x_u - x_a)^2 \\
&\quad + \sum_{\substack{(w_1,c)\in E_{G'} \\ c \neq w_2, u}} (x_{w_1} - x_c)^2 + \sum_{(v,b)\in E_{G'}} (x_v - x_b)^2 + \sum_{\substack{(w_2,d)\in E_{G'} \\ d \neq w_1, w_3}} (x_{w_2} - x_d)^2.
\end{aligned}$$

We observe that **(i)** The first three terms are equal to $\frac{1}{9}$. **(ii)** There is at most one edge (w_1, c) for $c \neq w_2, u$. Also, since w_1 is not incident to v, we have $x_c = 1$. Thus the fifth term is at most $\frac{4}{9}$. **(iii)** There is at most one edge (w_2, d) for $d \neq w_1, w_3$. In addition, G' is a subgrid, so there is no cycle of length 3 and w_2 is not incident to u. Also, w_2 is not incident to v, by assumption. So, it must be that $x_d = 1$ and the last term is at most equal to $\frac{1}{9}$. **(iv)** Since G' and H' do not share an edge, u is not connected to v. By assumption u is also not incident to w_2. So, it must be that $x_a = 1$ and the fourth term is equal to $deg_{G'}(u) - 1$. **(v)** Vertex v is not connected to u, w_1, w_2. Thus it must be $x_b = 1$ and the sixth term is equal to $deg_{G'}(v)$. Collecting the terms gives $\mathcal{R}(G, x) \leq deg_{G'}(u) + deg_{G'}(v) - \frac{1}{9}$ and the Lemma follows. ◀

▶ **Lemma 7.** *If there exist four different vertices u, v, w_1, w_2 such that*
- *w_1 has only two black adjacent edges (u, w_1) and (w_1, w_2)*
- *(u, v) is a blue edge.*

Then, there exists a vector x such that $\mathcal{R}(H', x) > \mathcal{R}(G', x)$.

Proof. Let x be a vector with $x_u = 0, x_v = 2, x_{w_1} = \frac{1}{2}$ and $x_t = 1$ otherwise. We have

$$\begin{aligned}
\mathcal{R}(H', x) &\geq (x_u - x_v)^2 + \sum_{\substack{(u,a)\in E_{H'} \\ a \neq v}} (x_u - x_a)^2 + \sum_{\substack{(v,b)\in E_{H'} \\ b \neq u}} (x_v - x_b)^2 \\
&= 4 + (deg_{H'}(u) - 1) \cdot (0 - 1)^2 + (deg_{H'}(v) - 1) \cdot (2 - 1)^2 \qquad \text{(no shared edges)} \\
&= deg_{H'}(u) + deg_{H'}(v) + 2 \geq deg_{G'}(u) + deg_{G'}(v) \qquad \text{(Claim 3)}
\end{aligned}$$

and

$$\mathcal{R}(G',x) = (x_u - x_{w_1})^2 + (x_{w_1} - x_{w_2})^2 + \sum_{\substack{(u,a)\in E_{G'} \\ a\neq w_1}} (x_u - x_a)^2 + \sum_{(v,b)\in E_{G'}} (x_v - x_b)^2$$

Since G' and H' do not share an edge, $(x_u - x_a)^2$ and $(x_v - x_b)^2$ terms are $(0-1)^2$ and $(2-1)^2$ respectively. We have

$$\mathcal{R}(G',x) = \frac{1}{4} + \frac{1}{4} + (deg_{G'}(u) - 1)\cdot 1 + deg_{G'}(v)\cdot 1 = deg_{G'}(u) + deg_{G'}(v) - \frac{1}{2}.$$

The Lemma follows. ◀

▶ **Lemma 8.** *If there exists a degree three vertex in G', then there exists a vector x such that $\mathcal{R}(H',x) > \mathcal{R}(G',x)$.*

Proof. Since $deg_{G'}(u) = 3, deg_{H'}(u) \geq 2$ by claim 3. Consider the underlying grid of which G is a subgraph. Pick the edge $(u,v) \in E_{H'}$ which is either not axis-parallel or is axis-parallel and v is at distance at least 2 in the grid. Since u has degree 3 in G', there exists a neighbor w_1 of u in G' such that any path from w_1 to v in G' has length at least 3.

If w_1 has degree 2 in G', then we set w_2 to be the neighbor of w_1 other than u. It is then straightforward to check that u, v, w_1, w_2 satisfy the condition of Lemma 7. Hence, there exists x such that $\mathcal{R}(H',x) > \mathcal{R}(G',x)$.

If w_1 is not of degree 2 in G', it must have degree 3 since there are no degree 1 vertices in G'. Let w_2 be the neighbor of w_1 other than u such that $(u,w_2) \notin E'_H$. Such a neighbor exists since u has at most one neighbor in H' other than v and v is not incident to w_1 due to the fact that any path of length from w_1 to v has length at least 3. Let w_3 be the neighbor of w_2 other than w_1. Such a neighbor must exist since there is no vertex of degree 1 in G'. Now, we prove that these vertices satisfy the condition of Lemma 6. By construction $(u,w_1),(w_1,w_2),(w_2,w_3)$ are black eges. Any path from w_1 to v in G' has length at least 3 which implies that $(w_1,v),(w_2,v)$ are not black edges. Also, by construction, (u,v) is a blue edge and (u,w_2) is not a blue edge. Hence, by lemma 6 there exists x such that $\mathcal{R}(H',x) > \mathcal{R}(G',x)$. ◀

▶ **Lemma 9.** *If there exists a set S of vertices such that no edges leave S in G', but at least one edge leaves S in H' then then there exists a vector $x \in \mathbb{R}^n$ such that $\mathcal{R}(H',x) > \mathcal{R}(G',x)$.*

Proof. Let x be defined as follows: $x_u = 1$ for $u \in S$ and $x_u = 0$ for $u \notin S$. The $\mathcal{R}(G',x)$ is equal to the number of edges leaving S in G', and similarly for H'. The lemma follows. ◀

▶ **Lemma 10.** *If there exists a cycle of length more than 4 in G' such that all vertices of cycle have degree 2 in G', then there exists $x \in \mathbb{R}^n$ such that $\mathcal{R}(H',x) > \mathcal{R}(G',x)$.*

Proof. Let C be the set of vertices in the cycle. For any vertex v in C, $deg_{G'}(v) = 2$. By claim 3, $deg_{H'}(v) \geq 1$. If there is no blue edge connecting two vertices of C in G', then there are at least $|C|$ edges going out of C in H' and no edge going out of C in G'. Then, by lemma 9, there exists x such that $\mathcal{R}(H',x) > \mathcal{R}(G',x)$.

In the complementary case, suppose there is an edge $(a,b) \in E_{H'}$ such that $a, b \in C$. Let the two paths from a to b on C be $P_1 = a, w_1, \ldots, w_{k_1}, b$ and $P_2 = a, v_1, \ldots, v_{k_2}, b$. Since G' and H' do not share any edge, $\min(k_1,k_2) \geq 1$. And since the cycle has length at least 5, $\max(k_1,k_2) \geq 2$. Let a vector x be defined as follows: $x_a = 0, x_b = 1, x_{w_i} = \frac{i}{k_1+1}, x_{v_i} = \frac{i}{k_2+1}$ and for $u \notin C$, set $x_u = 0$. We have

$$\begin{aligned}\mathcal{R}(G',x) &= \sum_{(u,v)\in P_1}(x_u-x_v)^2+\sum_{(u,v)\in P_2}(x_u-x_v)^2\\ &= (k_1+1)\cdot\frac{1}{(k_1+1)^2}+(k_2+1)\cdot\frac{1}{(k_2+1)^2}\leq\frac{5}{6}.\end{aligned}$$

The last inequality holds because $\min(k_1,k_2)\geq 1, \max(k_1,k_2)\geq 2$.
On the other hand $\mathcal{R}(H',x)\geq(x_a-x_b)^2=1$ and the lemma follows. ◀

▶ **Lemma 11.** *If G' contains a set of disjoint cycles of length 4 and H' edges only have endpoints on the same cycle, then there is a cycle $\tilde{H}$ such that $|E_{\tilde{H}}\cap E_G|=|E_H\cap E_G|+2$.*

Proof. Consider a cycle C of length 4 in G' such that there is no blue edge between a vertex in the cycle and a vertex not in the cycle. Since $deg_{G'}(v)\geq 2$ for all vertices in the cycle, $deg_{H'}(v)\geq 1$ by claim 3. Since G' and H' do not share any edge and the cycle has length 4, we must have $deg_{H'}(v)=1$ for all $v\in C$. And for vertices not in the length 4 cycles, $deg_{H'}(v)=0$. Let the edges of H be $F_1\cup F_2$ where F_1 are the edges shared between G and H and F_2 are the diagonal edges in the disjoint cycles of length 4. Let C be one such cycle in G' with vertices v_1,v_2,v_3,v_4 in this order and $(v_1,v_3)\in F_2,(v_2,v_4)\in F_2$. Let $H_1=(V,F_1\cup F_2\backslash\{(v_1,v_3),(v_2,v_4)\}\cup\{(v_1,v_2),(v_3,v_4)\}), H_2=(V,F_1\cup F_2\backslash\{(v_1,v_3),(v_2,v_4)\}\cup\{(v_1,v_4),(v_2,v_3)\})$. Then, one of the H_1 or H_2 is a cycle of length n. We let $\tilde{H}$ be that cycle. ◀

Finishing the proof: Recall that we have assumed that G does not contain a Hamiltonian cycle and let H is a permutation of C such that $|E_G\cap E_H|$ is maximized. To show that G does **not** dominate H, we need to construct a vector x such that $\mathcal{R}(H,x)>\mathcal{R}(G,x)$.

Starting with G and H, we form two graphs G' and H' as follows: (i) delete from G and H all common edges, (ii) iteratively and greedily delete all vertices such that $deg_G(u)=1, deg_H(u)=0$. Then Claims 1 and 2 show that it suffices to find a vector x such that $\mathcal{R}(H',x)>\mathcal{R}(G',x)$.

If there is still a vertex with $deg_{G'}(u)=1$, then $deg_{H'}(u)$ must be at least 1 and hence, by Claim 4, there exists a vector x such that $\mathcal{R}(H',x)>\mathcal{R}(G',x)$. Also, if there is a vertex u with degree 3 in G', then by lemma 8 there exists x such that $\mathcal{R}(H',x)>\mathcal{R}(G',x)$.

If there are no degree 1 or degree 3 vertices G', then G' must be a collection of isolated vertices and cycles. If there is a vertex v such that $deg_{G'}(v)=0, deg_{H'}(v)\geq 1$, then by setting $S=\{v\}$, lemma 9 implies that there exists a vector x such that $\mathcal{R}(H',x)>\mathcal{R}(G',x)$.

So, if none of the above cases occurs, then G' is a collection of disjoint cycles and H' edges are only incident to vertices of the cycles. If there is a cycle of length at least 5, then by lemma 10 there exists x such that $\mathcal{R}(H',x)>\mathcal{R}(G',x)$. Otherwise, if there is at least one blue edge with end points on two different cycles of length 4, then by setting S to be the vertex set of the cycle of length 4 Lemma 9 implies that there exists x such that $\mathcal{R}(H',x)>\mathcal{R}(G',x)$.

So, either G' and H' are empty or G' consists of a collection of disjoint cycles of length 4 such that blue edges have end points in the same cycle. In the first case, G trivially contains a Hamiltonian cycle since H' is empty. This is a contradiction to the assumption that G does not contain a Hamiltonian cycle. In the second case G Lemma 11 contradicts our assumption about the maximality of $|E_G\cap E_H|$. ◀

Proof. (Theorem 4) The problem of detecting if a cubic subgrid contains a Hamiltonian cycle is NP-complete [17]. Hence Theorem 5 is a direct reduction, and the theorem follows. ◀

3 Spectrally Robust Graph Isomorphism on Trees

This section outlines a proof for Theorem 3. We first introduce necessary notation.

▶ **Definition 12.** The support $\sigma(G, H)$ of G by H is the smallest number γ such that γH dominates G.

▶ **Definition 13.** The condition $\kappa(G, H)$ of a pair of graphs G and H is the smallest number κ such that G and H are κ-similar. We have $\kappa(G, H) = \sigma(G, H)\sigma(H, G)$.

We denote by $d_G(u, v)$ the distance between u and v in G using the shortest path metric. For $S \subseteq V$, we denote by $\delta_G(S)$ the set of of edges crossing the cut $(S, V - S)$ in G.

We now briefly review well-known facts [8]; a more detailed version of this paragraph along with proofs can be found in the appendix of the full version of the paper [12]. Given two trees G and H there is an obvious way to embed the edges of G into H: each edge (u, v) is routed over the unique path between vertices (u, v) in H. The *dilation* of the embedding is defined by: $\mathbf{d} = \max_{(u,v)\in E_G} d_H(u, v)$. The congestion c_e of an edge $e \in E_H$ is the number of G-edges that are routed over e. The *congestion* $\mathbf{c}$ of the embedding is then defined as $\max_{e\in E_H} c_e$. An upper bound of κ on the condition number implies the same upper bound on both c and d. On the other hand, the product $\mathbf{cd}$ is an upper bound on $\sigma(G, H)$, which is at most a quadratic over-estimation of $\sigma(G, H)$.

Our algorithm finds a mapping that controls both the dilation and the congestion of the embeddings from G to H and vice versa, thus obtaining a quadratic approximation to the condition number as a corollary.

▶ Remark. To simplify the presentation and the proof, we assume uniform upper bounds on the congestion and the dilation of both embeddings (G to H and H to G), rather than handling them separately. This formally proves a κ^3-approximation to κ-similarity. A κ-approximation algorithm may be possible with a refined argument that tracks the two embeddings separately.

Formally, our result can be stated as follows:

▶ **Theorem 14.** *Suppose G and H are two trees for which there exists a bijective mapping $\pi : V(G) \to V(H)$ satisfying the following properties:*

- *For all $(u, v) \in E(G)$, $d_H(\pi(u), \pi(v)) \leq \ell$*
- *For all $(u, v) \in E(H)$, $d_G(\pi^{-1}(u), \pi^{-1}(v)) \leq \ell$*
- *For $S \subset V(G)$ such that $|\delta_G(S)| = 1$, $|\delta_H(\pi(S))| \leq k$.*
- *For $S \subset V(H)$ such that $|\delta_H(S)| = 1$, $|\delta_G(\pi^{-1}(S))| \leq k$.*

Then, there exists an algorithm to find such a mapping in time $n^{O(k^2 d)}$ where d is the maximum degree of a vertex in G or H.

Our main result, theorem 3, follows immediately as a corollary from the fact that $\max\{k, l\} \leq \sigma(H, G) \leq kl$ (which is proved in the full version of the paper) and using the fact that $\max\{\sigma(G, H), \sigma(H, G)\} \leq \kappa(G, H) \leq \sigma(G, H)\sigma(H, G)$.

▶ **Corollary 15.** *Given two tree graphs G and H with condition number κ and maximum degree d, there exists an algorithm running in time $n^{O(\kappa^2 d)}$ which finds a mapping certifying that condition number is at most κ^4.*

The algorithm uses dynamic programming; it proceeds by recursively finding mappings for different subtrees and merging them. The challenge is to find partial mappings of subtrees which also map their boundaries in such a way that enables different mappings to

be appropriately merged. Notice that it is not enough to consider just the boundary vertices of the subtrees and their images. Instead, we need to additionally consider the boundary edges of those vertex sets, which correspond to cuts induced on the graph.

Definitions and Lemmas. To proceed with the proof, we introduce some definitions. We fix k and ℓ to be defined as in Theorem 14. Also, we fix an arbitrary ordering L on the edges of H. Without loss of generality it is convenient to root the trees such that we always map the two roots to each other. Let r_G be the root of tree G and r_H be the root of tree H.

Suppose that u is a vertex in G and T_u^G is the subtree rooted at u in G. If T_u^G is mapped to the set T in H, then its boundary includes the vertex u, the edge incident to u, the boundary vertices of T, and the cuts induced by edges going out of T. Hence, in addition to considering the mapping of boundary vertices, we need to consider the mapping of sets T' such that $\delta_H(T') = \{e\}$ where $e \in \delta_H(T)$. This notion is formalized in the following two definitions.

▶ **Definition 16.** Let Γ be the set of tuples $(u, T, v, u_1, \ldots, u_x, S_1, \ldots, S_x)$ satisfying the following properties:

- $u, u_1, \ldots, u_x \in V(G), v \in V(H), T \subset V(H), S_1, \ldots, S_x \subset V(G)$;
- $r_G \notin S_1, \ldots, S_x, r_H \notin T$;
- $u, u_1, \ldots, u_x \neq r_G, v \neq r_H$;
- $|\delta_H(T)| = x \leq k$ and $\forall j \in [1, x], |\delta_G(S_j)| \leq k$.

For $\alpha \in \Gamma$, we use the indicator variable z_α to denote if there is a mapping π which realizes α and preserves the distances and cuts for edges in T_u^G and T. A permutation π realizing α is formally defined below. Intuitively, this mapping maps the subtree rooted at u in G to the set T in H, vertex u to vertex v. It also maps $u_1, \ldots, u_x$ to the vertex boundary of the set T, and maps sets $S_1, \ldots, S_x$ to the cuts induced by the boundary edges of T. The formal definition of z_α is as follows:

▶ **Definition 17.** For $\alpha = (u, T, v, u_1, \ldots, u_x, S_1, \ldots, S_x) \in \Gamma$, let $\delta_H(T) = \{e_1, \ldots, e_x\}$ be such that for $i < j$, e_i is ordered before e_j in ordering L. Let $v_j = e_j \cap T$, T_u^G be the vertex set in the subtree rooted at u in G and for $e \in E(G)$, let T_e^G be the vertex set in the subtree under edge e. Formally speaking $T_e^G \subset V(G)$ such that $\delta_G(T_e^G) = \{e\}$ and $r_G \notin T_e^G$ (T_e^H is similarly defined). We define $z_\alpha = 1$ if there exists a mapping $\pi : V(G) \to V(H)$ such that:

1. $\pi(T_u^G) = T, \pi(u) = v, \forall j \in [1, x], \pi(u_j) = v_j, \pi(S_j) = T_{e_j}^H$, $\pi(r_G) = r_H$.
2. $\forall (u, v) \in E[G[T_u^G]], d_H(\pi(u), \pi(v)) \leq \ell$
3. $\forall (u, v) \in E[H[T]], d_G(\pi^{-1}(u), \pi^{-1}(v)) \leq \ell$
4. $\forall e \in E[G[T_u^G]]$, $|\delta_H(\pi(T_e^G)| \leq k$.
5. $\forall e \in E[H[T]]$, $|\delta_G(\pi^{-1}(T_e^H)| \leq k$.

We refer to such a mapping π as a certificate of $z_\alpha = 1$. Moreover, we define $z_{\alpha,\pi} = 1$ if π is a certificate of $z_\alpha = 1$ and 0 otherwise.

▶ **Claim 5.** *There exists a poly(n) time algorithm which given $\alpha \in \Gamma, \pi : V(G) \to V(H)$, outputs the value of $z_{\alpha,\pi}$.*

Our goal is to design an algorithm which computes z_α for every $\alpha \in \Gamma$. However, for our algorithm to run in polynomial time, we need Γ to not be exponentially large.

▶ **Lemma 18.** $|\Gamma| \leq n^{O(k^2)}$.

Proof. Let $\alpha = (u, T, v, u_1, \ldots, u_x, S_1, \ldots, S_x)$. We prove the lemma by bounding the number of choices for each parameter.

- The number of choices of u is upper bounded by n.
- Since $|\delta_H(T)| = x$, the number of choices $\delta_H(T)$ is upper bounded by $\binom{m}{x}$ where m is the number of edges. By substituting $m = n - 1$, we get that the number of different $\delta_H(T)$, i.e. the number of different T's, is upper bounded by $\binom{n-1}{x}$.
- The number of different v and u_j is at most n for each $j \in [1, x]$.
- Similarly to the argument for T, the number of different S_j with $|\delta_H(S_j)| \leq k$ is at most $\sum_{t=1}^{k} \binom{n-1}{t}$.

For $x \in [1, k]$, the number of different tuples α in Γ with $|\delta_H(T)| = x$ is at most:

$$n \cdot \binom{n-1}{x} n \cdot n^x \cdot \left[\sum_{t=1}^{k} \binom{n-1}{t}\right]^x = n^{O(k \cdot x)}.$$

Since $x \leq k$, this gives us an upper bound of $n^{O(k^2)}$ on $|\Gamma|$. ◀

Suppose π is the optimal mapping from G to H which yields a mapping with cut distortion k and distance distortion ℓ and also certifies $z_\alpha = 1$ for some α. Our recursive algorithm does not necessarily obtain the same certificate as π for $z_\alpha = 1$. So, before we show how to compute z_α, we examine certain properties of z_α. In particular, we start by proving that if both π and γ certify $z_\alpha = 1$ so that $z_{\alpha,\pi} = z_{\alpha,\gamma} = 1$, then they not only match on the boundary vertices but also on the cuts induced by boundary edges.

▶ **Lemma 19.** *For $\alpha = (u, T, v, u_1, \ldots, u_x, S_1, \ldots, S_x)$, let π and γ be two mappings such that $z_{\alpha,\pi} = z_{\alpha,\gamma} = 1$. Then:*

1. $\pi(u) = \gamma(u)$.
2. $\pi(T_u^G) = \gamma(T_u^G)$.
3. *For every boundary vertex w of T (in T with an incident edge in $\delta_H(T)$), $\pi^{-1}(w) = \gamma^{-1}(w)$. Equivalently, $\pi(u_j) = \gamma(u_j)$ for $j \in [1, x]$.*
4. *For every edge $e \in \delta_H(T)$, $\pi^{-1}(T_e^H) = \gamma^{-1}(T_e^H)$.*
5. *For every connected component C in $H \setminus \delta_H(T)$, $\pi^{-1}(C) = \gamma^{-1}(C)$.*

Proof. Items 1-4. follow directly from the definition of $z_{\alpha,\pi}$. Consider a connected component C in $H \setminus \delta_H(T)$. Let $\delta_H(C) = \{e_{i_1}, \ldots, e_{i_t}\}$. Without loss of generality, assume that e_{i_1} is the edge closest to the root r_H. Then:

$$\gamma^{-1}(C) = \gamma^{-1}(T_{e_{i_1}}) \setminus \cup_{j=2}^{t} \gamma^{-1}(T_{e_{i_j}}).$$

Item 3 implies that $\gamma^{-1}(T_{e_{i_j}}) = \pi^{-1}(T_{e_{i_j}})$ for $j \in [1, t]$ thus proving $\pi^{-1}(C) = \gamma^{-1}(C)$. ◀

The next lemma is somewhat like a converse of the previous lemma. It shows that if we have a mapping π such that $z_{\alpha,\pi} = 1$ and another mapping γ such that γ matches with π on the subtree and the boundary vertices and edges, then $z_{\alpha,\gamma} = 1$ as well.

▶ **Lemma 20.** *Let $\alpha = (u, T, v, u_1, \ldots, u_x, S_1, \ldots, S_x)$ and $\pi : V(G) \to V(H)$ be such that $z_{\alpha,\pi} = 1$. Let $\gamma : V(G) \to V(H)$ be such that*

1. $\gamma(w) = \pi(w)$ *for* $w \in T_u^G$
2. $\gamma(u_j) = \pi(u_j)$ *for* $j \in [1, x]$
3. $\gamma(S_j) = \pi(S_j)$ *for* $j \in [1, x]$ *(π and γ may not be identical on every element of S_j)*

Then, $z_{\alpha,\gamma} = 1$.

Proof. Follows immediately from definition 17. ◀

Next we show how to change the optimal mapping such that it agrees with the mapping found by our algorithm on the subtree and is still optimal. Following lemma formalizes this statement:

▶ **Lemma 21.** *Let π be a mapping such that $z_{\alpha,\pi} = z_{\alpha_1,\pi} = 1$ where*

$$\alpha = (a, T, b, u_1, \ldots, u_x, S_1, \ldots, S_x) \in \Gamma \text{ and } \alpha_1 = (a^1, T^1, b^1, u_1^1, \ldots, u_{x_1}^1, S_1^1, \ldots, S_{x_1}^1) \in \Gamma$$

such that a_1 is a child of a in G. Suppose, γ_1 is another mapping such that $z_{\alpha_1,\gamma_1} = 1$. Let ζ be defined as follows: $\zeta(u) = \gamma_1(u)$ for $u \in T_{a^1}^G$ and $\zeta(u) = \pi(u)$ otherwise. Then, $z_{\alpha,\zeta} = 1$.

Proof. Items 1-4 of lemma 17 can be easily verified for $z_{\alpha,\zeta}$. Here, we prove that the following property holds: $\forall e \in E[H[T]], |\delta_G(\zeta^{-1}(T_e^H))| \leq k$.

There are three possible cases, that we consider separately.

1. $e = (b, b_1)$, $e \in \delta_H(T^1)$.
   By definition, $\zeta^{-1}(T_e^H) = \gamma_1^{-1}(T_e^H)$. Since, $z_{\alpha_1,\gamma_1} = 1$, we get $|\zeta^{-1}(T_e^H)| = |\gamma_1^{-1}(T_e^H)| \leq k$.
2. $e \in E[H[T \setminus T^1]]$.
   By definition, $\zeta^{-1}(T_e^H) = \pi^{-1}(T_e^H)$. Since, $z_{\alpha,\pi} = 1$,, we get $|\zeta^{-1}(T_e^H)| = |\pi^{-1}(T_e^H)| \leq k$.
3. $e \in E[H[T^1]]$.
   By definition, $\zeta^{-1}(T_e^H) = \gamma_1^{-1}(T_e^H)$ and since, $z_{\alpha_1,\gamma_1} = 1$, we get $|\zeta^{-1}(T_e^H)| \leq k$. ◀

The above lemmas show that even if we find mappings for subtrees which are different from the optimal mappings, they can still be merged with the optimal mappings. Hence, we may just find any of the mappings for each α and then recursively combine mappings. The following lemma states the result and shows how to make it constructive:

▶ **Lemma 22.** *Let $a \in V(G)$ be a vertex in G with children $a^1, \ldots, a^t$. Let*

$$\alpha = (a, T, b, u_1, \ldots, u_x, S_1, \ldots, S_x) \text{ and}$$
$$\alpha_1 = (a^1, T^1, b^1, u_1^1, \ldots, u_{x_1}^1, S_1^1, \ldots, S_{x_1}^1), \ldots, \alpha_t = (a^t, T^t, b^t, u_1^t, \ldots, u_{x_t}^t, S_1^t, \ldots, S_{x_t}^t) \in \Gamma.$$

Let $\pi : V(G) \to V(H)$ be a mapping such that $z_{\alpha,\pi} = z_{\alpha_1,\pi} = \cdots = z_{\alpha_j,\pi} = 1$ for all $j \in [1, t]$. If for each $j \in [1, t]$ there exists a mapping $\gamma_j : V(G) \to V(H)$ with $z_{\alpha_j,\gamma_j} = 1$, then there exists $\pi' : V(G) \to V(H)$ such that $z_{\alpha,\pi'} = 1$ and $\pi'(w) = \gamma_j(w)$ for $w \in T_{a_j}^G$ where $j \in [1, t]$. Moreover, given $\{\gamma_j \mid j \in [1, t]\}$, such π' can be found in time poly(n).

Proof. Let $\zeta : V(G) \to V(H)$ such that $\zeta(w) = \gamma_j(w)$ for $w \in T_{a_j}^G$ where $j \in [1, t]$ and $\zeta(w) = \pi(w)$ otherwise. By lemma 21, $z_{\alpha,\zeta} = 1$.

Construction of π': Let $\pi'(w) = \gamma_j(w)$ for $w \in T_{a_j}^G, j \in [1, t]$ and $\pi'(a) = b$. For $w \notin T_a^G$, define π' such that $\pi'(S_j) = T_j$ for $j \in [1, x]$. Setting $\pi = \zeta, \gamma = \pi'$ in lemma 20, we get $z_{\alpha,\pi'} = 1$. Easy to see that π' is constructed in polynomial time. ◀

Lemma 22 suggests that we can recursively compute z_α. Namely, we can show the following:

▶ **Lemma 23.** *There exists an algorithm with running time poly$(n, |\Gamma|^d)$ which calculates z_α for each $\alpha \in \Gamma$. Additionally if $z_\alpha = 1$, it also computes π_α such that $z_{\alpha,\pi_\alpha} = 1$.*

Proof. Consider $\alpha = (a, T, b, u_1, \ldots, u_x, S_1, \ldots, S_x) \in \Gamma$ with $z_\alpha = 1$ and $\pi : V(G) \to V(H)$ be the mapping such that $z_{\alpha,\pi} = 1$. Let the children of a be $a^1, \ldots, a^t$.

▶ **Claim 6.** *For $j \in [1, t], \exists \alpha_j = (a^j, T^j, b^j, u_j^1, \ldots, u_{x_j}^1, S_1^1, \ldots, S_{x_j}^1) \in \Gamma$ such that $z_{\alpha_j,\pi} = 1$.*

To construct a mapping π' such that $z_{\alpha,\pi'} = 1$, we guess $\alpha_1, \ldots, \alpha_t$ and use lemma 22 to construct such a mapping. It requires mapping γ_j such that $z_{\alpha_j,\gamma_j} = 1$ which can be assumed to be constructed recursively. The number of choices of $\alpha_1, \ldots, \alpha_t$ is upper bounded by $|\Gamma|^t$ which is upper bounded by $|\Gamma|^d$, as the degree of any vertex is at most d. For any such choice, algorithm in lemma 22 runs in time $poly(n)$. Hence, computing z_α takes $|\Gamma|^d poly(n)$ time for each α and $|\Gamma|^{d+1} poly(n) = poly(n, |\Gamma|^d)$ time for all $\alpha \in \Gamma$.

If $z_\alpha = 0$, then for any of the mappings π' considered above has $z_{\alpha,\pi'} = 0$. This can be checked in $poly(n)$ time for each π' (proposition 5). ◀

Proof. (of theorem 14) Let π be a mapping $\pi : V(G) \to V(H)$ such that:

(a) For all $(u, v) \in E(G)$, $d_H(\pi(u), \pi(v)) \leq \ell$

(b) For all $(u, v) \in E(H)$, $d_G(\pi^{-1}(u), \pi^{-1}(v)) \leq \ell$

(c) For $S \subset V(G)$ s.t. $|\delta_G(S)| = 1$, $|\delta_H(\pi(S))| \leq k$.

(d) For $S \subset V(H)$ s.t. $|\delta_H(S)| = 1$, $|\delta_G(\pi^{-1}(S))| \leq k$.

First, we start by guessing the roots of G and H and define Γ. Then, using lemma 23, we can calculate z_α for $\alpha \in \Gamma$. It does not give us a mapping π' satisfying the conditions above since for $\alpha = (u, T, v, u_1, \ldots, u_x, S_1, \ldots, S_x) \in \Gamma$, we have $u \neq r_G$. However, a proof almost identical to that of lemma 23 works here as well. Assume r_G has children $a_1, \ldots, a_t$. Then there exists $\alpha_j = (a^j, T^j, b^j, u^1_j, \ldots, u^1_{x_j}, S^1_1, \ldots, S^1_{x_j}) \in \Gamma$ such that $z_{\alpha_j,\pi} = 1$. Then, similarly to the proof of lemma 23 we can guess $\alpha_j, j \in [1, t]$ and compute π' in time $poly(n) \cdot |\Gamma|^d$, which satisfies the conditions described above. ◀

4 Final Remarks

From an algebraic standpoint, the problems we considered in this work have natural generalizations to pairs of positive definite matrices (A, B), and the corresponding eigenvalue problem $Ax = \lambda P^T BPx$. SGD generalizes to minimizing the maximum eigenvalue, and SGRI generalizes to finding the permutation P that minimizes the condition number $\kappa(A, B)$. But the problem appears to be much harder in some sense: one can construct 'pathological' examples of A and B with just two distinct eigenspaces that are nearly identical, but different enough to cause unbounded condition numbers due to the eigenvalue gap. This makes implausible the existence of non-trivial subexponential time algorithms for the general case.

On the other hand, besides their potential for applications, Laplacians seem to offer an interesting mathematical ground with a wealth of open problems. In this paper we presented the first algorithmic result, for unweighted trees. The algorithm is admittedly complicated, but it can at least be viewed as an indication of algorithmic potential, as we are not aware of any fact that would preclude a similar approximation for general graphs. To make such algorithmic progress, we would likely have to give up on the combinatorial interpretations of the condition number, and use deeper spectral properties of Laplacians.

Abstract

The theory of n-fold integer programming has been recently emerging as an important tool in parameterized complexity. The input to an n-fold integer program (IP) consists of parameter A, dimension n, and numerical data of binary encoding length L. It was known for some time that such programs can be solved in polynomial time using $O(n^{g(A)}L)$ arithmetic operations where g is an exponential function of the parameter. In 2013 it was shown that it can be solved in fixed-parameter tractable time using $O(f(A)n^3L)$ arithmetic operations for a single-exponential function f. This, and a faster algorithm for a special case of *combinatorial* n-fold IP, have led to several very recent breakthroughs in the parameterized complexity of scheduling, stringology, and computational social choice. In 2015 it was shown that it can be solved in strongly polynomial time using $O(n^{g(A)})$ arithmetic operations.

Here we establish a result which subsumes all three of the above results by showing that n-fold IP can be solved in strongly polynomial fixed-parameter tractable time using $O(f(A)n^6 \log n)$ arithmetic operations. In fact, our results are much more general, briefly outlined as follows.

- There is a strongly polynomial algorithm for integer linear programming (ILP) whenever a so-called Graver-best oracle is realizable for it.
- Graver-best oracles for the large classes of multi-stage stochastic and tree-fold ILPs can be realized in fixed-parameter tractable time. Together with the previous oracle algorithm, this newly shows two large classes of ILP to be strongly polynomial; in contrast, only few classes of ILP were previously known to be strongly polynomial.
- We show that ILP is fixed-parameter tractable parameterized by the largest coefficient $\|A\|_\infty$ and the primal or dual treedepth of A, and that this parameterization cannot be relaxed, signifying substantial progress in understanding the parameterized complexity of ILP.

1 Introduction

In this article we consider the general linear integer programming (ILP) problem in standard form,

$$\min\{\mathbf{wx} \mid A\mathbf{x} = \mathbf{b}\,,\ \mathbf{l} \le \mathbf{x} \le \mathbf{u}\,,\ \mathbf{x} \in \mathbb{Z}^n\}\,. \tag{ILP}$$

with A an integer $m \times n$ matrix, $\mathbf{b} \in \mathbb{Z}^m$, $\mathbf{w} \in \mathbb{Z}^n$, $\mathbf{l}, \mathbf{u} \in (\mathbb{Z} \cup \{\pm\infty\})^n$. It is well known to be strongly NP-hard, which motivates the search for tractable special cases.

The first important special case is ILP in fixed dimension. In the '80s it was shown by Lenstra and Kannan [17, 20] that (ILP) can be solved in time $n^{O(n)}L$, where L is the length of the binary encoding of the input. Secondly, it is known that if the matrix A is totally unimodular (all subdeterminants between -1 and 1), all vertices of the feasible region are integral and thus applying any polynomial algorithm for linear programming (LP) suffices. Later, Veselov and Chirkov [25] have shown that the more general class of bimodular ILP is also polynomial-time solvable. Other results exploit certain structural properties of A. These include the large classes of n-fold [13], tree-fold [4], 2-stage and multi-stage stochastic [3], and 4-block n-fold [12] ILPs, as well as algorithms for ILPs with bounded treewidth [11], treedepth [10] and fracture number [7] of certain graphs related to the matrix A.

A fundamental question regarding problems involving large numbers is whether there exists an algorithm whose number of arithmetic operations does not depend on the length of the numbers involved; if this number is polynomial, this is a *strongly polynomial algorithm* [24]. For example, the ellipsoid method or the interior-point method which solve LP take time which does depend on the encoding length, and the existence of a strongly polynomial algorithm for LP remains a major open problem. So far, the only strongly polynomial ILP algorithms we are aware of exist for totally unimodular ILP [14], bimodular ILP [2], so-called binet ILP [1], and n-fold IP with constant block dimensions [6]. All remaining results, such as Lenstra's famous algorithm or the fixed-parameter tractable algorithm for n-fold IP which has recently led to several breakthroughs [4, 16, 18, 19], are not strongly polynomial.

1.1 Our Contributions

To clearly state our results we introduce the following terminology. The input to a problem will be partitioned into three parts (α, β, γ), where α is the *parametric input*, β is the *arithmetic input*, and γ is the *numeric input*. A *strongly fixed-parameter tractable* (FPT) *algorithm* for the problem is one that solves it using $f(\alpha)\text{poly}(\beta)$ arithmetic operations and $g(\alpha)\text{poly}(\beta, \gamma)$ time, where f, g are some computable functions. If such an algorithm exists, we say that the problem is *strongly fixed-parameter tractable* (FPT) *parameterized by* α. Thus, such an algorithm both demonstrates that the problem is FPT *parameterized by* α because it runs in FPT time $g(\alpha)\text{poly}(\beta, \gamma)$, and provides a strongly polynomial algorithm for each fixed α. Having multiple parameters $\alpha_1, \ldots, \alpha_k$ simultaneously is understood as taking the *aggregate parameter* $\alpha = \alpha_1 + \cdots + \alpha_k$. If the algorithm involves oracles then the oracle queries are also counted as arithmetic operations and the answers to oracle queries should be polynomial in (β, γ). Each part of the input may have several entities, which may be presented in unary or binary, where $\langle e \rangle$ denotes the encoding length of an entity e presented in binary. For the parametric input the distinction between unary and binary is irrelevant.

ILP abounds in natural parameters: the dimension n, number of inequalities m, largest coefficient $\|A\|_\infty$, largest right-hand side $\|\mathbf{b}\|_\infty$, various structural parameters of A, etc. Here, we are interested in algorithms which are both strongly polynomial *and* FPT.

Recently it was shown that, if we have access to the so-called *Graver basis* of A, the problem (ILP) is polynomial time solvable even for various nonlinear objective functions [5, 21]. We show that all of these results can be extended to be strongly polynomial with only $\langle A \rangle$ as the arithmetic input.

▶ **Theorem 1.** *The problem* (ILP) *with arithmetic input* $\langle A \rangle$ *and numeric input* $\langle \mathbf{w}, \mathbf{b}, \mathbf{l}, \mathbf{u} \rangle$*, endowed with a Graver-best oracle for* A*, is solvable by a strongly polynomial oracle algorithm.*

The existence of Graver-best oracles is thus of prime interest. We show such oracles for the wide classes of multi-stage stochastic and tree-fold ILPs; for precise definitions of these classes cf. Section 3.1.2. See Table 1 for a summary of improvements over the current state of the art.

▶ **Theorem 2.** *Multi-stage stochastic ILP with blocks* $B_1, \ldots, B_\tau$*,* $B_i \in \mathbb{Z}^{l \times n_i}$*, is strongly* FPT *parameterized by* $l + n_1 + \cdots + n_\tau$ *and* $\|A\|_\infty$*.*

▶ **Theorem 3.** *Tree-fold ILP with blocks* $A_1, \ldots, A_\tau$*,* $A_i \in \mathbb{Z}^{r_i \times t}$*, is strongly* FPT *parameterized by* $r_1 + \cdots + r_\tau$ *and* $\|A\|_\infty$*.*

This improves on the algorithm for tree-fold ILP [4] not only by making it strongly FPT, but also by leaving the block length t out of the parameter. Similarly, the following algorithm for the special case of n-fold ILP greatly improves both on the previous results of Hemmecke et al. [13] and Knop et al. [18] and is the currently fastest algorithm for this problem:

▶ **Theorem 4.** *n-fold ILP with blocks* $A_1 \in \mathbb{Z}^{r \times t}$ *and* $A_2 \in \mathbb{Z}^{s \times t}$ *can be solved in time* $a^{O(r^2 s + r s^2)}(nt)^6 \log(nt) + \mathcal{L}(\langle A \rangle)$*, where* $\mathcal{L}(\langle A \rangle)$ *is the runtime of a strongly polynomial LP algorithm.*

Next, we turn our attention to structural parameters of the constraint matrix A. We focus on two graphs which can be associated with A:

- the *primal graph* $G_P(A)$, which has a vertex for each column and two vertices are connected if there exists a row such that both columns are non-zero, and,
- the *dual graph* $G_D(A) = G_P(A^\intercal)$, which is the above with rows and columns swapped.

Two standard parameters of structural sparsity are the *treewidth* (measuring the "tree-likeness" of a graph) and the more restrictive *treedepth* (measuring its "star-likeness"). We denote the treewidth of $G_P(A)$ and $G_D(A)$ by $\mathrm{tw}_P(A)$ and $\mathrm{tw}_D(A)$; for treedepth we have $\mathrm{td}_P(A)$ and $\mathrm{td}_D(A)$. Note that bounded treedepth implies bounded treewidth but not vice versa.

We show that ILP parameterized by $\mathrm{td}_P(A) + \|A\|_\infty$ and $\mathrm{td}_D(A) + \|A\|_\infty$ can be reduced to the previously mentioned classes, respectively, implying (ILP) with these parameters is strongly FPT.

▶ **Theorem 5.** (ILP) *is strongly* FPT *parameterized by* $\mathrm{td}_P(A)$ *and* $\|A\|_\infty$*.*

This improves in two ways upon the result of Ganian and Ordyniak [10] who show that (ILP) with $\mathbf{w} \equiv \mathbf{0}$ (i.e. deciding the feasibility) is FPT parameterized by $\mathrm{td}_P(A) + \|A, \mathbf{b}\|_\infty$ [10]. First, we use the smaller parameter $\|A\|_\infty$ instead of $\|A, \mathbf{b}\|_\infty$, and second, we solve not only the feasibility but also the optimization problem. An analogous result holds for the parameter $\mathrm{td}_D(A)$, for which previously nothing was known at all.

▶ **Theorem 6.** (ILP) *is strongly* FPT *parameterized by* $\mathrm{td}_D(A)$ *and* $\|A\|_\infty$*.*

Table 1 Run time improvements implied by this paper. We denote by L the binary length of the numeric input $\mathbf{b}, \mathbf{l}, \mathbf{u}, \mathbf{w}$, i.e., $L = \langle \mathbf{b}, \mathbf{l}, \mathbf{u}, \mathbf{w} \rangle$, and consider $\langle A \rangle$ to be part of the arithmetic input. We denote by $a = \max\{2, \|A\|_\infty\}$, by r, s, t the relevant block dimensions (cf. Section 3.1), and by $\mathcal{L}(\langle A \rangle)$ the runtime of a strongly polynomial LP algorithm [24].

Bounded dual treedepth	Open whether fixed-parameter tractable	$f_D(a, \text{td}_D(A)(nt)^3 + \mathcal{L}(\langle A \rangle)$ Thm 6
Bounded primal treedepth	$f_{P'}(a, \|\mathbf{b}\|_\infty, \text{td}_P(A))nL$ [10]	$f_P(a, \text{td}_P(A))n^3 + \mathcal{L}(\langle A \rangle)$ Thm 5

We emphasize that the parameterizations cannot be relaxed neither from treedepth to treewidth, nor by removing the parameter $\|A\|_\infty$: (ILP) is NP-hard already on instances with $\text{tw}_P(A) = 3$ and $\|A\|_\infty = 2$ [10, Thm 12], and it is strongly W[1]-hard parameterized by $\text{td}_P(A)$ alone [10, Thm 11]; the fact that a problem is W[1]-hard is strong evidence that it is not FPT. Similarly, deciding feasibility is NP-hard on instances with $\text{tw}_D(A) = 3$ and $\|A\|_\infty = 2$ (Lemma 18) and strongly W[1]-hard parameterized by $\text{td}_D(A)$ alone [19, Thm 5].

1.2 Interpretation of Results

We believe our approach also leads to several novel insights. First, we make it clear that the central question is finding Graver-best oracles; provided these oracles, Theorem 1 shows that tasks such as optimization and finding initial solutions can be handled under very mild assumptions. Even though we show these tasks are routine, they have been reimplemented repeatedly [4, 12, 13, 18].

Second, we show that the special classes of highly uniform block structured ILPs, namely multi-stage stochastic and tree-fold ILPs, are in some sense *universal* for all ILPs of bounded primal or dual treedepth, respectively. Specifically, we show that any ILP with bounded primal or dual treedepth can be embedded in an equivalent multi-stage stochastic or tree-fold ILP, respectively (Lemmas 25 and 26).

Third, we show that, besides bounded primal or dual treedepth, the crucial property for efficiency is the existence of augmenting steps with bounded ℓ_∞- or ℓ_1-norms, respectively (Lemmas 19 and 21). This suggests that for ILPs whose primal or dual graph is somehow "sparse" and "shallow", finding augmenting steps of bounded ℓ_∞- or ℓ_1-norm might be both sufficient for reaching the optimum and computationally efficient.

1.3 Related Work

We have already covered all relevant work regarding strongly polynomial algorithms for ILP.

Let us focus on structural parameterizations. It follows from Freuder's algorithm [9] and was reproven by Jansen and Kratsch [15] that (ILP) is FPT parameterized by $\text{tw}_P(A)$ and the largest domain $\|\mathbf{u} - \mathbf{l}\|_\infty$. Regarding the dual graph $G_D(A)$, the parameters $\text{td}_D(A)$ and $\text{tw}_D(A)$ were only recently considered by Ganian et al. [11]. They show that even deciding feasibility of (ILP) is NP-hard on instances with $\text{tw}_I(A) = 3$ ($\text{tw}_I(A)$ denotes the treewidth of the *incidence graph*; $\text{tw}_I(A) \leq \text{tw}_D(A) + 1$ always holds) and $\|A\|_\infty = 2$ [11, Theorem 12].

Furthermore, they show that (ILP) is FPT parameterized by $\mathrm{tw}_I(A)$ and parameter Γ, which is an upper bound on any prefix sum of $A\mathbf{x}$ for any feasible solution $\mathbf{x}$.

Dvořák et al [7] introduce the parameter fracture number; having a bounded *variable fracture number* $\mathfrak{p}^V(A)$ implies that deleting a few columns of A breaks it into independent blocks of small size; similarly for *constraint fracture number* $\mathfrak{p}^C(A)$ and deleting a few rows. Because bounded $\mathfrak{p}^V(A)$ implies bounded $\mathrm{td}_P(A)$ and bounded $\mathfrak{p}^C(A)$ implies bounded $\mathrm{td}_D(A)$, our results generalize theirs. The remaining case of *mixed fracture number* $\mathfrak{p}(A)$, where deleting both rows and columns is allowed, reduces to the 4-block n-fold ILP problem, which is not known to be either FPT or W[1]-hard. Because bounded $\mathfrak{p}(A)$ implies bounded $\mathrm{td}_I(A)$, ILP parameterized by $\mathrm{td}_I(A) + \|A\|_\infty$ is at least as hard as 4-block n-fold ILP, highlighting its status as an important open problem.

Organization. The paper contains three main parts. In Section 2, we provide the proof of Theorem 1, showing the existence of a strongly polynomial algorithm whenever a Graver-best oracle is provided. Then, in Section 3, we provide Graver-best oracles for multi-stage stochastic and tree-fold ILPs and discuss n-fold ILP, and prove Theorems 2, 3 and 4. Finally, in Section 4 we show how to embed any instance of bounded primal or dual treedepth into a multi-stage stochastic or tree-fold ILP without increasing the relevant parameters, proving Theorems 5 and 6. Due to space restrictions the proofs of our technical statement and other supplementary material are moved to the full version available at `https://arxiv.org/abs/1802.05859`; the statements whose proofs are presented there are marked with (*) .

2 The Graver-best Oracle Algorithm

2.1 Preliminaries

For positive integers m, n, $m \leq n$, we set $[m, n] = \{m, \ldots, n\}$ and $[n] = [1, n]$. We write vectors in boldface (e.g., $\mathbf{x}, \mathbf{y}$) and their entries in normal font (e.g., the i-th entry of $\mathbf{x}$ is x_i). If A is a matrix, A_r denotes its r-th column. For an integer $a \in \mathbb{Z}$, we denote by $\langle a \rangle = 1 + \log_2 a$ the binary encoding length of a; we extend this notation to vectors, matrices and tuples of these objects. For example, $\langle A, \mathbf{b} \rangle = \langle A \rangle + \langle \mathbf{b} \rangle$, and $\langle A \rangle = \sum_{i,j} \langle a_{ij} \rangle$. For a graph G we denote by $V(G)$ its set of vertices.

Graver bases and augmentation. Let us now introduce Graver bases and discuss how they are used for optimization. We define a partial order $\sqsubseteq$ on $\mathbb{R}^n$ as follows: for $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$ we write $\mathbf{x} \sqsubseteq \mathbf{y}$ and say that $\mathbf{x}$ is *conformal* to $\mathbf{y}$ if $x_i y_i \geq 0$ (that is, $\mathbf{x}$ and $\mathbf{y}$ lie in the same orthant) and $|x_i| \leq |y_i|$ for $i \in [n]$. It is well known that every subset of $\mathbb{Z}^n$ has finitely many $\sqsubseteq$-minimal elements.

▶ **Definition 7** (Graver basis)**.** The *Graver basis* of an integer $m \times n$ matrix A is the finite set $\mathcal{G}(A) \subset \mathbb{Z}^n$ of $\sqsubseteq$-minimal elements in $\{\mathbf{x} \in \mathbb{Z}^n : A\mathbf{x} = 0,\ \mathbf{x} \neq 0\}$.

We say that $\mathbf{x}$ is *feasible* for (ILP) if $A\mathbf{x} = \mathbf{b}$ and $\mathbf{l} \leq \mathbf{x} \leq \mathbf{u}$. Let $\mathbf{x}$ be a feasible solution for (ILP). We call $\mathbf{g}$ a *feasible step* if $\mathbf{x} + \mathbf{g}$ is feasible for (ILP). Further, call a feasible step $\mathbf{g}$ *augmenting* if $\mathbf{w}(\mathbf{x} + \mathbf{g}) < \mathbf{w}(\mathbf{x})$. An augmenting step $\mathbf{g}$ and a *step length* $\alpha \in \mathbb{Z}$ form an $\mathbf{x}$-*feasible step pair* with respect to a feasible solution $\mathbf{x}$ if $\mathbf{l} \leq \mathbf{x} + \alpha\mathbf{g} \leq \mathbf{u}$. An augmenting step $\mathbf{h}$ is a *Graver-best step* for $\mathbf{x}$ if $\mathbf{w}(\mathbf{x} + \mathbf{h}) \leq \mathbf{w}(\mathbf{x} + \lambda\mathbf{g})$ for all $\mathbf{x}$-feasible step pairs $(\mathbf{g}, \lambda) \in \mathcal{G}(A) \times \mathbb{Z}$. The *Graver-best augmentation procedure* for (ILP) with a given feasible solution $\mathbf{x}_0$ works as follows:

1. If there is no Graver-best step for $\mathbf{x}_0$, return it as optimal.
2. If a Graver-best step $\mathbf{h}$ for $\mathbf{x}_0$ exists, set $\mathbf{x}_0 := \mathbf{x}_0 + \mathbf{h}$ and go to 1.

▶ **Proposition 8** ([21, Lemma 3.10]). *Given a feasible solution* $\mathbf{x}_0$ *for* (ILP)*, the Graver-best augmentation procedure finds an optimum of* (ILP) *in at most* $(2n-2)\log F$ *steps, where* $F = \mathbf{w}\mathbf{x}_0 - \mathbf{w}\mathbf{x}^*$ *and* $\mathbf{x}^*$ *is any minimizer of* $\mathbf{w}\mathbf{x}$*.*

▶ **Definition 9** (Graver-best oracle). A *Graver-best oracle* for an integer matrix A is one that, queried on $\mathbf{w}, \mathbf{b}, \mathbf{l}, \mathbf{u}$ and $\mathbf{x}$ feasible to (ILP), returns a Graver-best step $\mathbf{h}$ for $\mathbf{x}$.

2.2 The Algorithm

It follows from Proposition 8 that given a Graver-best oracle, problem (ILP) can be solved in time which is polynomial in the binary encoding length $\langle A, \mathbf{w}, \mathbf{b}, \mathbf{l}, \mathbf{u}\rangle$ of the input. We now show that, in fact, given such an oracle, the problem admits a *strongly* polynomial algorithm. In the next theorem the input has only arithmetic and numeric parts and no parametric part.

▶ **Theorem 1.** *The problem* (ILP) *with arithmetic input* $\langle A\rangle$ *and numeric input* $\langle \mathbf{w}, \mathbf{b}, \mathbf{l}, \mathbf{u}\rangle$*, endowed with a Graver-best oracle for* A*, is solvable by a strongly polynomial oracle algorithm.*

▶ Remark. The partition of the input to the arithmetic input $\langle A\rangle$ and the numeric input $\langle \mathbf{w}, \mathbf{b}, \mathbf{l}, \mathbf{u}\rangle$ is the same as in the classical results for linear programming [8, 24].

Proof. The algorithm which demonstrates the theorem consists of several steps as follows.

Step 1: Reducing $\mathbf{b}, \mathbf{l}, \mathbf{u}$. Apply the strongly polynomial algorithm of Tardos [24] to the linear programming relaxation $\min\{\mathbf{w}\mathbf{y} \mid \mathbf{y} \in \mathbb{R}^n,\ A\mathbf{y} = \mathbf{b},\ \mathbf{l} \le \mathbf{y} \le \mathbf{u}\}$; the algorithm performs $\mathcal{L}(\langle A\rangle) = \mathrm{poly}(\langle A\rangle)$ arithmetic operations. If the relaxation is infeasible then so is (ILP) and we are done. If it is unbounded then (ILP) is either infeasible or unbounded too, and in this case we set $\mathbf{w} := \mathbf{0}$ so that all solutions are optimal, and we proceed as below and terminate at the end of step 3. Suppose then that we obtain an optimal solution $\mathbf{y}^* \in \mathbb{R}^n$ to the relaxation, with round down $\lfloor \mathbf{y}^* \rfloor \in \mathbb{Z}^n$. Let $a := \max\{2, \|A\|_\infty\}$. Let $\mathcal{C}(A) \subseteq \mathcal{G}(A)$ be the set of *circuits* of A, which are those $\mathbf{c} \in \mathcal{G}(A)$ with support which is a circuit of the linear matroid of A. Let $c_\infty := \max_{\mathbf{c}\in\mathcal{C}(A)} \|\mathbf{c}\|_\infty$. We have $c_\infty \le n^{\frac{n}{2}} a^n$ [21, Lemma 3.18].

We now use the proximity results of [12, 14] which assert that either (ILP) is infeasible or it has an optimal solution $\mathbf{x}^*$ with $\|\mathbf{x}^* - \mathbf{y}^*\|_\infty \le n c_\infty$ and hence $\|\mathbf{x}^* - \lfloor \mathbf{y}^* \rfloor\|_\infty \le n^{\frac{n}{2}+1} a^n + 1$. Thus, making the variable transformation $\mathbf{x} = \mathbf{z} + \lfloor \mathbf{y}^* \rfloor$, problem (ILP) reduces to following,

$$\min\left\{\mathbf{w}(\mathbf{z} + \lfloor \mathbf{y}^* \rfloor) \mid \mathbf{z} \in \mathbb{Z}^n\,,\ A(\mathbf{z} + \lfloor \mathbf{y}^* \rfloor) = \mathbf{b}\,,\ \mathbf{l} \le \mathbf{z} + \lfloor \mathbf{y}^* \rfloor \le \mathbf{u}\,,\ \|\mathbf{z}\|_\infty \le n^{\frac{n}{2}+1} a^n + 1\right\},$$

which is equivalent to the program

$$\min\left\{\mathbf{w}\mathbf{z} \mid \mathbf{z} \in \mathbb{Z}^n\,,\ A\mathbf{z} = \bar{\mathbf{b}}\,,\ \bar{\mathbf{l}} \le \mathbf{z} \le \bar{\mathbf{u}}\right\} \tag{1}$$

where

$$\bar{\mathbf{b}} := \mathbf{b} - A\lfloor \mathbf{y}^* \rfloor,\ \ \bar{l}_i := \max\{l_i - \lfloor y_i^* \rfloor, -(n^{\frac{n}{2}+1} a^n + 1)\},\ \ \bar{u}_i := \min\{u_i - \lfloor y_i^* \rfloor, n^{\frac{n}{2}+1} a^n + 1\}\quad .$$

If some $\bar{l}_i > \bar{u}_i$ then (1) is infeasible and hence so is (ILP), so we may assume that

$$-(n^{\frac{n}{2}+1} a^n + 1) \le \bar{l}_i \le \bar{u}_i \le n^{\frac{n}{2}+1} a^n + 1, \quad \text{for all } i\ .$$

This implies that if $\mathbf{z}$ is any feasible point in (1) then $\|A\mathbf{z}\|_\infty \le na(n^{\frac{n}{2}+1} a^n + 1)$ and so we may assume that $\|\bar{\mathbf{b}}\|_\infty \le na(n^{\frac{n}{2}+1} a^n + 1)$ else there is no feasible solution. So we have

$$\|\bar{\mathbf{b}}\|_\infty, \|\bar{\mathbf{l}}\|_\infty, \|\bar{\mathbf{u}}\|_\infty \le 2^{O(n\log n)} a^{O(n)} \text{ and hence } \langle \bar{\mathbf{b}}, \bar{\mathbf{l}}, \bar{\mathbf{u}}\rangle \text{ is polynomial in } \langle A\rangle\quad .$$

Step 2: Solving the system of equations. We first search for an integer solution to the system of equations $A\mathbf{z} = \bar{\mathbf{b}}$. This can be done by computing the Hermite normal form of A, see [23], using a number of arithmetic operations polynomial in $\langle A\rangle$ and time polynomial in $\langle A, \bar{\mathbf{b}}\rangle$ which is polynomial in $\langle A\rangle$, and hence strongly polynomially in our original input. Then either we conclude that there is no integer solution to $A\mathbf{z} = \bar{\mathbf{b}}$ and hence (1) is infeasible, or we find a solution $\mathbf{z} \in \mathbb{Z}^n$ with $\langle \mathbf{z}\rangle$ polynomially bounded in $\langle A, \bar{\mathbf{b}}\rangle$ and hence also in $\langle A\rangle$.

Step 3: Finding a feasible point. Define relaxed bounds by

$$\hat{l}_i := \min\{\bar{l}_i, z_i\}, \quad \hat{u}_i := \max\{\bar{u}_i, z_i\}, \quad i \in [n] \ .$$

Now for $i \in [n]$ iterate the following. If $\bar{l}_i \le z_i \le \bar{u}_i$ then simply increment i and repeat. If $z_i < \bar{l}_i$ (and hence $\hat{l}_i = z_i$ and $\hat{u}_i = \bar{u}_i$) then consider the following auxiliary integer program,

$$\max\left\{x_i \mid \mathbf{x} \in \mathbb{Z}^n \,,\ A\mathbf{x} = \bar{\mathbf{b}} \,,\ \hat{\mathbf{l}} \le \mathbf{x} \le \hat{\mathbf{u}}\right\}. \tag{2}$$

Starting from the point $\mathbf{z}$ feasible in (2), and using the Graver-best oracle for A, we can solve program (2) using Proposition 8 in polynomial time and in a number of arithmetic operations and oracle queries which is polynomial in n and $\log F$ (recall $F = z_i^* - z_i$ for some minimizer z_i^*), which is bounded by $\log(\hat{u}_i - \hat{l}_i) = \log(\bar{u}_i - z_i)$, thus polynomial in $\langle A\rangle$.

Let $\mathbf{x}$ be an optimal solution of (2). If $x_i < \bar{l}_i$ then (1) is infeasible and we are done. Otherwise (in which case $\bar{l}_i \le x_i \le \bar{u}_i$) we update $\hat{l}_i := \bar{l}_i$ and $\mathbf{z} := \mathbf{x}$, increment i and repeat. The last case $z_i > \bar{u}_i$ is treated similarly where in (2) we minimize rather than maximize x_i.

Thus, strongly polynomially we either conclude at some iteration i that program (1) is infeasible or complete all iterations and obtain $\hat{\mathbf{l}} = \bar{\mathbf{l}}$, $\hat{\mathbf{u}} = \bar{\mathbf{u}}$, and a point $\mathbf{z}$ feasible in (1).

Step 4: Reducing $\mathbf{w}$. Let $N := 2n(n^{\frac{n}{2}+1}a^n + 1) + 1$. Now apply the strongly polynomial algorithm of Frank and Tardos [8], which on arithmetic input $n, \langle N\rangle$ and numeric input $\langle \mathbf{w}\rangle$, outputs $\bar{\mathbf{w}} \in \mathbb{Z}^n$ with $\|\bar{\mathbf{w}}\|_\infty \le 2^{O(n^3)}N^{O(n^2)}$ such that $\operatorname{sign}(\mathbf{wx}) = \operatorname{sign}(\bar{\mathbf{w}}\mathbf{x})$ for all $\mathbf{x} \in \mathbb{Z}^n$ with $\|\mathbf{x}\|_1 < N$. Since $\langle N\rangle = O(\log N) = O(n\log n + n\log a)$ is polynomial in $\langle A\rangle$, this algorithm is also strongly polynomial in our original input. Now, for every two points $\mathbf{x}, \mathbf{z}$ feasible in (1) we have $\|\mathbf{x} - \mathbf{z}\|_1 < 2n(n^{\frac{n}{2}+1}a^n + 1) + 1 = N$, so that for any two such points we have $\mathbf{wx} \le \mathbf{wz}$ if and only if $\bar{\mathbf{w}}\mathbf{x} \le \bar{\mathbf{w}}\mathbf{z}$, and therefore we can replace (1) by the equivalent program

$$\min\left\{\bar{\mathbf{w}}\mathbf{z} \ :\ \mathbf{z} \in \mathbb{Z}^n \,,\ A\mathbf{z} = \bar{\mathbf{b}} \,,\ \bar{\mathbf{l}} \le \mathbf{z} \le \bar{\mathbf{u}}\right\}, \tag{3}$$

where

$$\|\bar{\mathbf{w}}\|_\infty = 2^{O(n^3\log n)}a^{O(n^3)} \text{ and hence } \langle \bar{\mathbf{w}}, \bar{\mathbf{b}}, \bar{\mathbf{l}}, \bar{\mathbf{u}}\rangle \text{ is polynomial in } \langle A\rangle \quad .$$

Step 5: Finding an optimal solution. Starting from the point $\mathbf{z}$ which is feasible in (3), and using the Graver-best oracle for A, we can solve program (3) using again Proposition 8 in polynomial time and in a number of arithmetic operations and oracle queries which is polynomial in n and in $\log F$, which is bounded by $\log\left(n\|\bar{\mathbf{w}}\|_\infty\|\bar{\mathbf{u}} - \bar{\mathbf{l}}\|_\infty\right)$, which is polynomial in $\langle A\rangle$, and hence strongly polynomially. ◀

▶ Remark. In fact, the reduced objective $\bar{\mathbf{w}}$ in step 4 need not be constructed: already its *existence* implies that (1) is solved in the same number of iterations as (3).

3 Multi-stage Stochastic and Tree-fold ILP

In this section we prove Theorems 2 and 3. We first formalize a common construction for a Graver-best oracle: one constructs a set of relevant step lenghts Λ and then for each $\lambda \in \Lambda$ finds a λ-Graver-best step. A step with the best improvement among these is then guaranteed to be a Graver-best step. Thus, we reduce our task to constructing a Λ-Graver-best oracle.

Both algorithms for multi-stage stochastic ILP and tree-fold ILP follow the same pattern:

1. show that all elements of $\mathcal{G}(A)$ have bounded norms (ℓ_∞ and ℓ_1, respectively),
2. show that A has bounded treewidth (primal and dual, respectively),
3. apply existing algorithms for (ILP) which are FPT parameterized by $\|A\|_\infty$, $\max \|\mathbf{x}\|_\infty$ and $\max \|\mathbf{x}\|_1$, and $\mathrm{tw}_P(A)$ and $\mathrm{tw}_D(A)$, respectively.

3.1 Preliminaries

3.1.1 Relevant Step Lengths

We say that $\mathbf{h} \in \{\mathbf{x} \in \mathbb{Z}^n \mid A\mathbf{x} = \mathbf{0}\}$ is a *λ-Graver-best step* if $\lambda\mathbf{h}$ is a feasible step and $\lambda\mathbf{w}\mathbf{h} \leq \lambda\mathbf{w}\mathbf{g}$ for any $\mathbf{g} \in \mathcal{G}(A)$ such that $\lambda\mathbf{g}$ is a feasible step. We denote by $g_1(A) = \max_{\mathbf{g}\in\mathcal{G}(A)} \|\mathbf{g}\|_1$ and $g_\infty(A) = \max_{\mathbf{g}\in\mathcal{G}(A)} \|\mathbf{g}\|_\infty$. The following lemma states that provided a bound on $g_\infty(A)$, in order to find a Graver-best step, it is sufficient to find a λ-Graver-best step for all $\lambda \in \Lambda$ for some not too large set Λ.

▶ **Definition 10** (Graver-best step-lengths)**.** Let $\mathbf{x}$ be a feasible solution to (ILP). We say that $\lambda \in \mathbb{N}$ is a *Graver-best step-length for* $\mathbf{x}$ if there exists $\mathbf{g} \in \mathcal{G}(A)$ with $\mathbf{x} + \lambda\mathbf{g}$ feasible, such that $\forall \lambda' \in \mathbb{N}$ and $\forall \mathbf{g}' \in \mathcal{G}(A)$, $\mathbf{x} + \lambda'\mathbf{g}'$ is either infeasible or $\mathbf{w}(\mathbf{x} + \lambda\mathbf{g}) \leq \mathbf{w}(\mathbf{x} + \lambda'\mathbf{g}')$. We denote by $\Lambda(\mathbf{x}) \subseteq \mathbb{N}$ the set of Graver-best step-lengths for $\mathbf{x}$.

▶ **Lemma 11** (Polynomial $\Lambda \supseteq \Lambda(\mathbf{x})$)**. (*)** *Let $\mathbf{x}$ be a feasible solution to* (ILP)*, let $M \in \mathbb{N}$ be such that $g_\infty(A) \leq M$. Then it is possible to construct in time $O(Mn)$ a set $\Lambda \subseteq \mathbb{N}$ of size at most $2Mn$ such that $\Lambda(\mathbf{x}) \subseteq \Lambda$.*

With this Λ at hand, in order to realize a Graver-best oracle, it suffices to realize an oracle which finds a λ-Graver-best step for a given λ:

▶ **Definition 12** (Λ-Graver-best oracle)**.** A *Λ-Graver-best oracle* for an integer matrix A is one that, queried on $\mathbf{w}, \mathbf{b}, \mathbf{l}, \mathbf{u}$, $\mathbf{x}$ feasible to (ILP), and an integer $\lambda \in \mathbb{N}$, returns a λ-Graver-best step $\mathbf{h}$ for $\mathbf{x}$.

▶ **Lemma 13** (Λ-Graver-best oracle $\Rightarrow$ Graver-best oracle)**. (*)** *Let A be an integer matrix and let $M \in \mathbb{N}$ satisfy $g_\infty(A) \leq M$. Then a Graver-best oracle for A can be realized with $2Mn$ calls to a Λ-Graver-best oracle for A.*

3.1.2 Multi-stage Stochastic and Tree-fold Matrices

Let the *height* of a rooted tree or forest be the maximum root-to-leaf distance in it (i.e., the number of edges along the root-to-leaf path). In the following we let T be a rooted tree of height $\tau - 1 \in \mathbb{N}$ whose all leaves are at *depth* $\tau - 1$, that is, the length of every root-leaf path is exactly $\tau - 1$. For a vertex $v \in T$, let T_v be the subtree of T rooted in v and let $\ell(v)$ denote the number of leaves of T contained in T_v. Let $B_1, B_2, \ldots, B_\tau$ be a sequence of integer matrices with each B_s having $l \in \mathbb{N}$ rows and n_s columns, where $n_s \in \mathbb{N}$, $n_s \geq 1$. We shall define a *multi-stage stochastic* matrix $T^P(B_1, \ldots, B_\tau)$ inductively; the superscript P

refers to the fact that $T^P(B_1,\dots,B_\tau)$ has bounded *primal* treedepth td_P, as we will later see.

For a leaf $v \in T$, $T^P_v(B_\tau) := B_\tau$. Let $d \in \mathbb{N}$, $0 \le d \le \tau - 2$, and assume that for all vertices $v \in T$ at depth $d+1$, matrices $T^P_v(B_{\tau-d},\dots,B_\tau)$ have been defined. For $s \in \mathbb{N}$, $1 \le s \le \tau$, we set $T^P_v(B_{[s:\tau]}) = T^P_v(B_s,\dots,B_\tau)$. Let $v \in T$ be a vertex at depth d with δ children $v_1,\dots,v_\delta$. We set

$$T^P_v(B_{[\tau-d-1:\tau]}) := \begin{pmatrix} B_{\tau-d-1,\ell(v_1)} & T^P_{v_1}(B_{[\tau-d:\tau]}) & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ B_{\tau-d-1,\ell(v_\delta)} & 0 & \cdots & T^P_{v_\delta}(B_{[\tau-d:\tau]}) \end{pmatrix}$$

where, for $N \in \mathbb{N}$, $B_{s,N} = \begin{pmatrix} B_s \\ \vdots \\ B_s \end{pmatrix}$ consists of N copies of the matrix B_s.

The structure of a multi-stage stochastic matrix makes it natural to partition any solution of a multi-stage stochastic ILP into *bricks*. Bricks are defined inductively: for $T^P_v(B_\tau)$ there is only one brick consisting of all coordinates; for $T^P_v(B_{[s:\tau]})$ the set of bricks is composed of all bricks for all descendants of v, plus the first n_s coordinates form an additional brick.

▶ **Example 14.** For $\tau = 3$ and T with root r of degree 2 and its children u and v of degree 2 and 3, we have $T^P_u(B_2,B_3) = \left(\begin{smallmatrix} B_2 & B_3 \\ B_2 & B_3 \end{smallmatrix}\right)$, $T^P_v(B_2,B_3) = \left(\begin{smallmatrix} B_2 & B_3 & \\ B_2 & & B_3 \\ B_2 & & B_3 \end{smallmatrix}\right)$, and $T^P(B_1,B_2,B_2) = T^P_r(B_1,B_2,B_2) = \left(\begin{smallmatrix} B_1 & B_2 & B_3 & & \\ B_1 & B_2 & & B_3 & \\ B_1 & & B_2 & B_3 & \\ B_1 & & B_2 & & B_3 \end{smallmatrix}\right)$, with a total of 8 bricks.

Tree-fold matrices are essentially transposes of multi-stage stochastic ILP matrices. Let T be as before and $A_1,\dots,A_\tau$ be a sequence of integer matrices with each $A_s \in \mathbb{Z}^{r_s \times t}$, where $t \in \mathbb{N}$, $r_s \in \mathbb{N}$, $r_s \ge 1$. We shall define $T^D(A_1,\dots,A_\tau)$ inductively; the superscript D refers to the fact that $T^D(A_1,\dots,A_\tau)$ has bounded *dual* treedepth. The inductive definition is the same as before except that, for a vertex $v \in T$ at depth d with δ children $v_1,\dots,v_\delta$, we set

$$T^D_v(A_{[\tau-d-1:\tau]}) := \begin{pmatrix} A_{\tau-d-1,\ell(v_1)} & A_{\tau-d-1,\ell(v_2)} & \cdots & A_{\tau-d-1,\ell(v_\delta)} \\ T^D_{v_1}(A_{[\tau-d:\tau]}) & 0 & \cdots & 0 \\ 0 & T^D_{v_2}(A_{[\tau-d:\tau]}) & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & T^D_{v_\delta}(A_{[\tau-d:\tau]}) \end{pmatrix}$$

where, for $N \in \mathbb{N}$, $A_{s,N} = (A_s \cdots A_s)$ consists of N copies of the matrix A_s. A solution $\mathbf{x}$ of a tree-fold ILP is partitioned into bricks $(\mathbf{x}^1,\dots,\mathbf{x}^n)$ where n is the number of leaves of T, and each $\mathbf{x}^i$ is a t-dimensional vector.

3.1.3 Structural Parameters

We consider two graph parameters, namely *treewidth* $\mathrm{tw}(G)$ and *treedepth* $\mathrm{td}(G)$. We postpone the definition of treewidth to the full version as it is not central for us.

▶ **Definition 15** (Treedepth)**.** The *closure* $\mathrm{cl}(F)$ of a rooted forest F is the graph obtained from F by making every vertex adjacent to all of its ancestors. The *treedepth* $\mathrm{td}(G)$ of a graph G is one more than the minimum height of a forest F such that $G \subseteq \mathrm{cl}(F)$.

It is known that $\mathrm{tw}(G) \le \mathrm{td}(G)$. The treedepth $\mathrm{td}(G)$ of a graph G with a witness forest F can be computed in time $f_{\mathrm{td}}(\mathrm{td}(G)) \cdot |V(G)|$ for some computable function f_{td} [22].

▶ **Definition 16** (Primal and dual graph)**.** Given a matrix $A \in \mathbb{Z}^{m\times n}$, its *primal graph* $G_P(A) = (V, E)$ is defined as $V = [n]$ and $E = \{\{i, j\} \in \binom{[n]}{2} \mid \exists k \in [m] : A_{k,i}, A_{k,j} \neq 0\}$. In other words, its vertices are the columns of A and two vertices are connected if there is a row with non-zero entries at the corresponding columns. The *dual graph of* A is defined as $G_D(A) = G_P(A^\intercal)$, that is, the primal graph of the transpose of A.

▶ **Definition 17** (Matrix treewidth)**.** Given a matrix A, its *primal treewidth* $\mathrm{tw}_P(A)$ is defined as the treewidth of its primal graph, i.e., $\mathrm{tw}(G_P(A))$, and its *dual treewidth* $\mathrm{tw}_D(A)$ is $\mathrm{tw}(G_D(A))$. Similarly, we define the *primal* and *dual treedepth* as $\mathrm{td}_P(A) = \mathrm{td}(G_P(A))$ and $\mathrm{td}_D(A) = \mathrm{td}(G_D(A))$, respectively.

Using a proof of Ganian et al. [11, Theorem 12] we show that we cannot hope to relax the parameter $\mathrm{td}_D(A)$ to $\mathrm{tw}_D(A)$, even if $\|A\|_\infty$ was a constant.

▶ **Lemma 18. (*)** (ILP) *is* NP*-hard already when* $\mathrm{tw}_D(A) = 3$*,* $\|A\|_\infty = 2$*, and* $\mathbf{w} = \mathbf{0}$*.*

3.2 Multi-stage Stochastic ILP is strongly FPT

To prove Theorem 2, we need two ingredients: a bound on $g_\infty(A)$, and an algorithm for (ILP) with bounded $\mathrm{tw}_P(A)$ and $\max \|\mathbf{x}\|_\infty$.

▶ **Lemma 19** (Multi-stage stochastic ⇒ bounded $g_\infty(A)$)**. (*)** *Let* $A = T^P(B_1, \ldots, B_\tau)$*. Then* $g_\infty(A) \leq f_{mss\text{-}norm}(a, n_1, \ldots, n_\tau, l)$ *for some computable function* $f_{mss\text{-}norm}$*.*

▶ **Lemma 20. (*)** *Let* $X \in \mathbb{N}$*. Problem* (ILP) *with the additional constraint* $\|\mathbf{x}\|_\infty \leq X$ *can be solved in time* $(X + 1)^{O(\mathrm{tw}_P(A))} \cdot (n + m)$*.*

Proof of Theorem 2. Let $A = T^P(B_1, \ldots, B_\tau)$ be a multi-stage stochastic matrix. By Lemma 19, $g_\infty(A)$ is bounded by $M = f_{\text{mss-norm}}(a, n_1, \ldots, n_\tau, l)$. We show how to construct a Λ-Graver-best oracle. Given an integer $\lambda \in \mathbb{N}$, use Lemma 20 to solve

$$\min\{\lambda\mathbf{wh} \mid A\mathbf{h} = 0,\ \mathbf{l} \leq \mathbf{x} + \lambda\mathbf{h} \leq \mathbf{u},\ \|\mathbf{h}\|_\infty \leq M\}\ .$$

This returns a λ-Graver-best step, because any optimal solution satisfies $\lambda\mathbf{h} \leq \lambda\mathbf{g}$ for all $\mathbf{g} \in \mathcal{G}(A)$. Using a simple induction and the inductive construction of A, one gets that A has $\mathrm{tw}_P(A) \leq \mathrm{td}_P(A) \leq n_1 + \cdots + n_\tau + 1$ and thus the oracle is realized in FPT time. Lemma 13 then yields a Graver-best oracle, which, combined with Theorem 1, finishes the proof. ◀

3.3 Tree-fold ILP is strongly FPT

As before, to prove Theorem 3, we need two ingredients: a bound on $g_1(A)$, and an algorithm for (ILP) with bounded $\mathrm{tw}_D(A)$ and $\max \|\mathbf{x}\|_1$.

▶ **Lemma 21** (Tree-fold ⇒ bounded $g_1(A)$)**. (*)** *Let* $A_i \in \mathbb{Z}^{r_i\times t}$ *for* $i \in [\tau]$ *with* $a = \max\{2, \max_{i\in[\tau]} \|A_i\|_\infty\}$*,* $r = \sum_{i=1}^{\tau} r_i$*. Let* $A = T^D(A_1, \ldots, A_\tau)$*. There exists a computable function* $f_{tf\text{-}norm}(a, r_1, \ldots, r_\tau)$ *such that* $g_1(A) \leq f_{tf\text{-}norm}(a, r_1, \ldots, r_\tau)$*.*

Proof sketch. Chen and Marx [4] prove a similar result under the assumption that t is also a parameter; thus, the remaining problem are essentially duplicitous columns. However, De Loera et al. [5] show that repeating columns of any matrix A' does not increase $g_1(A')$, and thus we can take A, delete duplicitous columns, apply the result of Chen and Marx, and our Lemma follows.

▶ **Lemma 22. (*)** *Let* $X \in \mathbb{N}$*. Problem* (ILP) *with the additional constraint* $\|\mathbf{x}\|_1 \leq X$ *can be solved in time* $(aX)^{O(\mathrm{tw}_D(A))} \cdot n$*, where* $a = \max\{2, \|A\|_\infty\}$*.*

Proof sketch. Lemma 22 is proved by reformulating the nonlinear constraint $\|\mathbf{x}\|_1 \leq X$ by "splitting" each variable x_i into two non-negative variables $x_i = x_i^+ - x_i^-$, imposing the constraint $\sum_{i=1}^n (x_i^+ + x_i^-) \leq X$, and showing that this does not increase $\mathrm{tw}_D(A)$ much; then, a recent dynamic programming algorithm of Ganian et al. [11, Theorem 6] does the job.

Proof of Theorem 3. Let $A = T^D(A_1, \ldots, A_\tau)$ be a tree-fold matrix. By Lemma 21 we have that $g_1(A) \leq f_{\text{tf-norm}}(a, r_1, \ldots, r_\tau) =: M$ We show how to construct a Λ-Graver-best oracle. Given an integer $\lambda \in \mathbb{N}$, solve $\min\{\lambda \mathbf{wh} \mid A\mathbf{h} = 0, \mathbf{l} \leq \mathbf{x} + \lambda\mathbf{h} \leq \mathbf{u}, \|\mathbf{h}\|_1 \leq M\}$ using Lemma 22; clearly the result is a λ-Graver-best step. Using a simple induction and the inductive construction of A, one gets that A has $\mathrm{tw}_D(A) \leq \mathrm{td}_D(A) \leq r_1 + \cdots + r_\tau + 1$ and thus the oracle is realized in FPT time. Lemma 13 then yields a Graver-best oracle, which, combined with Theorem 1, finishes the proof. ◀

***n*-fold ILP.** A special case of tree-fold ILP is n-fold ILP, obtained by taking T to be the star with n leaves and $A = T^D(A_1, A_2)$, where $A_1 \in \mathbb{Z}^{r \times t}$ and $A_2 \in \mathbb{Z}^{s \times t}$.

Proof of Theorem 4. Before we apply Lemma 22, we need to bound $g_1(A)$. It follows from the proof of [13, Lemma 6.1] that there is a number $g(A) = \max_{\mathbf{v} \in \mathcal{G}(A_1\mathcal{G}(A_2))} \|\mathbf{v}\|_1$ such that $g_1(A) \leq g(A) \cdot g_1(A_2)$.

Let $d_2 \leq (2a+1)^s$ be the number of distinct columns of A_2. De Loera et al. [5] give a bound on $g_1(A)$ in terms of the number of distinct columns of a matrix A:

▶ **Lemma 23** ([5, Corollary 3.7.4]). *Let $A \in \mathbb{Z}^{m \times n}$ be a matrix of rank r, let d be the number of different columns in A, and let $a = \max\{2, \|A\|_\infty\}$. Then $g_1(A) \leq (d-r)(r+1)(\sqrt{ma})^m$.*

Thus, $g_1(A_2) \leq (d_2 - s)(s+1)(\sqrt{s}a)^s \leq (as)^{O(s)}$. Let G_2 be a matrix whose columns are elements of $\mathcal{G}(A_2)$. We have that $\|A_1G_2\|_\infty \leq a \cdot (as)^{O(s)} \leq (as)^{O(s)}$. Moreover, since A_1G_2 has r rows, it has at most $d_1 = \left((as)^{O(s)}\right)^r = (as)^{O(rs)}$ distinct columns. Again, by Lemma 23 we have that $g(A) = g_1(A_1G_2) \leq (d_1 - r)(r+1)(\sqrt{r}as)^{O(s)})^r \leq (ars)^{O(rs)}$. Combining, we get $g_1(A) \leq (ars)^{O(rs)} \cdot (as)^{O(s)} \leq (ars)^{O(rs)} =: M$.

We have $\mathrm{tw}_D(A) \leq r + s + 1$ and thus running the algorithm of Lemma 22 once takes time $\left((ars)^{O(rs)}\right)^{r+s} nt \leq (ars)^{O(r^2s+rs^2)}nt$ and finds the λ-Graver-best step. Lemma 13 then yields a Graver-best oracle. The reduced objective function $\bar{\mathbf{w}}$ in Step 4 of the proof of Theorem 1 satisfies $\|\bar{\mathbf{w}}\|_\infty \leq (ant)^{O((nt)^3)}$ and thus the number of calls to the Graver-best oracle is bounded by $(nt)^3 \log(nt)$, concluding the proof. ◀

4 Primal and Dual Treedepth

We prove Theorems 5 and 6 by showing that an ILP with bounded primal (dual) treedepth can be embedded into a multi-stage stochastic (tree-fold) ILP without increasing the parameters too much. The precise notion of how one ILP is embedded in another is captured as follows.

▶ **Definition 24** (Extended formulation). Let $n' \geq n$, $m' \in \mathbb{N}$, $A \in \mathbb{Z}^{m \times n}$, $\mathbf{b} \in \mathbb{Z}^m$, $\mathbf{l}, \mathbf{u} \in (\mathbb{Z} \cup \{\pm\infty\}^n$ and $A' \in \mathbb{Z}^{m' \times n'}$, $\mathbf{b}' \in \mathbb{Z}^{m'}$, $\mathbf{l}', \mathbf{u}' \in (\mathbb{Z} \cup \{\pm\infty\})^{n'}$. We say that $A'(\mathbf{x}, \mathbf{y}) = \mathbf{b}', \mathbf{l}' \leq (\mathbf{x}, \mathbf{y}) \leq \mathbf{u}'$ is an *extended formulation* of $A\mathbf{x} = \mathbf{b}, \mathbf{l} \leq \mathbf{x} \leq \mathbf{u}$ if $\{\mathbf{x} \mid A\mathbf{x} = \mathbf{b}, \mathbf{l} \leq \mathbf{x} \leq \mathbf{u}\} = \{\mathbf{x} \mid \exists \mathbf{y} : A'(\mathbf{x}, \mathbf{y}) = \mathbf{b}', \mathbf{l}' \leq (\mathbf{x}, \mathbf{y}) \leq \mathbf{u}'\}$.

We note that from here on we always assume that if $\mathrm{td}_P(A) = k$ or $\mathrm{td}_D(A) = k$, then there is a *tree* (not a forest) F of height $k-1$ such that $G_P(A) \subseteq \mathrm{cl}(F)$ or $G_D(A) \subseteq \mathrm{cl}(F)$, respectively. Otherwise $G_P(A)$ is not connected and each component corresponds to a subset of variables which defines an ILP that can be solved independently; similarly for $G_D(A)$.

4.1 Primal Treedepth

▶ **Lemma 25** (Bounded primal treedepth ⇒ multi-stage stochastic). *Let $A, \mathbf{b}, \mathbf{l}$ and $\mathbf{u}$ as in* (ILP) *be given, let $a = \max\{2, \|A\|_\infty\}$ and $\tau + 1 = \mathrm{td}_P(A)$. Then there exists $C \in \mathbb{Z}^{m' \times n'}$, $\mathbf{b}' \in \mathbb{Z}^{m'}$ and $\mathbf{l}', \mathbf{u}' \in (\mathbb{Z} \cup \{\pm\infty\})^{n'}$, $n' \leq n\tau$, $m' \leq (2a+1)^{\tau^2}$, which define an integer program $C(\mathbf{x}, \mathbf{y}) = \mathbf{b}', \mathbf{l}' \leq (\mathbf{x}, \mathbf{y}) \leq \mathbf{u}'$, which is an extended formulation of $A\mathbf{x} = \mathbf{b}, \mathbf{l} \leq \mathbf{x} \leq \mathbf{u}$. Moreover, there exist matrices $B_1, \ldots, B_{\tau-1} \in \mathbb{Z}^{(2a+1)^{\tau^2} \times \tau}$ and $B_\tau \in \mathbb{Z}^{(2a+1)^{\tau^2} \times \left(\tau + (2a+1)^{\tau^2}\right)}$ and a tree T such that $C = T^P(B_1, \ldots, B_\tau)$ is a multi-stage stochastic constraint matrix, and all can be computed in time $f_{P\text{-}embed}(a, \mathrm{td}_P(A)) \cdot n^2$ for some computable function $f_{P\text{-}embed}$.*

Proof. Let F be a rooted tree of height τ such that $G_P(A) \subseteq \mathrm{cl}(F)$ (recall that it can be computed in time $f_{\mathrm{td}}(\mathrm{td}_P(A)) \cdot |V(G_P(A))|$).

Step 1: Dummy columns. We make F structured by adding dummy columns. Observe that every root-leaf path is of length at most τ and thus contains at most τ branching vertices. Unless F is a path, obtain a matrix A' from A by inserting zero columns into A in order to make the path between any two branching vertices of length τ; a special case is the root which we force to be in distance $\tau - 1$ from the closest branching vertex. Set lower and upper bounds on the corresponding new variables to 0. A zero column is an isolated vertex in the primal graph and thus can be inserted to an arbitrary path of the tree F. Moreover, if any leaf is at depth less than $\tau^2 - 1$, insert zero columns in the same way to make it be at depth exacty $\tau^2 - 1$. Now there exists a rooted tree F' of height $\tau^2 - 1$ such that $G_P(A') \subseteq \mathrm{cl}(F')$, all branching vertices are in distances $0, \tau - 1, 2\tau - 1, \ldots, (\tau - 1)\tau - 1$ from the root, and all leaves are at depth exactly $\tau^2 - 1$. We call all vertices at depth 0 or $i\tau - 1$, for $i \in [\tau]$, *frets*, including the root and leaves.

Step 2: Multi-stage stochastic extended formulation. Consider a root-leaf path P in F': its vertex set $V(P)$ corresponds to a certain subset of the columns of A', with $|V(P)| \leq \tau^2$. Furthermore, any row $\mathbf{a}$ of A' with $\mathrm{supp}(\mathbf{a}) \subseteq V(P)$ can be written as a vector $(\mathbf{a}^1, \ldots, \mathbf{a}^\tau) \in \mathbb{Z}^{\tau^2}$ with $\mathbf{a}^i \in \mathbb{Z}^\tau$ for each $i \in [\tau]$, and with $\|\mathbf{a}\|_\infty \leq a$. The *bricks* $\mathbf{a}^i$ correspond to segments between frets (including the end fret, i.e., the fret farthest from the root; segments adjacent to the root also contain the root). Also, for any row $\mathbf{a}$ of A', there exists some root-leaf path P such that $\mathrm{supp}(\mathbf{a}) \subseteq V(P)$.

This inspires the following construction: let $B \in \mathbb{Z}^{(2a+1)^{\tau^2} \times \tau^2}$ be the matrix whose columns are all the possible vectors $\mathbf{a} \in \mathbb{Z}^{\tau^2}$ with $\|\mathbf{a}\|_\infty \leq \|A\|_\infty$. Let $B_i \in \mathbb{Z}^{(2a+1)^{\tau^2} \times \tau}$, for $i \in [\tau]$, be the submatrix of B formed by rows $(i-1)\tau + 1, \ldots, i\tau$ and modify the last such submatrix B_τ by putting $B_\tau := (B_\tau \mid I)$ where $I \in \mathbb{Z}^{(2a+1)^{\tau^2} \times (2a+1)^{\tau^2}}$ is the identity matrix; the variables corresponding to columns of I will play the role of slack variables. Let T be the tree of height τ obtained from F' by contracting all paths between frets.

Now, let $C = T^P(B_1, \ldots, B_\tau)$. Obtain $\tilde{F}$ from F' by appending a leaf to every leaf, and observe that $G_P(T^P(B_1, \ldots, B_\tau)) \subseteq \mathrm{cl}(\tilde{F})$; the new leaves correspond to the slack variables in B_τ. Our goal now is to construct a right hand side vector $\mathbf{b}'$ and lower and upper bounds $\mathbf{l}', \mathbf{u}'$ to enforce exactly the constraints present in $A\mathbf{x} = \mathbf{b}$. For every root-leaf path P in F' there is a corresponding root-leaf path $\tilde{P}$ in $\tilde{F}$ such that $\tilde{P}$ is P with an additional leaf. Fix a root-leaf path P in F'. For every row $\mathbf{a}$ of A' with $\mathrm{supp}(\mathbf{a}) \subseteq V(P)$ and right hand side β, there exists a unique row $\mathbf{c}$ of C with $\mathrm{supp}(\mathbf{c}) \subseteq V(\tilde{P})$ such that $\mathbf{c} = (\mathbf{a}, 1)$, and we set the right hand side of row $\mathbf{c}$ to β.

For every row $\mathbf{c}$ of C which was not considered in the previous paragraph, set the right hand side to 0 and for the slack variable of this row set the lower bound to $-\infty$ and the

upper bound to ∞. Let us remark in passing that we are not limited by using the standard equality form of ILP: transforming an instance $A\mathbf{x} \leq \mathbf{b}$ into the standard equality form by adding slack variables only possibly increases the treedepth by 1. ◀

4.2 Dual Treedepth

▶ **Lemma 26** (Bounded dual treedepth ⇒ tree-fold)**. (*)** *Let $A, \mathbf{b}, \mathbf{l}$ and $\mathbf{u}$ be as in* (ILP)*, $a = \max\{2, \|A\|_\infty\}$ and $\tau + 1 = \mathrm{td}_D(A)$. Then there exists $D \in \mathbb{Z}^{m' \times n'}$, $\mathbf{b}' \in \mathbb{Z}^{m'}$ and $\mathbf{l}', \mathbf{u}' \in (\mathbb{Z} \cup \{\pm\infty\})^{n'}$, $n' \leq nt$, $t \leq n$, $m' \leq m \cdot \tau$, which define an extended formulation of $A\mathbf{x} = \mathbf{b}, \mathbf{l} \leq \mathbf{x} \leq \mathbf{u}$. Moreover, there exist matrices $A_1, \ldots, A_\tau \in \mathbb{Z}^{\tau \times t}$ and a tree T such that $D = T^D(A_1, \ldots, A_\tau)$ is a tree-fold constraint matrix, and all can be computed in time $f_{D\text{-}embed}(a, \mathrm{td}_D(A)) \cdot n^2$ for some computable function $f_{D\text{-}embed}$.*

Finer Tight Bounds for Coloring on Clique-Width

Michael Lampis

michail.lampis@dauphine.fr

Abstract

We revisit the complexity of the classical k-Coloring problem parameterized by clique-width. This is a very well-studied problem that becomes highly intractable when the number of colors k is large. However, much less is known on its complexity for small, concrete values of k. In this paper, we completely determine the complexity of k-Coloring parameterized by clique-width for any fixed k, under the SETH. Specifically, we show that for all $k \geq 3, \epsilon > 0$, k-Coloring cannot be solved in time $O^*\left((2^k - 2 - \epsilon)^{\text{cw}}\right)$, and give an algorithm running in time $O^*\left((2^k - 2)^{\text{cw}}\right)$. Thus, if the SETH is true, $2^k - 2$ is the "correct" base of the exponent for every k.

Along the way, we also consider the complexity of k-Coloring parameterized by the related parameter modular treewidth (mtw). In this case we show that the "correct" running time, under the SETH, is $O^*\left(\binom{k}{\lfloor k/2 \rfloor}^{\text{mtw}}\right)$. If we base our results on a weaker assumption (the ETH), they imply that k-Coloring cannot be solved in time $n^{o(\text{cw})}$, even on instances with $O(\log n)$ colors.

1 Introduction

Graph Coloring (from now on simply Coloring) is one of the most intensely studied problems in theoretical computer science. In this classical problem we are given a graph $G = (V, E)$ and an integer k and are asked if we can partition V into k sets inducing edge-less graphs. Coloring is a notoriously hard problem as it remains NP-hard even in very restricted cases (e.g. 4-regular planar graphs [10]) and is essentially completely inapproximable in general [11, 30]. This intractability has motivated the study of the problem in the framework of parameterized complexity, especially with respect to structural graph parameters.[1]

Treewidth is by far the most widely studied among such graph parameters, and Coloring has long been known to be FPT by treewidth. This can be seen by either invoking Courcelle's theorem [4], or by applying a straightforward dynamic programming technique which, for each bag of a tree decomposition of width tw considers all possible k^{tw} colorings. Remarkably, thanks to the work of Lokshtanov, Marx, and Saurabh [23], we know that this basic algorithm is likely to be optimal, or at least that improving it would require a major breakthrough on SAT-solving, as, for any $k \geq 3, \epsilon > 0$, the existence of a $(k-\epsilon)^{\text{tw}}$ algorithm would contradict the Strong Exponential Time Hypothesis of Impagliazzo and Paturi [18, 19]. More recently, these lower bounds were strengthened, as Jaffke and Jansen showed that a $(k-\epsilon)^w$ algorithm would contradict the SETH when w is the graph's vertex edit distance from being a path

[1] In the remainder, we assume that the reader is familiar with the basics of parameterized complexity, such as the class FPT, as given in relevant textbooks [8, 13]

[20]. The same paper showed that the trivial algorithm can, however, be improved when one considers more restrictive parameters, such as vertex cover, but still not to the point that the base of the exponent becomes a constant. These results thus paint a very clear picture of the complexity of Coloring with respect to treewidth and its restrictions.

One of the drawbacks of treewidth is that it does not cover dense graphs, even if they have a very simple structure. This has led to the introduction of clique-width, which is by now (arguably) the second most well-studied parameter. The complexity of Coloring parameterized by clique-width has also been investigated. Even though Coloring is polynomial-time solvable when clique-width is constant, the best known algorithm for this case runs in time $n^{2^{O(\mathrm{cw})}}$ [21]. Fomin et al. [14] showed that Coloring is not FPT for clique-width (under standard assumptions), and this was recently followed up by Golovach et al. [17] who showed, somewhat devastatingly, that the aforementioned algorithm is likely to be optimal, as an algorithm running in $n^{2^{o(\mathrm{cw})}}$ would contradict the ETH. The problem thus seems to become significantly harder for clique-width, and this has, in part, motivated the study of alternative dense graph parameters, such as split-matching width [28], modular-width [15], and twin cover [16], all of which make Coloring FPT.

Contribution. Although the results mentioned above demonstrate a clear jump in the complexity of Coloring when moving from treewidth to clique-width, we observe that they leave open a significant hole: all the aforementioned hardness results for clique-width ([14, 17]) only apply to the case where k is large (polynomially related to the size of the graph). It is not hard to see that the problem becomes significantly easier if both cw and k are assumed to have moderate values; indeed Coloring is FPT when parameterized by $\mathrm{cw}+k$ [21]. Since the case where k is relatively small is arguably the most interesting scenario for most applications, we are strongly motivated to take a closer look at the complexity of Coloring parameterized by clique-width, in order to obtain a more fine-grained and quantitative estimate of the "price of generality" for this problem *for each fixed value of* k. Our aim is to reach tight bounds that paint a crisper picture of the complexity of the problem than what can be inferred by lower bounds parameterized only by clique-width, in the same way that the results of [23] do for k-Coloring on treewidth.

The main result of this paper is a lower bound which states that for all $k \geq 3, \epsilon > 0$, k-Coloring cannot be solved in time $O^*\left((2^k - 2 - \epsilon)^{\mathrm{cw}}\right)$, unless the SETH is false. This result gives a concrete, detailed answer to the question of how much the complexity of 3-Coloring, 4-Coloring, and generally k-Coloring, increases as one moves from treewidth to clique-width. As in the lower bound of [23], this result is established through a reduction from SAT. The main challenge here is that we need to pack a much larger amount of information per unit of width, and in particular that the graph induced by most label sets must be edge-less (otherwise many of the $2^k - 2$ choices we need to encode would be invalid). We work around this difficulty by a delicate use of the rename operation used in clique-width expressions.

Though having $2^k - 2$ in the base of the running time may seem somewhat curious (and certainly less natural than the k^{tw} bounds of [23]), we then go on to prove that this is the "correct" bound by giving a matching algorithm. The algorithm is based on standard DP techniques (including subset convolution [1, 29]), but requires a non-standard trick that "looks ahead" in the decomposition to lower the table size from $(2^k - 1)^{\mathrm{cw}}$ to $(2^k - 2)^{\mathrm{cw}}$. This improves the previously known DP algorithm of [21], which runs in $O^*\left(4^{k \cdot \mathrm{cw}}\right)$.

Beyond these results for clique-width we also consider the closely related parameters modular treewidth and modular pathwidth, which have more recently been considered as

more restricted versions of clique-width [25, 27]. The modular treewidth of a graph G is defined as the treewidth of the graph obtained from G if one collapses each twin class into a single vertex, where two vertices are twins if they have the same neighbors. By slightly altering our results for clique-width we tightly characterize the complexity of k-Coloring for these parameters: the problem is solvable in time $O^*\left(\binom{k}{\lfloor k/2 \rfloor}^{\mathrm{mtw}}\right)$, but not solvable in $O^*\left(\left(\binom{k}{\lfloor k/2 \rfloor}-\epsilon\right)^{\mathrm{mpw}}\right)$ under the SETH. Using the same reduction but relaxing the hypothesis to the ETH, we show that k-Coloring cannot be solved in time $n^{o(\mathrm{mpw})}$, and hence neither in time $n^{o(\mathrm{cw})}$ even on instances where $k = O(\log n)$. This can be seen as a strengthening of the lower bound of [14], which applies only to clique-width and uses $\Omega(n)$ colors. Our result is incomparable to the more recent double-exponential bound of [17] as it applies to the more restricted case where the number of colors is logarithmic, and is tight for this case. Indeed, any reduction giving a double-exponential bound, such as the one in [17], must inevitably use more than $\log n$ colors, otherwise it would contradict the aforementioned algorithms.

Non-binary CSPs. We mention as a secondary contribution of this paper a proof that, under the SETH, n-variable CSPs over an alphabet of size B cannot be solved in time $(B-\epsilon)^n$, for any B, ϵ. The interest of such a result is not so much technical (its proof is implicit in previous SETH-based bounds, going back to [23]), as conceptual. Such CSPs provide a convenient starting point for a SETH-based lower bound for *any base* of the exponential and hence allow us to isolate a technical part of such proofs from the main part of the reduction. This explicit statement on the hardness of CPSs has allowed the proofs of this paper to be significantly shortened, and may facilitate the design of other SETH-based hardness proofs.

2 Definitions and Preliminaries

We use standard graph-theoretic notation and assume that the reader is familiar with the basics of parameterized complexity, as well as standard notions such as treewidth [8, 13]. Let us recall the definition of clique-width (see [6, 5] for more details). A labeled graph G has clique-width w if it can be constructed using w labels and the following four basic operations: Introduce(i), for $i \in \{1, \ldots, w\}$, which constructs a single-vertex graph whose vertex has label i; Union(G_1, G_2), which constructs the disjoint union of two labeled graphs of clique-width w; Rename(i, j) which changes the label of all vertices labeled i to j; and Join(i, j) which adds all possible edges between vertices labeled i and vertices labeled j. Computing a graph's clique-width is NP-hard [12], and the best currently known approximation is exponential in clique-width [26]. In this paper, we will often assume that we are given together with a graph G, a clique-width expression constructing G. Since most of our results are negative, this only makes them stronger, as it shows that our lower bounds do not rely on the hardness of computing clique-width. We view a clique-width expression as a rooted binary tree, where the sub-tree rooted in each internal node represents the corresponding sub-graph of G. We use $\mathrm{cw}(G)$ to denote the minimum number of labels needed to construct a clique-width expression of G, and $\mathrm{tw}(G), \mathrm{pw}(G)$ to denote the treewidth and pathwidth of G respectively.

In a graph $G = (V, E)$ we say that $u, v \in V$ are false twins if $N(u) = N(v)$ and true twins if $N[u] = N[v]$, where $N[u] = N(u) \cup \{u\}$ denotes the closed neighborhood of u. We say that u, v are twins if they are true or false twins. We note that in any graph G the partition of vertices into twin classes is always unique, as the property of being twins is an equivalence relation [22]. Let G^t be the graph obtained from G by deleting from each twin class all but a single vertex. We define (following [25]) the modular treewidth of G, denoted $\mathrm{mtw}(G)$, as $\mathrm{tw}(G^t)$, and similarly the modular pathwidth $\mathrm{mpw}(G)$ as $\mathrm{pw}(G^t)$.

▶ **Lemma 1.** *For all* G, $\mathrm{pw}(G) \geq \mathrm{mpw}(G) \geq \mathrm{cw}(G) - 2$ *and* $\mathrm{pw}(G) \geq \mathrm{mpw}(G) \geq \mathrm{mtw}(G)$.

The Exponential Time Hypothesis (ETH) of Impagliazzo, Paturi, and Zane [19] states that there exists a constant $c_3 > 1$ such that 3-SAT on instances with n variables cannot be solved in time c_3^n. If the ETH is true then we can define, for all $q \geq 3$ a constant $c_q > 1$ such that q-SAT, that is, SAT on instances where clauses have maximum size q, cannot be solved in time c_q^n. The Strong Exponential Time Hypothesis (SETH) [18] states that $\lim_{q\to\infty} c_q = 2$, or equivalently that, for each $\epsilon > 0$ there exists a q such that q-SAT cannot be solved in $(2-\epsilon)^n$. We note that sometimes a slightly weaker form of the SETH is used, which states simply that SAT cannot be solved in $(2-\epsilon)^n$ for any $\epsilon > 0$. The two formulations are not currently known to be equivalent. In this paper we use the original, stronger formulation of [18] (see also e.g. [7]) which assumes that c_q tends to 2.

For any $q, B \geq 2$ we define the q-CSP-B problem as follows: we are given a set X of n variables which take values in $\{1, \ldots, B\}$, and a set $\mathcal{C}$ of q-constraints on X. A q-constraint c is defined by an ordered tuple $V(c)$ of q variables of X, and a set $S(c) \subseteq \{1, \ldots, B\}^q$ of satisfying assignments for c. The question is whether there exists an assignment $\sigma : X \to \{1, \ldots, B\}$ which satisfies all constraints $c \in \mathcal{C}$. We say that a constraint $c \in \mathcal{C}$ is satisfied if applying σ to $V(c)$ produces a tuple of assignments that appears in $S(c)$. To simplify presentation, we will assume that in the input the list $S(c)$ of the at most B^q satisfying assignments of each constraint is given explicitly, and that a q-CSP-B instance is allowed to contain constraints on fewer than q variables (as we can add dummy variables to a constraint).

3 SETH and Non-binary CSPs

The SETH states, informally, that as SAT clauses become larger, eventually the best algorithm for SAT is simply to try out all possible assignments to all variables. In this section we show that the same is essentially true for CSP with a larger, non-binary alphabet. The interest in presenting such a result is that very often we seek to prove a SETH-based lower bound showing that a problem does not admit an algorithm running in c^w, for some constant c and width parameter w (such as treewidth, or in our case clique-width). This becomes complicated when we reduce directly from SAT if c is not a power of 2 as one cannot make a one-to-one correspondence between binary SAT variables and "units of width" (in our case labels) in the new instance, which are intended to encode c choices. As a result, essentially all known SETH lower bounds of this form include as part of their construction a group gadget, which maps every t variables of the original SAT instance to p elements of the new problem, for appropriately chosen integers p, t (see e.g. [3, 9, 20, 23]). Such gadgets are, however, often cumbersome to design, because they require a problem-specific trick that expresses a mapping of assignments from a binary to a non-binary domain. We therefore prefer to construct a custom-made CSP with a convenient running time bound, which will later allow us to reduce directly to the problem we are interested in (Coloring on clique-width), in a way that maps exactly one variable to one clique-width label. This will allow our SETH-based bounds to be significantly simplified, as we will no longer have to worry about a discrepancy between the bases of the exponentials.

▶ **Theorem 2.** *For any* $B \geq 2$, $\epsilon > 0$ *we have the following: if the SETH is true, then there exists a* q *such that* n*-variable* q-CSP-B *cannot be solved in time* $O^*\left((B-\epsilon)^n\right)$.

4 SETH-based Lower Bound for Clique-width

In this section we present our main lower bound result stating that k-Coloring cannot be solved in time $O^*\left((2^k-2-\epsilon)^{\text{cw}}\right)$, for any $k \geq 3, \epsilon > 0$, under the SETH. In Section 4.1 we present some basic gadgets that will also be of use in our lower bound for modular pathwidth (Section 5). We then present the main part of the proof in Section 4.2.

4.1 List Coloring and Basic Gadgets

The high-level machinery that we will make use of in our reduction consists of two major points: first, we would like to be able to express implication constraints, that is, constraints of the form "if vertex u received color c_1, then vertex v must receive color c_2"; second, we would like to express disjunction constraints of the form "at least one of the vertices of the set $S \subseteq V$ must take a special color 1". We build this machinery in the following steps: first, we show that we can (almost) equivalently produce an instance of the more general List Coloring problem; then we use the ability to construct lists to make *weak edge gadgets*, which for a given pair of vertices (u_1, u_2) rule out a specific pair of assigned colors; using these weak edges we construct the aforementioned implication gadgets; and finally we are able to implement OR constraints using paths on vertices with appropriate lists.

We give all details for these constructions below. We remark however, for the convenience of the reader, that a high-level understanding of the informal meaning of implication gadgets and OR gadgets (precisely stated in Lemmata 7, 10) is already sufficient to follow the description of the main part of the reduction, given in Section 4.2. See also Figure 1.

List Coloring. To simplify the presentation of our reduction it will be convenient to use a slightly more general problem. In List Coloring, we are given a graph G and a list of possible colors associated with each vertex and are asked if there is a proper coloring such that each vertex uses a color from its list. This problem clearly generalizes k-Coloring, as all lists may be $\{1, \ldots, k\}$. We will make use of a reduction in the opposite direction.

▶ **Lemma 3.** *There is a polynomial-time algorithm which, given an instance of* List Coloring *on a graph G where all lists are subsets of $\{1, \ldots, k\}$, transforms it into an equivalent instance of k-*Coloring *on a graph G'. Furthermore, the algorithm transforms a clique-width expression of G with* cw *labels, to a clique-width expression of G' with* $\text{cw} + k$ *labels. If all twins of G share the same list, the algorithm transforms a modular path decomposition of width* mpw *for G, to a modular path decomposition of G' of width* $\text{mpw} + k$.

Weak Edges and Implications. Normally, the existence of an edge (u, v) in an instance of Coloring forbids the vertices u, v from obtaining the same color, whatever that color may be. We will find it convenient to construct edges that forbid only a specific pair of colors from appearing on u, v, while allowing any other combination of colors to be used on these two vertices. Similar versions of this gadget have appeared before, for example [23, 24].

▶ **Definition 4.** For two vertices u_1, u_2 of a graph G and two colors c_1, c_2 a (c_1, c_2)-*weak edge* from u_1 to u_2 consists of the following:

1. Three new vertices v_1, v_2, v_3 such that $\{u_1, v_1, v_2, v_3, u_2\}$ induces a path in this order, with endpoints u_1, u_2, and v_1, v_2, v_3 having no edges to the rest of G.
2. If $c_1 \neq c_2$ let c' be a color distinct from c_1, c_2. We assign to v_1, v_2, v_3 the lists $\{c_1, c_2\}, \{c_2, c'\}, \{c_2, c'\}$. If $c_1 = c_2$, we assign lists $\{c_1, c'\}, \{c', c''\}, \{c_1, c''\}$ to v_1, v_2, v_3 respectively, where c', c'' are two distinct colors, different from c_1.

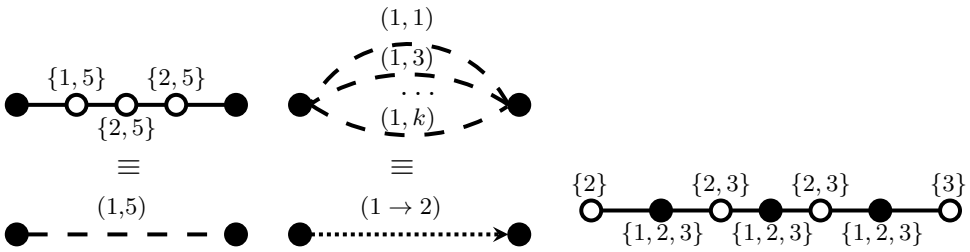

Figure 1 Basic gadgets, where empty vertices are internal and solid vertices are endpoints that will be connected to the rest of the graph. On the left, a weak edge that forbids the combination $(1, 5)$ on its endpoints. In the middle, an implication that forces color 2 on the right if color 1 is used on the left. On the right an OR gadget: one of the solid vertices must take color 1.

▶ **Lemma 5.** *Let G be an instance of* List Coloring *that contains a (c_1, c_2)-weak edge from u_1 to u_2. Then G does not admit a valid coloring that assigns colors (c_1, c_2) to (u_1, u_2). Furthermore, if G' denotes the graph obtained by deleting the internal vertices of the weak edge, any proper list coloring of G' that does not assign c_1 to u_1 or does not assign c_2 to u_2 can be extended to a proper list coloring of G.*

Let us now use the weak edges we have defined above to construct an implication gadget. The intuitive meaning of placing an implication gadget from a vertex u_1 to a vertex u_2 is to impose the constraint that if u_1 is assigned color c_1, then u_2 must be assigned color c_2.

▶ **Definition 6.** For two vertices u_1, u_2 and two colors (c_1, c_2) a $(c_1 \to c_2)$-implication from vertex u_1 to vertex u_2 is constructed as follows: for each color $c' \neq c_2$, we add a (c_1, c')-weak edge from u_1 to u_2.

▶ **Lemma 7.** *Let G be an instance of* List Coloring *that contains a $(c_1 \to c_2)$-implication from u_1 to u_2. Then G does not admit a list coloring that gives color c_1 to u_1 and a color $c' \neq c_2$ to u_2. Furthermore, if G' is the graph obtained from G by deleting the internal vertices of the implication gadget, any coloring of G' that either does not assign c_1 to u_1, or assigns c_2 to u_2 can be extended to a coloring of G.*

▶ **Lemma 8.** *Let G be an instance of* List Coloring*, and G' be the graph obtained from G by replacing every (c_1, c_2)-weak edge or $(c_1 \to c_2)$-implication gadget with endpoints u_1, u_2 with an edge (u_1, u_2) (or simply deleting the internal vertices of the weak edge if (u_1, u_2) already exists). Then* $\mathrm{pw}(G) \leq \mathrm{pw}(G') + 3$.

OR gadgets. We will also make use of a gadget that forces any valid list coloring of a graph to assign a special color 1 to one vertex out of a set of vertices. Invariably, the idea will be that this will be a color that activates some implications, allowing us to propagate information about the coloring between parts of the graph. We recall that a similar version of an OR gadget was also used in [23].

▶ **Definition 9.** An OR gadget on an independent set of vertices S, denoted $\mathrm{OR}(S)$, is constructed as follows: we assign list $\{1, 2, 3\}$ to all vertices of S; we construct a new set S' of internal vertices (that will not be connected to the rest of G), such that $|S'| = |S| + 1$ and $S \cup S'$ induces a path alternating between vertices of S and S'; we assign list $\{2, 3\}$ to all vertices of S', except the two endpoints of the path, which receive lists $\{2\}, \{3\}$, respectively.

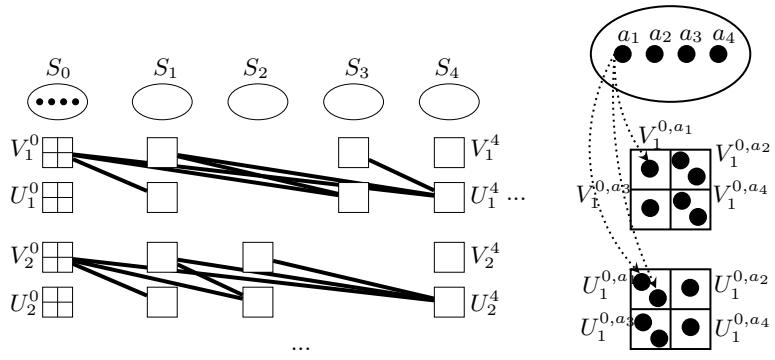

Figure 2 Left: high-level view of the reduction. Rows correspond to variables, columns to constraints. Here, variable x_1 appears in constraints c_0, c_1, c_3, c_4. Right: connections between the OR gadgets $\mathrm{OR}(S_j)$ and the V_i^j, U_i^j sets. Giving color 1 to a_1 represents selecting this assignment. This forces the use of some colors in V_1^{0,a_1} and the complementary set in U_1^{0,a_1}.

▶ **Lemma 10.** *If G is a* List Coloring *instance that contains an OR(S) gadget then G does not admit a list coloring that does not use color* 1 *in any vertex of S. Furthermore, for any vertex $u \in S$, there exists a proper list coloring of the graph induced by the gadget that assigns color* 1 *only to u.*

4.2 Reduction for Clique-width

▶ **Theorem 11.** *For any $k \geq 3, \epsilon > 0$, if there exists an algorithm solving k-coloring in time $O^*\left((2^k - 2 - \epsilon)^{\mathrm{cw}}\right)$, where* cw *is the input graph's clique-width, then the SETH is false.*

The proof of Theorem 11 consists of a reduction from a CSP produced by Theorem 2. Before giving details, let us give some intuition. Our new instance will be a graph and a clique-width expression with, roughly, n labels, where n is the number of variables of the CSP instance. The set of colors used in each label will encode the value given to a variable in a satisfying assignment. As a result, with k colors, we will have $2^k - 2$ encodings available, as every label set uses at least one color, but will never use all k colors. To verify that these assignments are correct, we will construct for each constraint an OR gadget which forces the use of color 1 on a vertex representing a particular assignment. This assignment dictates the value of each variable of the constraint, and therefore the set of colors used in some of our label sets. To verify that the assignment is consistent we use implication gadgets that force some auxilliary vertices to receive the complement of the colors dictated by the constraint assignment, and then connect these with the vertices encoding the true assignment. If the assignment used is truly consistent, these edges will end up being properly colored.

Construction. We are given $k \geq 3, \epsilon > 0$. Let $B = 2^k - 2$. Let q be the smallest integer such that n-variable q-CSP-B does not admit an $O^*\left((B - \epsilon)^n\right)$ algorithm. According to Theorem 2, q exists if the SETH is true, and it depends only on B, ϵ. Consider an arbitrary n-variable instance of q-CSP-B, call it ϕ. We use the existence of the supposed $O^*\left((2^k - 2 - \epsilon)^{\mathrm{cw}}\right)$ algorithm to obtain an $O^*\left((B - \epsilon)^n\right)$ algorithm that decides ϕ, contradicting the SETH.

We define in some arbitrary way a translation function T which, given a value $v \in \{1, \ldots, B\}$ returns a non-empty proper subset of $\{1, \ldots, k\}$. We make sure that T is defined in such a way that it is one-to-one; this is possible since the number of non-empty proper subsets of $\{1, \ldots, k\}$ is exactly $B = 2^k - 2$.

Let $X = \{x_1, \ldots, x_n\}$ be the set of the n variables of the q-CSP-B instance and $C = \{c_0, \ldots, c_{m-1}\}$ the set of its m constraints. Let $L = 3m(nk+1)$. We now construct our graph, where if we don't specify the list of a vertex it can be assumed to be $\{1, \ldots, k\}$. For each $j \in \{0, \ldots, L-1\}$ we do the following:

1. Let $j' = j \bmod m$ and let S be the set of satisfying assignments of the constraint $c_{j'}$. We construct an independent set of vertices S_j that contains a vertex for every assignment of S. We construct an $\mathrm{OR}(S_j)$ gadget on these vertices.
2. For each x_i which appears in $c_{j'}$ and for each assignment $a \in S$ we do the following:
   a. Let $v \in \{1, \ldots, B\}$ be the value given to x_i by the assignment a. Construct an independent set $V_i^{j,a}$ of $|T(v)|$ vertices and an independent set $U_i^{j,a}$ of $k - |T(v)|$ vertices. Recall that $T(v)$, the translation function, returns a set of size between 1 and $k-1$, so both these sets are non-empty.
   b. For each color $c \in T(v)$ select a distinct vertex in $V_i^{j,a}$ and add a $(1 \to c)$-implication gadget from the vertex that represents the assignment a in S_j to this vertex of $V_i^{j,a}$.
   c. For each color $c \in \{1, \ldots, k\} \setminus T(v)$ select a distinct vertex in $U_i^{j,a}$ and add a $(1 \to c)$-implication gadget from the vertex that represents the assignment a in S_j to this vertex of $U_i^{j,a}$.
   d. Connect all vertices of $U_i^{j,a}$ with all vertices of previously constructed sets $V_i^{l,a'}$, for all $l < j$ and all assignments a'.

This completes the construction, and we call the constructed List Coloring instance $G(\phi)$. The intended meaning is that the sets $V_i^{j,a}$ will use a set of colors that encodes the value of the variable x_i, while the sets $U_i^{j,a}$ will use colors from the complement of this set.

▶ **Lemma 12.** *If ϕ is a satisfiable q-CSP-B instance, then $G(\phi)$ admits a proper list coloring.*

Proof. Suppose that we have a satisfying assignment for ϕ which gives value v_i to variable x_i. The invariant we will maintain is that for all j, a, all vertices of sets $V_i^{j,a}$ will use only colors from $T(v_i)$, while all vertices of sets $U_i^{j,a}$ will use only colors from $\{1, \ldots, k\} \setminus T(v_i)$. As a result, all edges added in step 2d will be properly colored. The rest of the graph will be easy to color if we respect the informal meaning of OR and implication gadgets.

More specifically, for each $\mathrm{OR}(S_j)$ gadget we let $j' = j \bmod m$ and consider the constraint $c_{j'}$. The supposed assignment to ϕ assigns to the variables of the constraint values consistent with a satisfying assignment a of $c_{j'}$. We give color 1 to the corresponding vertex of S_j. We use colors $\{2, 3\}$ to color all remaining vertices of the OR gadget. Note that the OR gadget is connected to the rest of the graph only through implication gadgets activated by color 1. Hence, by Lemma 7 we can remove all non-activated implication gadgets. For the remaining, activated implication gadgets we color their other endpoints, which are found in the sets $V_i^{j,a}$ and $U_i^{j,a}$ with the unique viable color. For every other assignment $a' \neq a$ we color all vertices of $V_i^{j,a'}$ using a color we used in $V_i^{j,a}$, and the vertices of $U_i^{j,a'}$ using a color we used in $U_i^{j,a}$.

The promised invariant is maintained, as the vertices of $V_i^{j,a}$ are forced to receive colors from $T(v_i)$, while vertices of $U_i^{j,a}$ are forced to receive colors from the complementary set. Thus, all edges of step 2d are properly colored, and since we also properly colored the OR gadgets and implication gadgets, we have a proper coloring of the whole graph. ◀

▶ **Lemma 13.** *If $G(\phi)$ admits a proper list coloring, then ϕ is a satisfiable q-CSP-B instance.*

Proof. Suppose we have a list coloring of $G(\phi)$ given by the function $\mathbf{c} : V \to \{1, \ldots, k\}$. For a set $V' \subseteq V$ we will write $\mathbf{c}(V')$ to denote the set of colors used by $\mathbf{c}$ for vertices of V', that is, $\mathbf{c}(V') = \{c \mid \exists u \in V',\ \mathbf{c}(u) = c\ \}$. Let $j \in \{0, \ldots, L-1\}$, $j' = j \bmod m$, and S be the set

of satisfying assignment of the constraint $c_{j'}$, which contains a variable x_i. Consider the set $V_i^j = \cup_{a \in S} V_i^{j,a}$. We define the *candidate assignment* of x_i at index j as $v_i^j := T^{-1}(\mathbf{c}(V_i^j))$. In other words, to obtain the candidate assignment for x_i at index j, we take the union of all colors used in $V_i^{j,a}$, and then translate this set back into a value in $\{1, \ldots, B\}$.

We observe that for all i, j, such that x_i appears in $c_{j'}$, where $j' = j \bmod m$, there exists an assignment a such that $\mathbf{c}(V_i^{j,a}) = \{1, \ldots, k\} \setminus \mathbf{c}(U_i^{j,a})$. To see this, note that by Lemma 10, one of the vertices of the $\mathrm{OR}(S_j)$ gadget must have received color 1, say the vertex that corresponds to assignment a. All the implications incident on this vertex are therefore activated, which means that, if a gives value $v \in \{1, \ldots, B\}$ to x_i, then $\mathbf{c}(V_i^{j,a}) = T(v)$ and $\mathbf{c}(U_i^{j,a}) = \{1, \ldots, k\} \setminus T(v)$ (because of the implications of steps 2b,2c and Lemma 7).

A key observation now is the following: for all $j_2 > j_1$ and for all i such that variable x_i appears in constraints $c_{j_1'}, c_{j_2'}$ with $j_1' = j_1 \bmod m$, $j_2' = j_2 \bmod m$, we have $\mathbf{c}(V_i^{j_1}) \subseteq \mathbf{c}(V_i^{j_2})$. In other words, the set of colors used in V_i^j can only increase as j increases. To see this, suppose that there exists $c \in \mathbf{c}(V_i^{j_1}) \setminus \mathbf{c}(V_i^{j_2})$. As argued in the previous paragraph, there exists an assignment a_2 such that $\mathbf{c}(V_i^{j_2}) \supseteq \mathbf{c}(V_i^{j_2,a_2}) = \{1, \ldots, k\} \setminus \mathbf{c}(U_i^{j_2,a_2})$. Because $c \notin \mathbf{c}(V_i^{j_2,a_2})$ we must have $c \in \mathbf{c}(U_i^{j_2,a_2})$, but because of step 2d, all vertices of $U_i^{j_2,a_2}$ are connected to all of $V_i^{j_1}$. Since $c \in \mathbf{c}(V_i^{j_1})$, this contradicts the correctness of the coloring.

The property established in the previous paragraph implies that for each i there exist at most k distinct candidate assignments v_i^j we can obtain for different values of j, as each assignment is obtained by translating the set of colors used in V_i^j, this set only increases, it always contains at least one color and at most k colors. Let us say that an index j_1 is problematic if, for some $i \in \{1, \ldots, n\}$ we have the following: x_i appears in constraint $c_{j_1'}$, where $j_1' = j_1 \bmod m$; and if j_2 is the minimum index such that $j_2 > j_1$ and x_i appears in constraint $c_{j_2'}$, where $j_2' = j_2 \bmod m$, then $v_i^{j_1} \neq v_i^{j_2}$. In other words, an index is problematic if the candidate assignment it produces for a variable disagrees with the candidate assignment produced for the same variable in the next index that involves this variable. It is not hard to see that there are at most kn problematic indices, because for each variable there are at most k problematic indices. Therefore, since $L = 3m(nk + 1)$, by pigeonhole principle, there exists an interval L' of at least $3m$ consecutive non-problematic indices.

We now obtain an assignment for the original instance as follows: for each variable i we take an index $j \in L'$ such that x_i appears in constraint $c_{j'}$, where $j' = j \bmod m$, and give x_i the candidate value v_i^j from that index. Observe that, by the definition of L' the index we select is irrelevant, as all candidate values are constant throughout the interval L'.

We claim that this is a satisfying assignment. Suppose not, so there exists an unsatisfied constraint $c_{j'}$. Because L' contains $3m$ consecutive indices, there exists three indices $j_1 < j_2 < j_3 \in L'$ such that $j' = j_1 \bmod m = j_2 \bmod m = j_3 \bmod m$. We observe that for all variables x_i appearing in $c_{j'}$ we have given value $v_i^{j_2}$, that is the candidate value obtained at index j_2, since all indices in L' give the same candidate values to all variables.

Now, there exists a vertex in S_{j_2} that received color 1, representing an assignment a. If the assignment we produced is not consistent with a, there exists a variable x_i such that we have given x_i value $v = v_i^{j_2}$, while a gives it value $v' \neq v$. Consider now the set $V_i^{j_2,a}$. Because of the implication gadgets, it uses the colors $T(v') \neq T(v)$. If there exists $c \in T(v) \setminus T(v')$ then $c \in \mathbf{c}(U_i^{j_2,a})$. But $U_i^{j_2,a}$ is connected to all vertices of $V_i^{j_1}$, which, we assumed use all colors of $T(v)$, therefore also color c, contradicting the correctness of the coloring. If on the other hand there exists $c \in T(v') \setminus T(v)$, then since $\mathbf{c}(V_i^{j_3}) = T(v)$, there exists an a' such that $\mathbf{c}(U_i^{j_3,a'}) = \{1, \ldots, k\} \setminus T(v)$. Therefore, $c \in \mathbf{c}(U_i^{j_3,a'})$, while $c \in \mathbf{c}(V_i^{j_2,a})$, and by step 2d these sets are connected, again obtaining a contradiction. We therefore conclude that we must have a consistent satisfying assignment. ◀

▶ **Lemma 14.** *$G(\phi)$ can be constructed in time polynomial in $|\phi|$, and we have* $\mathrm{cw}(G(\phi)) \leq n + O(qk^2B^q) = n + f(\epsilon, k)$ *for some function f.*

Proof. For fixed $k \geq 3, \epsilon > 0$, we have that $B = 2^k - 2$ and q is a constant that only depends on B, ϵ (that is, on k, ϵ). Each constraint of the q-CSP-B instance has at most B^q satisfying assignments. Therefore, it is not hard to see that the whole construction can be performed in polynomial time, if k, ϵ, B, q are constants. For clique-width we use the following labels:

1. n main labels, representing the variables of ϕ.
2. A single junk label. Its informal meaning is that a vertex that receives this label will not be connected to anything else not yet introduced in the graph.
3. $O(B^q)$ constraint work labels.
4. $O(qk^2B^q)$ variable-constraint incidence work labels.

To give a clique-width expression we will describe how to build the graph, following essentially the steps given in the description of the construction by maintaining the following invariant: before starting iteration j, all vertices of the set $\bigcup_{j'<j} V_i^{j',a}$ (where we take the union over all assignments a), have label i, and all other vertices have the junk label.

This invariant is vacuously satisfied before the first iteration, since the graph is empty. Suppose that for some $j \in \{0, \ldots, L-1\}$ the invariant is true. We use the $O(B^q)$ constraint work labels to introduce the vertices of the $\mathrm{OR}(S_j)$ gadget of step 1, giving each vertex a distinct label. We use join operations to construct the internal edges of the OR gadget.

Then, for each variable x_i that appears in the current constraint we do the following: we use $O(k^2B^q)$ of the variable-constraint incidence work labels to introduce the vertices of $V_i^{j,a}$, $U_i^{j,a}$ as well as the implication gadgets connecting these to S_j. Again we use a distinct label for each vertex, but the number of vertices (including internal vertices of the implication gadgets) is $O(k^2B^q)$, so we have sufficiently many labels to use distinct labels for each of the q variables of the constraint. We use join operations to add the edges inside all implication gadgets. Then we use join operations to connect $U_i^{j,a}$ to all vertices $\bigcup_{j'<j} V_i^{j',a}$, for $j' < j$. This is possible, since the invariant states that all the vertices of $\bigcup_{j'<j} V_i^{j',a}$ have the same label. We then rename all the vertices of $U_i^{j,a}$, for all a to the junk label, and do the same also for internal vertices of all implication gadgets. We proceed to the next variable of the same constraint and handle it using its own $O(k^2B^q)$ labels. Once we have handled all variables of the current constraint, we rename all vertices of each $V_i^{j,a}$ to label i for all a. We then rename all vertices of the $\mathrm{OR}(S_j)$ gadget to the junk label and increase j by 1. It is not hard to see that we have maintained the invariant and constructed all edges induced by the vertices introduced in steps up to j, so repeating this process constructs the graph. ◀

5 Modular Pathwidth and ETH

We present a lower bound on the complexity of k-Coloring parameterized by modular pathwidth. Specifically, we show that, under the SETH, no algorithm can solve k-Coloring in $O^*\left(\left(\binom{k}{\lfloor k/2 \rfloor} - \epsilon\right)^{\mathrm{mpw}}\right)$. This bound is somewhat weaker than the one in Theorem 11, which is natural since modular pathwidth is more restrictive than clique-width. As we see in Section 6, however, this bound is tight. We complete this section by performing the same reduction with the ETH, rather than the SETH, as a starting point. Under this weaker assumption we prove that k-Coloring does not admit an algorithm running in $n^{o(\mathrm{mpw})}$, even when $k = O(\log n)$, which implies that the problem does not admit an algorithm running in $2^{o(k \cdot \mathrm{mpw})}$. This is tight, and also applies to clique-width (Lemma 1). In this way, our reduction gives an alternative proof that k-Coloring is unlikely to be FPT parameterized by clique-width, even in instances with a logarithmic number of colors.

5.1 SETH-based Lower Bound

▶ **Theorem 15.** *For any $k \geq 3, \epsilon > 0$, if there exists an algorithm solving k-coloring in time $O^*\left(\left(\binom{k}{\lfloor k/2 \rfloor} - \epsilon\right)^{\text{mpw}}\right)$, where* mpw *is the graph's modular pathwidth, then the SETH is false.*

As in Theorem 11, we begin our reduction from a q-CSP-B instance, where the alphabet size B is equal to the base of the exponential in our lower bound. The intuition will be that the "important" vertices of the bags in a modular tree decomposition of our graph will correspond to classes of $\lfloor k/2 \rfloor$ true twin vertices. The set of $\lfloor k/2 \rfloor$ colors used to color them will encode the value of one variable of the original instance.

Construction. We are given some $k \geq 3, \epsilon > 0$. Let $B = \binom{k}{\lfloor k/2 \rfloor}$. Let q be the smallest integer such that n-variable q-CSP-B does not admit an $O^*\left((B-\epsilon)^n\right)$ algorithm. Consider an arbitrary n-variable instance of q-CSP-B, call it ϕ. We use the existence of the supposed algorithm to obtain an $O^*\left((B-\epsilon)^n\right)$ algorithm that decides ϕ, contradicting the SETH.

As in Theorem 11 we define a one-to-one translation function T. This time, when T is given as input a value $v \in \{1, \ldots, B\}$, it returns a subset of $\{1, \ldots, k\}$ of cardinality $\lfloor k/2 \rfloor$. Let $X = \{x_1, \ldots, x_n\}$ be the set of the n variables of the q-CSP-B instance and $C = \{c_0, \ldots, c_{m-1}\}$ the set of its m constraints. We construct our graph $G(\phi)$ as follows, where if we don't specify a list for a vertex its list is $\{1, \ldots, k\}$:

1. For each variable $i \in \{1, \ldots, n\}$ we construct a clique V_i on $\lfloor k/2 \rfloor$ vertices.
2. For each $j \in \{0, \ldots, m-1\}$, let S be the set of satisfying assignments of the constraint c_j. We construct an independent set S_j with one vertex for each element of S. We construct an $\text{OR}(S_j)$ gadget on the set S_j.
3. For each $j \in \{0, \ldots, m-1\}$, each satisfying assignment a for the constraint c_j, and each variable x_i appearing in c_j we do the following:
   a. We construct a set $U_i^{j,a}$ of $\lceil k/2 \rceil$ vertices.
   b. Suppose a assigns value v to x_i. For each color $c \in \{1, \ldots, k\} \setminus T(v)$ we select a vertex of $U_i^{j,a}$. We construct a $(1 \to c)$-implication gadget from the vertex representing a in S_j to this vertex of $U_i^{j,a}$.
   c. We connect all vertices of $U_i^{j,a}$ with all vertices of V_i.

▶ **Lemma 16.** *If ϕ is a satisfiable q-CSP-B instance, then $G(\phi)$ admits a proper list coloring.*

▶ **Lemma 17.** *If $G(\phi)$ admits a proper list coloring, then ϕ is a satisfiable q-CSP-B instance.*

▶ **Lemma 18.** *$G(\phi)$ can be constructed in time polynomial in $|\phi|$, and $\text{mpw}(G) \leq n + O(1)$.*

5.2 ETH-based Lower Bound

▶ **Theorem 19.** *If there exists an algorithm that solves k-Coloring on instances with n vertices and $k = O(\log n)$ in time $n^{o(\text{mpw})}$, then the ETH is false. As a result, if there is an algorithm solving k-Coloring in time $2^{o(k \cdot \text{mpw})}$, then the ETH is false.*

6 Algorithms

We present two algorithms establishing that the lower bounds of Sections 4,5 are essentially tight. Though both algorithms are based on standard techniques, we remark that the algorithm for clique-width requires some extra effort to obtain a DP of the promised size.

6.1 Clique-width algorithm

Our algorithm is based on standard DP. Its basic idea is that a partial solution is characterized by the set of colors it uses to color a set of vertices that share the same label. This leads to a DP table of size $(2^k-1)^{\mathrm{cw}}$, by observing that for any non-empty label set, any viable partial solution will use at least one color, hence there are 2^k-1 possible subsets of $\{1,\ldots,k\}$ to consider. To improve this to $(2^k-2)^{\mathrm{cw}}$, which would match the lower bound of Theorem 11 we need a further idea which will allow us to also rule out the set that uses all k colors.

Let t be a node of the binary tree representing the clique-width expression of G, and let V_t^i be the set of vertices that have label $i \in \{1,\ldots,\mathrm{cw}\}$ in the labeled graph G_t produced by the sub-expression rooted at t. We will say that V_t^i is a *live* label set if there exists an edge in G that is incident on a vertex of V_t^i and does not appear in G_t. In other words, a label set is live if there is a join operation that involves its vertices which has not yet appeared in t. The main observation is that live label sets cannot use all k colors in a valid partial solution, since then the subsequent join operation will fail. Non-live label sets, on the other hand, are irrelevant, since if the coloring is already valid for such a set it is guaranteed to remain valid. Our DP algorithm will therefore keep track of the partial colorings only of live label sets, and thus produce a DP table of size $(2^k-2)^{\mathrm{cw}}$. In this sense, our DP algorithm is slightly non-standard, as part of its procedure involves "looking ahead" in the graph to determine if a label set is live or not. What remains is the problem of implementing the DP so that it takes time linear in the table size; this is handled using the techniques introduced in [1, 29].

▶ **Theorem 20.** *There is an algorithm which, given a graph G, an integer k, and a clique-width expression for G with* cw *labels decides if G is k-colorable in time $O^*\left((2^k-2)^{\mathrm{cw}}\right)$.*

6.2 Modular Treewidth Algorithm

For modular treewidth, we remark that k-Coloring for this parameter can be seen as an equivalent version of Multi-Coloring parameterized by treewidth. In Multi-Coloring, each vertex v has a demand $b(v)$, and we are asked to assign $b(v)$ distinct colors to each vertex so that neighboring vertices have disjoint colors (see e.g. [2]). In our context, the vertex representing a class of b true twins corresponds to a vertex with demand b.

▶ **Theorem 21.** *There is an algorithm which, given a graph G, an integer k, and a modular tree decomposition of G of width* mtw*, decides if G is k-colorable in time $O^*\left(\binom{k}{\lfloor k/2\rfloor}^{\mathrm{mtw}}\right)$.*

7 Conclusions – Open Problems

We have given tight bounds for k-Coloring parameterized by clique-width, complementing previously known bounds for treewidth. A natural question is now how robust these bounds are, especially in the context of approximation. Specifically, does there exist a constant factor approximation algorithm for k-Coloring running in $O^*\left((k-\epsilon)^{\mathrm{tw}}\right)$ or $O^*\left((2^k-2-\epsilon)^{\mathrm{cw}}\right)$? Current knowledge cannot even rule out the existence of such algorithms with a small *additive* approximation error and this area is still largely unexplored.

Abstract

Constructing a sparse *spanning subgraph* is a fundamental primitive in graph theory. In this paper, we study this problem in the Centralized Local model, where the goal is to decide whether an edge is part of the spanning subgraph by examining only a small part of the input; yet, answers must be globally consistent and independent of prior queries.

Unfortunately, maximally sparse spanning subgraphs, i.e., spanning trees, cannot be constructed efficiently in this model. Therefore, we settle for a spanning subgraph containing at most $(1+\epsilon)n$ edges (where n is the number of vertices and ϵ is a given approximation/sparsity parameter). We achieve a query complexity of $\tilde{O}(\text{poly}(\Delta/\varepsilon)n^{2/3})$,[2] where Δ is the maximum degree of the input graph. Our algorithm is the first to do so on arbitrary bounded degree graphs. Moreover, we achieve the additional property that our algorithm outputs a spanning subgraph of bounded stretch i.e., distances are approximately preserved. With high probability, for each deleted edge there is a path of $O(\log n \cdot (\Delta + \log n)/\epsilon)$ hops in the output that connects its endpoints.

1 Introduction

When operating on very large graphs, it is often impractical or infeasible to (i) hold the entire graph in the local memory of a processing unit, (ii) run linear-time (or even slower) algorithms, or even (iii) have only a single processing unit perform computations sequentially. These constraints inspired the Centralized Local model [17], which essentially views the input as being stored in a (likely distributed) database that provides query access to external processing units. To minimize the coordination overhead of such a system, it is furthermore required that there is no shared memory or communication between the querying processes, except for shared randomness provided alongside the access to the input. The idea is now to

run sublinear-time algorithms that extract useful global properties of the graph and/or to examine the input graph locally upon demand by applications.

Studying graphs in this model, lead to the emergence of algorithms that provide query access to a variety of graph-theoretical structures like, e.g., independent or dominating sets. In such a case, it is crucial that locally evaluating whether a node participates in such a set is *consistent* with the same evaluation for other nodes. This is a non-trivial task, as local decisions can only be coordinated implicitly via the structure of the input (which is to be examined as little as possible) and the shared randomness. Nonetheless, this budding field brought forth a number of elegant algorithms solving, e.g., maximal independent set, hypergraph coloring, k-CNF, approximate maximum matching and approximate minimum vertex cover for bipartite graphs [1, 4, 5, 11, 12, 13, 17].

In this work, we consider another very basic graph structure: sparse spanning subgraphs. Here, the task is to select a subset of the edges of the (connected) input graph so that the output is still connected, but has only few edges. By "few" we mean that, for some input parameter $\varepsilon > 0$, the number of selected edges is at most $(1 + \varepsilon)n$, where n denotes the number of nodes. One may see this as a relaxed version of the problem of outputting a spanning tree of the graph, which is a too rigid requirement when looking for fast algorithms: on a cycle, a single edge has to be deleted, but this necessitates to first verify that the input graph is not, in fact, a line.

▶ **Definition 1** ([9]). An algorithm $\mathcal{A}$ is a *Local Sparse Spanning Graph (LSSG) algorithm* if, given $n, \Delta \geq 1$, a parameter $\epsilon \geq 0$, and query access to the incidence list representation of a connected graph $G = (V, E)$ over n vertices and of degree at most Δ, it provides oracle access to a subgraph $G' = (V, E')$ of G such that:

1. G' is connected.
2. $|E'| \leq (1 + \epsilon) \cdot n$ with high probability (w.h.p.),[3] where E' is determined by G and the internal randomness of $\mathcal{A}$.

By "providing oracle access to G'" we mean that on input $\{u, v\} \in E$, $\mathcal{A}$ returns whether $\{u, v\} \in E'$, and for any sequence of edges, $\mathcal{A}$ answers consistently with respect to the same G'.

We are interested in LSSG algorithms that, for each given edge, perform as few queries as possible to G. Observe that Item 2 implies that the answers of an LLSG algorithm to queries cannot depend on previously asked queries.

We note that relaxing from requiring a tree as output makes it possible to ask for additional guarantees that, in general, cannot be met by a spanning tree. Instead of merely preserving connectivity, it becomes possible to maintain *distances* up to small factors (for unweighted graphs). Such subgraphs are known as (sparse, multiplicative) *spanners* [14, 15]. In fact, choosing $\varepsilon \in o(1)$ then yields *ultra-sparse* spanners that are $o(n)$ edges away from being trees.

1.1 Our Contribution

We give the first non-trivial LSSG algorithm in the Centralized Local model that runs on arbitrary graphs. We achieve a query complexity of $\tilde{O}(\text{poly}(\Delta/\varepsilon)n^{2/3})$ per edge, w.h.p. Moreover, we guarantee that for each edge that is not selected into the spanner, w.h.p. there

[3] That is, with probability at least $1 - 1/n^c$ for an arbitrary constant $c > 0$ that is chosen upfront.

is a path of $O(\log n \cdot (\Delta + \log n)/\epsilon)$ hops consisting of edges that are selected into the spanner; this is referred to as a *stretch* of $O(\log n \cdot (\Delta + \log n)/\epsilon)$.

For simplicity, assume for the moment that Δ and ε are constants. Our algorithm combines the following key ideas.

- We classify edges as expanding if there are sufficiently many (roughly $n^{1/3}$) nodes within $O(\log n)$ hops of their endpoints. For non-expanding edges, we can efficiently simulate a standard distributed spanner algorithm at small query complexity, as solutions of running time $O(\log n)$ are known (e.g. [3]).
- On the node set induced by expanding edges, we can construct a partition into Voronoi cells with respect to roughly $n^{2/3}$ randomly sampled centers. The Voronoi cells are spanned by trees of depth $O(\log n)$, as expanding nodes have their closest center within $O(\log n)$ hops w.h.p. Finding the closest center has query complexity $\tilde{O}(n^{1/3})$.
- We refine the partition into Voronoi cells further into *clusters* of $\tilde{O}(n^{1/3})$ nodes. We simply let a node be a singleton cluster if its subtree in the spanning tree of its cell contains more than $\tilde{O}(n^{1/3})$ nodes. This construction has query complexity $\tilde{O}(n^{2/3})$ for constructing a complete cluster, yet ensures that there are $\tilde{O}(n^{2/3})$ clusters in total due to the low depth of the trees that span the Voronoi cells; moreover, each cluster is completely contained in some Voronoi cell.
- It remains to select few edges to interconnect the Voronoi cells. This is the main challenge, for which the above properties of the partition are crucial. To keep the number of selected edges small in expectation, we mark a subset of expected size $\tilde{\Theta}(n^{1/3})$ of the clusters by marking each Voronoi cell (and thereby its constituent clusters) with probability $n^{-1/3}$. We then try to ensure that (i) clusters select an edge to each adjacent marked Voronoi cell and (ii) for each marked Voronoi cell adjacent to an adjacent cluster, they select one edge connecting to *some* cluster adjacent to this cell.
- The main issue with the previous step is that we cannot afford to construct each adjacent cluster, preventing us from guaranteeing (ii). We circumvent this obstacle by identifying for adjacent clusters in which cell they are and keeping an edge for the purpose of (ii) if it satisfies a certain minimality requirement with respect to the *rank* of the cell used for symmetry breaking purposes. This way, we avoid construction of adjacent clusters, instead needing to determine the rank of their Voronoi cells only. This way, we maintain query complexity $\tilde{O}(n^{2/3})$.
- However, this now entails an inductive argument for ensuring connectivity, which also affects stretch. By choosing Voronoi cell ranks uniformly at random, we ensure that the length of such an inductive chain is bounded by $O(\log n)$ w.h.p. Together with the depth of the Voronoi cell trees of $O(\log n)$ and the stretch of the spanner algorithm for non-expanding edges (also $O(\log n)$), this yields the total bound of $O(\log^2 n)$ on the stretch of our scheme.

Finally, we note that we can place the above routine in a wrapper verifying that, w.h.p., the number of globally selected edges does not significantly exceed the expectation. If this is not the case, the wrapper starts the process all over. Since in each attempt the success probability is constant (and the verifier succeeds w.h.p.), we get within $O(\log n)$ attempts that the bound on the number of selected edges is satisfied w.h.p. and the routine terminates.

Relation to Property Testing. As observed in [10], testing cycle-freeness with one sided-error in the bounded-degree model can be reduced to the LSSG problem. From this reduction it follows that we obtain a tester for cycle-freeness that works in $\tilde{O}(n^{2/3})$ time. Czumaj et al. [2] studied the problem of C_k-minor freeness with one sided-error. For cycle-freeness

(C_3-minor freeness) their complexity is $\tilde{O}(\sqrt{n})$, therefore their complexity is better than ours. However, we would like to point out that an LSSG algorithm gives a stronger guarantee than a one-sided error tester for cycle-freeness. An LSSG algorithm can be used to find for all but at most $(1+\epsilon)|V|$ edges e, a cycle that e belongs to, i.e., a witness for the violation by e can be provided. In contrast, a one-sided error tester merely guarantees to find a single cycle in instances that are ϵ-far from being cycle-free.

Perhaps more importantly, our approach proves useful when testing for other minors. Recently, Fichtenberger et al. [6] built on our work to construct one-sided error tester for outerplanarity and other properties that are characterized by a set of forbidden minors.

1.2 Related work

The problem of finding a sparse spanning subgraph in the Centralized Local model was first studied in [9], where the authors show a lower bound of $\Omega(\sqrt{n})$ queries for constant ϵ and Δ (see also survey by Rubinfeld [18]). They also present an upper bound with nearly tight query complexity for graphs that have very good expansion properties. However, for general (bounded degree) graphs their algorithm might query the entire graph for completing a single call to the oracle. They also provide an efficient algorithm for minor-free graphs that was later improved in [8]. The algorithm presented in [8] achieves a query complexity that is polynomial in Δ and $1/\epsilon$ and is independent of n. The stretch factor of this algorithm is also independent of n and depends only on Δ, $1/\epsilon$, and the size of the excluded minor.

A characterization of the query complexity of the problem was presented in [7]. Specifically, [7] provide an upper bound (which builds on an algorithm in [9]) that has a query complexity that is independent of n (however, super-exponential in $1/\epsilon$) for families of graphs which are, roughly speaking, sufficiently non-expanding everywhere. On the other hand, they show that, for a family of graphs with expansion properties that are slightly better, any local algorithm must have a query complexity that depends on n.

In the (distributed) Local model, Ram and Vicari [16] study the same problem and provide an algorithm that runs in $\min\{D, O(\log n)\}$ rounds, where D is diameter of the input graph. Their algorithm achieves the sparsity property by breaking all short cycles.

2 Preliminaries

The graphs we consider are undirected and have a known degree bound Δ, and we assume we have query access to their incidence list representation. Namely, for any vertex v and index $1 \leq i \leq \Delta$, it is possible to obtain the i^{th} neighbor of v by performing a query to the graph (if v has less than i neighbors, then a special symbol is returned). Without loss of generality, we assume that graphs are simple, i.e., contain neither loops nor parallel edges.[4] The number of vertices in the graph is n and we assume that each vertex v has a unique id, which for simplicity we also denote by v. There is a total order on the ids, i.e., given any two distinct ids u and v, we can decide whether $u < v$ or $v < u$.

Let $G = (V, E)$ be a graph, where $V = [n]$. We denote the distance between two vertices u and v in G by $d_G(u, v)$. For vertex $v \in V$ and an integer r, let $\Gamma_r(v, G)$ denote the set of vertices at distance at most r from v. When the graph G is clear from the context, we shall use the shorthands $d(u, v)$ and $\Gamma_r(v)$ for $d_G(u, v)$ and $\Gamma_r(v, G)$, respectively.

[4] The answer on a self-loop can always be negative, and we can default to rejecting all but the first edge between two nodes.

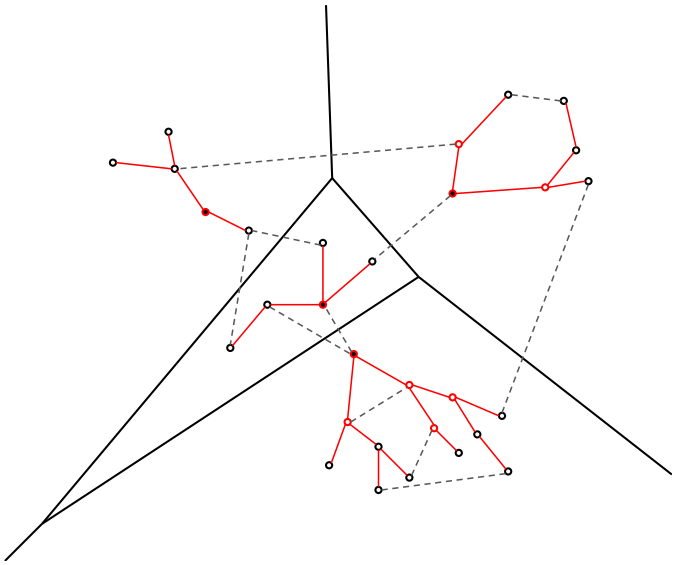

Figure 1 Partition of a graph into cells and clusters, where $k = 6$. Black lines are the borders of Voronoi cells, whose centers have black fillings. Red edges belong to the BFS trees spanning the clusters, while dashed gray lines are non-tree edges. Red circles indicate singleton clusters (if the node has a red child) or the roots of subtrees that form a cluster (if the children are black).

The total order on the vertices induces a total order r on the edges of the graph in the following straightforward manner: $r(\{u,v\}) < r(\{u',v'\})$ if and only if $\min\{u,v\} < \min\{u',v'\}$ or $\min\{u,v\} = \min\{u',v'\}$ and $\max\{u,v\} < \max\{u',v'\}$. The total order over the vertices also induces an order over those vertices visited by a Breadth First Search (BFS) starting from any given vertex v, and whenever we refer to a BFS, we mean that it is performed according to this order.

Whenever referring to one of the above orders, we may refer to the *rank* of an element in the respective order. This is simply the index of the respective element when listing all elements ascendingly with respect to the order.

For a graph $G = (V,E)$ and a pair of disjoint subsets of vertices $A \subset V$ and $B \subset V$ let $E_G(A,B) \stackrel{\text{def}}{=} \{(u,v) \in E \,|\, u \in A \wedge v \in B\}$. When it is clear from the context, we omit the subscript. We say that a pair of subsets of vertices A and B are *adjacent* if $E_G(A,B) \neq \emptyset$.

3 An Algorithm that Works under a Promise

We begin by describing an LSSG algorithm which works under the following promise on the input graph $G = (V,E)$. Sample ℓ uniformly at random from $[b \log n / \log(1+\epsilon), b \log n / \log(1+\epsilon) + \Delta/\epsilon\}]$, and let $k \stackrel{\text{def}}{=} cn^{1/3} \ln n \cdot \ell\Delta/\epsilon$, where c and b are sufficiently large constants. For every $v \in V$, let $i_v \stackrel{\text{def}}{=} \min_r\{|\Gamma_r(v)| \geq k\}$. We are promised that $\max_{v \in V}\{i_v\} \leq \ell$. In words, we assume that the ℓ-hop neighborhood of every vertex in G contains at least k vertices. First, we fix a simple partition of V.

3.1 The Underlying Partition

Centers. Pick a set $S \subset |V|$ of $r \stackrel{\text{def}}{=} \Theta(\epsilon n^{2/3} / \ln n)$ vertices at random. We shall refer to the vertices in S as *centers*. For each vertex $v \in V$, its *center*, denoted by $c(v)$, is the center which is closest to v amongst all centers (break ties between centers according to the id of the center).

Voronoi cells. The *Voronoi cell* of a vertex v, denoted by $\mathrm{Vor}(v)$, is the set of all vertices u for which $c(u) = c(v)$. Additionally, we assign to each cell a random rank, so that there is a uniformly random total order on the cells; note carefully that the rank of a cell thus differs from the rank of its center (which is given by its identifier, which is not assigned randomly). We remark that we can determine the rank of the cell from the shared randomness and the cell's identifier, for which we simply use the identifier of its center.

Clusters. For each Voronoi cell, consider the BFS tree spanning it, which is rooted at the respective center. For every $v \in V$, let $p(v)$ denote the *parent* of v in this BFS tree. If v is a center then $p(v) = v$. For every $v \in V \setminus S$, let $T(v)$ denote the subtree of v in the above-mentioned BFS tree when we remove the edge $\{v, p(v)\}$; for $v \in S$, $T(v)$ is simply the entire tree. Now consider a Voronoi cell. If the cell contains at most k vertices, then the *cluster* of all the vertices in the Voronoi cell is the cell itself. Otherwise, there are two cases. If $T(v)$ contains at least k vertices, then the cluster of v is the singleton $\{v\}$. Otherwise, v has a unique ancestor u (including v) for which $T(u)$ contains less than k vertices and $T(p(u))$ contains at least k vertices. The cluster of v is the set of vertices in $T(u)$. For a cluster C, let $c(C)$ denote the center of the vertices in C (all the vertices in the same cluster have the same center as they all belong to the same Voronoi cell). Let $\mathrm{Vor}(C)$ denote the Voronoi cell of the vertices in C.

This describes a partition of V into Voronoi cells, and a refinement of this partition into clusters. See Figure 1 for an illustration.

3.2 The Edge Set

Our spanner, $H = (V, E')$, initially contains, for each Voronoi cell Vor the edges of the BFS tree that spans Vor, i.e., the BFS tree rooted at the center of Vor spanning the subgraph induced by Vor (see Section 2 for more details). Clearly, these edges also span the clusters. Next, we describe which edges we add to E' in order to connect the clusters.

Marked Clusters and Clusters-of-Clusters

Each center in S is *marked* independently with probability $p \stackrel{\text{def}}{=} 1/n^{1/3}$. If a center is marked, then we say that its Voronoi cell is marked and all the clusters in this cell are marked as well.

Cluster-of-clusters. For every marked cluster, C, define the *cluster-of-clusters* of C, denoted by $\mathcal{C}(C)$, to be the set of clusters which consists of C and all the clusters which are adjacent to C. A cluster B is *participating* in $\mathcal{C}(C)$ if $B \in \mathcal{C}(C)$ and the edge of minimum rank in $E(B, \mathrm{Vor}(C))$ also belongs to $E(B, C)$. Thus, if B is adjacent to $\mathrm{Vor}(C)$ and $\mathrm{Vor}(C)$ is marked, then there is a unique cluster $D \subseteq \mathrm{Vor}(C)$ such that B participates in $\mathcal{C}(D)$. See Figure 2 for a visualization.

The Edges between Clusters

By saying that we *connect* two adjacent subsets of vertices A and B, we mean that we add the minimum ranked edge in $E(A, B)$ to E'. For a cluster A, define its *adjacent centers* $\mathrm{Vor}(\partial A) \stackrel{\text{def}}{=} \{\mathrm{Vor}(v) \mid \exists u \in A \text{ such that } \{u, v\} \in E\} \setminus \{\mathrm{Vor}(A)\}$, i.e., the set of Voronoi cells that are adjacent to A. This definition explicitly excludes $\mathrm{Vor}(A)$, as there is no need to connect A to its own Voronoi cell.

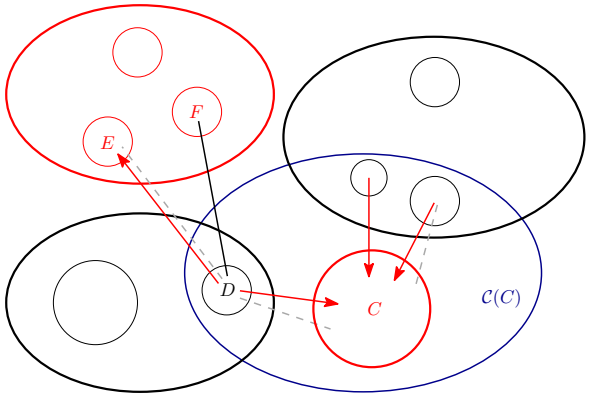

Figure 2 Illustration of marked clusters and clusters of clusters. Thick red and black ovals are marked and unmarked cells, respectively. Thin circles are clusters, where cluster C comprises its entire cell. Thick edges are the ones of minimum rank between their incident clusters, while the dotted edges do not meet this criterion. The arrows of red edges indicate participation in the respective adjacent marked cluster; note that D does not participate in $\mathcal{C}(F)$, as for each adjacent marked cell Vor it exclusively participates in the cluster-of-clusters connected to it by the edge of minimum rank in $E(D, \mathrm{Vor})$. $\mathcal{C}(C)$ is marked in blue; all its constituent clusters also participate in $\mathcal{C}(C)$, as $\mathrm{Vor}(C) = C$.

We next describe how we connect the clusters. The high-level idea is to make sure that every marked cluster and the clusters that participate in the respective cluster-of-clusters remains connected. This implies that the cluster-of-clusters remain connected as well, as every Voronoi cell is connected. For clusters which are not adjacent to any marked cluster we make sure to keep them connected to all adjacent Voronoi cells. Formally:

1. We connect every cluster to every adjacent marked cluster.
2. Each cluster A that is not participating in any cluster-of-clusters (i.e., no cell adjacent to A is marked) we connect to each adjacent cell.
3. Suppose cluster A is adjacent to cluster B, where B is adjacent to a marked cell Vor. Denote by C the (unique) cluster in cell Vor for which B participates in $\mathcal{C}(C)$. We connect A with B if the following conditions hold:
   - $\mathrm{Vor}(B)$ has minimum rank amongst $\mathrm{Vor}(\partial A) \cap \mathrm{Vor}(\partial C)$
   - the minimum ranked edge in $E(A, \mathrm{Vor}(B))$ is also in $E(A, B)$

Figure 3 showcases the third rule. Roughly speaking, the idea is that we want to connect cluster A with $\mathcal{C}(C)$ to preserve connectivity, however, at the same time, we want to make sure that we do not add too many edges to our spanning subgraph. Therefore, we connect A and B only if we do not see an evidence that A and $\mathcal{C}(C)$ remain connected through a different path.

3.3 Sparsity

▶ **Lemma 1.** *The number of clusters, denoted by s, is at most $|S| + n\ell(\Delta + 1)/k$.*

Proof. We first observe that, due to the promise on G, it follows that for every $v \in V$, $d(v, c(v)) \leq \ell$ w.h.p. Recall the terminology from Subsection 3.1. Consider v for which $|T(v)| \geq k$ and therefore its cluster is the singleton $\{v\}$. We say that a vertex u is *special* if $|T(u)| \geq k$ and for every child of u in $T(u)$, t, it holds that $|T(t)| < k$. By an inductive argument, it follows that v is an ancestor of a special vertex. Since for every pair of special vertices u and w, $T(u)$ and $T(w)$ are vertex disjoint, we obtain that there are at most n/k

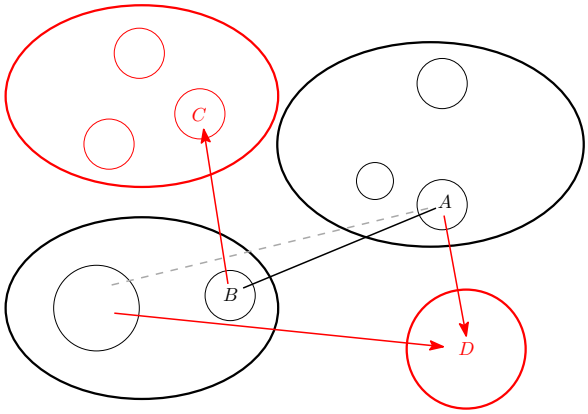

Figure 3 Illustration of the third edge selection rule. In this example, the thick black edge has minimum rank in $E(A, \mathrm{Vor}(B))$ and B has minimum rank in $\partial A \cap \partial C$. However, the rank of $\mathrm{Vor}(D)$ is smaller than that of $\mathrm{Vor}(B)$, and hence the dashed edge is not selected. Here, A will select the direct edge connecting it to D, due to the first rule.

special vertices. Since for every special vertex, there are at most ℓ ancestors, the total number of vertices v with $|T(v)| \geq k$ is bounded by $n\ell/k$.

Observe that any cluster either (i) is a singleton $\{v\}$ with $|T(v)| \geq k$, (ii) contains a node v such that $|T(p(v))| \geq k$, or (iii) is an entire Voronoi cell. We just bounded the number of clusters of type (i) by $n\ell/k$, and immediately get a bound on the number of type (ii) clusters of $n\ell\Delta/k$. The number of type (iii) clusters is bounded by the number of Voronoi cells $|S|$, showing the desired bound on s. ◀

▶ **Lemma 2.** $\mathrm{Exp}(|E'|) \leq (1 + O(\epsilon))|V|$.

Proof. The number of edges which are taken due to Condition 1 is at most s times the number of marked clusters. In expectation, there are $s \cdot p$ marked clusters, yielding at most $s^2 p$ edges in expectation. Since $s = O(\epsilon n^{2/3}/\ln n)$ and $p = 1/n^{1/3}$ we obtain that $s^2 p = O(\epsilon n/\ln n)$.

Let A be a cluster. The number of edges which are adjacent to A and are taken due to Condition 3 is bounded by the total number of clusters-of-clusters. The number of clusters-of-clusters is exactly the number of marked clusters. Thus, the total number of edges which are taken due to Condition 3 is bounded by $s^2 p$.

Observe that the probability that cluster A is not adjacent to a marked cell is $(1-p)^{|\mathrm{Vor}(\partial A)|} \leq e^{-p|\mathrm{Vor}(\partial A)|}$. Hence, if $|\mathrm{Vor}(\partial A)| \geq 3p^{-1}\ln n$, A is adjacent to a marked cell w.h.p. Using a union bound over all clusters, it follows that w.h.p. each cluster A without an adjacent marked cell satisfies that $|\mathrm{Vor}(\partial A)| \leq 3p^{-1}\ln n$ with probability at least $1 - 1/n^2$; the probability at most $1/n^2$ event that this bound is violated cannot contribute more than $|E|/n^2 < 1$ to the expectation. Therefore, the total number of edges which are taken due to Condition 2 is bounded by $(3s\ln n)/p + 1 = O(\epsilon n)$.

Since the number of edges we add due to the BFS trees of the Voronoi cells is at most $|V| - 1$, we conclude that $\mathrm{Exp}(|E|') \leq (1 + O(\epsilon))|V|$, as desired. ◀

3.4 Connectivity and Stretch

▶ **Lemma 3.** *H is connected.*

Proof. Recall that H contains a spanning tree on every Voronoi cell, hence it suffices to show that we can connect any pair of Voronoi cells by a path between some of their vertices. Moreover, the facts that G is connected and the Voronoi cells are a partition of V imply that it is sufficient to prove this for any pair of adjacent Voronoi cells. Accordingly, let Vor and Vor_1 be two cells such that $E(\mathrm{Vor}, \mathrm{Vor}_1) \neq \emptyset$.

Consider clusters $A \subseteq \mathrm{Vor}$ and $B \subseteq \mathrm{Vor}_1$ such that the edge e of minimum rank in $E(\mathrm{Vor}, \mathrm{Vor}_1)$ is in $E(A, B)$. If B is not adjacent to a marked cell, then Condition 2 implies that e is selected into H. Thus, we may assume that B is adjacent to a marked cell Vor'. Accordingly, there exists a marked cluster $C \subseteq \mathrm{Vor}'$ such that B is participating in $\mathcal{C}(C)$.

If the rank of Vor_1 is minimum in $\mathrm{Vor}(\partial C) \cap \mathrm{Vor}(\partial A)$, then e is selected into H by Condition 3 and we are done. Otherwise, observe that Vor_1 is connected to Vor', as the edge of minimum rank in $E(B, C)$ is selected into H by Condition 1. Therefore, it suffices to show that Vor gets connected to Vor'. Let Vor_2 be the cell of minimum rank among $\mathrm{Vor}(\partial C) \cap \mathrm{Vor}(\partial A)$. Let $D \subseteq \mathrm{Vor}_2$ be the cluster satisfying that the edge e' of minimum rank in $E(A, \mathrm{Vor}_2)$ is in $E(A, D)$. Note that Vor_2 is connected to Vor' (which we saw to be connected to Vor_1), as there is some cluster $D' \subseteq \mathrm{Vor}(D)$ that is adjacent to C and selects the edge of minimum rank in $E(D', C)$ by Condition 1.

Overall, we see that it is sufficient to show that Vor gets connected to Vor_2, where Vor_2 has smaller rank than Vor_1. We now repeat the above reasoning inductively. In step i, we either succeed in establishing connectivity between Vor and Vor_i, or we determine a cell Vor_{i+1} that has smaller rank than Vor_i and is connected to Vor_i. As any sequence of Voronoi cells of descending ranks must be finite, the induction halts after finitely many steps. Because the induction invariant is that Vor_{i+1} is connected to Vor_i, this establishes connectivity between Vor and Vor_1, completing the proof. ◀

▶ **Lemma 4.** *Denote by G_{Vor} the graph obtained from G by contracting Voronoi cells and by H_{Vor} its subgraph obtained when doing the same in H. If the cells' ranks are uniformly random, w.h.p. H_{Vor} is a spanner of G_{Vor} of stretch $O(\log n)$.*

Proof. Recall the proof of Lemma 3. We established connectivity by an inductive argument, where each step increased the number of traversed Voronoi cells by two. Hence, it suffices to show that the induction halts after $O(\log n)$ steps w.h.p.

To see this, observe first that G_{Vor} is independent of the ranks assigned to Voronoi cells and pick any pair of adjacent cells Vor, Vor_1, i.e., neighbors in G_{Vor}. We perform the induction again, assigning ranks from high to low only as needed in each step, according to the following process. In each step, we query the rank of some cells, and given an answer of rank r, the ranks of all cells of rank at least r are revealed as well. In step i, we begin by querying the rank of Vor_i. Consider the cluster $D_i \subseteq \mathrm{Vor}_i$ adjacent to A satisfying that the edge with minimum rank in $E(\mathrm{Vor}_i, A)$ is also in $E(D_i, A)$. We can assume without loss of generality that D_i is adjacent to a marked cluster F_i and that it is participating in $\mathcal{C}(F_i)$ (as otherwise D_i connects to A directly and we can terminate the process). If the ranks of all the cells adjacent to both F_i and A were already revealed, then the process terminates. Otherwise, we query the rank of all such cells whose rank is still unrevealed. We set the cell of the queried cluster that has minimum rank to be Vor_{i+1} and we continue to the next step.

We claim that, in each step i, either the process terminates, or the rank of Vor_{i+1} is at most half of the rank of Vor_i with probability at least $1/2$. To verify this, observe that in the beginning of step i, any cell center whose rank was not revealed so far has rank which

is uniformly distributed in $[r_i - 1]$, where r_i is the rank of Vor_i.[5] With probability at least $1/2$, such a rank is at most $r_i/2$. If Vor_i has no adjacent cells whose ranks have not been revealed yet, the process terminates. Hence, regardless of whether the process terminates or not, the claim holds.

By Chernoff's bound, we conclude that the process terminates within $O(\log n)$ steps w.h.p., as r_1 is bounded by the number of Voronoi cells, which itself is trivially bounded by n. By the union bound over all pairs of cells Vor and Vor_1, we get the desired guarantee. ◀

▶ **Corollary 1.** *W.h.p., H is a spanner of G of stretch $O(\log n \cdot (\Delta + \log n)/\epsilon)$.*

Proof. Due to the promise on G, w.h.p. the spanning trees on Voronoi cells have depth $\ell \in O((\Delta + \log n)/\epsilon)$. Hence, for any edge within a Voronoi cell, the claim holds w.h.p. Moreover, for an edge connecting different Voronoi cells, by Lemma 4, w.h.p. there is a path of length $O(\log n)$ in H_{Vor} connecting the respective cells. Navigating with at most $2\ell \in O((\Delta + \log n)/\epsilon)$ hops in each traversed cell, we obtain a suitable path of length $O(\log n \cdot (\Delta + \log n)/\epsilon)$ in H. ◀

4 The Algorithm for General Graphs

We use a combination of the algorithm in Section 3 with the algorithm by Elkin and Neiman for ultra-sparse spanners [3]. We call a vertex v *remote*, with respect to a set of centers, if the ℓ-hop neighborhood of v does not include a center. Fix S, let R denote the set of remote vertices with respect to S, and abbreviate $\bar{R} \stackrel{\text{def}}{=} V \setminus R$.

First Step. Run the algorithm from Section 3 on the subgraph induced by $\bar{R}$, i.e., $\{u, v\} \in E$ with $u, v \in \bar{R}$ is added to E' if and only if the algorithm outputs the edge.

Second Step. Run the algorithm of Elkin and Neiman [3] on the subgraph induced by R, i.e., $\{u, v\} \in E$ with $u, v \in R$ is added to E' if and only if the algorithm outputs the edge.[6] Their algorithm proceeds as follows. Given an integer h, each vertex v draws r_v according to the exponential distribution with parameter $\beta = \ln(n/\delta)/h$, where δ is a parameter that controls the success probability of the algorithm. Each vertex v receives r_u from every vertex u within distance h, and stores $m_u(v) = r_u - d(u, v)$ and a neighbor on a shortest path between v and u, denoted by $n_u(v)$. The edges that are added to the spanner are $C(v) = \{\{v, n_u(v)\} \mid m_u(v) \geq \max_{w \in V}\{m_w(v) - 1\}\}$, for every $v \in R$.

▶ **Corollary 2.** *M[Claim 2.3 in [3]] With probability at least $1 - \delta$, $r_v < h$ for all $v \in V$.*

M We choose $\delta = 1/n^{b-1}$, where $b \geq 2$ is a constant (see begining of Section 3), and $h = \ell$. The following lemma implies that the total number of edges that we add to H in the second step is at most $|R| \cdot (n^b)^{1/\ell} \leq |R|(1 + \epsilon)$ in expectation.

▶ **Lemma 5** (Proof of Lemma 2.2 in [3]). *For every $v \in R$, $\mathrm{Exp}[C(v)] \leq (n/\delta)^{1/h}$.*

[5] In step 1, we first query Vor_1 and then observe that this statement holds.
[6] The algorithm is described for connected graphs; we simply apply it to each connected component of R.

Third Step. Add to E' all edges $e \in E(R, \bar{R})$.

The following lemma implies that the expected number of edges which are added in the third step is at most ϵn.

▶ **Lemma 6.** $\mathrm{Exp}[|E(R, \bar{R})|] \leq \epsilon n$.

Proof. Observe that for an edge $\{u, v\} \in E$, there is at most one integer r such that $\Gamma_r(u) \cap S = \emptyset$ and $\Gamma_r(v) \cap S \neq \emptyset$ (or vice versa). If there is no such r or $\ell \neq r$, then the edge is not in $E(R, \bar{R})$. Over the random choice of ℓ, the probability of the event that the edge is included is at most $\Pr[\ell = r] \leq \epsilon/\Delta$. The lemma follows by linearity of expectation. ◀

4.1 Stretch Factor

Consider any edge $e = \{u, v\} \in E \setminus E'$ we removed. If $u, v \in \bar{R}$, e was removed by the Algorithm from Section 3, which was applied to the subgraph induced by $\bar{R}$. Applying Corollary 1 to the connected component of e, we get that w.h.p. there is a path of length $O(\log n \cdot (\Delta + \log n)/\epsilon)$ from u to v in H. If $u, v \in R$, by Claim 2 and the choice of parameters, w.h.p. there is a path of length $O((\Delta + \log n)/\epsilon)$ from u to v in H. As $e \notin E(R, \bar{R})$ by the third step, we arrive at the following corollary.

▶ **Corollary 3.** *The above algorithm guarantees stretch $O(\log n \cdot (\Delta + \log n)/\epsilon)$ w.h.p. and satisfies that $\mathrm{Exp}[|E'|] \in (1 + O(\epsilon))n$.*

5 The Local Algorithm

In this section we prove our main theorem.

▶ **Theorem 2.** *Algorithm 1 is an LSSG algorithm. For any graph G over n vertices of maximum degree at most Δ and $\epsilon > 0$, its query complexity, space complexity (length of the random seed), and running time are $\tilde{O}(n^{2/3}) \cdot \mathrm{poly}(1/\epsilon, \Delta)$.*

Proof. The correctness of the algorithm follows from the previous sections. We shall prove that its complexity is as claimed. We analyze the complexity in terms of n. There are additional factors that depend polynomially in Δ and $1/\epsilon$. The following claims hold w.h.p., simultaneously, for all vertices.

Recall that a vertex u is remote if $\Gamma_\ell(u)$ does not contain a center. Due to the sampling probability for centers, a center is found after exploring $\tilde{O}(n^{1/3})$ vertices. Therefore, we can decide for any vertex u whether it is in R with query and time complexity $\tilde{O}(n^{1/3})$. Moreover, if $u \in \bar{R}$, without additional cost the respective subroutine can return $c(u)$, the center of u, and $d(u, c(u))$ (as we explore in a BFS fashion).

For Step 1, we need to determine $\Gamma_\ell(u) \cap R$. To do this, it suffices to explore $\Gamma_\ell(u)$, and for each vertex in it, to determine whether it is in R or not. Since $|\Gamma_\ell(u)| = \tilde{O}(n^{1/3})$ for every vertex $u \in R$, we obtain that the query and time complexity of this step is $\tilde{O}(n^{2/3})$, in total. Accordingly, Step 2 has query and time complexity $\tilde{O}(n^{1/3})$.

If $u, v \in \bar{R}$, the algorithm proceeds as in Section 3. We show first that we can reconstruct clusters efficiently. W.l.o.g., consider u. We determine $c(u)$ and $d(u, c(u))$. For each neighbor w of u, we determine whether it is in $\bar{R}$ (if not, the node is discarded), its center $c(w)$, and the distance $d(w, c(w))$. As $u \in \bar{R}$, and assuming that $u \neq c(u)$, it must have at least one neighbor w in distance $d(u, c(u)) - 1$ of $c(u)$; any such w satisfies that $c(w) = c(u)$, as otherwise $d(u, c(w)) = d(w, c(w))$ and $c(w) < c(u)$, a contradiction to the tie-breaking rule for centers. Among these candidates w, we know that the one with minimum rank is the

Algorithm 1 LSSG for general graphs.

Input: $\{u, v\} \in E$

Output: whether $\{u, v\}$ is in E' or not.

1. If $u, v \in R$, compute the output of algorithm of Elkin and Neiman at u and v when running it on the connected component of u and v in the subgraph induced by R. Return **true** if $\{u, v\} \in C(u) \cup C(v)$ and **false** otherwise.
2. If $\{u, v\} \in E(R, \bar{R})$, return **true**.
3. Otherwise, $u, v \in \bar{R}$ and we proceed according to Section 3, where all nodes in R are ignored:
   a. If $\mathrm{Vor}(u) = \mathrm{Vor}(v)$, return **true** if $\{u, v\}$ is in the BFS tree of $\mathrm{Vor}(u)$ and **false** otherwise.
   b. Otherwise, let Q and W denote the clusters of u and v, respectively. Return **true** if at least one of the following conditions hold for $A = Q$ and $B = W$, or symmetrically, for $A = W$ and $B = Q$, and **false** otherwise.
      i. A is a marked cluster and $\{u, v\}$ has minimum rank amongst the edges in $E(A, B)$.
      ii. A is not participating in any cluster-of-clusters. Namely, all the clusters which are adjacent to A are not marked. In this case, we take $\{u, v\}$ if it has minimum rank amongst the edges in $E(A, \mathrm{Vor}(B))$.
      iii. There exists a marked cluster C such that A is participating in $\mathcal{C}(C)$, and the following holds:
         - $\mathrm{Vor}(A)$ has minimum rank amongst $\mathrm{Vor}(\partial B) \cap \mathrm{Vor}(\partial C)$
         - $\{u, v\}$ has minimum rank amongst the edges in $E(B, \mathrm{Vor}(A))$.

parent of u in the BFS tree of $\mathrm{Vor}(u)$ rooted at $c(u)$, due to the tie-breaking rule for the BFS construction. We can use this subroutine to partially explore the BFS of $\mathrm{Vor}(u)$: given any node $w \in \bar{R}$, we can determine its parent, $p(w)$, and children in $\mathrm{Vor}(w)$ at query and time complexity $\tilde{O}(n^{1/3})$ as follows. The shortest path that has the smallest lexicographical order from $c(w)$ to w is the path connecting these vertices in the BFS tree. Therefore, the parent of w in this tree can be found by performing a BFS from w until the first level in which $c(w)$ is reached. To determine the children we simply run this subroutine for each neighbor, y, of w and find out whether $w = p(y)$ or not. In order to determine whether $T(w) < k$ or $T(w) \geq k$ (by partially or completely exploring $T(w)$), we need to run this subroutine $O(k)$ times, therefore this can be obtained with query complexity $\tilde{O}(n^{2/3})$. if $T(w) < k$, we determine $T(w)$ completely. We collect this information for u and its $\ell - 1$ ancestors, and determine the cluster Q of u. Finally, we repeat the procedure to reconstruct the cluster W of v, and determine for all nodes adjacent to either cluster whether they are in $\bar{R}$ and, if so, their centers. The query and time complexity of this operation is $\tilde{O}(n^{2/3})$ in total.

For the cases $A = Q$, $B = W$ and $A = W$, $B = Q$, respectively, with the above information we can determine

- whether $\mathrm{Vor}(u) = \mathrm{Vor}(v)$,
- if $\mathrm{Vor}(u) = \mathrm{Vor}(v)$, whether $p(u) = v$ or $p(v) = u$,
- if $\mathrm{Vor}(u) \neq \mathrm{Vor}(v)$,
  - whether A is marked (i.e., $c(A)$ has been marked) and whether $\{u, v\}$ has minimum rank in $E(A, B)$,
  - whether A is not adjacent to any marked cluster (i.e., none of the adjacent nodes' centers has been marked) and whether $\{u, v\}$ has minimum rank in $E(A, \mathrm{Vor}(B))$, and
  - whether there is a marked cluster C adjacent to A so that A participates in $\mathcal{C}(C)$,

$\mathrm{Vor}(A)$ has minimum rank in $\mathrm{Vor}(\partial B) \cap \mathrm{Vor}(\partial C)$, and $\{u, v\}$ has minimum rank in $E(B, \mathrm{Vor}(A))$. We note that since we have degree bounded by Δ, the number of vertices in A is $\tilde{O}(n^{1/3})$, and the probability that a cell is marked is $n^{-1/3}$, the number of cluster-of-clusters that A participates in is $\tilde{O}(\Delta)$ w.h.p.

In other words, we can perform all necessary checks to decide whether $\{u, v\} \in E'$ or not.

The algorithm in Section 3 requires $\tilde{O}(n^{2/3})$ random bits for the selection of centers and marked clusters. For the emulation of the algorithm of Elkin and Neiman it suffices that the random variables $\{r_u\}$ be $\tilde{O}(n^{1/3})$-wise independent, because the outcome of the algorithm for a vertex $v \in R$ depends only on the random variables of at most $\tilde{O}(n^{1/3})$ vertices (the vertices in $\Gamma_\ell(v)$). Thus, overall $\tilde{O}(n^{2/3})$ random bits (up to $\mathrm{poly}(\Delta/\epsilon)$ factors) are sufficient. ◀

Abstract

We present the current fastest deterministic algorithm for k-SAT, improving the upper bound $(2-2/k)^{n+o(n)}$ due to Moser and Scheder in STOC 2011. The algorithm combines a branching algorithm with the derandomized local search, whose analysis relies on a special sequence of clauses called chain, and a generalization of covering code based on linear programming.

We also provide a more intelligent branching algorithm for 3-SAT to establish the upper bound 1.32793^n, improved from 1.3303^n.

1 Introduction

As the fundamental NP-complete problems, k-SAT and especially 3-SAT have been extensively studied for decades. Numerous conceptual breakthroughs have been put forward via continued progress of exponential-time algorithms, including randomized and deterministic ones.

The first provable algorithm solving k-SAT on n variables in less than 2^n steps is presented by Monien and Speckenmeyer, using the concept of autark assignment [10]. Later their bound 1.619^n for 3-SAT is improved to 1.579^n and 1.505^n respectively [15, 8]. One should note that these algorithms follow a branching manner, i.e., recursively reducing the formula size by branching and fixing variables deterministically, thus are called branching algorithms.

As for randomized algorithm, two influential ones are PPSZ and Schöning's local search [12, 16]. There has been a long line of research improving the bound $(4/3)^n$ of local search for 3-SAT, including HSSW and combining with PPSZ [5, 6], until Hertli closes the gap between unique and general cases for PPSZ [4] (by unique it means the formula has only one satisfying assignment). In a word, considering randomized algorithm, PPSZ for k-SAT is currently the fastest, although with one-sided error (see PPSZ in Table 1). Unfortunately, general PPSZ seems tough to derandomize due to the excessive usage of random bits [13].

In contrast to the hardness in derandomizing PPSZ, local search can be derandomized using the so-called covering code [2]. Subsequent deterministic algorithms focus on boosting local search for 3-SAT to the bounds 1.473^n and 1.465^n [1, 14]. In 2011, Moser and Scheder fully derandomize Schöning's local search with another covering code for the choice of flipping

Table 1 The rounded up base c in the upper bound c^n of our deterministic algorithm for k-SAT and the corresponding upper bound in previous results [9, 11, 2] and randomized algorithm [12, 4].

k	Our Results	Makino et al.	Moser&Scheder	Dantsin et al.	PPSZ(randomized)
3	**1.32793**	1.3303	1.33334	1.5	1.30704
4	**1.49857**	-	1.50001	1.6	1.46895
5	**1.59946**	-	1.60001	1.66667	1.56943
6	**1.66646**	-	1.66667	1.71429	1.63788

variables within the unsatisfied clauses, which is immediately improved by derandomizing HSSW for 3-SAT, leading to the current best upper bounds for k-SAT (see Table 1) [11, 9]. Since then, all random coins in Schöning's local search are replaced by deterministic choices, and the bounds remain untouched. How to break the barrier?

The difficulty arises in both directions. If attacking this without local search, one has to derandomize PPSZ or propose radically new algorithm. Else if attacking this from derandomizing local search-based algorithm, one must greatly reduce the searching space.

Our method is a combination of a branching algorithm and the derandomized local search. As we mentioned in the second paragraph of this paper, branching algorithm is intrinsically deterministic, therefore it remains to leverage the upper bounds for both of them by some tradeoff. The tradeoff we found is the weighted size of set of chains, where a chain is a sequence of clauses sharing variable with the clauses next to them only, such that a branching algorithm either solves the formula within desired time or returns a large enough set of chains. The algorithm is based on the study of autark assignment from [10] with further refinement, whose output can be regarded as a generalization of maximal independent clauses set from HSSW [5], which reduces the k-CNF to a $(k-1)$-CNF. The searching space equipped with chains is rather different from those in previous derandomizations [2, 9, 11]: It is a Cartesian product of finite number of non-uniform spaces. Using linear programming, we prove that such space can be perfectly covered, and searched by derandomized local search within aimed time. Additionally, unlike the numerical upper bound in HSSW, we give the closed-form.

The rest of the paper is organized as follows. In §2 we give basic notations, definitions related to chain and algorithmic framework. We show how to generalize covering code to cover any space equipped with chains in §3. Then we use such code in derandomized local search in §4. In §5, we prove upper bound for k-SAT, followed by an intelligent branching algorithm for 3-SAT in §6 for improvement. Some upper bound results are highlighted in Table 1, with main results formally stated in Theorem 14 of §5 and Theorem 21 of §6.

2 Preliminaries

2.1 Notations

We study formula in Conjunctive Normal Form (CNF). Let $V = \{v_i | i \in [n]\}$ be a set of n boolean variables. For all $i \in [n]$, a literal l_i is either v_i or $\bar{v}_i$. A clause C is a disjunction of literals and a CNF F is a conjunction of clauses. A k-clause is a clause that consists of exactly k literals, and an $\leq k$-clause consists of at most k literals. If every clause in F is $\leq k$-clause, then F is a k-CNF.

An *assignment* is a function $\alpha : V \mapsto \{0, 1\}$ that maps each $v \in V$ to truth value $\{0, 1\}$. A *partial assignment* is the function restricted on $V' \subseteq V$. We use $F|\alpha(V')$ to denote the formula derived by fixing the values of variables in V' according to partial assignment $\alpha(V')$.

A clause C is said to be *satisfied* by α if α assigns at least one literal in C to 1. F is *satisfiable* iff there exists an α satisfying all clauses in F, and we call such α a *satisfying assignment* of F. The k-SAT problem asks to find a satisfying assignment of a given k-CNF F or to prove its non-existence if F is unsatisfiable.

Let X be a literal or a clause or a collection of either of them, we use $V(X)$ to denote the set of all the variables appear in X. We say that X and X' are *independent* if $V(X) \cap V(X') = \emptyset$, or X *overlaps* with X' if otherwise.

A *word* of length n is a vector from $\{0,1\}^n$. The *Hamming space* $H \subseteq \{0,1\}^n$ is a set of words. Given two words $\alpha_1, \alpha_2 \in H$, the *Hamming distance* $d(\alpha_1, \alpha_2) = \|\alpha_1 - \alpha_2\|_1$ is the number of bits α_1 and α_2 disagree. The reason of using α for word as same as for assignment is straightforward: Giving each variable an index $i \in [n]$, a word of length n naturally corresponds to an assignment, which will be used interchangeably.

Throughout the paper, n always denotes the number of variables in the formula and will be omitted if the context is clear. We use $O^*(f(n)) = \text{poly}(n) \cdot f(n)$ to suppress polynomial factor, and use $\mathcal{O}(f(n)) = 2^{o(n)} \cdot f(n)$ to suppress sub-exponential factor.

2.2 Preliminaries for Chain

In this subsection, we propose our central concepts, which are the basis of our analysis.

▶ **Definition 1.** Given integers $k \geq 3$ and $\tau \geq 1$, a *τ-chain* $\mathcal{S}^{(k)}$ is a sequence of τ k-clauses $\langle C_1, \ldots, C_\tau \rangle$ satisfies that $\forall i, j \in [\tau]$, $V(C_i) \cap V(C_j) = \emptyset$ iff $|i - j| > 1$.

If the context is clear, we will use $\mathcal{S}$, τ-chain or simply chain for short.

▶ **Definition 2.** A set of chains $\mathcal{I}$ is called an *instance* if $\forall \mathcal{S}, \mathcal{S}' \in \mathcal{I}$, $V(\mathcal{S}) \cap V(\mathcal{S}') = \emptyset$ for $\mathcal{S} \neq \mathcal{S}'$.

In other words, each clause in chain only and must overlap with the clauses next to it (if exist), and chains in an instance are mutually independent.

▶ **Definition 3.** Given chain $\mathcal{S}$, define the *solution space* of $\mathcal{S}$ as $A \subseteq \{0,1\}^{|V(\mathcal{S})|}$ such that partial assignment α on $V(\mathcal{S})$ satisfies all clauses in $\mathcal{S}$ iff $\alpha(V(\mathcal{S})) \in A$. [1]

We define vital algebraic property of chain, which will play a key role in the construction of covering code.

▶ **Definition 4.** Let A be the solution space of chain $\mathcal{S}^{(k)}$, define $\lambda \in \mathbb{R}$ and $\pi : A \mapsto [0,1]$ as the *characteristic value* and *characteristic distribution* of $\mathcal{S}^{(k)}$ respectively, where λ and π are feasible solution to the following linear programming LP_A:

$$\sum_{a \in A} \pi(a) = 1$$

$$\lambda = \sum_{a \in A} \left(\pi(a) \cdot \left(\frac{1}{k-1}\right)^{d(a,a^*)} \right) \qquad \forall a^* \in A$$

$$\pi(a) \geq 0 \qquad \forall a \in A$$

▶ Remark. The variables in LP_A are λ and $\pi(a)$ ($\forall a \in A$). There are $|A| + 1$ variables and $|A| + 1$ equality constraints in LP_A. One can work out the determinant of the coefficient matrix to see it has full rank, so the solution is unique if feasible. Specifically, $\lambda \in (0,1)$.

[1] This essentially defines the set of all satisfying assignments for a chain. As a simple example in 3-CNF, 1-chain $\langle x_1 \vee x_2 \vee x_3 \rangle$ has solution space $A = \{0,1\}^3 \backslash 0^3$.

Algorithm 1: Algorithmic Framework.

Input: k-CNF F
Output: a satisfying assignment or `Unsatisfiable`
1: $\mathsf{BR}(F)$ solves F or returns an instance $\mathcal{I}$
2: **if** F is not solved **then**
3: $\quad\mathsf{DLS}(F, \mathcal{I})$
4: **end if**

2.3 Algorithmic Framework

Our algorithm (Algorithm 1) is a combination of a branching algorithm called BR, and a derandomized local search called DLS. BR either solves F or provides a large enough instance to DLS for further use, which essentially reduces the Hamming space exponentially.

3 Generalization of Covering Code

First of all, we introduce the covering code, then show how to generalize it for the purpose of our derandomized local search.

3.1 Preliminaries for Covering Code

The *Hamming ball* of *radius* r and *center* α $B_\alpha(r) = \{\alpha' | d(\alpha, \alpha') \leq r\}$ is the set of all words with Hamming distance at most r from α. A *covering code* of *radius* r for Hamming space H is a set of words $C(r) \subseteq H$ satisfies $\forall \alpha' \in H, \exists \alpha \in C(r)$, such that $d(\alpha, \alpha') \leq r$, i.e., $H \subseteq \bigcup_{\alpha \in C(r)} B_\alpha(r)$, and we say $C(r)$ *covers* H.

Let ℓ be a non-negative integer and set $[\ell]^* = [\ell] \cup \{0\}$, a set of covering codes $\{C(r) | r \in [\ell]^*\}$ is an *ℓ-covering code* for H if $\forall r \in [\ell]^*, C(r) \subseteq H$ and $H \subseteq \bigcup_{r \in [\ell]^*} \bigcup_{\alpha \in C(r)} B_\alpha(r)$, i.e., $\{C(r) | r \in [\ell]^*\}$ covers H.

The following lemma gives the construction time and size of covering codes for the uniform Hamming spaces $\{0,1\}^n$.

▶ **Lemma 5** ([2]). *Given $\rho \in (0, \frac{1}{2})$, there exists a covering code $C(\rho n)$ for Hamming space $\{0,1\}^n$, such that $|C(\rho n)| \leq O^*(2^{(1-h(\rho))n})$ and $C(\rho n)$ can be deterministically constructed in time $O^*(2^{(1-h(\rho))n})$, where $h(\rho) = -\rho \log \rho - (1-\rho) \log (1-\rho)$ is the* binary entropy function.

3.2 Generalized Covering Code

In this subsection we introduce our generalized covering code, including its size and construction time.

First of all we take a detour to define the *Cartesian product* of σ sets of words as $X_1 \times \cdots \times X_\sigma = \prod_{i \in [\sigma]} X_i = \{\uplus_{i \in [\sigma]} \alpha_i | \forall i \in [\sigma], \alpha_i \in X_i\}$, where $\uplus_{i \in [\sigma]} \alpha_i$ is the concatenation from α_1 to α_σ. Then we claim that the Cartesian product of covering codes is also a good covering code for the Cartesian product of the Hamming spaces they covered separately. The proof of this general result can be found in the full version of the paper.

▶ **Lemma 6.** *Given integer $\chi > 1$, for each $i \in [\chi]$, let H_i be a Hamming space and $C_i(r_i)$ be a covering code for H_i. If $C_i(r_i)$ can be deterministically constructed in time $O^*(f_i(n))$ and $|C_i(r_i)| \leq O^*(g_i(n))$ for all $i \in [\chi]$, then there exists covering code $\mathfrak{C}$ of radius $\sum_{i \in [\chi]} r_i$ for Hamming space $\prod_{i \in [\chi]} H_i$ such that $\mathfrak{C}$ can be deterministically constructed in time $O^*(\sum_{i \in [\chi]} f_i(n) + \prod_{i \in [\chi]} g_i(n))$ and $|\mathfrak{C}| \leq O^*(\prod_{i \in [\chi]} g_i(n))$.*

Algorithm 2: Derandomized Local Search: DLS.

Input: k-CNF F, instance $\mathcal{I}$
Output: a satisfying assignment or `Unsatisfiable`

1: construct covering code $\mathfrak{C}$ for Hamming space $H(F,\mathcal{I})$ (Definition 9)
2: **for** every word $\alpha \in \mathfrak{C}$ **do**
3: **if** searchball-fast(F,α,r) find a satisfying assignment α^* for F **then**
4: **return** α^*
5: **end if**
6: **end for**
7: **return** `Unsatisfiable`

Our result on generalized covering code is given below. We give its proof sketch here, and the detailed proof can be found in full version of the paper.

▶ **Lemma 7.** *Let A be the solution space of chain $\mathcal{S}^{(k)}$ whose characteristic value is λ, for any $\nu = \Theta(n)$, there exists an ℓ-covering code $\{C(r)|r \in [\ell]^*\}$ for Hamming space $H = A^\nu$ where $\ell = \lfloor -\nu \log_{k-1} \lambda + 2 \rfloor$, such that $|C(r)| \leq O^*(\lambda^{-\nu}/(k-1)^r)$ and $C(r)$ can be deterministically constructed in time $O^*(\lambda^{-\nu}/(k-1)^r)$, for all $r \in [\ell]^*$.*

Proof Sketch. Firstly, we show the existence of such ℓ-covering code by a probabilistic method. For each $r \in [l]^*$, we build $C(r)$ from $\emptyset$ by repeating the following for $O^*(\lambda^{-\nu}/(k-1)^r)$ times independently: Choose ν words independently from A according to characteristic distribution π (Definition 4) and concatenate them to get a word $\alpha \in A^\nu$, then add α to $C(r)$ with replacement. Clearly, $|C(r)| \leq O^*(\lambda^{-\nu}/(k-1)^r)$. By deliberately choosing the repeating rounds, we can prove that the probability of the event that any code in A^ν is not covered by $C(r)$ is extremely small, such that a union bound for all codes is strictly less than 1, therefore proved the existence.

Secondly, we construct the code deterministically. W.l.o.g., let $d \geq 2$ be a constant divisor of ν. By partitioning H into d blocks and applying the approximation algorithm for the set covering problem in [2], we obtain a good covering code for each block within affordable time. Then we concatenate all covering code by taking their Cartesian product, and the size and construction time follows from Lemma 6. ◀

4 Derandomized Local Search

In this section, we present our derandomized local search (DLS), see Algorithm 2.

The algorithm first constructs the generalized covering code and stores it (Line 1), then calls searchball-fast (Line 3) to search inside each Hamming ball, where searchball-fast refers to the same algorithm proposed in [11], whose running time is stated in the following lemma.

▶ **Lemma 8** ([11]). *Given k-CNF F, if there exists a satisfying assignment α^* for F in $B_\alpha(r)$, then α^* can be found by searchball-fast in time $(k-1)^{r+o(r)}$.*

Our generalized covering code is able to cover the following Hamming space.

▶ **Definition 9.** Given k-CNF F and instance $\mathcal{I}$, the Hamming space for F and $\mathcal{I}$ is defined as $H(F,\mathcal{I}) = H_0 \times \prod_i H_i$, where:

- $H_0 = \{0,1\}^{n'}$ where $n' = n - |V(\mathcal{I})|$.
- $H_i = {A_i}^{\nu_i}$ for all i, where A_i is a solution space and $\nu_i = \Theta(n)$ is the number of chains in $\mathcal{I}$ with solution space A_i. [2]

[2] As we shall see in §5 and §6, there are only finite number of different solution spaces and finite elements

Apparently all satisfying assignments of F lie in $H(F,\mathcal{I})$, because $\prod_i H_i$ contains all assignments on $V(\mathcal{I})$ which satisfy all clauses in $\mathcal{I}$ and H_0 contains all possible assignments of variables outside $\mathcal{I}$. Therefore to solve F, it is sufficient to search the entire $H(F,\mathcal{I})$.

▶ **Definition 10.** Given $\rho \in (0, \frac{1}{2})$ and Hamming space $H(F,\mathcal{I})$ as above, for $L \in \mathbb{Z}^*$, define covering code $\mathfrak{C}(L)$ for $H(F,\mathcal{I})$ as a set of covering codes $\{C(r)|(r-\rho n') \in [L]^*\}$ satisfies that $C(r) \subseteq H(F,\mathcal{I})$ for all r and $H(F,\mathcal{I}) \subseteq \bigcup_{(r-\rho n')\in[L]^*} \bigcup_{\alpha\in C(r)} B_\alpha(r)$, i.e., $\mathfrak{C}(L)$ covers $H(F,\mathcal{I})$.

▶ **Lemma 11.** *Given Hamming space $H(F,\mathcal{I})$ and A_i, ν_i as above, let $L = \sum_i \ell_i$ where $\ell_i = \lfloor -\nu_i \log \lambda_i + 2 \rfloor$ and λ_i is the characteristic value of chain with solution space A_i. Given $\rho \in (0, \frac{1}{2})$, covering code $\mathfrak{C}(L) = \{C(r)|(r-\rho n') \in [L]^*\}$ for $H(F,\mathcal{I})$ can be deterministically constructed in time $O^*(2^{(1-h(\rho))n'} \prod_i {\lambda_i}^{-\nu_i})$ and $|C(r)| \leq O^*(2^{(1-h(\rho))n'}/(k-1)^{r-\rho n'} \prod_i {\lambda_i}^{-\nu_i})$ for all $(r-\rho n') \in [L]^*$.*

Proof. To construct $\mathfrak{C}(L)$ for $H(F,\mathcal{I})$, we construct covering code $C_0(\rho n')$ for $H_0 = \{0,1\}^{n'}$ and ℓ_i-covering code for $H_i = {A_i}^{\nu_i}$ for all i, then take a Cartesian product of all the codes. By Lemma 5, the time taken for constructing $C_0(\rho n')$ is $O^*(2^{(1-h(\rho))n'})$, and $|C_0(\rho n')| \leq O^*(2^{(1-h(\rho))n'})$. By Lemma 7, for each i, the time taken for constructing $C(r_i)$ for each $r_i \in [\ell_i]^*$ is $O^*({\lambda_i}^{-\nu_i}/(k-1)^{r_i})$ and $|C(r_i)| \leq O^*({\lambda_i}^{-\nu_i}/(k-1)^{r_i})$. So by Lemma 6, we have that $|C(r)|$ can be upper bounded by:

$$2^{(1-h(\rho))n'} \cdot \sum_{\sum_i r_i = r-\rho n'} \left(\prod_i O^*({\lambda_i}^{-\nu_i}/(k-1)^{r_i}) \right) = O^*(2^{(1-h(\rho))n'}/(k-1)^{r-\rho n'} \prod_i {\lambda_i}^{-\nu_i}).$$

The equality holds because L is a linear combination of ν_i with constant coefficients and $\nu_i = \Theta(n)$, thus there are $O(1)$ terms in the product since $\sum_i \nu_i \leq n$. Meanwhile, there are $O^*(1)$ ways to partition $(r-\rho n')$ into constant number of integers, thus the outer sum has $O^*(1)$ terms. Together we get an $O^*(1)$ factor in RHS.

The construction time includes constructing each covering code for H_i $(i \geq 0)$ and concatenating each of them by Lemma 6, which is dominated by the concatenation time. As a result, the time taken to construct $C(r)$ for all $(r-\rho n') \in [L]^*$ is:

$$\sum_{(r-\rho n')\in[L]^*} O^*(2^{(1-h(\rho))n'}/(k-1)^{r-\rho n'} \prod_i {\lambda_i}^{-\nu_i}) = O^*(2^{(1-h(\rho))n'} \prod_i {\lambda_i}^{-\nu_i}),$$

because it is the sum of a geometric series. Therefore conclude the proof. ◀

Using our generalized covering code and applying Lemma 8 for searchball-fast (Line 3 in Algorithm 2), we can upper bound the running time of DLS.

▶ **Lemma 12.** *Given k-CNF F and instance $\mathcal{I}$, DLS runs in time $T_{DLS} = \mathcal{O}((\frac{2(k-1)}{k})^{n'} \cdot \prod_i {\lambda_i}^{-\nu_i})$, where $n' = n - |V(\mathcal{I})|$, λ_i is the characteristic value of chain $\mathcal{S}_i$ and ν_i is number of chains in $\mathcal{I}$ with the same solution space to $\mathcal{S}_i$.*

Proof. The running time includes the construction time for $\mathfrak{C}(L)$ and the total searching time in all Hamming balls. It is easy to show that the total time is dominated by the

in each solution space. Thus for those $\nu_i = o(n)$, we can enumerate all possible combinations of assignments on them and just get a sub-exponential slowdown, i,e., an $\mathcal{O}(1)$ factor in the upper bound.

Algorithm 3: Branching Algorithm BR for k-SAT.

Input: k-CNF F
Output: a satisfying assignment or `Unsatisfiable` or an instance $\mathcal{I}$

staring from $\mathcal{I} \leftarrow \emptyset$, **for** 1-chain $\mathcal{S} : V(\mathcal{I}) \cap V(\mathcal{S}) = \emptyset$, **do** $\mathcal{I} \leftarrow \mathcal{I} \cup \mathcal{S}$
if $|\mathcal{I}| < \nu n$ **then**
  for each assignment $\alpha \in \{\{0,1\}^k \backslash 0^k\}$ of $\mathcal{I}$ **do**
    solve $F|\alpha$ by deterministic $(k-1)$-SAT algorithm
    return the satisfying assignment if satisfiable
  end for
  return `Unsatisfiable`
else
  return $\mathcal{I}$
end if

searching time using Lemma 11, thus we have the following equation after multiplying a sub-exponential factor $\mathcal{O}(1)$ for the other $o(n)$ chains not in $\mathcal{I}$:

$$\begin{aligned} T_{\text{DLS}} &= \mathcal{O}(1) \cdot \sum_{(r-\rho n')\in[L]^*} \left(|C(r)| \cdot (k-1)^{r+o(r)} \right) \\ &= \mathcal{O}(1) \cdot \sum_{(r-\rho n')\in[L]^*} \left(O^*(2^{(1-h(\rho))n'}/(k-1)^{r-\rho n'} \prod_i {\lambda_i}^{-\nu_i}) \cdot (k-1)^{r+o(r)} \right) \\ &= \mathcal{O}(2^{(1-h(\rho)+\rho\log(k-1))n'} \cdot \prod_i {\lambda_i}^{-\nu_i}) = \mathcal{O}((\frac{2(k-1)}{k})^{n'} \cdot \prod_i {\lambda_i}^{-\nu_i}). \end{aligned}$$

The first equality follows from Lemma 8, the second inequality is from Lemma 11, and the last equality follows by setting $\rho = \frac{1}{k}$. Therefore we proved this lemma. ◀

5 Upper Bound for k-SAT

In this section, we give our main result on upper bound for k-SAT.

A simple branching algorithm BR for general k-SAT is given in Algorithm 3: Greedily construct a maximal instance $\mathcal{I}$ consisting of independent 1-chains and branch on all satisfying assignments of it if $|\mathcal{I}|$ is small. [3] After fixing all variables in $V(\mathcal{I})$, the remaining formula is a $(k-1)$-CNF due to the maximality of $\mathcal{I}$. Therefore the running time of BR is at most:

$$T_{\text{BR}} = \mathcal{O}((2^k-1)^{|\mathcal{I}|} \cdot {c_{k-1}}^{n-k|\mathcal{I}|}), \tag{1}$$

where $\mathcal{O}({c_{k-1}}^n)$ is the worst-case upper bound of a deterministic $(k-1)$-SAT algorithm.

On the other hand, since there are only 1-chains in $\mathcal{I}$, by Lemma 12 we have:

$$T_{\text{DLS}} = \mathcal{O}((\frac{2(k-1)}{k})^{n-k|\mathcal{I}|} \cdot \lambda^{-|\mathcal{I}|}). \tag{2}$$

It remains to calculate the characteristic value λ of 1-chain $\mathcal{S}^{(k)}$. We prove the following lemma for the unique solution of linear programming LP_A in Definition 4.

[3] W.l.o.g., one can negate all negative literals in $\mathcal{I}$ to transform the solution space of 1-chain to $\{0,1\}^k \backslash 0^k$.

▶ **Lemma 13.** *For 1-chain $\mathcal{S}^{(k)}$, let A be its solution space, then the characteristic distribution π satisfies*

$$\pi(a) = \frac{(k-1)^k}{(2k-2)^k-(k-2)^k} \cdot (1-(\frac{-1}{k-1})^{d(a,0^k)}) \text{ for all } a \in A,$$

and the characteristic value $\lambda = \frac{k^k}{(2k-2)^k-(k-2)^k}$.

Proof. We prove that this is a feasible solution to LP_A. Constraint $\pi(a) \geq 0$ ($\forall a \in A$) is easy to verify. To show constraint $\sum_{a\in A}\pi(a) = 1$ holds, let $y = d(a, 0^k)$ and note there are $\binom{k}{y}$ different $a \in A$ with $d(a, 0^k) = y$, then multiply $\frac{(2k-2)^k-(k-2)^k}{(k-1)^k}$ on both sides:

$$\frac{(2k-2)^k-(k-2)^k}{(k-1)^k} \cdot \sum_{a\in A}\pi(a) = \sum_{1\leq y\leq k}\left((1-(\frac{-1}{k-1})^y)\cdot\binom{k}{y}\right)$$

$$= \sum_{0\leq y\leq k}\binom{k}{y} - \sum_{0\leq y\leq k}\binom{k}{y}(\frac{-1}{k-1})^y = 2^k - (\frac{k-2}{k-1})^k.$$

Thus $\sum_{a\in A}\pi(a) = 1$ holds.

To prove $\lambda = \sum_{a\in A}\left(\pi(a)\cdot(\frac{1}{k-1})^{d(a,a^*)}\right)$, similar to the previous case, we multiply $\frac{(2k-2)^k-(k-2)^k}{(k-1)^k}$ on both sides. Note that adding the term at $a = 0^k$ does not change the sum, then for all $a^* \in A$, we have:

$$\text{RHS} = \sum_{a\in\{0,1\}^k}(1-(\frac{-1}{k-1})^{d(a,0^k)})\cdot(\frac{1}{k-1})^{d(a,a^*)}$$

$$= \sum_{a\in\{0,1\}^k}(\frac{1}{k-1})^{d(a,a^*)} - \sum_{a\in\{0,1\}^k}(-1)^{d(a,0^k)}(\frac{1}{k-1})^{d(a,0^k)+d(a,a^*)}.$$

The first term is equal to $(\frac{k}{k-1})^k = \text{LHS}$. To prove the second term is 0, note that $\exists i \in [k]$ such that some bit $a_i^* = 1$. Partition $\{0,1\}^k$ into two sets $S_0 = \{a \in \{0,1\}^k | a_i = 0\}$ and $S_1 = \{a \in \{0,1\}^k | a_i = 1\}$. We have the following bijection: For each $a \in S_0$, negate the i-th bit to get $a' \in S_1$. Then $d(a, 0^k) + d(a, a^*) = d(a', 0^k) + d(a', a^*)$ and $(-1)^{d(a,0^k)} = -(-1)^{d(a',0^k)}$, so the sum is 0. Therefore we verified the constraint and proved the lemma. ◀

Observe from (1) and (2) that T_{BR} is an increasing function of $|\mathcal{I}|$, while T_{DLS} is a decreasing function of it, so $T_{\mathsf{BR}} = T_{\mathsf{DLS}}$ gives the worst-case upper bound for k-SAT. We solve this equation by plugging in λ from Lemma 13 to get νn as the worst-case $|\mathcal{I}|$, and obtain the following theorem as our main result on k-SAT.

▶ **Theorem 14.** *Given $k \geq 3$, if there exists a deterministic algorithm for $(k-1)$-SAT that runs in time $\mathcal{O}({c_{k-1}}^n)$, then there exists a deterministic algorithm for k-SAT that runs in time $\mathcal{O}({c_k}^n)$, where $c_k = (2^k-1)^\nu \cdot {c_{k-1}}^{1-k\nu}$ and $\nu = \frac{\log(2k-2)-\log k-\log c_{k-1}}{\log(2^k-1)-\log(1-(\frac{k-2}{2k-2})^k)-k\log c_{k-1}}$.*

Note that the upper bound for 3-SAT implied by this theorem is $O(1.33026^n)$, but we can do better by applying Theorem 21 (presented later) for $c_3 = 3^{\log\frac{4}{3}/\log\frac{64}{21}} < 1.32793$ to prove all upper bounds for k-SAT ($k \geq 4$) in Table 1 of §1.

6 Upper Bound for 3-SAT

We provide a better upper bound for 3-SAT by a more intelligent branching algorithm.

First of all, we introduce some additional notations in 3-CNF simplification, then we present our branching algorithm for 3-SAT from high-level to all its components. Lastly we show how to combine it with derandomized local search to achieve a tighter upper bound.

Algorithm 4: Branching Algorithm BR for 3-SAT.

Input: 3-CNF F, clause sequence $\mathcal{C}$
Output: a satisfying assignment or `Unsatisfiable` or a clause sequence $\mathcal{C}$

1: simplify F by *procedure* $\mathcal{P}$
2: **if** $\bot \in F$ **then**
3: **return** `Unsatisfiable`
4: **else if** *condition* Φ holds **then**
5: stop the recursion, *transform* $\mathcal{C}$ to an instance $\mathcal{I}$ and **return** $\mathcal{I}$
6: **else if** F is 2-CNF **then**
7: deterministically solve F in polynomial time
8: **if** F is satisfiable **then**
9: stop the recursion and **return** the satisfying assignment
10: **else**
11: **return** `Unsatisfiable`
12: **end if**
13: **else**
14: choose a clause C according to *rule* Υ
15: for every satisfying assignment α_C of C, call $\mathsf{BR}(F|\alpha_C, \mathcal{C} \cup C^{\mathcal{F}})$
16: **return** `Unsatisfiable`
17: **end if**

6.1 Additional Notations

For every clause $C \in F$, if partial assignment α satisfies C, then C is removed in $F|\alpha$. Otherwise, the literals in C assigned to 0 under α are removed from C. If all the literals in C are removed, which means C is unsatisfied under α, we replace C by $\bot$ in $F|\alpha$. Let $G = F|\alpha$, for every $C \in F$, we use C^F to denote the clause C in F and $C^G \in G$ the new clause derived from C by assigning variables according to α. We use $\mathcal{F}$ to denote the original input 3-CNF without instantiating any variable, and $C^{\mathcal{F}}$ is called the *original form* of clause C.

Let $\mathsf{UP}(F)$ be the CNF derived by running *Unit Propagation* on F until there is no 1-clause in F. Clearly F is satisfiable iff $\mathsf{UP}(F)$ is satisfiable, and UP runs in polynomial time [3].

We will also use the set definition of CNF, i.e., for a CNF $F = \bigwedge_{i\in[m]} C_i$, it is equivalent to write $F = \{C_i | i \in [m]\}$. Define $\mathcal{T}(F), \mathcal{B}(F), \mathcal{U}(F)$ as the set of all the 3-clauses, 2-clauses and 1-clauses in F respectively. We have that any 3-CNF $F = \mathcal{T}(F) \cup \mathcal{B}(F) \cup \mathcal{U}(F)$.

6.2 Branching Algorithm for 3-SAT

In this subsection, we give our branching algorithm for 3-SAT (Algorithm 4). The algorithm is recursive and follows a depth-first search manner:

- Stop the recursion when certain conditions are met (Line 4 and Line 8).
- Backtrack when the current branch is unsatisfiable (Line 3, Line 11 and Line 16).
- Branch on all possible satisfying assignments on a clause and recursively call itself (Line 15). Return `Unsatisfiable` if all branches return `Unsatisfiable`.
- Clause sequence $\mathcal{C}$ stores all the branching clauses from root to the current node.

It is easy to show this algorithm is correct as long as *procedure* $\mathcal{P}$ maintains satisfiability.

In what follows, we introduce (i) the *procedure* $\mathcal{P}$ for simplification (Line 1); (ii) the clause choosing *rule* Υ (Line 14); (iii) the *transformation* from clause sequence to instance (Line 5); (iv) the termination *condition* Φ (Line 4). All of them are devoted to analyzing the running time of BR as a function of instance.

6.2.1 Simplification Procedure

The simplification relies on the following two lemmas.

▶ **Lemma 15** ([10]). *Given 3-CNF F and partial assignment α, define $\mathcal{TB}(F,\alpha) = \{C | C \in \mathcal{B}(\mathsf{UP}(F|\alpha), C^F \in \mathcal{T}(F)\}$. If $\bot \notin \mathsf{UP}(F|\alpha)$ and $\mathcal{TB}(F,\alpha) = \emptyset$, then F is satisfiable iff $\mathsf{UP}(F|\alpha)$ is satisfiable and α is called an* autark.

We refer our readers to Chapter 11 in [7] for a simple proof (also see full version of the paper). We also provide the following stronger lemma to further reduce the formula size.

▶ **Lemma 16.** *Given 3-CNF F and $(l_1 \vee l_2) \in \mathcal{B}(F)$, if $\exists C \in \mathcal{TB}(F, l_1 = 1)$ such that $l_2 \in C$, then F is satisfiable iff $F \backslash C^F \cup C$ is satisfiable.*

Proof. Clearly F is satisfiable if $F \backslash C^F \cup C$ is. Suppose $C = l_2 \vee l_3$ and let α be a satisfying assignment of F. If $\alpha(l_1) = 1$, then $\mathsf{UP}(F|l_1 = 1)$ is satisfiable, thus $F \backslash C^F \cup C$ is also satisfiable since $C \in \mathsf{UP}(F|l_1 = 1)$. Else if $\alpha(l_1) = 0$, then $\alpha(l_2) = 1$ due to $l_1 \vee l_2$, so α satisfies C and the conclusion follows. ◀

As a result, 3-CNF F can be simplified by the following polynomial-time *procedure* $\mathcal{P}$: for every $(l_1 \vee l_2) \in \mathcal{B}(F)$, if $l_1 = 1$ or $l_2 = 1$ is an autark, then apply Lemma 15 to simplify F; else apply Lemma 16 to simplify F if possible.

▶ **Lemma 17.** *After running $\mathcal{P}$ on 3-CNF F, for any $(l_1 \vee l_2) \in \mathcal{B}(F)$ and for any 2-clause $C \in \mathcal{TB}(F, l_1 = 1)$, it must be $l_2 \notin C$. This also holds when switching l_1 and l_2.*

Proof. If $\mathcal{TB}(F, l_1 = 1) = \emptyset$, then $l_1 = 1$ is an autark and F can be simplified by Lemma 15. If $C \in \mathcal{TB}(F, l_1 = 1)$ and $l_2 \in C$, then F can be simplified by Lemma 16. ◀

6.2.2 Clause Choosing Rule

Now we present our clause choosing *rule* Υ. By Lemma 15 we can always begin with branching on a 2-clause with a cost of factor 2 in the upper bound: Choose an arbitrary literal in any 3-clause and branch on its two assignments $\{0, 1\}$. This will result in a new 2-clause otherwise it is an autark and we fix it and continue to choose another literal.

Now let us show the overlapping cases between the current branching clause to the next branching clause. Let C_0 be the branching clause in the father node where $C_0^{\mathcal{F}} = l_0 \vee l_1 \vee l_2$, and let F_0 be the formula in the father node. The *rule* Υ works as follows: if $\alpha_{C_0}(l_1) = 1$, choose arbitrary $C_1 \in \mathcal{TB}(F_0, l_1 = 1)$; else if $\alpha_{C_0}(l_2) = 1$, choose arbitrary $C_1 \in \mathcal{TB}(F_0, l_2 = 1)$.

We only discuss the case $\alpha_{C_0}(l_1) = 1$ due to symmetry. We enumerate all the possible forms of $C_1^{\mathcal{F}}$ by discussing what literal is eliminated followed by whether l_2 or $\bar{l}_2$ is contained:

1. $C_1^{\mathcal{F}} \backslash C_1 = l_3$. C_1 becomes a 2-clause due to elimination of l_3. There are three cases: (i) $C_1 = l_2 \vee l_4$, (ii) $C_1 = \bar{l}_2 \vee l_4$ or (iii) $C_1 = l_4 \vee l_5$.
2. $C_1^{\mathcal{F}} \backslash C_1 = \bar{l}_1$. C_1 becomes a 2-clause due to elimination of $\bar{l}_1$. There are three cases: (i) $C_1 = l_2 \vee l_3$, (ii) $C_1 = \bar{l}_2 \vee l_3$ or (iii) $C_1 = l_3 \vee l_4$.
3. $C_1^{\mathcal{F}} \backslash C_1 = l_2$. This means $l_1 = 1 \Rightarrow l_2 = 0$, and $\alpha_{C_0}(l_1 l_2) = 11$ can be excluded.
4. $C_1^{\mathcal{F}} \backslash C_1 = \bar{l}_2$. This means $l_1 = 1 \Rightarrow l_2 = 1$, and $\alpha_{C_0}(l_1 l_2) = 10$ can be excluded.

Both Case 1.(i) and Case 2.(i) are impossible due to Lemma 17. To sum up, we immediately have the following by merging similar cases with branch number bounded from above:

- Case 1.(iii): it takes at most 3 branches in the father node to get $l_3 \vee l_4 \vee l_5$.
- Case 1.(ii), Case 2.(iii) and Case 4: it takes at most 3 branches in the father node to get $\bar{l}_1 \vee l_3 \vee l_4$ or $\bar{l}_2 \vee l_3 \vee l_4$.
- Case 3: it takes at most 2 branches in the father node to get $l_2 \vee l_3 \vee l_4$.
- Case 2.(ii): it takes at most 3 branches in the father node to get $\bar{l}_1 \vee \bar{l}_2 \vee l_3$.

To fit *rule* Υ, there must be at least one literal assigned to 1 in the branching clause. Except Case 2.(ii), we get a 2-clause C_1, and *rule* Υ still applies.

Now consider the case $C_1^{\mathcal{F}} = \bar{l}_1 \vee \bar{l}_2 \vee l_3$. If $\alpha(l_1 l_2) = 11$, we have $C_1^F = l_3$, otherwise we have $C_1^F = 1 \vee l_3$. In other words, the assignment satisfying $C_0 \wedge C_1$ should be $\alpha(l_1 l_2 l_3) \in \{010, 100, 011, 101, 111\}$. Note that $\alpha(l_3) = 0$ in the first two assignments, which does not fit *rule* Υ. In this case, we do the following: Choose an arbitrary literal in any 3-clause and branch on its two assignments $\{0, 1\}$. Continue this process we will eventually get a new 2-clause (Lemma 15). Now the first two assignments $\alpha(l_1 l_2 l_3) \in \{010, 100\}$ has 4 branches because of the new branched literal, and we have that all 7 branches fit *rule* Υ because either $l_3 = 1$ or there is a new 2-clause. Our key observation is the following: These 7 branches correspond to all satisfying assignments of $C_0 \wedge C_1$, which can be amortized to think that C_1 has 3 branches and C_0 has 7/3 branches. As a conclusion, we modify the last case to be:

- Case 2.(ii): it takes at most 7/3 branches in the father node to get $\bar{l}_1 \vee \bar{l}_2 \vee l_3$.

6.2.3 Transformation from Clause Sequence to Instance

We show how to transform a clause sequence $\mathcal{C}$ to an instance, then take a symbolic detour to better formalize the cost of generating chains, i.e., the running time of BR.

Similar to above, let C_1 be the clause chosen by *rule* Υ and let C_0 be the branching clause in the father node, moreover let C be the branching clause in the grandfather node. In other words, C_1, C_0, C are the last three clauses in $\mathcal{C}$. C_1 used to be a 3-clause in the father node since $C_1 \in \mathcal{T}(F)$, thus C_1 is independent with C because all literals in C are assigned to some values in F, so C_1 can only overlap with C_0. Therefore, clauses in $\mathcal{C}$ can only (but not necessarily) overlap with the clauses next to them.

By the case discussion in §6.2.2, there are only 4 overlapping cases between C_0 and C_1, which we call *independent* for $\langle l_0 \vee l_1 \vee l_2,\ l_3 \vee l_4 \vee l_5\rangle$, *negative* for $\langle l_0 \vee l_1 \vee l_2,\ \bar{l}_1 \vee l_3 \vee l_4\rangle$ or $\langle l_0 \vee l_1 \vee l_2,\ \bar{l}_2 \vee l_3 \vee l_4\rangle$, *positive* for $\langle l_0 \vee l_1 \vee l_2,\ l_2 \vee l_3 \vee l_4\rangle$ and *two-negative* for $\langle l_0 \vee l_1 \vee l_2,\ \bar{l}_1 \vee \bar{l}_2 \vee l_3\rangle$. There is a natural mapping from clause sequence to a string.

▶ **Definition 18.** Let $\mathcal{C}$ be a clause sequence, define function $\zeta : \mathcal{C} \mapsto \Gamma^{|\mathcal{C}|}$, where $\Gamma = \{*, \mathtt{n}, \mathtt{p}, \mathtt{t}\}$, satisfies that the i-th bit of $\zeta(\mathcal{C})$ is $*$ if $\mathcal{C}_i$ and $\mathcal{C}_{i+1}$ are independent, or $\mathtt{n}$ if negative, or $\mathtt{p}$ if positive, or $\mathtt{t}$ if two-negative for all $i \in [|\mathcal{C}| - 1]$, and the $|\mathcal{C}|$-th bit of $\zeta(\mathcal{C})$ is $*$. A τ-chain $\mathcal{S}$ is also a clause sequence of length τ, so ζ maps $\mathcal{S}$ to Γ^τ. Two chains $\mathcal{S}_1$ and $\mathcal{S}_2$ are *isomorphic* if $\zeta(\mathcal{S}_1) = \zeta(\mathcal{S}_2)$.

Then the *transformation* from $\mathcal{C}$ to $\mathcal{I}$ naturally follows: Partition $\zeta(\mathcal{C})$ by $*$, then every substring corresponds to a chain, just add this chain to $\mathcal{I}$. Now we can formalize the cost.

▶ **Lemma 19.** *Given 3-CNF $\mathcal{F}$, let $\mathcal{C}$ be the clause sequence in time T of running BR$(\mathcal{F}, \emptyset)$, it must be $T \le O^*(2^{\kappa_1} \cdot 3^{\kappa_2} \cdot (7/3)^{\kappa_3})$, where κ_1 is the number of $\mathtt{p}$ in $\zeta(\mathcal{C})$, κ_2 is the number of $*$ and $\mathtt{n}$ in $\zeta(\mathcal{C})$, and κ_3 is the number of $\mathtt{t}$ in $\zeta(\mathcal{C})$.*

Proof. By Definition 18 and case discussion in §6.2.2, the conclusion follows. ◀

6.2.4 Termination Condition

We show how the cost of generating chains implies the termination *condition* Φ. We map every chain to an integer as the *type* of the chain such that isomorphic chains have the same type. Formally, let $\mathcal{I}(\mathcal{C})$ be the instance transformed from $\mathcal{C}$, and let $\Sigma = \{\zeta(\mathcal{S}) | \mathcal{S} \in \mathcal{I}(\mathcal{C})\}$ be the set of distinct strings with no repetition. Define bijective function $g : \Sigma \mapsto [\theta]$ that maps each string $\zeta(\mathcal{S})$ in Σ to a distinct integer as the *type* of chain $\mathcal{S}$, where $\theta = |\Sigma|$ is the number of types of chain in $\mathcal{C}$ and g can be arbitrary fixed bijection. Define *branch number* b_i of type-i chain $\mathcal{S}$ as $b_i = 2^{\kappa_1} \cdot 3^{\kappa_2} \cdot (7/3)^{\kappa_3}$, where κ_1 is the number of `p` in $\zeta(\mathcal{S})$, κ_2 is the number of `*` and `n` in $\zeta(\mathcal{S})$, and κ_3 is the number of `t` in $\zeta(\mathcal{S})$. Also define the *chain vector* $\vec{\nu} \in \mathbb{Z}^\theta$ for $\mathcal{I}(\mathcal{C})$ satisfies $\nu_i = |\{\mathcal{S} \in \mathcal{I}(\mathcal{C}) | (g \circ \zeta)(\mathcal{S}) = i\}|$ for all $i \in [\theta]$, i.e., ν_i is the number of type-i chains in $\mathcal{I}(\mathcal{C})$. We can rewrite Lemma 19 as the following.

▶ **Corollary 20.** *Given 3-CNF $\mathcal{F}$, let $\mathcal{I}$ be the instance in time T of running $\mathsf{BR}(\mathcal{F}, \emptyset)$, it must be $T \le T_{\mathsf{BR}} = O^*(\prod_{i\in[\theta]} b_i^{\nu_i})$, where b_i is the branch number of type-i chain and $\vec{\nu}$ is the chain vector for $\mathcal{I}$.*

To achieve worst-case upper bound $\mathcal{O}(c^n)$ for solving 3-SAT, we must have $T_{\mathsf{BR}} \le \mathcal{O}(c^n)$, which is $\prod_{i=1}^{\theta} b_i^{\nu_i} \le c^n$. This immediately gives us the termination *condition* Φ: $(\sum_{i\in[\theta]} \nu_i \cdot \log b_i)/\log c > n$.

Therefore, we can hardwire such condition into the algorithm to achieve the desired upper bound, as calculated in next subsection.

6.3 Combination of Two Algorithms

By combining BR and DLS as in Algorithm 1, we have that the worst-case upper bound $\mathcal{O}(c^n)$ is attained when $T_{\mathsf{BR}} = T_{\mathsf{DLS}}$, which is:

$$c^n = \prod_{i\in[\theta]} b_i^{\nu_i} = (\frac{4}{3})^{n'} \cdot \prod_{i\in[\theta]} {\lambda_i}^{-\nu_i}, \tag{3}$$

followed by Corollary 20 and Lemma 12. Let η_i be the number of variables in a type-i chain for all $i \in [\theta]$, we have that $n' = n - |V(\mathcal{I})| = n - \sum_{i\in[\theta]} \eta_i \nu_i$. Taking the logarithm and divided by n, (3) becomes:

$$\log c = \sum_{i\in[\theta]} \frac{\nu_i}{n} \log b_i = \log \frac{4}{3} - \sum_{i\in[\theta]} \frac{\nu_i}{n} (\eta_i \log \frac{4}{3} + \log \lambda_i). \tag{4}$$

The second equation is a linear constraint over $\frac{1}{n} \cdot \vec{\nu}$, which gives that $\log c$ is maximized when $\nu_i = 0$ for all $i \neq \arg\max_{i\in[\theta]} \{\log b_i/(\log b_i + \eta_i \log \frac{4}{3} + \log \lambda_i)\}$.

Based on calculation of LP_A (see full version of the paper), we show that chain $\mathcal{S}$ with $\zeta(\mathcal{S}) =$ `*` (say, type-1 chain) corresponds to the maximum value above, namely:

$$\arg\max_{i\in[\theta]} \{\log b_i/(\log b_i + \eta_i \log \frac{4}{3} + \log \lambda_i)\} = 1.$$

In other words, all chains in $\mathcal{I}$ are 1-chain. Substitute $\lambda_1 = \frac{3}{7}, b_1 = 3, \eta_1 = 3$ and $\nu_i = 0$ for all $i \in [2, \theta]$ into (4), we obtain our main result on 3-SAT as follow.

▶ **Theorem 21.** *There exists a deterministic algorithm for 3-SAT that runs in time $\mathcal{O}(3^{n \log \frac{4}{3} / \log \frac{64}{21}})$.*

This immediately implies the upper bound $O(1.32793^n)$ for 3-SAT in Table 1 of §1.

Abstract

We study algorithms and combinatorial complexity bounds for *stable-matching Voronoi diagrams*, where a set, S, of n point sites in the plane determines a stable matching between the points in $\mathbb{R}^2$ and the sites in S such that (i) the points prefer sites closer to them and sites prefer points closer to them, and (ii) each site has a quota indicating the area of the set of points that can be matched to it. Thus, a stable-matching Voronoi diagram is a solution to the classic post office problem with the added (realistic) constraint that each post office has a limit on the size of its jurisdiction. Previous work provided existence and uniqueness proofs, but did not analyze its combinatorial or algorithmic complexity. We show that a stable-matching Voronoi diagram of n sites has $O(n^{2+\varepsilon})$ faces and edges, for any $\varepsilon > 0$, and show that this bound is almost tight by giving a family of diagrams with $\Theta(n^2)$ faces and edges. We also provide a discrete algorithm for constructing it in $O(n^3 + n^2 f(n))$ time, where $f(n)$ is the runtime of a geometric primitive that can be performed in the real-RAM model or can be approximated numerically. This is necessary, as the diagram cannot be computed exactly in an algebraic model of computation.

1 Introduction

The *Voronoi diagram* is a well-known geometric structure with a broad spectrum of applications in computational geometry and other areas of Computer Science, e.g., see [3, 5, 8, 18, 20, 22, 24, 7]. The Voronoi diagram partitions the plane into regions. Given a finite set S of points, called sites, each point in the plane is assigned to the region of its closest site in S. Although the Voronoi diagram has been generalized in many ways, its standard definition specifies that each *Voronoi cell* or *region* of a site s is the set $V(s)$ defined as $\{p \in \mathbb{R}^2 \mid d(p,s) \leq d(p,s') \quad \forall s' \neq s \in S\}$, where $d(\cdot,\cdot)$ denotes the distance between two points. The properties of standard Voronoi diagrams have been thoroughly studied (e.g., see [3, 5]). For example, it is well-known that in a standard Voronoi diagram for point sites in the plane every Voronoi cell is a connected, convex polygon whose boundaries lie along perpendicular bisectors of pairs of sites.

On a seemingly unrelated topic, the theory of *stable matchings* studies how to match entities in two sets, each of which has its own preferences about the elements of the other set, in a "stable" manner. It is used, for instance, to match hospitals and medical students starting their residencies [21], as well as in on-line advertisement auctions (e.g., see [2]). It was originally formulated by Gale and Shapley [12] in the context of establishing marriages between n men and n women, where each man ranks the women by preference, and the women rank the men. A matching between the men and women is *stable* if there is no *blocking pair*, that is, a man and woman who prefer each other over their assigned partners according to the matching. Gale and Shapley [12] show that a stable solution always exists for any set of preferences, and they provide an algorithm that runs in $O(n^2)$ time.

When generalized to the one-to-many case, the stable matching problem is also known as the *college admission* problem [23] and can be formulated as a matching of n students to k colleges, where each student has a preference ranking of the colleges and each college has a preference ranking of the students and a *quota* indicating how many students it can accept.

In this paper, we are interested in studying the algorithmic and combinatorial complexity of the diagrams that we call *stable-matching Voronoi diagrams*, which combine the notions of Voronoi diagrams and the one-to-many stable matching problem. These diagrams were introduced by Hoffman *et al.* [15], who provided a mathematical definition and existence and uniqueness proofs for such structures for potentially countably infinite sets of sites, but they did not study their algorithmic or combinatorial complexities. A stable-matching Voronoi diagram is defined with respect to a set of sites in $\mathbb{R}^2$, which in this paper we restrict to finite sets of n distinct points, each of which has an assigned numerical *quota* (which is also known as its "*appetite*") indicating the area of the region of points assigned to it. A preference relationship is defined in terms of distance, so that each point p in $\mathbb{R}^2$ prefers sites ordered by distance, from closest to farthest, and each site likewise prefers points ordered by distance. The stable-matching Voronoi diagram, then, is a partition of the plane into regions, such that (i) each site is associated with a region of area equal to its appetite, and (ii) the assignment of points to sites is stable in the sense that there is no site–point pair whose members prefer each other over their assigned matches. See Figure 1.

Formally, we can define a stable-matching Voronoi diagram for a set of sites as follows.

▶ **Definition 1.** Given a set S of n points (called sites) in $\mathbb{R}^2$ and a numerical appetite $A_s > 0$ for each $s \in S$, the *stable-matching Voronoi diagram* of S is a division of $\mathbb{R}^2$ into $n+1$ regions, such that for each site $s \in S$ there is a corresponding region C_s of area A_s, and there is an extra region, $C_\emptyset$, for the the remaining "unmatched" points, and such that there are no blocking pairs. A blocking pair is a site $s \in S$ and a point $p \in \mathbb{R}^2$ such that (i)

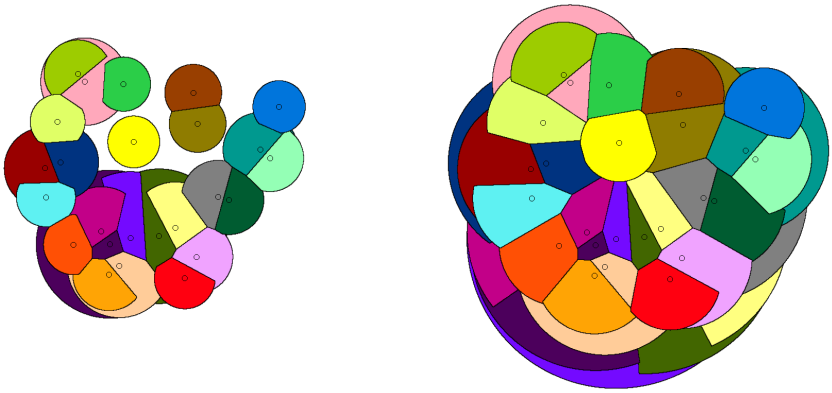

Figure 1 Stable-matching Voronoi diagrams for a set of 25 sites, where each site in the left diagram has an appetite of 1 and each site in the right diagram has an appetite of 2. Each color corresponds to an individual cell, which is not necessarily convex or even connected.

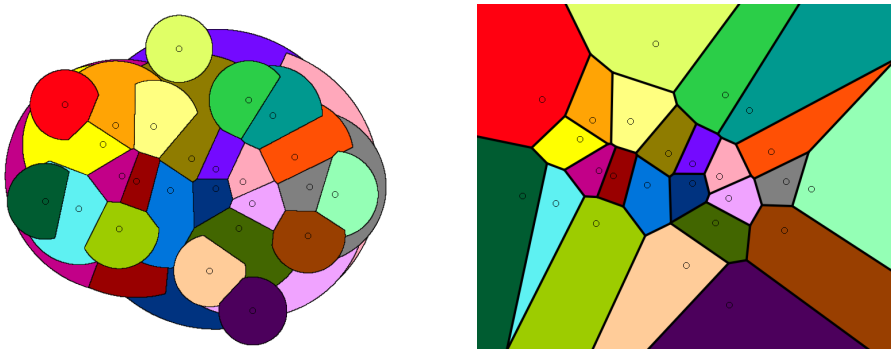

Figure 2 A stable-matching Voronoi diagram (left) and a standard Voronoi diagram (right) for the same set of 25 sites. Each color represents a region.

$p \notin C_s$, (*ii*) $d(p,s) < \max\{d(p',s) \mid p' \in C_s\}$, and (*iii*) $p \in C_\emptyset$ or $d(p,s) < d(p,s')$, where s' is the site such that $p \in C_{s'}$.

Figure 2 shows a side-by-side comparison of the standard and stable-matching Voronoi diagrams. Note that the standard Voronoi diagram is stable in the same sense as the stable-matching Voronoi diagram. This is because, by definition, every point is matched to its first choice among the sites, so there can be no blocking pairs. Thus, standard Voronoi diagram can be seen as a stable-matching Voronoi diagram with infinite appetites, in the following sense: for any point p in $\mathbb{R}^2$, for sufficiently large appetites for all the sites, p will belong to the region of the same site in the standard and stable-matching Voronoi diagrams.

In this paper, we focus on the case where all the appetites are equal, i.e., $A_s = A$, for some $A > 0$, but our results are easily adapted to the general case of arbitrary positive appetites.

A stable-matching Voronoi diagram solves the *post office* problem [19], of assigning points to their closest post office, under the (realistic) real-world assumption that each post office has an upper bound on the size of its jurisdiction. Such notions may also be useful for political districting, where sites could, for instance, represent polling stations, and appetites could represent their capacities. In this context, the distance preferences for a stable-matching Voronoi diagram might determine a type of "compactness" that avoids the strange regions

that are the subjects of recent court cases involving gerrymandering. Nevertheless, depending on the appetites and sites, the regions for sites in a stable-matching Voronoi diagram are not necessarily convex or even connected (e.g., see Figure 1). Thus, we are interested in this paper in characterizing the worst-case combinatorial complexity of such diagrams as well as finding an efficient algorithm for constructing them.

Previous Related Work. There are large volumes of work on the topics of Voronoi diagrams and stable matchings; hence, we refer the interested reader to surveys or books on the subjects (e.g., see [3, 5, 14, 16]).

A generalization of Voronoi diagram of particular relevance are *power diagrams*, where a weight associated to each site indicates how strongly the site draws the points in its neighborhood. Aurenhammer *et al.* [4] showed that, given a quota for each site, it is always possible to find weights for the sites such that, in the power diagram, the region of each site will have area equal to its prescribed quota. Thus, both stable-matching Voronoi diagrams and power diagrams are Voronoi-like diagrams with predetermined region sizes. Power diagrams minimize the total square distance between the sites and their associated points, while stable-matching Voronoi diagrams result in a stable matching.

As mentioned above, Hoffman *et al.* [15] gave definitions and existence and uniqueness proofs for the structures we call stable-matching Voronoi diagrams, albeit for potentially countably infinite sets of point sites. Rather than giving a discrete algorithm for constructing such diagrams, however, they described a continuous process that results in the stable-matching Voronoi diagram: Start growing a circle from all the sites at the same time and at the same rate, matching the sites with all the points encountered by the circles that are not matched yet – when a site fulfills its appetite, its circle stops growing. The process ends when all the circles have stopped growing. Of course, such a continuous process could be approximated numerically, but it is not an effective discrete algorithm, which is one of the interests of the present paper.

In other previous work, Eppstein *et al.* [10] studied the problem of constructing a stable-matching Voronoi diagram in a discrete $n \times n$ grid setting, where both sites and points are pixels. Later, Eppstein *et al.* [9] considered a related stable-matching problem in the context of planar graphs and road networks. In these two previous works, the entities analogous to sites and points are either pixels or vertices; hence, these previous algorithms did not encounter the algorithmic and combinatorial challenges raised by stable-matching Voronoi diagrams for sites and points in the plane.

Our Contributions. In Section 2, we give a geometric interpretation of stable-matching Voronoi diagrams as the lower envelope of a set of cones, and discuss some basic properties of stable-matching Voronoi diagrams.

In Section 3, we give an $O(n^{2+\varepsilon})$ upper bound, for any $\varepsilon > 0$, and an $\Omega(n^2)$ lower bound for the number of faces and edges of a stable-matching Voronoi diagrams in the worst case, where n is the number of sites.

In Section 4, we show that stable-matching Voronoi diagrams cannot be computed exactly in an algebraic model of computation. In light of this, we provide a discrete algorithm for constructing them that runs in $O(n^3 + n^2 f(n))$ time, where $f(n)$ is the runtime of a geometric primitive (which we identify) that encapsulates this difficulty. The geometric primitive can be computed in the real-RAM model or can be approximated numerically. We conclude in Section 5.

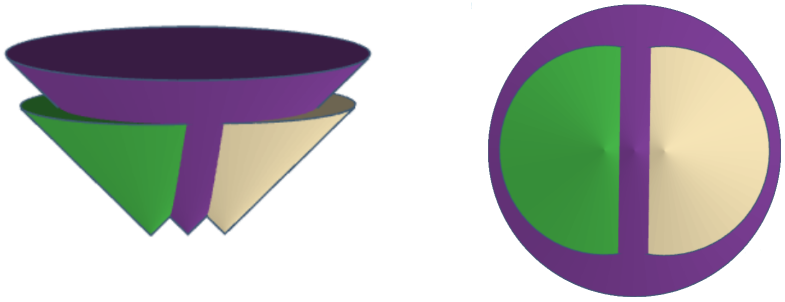

Figure 3 View of a stable-matching Voronoi diagram of 3 sites as the lower envelope of a set of cones.

2 The Geometry of Stable-Matching Voronoi Diagrams

As is now well-known, a (2-dimensional) Voronoi diagram can be viewed as a lower envelope of cones in 3 dimensions, as follows [11]. Suppose that the sites are embedded in the plane $z = 0$. That is, we map each site $s = (x_s, y_s)$ to the 3-dimensional point $(x_s, y_s, 0)$. Then, we draw one cone for each site, with the site as the apex, and growing to $+\infty$ all with the same slope. If we then view the cones from below, i.e., from $z = -\infty$ towards $z = +\infty$, the part of the cone of each site that we see corresponds to the Voronoi cell of the site. This is because two such cones intersect at points that are equally distant to the two apices. As a result, the xy-projection of their intersection corresponds to the perpendicular bisector of the apices, and the boundaries of the Voronoi cells in the Voronoi diagram are determined by the perpendicular bisectors with neighboring sites.

Similarly, a stable-matching Voronoi diagram can also be viewed as the lower envelope of a set of cones, where, instead of extending to $+\infty$, cones are cut off at a finite height (which is a potentially different height for each cone, even if the associated sites have the same appetite). This system of cones can be generated by a dynamic process that begins with cones of height zero and then grows them all at the same rate, halting the growth of each cone as soon as its area in the lower envelope reaches its appetite (see Figure 3).

A stable-matching Voronoi diagram consists of three types of elements:

- A *face* is a maximal, closed, connected subset of a stable cell. The stable cells can be disconnected, that is, a cell can have more than one face. There is also one or more *empty faces*, which are maximal connected regions not assigned to any site. One of the empty faces is the *external face*, which is the only face with infinite area.
- An *edge* is a maximal line segment or circular arc on the boundary of two faces. We call the two types of edges *straight* and *curved edges*, respectively. For curved edges, we distinguish between its incident convex face (the one inside the circle along which the edge lies) and its incident concave face.
- A *vertex* is a point shared by more than one edge. Generally, edges end at vertices, but curved edges may have no endpoints when they form a complete circle. This situation arises when the region of a site is isolated from other sites.

For a given appetite, shared by all the sites, we say that sites are not in general position if two curved boundaries of the stable-matching Voronoi diagram touch at a point, p, that is not an endpoint (e.g., two circles of radius 1 with centers 2 units apart) and, hence, for those curved edges, the concave face is the same at both sides of p. In this special case, we consider that the curved edges end at the vertex p.

In order to study the topology of the distance-stable Voronoi diagram, let the *bounding*

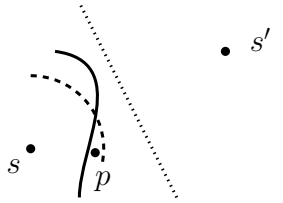

Figure 4 Illustration of the setting in the proof of Lemma 2. It shows the perpendicular bisector of two sites s and s' (as a dotted line), the boundary of the bounding disk, B_s, of s (as a dashed circular arc), and a hypothetical boundary between the regions of sites s and s' (as a solid curve). In this setting, s and p would be a blocking pair.

disk, B_s, of a site, s, be the smallest (closed) disk centered at s that contains the stable cell of s. The bounding disks arise in the topology of the diagram due to the following lemma:

▶ **Lemma 2.** *If part of the boundary between a face of site s and a face of site s' lies in the half-plane closer to s than to s', then that part of the boundary must lie along the boundary of the bounding disk B_s of s, and the convex face must belong to s.*

Proof. The boundary between the faces of s and s' cannot lie outside of B_s, by definition of the bounding disk. If the boundary is in the half-plane closer to s, then it also cannot be in the interior of B_s, because then there would exist a point p inside B_s and in the half-plane closer to s, but matched to s' (see Figure 4). In such a situation, s and p would be a blocking pair: s prefers p to the point(s) matched to it along B_s, and p prefers s to s'. ◀

▶ **Lemma 3.** *The union of non-empty faces of the diagram is the union of the bounding disks of all the sites.*

Proof. For any site s, all the points inside the bounding disk of s must be matched. Otherwise, there would be a point, say, p, not matched to anyone but closer to s than points actually matched to s (along the boundary of B_s), which would be unstable, as p and s would be a blocking pair. Moreover, points outside of all the bounding disks cannot be matched to anyone, by definition of the bounding disks. ◀

▶ **Lemma 4** (Characterization of edges)**.**

1. *A straight edge separating faces of sites s and s' can only lie along the perpendicular bisector of s and s'.*
2. *A curved edge whose convex face belongs to site s lies along the boundary of the bounding disk of s. Moreover, if the concave face belongs to a site s', the edge must be contained in the half-plane closer to s than s'.*
3. *Empty faces can only be concave faces of curved edges.*

Proof. Claims (1) and (2) are consequences of Lemma 2, and Claim (3) is a consequence of Lemma 3. ◀

Generally, every site has at least one curved edge. The only case where that may not happen is when the appetite of a site is exactly the same as the area of its Voronoi cell.

3 Combinatorial Complexity

3.1 An Upper Bound on the Number of Faces

As mentioned in Section 2, a stable-matching Voronoi diagram can be viewed as the lower envelope of a set of cones. The study of *Davenport-Schinzel sequences* has yielded results that characterize the combinatorial complexity of the lower envelope of certain sets of functions (e.g., see Sharir and Agarwal [1]), including cones.

Formally, the *lower envelope* (also called *minimization diagram*) of a set of bivariate continuous functions $F = \{f_1(x, y), \ldots, f_n(x, y)\}$ is the function $E_F(x, y) = \min_{1 \leq i \leq n} f_i(x, y)$. The lower envelope of F partitions the plane into maximal connected regions such that E_F is attained by a single function f_i (or by no function at all). The *combinatorial complexity* of the lower envelope E_F, denoted $K(F)$, is the number of maximal connected regions of E_F. To prove our upper bound, we use the following result:

▶ **Lemma 5.** *Sharir and Agarwal [1, p. 191] The combinatorial complexity $K(F)$ of the lower envelope of a collection F of n (partially defined) functions that satisfy the assumptions below* [1] *is $O(n^{2+\varepsilon})$, for any $\varepsilon > 0$.*

- *Each $f_i \in F$ is a portion of an algebraic surface of the form $P(x_1, \ldots, x_d) = 0$, for some polynomial P of constant maximum degree.*
- *The vertical projection of each $f_i \in F$ onto the xy-plane is a planar region bounded by a constant number of algebraic arcs of constant maximum degree.*

▶ **Corollary 6.** *A stable-matching Voronoi diagram for n sites has $O(n^{2+\varepsilon})$ faces, for any $\varepsilon > 0$.*

Proof. It is clear that the finite, "upside-down" cones whose lower envelope forms the stable-matching Voronoi diagram of a set of sites satisfy the assumptions from Lemma 5. In particular, their projection onto the xy-plane are disks. Note that the bound still applies if we include the empty faces, as the assumptions still hold if we add an extra bivariate function $f_{n+1}(x, y) = z^*$, where z^* is any value higher than the height of any cone (i.e., f_{n+1} is a plane that "hovers" over the cones). Such a function would have a face in the lower envelope for each empty face in the stable-matching Voronoi diagram. ◀

3.2 An Upper bound on the Number of Edges and Vertices

Euler's formula relates the number of faces in a planar graph with the number of vertices and edges. By viewing the stable-matching Voronoi diagram as a graph, we can use Euler's formula to prove that the $O(n^{2+\varepsilon})$ upper bound also applies to the number of edges and vertices. In order to do so, we need the following lemma, for which we defer the proof to the full version of the paper [6] due to space constraints.

▶ **Lemma 7.** *The average degree is at least* 2.25.

In this section (Lemmas 7 and 8), we assume that sites are in general position (as defined in Section 2). However, note that non-general-position constructions cannot yield the worst-case complexity. This is because if two curved boundaries coincide exactly at a point that is not an endpoint, we can perturb slightly the site locations to move them a little closer, which creates a new vertex and edge.

[1] The theorem, as stated in [1] (Theorem 7.7), includes some additional assumptions, but then shows that they are not essential.

▶ **Lemma 8.** *Let V, E and F be the number of vertices, edges, and faces of the stable-matching Voronoi diagram of a set of sites S. Then, $V \leq 8F - 16$ and $E \leq 9F - 18$.*

Proof. For this proof, suppose that there are no curved edges that form a full circle. Note that the presence of such edges can only reduce the number of vertices and edges, as for each such edge there is a site with a single edge and no vertices.

Without such edges, the vertices and edges of the stable-matching Voronoi diagram form a planar graph, and V, E, F are the number of vertices, edges, and faces of this graph, respectively. Moreover, let C be the number of connected components. Due to Euler's formula for planar graphs, we have $F = E - V + C + 1$, and thus $F \geq E - V + 2$. Moreover, by Lemma 7, the sum of degrees is at least $2.25V$, so $2E \geq 2.25V$. Combining the two relations above, we have $V \leq 8F - 16$ and $E \leq 9F - 18$. ◀

We conclude by stating the main theorem of this section, which is a combination of Corollary 6 and Lemma 8:

▶ **Theorem 9.** *A stable-matching Voronoi diagram for n sites has $O(n^{2+\varepsilon})$ faces, vertices, and edges, for any $\varepsilon > 0$.*

3.3 Lower Bound

▶ **Lemma 10.** *A stable-matching Voronoi diagram for n sites has $\Omega(n^2)$ faces in the worst case.*

Proof. Let $m = \lfloor n/2 \rfloor$. We will construct a diagram in two steps, first placing m sites, and then m more. If n is odd, the remaining site can be placed anywhere in the plane that does not intersect with the others.

First, consider the stable-matching Voronoi diagram of m sites, each with appetite one, placed evenly on a circle with very small radius ε_1. Then, perturb them slightly so that the circular angle between two specific sites s, s' is slightly bigger than the rest: $2\pi/n + \varepsilon_2$, while the angle between any other pair of sites is $2\pi/n - \varepsilon_2/(n-1)$, again for a very small $\varepsilon_2 > 0$. As a result, the standard Voronoi regions of the sites are infinite angular regions, but those of s and s' are slightly wider than those of the remaining sites.

The result is a diagram such as the one in Figure 5, Left. To see this, consider the circle-growing method from [15] described in Section 1. All the sites start growing their region as a circle, which quickly overlap with the other sites. As a result, each site is constrained to grow in the angular region corresponding to its own Voronoi region. Since s and s' have wider angles, they fill their appetite slightly before the rest, which grow at the same rate. After s and s' stop growing, the angular regions "available" to grow for the sites adjacent to s and s' increases to include the Voronoi regions of s and s'. Since now the neighbors of s and s' grow their regions faster than the rest, they also fill their appetite before the remaining sites. This process continues so that, in the end, one half of the sites "wrap" around the circle all the way to the Voronoi region of s, and the other half wrap around to the Voronoi region of s'.

As a result, we get m almost equal-area wedges surrounded by $O(m)$ very thin circular strips. We can choose ε_2 to set exactly how far the stable cell of s and s' reach, and therefore the overall width of all the circular strips. Then, we can set ε_1 small enough to ensure that all the circular strips wrap around the entire circle. Note that, as ε_1 approaches 0, the entire diagram approaches a circle of area m where all the sites want to grow equally far in every angular region.

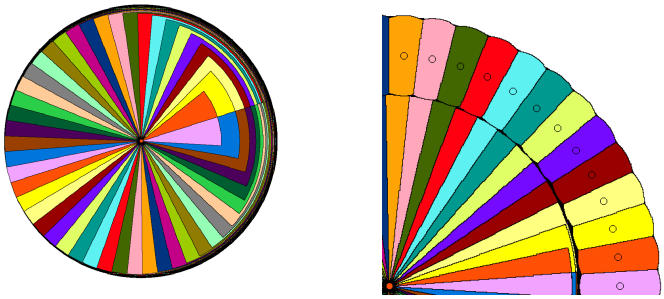

Figure 5 Left: A stable-matching Voronoi diagram of 50 sites situated around a small circle with the perturbed angles. **Right:** Zoom of a section of the stable-matching Voronoi diagram after adding 50 more sites situated evenly along a bigger, concentric circle (and with a smaller ε_2 than in the left figure).

Then, we place the remaining m sites evenly along an exterior concentric circle (see Figure 5, Right), and at a distance so that each outer site will have its appetite satisfied only by cutting into the circular strip. Because the wedges of the sites along the interior circle are very thin, the outer sites are closer to the circular strips than the inner sites; hence, each one can "steal" points in the strips away from the inner sites (which then need to get additional points from beyond the regions of the outer sites). At least half of the strips are as long as half the circle, and hence they get each broken into $\Theta(m)$ faces. Therefore, the circular strips are collectively broken into a total of $\Theta(m^2) = \Theta(n^2)$ faces. ◀

4 Paint-by-Numbers Algorithm

There are two similar incremental approaches to construct the stable matching Voronoi-diagram by processing sites one at a time. One option is to add the region of a site at each step. The other option, which we describe in this section, is to add the bounding disk of a site at each step, partitioned according to the diagram. In both cases, the key is to process the sites by increasing radii of their bounding disks. The major challenge lies in finding the bounding disks, which we will encapsulate in a geometric primitive (Definition 16). We focus on the second approach because the needed geometric primitive is simpler.

Finding the sites by increasing radii of their bounding disks might seem impossible at first, since, when our algorithm starts, the radii of the bounding disks for almost all the sites will, in general, be unknown. Nevertheless, as our algorithm progresses, we can know the radius of the smallest bounding disk of the sites remaining to be processed. Thus, at each iteration, we find a site, s, with smallest-radius bounding disk, B_s, from among the remaining unprocessed sites. Then, reminiscent of a "paint-by-numbers" drawing, we add to the matching all the unmatched points in B_s, using the boundary of B_s and the cells of a standard Voronoi diagram of the remaining unprocessed sites as the guides of how to "color" points. Figure 6 shows two snapshots of the intermediate steps of our paint-by-numbers algorithm. Suppose, then, that we are given a set, S, of n sites in the plane, each with appetite A.

Our algorithm is based on the following result. For a site s, let r_s be the radius of its bounding circle, B_s.

▶ **Lemma 11.** *If $r_s \leq r_{s'}$, no point p inside B_s such that $d(p, s') < d(p, s)$ is matched to s.*

Proof. Any such point p prefers s' to s. Moreover, we have that $d(p, s') < d(p, s) \leq r_s \leq r_{s'}$.

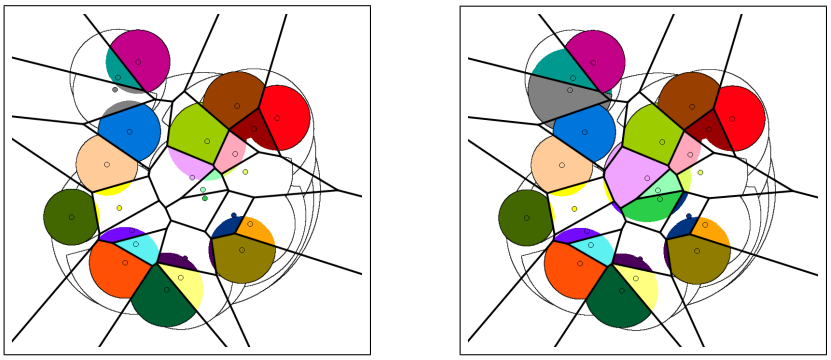

Figure 6 Partial matching done by the incremental paint-by-numbers algorithm after 10 iterations (left) and 12 iterations (right). The sites with the 11th and 12th smallest bounding disks are the gray site in the top-left and the light violet site in the center, respectively. In each case, the edges of the standard Voronoi diagram and the stable-matching Voronoi diagram are overlaid in thick and thin black lines, respectively.

Thus, s' prefers p to the points matched to s' along the boundary of $B_{s'}$. Hence, if p was matched to s, p and s' would be a blocking pair. ◀

▶ **Corollary 12.** *The stable cell of a site s is contained in $V(s)$, the Voronoi cell of s in the standard Voronoi diagram of the subset of sites whose bounding disks have radius at least r_s.*

Proof. The stable cell of s is contained in B_s, but any point in B_s that is not in $V(s)$ is closer to a site other than s whose bounding disk has radius at least r_s. According to Lemma 11, any such point cannot be matched to s. ◀

Our incremental paint-by-numbers algorithm proceeds as follows:

1. Initialize $X = S$ as the set of sites remaining to be processed and $X^* = \emptyset$ as the set of sites that have already been processed. Moreover, for each site s, initialize its partially constructed stable cell C_s as empty, and its remaining appetite, $A_s = A$.
2. Compute a standard Voronoi diagram, V, of the sites in X.
3. Repeat until X is empty:
   a. For each site s in X, calculate r_s, the current estimate for the radius of the bounding disk for s, as follows; r_s is the radius such that the area of the subset of $V(s)$ (the Voronoi cell of s in V) within that radius of s, excluding the bounding disks of sites in X^*, equals A_s.
   b. Choose a site s whose radius r_s is minimum. (By Corollary 12, r_s is the radius of B_s.)
   c. Compute $B_s^* = B_s \setminus \{B_{s'} \mid s' \in X^*\}$, the bounding disk of s minus the already-matched bounding disks.
   d. Match the points in B_s^*: for each site s' in X (including s), add to $C_{s'}$ the (possibly empty) intersection $B_s^* \cap V(s')$, and decrease the appetite, $A_{s'}$, of s', by the area of this intersection.
   e. Move s from X to X^*, and remove s from V.

▶ **Theorem 13.** *The stable-matching Voronoi diagram of a set, S, of n sites can be computed in the real-RAM model in $O(n^3)$ time plus $O(n^2)$ calls to a geometric primitive that has input complexity $O(n)$.*

Let us provide a proof of Theorem 13, beginning with the correctness of our paint-by-numbers algorithm.

▶ **Lemma 14** (Correctness). *The paint-by-numbers algorithm correctly computes the stable-matching Voronoi diagram of a set, S, of n sites.*

Proof. The algorithm matches all the points inside the bounding disks of the sites, and only those. Therefore, it matches precisely the points in the stable-matching Voronoi diagram (Lemma 3). Note that, when finding the site s in X with the smallest bounding disk, we can rely on Corollary 12, which says that the stable cell of s must be contained in $V(s)$.

It remains to be seen that the matching of the points in each bounding disk is correct. Consider the iteration where we process the site s, and let p be a point in B_s^* and in the inside of $V(s')$ (such that $s' \neq s$). The algorithm matches p to s', so we need to see that p belongs to the stable cell of s'. On the one hand, p does not belong to the stable cell of any site in X^* because p lies outside their bounding disks. Moreover, by virtue of being in $V(s')$, p prefers s' to any other site in X. On the other hand, $d(p, s') < d(p, s) \leq r_s \leq r_{s'}$, so s' also prefers p to some of its matched points. Hence, if p and s' were not matched to each other, they would be a blocking pair.

Similarly, in the case where p is in the inside of $V(s)$, the algorithm matches p to s and p belongs in the stable cell of s. ◀

Finding the radii r_s (Step 3a) is the most challenging step in our algorithm. In fact, Observation 15, which we prove in the full version of the paper [6], speaks to its difficulty.

▶ Observation 15. For infinitely-many sets of sites in general position and with algebraic coordinates, the radius of some of the sites' bounding disks cannot be computed exactly in an algebraic model of computation.

To circumvent this problem, we encapsulate the difficulty in computing each r_s analytically in a geometric primitive that can be performed in the real-RAM model or approximated numerically in an algebraic model of computation. That is, for the sake of the algorithm description, we assume the existence of a black-box function that allows us to compute the following geometric primitive.

▶ **Definition 16** (Geometric primitive). Given a convex polygon P, a point s in P, an appetite A, and a set C of disks, return the radius r (if it exists) such that A equals the area of the intersection of $P \setminus C$ and a disk centered at s with radius r.

In the context of our algorithm, the point s is a site in X, the appetite, A, is the remaining appetite, A_s, of s, the polygon P is the Voronoi cell $V(s)$, and the set of disks C is the set of bounding disks of the sites in X^*. Note that such a primitive could be approximated numerically to arbitrary precision, e.g., with a binary search and a simple decision algorithm.

Another detail for our algorithm that we need to spell out is how to maintain the partially constructed cell C_s of each site s. The structure C_s consists of a set of disjoint regions, each of which is delimited by straight and curved edges. Note that the straight edges are part of actual edges of the stable cell of s, as the other side is already matched to some other site. However, the convex curved edges (edges such that the convex face belongs to C_s) found before the iteration of s are not part of edges in the stable cell of s, as they lie along the boundary of the bounding disks of sites other than s (see, e.g., the gray regions in Figure 6, Left). Only at the iteration of s we find the proper convex curved edges of the stable cell of s. The points on the concave face of one of these "fake" convex edges of C_s must also belong to C_s. In some posterior iteration, when the region in the concave face is matched as part of another bounding disk $B_{s'}^*$, the region of $B_{s'}^*$ added to C_s will have a matching concave edge. Thus, when we add a concave edge to C_s, we look for a corresponding convex edge in C_s,

and if we find one, we "glue" them together, by removing the overlapping part. Similarly, we also merge straight edges sharing an endpoint.

Let us turn, then, to the analysis of the running time of the paint-by-numbers algorithm. For the number of calls to the geometric primitive, note that there are n iterations, and at each iteration we call the geometric primitive $O(n)$ times. The Voronoi diagram V has $O(n)$ edges and there are $O(n)$ already-matched disks, so the input of each call has $O(n)$ size. That is, we make $O(n^2)$ calls to the geometric primitive, each of which has combinatorial complexity $O(n)$.

The remaining steps of each iteration all can be done in $O(n^2)$ time, by the following observations:

1. The running time of Step 3b is clearly $O(n)$.
2. The combinatorial complexity of the standard Voronoi diagram, V, is $O(n)$ and it can be initially computed (Step 2) in $O(n \log n)$ time (e.g., see [3, 5]) and updated after the removal of any point site (Step 3e) in $O(n)$ time [13].
3. By the previous observation (2), for any single bounding disk, B_s, chosen in an iteration of our algorithm, B_s has an intersection with V that has combinatorial complexity $O(n)$.
4. The union of the set of bounding disks for the points in X^* has combinatorial complexity $O(n)$ [17, 1].
5. By the previous observation (4), for any single bounding disk, B_s, chosen in an iteration of our algorithm, the combinatorial complexity of B_s^*, that is, B_s minus all the bounding disks for sites in X^*, is $O(n)$. Thus, the running time of Step 3c in any iteration is $O(n)$.
6. Combining the above observations 3 and 5, the combinatorial complexity of the pieces of B_s^* intersecting V has combinatorial complexity $O(n^2)$. Thus, the running time of Step 3d in any iteration is $O(n^2)$.

Therefore, the total running time of our paint-by-numbers algorithm is $O(n^3 + n^2 f(n))$, where $f(n)$ is the running time of the geometric primitive defined above. This completes the proof of Theorem 13.

5 Conclusions

We have studied stable-matching Voronoi diagrams, providing characterizations of their combinatorial complexity and a first discrete algorithm for constructing them. The fact that (*i*) both the standard and stable-matching Voronoi diagrams share the stability property, in terms of preferences based on distances, and that (*ii*) both have similar geometric constructions in terms of the lower envelopes of cones, supports the idea that stable-matching Voronoi diagrams are a natural generalization of the standard Voronoi diagram to sized-constrained regions. However, this comes at the cost of convexity and connectivity; indeed, we have shown that a stable-matching Voronoi diagram may have $O(n^{2+\varepsilon})$ faces and edges, for any $\varepsilon > 0$. It would be interesting to see if this bound can be brought down to $O(n^2)$, which would make it tight. Constructing a stable-matching Voronoi diagram is also more computationally challenging than the construction of a standard Voronoi diagram. We have given a first algorithm which runs in $O(n^3 + n^2 f(n))$-time, where $f(n)$ is the runtime of a geometric primitive that we defined to encapsulate the computations that cannot be carried analytically. While such primitives cannot be avoided, a step forward from our algorithm would be one that relies only in primitives with constant-sized inputs.

Abstract

In the problem of adaptive compressed sensing, one wants to estimate an approximately k-sparse vector $x \in \mathbb{R}^n$ from m linear measurements $A_1x, A_2x, \ldots, A_mx$, where A_i can be chosen based on the outcomes $A_1x, \ldots, A_{i-1}x$ of previous measurements. The goal is to output a vector $\hat{x}$ for which

$$\|x - \hat{x}\|_p \leq C \cdot \min_{k\text{-sparse } x'} \|x - x'\|_q,$$

with probability at least $2/3$, where $C > 0$ is an approximation factor. Indyk, Price and Woodruff (FOCS'11) gave an algorithm for $p = q = 2$ for $C = 1+\epsilon$ with $\mathcal{O}((k/\epsilon)\text{loglog}(n/k))$ measurements and $\mathcal{O}(\log^*(k)\text{loglog}(n))$ rounds of adaptivity. We first improve their bounds, obtaining a scheme with $\mathcal{O}(k \cdot \text{loglog}(n/k) + (k/\epsilon) \cdot \text{loglog}(1/\epsilon))$ measurements and $\mathcal{O}(\log^*(k)\text{loglog}(n))$ rounds, as well as a scheme with $\mathcal{O}((k/\epsilon) \cdot \text{loglog}(n \log(n/k)))$ measurements and an optimal $\mathcal{O}(\text{loglog}(n))$ rounds. We then provide novel adaptive compressed sensing schemes with improved bounds for (p, p) for every $0 < p < 2$. We show that the improvement from $O(k \log(n/k))$ measurements to $O(k \log\log(n/k))$ measurements in the adaptive setting can persist with a better ϵ-dependence for other values of p and q. For example, when $(p, q) = (1, 1)$, we obtain $O(\frac{k}{\sqrt{\epsilon}} \cdot \log\log n \log^3(\frac{1}{\epsilon}))$ measurements. We obtain nearly matching lower bounds, showing our algorithms are close to optimal. Along the way, we also obtain the first nearly-optimal bounds for (p, p) schemes for every $0 < p < 2$ even in the non-adaptive setting.

1 Introduction

Compressed sensing, also known as sparse recovery, is a central object of study in data stream algorithms, with applications to monitoring network traffic [7], analysis of genetic data [19, 12], and many other domains [16]. The problem can be stated as recovering an underlying signal $x \in \mathbb{R}^n$ from *measurements* $A_1 \cdot x, ..., A_m \cdot x$ with the C-approximate ℓ_p/ℓ_q recovery guarantee being

$$\|x - \hat{x}\|_p \leq C \min_{k\text{-sparse } x'} \|x - x'\|_q, \tag{1}$$

where the A_i are drawn from a distribution and $m \ll n$. The focus of this work is on *adaptive compressed sensing*, in which the measurements are chosen in rounds, and the choice of measurement in each round depends on the outcome of the measurements in previous rounds.

Adaptive compressed sensing has been studied in a number of different works [11, 4, 8, 9, 14, 1, 10, 18] in theoretical computer science, machine learning, image processing, and many other domains [10, 18, 2]. In theoretical computer science and machine learning, adaptive compressed sensing serves as an important tool to obtain sublinear algorithms for active learning in both time and space [10, 5, 18, 2]. In image processing, the study of adaptive compressed sensing has led to compressed acquisition of sequential images with various applications in celestial navigation and attitude determination [6].

Despite a large amount of works on adaptive compressed sensing, the power of adaptivity remains a long-standing open problem. Indyk, Price, and Woodruff [10] were the first to show that without any assumptions on the signal x, one can obtain a number m of measurements which is a $\log(n)/\log\log(n)$ factor smaller than what can be achieved in the non-adaptive setting. Specifically, for $p = q = 2$ and $C = 1 + \epsilon$, they show that $m = \mathcal{O}(\frac{k}{\epsilon}\log\log(n))$ measurements suffice to achieve guarantee (1), whereas it is known that any non-adaptive scheme requires $k = \Omega(\frac{k}{\epsilon}\log(\frac{n}{k}))$ measurements, provided $\epsilon > \sqrt{\frac{k\log n}{n}}$ (Theorem 4.4 of [17], see also [3]). Improving the sample complexity as much as possible is desired, as it might correspond to, e.g., the amount of radiation a hospital patient is exposed to, or the amont of time a patient must be present for diagnosis.

The ℓ_1/ℓ_1 problem was studied in [17], for which perhaps surprisingly, a better dependence on ϵ was obtained than is possible for ℓ_2/ℓ_2 schemes. Still, the power of adaptivity for the ℓ_1/ℓ_1 recovery problem over its non-adaptive counterpart has remained unclear. An $O(\frac{k}{\sqrt{\epsilon}}\log n\log^3(\frac{1}{\epsilon}))$ non-adaptive bound was shown in [17], while an adaptive lower bound of $\Omega(\frac{k}{\sqrt{\epsilon}}/\log\frac{k}{\sqrt{\epsilon}})$ was shown in [18]. Recently several works [20, 15] have looked at other values of p and q, even those for which $0 < p, q < 1$, which do not correspond to normed spaces. The power of adaptivity for such error measures is also unknown.

1.1 Our Results

Our work studies the problem of adaptive compressed sensing by providing affirmative answers to the above-mentioned open questions. We improve over the best known results for $p = q = 2$, and then provide novel adaptive compressed sensing guarantees for $0 < p = q < 2$ for every p and q. See Table 1 for a comparison of results.

For ℓ_1/ℓ_1, we design an adaptive algorithm which requires only $\mathcal{O}(\frac{k}{\sqrt{\epsilon}}\text{loglog}(n)\log^{\frac{5}{2}}(\frac{1}{\epsilon}))$ measurements for the ℓ_1/ℓ_1 problem. More generally, we study the ℓ_p/ℓ_p problem for $0 < p < 2$. One of our main theorems is the following.

▶ **Theorem 1** (ℓ_p/ℓ_p Recovery Upper Bound). *Let $x \in \mathbb{R}^n$ and $0 < p < 2$. There exists a randomized algorithm that performs $\mathcal{O}(\frac{k}{\epsilon^{p/2}}\text{loglog}(n)\,\text{poly}(\log(\frac{1}{\epsilon})))$ adaptive linear measurements*

Table 1 The sample complexity of adaptive compressed sensing. Results without any citation given correspond to our new results.

C, Guarantees	Upper Bounds	Rounds	Lower Bounds
$1+\epsilon$, ℓ_1/ℓ_1	$\mathcal{O}(\frac{k}{\sqrt{\epsilon}}\text{loglog}(n)\log^{\frac{5}{2}}(\frac{1}{\epsilon}))$	$\mathcal{O}(\text{loglog}(n))$	$\Omega(\frac{k}{\sqrt{\epsilon}\log(k/\sqrt{\epsilon})})$ [18]
$1+\epsilon$, ℓ_p/ℓ_p	$\mathcal{O}(\frac{k}{\epsilon^{p/2}}\text{loglog}(n)\,\text{poly}(\log(\frac{1}{\epsilon})))$	$\mathcal{O}(\text{loglog}(n))$	$\Omega(\frac{k}{\epsilon^{p/2}}\frac{1}{\log^2(k/\epsilon)})$
$\sqrt{\frac{1}{k}}$, ℓ_∞/ℓ_2	$\mathcal{O}(k\text{loglog}(n)+k\log(k))$	$\mathcal{O}(\text{loglog}(n))$	-
$1+\epsilon, \ell_2/\ell_2$	$\mathcal{O}(\frac{k}{\epsilon}\text{loglog}(\frac{n\epsilon}{k}))$ [10] $\mathcal{O}(k\text{loglog}(\frac{n}{k})+\frac{k}{\epsilon}\text{loglog}(\frac{1}{\epsilon}))$ $\mathcal{O}(\frac{k}{\epsilon}\text{loglog}(\frac{n\log(n\epsilon)}{k}))$	$\mathcal{O}(\log^*(k)\text{loglog}(\frac{n\epsilon}{k}))$ [10] $\mathcal{O}(\log^*(k)\text{loglog}(\frac{n}{k}))$ $\mathcal{O}(\text{loglog}(n\log(\frac{n\epsilon}{k}))$	$\Omega(\frac{k}{\epsilon}+\text{loglog}(n))$ [18]

on x in $\mathcal{O}(\text{loglog}(n))$ rounds, and with probability $2/3$, returns a vector $\hat{x}\in\mathbb{R}^n$ such that $\|x-\hat{x}\|_p \le (1+\epsilon)\|x_{-k}\|_p$.

Theorem 1 improves the previous sample complexity upper bound for the case of $C=1+\epsilon$ and $p=q=1$ from $\mathcal{O}(\frac{k}{\sqrt{\epsilon}}\log(n)\log^3(\frac{1}{\epsilon}))$ to $\mathcal{O}(\frac{k}{\sqrt{\epsilon}}\text{loglog}(n)\log^{\frac{5}{2}}(\frac{1}{\epsilon}))$. Compared with the non-adaptive $(1+\epsilon)$-approximate ℓ_1/ℓ_1 upper bound of $\mathcal{O}(\frac{k}{\sqrt{\epsilon}}\log(n)\log^3(\frac{1}{\epsilon}))$, we show that adaptivity exponentially improves the sample complexity w.r.t. the dependence on n over non-adaptive algorithms while retaining the improved dependence on ϵ of non-adaptive algorithms. Furthermore, Theorem 1 extends the working range of adaptive compressed sensing from $p=1$ to general values of $p\in(0,2)$.

We also state a complementary lower bound to formalize the hardness of the above problem.

▶ **Theorem 2** (ℓ_p/ℓ_p Recovery Lower Bound). *Fix $0<p<2$, any $(1+\epsilon)$-approximate ℓ_p/ℓ_p recovery scheme with sufficiently small constant failure probability must make $\Omega(\frac{k}{\epsilon^{p/2}}/\log^2(\frac{k}{\epsilon}))$ measurements.*

Theorem 2 shows that our upper bound in Theorem 1 is tight up to the $\log(k/\epsilon)$ factor.

We also study the case when $p\neq q$. In particular, we focus on the case when $p=\infty, q=2$ and $C=\sqrt{\frac{1}{k}}$, as in the following theorem.

▶ **Theorem 3** (ℓ_∞/ℓ_2 Recovery Upper Bound). *Let $x\in\mathbb{R}^n$. There exists a randomized algorithm that performs $\mathcal{O}(k\log(k)+k\text{loglog}(n))$ linear measurements on x in $\mathcal{O}(\text{loglog}(n))$ rounds, and with probability $1-1/\text{poly}(k)$ returns a vector $\hat{x}$ such that $\|x-\hat{x}\|_\infty^2\le\frac{1}{k}\|x_{-k}\|_2^2$, where $x_{-k}\in\mathbb{R}^n$ is the vector with the largest $n-k$ coordinates (in the sense of absolute value) being zeroed out.*

We also provide an improved result for $(1+\epsilon)$-approximate ℓ_2/ℓ_2 problems.

▶ **Theorem 4** (ℓ_2/ℓ_2 Sparse Recovery Upper Bounds). *Let $x\in\mathbb{R}^n$. There exists a randomized algorithm that*

- *uses $\mathcal{O}(\frac{k}{\epsilon}\text{loglog}(\frac{1}{\epsilon})+k\text{loglog}(\frac{n}{k}))$ linear measurements on x in $\mathcal{O}(\text{loglog}(\frac{n}{k})\cdot\log^*(k))$ rounds;*
- *uses $\mathcal{O}(\frac{k}{\epsilon}\text{loglog}(\frac{n\log(n\epsilon)}{k}))$ linear measurements on x in $\mathcal{O}(\text{loglog}(\epsilon n\log(\frac{n}{k})))$ rounds;*

and with constant probability returns a vector $\hat{x}$ such that $\|x-\hat{x}\|_2\le(1+\epsilon)\|x_{-k}\|_2$.

Previously the best known tradeoff was $\mathcal{O}(\frac{k}{\epsilon}\text{loglog}(\frac{n\epsilon}{k}))$ samples and $\mathcal{O}(\log^*(k)\text{loglog}(\frac{n\epsilon}{k}))$ rounds for $(1+\epsilon)$-approximation for the ℓ_2/ℓ_2 problem [10]. Our result improves both the sample complexity (the first result) and the number of rounds (the second result). We summarize our results in Table 1.

1.2 Our Techniques

ℓ_∞/ℓ_2 Sparse Recovery. Our ℓ_∞/ℓ_2 sparse recovery scheme hashes every $i \in [n]$ to poly(k) buckets, and then proceeds by finding all the buckets that have ℓ_2 mass at least $\Omega(\frac{1}{\sqrt{k}}\|x_{-\Omega(k)}\|_2)$. We then find a set of buckets that contain all heavy coordinates, which are isolated from each other due to hashing. Then, we run a 1-sparse recovery in each bucket in parallel in order to find all the heavy coordinate. However, since we have $\mathcal{O}(k)$ buckets, we cannot afford to take a union bound over all one-sparse recovery routines called. Instead, we show that most buckets succeed and hence we can substract from x the elements returned, and then run a standard CountSketch algorithm to recover everything else. This algorithm obtains an optimal $\mathcal{O}(\text{loglog}(n))$ number of rounds and $\mathcal{O}(k\log(k) + k\text{loglog}(n))$ number of measurements, while succeeding with probability at least $1 - 1/\text{poly}(k)$.

We proceed by showing an algorithm for ℓ_2/ℓ_2 sparse recovery with $\mathcal{O}(\frac{k}{\epsilon}\text{loglog}(n))$ measurements and $\mathcal{O}(\text{loglog}(n))$ rounds. This will be important for our more general ℓ_p/ℓ_p scheme, saving a $\log^*(k)$ factor from the number of rounds, achieving optimality with respect to this quantity. For this scheme, we utilize the ℓ_∞/ℓ_2 scheme we just developed, observing that for small $k < \mathcal{O}(\log(n))$, the measurement complexity is $\mathcal{O}(k\text{loglog}(n))$. The algorithm hashes to $k/(\epsilon\log(n))$ buckets, and in each bucket runs ℓ_∞/ℓ_2 with sparsity k/ϵ. The ℓ_∞/ℓ_2 algorithm in each bucket succeeds with probability $1 - 1/\text{polylog}(n))$; this fact allows us to argue that all but a $1/\text{polylog}(n)$ fraction of the buckets will succeed, and hence we can recover all but a $k/\text{polylog}(n))$ fraction of the heavy coordinates. The next step is to subtract these coordinates from our initial vector, and then run a standard ℓ_2/ℓ_2 algorithm with decreased sparsity.

ℓ_p/ℓ_p Sparse Recovery. Our ℓ_p/ℓ_p scheme, $0 < p < 2$, is based on carefully invoking several ℓ_2/ℓ_2 schemes with different parameters. We focus our discussion on $p = 1$, then mention extensions to general p. A main difficulty of adapting the ℓ_1/ℓ_1 scheme of [17] is that it relies upon an ℓ_∞/ℓ_2 scheme, and all known schemes, including ours, have at least a $k\log k$ dependence on the number of measurements, which is too large for our overall goal.

A key insight in [17] for ℓ_1/ℓ_1 is that since the output does not need to be exactly k-sparse, one can compensate for mistakes on approximating the top k entries of x by accurately outputting enough smaller entries. For example, if $k = 1$, consider two possible signals $x = (1, \epsilon, \ldots, \epsilon)$ and $x' = (1 + \epsilon, \epsilon, \ldots, \epsilon)$, where ϵ occurs $1/\epsilon$ times in both x and x'. One can show, using known lower bound techniques, that distinguishing x from x' requires $\Omega(1/\epsilon)$ measurements. Moreover, $x_1 = (1, 0, \ldots, 0)$ and $x'_1 = (1 + \epsilon, 0, \ldots, 0)$, and any 1-sparse approximation to x or x' must therefore distinguish x from x', and so requires $\Omega(1/\epsilon)$ measurements. An important insight though, is that if one does not require the output signal y to be 1-sparse, then one can output $(1, \epsilon, 0, \ldots, 0)$ in both cases, without actually distinguishing which case one is in!

As another example, suppose that $x = (1, \epsilon, \ldots, \epsilon)$ and $x' = (1 + \epsilon^c, \epsilon, \ldots, \epsilon)$ for some $0 < c < 1$. In this case, one can show that one needs $\Omega(1/\epsilon^c)$ measurements to distinguish x and x', and as before, to output an exactly 1-sparse signal providing a $(1 + \epsilon)$-approximation requires $\tilde{\Theta}(1/\epsilon^c)$ measurements. In this case if one outputs a signal y with $y_1 = 1$, one cannot simply find a single other coordinate ϵ to "make up" for the poor approximation on the first coordinate. However, if one were to output $1/\epsilon^{1-c}$ coordinates each of value ϵ, then the ϵ^c "mass" lost by poorly approximating the first coordinate would be compensated for by outputting $\epsilon \cdot 1/\epsilon^{1-c} = \epsilon^c$ mass on these remaining coordinates. It is not clear how to find such remaining coordinates though, since they are much smaller; however, if one randomly subsamples an ϵ^c fraction of coordinates, then roughly $1/\epsilon^{1-c}$ of the coordinates of value ϵ

survive and these could all be found with a number of measurements proportional to $1/\epsilon^{1-c}$. Balancing the two measurement complexities of $1/\epsilon^c$ and $1/\epsilon^{1-c}$ at $c = 1/2$ gives roughly the optimal $1/\epsilon^{1/2}$ dependence on ϵ in the number of measurements.

To extend this to the adaptive case, a recurring theme of the above examples is that the top k, while they need to be found, they do not need to be approximated very accurately. Indeed, they do need to be found, if, e.g., the top k entries of x were equal to an arbitrarily large value and the remaining entries were much smaller. We accomplish this by running an ℓ_2/ℓ_2 scheme with parameters $k' = \Theta(k)$ and $\epsilon' = \Theta(\sqrt{\epsilon})$, as well as an ℓ_2/ℓ_2 scheme with parameters $k' = \Theta(k/\sqrt{\epsilon})$ and $\epsilon' = \Theta(1)$ (up to logarithmic factors in $1/\epsilon$). Another theme is that the mass in the smaller coordinates we find to compensate for our poor approximation in the larger coordinates also does not need to be approximated very well, and we find this mass by subsampling many times and running an ℓ_2/ℓ_2 scheme with parameters $k' = \Theta(1)$ and $\epsilon' = \Theta(1)$. This technique is surprisingly general, and does not require the underlying error measure we are approximating to be a norm. It just uses scale-invariance and how its rate of growth compares to that of the ℓ_2-norm.

ℓ_2/ℓ_2 Sparse Recovery. Our last algorithm, which concerns ℓ_2/ℓ_2 sparse recovery, achieves $\mathcal{O}(k\text{loglog}(n) + \frac{k}{\epsilon}\text{loglog}(1/\epsilon))$ measurements, showing that ϵ does not need to multiply loglog(n). The key insight lies in first solving the 1-sparse recovery task with $\mathcal{O}(\text{loglog}(n) + \frac{1}{\epsilon}\text{loglog}(1/\epsilon))$ measurements, and then extending this to the general case. To achieve this, we hash to polylog$(1/\epsilon)$ buckets, then solve ℓ_2/ℓ_2 with constant sparsity on a new vector, where coordinate j equals the ℓ_2 norm of the jth bucket; this steps requires only $\mathcal{O}(\frac{1}{\epsilon}\text{loglog}(1/\epsilon))$ measurements. Now, we can run standard 1-sparse recovery in each of these buckets returned. Extending this idea to the general case follows by plugging this sub-routine in the iterative algorithm of [10], while ensuring that sub-sampling does not increase the number of measurements. For that we also need to sub-sample at a slower rate, slower roughly by a factor of ϵ.

Notation: For a vector $x \in \mathbb{R}^n$, we define $H_k(x)$ to be the set of its largest k coordinates in absolute value. For a set S, denote by x_S the vector with every coordinate $i \notin S$ being zeroed out. We also define $x_{-k} = x_{[n]\setminus H_k(x)}$ and $H_{k,\epsilon}(x) = \{i \in [n] : |x_i| \geq \frac{\epsilon}{k}\|x_{-k}\|_2^2\}$, where $[n]$ represents the set $\{1, 2, ..., n\}$. For a set S, let $|S|$ be the cardinality of S.

Due to space constraints, we defer the proof of Theorem 2 to the full version[1].

2 Adaptive ℓ_p/ℓ_p Recovery

This section is devoted to proving Theorem 1. Our algorithm for ℓ_p/ℓ_p recovery is in Algorithm 1.

Let $f = \epsilon^{p/2}$, $r = 2/(p\log(1/f))$ and $q = \max\{p - \frac{1}{2}, 0\} = (p - \frac{1}{2})^+$. We will invoke the following ℓ_2/ℓ_2 oracle frequently throughout the paper.

▶ **Oracle 1** (AdaptiveSparseRecovery$_{\ell_p/\ell_q}(x, k, \epsilon)$). *The oracle is fed with (x, k, ϵ) as input parameters, and outputs a set of coordinates $i \in [n]$ of size $\mathcal{O}(k)$ which corresponds to the support of vector $\hat{x}$, where $\hat{x}$ can be any vector for which $\|x-\hat{x}\|_p \leq (1+\epsilon)\min_{\mathcal{O}(k)\text{-sparse } x'} \|x-x'\|_q$.*

[1] see https://arxiv.org/pdf/1804.09673.pdf

Algorithm 1 Adaptive ℓ_p/ℓ_p Recovery.

1. $A \leftarrow \text{AdaptiveSparseRecovery}_{\ell_2/\ell_2}(x, 2k/f, 1/10)$.
2. $B \leftarrow \text{AdaptiveSparseRecovery}_{\ell_2/\ell_2}(x, 4k, f/r^2)$.
3. $S \leftarrow A \cup B$.
4. For $j = 1 : r$
5. Uniformly sample the entries of x with probability $2^{-j}f/k$ for $k/(2f(r+1)^q)$ times.
6. Run the adaptive $\text{AdaptiveSparseRecovery}_{\ell_2/\ell_2}(x, 2, 1/(4(r+1))^{\frac{2}{p}})$ algorithm on each of the $k/(2f(r+1)^q)$ subsamples to obtain sets $A_{j,1}, A_{j,2}, \ldots, A_{j,k/(2f(r+1)^q)}$.
7. Let $S_j \leftarrow \cup_{t=1}^{k/(2f(r+1)^q)} A_{j,t} \setminus \cup_{t=0}^{j-1} S_t$.
8. End For
9. Request the entries of x with coordinates $S_0, ..., S_r$.
Output: $\hat{x} = x_{S_0 \cup \cdots \cup S_r}$.

Existing algorithms can be applied to construct Oracle 1 for the ℓ_2/ℓ_2 case, such as [10]. Without loss of generality, we assume that the coordinates of x are ranked in decreasing value, i.e., $x_1 \geq x_2 \geq \cdots \geq x_n$.

▶ **Lemma 5.** *Suppose we subsample x with probability p and let y be the subsampled vector formed from x. Then with failure probability $e^{-\Omega(k)}$, $\|y_{-2k}\|_2 \leq \sqrt{2p}\left\|x_{-k/p}\right\|_2$.*

Proof. Let T be the set of coordinates in the subsample. Then $\mathbb{E}\left[\left|T \cap \left[\frac{3k}{2p}\right]\right|\right] = \frac{3k}{2}$. So by the Chernoff bound, $\Pr\left[\left|T \cap \left[\frac{3k}{2p}\right]\right| > 2k\right] \leq e^{-\Omega(k)}$. Thus $\left|T \cap \left[\frac{3k}{2p}\right]\right| \leq 2k$ holds with high probability. Let $Y_i = x_i^2$ if $i \in T$ $Y_i = 0$ if $i \in [n] \setminus T$. Then $\mathbb{E}\left[\sum_{i > \frac{3k}{2p}} Y_i\right] = p\left\|x_{-\frac{3k}{2p}}\right\|_2^2 \leq p\left\|x_{-k/p}\right\|_2^2$. Notice that there are at least $\frac{k}{2p}$ elements in $x_{-k/p}$ with absolute value larger than $\left|x_{\frac{3k}{2p}}\right|$. Thus for $i > \frac{3k}{2p}$, $Y_i \leq \left|x_{\frac{3k}{2p}}\right|^2 \leq \frac{2p}{k}\left\|x_{-k/p}\right\|_2^2$. Again by a Chernoff bound, $\Pr\left[\sum_{i > \frac{3k}{2p}} Y_i \geq \frac{4p}{3}\left\|x_{-k/p}\right\|_2^2\right] \leq e^{-\Omega(k)}$. Conditioned on the latter event not happening, $\|y_{-2k}\|_2^2 \leq \sum_{i > \frac{3k}{2p}} Y_i \leq \frac{4p}{3}\left\|x_{-k/p}\right\|_2^2 \leq 2p\left\|x_{-k/p}\right\|_2^2$. By a union bound, with failure probability $e^{-\Omega(k)}$, we have $\|y_{-2k}\|_2 \leq \sqrt{2p}\left\|x_{-k/p}\right\|_2$. ◀

▶ **Lemma 6.** *Let $\hat{x}$ be the output of the ℓ_2/ℓ_2 scheme on x with parameters $(k, \epsilon/2)$. Then with small constant failure probability, $\left\|x_{[k]}\right\|_p^p - \|\hat{x}\|_p^p \leq k^{1-\frac{p}{2}}\epsilon^{\frac{p}{2}}\|x_{-k}\|_2^p$.*

Proof. Notice that with small constant failure probability, the ℓ_2/ℓ_2 guarantee holds and we have

$$\left\|x_{[k]}\right\|_2^2 - \|\hat{x}\|_2^2 = \|x - \hat{x}\|_2^2 - \|x_{-k}\|_2^2 \leq (1+\epsilon)\|x_{-k}\|_2^2 - \|x_{-k}\|_2^2 = \epsilon\|x_{-k}\|_2^2.$$

Let $S \subset [n]$ be such that $x_S = \hat{x}$, and define $y = x_{[k]\setminus S}$, $z = x_{S\setminus[k]}$. Then if $\|y\|_p^p \leq k^{1-\frac{p}{2}}\epsilon^{\frac{p}{2}}\|x_{-k}\|_2^p$ we are done. Otherwise, let $1 \leq k' \leq k$ denote the size of $[k] \setminus S$, and define $c = \|y\|_2/\sqrt{k'}$.

$$\begin{aligned}\left\|x_{[k]}\right\|_p^p - \|\hat{x}\|_p^p = \|y\|_p^p - \|z\|_p^p &\leq k'^{1-\frac{p}{2}}\|y\|_2^p - \|z\|_p^p = \frac{\|y\|_2^2}{c^{2-p}} - \|z\|_p^p \\ &\leq \frac{\|y\|_2^2 - \|z\|_2^2}{c^{2-p}} = \frac{\left\|x_{[k]}\right\|_2^2 - \|\hat{x}\|_2^2}{c^{2-p}} \leq \frac{\epsilon\|x_{-k}\|_2^2}{c^{2-p}}.\end{aligned}$$

Since $c \geq \frac{\|y\|_p}{k'^{\frac{1}{p}}} \geq \frac{\|y\|_p}{k^{\frac{1}{p}}} \geq \sqrt{\frac{\epsilon}{k}} \|x_{-k}\|_2$, we have $\left\|x_{[k]}\right\|_p^p - \|\hat{x}\|_p^p \leq k^{\frac{2-p}{2}} \epsilon^{1-\frac{2-p}{2}} \|x_{-k}\|_2^{2-(2-p)} = k^{1-\frac{p}{2}} \epsilon^{\frac{p}{2}} \|x_{-k}\|_2^p$. ◀

▶ **Theorem 7.** *Fix $0 < p < 2$. For $x \in \mathbb{R}^n$, there exists a $(1+\epsilon)$-approximation algorithm that performs $\mathcal{O}(\frac{k}{\epsilon^{p/2}} \text{loglog}(n) \log^{\frac{2}{p}+1-(p-\frac{1}{2})^+}(\frac{1}{\epsilon}))$ adaptive linear measurements in $\mathcal{O}(\text{loglog}(n))$ rounds, and with probability at least $2/3$, we can find a vector $\hat{x} \in \mathbb{R}^n$ such that*

$$\|x - \hat{x}\|_p \leq (1+\epsilon) \|x_{-k}\|_p . \tag{2}$$

Proof. The algorithm is stated in Algorithm 1. We first consider the difference $\left\|x_{[k]}\right\|_p^p - \|x_{S_0}\|_p^p$.

Let $i^*(0)$ be the smallest integer such that for any $l > i^*(0)$, $|x_l| \leq \|x_{-2k/f}\|_2/\sqrt{k}$.

Case 1. $i^*(0) > 4k$

Then for all $k < j \leq 4k$, we have $|x_j| > \|x_{-2k/f}\|_2/\sqrt{k}$. Hence x_{S_0} must contain at least $1/2$ of these indices; if not, the total squared loss is at least $1/2 \cdot 3k \|x_{-2k/f}\|_2^2/k \geq (3/2)\|x_{-2k/f}\|_2^2$, a contradiction to $\epsilon' = 1/10$. It follows that $\|x_{S_0 \cap \{k+1,\ldots,4k\}}\|_p^p \geq \frac{3}{2}k \left[\frac{\|x_{-2k/f}\|_2}{\sqrt{k}}\right]^p = \frac{3}{2}k^{1-\frac{p}{2}} \|x_{-2k/f}\|_2^p$. On the other hand, $\left\|x_{[k]}\right\|_p^p - \|x_{S_0}\|_p^p$ is at most $1.1k^{1-\frac{p}{2}} \|x_{-2k/f}\|_2^p$, since by the ℓ_2/ℓ_2 guarantee

$$\|x_{[k]}\|_p^p - \|x_{S_0 \cap [k]}\|_p^p \leq k^{1-\frac{p}{2}} \|x_{[k]} - x_{S_0 \cap [k]}\|_2^p \leq k^{1-\frac{p}{2}} \|x - x_{S_0}\|_2^p \leq \frac{11}{10} k^{1-\frac{p}{2}} \|x_{-2k/f}\|_2^p.$$

It follows that

$$\begin{aligned} \|x_{[k]}\|_p^p - \|x_{S_0}\|_p^p &= \|x_{[k]}\|_p^p - \|x_{S_0 \cap [k]}\|_p^p - \|x_{S_0 \cap \{k+1,\ldots,4k\}}\|_p^p \\ &\leq \frac{11}{10} k^{1-\frac{p}{2}} \|x_{-2k/f}\|_2^p - \frac{3}{2} k^{1-\frac{p}{2}} \|x_{-2k/f}\|_2^p \leq 0. \end{aligned}$$

Case 2. $i^*(0) \leq 4k$, and $\sum_{j=i^*(0)+1}^{2k/f} x_j^2 \geq 4\|x_{-2k/f}\|_2^2$.

We claim that x_{S_0} must contain at least a $5/8$ fraction of coordinates in $\{i^*(0)+1, \ldots, 2k/f\}$; if not, then the cost for missing at least a $3/8$ fraction of the ℓ_2-norm of $x_{\{i^*(0)+1,\ldots,2k/f\}}$ will be at least $(3/2)\|x_{-2k/f}\|_2^2$, contradicting the ℓ_2/ℓ_2 guarantee. Since all coordinates x_j's for $j > i^*(0)$ have value at most $\|x_{-2k/f}\|_2/\sqrt{k}$, it follows that the p-norm of coordinates corresponding to $\{i^*(0)+1, \ldots, 2k/f\} \cap S_0$ is at least $\left\|x_{\{i^*(0)+1,\ldots,2k/f\} \cap S_0}\right\|_p^p \geq \frac{5}{2} k^{\frac{2-p}{2}} \frac{\|x_{-2k/f}\|_2^2}{\|x_{-2k/f}\|_2^{2-p}} = \frac{5}{2} k^{1-\frac{p}{2}} \|x_{-2k/f}\|_2^p$. Then

$$\begin{aligned} \|x_{[k]}\|_p^p - \|x_{S_0}\|_p^p &\leq \frac{11}{10} k^{1-\frac{p}{2}} \|x_{-2k/f}\|_2^p + k \left(\frac{\|x_{-2k/f}\|_2}{\sqrt{k}}\right)^p - \|x_{\{i^*(0)+1,\ldots,2k/f\} \cap S_0}\|_p^p \\ &\leq \frac{21}{10} k^{1-\frac{p}{2}} \|x_{-2k/f}\|_2^p - \frac{5}{2} k^{1-\frac{p}{2}} \|x_{-2k/f}\|_2^p \leq 0. \end{aligned}$$

Case 3. $i^*(0) \leq 4k$, and $\sum_{j=i^*(0)+1}^{2k/f} x_j^2 \leq 4\|x_{-2k/f}\|_2^2$.

With a little abuse of notation, let x_{S_0} denote the output of the ℓ_2/ℓ_2 with parameters $(4k, f/r^2)$. Notice that there are at most $8k$ non-zero elements in x_{S_0}, and $\|x_{-4k}\|_2^2 \leq \|x_{-i^*(0)}\|_2^2 = \sum_{j=i^*(0)+1}^{2k/f} x_j^2 + \|x_{-2k/f}\|_2^2 \leq 5\|x_{-2k/f}\|_2^2$. By Lemma 6, we have $\left\|x_{[k]}\right\|_p^p - \|x_{S_0}\|_p^p \leq \left\|x_{[4k]}\right\|_p^p - \|x_{S_0}\|_p^p \leq (4k)^{1-\frac{p}{2}} \frac{f^{\frac{p}{2}}}{r^p} \|x_{-4k}\|_2^p \leq \mathcal{O}\left(\frac{1}{r^p}\right) k^{1-\frac{p}{2}} f^{\frac{p}{2}} \|x_{-2k/f}\|_2^p$. According to the above three cases, we conclude that $\|x_{[k]}\|_p^p - \|x_{S_0}\|_p^p \leq \mathcal{O}\left(\frac{1}{r^p}\right) k^{1-\frac{p}{2}} f^{\frac{p}{2}} \|x_{-2k/f}\|_2^p$. Thus with failure probability at most $1/6$,

$$\|x - \hat{x}\|_p^p - \|x_{-k}\|_p^p = \|x_{[k]}\|_p^p - \sum_{j=0}^{r} \|x_{S_j}\|_p^p \leq \mathcal{O}\left(\frac{1}{r^p}\right) k^{1-\frac{p}{2}} f^{\frac{p}{2}} \|x_{-2k/f}\|_2^p - \sum_{j=1}^{r} \left\|x_{S_j}\right\|_p^p . \tag{3}$$

In order to convert the first term on the right hand side of (3) to a term related to the ℓ_p norm (which is a semi-norm if $0 < p < 1$), we need the following inequalities: for every u and s, by splitting into chunks of size s, we have

$$s^{1-\frac{p}{2}} \|u_{-2s}\|_2^p \le \|u_{-s}\|_p^p, \qquad \text{and} \qquad \left\|u_{\overline{[s]}\cap[2s]}\right\|_2 \le \sqrt{s}\,|u_s|\,.$$

Define $c = (r+1)^{\min\{p,1\}}$. This gives us that, for $0 < p < 2$ $\frac{1}{(r+1)^p} k^{1-\frac{p}{2}} f^{\frac{p}{2}} \left\|x_{-2k/f}\right\|_2^p \le \frac{k^{1-\frac{p}{2}} f^{\frac{p}{2}}}{c} \left\|x_{-2k/f^{1+\frac{2}{p}}}\right\|_2^p + \frac{k^{1-\frac{p}{2}} f^{\frac{p}{2}}}{c} \sum_{j=1}^{r} \left\|x_{\overline{[2^j k/f]}\cap[2^{j+1}k/f]}\right\|_2^p \le \frac{f^{(1-\frac{p}{2})(1+\frac{2}{p})+\frac{p}{2}}}{c} \left\|x_{-k/f^{1+\frac{2}{p}}}\right\|_p^p + \frac{1}{c}\sum_{j=1}^{r} k 2^{pj/2} \left|x_{2^j k/f}\right|^p$. Therefore,

$$\begin{aligned}\|\hat{x}-x\|_p^p - \|x_{-k}\|_p^p &\le \mathcal{O}\left(\frac{1}{c}\right) f^{\frac{2}{p}} \left\|x_{-k/f^{1+\frac{2}{p}}}\right\|_p^p + \sum_{j=1}^{r} \mathcal{O}\left(\frac{1}{c}\right) k 2^{pj/2} |x_{2^j k/f}|^p - \sum_{j=1}^{r} \|x_{S_j}\|_p^p \\ &\le \mathcal{O}\left(\frac{1}{c}\right) f^{\frac{2}{p}} \left\|x_{-k/f}\right\|_p^p + \sum_{j=1}^{r} \mathcal{O}\left(\frac{1}{c}\right) k 2^{pj/2} |x_{2^j k/f}|^p - \sum_{j=1}^{r} \|x_{S_j}\|_p^p. \end{aligned} \tag{4}$$

Let $y = x_T$ denote an independent subsample of x with probability $f/(2^j k)$, and $\hat{y}$ be the output of the ℓ_2/ℓ_2 algorithm with parameter $\mathrm{s}(2, 1/(4(r+1))^{\frac{2}{p}})$. Notice that $|S_j| \le 2k/(r+1)f$ by the adaptive ℓ_2/ℓ_2 guarantee. Define $Q = [2^j k/f] \setminus (S_0 \cup \cdots \cup S_{j-1})$. There are at least $2^j k/(2f)$ elements in Q, and every element in Q has absolute value at least $\left|x_{2^j k/f}\right|$. In each subsample, notice that $\mathbb{E}[|T \cap Q|] = \frac{1}{2}$. Thus with sufficiently small constant failure probability there exists at least 1 element in y with absolute value at least $|x_{2^j k/f}|$. On the other hand, by Lemma 6 and Lemma 5,

$$\left\|y_{[1]}\right\|_p^p - \|\hat{y}\|_p^p \le \left\|y_{[2]}\right\|_p^p - \|\hat{y}\|_p^p \le \frac{2^{1-\frac{p}{2}}}{4(r+1)} \|y_{-2}\|_2^p \le \frac{1}{2(r+1)} \left(\frac{f}{2^j k}\right)^{\frac{p}{2}} \left\|x_{-2^j k/f}\right\|_2^p, \tag{5}$$

with sufficiently small constant failure probability given by the union bound. For the $k/(2f(r+1)^q)$ independent copies of subsamples, by a Chernoff bound, a $1/4$ fraction of them will have the largest absolute value in Q and (5) will also hold, with the overall failure probability being $e^{-\Omega(k/(fr^q))}$. Therefore, since $k/f > 2^{pj/2}k$,

$$\begin{aligned}\left\|x_{S_j}\right\|_p^p &\ge \frac{2^{pj/2}k}{8(r+1)^q} \left[\left|x_{2^j k/f}\right|^p - \frac{1}{2(r+1)} \left(\frac{f}{2^j k}\right)^{\frac{p}{2}} \left\|x_{-2^j k/f}\right\|_2^p\right] \\ &\ge \frac{2^{pj/2}k}{8(r+1)^q} \left|x_{2^j k/f}\right|^p - \frac{k^{1-\frac{p}{2}} f^{\frac{p}{2}}}{16(r+1)^{q+1}} \left\|x_{-2k/f}\right\|_2^p, \end{aligned}$$

and by the fact that $0 < q < p < 2$,

$$\begin{aligned}\|x-\hat{x}\|_p^p - \|x_{-k}\|_p^p &\le \mathcal{O}(\frac{1}{r^p}) k^{1-\frac{p}{2}} f^{\frac{p}{2}} \|x_{-2k/f}\|_2^p - \sum_{j=1}^{r} \left\|x_{S_j}\right\|_p^p \\ &\le \left[\mathcal{O}\left(\frac{1}{r^p}\right) + \frac{r}{16(r+1)^{q+1}}\right] k^{1-\frac{p}{2}} f^{\frac{p}{2}} \|x_{-2k/f}\|_2^p - \sum_{j=1}^{r} \frac{2^{pj/2}k}{8(r+1)^q} \left|x_{2^j k/f}\right|^p \\ &\le \mathcal{O}\left(\frac{1}{c}\right) f^{\frac{2}{p}} \left\|x_{-k/f}\right\|_p^p + \left[\mathcal{O}\left(\frac{1}{c}\right) + \frac{1}{16(r+1)^q} - \frac{1}{8(r+1)^q}\right] \sum_{j=1}^{r} k 2^{pj/2} \left|x_{2^j k/f}\right|^p \\ &\le f^{\frac{2}{p}} \left\|x_{-k/f}\right\|_p^p \le \epsilon \|x_{-k}\|_p^p\,. \end{aligned}$$

The total number of measurements will be at most

$$\mathcal{O}\left(\frac{k}{f}\mathrm{loglog}(n) + \frac{4kr^2}{f}\mathrm{loglog}(n) + \frac{kr}{2fr^q} r^{\frac{2}{p}} \mathrm{loglog}(n)\right) = \mathcal{O}\left(\frac{k}{\epsilon^{\frac{p}{2}}} \mathrm{loglog}(n) \log^{\frac{2}{p}+1-(p-\frac{1}{2})^+}\left(\frac{1}{\epsilon}\right)\right),$$

while the total failure probability given by the union bound is $1/6 + e^{-\Omega(k/(fr^q))} < 1/3$, which completes the proof. ◀

3 ℓ_∞/ℓ_2 Adaptive Sparse Recovery

In this section, we will prove Theorem 3. Our algorithm first approximates $\|x_{-k}\|_2$. The goal is to compute a value V which is not much smaller than $\frac{1}{k}\|x_{-k}\|_2^2$, and also at least $\Omega(\frac{1}{k})\|x_{-\Omega(k)}\|_2^2$. This value will be used to filter out coordinates that are not large enough, while ensuring that heavy coordinates are included. We need the following lemma, which for example can be found in Section 4 of [13].

▶ **Lemma 8.** *Using* $\log(1/\delta)$ *non-adaptive measurements we can find with probability* $1-\delta$ *a value* V *such that* $\frac{1}{C_1 k}\|x_{-C_2 k}\|_2^2 \le V \le \frac{1}{k}\|x_{-k}\|_2^2$, *where* C_1, C_2 *are absolute constants larger than* 1.

We use the aforementioned lemma with $\Theta(\log k)$ measuremenents to obtain such a value V with probability $1-1/\text{poly}(k)$. Now let c be an absolute constant and let $g : [n] \to [k^c]$ be a random hash function. Then, with probability at least $1 - \frac{1}{\text{poly}(k)}$ we have that for every $i, j \in H_k(x)$, $g(i) \neq g(j)$. By running PartitionCountSketch $(x, 2C_1 k, \{g^{-1}(1), g^{-1}(2), \ldots, g^{-1}(k^c)\}$, we get back an estimate w_j for every $j \in [k^c]$; here C_1 is an absolute constant. Let γ' be an absolute constant to be chosen later. We set $S = \{j \in [k^c] : w_j^2 \ge \gamma' V\}$ and $T = \bigcup_{j \in S} g^{-1}(j)$. We prove the following lemma.

▶ **Lemma 9.** *Let* C' *be an absolute constant. With probability at least* $1 - 1/\text{poly}(k)$ *the following holds.*

1. $|S| = \mathcal{O}(k)$.
2. *Every* $j \in [k^c]$ *such that there exists* $i \in H_k(x) \cap g^{-1}(j)$, *will be present in* S.
3. *For every* $j \in S$, *there exists exactly one coordinate* $i \in g^{-1}(j)$ *with* $x_i^2 \ge \frac{1}{C' k}\|x_{-C_2 k}\|_2^2$.
4. *For every* $j \in S$, $\|x_{g^{-1}(j) \setminus H_k(x)}\|_2^2 \le \frac{1}{k^2}\|x_{-k}\|_2^2$.

Proof. Let C_0 be an absolute constant larger than 1. Note that with probability $1 - C_0^2 \cdot k^{6-c}$, all $i \in H_{C_0 k^3}(x)$ (and, hence, also in $H_{C_0 k^3, 1/k^3}(x)$) are isolated under g. Fix $j \in [k^c]$ and, for $i \in [n]$, define the random variable $Y_i = 1_{g(x_i)=j} x_i^2$. Now observe that

$$\mathbb{E}\left[\sum_{i \in g^{-1}(j) \setminus H_{C_0 k^3, 1/k^3}(x)} Y_i\right] = \frac{1}{k^c}\|x_{-C_0 k^3}\|_2^2.$$

Applying Bernstein's inequality to the variables Y_i with

$$K = \frac{1}{C_0 k^3}\|x_{-C_0 k^3}\|_2^2, \qquad \text{and} \qquad \sigma^2 < \frac{1}{k^{c+3}}\|x_{-C_0 k^3}\|_2^4,$$

we have that

$$\Pr\left[\sum_{i \in g^{-1}(j) \setminus H_{C_0 k^3, 1/k^3}(x)} x_i^2 \ge 1/k^2 \|x_{-C_0 k^2}\|_2^2\right] \le e^{-k},$$

where c is an absolute constant. This allows us to conclude that the above statement holds for all different k^c possible values j, by a union-bound. We now prove the bullets one by one. We remind the reader that PartitionCountSketch aproximates the value of every $\|x_{g^{-1}(j)}\|_2^2$ with a multiplicate error in $[1-\gamma, 1+\gamma]$ and additive error $\frac{1}{C_0 k}\|x_{-k}\|_2^2$.

1. Since there are at most $\frac{1}{\gamma'(1+\gamma)}C_2k + C_2k$ indices j with $(1+\gamma)\|x_{g^{-1}(j)}\|_2^2 \geq \frac{\gamma'}{k}\|x_{-k}\|_2^2 \geq \gamma' V$, the algorithm can output at most $\mathcal{O}(k)$ indices.
2. The estimate for such a j will be at least $(1-\gamma)\frac{1}{k}\|x_{-k}\|_2^2 - \frac{1}{2C_1k}\|x_{-C_2k}\|_2^2 \geq \gamma' V$, for some suitable choice of γ'. This implies that j will be included in S.
3. Because of the guarantee for V and the guarantee of PartitionCountSketch, we have that all j that are in S satisfy $(1+\gamma)\|x_{g^{-1}(j)}\|_2^2 + \frac{1}{k}\|x_{-2C_1k}\|_2^2 \geq \frac{\gamma'}{k}\|x_{-C_2k}\|_2^2$, and since

$$\sum_{i \in g^{-1}(j) \setminus H_{C_0k^3}(x)} x_i^2 \leq \frac{1}{k^2}\|x_{-k}\|_2^2,$$

   this implies that there exists $i \in H_{C_0k^3}(x) \cap g^{-1}(j)$. But since all $i \in H_{C_0k^3}(x)$ are perfectly hashed under g, this implies that this i should satisfy $x_i^2 \geq \frac{1}{C'k}\|x_{-C_2k}\|_2^2$, from which the claim follows.
4. Because elements in $H_{C_0k^3}(x)$ are perfectly hashed, we have that

$$\|x_{g^{-1}(j)\setminus H_k(x)}\|_2^2 = \|x_{g^{-1}(j)\setminus H_{C_0k^3}}(x)\|_2^2 \leq \frac{1}{k^2}\|x_{-k}\|_2^2$$

   for C_0 large enough. ◀

Given S, we proceed in the following way. For every $j \in S$, we run the algorithm guaranteed by Lemma 15 from the full version [2] to obtain an index i_j, using $\mathcal{O}(k\text{loglog}n)$ measurements. Then we observe directly x_{i_j} using another $\mathcal{O}(k)$ measurements, and form vector $z = x - x_{\{i_j\}_{j\in S}}$. We need the following lemma.

▶ **Lemma 10.** *With probability* $1 - 1/\text{poly}(k)$, $|H_k(x) \setminus \{i_j\}_{j\in S}| \leq \frac{k}{\log^2 n}$.

Proof. Let us consider the calls to the 1-sparse recovery routine in j for which there exists $i \in H_k(x) \cap g^{-1}(j)$. Since the 1-sparse recovery routine succeeds with probability $1 - 1/\text{poly}(\log n)$, then the probability that we have more than $\frac{k}{\log^2 n}$ calls that fail, is

$$\binom{k}{\frac{k}{\log^2 n}}\left(\frac{1}{\text{poly}(\log n)}\right)^{k/\log^2 n} \leq \frac{1}{\text{poly}(k)}.$$

This gives the proof of the lemma. ◀

For the last step of our algorithm, we run PartitionCountSketch$(z_T, k/\log(n), [n])$ to estimate the entries of z. We then find the coordinates with the largest $2k$ estimates, and observe them directly. Since

$$\frac{\log n}{k}\|(z_T)_{-k/\log n}\|_2^2 \leq \frac{\log n}{k} \cdot \frac{1}{k^2}\|x_{-k}\|_2^2 = \frac{\log n}{k^3}\|x_{-k}\|_2^2,$$

every coordinate will be estimated up to additive error $\frac{\log n}{k^3}\|x_{-k}\|_2^2$, which shows that every coordinate in $T \cap H_{k,1/k}(x)$ will be included in the top $2k$ coordinates. Putting everything together, we obtain the desired result.

[2] see https://arxiv.org/pdf/1804.09673.pdf

4 ℓ_2/ℓ_2 Adaptive Sparse Recovery in Optimal Rounds

In this section, we give an algorithm for ℓ_2/ℓ_2 compressed sensing using $\mathcal{O}(\text{loglog}n)$ rounds, instead of $\mathcal{O}(\log^* k \cdot \text{loglog}n)$ rounds. Specifically, we prove the first bullet of Theorem 4. We call this algorithm AdaptiveSparseRecovery$_{\ell_\infty/\ell_2}$.

We proceed with the design and the analysis of the algorithm. We note that for $k/\epsilon = \mathcal{O}(\log^5 n)$[3], ℓ_∞/ℓ_2 gives already the desired result. So, we focus on the case of $k/\epsilon = \Omega(\log^5 n)$. We pick a hash function $h : [n] \to [B]$, where $B = ck/(\epsilon \log n)$ for some constant c large enough. The following follows by an application of Bernstein's Inequality and the Chernoff Bound, similarly to ℓ_∞/ℓ_2.

▶ **Lemma 11.** *With probability* $1 - 1/\text{poly}(n)$*, the following holds:*

$$\forall j \in [B] : |H_{k/\epsilon}(x) \cap h^{-1}(j)| \le \log n, \qquad \text{and} \qquad \left| \sum_{i \in h^{-1}(j) \setminus H_{k/\epsilon}(x)} x_i^2 \right| \le \frac{\epsilon}{k} \|x_{-k}\|_2^2.$$

We now run the ℓ_∞/ℓ_2 algorithm for the previous section on vectors $x_{h^{-1}(1)}, x_{h^{-1}(2)}, \ldots, x_{h^{-1}(B)}$ with sparsity parameter $\mathcal{O}(\log n)$, to obtain vectors $\hat{x}_1, \hat{x}_2, \ldots, \hat{x}_B$. The number of rounds is $\mathcal{O}(\text{loglog}(n))$, since we can run the algorithm in every bucket in parallel. By the definition of the ℓ_∞/ℓ_2 algorithm, one can see that $|\text{supp}(\hat{x}_j)| \le \mathcal{O}(\log n)$. We set $S = \cup_{j \in B} |\text{supp}(x_j)|$, and observe that $|S| = ck/(\epsilon \log n) \cdot \mathcal{O}(\log n) = \mathcal{O}(k/\epsilon)$. The number of measurements equals $ck/(\epsilon \log n) \cdot \mathcal{O}(\log n \cdot \text{loglog}(n \log(n/k))) = \mathcal{O}((k/\epsilon) \cdot \text{loglog}(n \log(n/k)))$.

▶ **Lemma 12.** *With probability* $1 - 1/\text{poly}(n)$*, we have that* $|S \setminus H_{k/\epsilon}(x)| \le \frac{k}{\epsilon \log^2 n}$.

Proof. Since every call to ℓ_∞/ℓ_2 fails with probability $1/\text{poly}(\log n)$, the probability that we have more than a $\frac{1}{\log n}$ fraction of the calls that fail is at most

$$\binom{B}{B/\log^2 n} \left(\frac{1}{\log n}\right)^{B/\log n} \le (e \log^2 n)^{\log n} (\log n)^{-B/\log n} \le \frac{1}{\text{poly}(n)}.$$

This implies that S will contain all but at most $B/\log^2 n \cdot \log n = k/(\epsilon \log^2 n)$ coordinates $i \in H_k(x)$. ◀

We now observe x_S directly and form the vector $z = x - x_S$, for which $\|z_{-k/(\epsilon \log^2 n)}\|_2 \le \|x_{-k/\epsilon}\|_2$. We now run a standard ℓ_2/ℓ_2 algorithm that fails with probability $1/\text{poly}(n)$ to obtain a vector $\hat{z}$ that approximates z (for example PartitionCountSketch$(z, k/(\epsilon \log^2 n), [n])$ suffices). We then output $\hat{z} + x_S$, for which $\|\hat{z} + x_S - x\|_2 = \|\hat{z} - z\| \le (1+\epsilon)\|z_{-k/(\epsilon \log n)}\|_2 \le (1+\epsilon)\|x_{-k}\|_2$. The number of measurements of this step is $\mathcal{O}(\frac{1}{\epsilon} \frac{k}{\log^2 n} \cdot \log n) = o(\frac{k}{\epsilon})$. The total number of rounds is clearly $\mathcal{O}(\text{loglog}(n \log(\frac{n\epsilon}{k})))$.

5 ℓ_2/ℓ_2 with Improved Dependence on ϵ

In this section, we prove the second part of Theorem 4. We first need an improved algorithm for the 1-sparse recovery problem.

▶ **Lemma 13.** *Let* $x \in \mathbb{R}^n$*. There exists an algorithm* ImprovedOneSparseRecovery*, that uses* $\mathcal{O}(\text{loglog}n + \frac{1}{\epsilon}\text{loglog}(\frac{1}{\epsilon}))$ *measurements in* $\mathcal{O}(\text{loglog}(n))$ *rounds, and finds with sufficiently small constant probability an* $\mathcal{O}(1)$*-sparse vector* $\hat{x}$ *such that* $\|\hat{x} - x\|_2 \le (1 + \epsilon)\|x_{-1}\|_2$.

[3] the constant 5 is arbitrary

Proof. We pick a hash function $h : [n] \to [B]$, where $B = \lceil 1/\epsilon^h \rceil$ for a sufficiently large constant h. Observe that all elements of $H_{\sqrt{B}}(x)$ are perfectly hashed under h with constant probability, and, $\forall j \in [B]$, $\mathbb{E}\left[\left\|x_{h^{-1}(j)\setminus H_{\sqrt{B}}}(x)\right\|_2\right] \leq 1/B\|x_{-\sqrt{B}}\|_2$. As in the previous sections, invoking Bernstein's inequality we can get that with probability $1 - 1/\text{poly}(B)$, $\forall j \in [B]$, $\left\|x_{h^{-1}(j)\setminus H_{\sqrt{B}}(x)\|_2}\right\|_2^2 \leq \frac{c\log B}{B}\|x_{-\sqrt{B}}\|_2^2$, where c is some absolute constant, and the exponent in the failure probability is a function of c.

We now define the vector $z \in \mathbb{R}^B$, the j-th coordinate of which equals $z_j = \sum_{i\in h^{-1}(j)} \sigma_{i,j}x_i$. We shall invoke Khintchine inequality to obtain $\forall j$,

$$\Pr\left[\left|\sum_{i\in h^{-1}(j)\setminus H_{\sqrt{B}}(x)} \sigma_{i,j}x_i\right|^2 > \frac{c'}{\epsilon}\left\|x_{h^{-1}(j)\setminus H_{\sqrt{B}}(x)}\right\|_2^2\right] \leq e^{-\Omega(1/\epsilon^2)},$$

for some absolute constant c'. This allows us to take a union-bound over all $B = \lceil 1/\epsilon^h \rceil$ entries of z to conclude that there exists an absolute constant ζ such that $\forall j \in [B]$, $\left|\sum_{i\in h^{-1}(j)\setminus H_{\sqrt{B}}(x)} \sigma_{i,j}x_i\right|^2 \leq \frac{c'}{\epsilon}\|x_{h^{-1}(j)\setminus H_{\sqrt{B}}(x)}\|_2^2 < \zeta\epsilon\|x_{-1}\|_2^2$, by setting h large enough. Now, for every coordinate $j \in [B]$ for which $h^{-1}(j) \cap H_{1,\epsilon}(x) = i^*$ or some $i^* \in [n]$, we have that $|z_j| \geq \left||x_{i^*}| - \sqrt{\frac{c\log B}{B}\cdot\frac{c'}{\epsilon}}\|x_{-\sqrt{B}}\|_2\right| \geq (1-\zeta)\sqrt{\epsilon}\|x_{-1}\|_2$, whereas for every $j \in [B]$ such that $h^{-1}(j)\cap H_{1,\epsilon\zeta}(x) = \emptyset$ it holds that $|z_j| \leq 2\zeta\sqrt{\epsilon}\|x_{-1}\|_2$. We note that $H_{1,\epsilon}(x) \subset H_{\sqrt{B}}(x)$, and hence all elements of $H_{1,\epsilon}(x)$ are also perfectly hashed under h. Moreover, observe that $\mathbb{E}\|z_{-1}\|_2^2 \leq \|x_{-1}\|_2^2$, and hence by Markov's inequality, we have that $\|z_{-1}\|_2^2 \leq 10\|x_{-1}\|_2^2$ holds with probability $9/10$. We run the ℓ_2/ℓ_2 algorithm of Theorem 4 for vector z with the sparsity being set to 1, and obtain vector $\hat{z}$. We then set $S = \text{supp}(\hat{z})$. We now define $w = (|z_1|, |z_2|, \ldots)$, for which $\|w_{-1}\|_2 = \|z_{-1}\|_2$. Clearly, $\|z - z_S\|_2^2 \leq \|z - \hat{z}\|_2^2 \leq (1+\epsilon)\|z_{-1}\|_2^2 = (1+\epsilon)\|w_{-1}\|_2^2$. So $\|w - w_S\|_2^2 = \|z - z_S\|_2^2 \leq (1+\epsilon)\|w_{-1}\|_2^2$. We now prove that $\left\|x - x_{\cup_{j\in S}h^{-1}(j)}\right\|_2 \leq (1+\mathcal{O}(\epsilon))\|x_{-1}\|_2$. Let i^* be the largest coordinate in magnitude of x, and $j^* = h(i^*)$. If $j^* \in S$, then it follows easily that $\|x - x_{\cup_{j\in S}h^{-1}(j)}\|_2 \leq \|x_{-1}\|_2$. Otherwise, since $\sum_{j\neq j^*} w_j^2 = \|w_{-1}\|_2^2$, and $\sum_{j\notin S} w_j^2 \leq (1+\epsilon)\|w_{-1}\|_2^2$, it must be the case that $\left|w_{j^*}^2 - \|w_S\|_2^2\right| \leq \epsilon\|w_{-1}\|_2^2 \leq 10\epsilon\|x_{-1}\|_2^2$. The above inequality, translates to $\sum_{i\in h^{-1}(j^*)} x_i^2 \leq |S|\zeta\epsilon\|x_{-1}\|_2^2 + \zeta\epsilon\|x_{-1}\|_2^2 + 10\epsilon\|x_{-1}\|_2^2 + \sum_{j\in S}\sum_{i\in h^{-1}(j)} x_j^2 = \mathcal{O}(\epsilon)\|x_{-1}\|_2^2 + \sum_{j\in S}\sum_{i\in h^{-1}(j)} x_j^2$. This gives $\left\|x - x_{\cup_{j\in S}h^{-1}(j)}\right\|_2 = \sum_{i\in h^{-1}(j^*)} x_i^2 + \sum_{j\notin S\cup\{j^*\}}\sum_{i\in h^{-1}(j)} x_i^2 \leq \mathcal{O}(\epsilon)\|x_{-1}\|_2^2 + \mathcal{O}(1)\zeta\epsilon\|x_{-1}\|_2^2 + \sum_{j\in S}\sum_{i\in h^{-1}(j)} x_j^2 + \sum_{j\notin S\cup\{j^*\}}\sum_{i\in h^{-1}(j)} x_i^2 + \leq (1+\mathcal{O}(\epsilon))\|x_{-1}\|_2^2$.

Given S, we run the 1-sparse recovery routine on vectors x_j for $j \in S$, with a total of $\mathcal{O}(\text{loglog}n)$ measurements and $\mathcal{O}(\text{loglog}n)$ rounds. We then output $\{x_{i_j}\}_{j\in S}$. Let i_j be the index returned for $j \in S$ by the 1-sparse recovery routine. Since we have a constant number of calls to the 1-sparse recovery routine (because S is of constant size), all our 1-sparse recovery routines will succeed. We now have that $\|x - x_{\cup_{j\in S} i_j}\|_2 \leq \|x_{\bar{S}}\|_2 + \sum_{j\in S}\|x_{h^{-1}(j)} - x_{i_j}\|_2 \leq \|x_{\bar{S}}\|_2 + \sum_{j\in S}(1+\epsilon)\|x_{h^{-1}(j)\setminus H_1(x)}\|_1 \leq (1+\mathcal{O}(\epsilon))\|x_{-1}\|_2$. Rescaling ϵ, we get the desired result. ◀

The algorithm for general k is similar to [10], apart from the fact that we subsample at a slower rate, and also use our new 1-sparse recovery algorithm as a building block. In the algorithm below, R_r is the universe we are restricting our attention on at the rth round. Moreover, J is the set of coordinates that we have detected so far. We are now ready to prove Theorem 4.

Proof. The number of measurements is bounded in the exact same way as in Theorem 3.7 from [10].

Algorithm 2 Adaptive ℓ_2/ℓ_2 Sparse Recovery.

1. $R_0 \leftarrow [n]$.
2. $x_0 \leftarrow \vec{0}$.
3. $\delta_0 \leftarrow \delta/2, \epsilon_0 \leftarrow \epsilon/e, f_0 \leftarrow 1/32, k_0 \leftarrow k$.
4. $J \leftarrow \emptyset$.
5. **For** $r = 0$ to $\mathcal{O}(\log^* k)$ **do**
6. **For** $t = 0$ to $\Theta(k_r \log(1/(\delta_r f_r)))$ **do**
7. $S_t \leftarrow \textsc{Subsample}(x - x^{(r)}, R_r, 1/(C_0 k_r))$.
8. $J \leftarrow J \cup \textsc{ImprovedOneSparseRecovery}((x - x^{(r)})_{S_t})$.
9. **End For**
10. $R_{r+1} \leftarrow [n] \setminus J$.
11. $\delta_{r+1} \leftarrow \delta_r/8$.
12. $\epsilon_{r+1} \leftarrow \epsilon_r/2$.
13. $f_{r+1} \leftarrow 1/2^{1/(4^{i+r} f_r)}$.
14. $k_{r+1} \leftarrow f_r k_r$.
15. $R_{r+1} \leftarrow [n] \setminus J$.
16. **End For**
17. $\hat{x} \leftarrow x^{(r+1)}$.
18. Return $\hat{x}$.

We fix a round r and $i \in H_{k_r,\epsilon_r}(x^{(r)})$. Then the call to $\textsc{Subsample}(R_r, 1/(C_0 k_r))$ yields

$$\Pr\left[|H_{k_r,\epsilon_r}(x - x^{(r)}) \cap S_t| = \{i\}\right] \geq \frac{1}{C_0 k_r}, \quad \mathbb{E}\left[\|x_{S_t \setminus H_{k_r,\epsilon_i}(x^{(r)})}\|_2^2\right] = \frac{1}{C_0 k_r}\|x_{-k_r}\|_2^2.$$

Setting C_0 to be large enough and combining Markov's inequality with the guarantee of Lemma 13, we get that the probability that the call to $\textsc{ImprovedOneSparseRecovery}(x_{S_t})$ returns i is $\Theta(1/k_r)$. Because we repeat $k_r \log(1/(f_r\delta_r))$, the probability that i or a set S_i of size $\mathcal{O}(1)$ such that $\|x_{\{i\}} - x_{S_i}\|_2 \leq \epsilon_i \|x_{-k_r}\|_2^2$, is not added in J is at most $(1 - 1/k_r)^{k_r \log(1/(f_r\delta_r))} = f_r\delta_r$.

Given the above claim, the number of measurements is $\mathcal{O}((k\text{loglog}n + k/\epsilon\text{loglog}(1/\epsilon)\log(1/\delta))$ and the analysis of the iterative loop proceeds almost identically to Theorem 3.7 of [10]. ◀

Abstract

The No Low-Energy Trivial States (NLTS) conjecture of Freedman and Hastings (Quantum Information and Computation 2014), which asserts the existence of local Hamiltonians whose low-energy states cannot be generated by constant-depth quantum circuits, identifies a fundamental obstacle to resolving the quantum PCP conjecture. Progress towards the NLTS conjecture was made by Eldar and Harrow (Foundations of Computer Science 2017), who proved a closely related theorem called No Low-Error Trivial States (NLETS). In this paper, we give a much simpler proof of the NLETS theorem and use the same technique to establish superpolynomial circuit size lower bounds for noisy ground states of local Hamiltonians (assuming $\mathsf{QCMA} \neq \mathsf{QMA}$), resolving an open question of Eldar and Harrow. We discuss the new light our results cast on the relationship between NLTS and NLETS.

Finally, our techniques imply the existence of *approximate quantum low-weight check (qLWC) codes* with linear rate, linear distance, and constant weight checks. These codes are similar to quantum LDPC codes except (1) each particle may participate in a large number of checks, and (2) errors only need to be corrected up to fidelity $1 - 1/\mathsf{poly}(n)$. This stands in contrast to the best-known stabilizer LDPC codes due to Freedman, Meyer, and Luo which achieve a distance of $O(\sqrt{n \log n})$.

The principal technique used in our results is to leverage the Feynman-Kitaev clock construction to approximately embed a subspace of states defined by a circuit as the ground space of a local Hamiltonian.

1 Introduction

The quantum PCP conjecture [4, 2] is a central open question in quantum complexity theory. To understand the statement, it is helpful to review the dictionary translating between classical constraint satisfaction problems (CSPs) and their quantum analogue, the local Hamiltonian problem. A classical CSP on n variables corresponds to a local Hamiltonian $H = H_1 + \cdots + H_m$ acting on n qubits[1]. A solution to the CSP corresponds to an n qubit quantum state, and the number of violated constraints corresponds to the energy (eigenvalue) of that quantum state. The NP-hardness of SAT corresponds to the QMA-hardness of deciding whether the H has minimum eigenvalue at most a or at least b for given a, b such that $b - a = 1/\mathsf{poly}(n)$. The quantum analogue of the PCP theorem, called the qPCP conjecture, asserts that the problem remains QMA-hard even when $b - a \geq cm = c\|H\|$.

Just as the classical PCP theorem connects coding theory to constraint satisfaction problems, it is natural to expect any resolution of the quantum PCP conjecture to rely on — and to reveal — deep connections between the theory of quantum error-correcting codes and ground states (i.e. states of minimum energy) of local Hamiltonians. Examples of quantum error-correcting codes realized as the ground spaces of local Hamiltonians already play a central role in our understanding of the physical phenomenon known as topological order [30]. Moreover, it has been suggested that the qPCP conjecture is closely related to one of the biggest open problems in quantum coding theory: whether quantum low density parity check (qLDPC) codes with linear rate and linear distance exist [23, 13, 33].

The difficulty of the qPCP conjecture motivated Freedman and Hastings to formulate a simpler goal called the *No Low-Energy Trivial States (NLTS) Conjecture* [22]. One way to put one's finger on the additional difficulty of qPCP (beyond the "standard" difficulty of proving a classical PCP theorem) is that solutions of QMA-hard problems are expected to have high description complexity. For example, if NP $\neq$ QMA, then ground states of local Hamiltonians do not have classically checkable polynomial-size descriptions. The NLTS conjecture isolates this aspect of high description complexity by asserting the existence of a family of local Hamiltonians $\{H^{(n)}\}_{n=1}^{\infty}$ where $H^{(n)}$ acts on n particles, such that low-energy states (of energy less than $c\|H\|$) cannot be generated by quantum circuits of constant depth. A much stronger version of the NLTS conjecture is a necessary consequence of the qPCP conjecture: assuming QCMA $\neq$ QMA,[2] low-energy states cannot be described even by polynomial-size quantum circuits. However, one of the advantages of the NLTS conjecture is that it does not involve complexity classes such as QMA, but rather focuses on the entanglement complexity that is intrinsic to low-energy states of local Hamiltonians.

[1] For normalization, we assume that the terms of a local Hamiltonian have spectral norm at most 1.

[2] For precise definitions of the complexity classes QCMA and QMA, we refer the reader to [20, 29]. Roughly speaking, QMA is the class of problems for which the solution is a quantum state that can be efficiently checked by a quantum computer. QCMA is the class of problems where the solution is a *classical* string that can be efficiently checked by a quantum computer.

Like the qPCP conjecture, the NLTS conjecture remains unresolved. In [19], Eldar and Harrow proposed a variant of the NLTS called *No Low-Error Trivial States (NLETS)*, which is itself a necessary consequence[3] of NLTS. The difference was that rather than considering low-energy states of H, they considered a notion of "local corruption error", what they call *ϵ-error states*: these are states that differ from the ground state in at most ϵn qubits. More precisely, σ is ϵ-error for a local Hamiltonian H if there exists a ground state ρ of H and a set S of at most ϵn qudits such that $\mathrm{Tr}_S(\rho) = \mathrm{Tr}_S(\sigma)$. Under this definition they were able to establish a family of Hamiltonians for which any ϵ-error state requires circuit depth of $\Omega(\log n)$. This was welcomed as very encouraging progress towards establishing NLTS, since NLETS could be regarded as a close proxy for NLTS, with a technical change in definition of distance under which to examine the robustness of the ground space.

In this paper, we start by giving a simple argument for the $\Omega(\log n)$ circuit depth lower bound of Eldar and Harrow; our lower bound holds even under a more general error model, which allows any probabilistic mixture of ϵ-error states (we call these states *noisy ground states*). Moreover, we can use the same techniques to answer their open question of whether one can obtain circuit size lower bounds on low-error states that go beyond logarithmic depth: specifically, we show that there exists a family of local Hamiltonians whose noisy ground states require superpolynomial-size circuits, assuming $\mathsf{QCMA} \neq \mathsf{QMA}$.

One way to view these results is that they provide further progress towards the NLTS conjecture and beyond. However, it is instructive to take a step back to consider more closely the basic difference between NLETS and NLTS. This lies in the different notion of approximation: in NLETS, approximation corresponds to local corruptions in ϵn sites, where n is the total number of particles, whereas in NLTS approximation corresponds to energy at most $\epsilon \|H\|$ (intuitively, at most ϵ fraction of the terms of the Hamiltonian are violated). An alternative perspective on our results is that they suggest these two notions of approximation are quite different. This view is reinforced by the fact that our $\Omega(\log n)$-circuit depth lower bounds on noisy ground states holds for a family of 1D Hamiltonians, whereas we know that NLTS and qPCP Hamiltonians cannot live on any constant-dimensional lattice [2]. This suggests that in the context of the qPCP and NLTS conjectures, the correct notion of distance is given by the energy or number of violated terms of the Hamiltonian.

On the other hand, the local corruption distance as defined by Eldar and Harrow for their NLETS result is the natural one that arises in quantum error correction: the distance of a code is *defined* by the maximum number of qubits of a codeword that can be erased while maintaining recoverability. We give a construction of a family of codes (inspired by the construction used in our noisy ground state lower bound) that we call *quantum low weight check (qLWC) codes*. The family of codes we consider are approximate error-correcting codes in the sense of [16, 11]. They are closely related to qLDPC codes, with the difference that they are not stabilizer codes and therefore the low weight checks are not Pauli operators. Specifically, we give a family of approximate qLWCs with linear distance and linear rate. Constructing qLDPC codes with similar parameters is a central open question in coding theory, with the best-known stabilizer LDPC codes due to Freedman, Meyer, and Luo which achieve a distance of $O(\sqrt{n \log n})$ [23].

What is common to the above results is the technique. We start with the observation that the complicated part of the Eldar and Harrow proof is constructing a local Hamiltonian whose ground states share some of the properties of the cat state $|\circledast_n\rangle = (|0\rangle^{\otimes n} + |1\rangle^{\otimes n})/\sqrt{2}$.

[3] The local Hamiltonian family must be of bounded-degree, meaning no particle participates in more than a constant number of Hamiltonian terms.

To do so, they constructed a local Hamiltonian corresponding to a quantum error-correcting code (based on the Tillich-Zemor hypergraph product construction) and showed that its ground states have non-expansion properties similar to those of the cat state [19]. Our starting point is the observation that the Tillich-Zemor construction is unnecessary and that one can make the cat state *approximately* a ground state of a local Hamiltonian in the following sense: we construct a Feynman-Kitaev clock Hamiltonian corresponding to the circuit that generates $|\boxtimes_n\rangle$ from $|0\rangle^{\otimes n}$.[4] The ground state of this Hamiltonian is the history state of this computation, and we directly argue that the circuit depth necessary to generate this history state is at least $\Omega(\log n)$. This same argument even allows us to lower bound the circuit depth of *approximate* noisy ground states (i.e. states that are close in trace distance to a noisy ground state).

The Feynman-Kitaev clock Hamiltonian plays a central role in our construction of qLWCs, with history states playing the role of codewords. The fact that such a construction yields an error-correcting code flies in the face of classical intuition. After all, it is the brittleness of the Cook-Levin tableau [15, 32] (the classical analogue of the history state) that motivates the elaborate classical PCP constructions [7, 6, 18]. The difference is that *time* is in superposition in a quantum history state. We do not yet understand the implications of this observation. For example, is it possible that it might lead to new ways of constructing qLDPC codes with super-efficient decoding procedures? There are precedents for such connections between computational phenomena and codes, most notably with the PCP theorem and the construction of locally testable and locally checkable codes.

Furthermore, while quantum error-correcting codes have typically provided a wealth of examples of interesting local Hamiltonians, our construction of qLWCs also suggest that a fruitful connection exists in the opposite direction: by considering techniques to construct local Hamiltonians (such as the Feynman-Kitaev clock construction), we can construct an interesting example of a quantum error-correcting code. We note that this reverse connection is starting to take hold in other areas of quantum information theory and physics: see [12, 28].

2 Summary of Results

Before we present our results, we motivate our definition of *noisy ground states*.

2.1 Noisy ground states

The NLETS Theorem and NLTS conjecture describe different ways in which the ground space entanglement is robust. The ground states of NLETS Hamiltonians are robust against local corruptions in ϵn sites, where n is the total number of particles. NLTS Hamiltonians are robust against low-energy excitations in the sense that all states with energy at most $\epsilon\|H\|$ retain nontrivial circuit complexity.

In this paper, we study another way that ground space entanglement can be robust. We focus on the concept of *noisy ground state*, which is a generalization of low-error states: an ϵ-noisy ground state σ of a local Hamiltonian H is a probabilistic mixture of ϵ-error states $\{\sigma_i\}$.

This notion of noisy ground state is naturally motivated by the following situation: consider a ground state ρ of H. On each particle independently apply the following process

[4] A similar construction of a clock Hamiltonian was also considered by Crosson and Bowen in the context of idealized adiabatic algorithms [17]. The construction is inspired by techniques of [14, 10].

$\mathcal{M}$: with probability ϵ, apply a noisy channel $\mathcal{N}$, and with probability $1-\epsilon$ apply the identity channel $\mathcal{I}$. The resulting state is

$$\begin{aligned}\mathcal{M}(\rho) &= \left((1-\epsilon)\mathcal{I} + \epsilon\mathcal{N}\right)^{\otimes n}(\rho) \\ &= \sum_{S\subseteq[n]} (1-\epsilon)^{n-|S|}\epsilon^{|S|}\mathcal{N}^S(\rho) \\ &\approx \sum_{S:|S|\leq 2\epsilon n} (1-\epsilon)^{n-|S|}\epsilon^{|S|}\mathcal{N}^S(\rho)\end{aligned} \tag{1}$$

where $\mathcal{N}^S$ denotes the tensor product of the map $\mathcal{N}$ acting on the particles indexed by S. The last approximate equality follows from the fact that with overwhelmingly large probability, $\mathcal{N}^S$ acts on at most $2\epsilon n$ particles. Notice that the expression on the right hand side is (up to normalization) a 2ϵ-noisy ground state, because when $|S| \leq 2\epsilon n$, the state $\mathcal{N}^S(\rho)$ is a 2ϵ-error state.

This justifies the name "noisy ground state", as the operation $\mathcal{M}$ is is a reasonable model of noise that occurs in physical processes (and is frequently considered in work on quantum fault-tolerance). Furthermore, we believe that our model arises naturally in the context of noisy adiabatic quantum computation.

As mentioned before, noisy ground states are a generalization of low-error states but are a special case of low-energy states: since low-error states are themselves low-energy states, a convex combination of them is also low-energy.

We prove several results about the robustness of entanglement in noisy ground states.

2.2 Logarithmic circuit depth lower bound

First, we generalize Eldar and Harrow's logarithmic circuit depth lower bound [19] to encompass noisy ground states. Furthermore, we present a family of Hamiltonians that is *one-dimensional*; in other words, the particles of the Hamiltonian are arranged on a line and the Hamiltonian terms act on neighboring particles.

We call this the *Logarithmic Noisy Ground States (LNGS) Theorem*[5].

▶ **Theorem 1** (Logarithmic lower bound). *There exists a family of 3-local Hamiltonians $\{H^{(n)}\}$ on a line, acting on particles of dimension 3, such that for all $n \in \mathbb{N}$, for all $0 \leq \epsilon < 1/48$, $0 \leq \delta < \frac{1}{8} - 6\epsilon$, the δ-approximate circuit depth of any ϵ-noisy ground state σ for $H^{(n)}$ is at least $\frac{1}{2}\log(n/2)$.*

Here, the δ-approximate circuit depth of ρ means the circuit depth needed to produce a state that is δ-close to ρ in trace distance.

Our proof of Theorem 1 is simple and self-contained. As a consequence of our simpler local Hamiltonian construction, we obtain improved parameters over those in [19]. Furthermore, as we will discuss below in Section 2.4, the fact that our LNGS Hamiltonian is one-dimensional gives a strong separation between NLETS/LNGS and NLTS Hamiltonians.

2.2.1 Superpolynomial circuit size lower bound

A question that was left open by [19] is whether one can obtain circuit lower bounds on low-error states that are better than logarithmic – say polynomial or even exponential. We show that there exists a family of local Hamiltonians whose noisy ground states require

[5] We pronounce this "Longs."

superpolynomial[6] size circuits, assuming QCMA $\neq$ QMA. Since low-error states are noisy ground states, this provides an answer to Eldar and Harrow's open question.

We call this the *Superpolynomial Noisy Ground States (SNGS) Theorem*[7].

▶ **Theorem 2** (Superpolynomial Noisy Ground States (SNGS)). *If* QCMA $\neq$ QMA*, then there exists* $q, \epsilon > 0$ *and a family of* 7*-local Hamiltonians* $\{H^{(n)}\}$ *acting on dimension-*q *qudits such that for all* $0 \leq \delta < 1/5$*, the* δ*-approximate circuit complexity of any family* $\{\sigma_n\}$ *of* ϵ*-noisy ground states for* $\{H^{(n)}\}$ *grows faster than any polynomial in* n*.*

We call such a family $\{H^{(n)}\}$ *SNGS Hamiltonians*. The following is a proof sketch. Let $L = (L_{yes}, L_{no})$ be the QMA-complete language consisting of descriptions of polynomial-size verifier circuits acting on a witness state and ancilla qubits. We convert each circuit $C \in L$, into a circuit C' where C' applies in order: (a) a unitary V to encode the state in an error-correcting code[8], (b) a collection of identity gates, (c) the unitary $V^\dagger$ to decode the state, and (d) the gate circuit C. The construction maintains that the circuits C' and C are equivalent. We then generate the Feynman-Kitaev clock Hamiltonian for C'. Let H_C be this Hamiltonian. The family of SNGS Hamiltonians is precisely $\{H_C : C \in L_{yes}\}$.

In order to prove that all noisy ground states of this Hamiltonian must have superpolynomial circuit size, we show that if there was a noisy ground state with a polynomial-size generating circuit, then the description of the generating circuit would suffice as a *classical* witness for the original QMA-complete problem. In the *yes* case, the construction of C' from C enforces that tracing out the time register of the noisy ground state will yield a state close to a convex combination of $\{\mathrm{Enc}(|\xi_i, 0\rangle)\}$ where $\mathrm{Enc}(\cdot)$ is the encoding function for the error-correcting code and $\{|\xi_i\rangle\}$, a collection of accepting witness. Therefore, given the description of the generating circuit for the noisy ground state, we can generate the noisy ground state and decode the original witness state. It suffices then to check the witness by running the original circuit C. The *no* case follows easily from the definition of L_{no}. This proves that $L \in$ QCMA, proving QCMA = QMA, contradicting the original assumption.

2.2.2 Semi-explicit SNGS Hamiltonians via oracle separations

It is an open question in quantum complexity theory of whether QCMA is equal to QMA. Aaronson and Kuperberg gave the first complexity-theoretic evidence that they are different by constructing a *quantum* oracle $\mathcal{O}$ such that $\mathsf{QCMA}^{\mathcal{O}} \subsetneq \mathsf{QMA}^{\mathcal{O}}$ [1]. Fefferman and Kimmel later showed that one can obtain the same oracle separation with *in-place* oracles $\mathcal{O}$, which are permutation matrices in the standard basis [20]. The separations of [1, 20] hold as long as the locality of the oracles $\mathcal{O}$ is $\omega(\log n)$ (i.e. superlogarithmic in the problem size).

We show that any oracle separation between QCMA and QMA can be leveraged to obtain a semi-explicit family of SNGS Hamiltonians:

▶ **Theorem 3.** *There exists* $q, \epsilon > 0$*, a function* $k(n) = O(\log^{1+\alpha} n)$ *for arbitrarily small* $\alpha > 0$ *and a family of* k*-local Hamiltonians* $\{H^{(n)}\}$ *acting on dimension-*q *qudits such that the following holds: The circuit complexity of any family* $\{\sigma_n\}$ *of* ϵ*-noisy ground states for* $\{H^{(n)}\}$ *grows faster than any polynomial in* n*. Furthermore, there is exactly one term in* $H^{(n)}$ *that is* $k(n)$*-local; all other terms are* 7*-local.*

[6] Here, "superpolynomial" refers to functions $f(n)$ that grow faster than any polynomial in n.
[7] We pronounce this "Songs".
[8] Such asymptotically good codes are known to exist (e.g, [8, 24]).

Unlike Theorem 2, the superpolynomial lower bound on the circuit complexity of noisy ground states does not require any complexity-theoretic assumption! The caveat is that this family is only known to exist via a counting argument; there is exactly *one* term of the Hamiltonian that has $\omega(\log n)$-locality and does not have an explicit description. However, however, all of other the terms of the local Hamiltonians are 7-local and have explicit descriptions.

The essential idea is to apply the proof of Theorem 2 to the $\mathsf{QMA}^{\mathcal{O}}$ verifier that decides a language L which is not in $\mathsf{QCMA}^{\mathcal{O}}$. In both [1, 20], this verifier only makes a single call to the oracle $\mathcal{O}$. Thus there is one term in the Feynman-Kitaev clock Hamiltonian corresponding to the propagation of that oracle call. Since we do not have an explicit description of a separating oracle $\mathcal{O}$, this Hamiltonian term is non-explicit.

2.3 Asymptotically good approximate low-weight check codes

The techniques from the previous sections also give rise to what we call *approximate quantum low-weight check (qLWC) codes*. These are closely related to quantum low-density parity check (qLDPC) codes, which are stabilizer codes where each parity check acts on a bounded number of particles, and each particle participates in a bounded number of parity checks. It is a long-standing open question of whether asymptotically good qLDPC codes exist (i.e. constant locality, constant rate, and constant relative distance). The qLDPC conjecture posits that such codes exist.

We show that if one relaxes the conditions of (a) each particle participating in a small number of constraints, and (b) that we can *exactly* recover from errors, we can obtain locally defined quantum error-correcting codes with such good parameters. First, we define our notion of approximate qLWC codes:

▶ **Definition 4** (Approximate qLWC code)**.** A local Hamiltonian $H = H_1 + \cdots + H_m$ acting on n dimension-q qudits is a $[[n, k, d]]_q$ *approximate quantum LWC code* with error δ and locality w iff each of the terms H_i act on at most w qudits and there exists encoding and decoding maps Enc, Dec such that

1. $\langle\Psi| H |\Psi\rangle = 0$ if and only if $|\Psi\rangle\langle\Psi| = \mathrm{Enc}(|\xi\rangle\langle\xi|)$ for some $|\xi\rangle \in (\mathbb{C}^q)^{\otimes k}$.
2. For all $|\phi\rangle \in (\mathbb{C}^q)^{\otimes k} \otimes \mathcal{R}$ where $\mathcal{R}$ is some purifying register, for all completely positive trace preserving maps $\mathcal{E}$ acting on at most $(d-1)/2$ qudits,

$$\|\mathrm{Dec} \circ \mathcal{E} \circ \mathrm{Enc}(|\phi\rangle\langle\phi|) - |\phi\rangle\langle\phi|\|_1 \leq \delta. \tag{2}$$

Here, the maps Enc, $\mathcal{E}$, and Dec do not act on register $\mathcal{R}$.

The first condition of the above definition enforces that the ground space of the Hamiltonian H of an approximate qLWC code is a q^k-dimensional codespace; it is the exactly the image of the encoding map Enc. The second condition corresponds to the approximate error-correcting condition, where we only require that the decoded state is *close* to the original state (i.e., we no longer insist that $\mathrm{Dec} \circ \mathcal{E} \circ \mathrm{Enc}$ is exactly the identity channel $\mathcal{I}$). Although there are few results on approximate quantum error-correcting codes, we do know that relaxing the exact decoding condition yields codes with properties that cannot be achieved using exact codes [31, 16, 11].

Our proof of Theorem 2 yields a construction of an approximate quantum LWC code with distance $\Omega(n)$.We believe this may be of independent interest.

▶ **Theorem 5** (Good approximate qLWC codes exist)**.** *For all error functions $\delta(n)$ there exist a family of $[[n,k,d]]_q$ approximate quantum LWC codes with the following parameters:*

$$\begin{aligned} \textit{Qudit dimension} \quad & q = O(1), \\ \textit{Error} \quad & \delta = \delta(n), \\ \textit{Locality} \quad & w = 3 + 2r, \\ \textit{Blocklength} \quad & n = O(rk), \\ \textit{Distance} \quad & d = \Omega(n/r) \end{aligned}$$

where

$$r = O\left(\frac{\log\left(1 + 4/\delta^2\right)}{\log n}\right) + 2. \tag{3}$$

Furthermore, the encoding and decoding maps for these codes are explicit and efficiently computable.

Observe that when $\delta(n) = 1/\mathsf{poly}(n)$, the parameter $r = O(1)$.

By comparison, the best-known qLDPC codes (of the stabilizer variety) with constant locality have distance bounded by $O(\sqrt{n \log n})$ [23]. Hastings constructs a qLDPC stabilizer code with constant locality that has distance $n^{1-\epsilon}$ for any $\epsilon > 0$, assuming a conjecture in high-dimensional geometry [26, 25]. Bacon, et al. were able to construct sparse subsystem codes (a generalization of stabilizer codes) with constant locality and distance $n^{1-o(1)}$ [9]. We note that, interestingly, the codes of [9] are constructed from fault-tolerant quantum circuits that implement a stabilizer code — this is similar to the way we construct our approximate qLWC codes!

2.4 Implications for NLTS, quantum PCP and quantum LDPC

Our investigation into noisy ground states and approximate low-weight check codes is motivated by a number of important open questions in quantum information theory: NLTS, quantum PCP, and quantum LDPC. We believe that our results help clarify the status of these open problems, and the relationships between them.

A separation between LNGS/SNGS and NLTS Hamiltonians.

First, our logarithmic circuit-depth lower bound for noisy ground states (Theorem 1) gives a strong separation between the notions of entanglement robustness in NLETS and NLTS: we showed that a one-dimensional local Hamiltonian is NLETS. However, it is easy to see that one-dimensional Hamiltonians (or any Hamiltonian on a constant-dimensional lattice) cannot be NLTS. To see this, consider taking a n-particle ground state $|\Psi\rangle$ of a 1D Hamiltonian H; divide up the n particles into contiguous chunks of length L. Let $\sigma = \rho_1 \otimes \rho_2 \otimes \cdots \otimes \rho_{n/L}$ where ρ_i is the reduced density matrix of $|\Psi\rangle$ on the i'th chunk. This state σ violates $O(n/L)$ terms of the Hamiltonian (since H is one-dimensional). Therefore, it is a ϵ-energy state of H for $L = \Theta(1/\epsilon)$. On the other hand, σ is a tensor product state that can be generated by $2^{O(1/\epsilon)}$-depth circuits, which is constant for constant ϵ. This indicates that the form of entanglement robustness as expressed in NLETS and in our LNGS/SNGS Hamiltonian constructions is much weaker than the entanglement robustness required by the NLTS conjecture and quantum PCP, where one has to look for Hamiltonians on high-dimensional geometries.

Quantum LDPC codes and the Quantum PCP conjecture.

Resolving the qPCP conjecture would likely involve a transformation from H to H' that (at the very least) has the property that exact ground states of H (or closeby states in trace distance) can be recovered from *low-energy* states of H'. It has been suggested that such a transformation would involve some kind of qLDPC code [22, 3, 26, 19]. In fact, it is believed that a special kind of qLDPC code, called a *quantum locally testable code (qLTC)*, is necessary [3]. However, the existence of qLTCs (or even qLDPC codes) with constant relative distance is a major open problem.

We believe our results on approximate quantum LWC codes present two take-home messages for the qPCP and qLDPC conjectures. First, it is important that a qPCP (or a qLTC) Hamiltonian be local, but it is *not* necessary that the Hamiltonian be bounded degree (meaning that each particle only participates in a few terms). The bounded degree condition is useful in the original context for qLDPCs, where an important motivation is to find fast decoding algorithms. In the context of qPCP/qLTC, however, decoding efficiency is not an immediate concern; thus resolving the qPCP conjecture *need not* resolve the qLDPC conjecture.

Second, we believe this gives evidence that considering codes other than stabilizer codes — such as approximate codes or subsystem codes — may be useful in the quest for both qPCP and qLDPC. Most work on qLDPC codes has focused on constructing CSS and stabilizer codes, but it may be fruitful to branch out beyond the CSS/stabilizer setting for the purposes of understanding the possibilities (or limits) of qPCP/qLDPC. For example, our qLWC codes are unconventional in a few ways: they are defined by non-commuting Hamiltonians, they only admit approximate recovery, and each particle participates in a large number of checks.

2.5 Open questions

We list a few open problems.

1. Are there SNGS Hamiltonians or (approximate) qLWC codes that are geometrically local (with respect to, say, the Euclidean metric)? Our construction of a one-dimensional NLGS Hamiltonian uses a simplification of a technique of Aharanov et. al. [5] of converting a quantum circuit into a two-dimensional local Hamiltonian. This technique works because of the specific structure of the circuit generating the $|\boxtimes\rangle$ state. In general, the transformation involves increasing the number of qudits by more than a constant factor. If this factor is $\Theta(n^\alpha)$, then the ground states are resilient to errors of size at most $n^{1-\alpha}$.
2. Is there a family of local Hamiltonians such that any *superposition* (not just convex combination) of low-error states have large circuit complexity? This notion is a generalization of a noisy state; such states have small *quantum Hamming distance* to the ground space. This is an interesting notion in the context of quantum locally testable codes (qLTCs) because low-energy states are equivalent to states with low quantum Hamming distance to the codespace (see [19] for definitions of quantum Hamming distance and qLTCs).
3. Are there applications of our qLWC constructions?
4. There has been a number of recent results about approximate quantum error-correcting codes in a variety of areas including many-body physics [12], the AdS/CFT correspondence [28], and quantum resource theories [27]. Could approximate error-correcting codes play a role in trying to resolve the qPCP and qLDPC conjectures?
5. Eldar and Harrow showed that quantum locally testable codes of the CSS type are NLTS [19]. Can this argument be extended to general qLTCs?

6. Is it possible for qLDPC codes (not necessarily stabilizer or exact error-correcting codes) to be defined as the codespace of a geometrically local Hamiltonian? There are a few no-go results that give limitations on codes living on lattices [13, 21], but they apply to special classes of codes such as stabilizer codes or locally-correctible codes. Our qLWC codes, by contrast, are neither.
7. Could the *combinatorial NLTS conjecture* be easier to prove than the NLTS conjecture? This conjecture posits that there exist a family of local Hamiltonians where states that have non-zero energy penalty on only a small constant fraction of Hamiltonian terms must have non-trivial circuit complexity.

Abstract

We consider the problem of maintaining a maximal independent set (MIS) in a dynamic graph subject to edge insertions and deletions. Recently, Assadi, Onak, Schieber and Solomon (STOC 2018) showed that an MIS can be maintained in *sublinear* (in the dynamically changing number of edges) amortized update time. In this paper we significantly improve the update time for *uniformly sparse graphs*. Specifically, for graphs with arboricity α, the amortized update time of our algorithm is $O(\alpha^2 \cdot \log^2 n)$, where n is the number of vertices. For low arboricity graphs, which include, for example, minor-free graphs as well as some classes of "real world" graphs, our update time is polylogarithmic. Our update time improves the result of Assadi *et al.* for all graphs with arboricity bounded by $m^{3/8-\epsilon}$, for any constant $\epsilon > 0$. This covers much of the range of possible values for arboricity, as the arboricity of a general graph cannot exceed $m^{1/2}$.

1 Introduction

The importance of the maximal independent set (MIS) problem is hard to overstate. In general, MIS algorithms constitute a useful subroutine for locally breaking symmetry between several choices. The MIS problem has intimate connections to a plethora of fundamental combinatorial optimization problems such as maximum matching, minimum vertex cover, and graph coloring. As a prime example, MIS is often used in the context of graph coloring, as all vertices in an independent set can be assigned the same color. As another important example, one can compute a large matching (approximating the maximum matching to within a factor arbitrarily close to 1) by applying maximal independent sets of longer and longer augmenting paths as observed by Hopcroft and Karp [11]. The seminal papers of Luby [18] and Linial [17] discuss additional applications of MIS. A non-exhaustive list of further direct and indirect

[1] Supported by the IBM Herman Goldstine Postdoctoral Fellowship.
[2] Supported by an NSF Graduate Fellowship.

applications of MIS includes resource allocation [25], leader election [7], the construction of network backbones [16, 12], and sublinear-time approximation algorithms [22].

In the 1980s, questions concerning the computational complexity of the MIS problem spurred a line of research that led to the celebrated parallel algorithms of Luby [18], and Alon, Babai, and Itai [1]. These algorithms find an MIS in $O(\log n)$ rounds without global coordination. More recently, Fischer and Noever [8] gave an even simpler greedy algorithm that considers vertices in random order and takes $O(\log n)$ rounds with high probability (see also an earlier result of Blelloch, Fineman, and Shun [4]).

In this work we continue the study of the MIS problem by considering the *dynamic setting*, where the underlying graph is not fixed, but rather evolves over time via edge updates. Formally, a *dynamic graph* is a graph sequence $\mathcal{G} = (G_0, G_1, \ldots, G_M)$ on n fixed vertices, where the initial graph is $G_0 = (V, \emptyset)$ and each graph $G_i = (V, E_i)$ is obtained from the previous graph G_{i-1} in the sequence by either adding or deleting a single edge. The basic goal in this context is to maintain an MIS in time significantly faster than it takes to recompute it from scratch following every edge update.

In STOC'18, Assadi, Onak, Schieber, and Solomon [2] gave the first sub-linear (amortized) update time fully dynamic algorithm for maintaining a MIS. Their amortized update time in $\min\{m^{3/4}, \Delta\}$, where m is the (dynamically changing) number of edges, and Δ is a fixed bound on the maximum degree of the graph. For graphs of high maximum degree, the update time of the algorithm of [2] decreases as the graph becomes sparser.

1.1 Our contribution

We focus on graphs that are "uniformly sparse" or "sparse everywhere", as opposed to the previous work by Assadi et al. [2] that considers unrestricted sparse graphs. We aim to improve the update time of [2] as a function of the "uniform sparsity" of the graph. This fundamental property of graphs has been studied in various contexts and names over the years, one of which is via the notion of *arboricity* [19, 20, 24]:

▶ **Definition 1.1.** The arboricity α of a graph $G = (V, E)$ is defined as $\alpha = \max_{U \subset V} \lceil \frac{|E(U)|}{|U|-1} \rceil$, where $E(U) = \{(u, v) \in E \mid u, v \in U\}$.

Thus a graph has bounded arboricity if every induced subgraph has bounded density. The family of low arboricity graphs contains, among others, bounded-degree graphs, all minor-closed graph classes (e.g., planar graphs, graphs with bounded treewidth), and randomly generated preferential attachment graphs. Moreover, it is believed that many real-world graphs such as the world wide web graph and social networks also have low arboricity [9].

A dynamic graph of *arboricity* α is a dynamic graph such that all graphs G_i have arboricity bounded by α. We prove the following result.

▶ **Theorem 1.2.** *For any dynamic n-vertex graph of arboricity α, an MIS can be maintained deterministically in $O(\alpha^2 \log^2 n)$ amortized update time.*

Theorem 1.2 improves the result of Assadi et al. for all graphs with arboricity bounded by $m^{3/8-\epsilon}$, for any constant $\epsilon > 0$. This covers much of the range of possible values for arboricity, as the arboricity of a general graph cannot exceed $\sqrt{m}$. Furthermore, we obtain polylogarithmic update time for graphs of polylogarithmic arboricity; in particular, for the family of constant arboricity graphs the update time is $O(\log^2 n)$.

1.2 Our and previous techniques

1.2.1 The dynamic edge orientation problem

Our algorithm utilizes two properties of arboricity α graphs: a) every subgraph contains a vertex of degree at most 2α, and b) there exists an orientation of the edges so that every vertex has out-degree at most α. The first property follows from Definition 1.1 and the second property is due to an alternate definition [20].

Brodal and Fagerberg [5] initiated the study of the dynamic edge orientation problem and gave an algorithm that maintains an $O(\alpha)$ out-degree orientation in amortized $O(\alpha + \log n)$ time; our algorithm uses the algorithm of [5] as a *black box*. (Refer to [14, 10, 13, 3] for additional results on the dynamic edge orientation problem.)

1.2.2 A comparison to Assadi et al.

As noted already by Assadi et al. [2], a central obstacle in maintaining an MIS in a dynamic graph is the maintenance of a detailed 2-hop neighborhood of a vertex. We need this information to update the MIS. Consider the "hard" case that an edge is added to the graph and as a result, one of its endpoints v is removed from the MIS. In this case, to maintain the maximality of the MIS we need to identify and add to the MIS all neighbors of v that are not adjacent to a vertex in the MIS. This means that for each of v's neighbors, we need to know whether it has a neighbor the MIS (other than v). Alas, dynamically maintaining the 2-neighborhood of each vertex *explicitly* is prohibitive.

To overcome this hurdle, we build upon the approach of Assadi et al. [2] and maintain an *incomplete* 2-hop neighborhood. Consequently, we may err by adding vertices to the MIS even though they are adjacent to MIS vertices. To fix this, we need to remove vertices from the MIS. The important property that we maintain, following [2], is that the number of added vertices is significantly higher than the number of removed vertices. Like Assadi et al., we use a potential function defined as the number of vertices not in the MIS. To amortize the update time, if an update takes a long time, then the size of the MIS increases substantially as a result. On the other hand, the size of the MIS can only decrease by one in each update. Our algorithm deviates significantly from Assadi et al. in several respects, described next.

I: An underlying bounded out-degree orientation. We apply the algorithm of [5] for efficiently maintaining a bounded out-degree orientation. Given such an orientation, we can maintain 2-hop neighborhoods with respect to *outgoing edges* explicitly, which helps significantly in the maintenance of the MIS. More specifically, the usage of a bounded out-degree orientation enables us to reduce the problem to a single nontrivial case.

II: An intricate "chain reaction". To handle the nontrivial case efficiently, we develop an intricate "chain reaction" process, initiated by adding vertices to the MIS that violate the independence property, which then forces the removal of other vertices from the MIS, which in turn forces the addition of other vertices, and so forth. Such a process may take a long time. However, a novel partition of a subset of the in-neighborhood of each vertex in the MIS into a logarithmic number of "buckets" (see below) together with a careful analysis allow for limiting this chain reaction to a logarithmic number of phases; upper bounding the number of phases is crucial for achieving a low update time. We note that such a careful analysis was not required in [2], where the chain reaction was handled by a simple recursive treatment.

III: A precise bucketing scheme. In order to achieve a sufficient increase in the size of the MIS, we need to carefully choose which vertices to add to the MIS so as to guarantee that at every step of the aforementioned chain reaction, even steps far in the future, we will be able to add enough vertices to the MIS. We achieve this by maintaining a precise *bucketing* of a carefully maintained subset of the in-neighborhood of each vertex, where vertices in larger-indexed buckets are capable of setting off longer and more fruitful chain reactions. At the beginning of the chain reaction, we add vertices in the larger-indexed buckets to the MIS, and gradually allow for vertices in smaller-indexed buckets to be added.

IV: A tentative set of MIS vertices. In contrast to the algorithm of Assadi et al., here we cannot iteratively choose which vertices to add to the MIS. Instead, we need to build a *tentative* set of vertices to add to the MIS, and only later prune this set to choose which vertices to add. If we do not carefully select vertices added to the MIS, we may not increase the size of the MIS sufficiently in order to amortize the cost of this process. To make sure that the size of the tentative set remains sufficiently large after the pruning, we make critical use of the first property of low arboricity graphs mentioned in Section 1.2.1. More details can be found at the beginning of Section 4.1.

1.2.3 A comparison to other previous work

Censor-Hillel, Haramaty, and Karnin [6] consider the problem of maintaining MIS in the dynamic distributed setting. They show that there is a randomized algorithm that requires only a constant number of rounds in expectation to update the maintained MIS, as long as the sequence of graph updates does not depend on the algorithm's randomness. This assumption is often referred to as *oblivious adversary*. As noted by Censor-Hillel et al., it is unclear whether their algorithm can be implemented with low total work in the centralized setting. This shortcoming is addressed by Assadi et al. [2] and by the current paper.

Kowalik and Kurowski [15] employ a dynamic bounded out-degree orientation to answer shortest path queries in (unweighted) planar graphs. Specifically, given a planar graph and a constant k, Kowalik and Kurowski maintain a data structure that can check in constant time whether two vertices are at distance at most k and if so produce a path of such length. This data structure is fully dynamic with polylogarithmic amortized update time. Like our data structure, their data structure maintains information on the 2-hop neighborhoods of the vertices, however, the nature of the 2-hop neighborhood information necessary for the two problems is different. For answering shortest path queries, one needs to maintain the *complete* 2-hop neighborhood. Whereas, to maintain an MIS, we only need to maintain *partial* information about the 2-hop neighborhood, however, the information that we store must be more detailed in the sense that for each 2-hop neighbor that we store, we need to know which 1-hop neighbors it is adjacent to. This is necessary because when we remove a vertex v from the MIS, we need to know which of v's neighbors have no neighbors in the MIS in order to know which vertices we need to add to the MIS.

1.3 Dynamic MIS vs. dynamic maximal matching

In the maximal matching problem, the goal is to compute a matching that cannot be extended by adding another edge. The problem is equivalent to finding an MIS in the line graph of the input graph. However, despite this very close relationship between the MIS and maximal matching problems, (efficiently) *maintaining* an MIS appears to be inherently harder than maintaining a maximal matching. As a first potential evidence, one may notice that there

is a significant gap in the performance of the naive algorithms for these dynamic problems. For the maximal matching problem, the naive algorithm works in $O(\Delta)$ time. For the MIS problem, the naive algorithm has to inspect not only neighbors of a vertex v that is being removed from MIS, but also their neighbors (i.e. its 2-hop neighborhood) in order to find out which neighbors need to be added to the MIS; as a result the update time is $O(m)$. Furthermore, the worst-case number of MIS changes (by any algorithm) may be as high as $\Omega(\Delta)$ [6, 2], whereas the worst-case number of changes to the maximal matching maintained by the naive algorithm is $O(1)$. Also, the available body of work on the dynamic MIS problem is significantly sparser than for the dynamic maximal matching problem.

It is therefore plausible that it may be hard to obtain, for MIS, a bound better than the best bounds known for the dynamic maximal matching problem. In particular, the state-of-the-art dynamic deterministic algorithm for maintaining a maximal matching has an update time of $O(\sqrt{m})$ [21], even in the amortized sense. Hence, in order to obtain update time bounds sub-polynomial in m, one may have to exploit the structure of the graph, and bounded arboricity graphs are a natural candidate. A maximal matching can be maintained in graphs of arboricity bounded by α with amortized update time $O(\alpha + \sqrt{\alpha \lg n})$ [21, 10]; as long as the arboricity is polylogarithmic in n, the amortized update time for maintaining a maximal matching is polylogarithmic. In this work we show that essentially the same picture applies to the seemingly harder problem of dynamic MIS.

2 Algorithm overview

Using a bounded out-degree orientation of the edges, a very simple algorithm suffices to handle edge updates that fall into certain cases. The nontrivial case occurs when we remove a vertex v from the MIS and need to determine which vertices in v's in-neighborhood have no neighbors in the MIS, and thus need to be added to the MIS. The in-neighborhood of v could be very large and it would be costly to spend even constant time per in-neighbor of v. Furthermore, it would be costly to maintain a data structure that stores for each vertex in the MIS which of its in-neighbors have no other neighbors in the MIS. Suppose we stored such a data structure for a vertex v. Then the removal of a vertex u from the MIS could cause the entirety of the common neighborhood of u and v to change their status in v's data structure. If this common neighborhood is large, then this operation is costly.

To address this issue, our algorithm does not even attempt to determine the exact set of neighbors of v that need to be added to the MIS. Instead, we maintain *partial* information about which vertices will need to be added to the MIS. Then, when we are unsure about whether we need to add a specific vertex to the MIS, we simply add it to the MIS and remove its conflicting neighbors from the MIS, which triggers a chain reaction of changes to the MIS. Despite the fact that this chain reaction may take a long time to resolve, we obtain an amortized time bound by using a potential function: the number of vertices not in the MIS. That is, we ensure that if we spend a lot of time processing an edge update, then the size of the MIS increases substantially as a result.

The core of our algorithm is to carefully choose which vertices to add to the MIS at each step of the chain reaction to ensure that the size of the MIS increases sufficiently. To accomplish this, we store an intricate data structure for each vertex which includes a partition of a subset of its in-neighborhood into numbered buckets. The key idea is to ensure that whenever we remove a vertex from the MIS, it has at least one full bucket of vertices, which we add to the MIS.

When we remove a vertex from the MIS whose top bucket is full of vertices, we begin the chain reaction by adding these vertices to the MIS (and removing the conflicting vertices from the MIS). In each subsequent step of the chain reaction, we process more vertices, and for each processed vertex, we add to the MIS the set of vertices in its *topmost full bucket*. To guarantee that every vertex that we process has at least one full bucket, we utilize an invariant (the "Main Invariant") which says that for all i, when we process a vertex whose bucket i is full, then in the next iteration of the chain reaction we will only process vertices whose bucket $i-1$ is full. This implies that if the number of iterations in the chain reaction is at most the number of buckets, then we only process vertices with at least one full bucket. To bound the number of iterations of the chain reaction, we prove that the number of processed vertices *doubles* at every iteration. This way, there cannot be more than a logarithmic number of iterations. Thus, by choosing the number of buckets to be logarithmic, we only process vertices with at least one full bucket, which results in the desired increase in the size of the MIS.

3 Algorithm setup

Let $\mathcal{M}$ be the MIS that we maintain. Our algorithm uses a dynamic edge orientation algorithm as a black box.

For each vertex v, let $N(v)$ denote the neighborhood of v, let $N^+(v)$ denote the out-neighborhood of v, and let $N^-(v)$ denote the in-neighborhood of v.

3.1 The trivial cases

For certain cases of edge updates, there is a simple algorithm to update the $\mathcal{M}$. Here, we introduce this simple algorithm and then describe the case that this algorithm does not cover.

▶ **Definition 3.1.** We say that a vertex v is *resolved* if either v is in $\mathcal{M}$ or a vertex in $N^-(v)$ is in $\mathcal{M}$. Otherwise we say that v is *unresolved*.

The data structure is simply that each vertex v stores a partition of its in-neighborhood into resolved vertices and unresolved vertices. To maintain this data structure, whenever a vertex v enters or exits $\mathcal{M}$, v notifies its 2-hop out-neighborhood.

DELETE(U,V):
- It cannot be the case that both u and v are in $\mathcal{M}$ since $\mathcal{M}$ is an independent set.
- If neither u nor v is in $\mathcal{M}$ then both must already have neighbors in $\mathcal{M}$ and we do nothing.
- If $u \in \mathcal{M}$ and $v \notin \mathcal{M}$, then we may need to add v to $\mathcal{M}$. If v is resolved, we do not add v to $\mathcal{M}$. Otherwise, we scan $N^+(v)$ and if no vertex in $N^+(v)$ is in $\mathcal{M}$, we add v to $\mathcal{M}$.

INSERT(U,V):
- If it is not the case that both u and v are in $\mathcal{M}$, then we do nothing and $\mathcal{M}$ remains maximal.
- If both u and v are in $\mathcal{M}$ we remove v from $\mathcal{M}$. Now, some of v's neighbors may need to be added to $\mathcal{M}$, specifically, those with no neighbors in $\mathcal{M}$. For each unresolved vertex $w \in N^+(v)$, we scan $N^+(w)$ and if $N^+(w) \cap \mathcal{M} = \emptyset$, then we add w to $\mathcal{M}$. For each resolved vertex $w \in N^-(v)$, we know not to add w to $\mathcal{M}$. On the other hand, for each unresolved vertex $w \in N^-(v)$, we do not know whether to add w to $\mathcal{M}$ and it could be costly to scan $N^+(w)$ for all such w. This simple algorithm does not handle the case where v has many unresolved in-neighbors.

In summary, the nontrivial case occurs when we delete a vertex v from $\mathcal{M}$ and v has many unresolved in-neighbors.

3.2 Data structure

As in the trivial cases, each vertex v maintains a partition of $N^-(v)$ into resolved vertices and unresolved vertices. In addition, we further refine the set of unresolved vertices. One important subset of the unresolved vertices in $N^-(v)$ is the *active set of* v, denoted A_v. As motivated in the algorithm overview, A_v is partitioned into b buckets $A_v(1), \ldots, A_v(b)$ each of size at most s. We will set b and s so that $b = \Theta(\log n)$ and $s = \Theta(\alpha)$.

The purpose of maintaining A_v is to handle the event that v is removed from $\mathcal{M}$. When v is removed from $\mathcal{M}$, we use the partition of A_v into buckets to carefully choose which neighbors of v to add to $\mathcal{M}$ to begin a chain reaction of changes to $\mathcal{M}$. For the rest of the vertices in A_v, we scan through them and update the data structure to reflect the fact that $v \notin \mathcal{M}$. This scan of A_v is why it is important that each active set is small (size $O(\alpha \log n)$).

One important property of active sets is that each vertex is in the active set of at most one vertex. For each vertex v, let $a(v)$ denote the vertex whose active set contains v. Let $B(v)$ denote the bucket of $A_{a(v)}$ that contains v.

For each vertex v the data structure maintains the following partition of $N^-(v)$:

- Z_v is the set of resolved vertices in $N^-(v)$.
- A_v (*the active set*) is a subset of the unresolved vertices in $N^-(v)$ partitioned into $b = \Theta(\log n)$ buckets $A_v(1), ..., A_v(b)$ each of size at most $s = \Theta(\alpha)$. A_v is empty if $v \notin \mathcal{M}$.
- P_v (*the passive set*) is the set of unresolved vertices in $N^-(v)$ in the active set of some vertex other than v. P_v is partitioned into b buckets $P_v(1), ..., P_v(b)$ such that each vertex $u \in P_v$ is in the set $P_v(i)$ if and only if $B(u) = i$.
- R_v (*the residual set*) is the set of unresolved vertices in $N^-(v)$ not in the active set of any vertex.

We note that while Z_v depends only on $\mathcal{M}$ and the orientation of the edges, the other three sets depend on internal choices made by the algorithm. In particular, for each vertex v, the algorithm picks at most one vertex $a(v)$ for which $v \in A_{a(v)}$ and this choice uniquely determines for every vertex $u \in N^+(v)$, which set (A_u, P_u, or R_u) v belongs to.

We now outline the purpose of the passive set and the residual set. Suppose a vertex v is removed from $\mathcal{M}$. We do not need to worry about the vertices in P_v because we know that all of these vertices are in the active set of a vertex in $\mathcal{M}$ and thus none of them need to be added to $\mathcal{M}$. On the other hand, we do not know whether the vertices in R_v need to be added to $\mathcal{M}$. We cannot afford to scan through them all and we cannot risk not adding them since this might cause $\mathcal{M}$ to not be maximal. Thus, we add them all to $\mathcal{M}$ and set off a chain reaction of changes to $\mathcal{M}$. That is, even though our analysis requires that we carefully choose which vertices of A_v to add to $\mathcal{M}$ during the chain reaction, it suffices to simply add every vertex in R_v to $\mathcal{M}$ (except for those with edges to other vertices we are adding to $\mathcal{M}$).

3.3 Invariants

We maintain several invariants of the data structure. The invariant most central to the overall argument is the Main Invariant (Invariant 6), whose purpose is outlined in the algorithm overview. The first four invariants follow from the definitions.

▶ **Invariant 1.** (Resolved Invariant). *For all resolved vertices v, for all $u \in N^+(v)$, v is in Z_u.*

▶ **Invariant 2.** (Orientation Invariant). *For all v, $Z_v \cup A_v \cup P_v \cup R_v = N^-(v)$.*

▶ **Invariant 3.** (Empty Active Set Invariant). *For all $v \notin \mathcal{M}$, A_v is empty.*

▶ **Invariant 4.** (Consistency Invariant).

- *If v is resolved, then for all vertices $u \in N^+(v)$, $v \notin A_u$.*
- *If v is unresolved then v is in A_u for at most one vertex $u \in N^+(v)$.*
- *If v is in the active set of some vertex u, then for all $w \in N^+(v) \setminus \{u\}$, v is in $P_w(i)$ where i is such that $B(v) = i$.*
- *If v is in the residual set for some vertex u, then for all $w \in N^+(v)$, v is in R_w.*

The next invariant says that the active set of a vertex is filled from lowest bucket to highest bucket and only then is the residual set filled.

▶ **Definition 3.2.** We say that a bucket $A_v(i)$ is *full* if $|A_v(i)| = s$. We say A_v is *full* if all b of its buckets are full.

▶ **Invariant 5.** (Full Invariant). *For all vertices v and all $i < b$, if $A_v(i)$ is not full then $A_v(i+1)$ is empty. Also, if A_v is not full then R_v is empty.*

The next invariant, the Main Invariant, says that if we were to move v from $A_{a(v)}$ to the active set of a different vertex u by placing v in the lowest non-full bucket of A_u, then $B(v)$ would not decrease.

▶ **Invariant 6.** (Main Invariant). *For all v, if $B(v) = i > 1$ then for all $u \in N^+(v) \cap \mathcal{M}$, $A_u(i-1)$ is full.*

4 Algorithm

The algorithm works in four phases.

1. Update $\mathcal{M}$.
2. Update the data structure.
3. Run a black-box edge orientation algorithm.
4. Update the data structure.

The data structure is completely static during phases 1 and 3.

4.1 Updating $\mathcal{M}$

When an edge (u, v) is deleted, we run the procedure DELETE(U,V) specified in the trivial cases section. When an edge (u, v) is inserted and it is not the case that both u and v are in $\mathcal{M}$, then we do nothing and $\mathcal{M}$ remains maximal. In the case that both u and v are in $\mathcal{M}$, we need to remove either u or v from $\mathcal{M}$ which may trigger many changes to $\mathcal{M}$.

The procedure of updating $\mathcal{M}$ happens in two stages. In the first stage, we iteratively build two sets of vertices, S^+ and S^-. Intuitively, S^+ is a subset of vertices that we intend to add to $\mathcal{M}$ and S^- is the set of vertices that we intend to delete from $\mathcal{M}$. The aforementioned chain reaction of changes to $\mathcal{M}$ is captured in the construction of S^+ and S^-. In the second stage we make changes to $\mathcal{M}$ according to S^+ and S^-. In particular, the set of vertices that we add to $\mathcal{M}$ contains a large subset of S^+ as well as some vertices not in S^+ and the set of vertices that we remove from $\mathcal{M}$ is a subset of S^-. In accordance with our goal of increasing

the size of $\mathcal{M}$ substantially, we ensure that S^+ is much larger than S^-. The most interesting part of updating $\mathcal{M}$ is captured in the first stage. We defer the description of the second stage to the full version [23].

Why is it important to build S^+ before choosing which vertices to add to $\mathcal{M}$? The answer is that it is important that we add a *large* subset of S^+ to $\mathcal{M}$ since our goal is to increase the size of $\mathcal{M}$ substantially. We find this large subset of S^+ by finding a large MIS in the graph induced by S^+, which exists (and can be found in linear time) because the graph has bounded arboricity (see the full version for details [23]). Suppose that instead of iteratively building S^+, we tried to iteratively add vertices directly to $\mathcal{M}$ in a greedy fashion. This could result in only very few vertices successfully being added to $\mathcal{M}$. For example, if we begin by adding the center of a star graph to $\mathcal{M}$ and subsequently try to add the leaves of the star, we will not succeed in adding any of the leaves to $\mathcal{M}$. On the other hand, if we first add the vertices of the star to S^+ then we can find a large MIS in the star (the leaves) to add it to $\mathcal{M}$.

For the rest of this section we consider an edge insertion (u, v).

4.1.1 Stage 1: Constructing S^+ and S^-

A key property of the construction is that S^+ is considerably larger than S^-:

▶ **Lemma 4.1.** *If* $|S^-| > 1$ *then* $|S^+| \geq 4\alpha|S^-|$.

After constructing S^+ and S^- we will add at least $\frac{|S^+|}{2\alpha}$ vertices to $\mathcal{M}$ and remove at most $|S^-|$ vertices from $\mathcal{M}$. Thus, Lemma 4.1 implies that $\mathcal{M}$ increases by $\Omega(\frac{|S^+|}{\alpha})$.

To construct S^+ and S^-, we define a recursive procedure Process(w) which adds at least one full bucket of A_w to S^+. A key idea in the analysis is to guarantee that for every call to Process(w), A_w indeed has at least one full bucket.

Algorithm description

We say that a vertex $w \in S^-$ has been *processed* if Process(w) has been called and otherwise we say that w is *unprocessed*. We maintain a partition of S^- into the processed set and the unprocessed set and we maintain a partition of the set of unprocessed vertices w into two sets based on whether A_w is full or not. We also maintain a queue $\mathcal{Q}$ of vertices to process, which is initially empty. Recall that (u, v) is the inserted edge and both u and v are in $\mathcal{M}$. The algorithm is as follows.

First, we add v to S^-. Then, if A_v is not full, we terminate the construction of S^+ and S^-. Otherwise, we call Process(v).

Process(w):

1. If A_w is full, then add all vertices in $A_w(b) \cup R_w$ to S^+. If A_w is not full, then let i be the largest full bucket of A_w and add all vertices in $A_w(i)$ and $A_w(i+1)$ to S^+. We will claim that such an i exists (Lemma 4.2).
2. For all vertices x added to S^+ in this call to Process, we add $N^+(x) \cap \mathcal{M}$ to S^-.
3. If S^- contains an unprocessed vertex x with full A_x, we call Process(x).

When a call to Process terminates, including the recursive calls, we check whether Lemma 4.1 is satisfied (that is, whether $|S^+| \geq 4\alpha|S^-|$), and if so, we terminate. Otherwise, if $\mathcal{Q}$ is not empty, we let w be the next vertex in $\mathcal{Q}$ and call Process(w). If $\mathcal{Q}$ is empty we enqueue a new batch of vertices to $\mathcal{Q}$. This batch consists of the set of all unprocessed vertices in S^-. We will claim that such vertices exist (Lemma 4.2).

▶ Remark. The reason we terminate without calling PROCESS(v) if A_v is not full (i.e. R_v is empty) is because R_v is the only set for which we cannot afford to determine whether or not each vertex has another neighbor in $\mathcal{M}$ (besides v): We know that each vertex $w \in Z_v \cup P_v$ has another neighbor in $\mathcal{M}$, and the set A_v is small enough to scan. For the same reason, step 3 of PROCESS is necessary because it ensures that for every vertex w in S^-, all vertices in R_w are in S^+. If this weren't the case and we removed a vertex w in S^- from $\mathcal{M}$, we might be left in the "hard case" of needing to deal with R_w.

Lemma 4.1 follows from the algorithm specification: either the algorithm terminates immediately with $S^- = \{v\}$ or the algorithm terminates according to the termination condition, which is that Lemma 4.1 is satisfied.

Several steps in the algorithm (Step 2 of PROCESS(w) and the last sentence of the algorithm specification) rely on Lemma 4.2:

▶ **Lemma 4.2.**
1. *If we call* PROCESS*(w), then A_w has at least one full bucket.*
2. *Every batch of vertices that we enqueue to $\mathcal{Q}$ is nonempty.*

Proof of Lemma 4.2

Let epoch 1 denote the period of time until the first batch of vertices has been enqueued to $\mathcal{Q}$. For all $i > 1$, let epoch i denote the period of time from the end of epoch $i-1$ to when the i^{th} batch of vertices has been enqueued to $\mathcal{Q}$.

To prove Lemma 4.2, we prove a collection of lemmas that together show that (i) Lemma 4.2 holds for all calls to PROCESS before epoch b ends (recall that b is the number of buckets) and (ii) the algorithm terminates before the end of epoch b.

For all i, let p_i and u_i be the number of processed and unprocessed vertices in S^- respectively, when epoch i ends. Let S_i^+ and S_i^- be the sets S^+ and S^- respectively when epoch i ends. Recall that s is the size of a full bucket. Let $s = 8\alpha$ and let $b = \log_2 n + 1$.

▶ **Lemma 4.3.** *For all $1 \le j \le b$, every time we call* PROCESS*(w) during epoch j, $A_w(b-j+1)$ is full.*

Proof. We proceed by induction on j.
Base case. If $j = 1$ then the algorithm only calls PROCESS(w) on vertices w with full A_w and thus full $A_w(b)$.
Inductive hypothesis. Suppose that during epoch j, all of the processed vertices have full $A_w(b-j+1)$.
Inductive step. We will show that during epoch $j+1$, all of the processed vertices have full $A_w(b-j)$. We first note that during PROCESS(w), the algorithm only adds the vertices in the topmost full bucket of A_w to S^+. Thus, the inductive hypothesis implies that at the end of epoch j for all vertices $x \in S^+$, $B(x) \ge b-j+1$.

Then, by the Main Invariant, at the end of epoch j, for all $x \in S^+$ and all $y \in N^+(x) \cap \mathcal{M}$, $A_y(b-j)$ is full. By construction, the only vertices in S^- other than v are those in $N^+(x) \cap \mathcal{M}$ for some $x \in S^+$. Thus, at the end of epoch j, for all vertices $y \in S^-$, $A_y(b-j)$ is full. During epoch $j+1$, the set of vertices that we process consists only of vertices w that are either in S^- at the end of epoch j or have full A_w. We have shown that all of these vertices w have full $A_w(b-j)$. ◀

▶ **Lemma 4.4.** *For all $1 \le j \le b$, $|S_j^+| \ge p_j s$.*

Proof. By Lemma 4.3, for all calls to PROCESS(w) until the end of epoch j, A_w has at least one full bucket. During each call to PROCESS(w), the algorithm adds at least one full bucket (of size s) of A_w to S^+. By the Consistency Invariant, (i) every vertex is in the active set of at most one vertex and (ii) if a vertex w appears in the active set of some vertex, then w is not in the residual set of any vertex. The only vertices added to S^+ are those in some active set or some residual set, so every vertex in some active set that is added to S^+, is added at most once. Thus, for each processed vertex, there are at least s distinct vertices in S^+. ◀

▶ **Lemma 4.5.** *For all $1 \leq j \leq b$, $p_j < u_j$. That is, there are more unprocessed vertices than processed vertices.*

Proof. At the end of epoch j, Lemma 4.1 is not satisfied because if it were then the algorithm would have terminated. That is, $|S_j^+| < 4\alpha|S_j^-|$. Combining this with Lemma 4.4 and the fact that $p_j + u_j = |S_j^-|$, we have $p_j s < 4\alpha(p_j + u_j)$. Choosing $s = 8\alpha$ completes the proof. ◀

▶ **Lemma 4.6.** *For all $1 \leq j \leq b$, $p_j > 2p_{j-1}$. That is, the number of processed vertices more than doubles during each epoch.*

Proof. At the end of epoch $j-1$, we add all unprocessed vertices to $\mathcal{Q}$. As a result of calling PROCESS on each vertex in $\mathcal{Q}$, the number of processed vertices increases by u_{j-1} by the end of epoch j. That is, $p_j \geq p_{j-1} + u_{j-1}$. By Lemma 4.5, $p_{j-1} < u_{j-1}$, so $p_j > 2p_{j-1}$. ◀

We apply these lemmas to complete the proof of Lemma 4.2:

1. In epoch 1 we process at least one vertex, so $p_1 \geq 1$. By Lemma 4.6, $p_j > 2p_{j-1}$. Thus, $p_j \geq 2^{j-1}$. If $j = b = \log_2 n + 1$, then $p_j > n$, a contradiction. Thus, the algorithm never reaches the end of epoch b. Then, by Lemma 4.3, every time we call PROCESS(w), A_w has at least one full bucket.
2. Suppose by way of contradiction that we enqueue no vertices to $\mathcal{Q}$ at the end of some epoch $1 \leq j \leq b$. Then, $u_j = 0$. By Lemma 4.5, $p_j < u_j$, so $p_j < 0$, a contradiction.

5 Analysis

In this section we present the most interesting part of the analysis and defer the rest of the analysis to the full version [23]. When a vertex v is added to $\mathcal{M}$, A_v is empty and needs to be populated in order to satisfy the Main Invariant. This process is the bottleneck of the runtime and we analyze it here.

We begin by analyzing the runtime of two basic processes that happen while updating the data structure: adding a vertex to some active set (Lemma 5.1) and removing a vertex from some active set (Lemma 5.2).

Recall that our algorithm uses a dynamic edge orientation algorithm as a black box. Let T be the amortized update time of this algorithm and let D be the out-degree of the orientation. Ultimately, we will apply the algorithm of Brodal and Fagerberg [5] to get $D = O(\alpha)$ and $T = O(\alpha + \log n)$.

▶ **Lemma 5.1.** *Suppose vertex v is not in any active set. Adding v to some active set and updating the data structure accordingly takes time $O(D)$.*

Proof. When we add a vertex v to some $A_u(i)$, for all $w \in N^+(v)$ this could causes a violation to the Consistency Invariant. To remedy this, it suffices to remove v from whichever set it was previously in with respect to w (which is not A_w) and add it to $P_w(i)$. ◀

▶ **Lemma 5.2.** *Removing a vertex v from some active set A_u and updating the data structure accordingly takes time $O(D \log n)$.*

Proof. When we remove a vertex v from some $A_u(i)$, this leaves bucket $A_u(i)$ not full so the Full Invariant might be violated. To remedy this, we move a vertex, the *replacement vertex*, from a higher bucket or the residual set to $A_u(i)$. That is, the replacement vertex w is chosen to be any arbitrary vertex from $R_u \cup A_u(i+1) \cup \cdots \cup A_u(b) \cup P_u(i+1) \cup \cdots \cup P_u(b)$. We can choose a vertex from this set in constant time by maintaining a list of all non-empty $P_x(i)$ and $A_x(i)$ for each vertex x. If w is chosen from P_u, we remove w from $A_{a(w)}$ before adding w to $A_u(i)$.

The removal of w from its previous bucket in its previous active set may leave this bucket not full, so again the Full Invariant might be violated and again we remedy this as described above, which sets off a chain reaction. The chain reaction terminates when either there does not exist a viable replacement vertex or until the replacement vertex comes from the residual set. Since the number of the bucket that we choose the replacement vertex from increases at every step of this process, the length of this chain reaction is at most b.[3]

For each vertex v that we add to an active set, we have already removed v from its previous active set, so Lemma 5.1 applies. Overall, we move at most b vertices to a new bucket and by Lemma 5.1, for each of these b vertices we spend time $O(D)$. Thus, the runtime is $O(bD) = O(D \log n)$. ◀

▶ **Lemma 5.3.** *The time to update the data structure in response to a violation of the Main Invariant triggered the addition of a single vertex to $\mathcal{M}$ is $O(D\alpha \log^2 n)$.*

Proof. To satisfy the Main Invariant, we need to populate A_v. We fill A_v in order from bucket 1 to bucket b. First, we add the vertices in R_v until either A_v is full or R_v becomes empty. If R_v becomes empty, then we start adding the vertices of $P_v(i)$ in order from $i = b$ to $i = 1$; however, we only add vertex u to A_v if this causes $B(u)$ to decrease. Once we reach a vertex u in P_v where moving u to the lowest numbered non-full bucket of A_v does not cause $B(u)$ to decrease, then we stop populating A_v. Each time we add a vertex u to A_v from P_v, we first remove u from $A_{a(u)}$ and apply Lemma 5.2. Also, each time we add a vertex to A_v, we apply Lemma 5.1. We note that this method of populating A_v is consistent with the Main Invariant.

We add at most $sb = O(\alpha \log n)$ vertices to A_v and for each one we could apply Lemmas 5.2 and 5.1 in succession. Thus, the total time is $O(\alpha D \log^2 n)$. ◀

Abstract

Osborne's iteration is a method for balancing $n \times n$ matrices which is widely used in linear algebra packages, as balancing preserves eigenvalues and stabilizes their numeral computation. The iteration can be implemented in any norm over $\mathbb{R}^n$, but it is normally used in the L_2 norm. The choice of norm not only affects the desired balance condition, but also defines the iterated balancing step itself.

In this paper we focus on Osborne's iteration in any L_p norm, where $p < \infty$. We design a specific implementation of Osborne's iteration in any L_p norm that converges to a strictly ϵ-balanced matrix in $\tilde{O}(\epsilon^{-2}n^9K)$ iterations, where K measures, roughly, the *number of bits* required to represent the entries of the input matrix.

This is the first result that proves a variant of Osborne's iteration in the L_2 norm (or any L_p norm, $p < \infty$) strictly balances matrices in polynomial time. This is a substantial improvement over our recent result (in SODA 2017) that showed weak balancing in L_p norms. Previously, Schulman and Sinclair (STOC 2015) showed strict balancing of another variant of Osborne's iteration in the L_∞ norm. Their result does not imply any bounds on strict balancing in other norms.

1 Introduction

1.1 Problem Statement and Motivation

This paper analyzes the convergence properties of Osborne's celebrated iteration [10] for balancing matrices. Given a norm $\|\cdot\|$ in $\mathbb{R}^n$, an $n \times n$ matrix A is balanced if and only if for all i, the i-th row of A and the i-th column of A have the same norm. The problem of balancing a matrix A is to compute a diagonal matrix D such that DAD^{-1} is balanced. The main motivation behind this problem is that balancing a matrix does not affect its eigenvalues, and balancing matrices in the L_2 norm increases the numerical stability of eigenvalue computations [10, 9]. Balancing also has a positive impact on the computational time needed for computing eigenvalues ([9, section 1.4.3]). In practice, it is sufficient to get a good approximation to the balancing problem. For $\alpha \geq 1$, a matrix $B = DAD^{-1}$ is an α-approximation to the problem of balancing A if and only if for all i, the ratio between the maximum and minimum of the norms of the i-th row and column is bounded by α. It is desirable to achieve $\alpha = 1 + \epsilon$ for some small $\epsilon > 0$. A matrix B that satisfies this relaxed balancing condition is also said to be strictly ϵ-balanced.

Osborne's iteration attempts to compute the diagonal matrix D by repeatedly choosing an index i and balancing the i-th row and column (this multiplies the i-th diagonal entry of D appropriately). Osborne proposed this iteration in the L_2 norm, and suggested round-robin choice of index to balance. However, other papers consider the iteration in other norms and propose alternative choices of index to balance [12, 15, 11]. Notice that a change of norm not only changes the target balance condition, but also changes the iteration itself, as in each step a row-column pair is balanced in the given norm. An implementation of Osborne's iteration is used in most numerical algebra packages, including MATLAB, LAPACK, and EISPACK, and is empirically efficient (see [9, 16] for further background). The main theoretical question about Osborne's iteration is its rate of convergence. How many rounds of the iteration are provably sufficient to get a strictly ϵ-balanced matrix?

1.2 Our Results

We consider Osborne's iteration in L_p norms for finite p. We design a new simple choice of the iteration (i.e., a rule to choose the next index to balance), and we prove that this variant provides a polynomial time approximation scheme to the balancing problem. More specifically, we show that in the L_1 norm, our implementation converges to a strictly ϵ-balanced matrix in $O\left(\epsilon^{-2} n^9 \log(wn/\epsilon) \log w / \log n\right)$ iterations, where $\log w$ is a lower bound on the number of bits required to represent the entries of A (exact definitions await Section 2). The time complexity of these iterations is $O\left(\epsilon^{-2} n^{10} \log(wn/\epsilon) \log w\right)$ arithmetic operations over $O(n \log(w/\epsilon))$-bit numbers. This result implies similar bounds for any L_p norm where p is fixed, and in particular the important case of $p = 2$. This is because applying Osborne's iteration in the L_p norm to $A = (a_{ij})_{n \times n}$ is equivalent to applying the iteration in the L_1 norm to $(a_{ij}^p)_{n \times n}$. Of course, the bit representation complexity of the matrix, and thus the bound on the number of iterations, grows by a factor of p.

Our results give the first theoretical analysis that indicates that Osborne's iteration in the L_2 norm, or any L_p norm for finite p, is indeed efficient in the worst case. This partially resolves the question that has been open since 1960 because we actually analyze a variant of Osborne's iteration which is different from the original iteration in the way it picks the next index to balance. Previously, Schulman and Sinclair [15] analyzed yet another variant of Osborne's iteration and answered this question only for the L_∞ norm. Concerning the

convergence rate for the L_p norms discussed here, we recently published a result [11] that considers a much weaker notion of approximation. The previous result only shows the rate of convergence to a matrix that is approximately balanced in an average sense. The matrix might still have row-column pairs that are highly unbalanced. The implementations in the common numerical linear algebra packages use as a stopping condition the strict notion of balancing, and not this weaker notion. We discuss previous work in greater detail below.

1.3 Previous Work

Osborne [10] studied the L_2 norm version of matrix balancing, proved the uniqueness of the L_2 solution, designed the iterative algorithm discussed above, and proved that it converges in the limit to a balanced matrix (without bounding the convergence rate). Parlett and Reinsch [12] generalized Osborne's iteration to other norms. Their implementation is the one widely used in practice (see Chen [3, Section 3.1], also the book [13, Chapter 11] and the code in [1]). Grad [6] proved convergence in the limit for the L_1 version (again without bounding the running time), and Hartfiel [7] showed that the L_1 solution is unique. Eaves et al. [5] gave a characterization of balanceable matrices. Kalantari et al. [8] gave an algorithm for ϵ-balancing a matrix in the L_1 norm. The algorithm reduces the problem to unconstrained convex optimization and uses the ellipsoid algorithm to approximate the optimal solution. This generates a weakly ϵ-balanced matrix, which satisfies the following definition. Given $\epsilon > 0$, a matrix $A = (a_{ij})_{n\times n}$ is weakly ϵ-balanced if and only if $\sqrt{\sum_{i=1}^{n}(\|a_{\cdot,i}\| - \|a_{i,\cdot}\|)^2} \leq \epsilon \cdot \sum_{i,j} |a_{i,j}|$. Compare this with the stronger condition of being strictly ϵ-balanced, which we use in this paper, and numerical linear algebra packages use as a stopping condition. This condition requires that for every $i \in \{1, 2, \ldots, n\}$, $\max\{\|a_{\cdot,i}\|, \|a_{i,\cdot}\|\} \leq (1+\epsilon) \cdot \min\{\|a_{\cdot,i}\|, \|a_{i,\cdot}\|\}$. In L_∞, Schneider and Schneider [14] gave a polynomial time algorithm that exactly balances a matrix. The algorithm does not use Osborne's iteration. Its running time was improved by Young et al. [17]. Both algorithms rely on iterating over computing a minimum mean cycle in a weighted strongly connected digraph, then contracting the cycle. Schulman and Sinclair [15] were the first to provide a quantitative bound on the running time of Osborne's iteration. They proposed a carefully designed implementation of Osborne's iteration in the L_∞ norm that strictly ϵ-balances an $n \times n$ matrix A in $O(n^3 \log(\varrho n/\epsilon))$ iterations, where ϱ measures the initial L_∞ imbalance of A. Their proof is an intricate case analysis. Following that work, in [11] we showed that several implementations of Osborne's iteration in L_p norms, including the original implementation, converge to a weakly ϵ-balanced matrix in polynomial time (which, in fact, can be either nearly linear in number of non-zero entries of matrix A or nearly linear in $1/\epsilon$). Very recently, Cohen et al. [4] gave an interior point algorithm that weakly ϵ-balances matrices in the L_1 norm in time $\tilde{O}(m^{3/2} \log(1/\epsilon))$, where m is the number of non-zero entries of A. Their results also apply to matrix scaling, a problem similar to matrix balancing, for which Allen-Zhu et al. [2] independently gave similar results. Notice that in the results of [4], due to the logarithmic dependence on ϵ one can choose ϵ that is exponentially small in the input representation, and thus get an algorithm for strict balancing with better worst case running time than our claimed analysis of Osborne's iteration. We note, however, that the purpose of our analysis is not to present a new algorithm for matrix balancing, but rather to provide some worst case guarantee for the time it takes some implementation of Osborne's iteration to achieve strict balancing. Osborne's iteration and strict balancing are the heuristic and stopping condition used in practice to balance matrices. We also note that by the lower bound proved in our previous paper [11], Osborne's iteration does not guarantee convergence in time polynomial in $\log(1/\epsilon)$ (the lower bound is $\Omega(1/\sqrt{\epsilon})$).

1.4 Our Contribution

The result of [11] is derived by observing that any implementation of Osborne's iteration can be interpreted as an application of coordinate descent to optimize the convex function from [8]. This is the starting point of this paper, but to make the approach guarantee strict balancing, we need to revise substantially previous implementations using novel algorithmic ideas. Nevertheless, the implementation itself remains a rather simple rule for choosing the next index to balance.

The main difficulty with respect to previous work is the following. The convergence rate of coordinate descent can be bounded effectively as long as there is a choice of coordinate (i.e., index) for which the drop in the objective function in a single step is non-negligible compared with the current objective value. But if this is not the case, then one can argue only about the balance of each index relative to the sum of norms of all rows and columns. Indices that have relatively heavy weight (row norm + column norm) will indeed be balanced at this point. However, light-weight indices may be highly unbalanced. The naive remedy to this problem is to work down by scales. After balancing the matrix globally, heavy-weight indices are balanced, approximately, so they can be left alone, deactivated. Now there are light-weight indices that have become heavy-weight with respect to the remaining active nodes, so we can continue balancing the active indices until the relatively heavy-weight among them become approximately balanced, and so forth. The problem with the naive solution is that balancing the active indices shifts the weights of both active and inactive indices, and they move out of their initial scale. This movement need not complicate the balancing rule—we can keep balancing far-from-balanced nodes in the current scale. However, if the scale sets of indices keep changing, it is harder to argue that the process converges. Shifting between scales is precisely what our algorithm and proof deal with. Light-weight indices that have become heavy-weight are easy to handle. They can keep being active. Heavy-weight indices that have become light-weight cannot continue to be inactive, because they are no longer guaranteed to be approximately balanced. Thus, in order to analyze convergence effectively, we need to bound the number (and global effect on weight) of these reactivation events.

2 Preliminaries

The input is a real square matrix $A = (a_{ij})_{n\times n}$. We denote the i-th row of such a matrix by $a_{i,\cdot}$ and the i-th column by $a_{\cdot,i}$. We also use the notation $[n] = \{1, 2, \ldots, n\}$. The matrix A is *balanced* in the L_p norm iff $\|a_{\cdot,i}\|_p = \|a_{i,\cdot}\|_p$ for every index $i \in [n]$. Since the condition for being balanced depends neither on the signs of the entries of A nor on the diagonal values, we will assume without loss of generality that A is non-negative with zeroes on the diagonal.

An invertible diagonal matrix $D = \mathtt{diag}(d_1, \cdots, d_n)$ *balances* A in the L_p norm iff DAD^{-1} is balanced in the L_p norm. A matrix A is *balanceable* iff there exists an invertible diagonal matrix D that balances A. Balancing a matrix $A = (a_{ij})_{n\times n}$ in the L_p norm is equivalent to balancing the matrix $(a_{ij}^p)_{n\times n}$ in the L_1 norm. Therefore, for the rest of the paper we focus on balancing matrices in the L_1 norm.

We use $a_{\min}$ to denote the minimum non-zero entry of A. We also define $w = \frac{1}{a_{\min}} \cdot \sum_{ij} a_{ij}$.

▶ **Definition 1.** Given $\epsilon > 0$ and an $n \times n$ matrix A, we say that the index i of A (where $i \in [n]$) is *ϵ-balanced* iff

$$\frac{\max\{\|a_{\cdot,i}\|_1, \|a_{i,\cdot}\|_1\}}{\min\{\|a_{\cdot,i}\|_1, \|a_{i,\cdot}\|_1\}} \leq 1 + \epsilon.$$

We say that A is *strictly ϵ-balanced* iff every index i of A is ϵ-balanced.

Any implementation of Osborne's iteration can be thought of as computing vectors $\mathbf{x^{(t)}} \in \mathbb{R}^n$ for $t = 1, 2, \ldots$, where iteration t is applied to the matrix $(a_{ij}^{(t)}) = DAD^{-1}$ for $D = \mathtt{diag}(e^{x_1^{(t)}}, e^{x_2^{(t)}}, \ldots, e^{x_n^{(t)}})$. Thus, for all i, j, $a_{ij}^{(t)} = a_{ij} \cdot e^{x_i^{(t)} - x_j^{(t)}}$. Initially, $\mathbf{x}^{(1)} = (0, 0, \ldots, 0)$. A balancing step of the iteration chooses an index i, then sets $x_i^{(t+1)} = x_i^{(t)} + \frac{1}{2} \cdot \left(\ln \|a_{.,i}^{(t)}\|_1 - \ln \|a_{i,.}^{(t)}\|_1 \right)$, and for all $j \neq i$, keeps $x_j^{(t+1)} = x_j^{(t)}$. For $\mathbf{x} \in \mathbb{R}^n$, we denote the sum of entries of the matrix DAD^{-1} for $D = \mathtt{diag}(e^{x_1}, e^{x_2}, \ldots, e^{x_n})$ by $f(\mathbf{x}) = f_A(\mathbf{x}) = \sum_{ij} a_{ij} \cdot e^{x_i - x_j}$. For any $n \times n$ non-negative matrix $B = (b_{ij})$, we denote by G_B the weighted directed graph with node set $\{1, 2, \ldots, n\}$, arc set $\{(i, j) : b_{ij} > 0\}$, where an arc (i, j) has weight b_{ij}. We will assume henceforth that the undirected version of G_A is connected, otherwise we can handle each connected component separately. We quote a few useful lemmas. The references contain the proofs.

▶ **Lemma 2** (Theorem 1 in Kalantari et al. [8]). *The input matrix A is balanceable if and only if G_A is strongly connected. Moreover, DAD^{-1} is balanced in the L_1 norm if and only if $D = \mathtt{diag}(e^{x_1^*}, e^{x_2^*}, \ldots, e^{x_n^*})$, where $\mathbf{x}^* = (x_1^*, x_2^*, \ldots, x_n^*)$ minimizes $f(\mathbf{x})$ over $\mathbf{x} \in \mathbb{R}^n$.*

Notice that f is a convex function and the gradient $\nabla f(\mathbf{x})$ of f at $\mathbf{x}$ is given by

$$\frac{\partial f(\mathbf{x})}{\partial x_i} = \sum_{j=1}^{n} a_{ij} \cdot e^{x_i - x_j} - \sum_{j=1}^{n} a_{ji} \cdot e^{x_j - x_i},$$

the difference between the total weight of arcs leaving node i and the total weights of arcs going into node i in the graph of DAD^{-1} for $D = \mathtt{diag}(e^{x_1}, e^{x_2}, \ldots, e^{x_n})$. If DAD^{-1} is balanced then the arc weights $a_{ij} \cdot e^{x_i - x_j}$ form a valid circulation in the graph G_A, since the gradient has to be 0. Some properties of f are given in the following lemma.

▶ **Lemma 3** (Lemmas 2.1 and 2.2 in Ostrovsky et al. [11]). *If $\mathbf{x}'$ is derived from $\mathbf{x}$ by balancing index i of a matrix $B = (b_{ij})_{n \times n}$, then $f(\mathbf{x}) - f(\mathbf{x}') = (\sqrt{\|b_{.,i}\|_1} - \sqrt{\|b_{i,.}\|_1})^2$. Also, for all $\mathbf{x} \in \mathbb{R}^n$, $f(\mathbf{x}) - f(\mathbf{x}^*) \leq \frac{n}{2} \cdot \|\nabla f(\mathbf{x})\|_1$.*

We also need the following absolute bounds on the arc weights.

▶ **Lemma 4** (Lemma 3.2 in Ostrovsky et al. [11]). *Suppose that a matrix B is derived from a matrix A through a sequence of balancing operations. Then, for every arc (i, j) of G_B,*

$$\left(\frac{a_{\min}}{\sum_{ij} a_{ij}} \right)^n \cdot \sum_{ij} a_{ij} \leq b_{ij} \leq \sum_{ij} a_{ij}.$$

(Notice that the arcs of G_B are identical to the arcs of G_A.)

Finally, we prove the following global condition on indices being ϵ-balanced.

▶ **Lemma 5.** *Consider a matrix $B = DAD^{-1} = (b_{ij})_{n \times n}$, where $D = \mathtt{diag}(e^{x_1}, e^{x_2}, \ldots, e^{x_n})$, that was derived from A by a sequence of zero or more balancing operations. Let $\epsilon \in (0, 1/2]$, and put $\epsilon' = \frac{\epsilon^2}{64n^4}$. Suppose that $\|\nabla f_A(\vec{0})\|_1 \leq \epsilon' \cdot f_A(\vec{0})$. Then, for every $i \in [n]$ we have the following implication. If $\|b_{.,i}\|_1 + \|b_{i,.}\|_1 \geq \frac{1}{8n^3} \cdot f_A(\mathbf{x})$, then index i is ϵ-balanced in B.*

Proof. We will show the contrapositive claim that if a node is not ϵ-balanced then it must have low weight (both with respect to B). Let i be an index that is not ϵ-balanced in B. Without loss of generality we may assume that the in-weight is larger than the out-weight,

so $\|b_{.,i}\|_1/\|b_{i,.}\|_1 > 1+\epsilon$. Consider what would happen if we balance index i in B, yielding a vector $\mathbf{x}'$ that differs from $\mathbf{x}$ only in the i-th coordinate.

$$\begin{aligned} f_A(\mathbf{x}) - f_A(\mathbf{x}') &= \left(\sqrt{\|b_{.,i}\|_1} - \sqrt{\|b_{i,.}\|_1}\right)^2 \\ &> \|b_{.,i}\|_1 \cdot \left(1 - \sqrt{\frac{1}{1+\epsilon}}\right)^2 \\ &> \frac{\epsilon^2}{16} \cdot (\|b_{.,i}\|_1 + \|b_{i,.}\|_1)\,, \end{aligned} \tag{1}$$

where the equation follows from Lemma 3 and the last inequality uses the fact that $\epsilon \leq \frac{1}{2}$. On the other hand, we have

$$\begin{aligned} f_A(\mathbf{x}) - f_A(\mathbf{x}') &\leq f_A(\vec{0}) - f(\mathbf{x}^*) \\ &\leq \frac{n}{2} \cdot \|\nabla f_A(\vec{0})\|_1 \\ &\leq \frac{n}{2} \cdot \epsilon' \cdot f_A(\vec{0}) \\ &= \frac{\epsilon^2}{128n^3} \cdot f_A(\vec{0}). \end{aligned} \tag{2}$$

where the first inequality follows from the the fact that every balancing step decreases f_A, the second inequality follows from Lemma 3, the third inequality follows from the assumption on $f_A(\vec{0})$, and the last equation follows from the choice of ϵ'. Combining the bounds on $f_A(\mathbf{x}) - f_A(\mathbf{x}')$ in Equations (1) and (2) gives

$$\|b_{.,i}\|_1 + \|b_{i,.}\|_1 < \frac{1}{8n^3} \cdot f_A(\vec{0}),$$

and this completes the proof. ◀

3 Strict Balancing

In this section we present a variant of Osborne's iteration and prove that it converges in polynomial time to a strictly ϵ-balanced matrix. The algorithm, a procedure named StrictBalance, is defined in pseudocode labeled Algorithm 1 on page 7. Lemma 5 above motivates the main idea of contracting heavy nodes in step 14 of StrictBalance.

Our main theorem is

▶ **Theorem 6.** *StrictBalance(A, ϵ) returns a strictly ϵ-balanced matrix $B = DAD^{-1}$ after at most $O\left(\epsilon^{-2}n^9 \log(wn/\epsilon) \log w/\log n\right)$ balancing steps, using $O\left(\epsilon^{-2}n^{10}\log(wn/\epsilon)\log w\right)$ arithmetic operations over $O(n\log(w/\epsilon))$-bit numbers.*

The proof of Theorem 6 uses a few arguments, given in the following lemmas. A *phase* of StrictBalance is one iteration of the outer while loop. Notice that in the beginning of this loop the variable s indexes the phase number (i.e., $s-1$ phases were completed thus far). Also in the beginning of the inner while loop the variable t indexes the total iteration number from all phases (i.e., $t-1$ balancing operations from all phases were completed thus far).

We identify outer loop iteration s with an interval $[t_s, t_{s+1}) = \{t_s, t_s+1, \ldots, t_{s+1}-1\}$ of the inner loop iterations executed during phase s. We denote by $\mathcal{B}_{s,t}$ the value of $\mathcal{B}_s$ in the beginning of the inner while loop iteration number t (dubbed time t). If $t \in [t_j, t_{j+1})$, then $\mathcal{B}_{s,t}$ is defined only for $s \leq j$. We also use $G^{(\mathcal{B}_{s,t})}$ to denote the graph that is obtained by contracting the nodes of set $\mathcal{B}_{s,t}$ in graph G_A. Also $f^{(\mathcal{B}_{s,t})}$ is the function corresponding to

Algorithm 1 StrictBalance(A, ϵ)

Input: Matrix $A \in \mathbb{R}^{n\times n}, \epsilon$
Output: A strictly ϵ-balanced matrix

1: $\mathcal{B}_1 = \varnothing$, $\tau_1 = 0$, $s = 1$, $\epsilon' = \epsilon^2/64n^4$, $\mathbf{x^{(1)}} = (0, \ldots, 0)$, $t = 1$
2: **while** $\mathcal{B}_s \neq [n]$ and there is $i \in [n]$ that is not ϵ-balanced **do**
3: Define $f^{(\mathcal{B}_s)} : \mathbb{R}^n \to \mathbb{R}$, $f^{(\mathcal{B}_s)}(\mathbf{x}) = \sum_{i,j:i\notin\mathcal{B}_s \text{ or } j\notin\mathcal{B}_s} a_{ij}e^{x_i-x_j}$
4: **while** $\frac{\|\nabla f^{(\mathcal{B}_s)}(\mathbf{x^{(t)}})\|_1}{f^{(\mathcal{B}_s)}(\mathbf{x^{(t)}})} > \epsilon'$ **do**
5: Pick $i = \arg\max_{i\notin\mathcal{B}_s} \left\{ \left(\sqrt{\|a^{(t)}_{.,i}\|_1} - \sqrt{\|a^{(t)}_{i,.}\|_1} \right)^2 \right\}$
6: Balance ith node: $\mathbf{x^{(t+1)}} = \mathbf{x^{(t)}} + \alpha_t \mathbf{e}_i$, where $\alpha_t = \ln \sqrt{\|a^{(t)}_{.,i}\|_1 / \|a^{(t)}_{i,.}\|_1}$
7: $t \leftarrow t + 1$
8: **if** $s > 1$ and $\|a^{(t)}_{.,i}\|_1 + \|a^{(t)}_{i,.}\|_1 < \tau_s$ for some $i \in \mathcal{B}_s \setminus \mathcal{B}_{s-1}$ **then**
9: $\mathcal{B}_s = \mathcal{B}_s \setminus \{i \notin \mathcal{B}_{s-1} : \|a^{(t)}_{.,i}\|_1 + \|a^{(t)}_{i,.}\|_1 < \tau_s\}$
10: Redefine $f^{(\mathcal{B}_s)} : \mathbb{R}^n \to \mathbb{R}$, $f^{(\mathcal{B}_s)}(\mathbf{x}) = \sum_{i,j:i\notin\mathcal{B}_s \text{ or } j\notin\mathcal{B}_s} a_{ij}e^{x_i-x_j}$
11: **end if**
12: **end while**
13: $\tau_{s+1} = \frac{1}{4n^3} f^{(\mathcal{B}_s)}(\mathbf{x^{(t)}})$
14: $\mathcal{B}_{s+1} = \mathcal{B}_s \cup \left\{ i : \|a^{(t)}_{.,i}\|_1 + \|a^{(t)}_{i,.}\|_1 \geq \tau_{s+1} \right\}$
15: $s \leftarrow s + 1$
16: **end while**
17: **return** the resulting matrix

graph $G^{(\mathcal{B}_{s,t})}$ and $f^{(\mathcal{B}_{s,t})}(\mathbf{x^{(t)}})$ denotes the sum of weights of arcs of graph $G^{(\mathcal{B}_{s,t})}$ at time t. If set B_s is unchanged during an interval and there is no confusion, we may use $G^{(\mathcal{B}_s)}$ instead of $G^{(\mathcal{B}_{s,t})}$. Particularly we use $f^{(\mathcal{B}_s)}(\mathbf{x^{(t)}})$ instead of $f^{(\mathcal{B}_{s,t})}(\mathbf{x^{(t)}})$. We refer to the quantity $\|a^{(t)}_{.,i}\|_1 + \|a^{(t)}_{i,.}\|_1$ as the *weight* of node i at time t.

▶ **Lemma 7.** *For every phase $s \geq 1$, for every $t \geq t_{s+1}$, $\mathcal{B}_{s,t} = \mathcal{B}_{s,t_{s+1}}$.*

Proof. The claim follows easily from the fact that any iteration $t \geq t_{s+1}$ belongs to a phase $s' > s$, so $\mathcal{B}_{s,t_{s+1}} \cap (\mathcal{B}_{s',t} \setminus \mathcal{B}_{s'-1,t}) = \emptyset$, and by line 8 and 9 of StrictBalance none of the nodes in $\mathcal{B}_{s,t_{s+1}}$ will be removed. ◀

▶ **Lemma 8.** *For all $s > 1$, for all $t \in [t_s, t_{s+1})$, $f^{(\mathcal{B}_{s,t})}(\mathbf{x^{(t)}}) \leq (n - |\mathcal{B}_{s,t}|) \cdot \tau_s$.*

Proof. Let $t_s = t_{s,1} < t_{s,2} < t_{s,3} < \cdots < t_{s,\ell_s}$ denote the time steps before which $\mathcal{B}_s$ changes during phase s. For simplicity, we abuse notation and use $\mathcal{B}_{s,j}$ instead of $\mathcal{B}_{s,t_{s,j}}$. Clearly $\mathcal{B}_{s,1} \supseteq \mathcal{B}_{s,2} \ldots \supseteq \mathcal{B}_{s,\ell_s}$, because we only remove nodes from $\mathcal{B}_s$ once it is set. Fix $s > 1$. We prove this lemma by induction on $r \in \{1, 2, \ldots, \ell_s\}$. For the basis, let $r = 1$. Clearly, by

the way the algorithm sets $\mathcal{B}_s$ before time $t_{s,1}$, all nodes with weight $\geq \tau_s$ are in $\mathcal{B}_s$, and therefore every node $i \notin \mathcal{B}_s$ has weight at most τ_s, so the lemma follows. Now, assume that the lemma is true for every $t \leq t_{s,r}$, we show that the lemma holds for every $t \leq t_{s,r+1}$. If $t \in [t_{s,r}, t_{s,r+1})$, then $\mathcal{B}_{s,t} = \mathcal{B}_{s,t_{s,r}}$, and we have:

$$f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t})}) \leq f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t_{s,r}})}) \leq \left(n - \left|\mathcal{B}_{s,t_{s,r}}\right|\right) \cdot \tau_s = (n - |\mathcal{B}_{s,t}|) \cdot \tau_s.$$

The first inequality holds because balancing operations from time $t_{s,r}$ to time t only reduce the value of $f^{(\mathcal{B}_s)}$, and the second inequality holds by the induction hypothesis.

Just before iteration $t = t_{s,r+1}$, the set $\mathcal{B}_s$ changes, and one or more nodes are removed from it. However, every removed node has weight at most τ_s, and its removal does not change the weights of the other nodes in $[n] \setminus \mathcal{B}_s$. Therefore, if k nodes are removed from $\mathcal{B}_s$,

$$f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t_{s,r+1}})}) \leq \left(n - \left|\mathcal{B}_{s,t_{s,r}}\right|\right) \cdot \tau_s + k \cdot \tau_s = \left(n - \left|\mathcal{B}_{s,t_{s,r+1}}\right|\right) \cdot \tau_s.$$

This completes the proof. ◀

▶ **Corollary 9.** *For all $s > 1$, $f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t_{s+1}})}) \leq \frac{1}{4n^2} \cdot f^{(\mathcal{B}_{s-1})}(\mathbf{x}^{(\mathbf{t_s})})$. If $s > 2$, then $\tau_s \leq \frac{\tau_{s-1}}{4n^2}$.*

Proof. Notice that

$$f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t_{s+1}})}) \leq n \cdot \tau_s = \frac{1}{4n^2} \cdot f^{(\mathcal{B}_{s-1})}(\mathbf{x}^{(\mathbf{t_s})}),$$

where the inequality follows from Lemma 8, and the equation follows from line 13 of StrictBalance. This proves the first assertion. As for the second assertion, notice that if $s > 2$ then $s - 1 > 1$, so using line 13 of StrictBalance and Lemma 8 again,

$$\tau_s = \frac{1}{4n^3} \cdot f^{(\mathcal{B}_{s-1})}(\mathbf{x}^{(\mathbf{t_s})}) \leq \frac{1}{4n^3} \cdot n\tau_{s-1} = \frac{1}{4n^2} \cdot \tau_{s-1},$$

as stipulated. ◀

▶ **Lemma 10.** *For every phase $s > 1$, for every $t \geq t_s$, all the nodes in $\mathcal{B}_{s,t}$ have weight $\geq \tau_s/2$ and are ϵ-balanced at time t.*

Proof. Fix $s > 1$ and let $i \in \mathcal{B}_{s,t}$. Without loss of generality $i \notin \mathcal{B}_{s-1,t}$, otherwise we can replace s with $s - 1$. (Recall that $\mathcal{B}_1 = \emptyset$ at all times.) Also note that it must be the case that $i \in \mathcal{B}_{s,t_s}$, because $\mathcal{B}_s$ does not accumulate additional nodes after being created. If $t \in [t_s, t_{s+1}]$, then lines 13-14 and 8-9 of StrictBalance guarantee that if $i \in \mathcal{B}_{s,t} \setminus \mathcal{B}_{s-1,t}$, then its weight at time t is at least τ_s.

Otherwise, consider $t > t_{s+1}$ and let $s' > s$ be the phase containing t. Consider a phase $j > s$. By Lemma 8 the total weight of $f^{(\mathcal{B}_j)}$ during phase j is at most $n\tau_j$, and $f^{(\mathcal{B}_j)}$ never drops below 0. So, the total weight that a node $i \in \mathcal{B}_j$ can lose (which is at most the total weight that $f^{(\mathcal{B}_j)}$ can lose) is at most $n\tau_j$. By Corollary 9, for every $j > s$, $\tau_{j+1} \leq \frac{\tau_j}{4n^2}$. Now, suppose that t is an iteration in phase $s' > s$. Then, the weight of i at time t is at least

$$\tau_s - \sum_{j=s+1}^{s'} n\tau_j \geq \tau_s \cdot \left(1 - n \cdot \sum_{k=1}^{s'-s} (2n)^{-2k}\right) \geq \frac{\tau_s}{2}.$$

Thus we have established that at any time $t \geq t_s$, if $i \in \mathcal{B}_{s,t}$ then its weight is at least $\frac{\tau_s}{2} = \frac{1}{8n^3} f^{(\mathcal{B}_{s-1})}(\mathbf{x}^{(\mathbf{t_s})})$. By line 4 of StrictBalance, $\|\nabla f^{(\mathcal{B}_{s-1,t_s})}(\mathbf{x}^{(\mathbf{t_s})})\|_1 \leq \epsilon' \cdot f^{(\mathcal{B}_{s-1,t_s})}(\mathbf{x}^{(\mathbf{t_s})})$. By Lemma 7, $\mathcal{B}_{s-1}$ does not change in the interval $[t_s, t]$. Therefore, we conclude from Lemma 5 that i is ϵ-balanced at time t. ◀

▶ **Lemma 11.** *Suppose that $t < t'$ satisfies $[t, t') \subseteq [t_s, t_{s+1})$, and furthermore, during the iterations in the interval $[t, t')$ the set $\mathcal{B}_s$ does not change (it could change after balancing step $t' - 1$). Then, the length of the interval*

$$t' - t = O\left(\epsilon^{-2} n^7 \log(wn/\epsilon)\right).$$

Proof. Rename the nodes so that $\mathcal{B}_{s,t} = \mathcal{B}_{s,t'-1} = \{p, p+1, \ldots, n\}$. The assumption that $\mathcal{B}_s$ does not change during the interval $[t, t')$ means that the weights of all the nodes $p, p+1, \ldots, n$ remain at least τ_s for the duration of this interval. During the interval $[t, t')$, the graph $G^{(\mathcal{B}_s)}$ (which remains fixed) is obtained by contracting the nodes $p, p+1, \ldots, n$ in G_A. So $G^{(\mathcal{B}_s)}$ has p nodes $1, 2, \ldots, p-1, p$, where the last node p is the contracted node. In each iteration in the interval $[t, t')$, one of the nodes $1, 2, \ldots, p-1$ is balanced. Consider some time step $t'' \in [t, t')$, and let I_i and O_i, respectively, denote the current sums of weights of the arcs of $G^{(\mathcal{B}_s)}$ into and out of node i, respectively. Let $j \in [p-1]$ be the node that maximizes $\frac{(I_j - O_j)^2}{I_j + O_j}$. We have

$$\begin{aligned}
f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t}'')}) - f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t}''+\mathbf{1})}) &= \max_{i \in [p-1]} \left(\sqrt{I_i} - \sqrt{O_i}\right)^2 \geq \left(\sqrt{I_j} - \sqrt{O_j}\right)^2 \\
&\geq \frac{(I_j - O_j)^2}{2(I_j + O_j)} \geq \frac{\sum_{i=1}^{p-1} (I_i - O_i)^2}{2 \sum_{i=1}^{p-1} (I_i + O_i)} \\
&\geq \frac{\left(\sum_{i=1}^{p-1} |I_i - O_i|\right)^2}{2n \sum_{i=1}^{p} (I_i + O_i)} \geq \frac{\left(\sum_{i=1}^{p} |I_i - O_i|\right)^2}{8n \sum_{i=1}^{p} (I_i + O_i)} \\
&= \frac{1}{16n} \cdot \frac{\|\nabla f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t}'')})\|_1^2}{f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t}'')})}. \qquad (3)
\end{aligned}$$

The first equation follows from the choice of i in line 5 StrictBalance, and Lemma 3. The third inequality follows from an averaging argument and the choice of j. The fourth inequality uses Cauchy-Schwarz. The last inequality holds because $\sum_{i=1}^{p} (I_i - O_i) = 0$, so $|I_p - O_p| = \left|\sum_{i=1}^{p-1} (I_i - O_i)\right| \leq \sum_{i=1}^{p-1} |I_i - O_i|$, and therefore $\sum_{i=1}^{p} |I_i - O_i| \leq 2 \sum_{i=1}^{p-1} |I_i - O_i|$.

Since the interval $[t, t')$ is contained in phase s, the stopping condition for the phase does not hold, so

$$\frac{\|\nabla f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t}'')})\|_1}{f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t}'')})} > \epsilon' = \frac{\epsilon^2}{64n^4}.$$

Therefore,

$$\begin{aligned}
f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t}'')}) - f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t}''+\mathbf{1})}) &\geq \frac{1}{16n} \cdot \frac{\|\nabla f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t}'')}\|_1^2}{f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t}'')})} \\
&> \frac{\epsilon'}{16n} \cdot \|\nabla f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t}'')})\|_1 \\
&\geq \frac{\epsilon'}{8n^2} \cdot (f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t}'')}) - f^{(\mathcal{B}_s)}(\mathbf{x}^*)),
\end{aligned}$$

where the last inequality follows from Lemma 3. Rearranging the terms gives

$$f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t}''+\mathbf{1})}) - f^{(\mathcal{B}_s)}(\mathbf{x}^*) \leq \left(1 - \frac{\epsilon'}{8n^2}\right) \cdot (f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t}'')}) - f^{(\mathcal{B}_s)}(\mathbf{x}^*)).$$

Iterating for T step yields

$$f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t}+\mathbf{T})}) - f^{(\mathcal{B}_s)}(\mathbf{x}^*) \leq \left(1 - \frac{\epsilon'}{8n^2}\right)^T \cdot (f^{(\mathcal{B}_s)}(\mathbf{x}^{(\mathbf{t})}) - f^{(\mathcal{B}_s)}(\mathbf{x}^*)).$$

Now, by Lemma 4, we have that $f^{(\mathcal{B}_s)}(\mathbf{x^{(t)}}) - f^{(\mathcal{B}_s)}(\mathbf{x}^*) \le f^{(\mathcal{B}_s)}(\mathbf{x^{(t)}}) \le \sum_{i,j=1}^{n} a_{ij}$, and for all t'', $f^{(\mathcal{B}_s)}(\mathbf{x^{(t'')}}) \ge \frac{1}{w^n}\sum_{i,j=1}^{n} a_{ij}$. Therefore, if $t' - t \ge \frac{8n^2}{\epsilon'} \cdot \ln\left(16nw^n/(\epsilon')^2\right) + 1$, then

$$f^{(\mathcal{B}_s)}(\mathbf{x^{(t'-1)}}) - f^{(\mathcal{B}_s)}(\mathbf{x}^*) \le \left(\frac{\epsilon'}{4\sqrt{n}}\right)^2 \cdot \frac{1}{w^n} \cdot \sum_{i,j=1}^{n} a_{ij} \le \left(\frac{\epsilon'}{4\sqrt{n}}\right)^2 \cdot f^{(\mathcal{B}_s)}(\mathbf{x^{(t'-1)}}).$$

Therefore,

$$\begin{aligned} \frac{1}{16n} \cdot \frac{\|\nabla f^{(\mathcal{B}_s)}(\mathbf{x^{(t'-1)}})\|_1^2}{(f^{(\mathcal{B}_s)}(\mathbf{x^{(t'-1)}}))^2} &\le \frac{f^{(\mathcal{B}_s)}(\mathbf{x^{(t'-1)}}) - f^{(\mathcal{B}_s)}(\mathbf{x^{(t')}})}{f^{(\mathcal{B})}(\mathbf{x^{(t'-1)}})} \\ &\le \frac{f^{(\mathcal{B}_s)}(\mathbf{x^{(t'-1)}}) - f^{(\mathcal{B}_s)}(\mathbf{x}^*)}{f^{(\mathcal{B})}(\mathbf{x^{(t'-1)}})} \le \left(\frac{\epsilon'}{4\sqrt{n}}\right)^2, \end{aligned}$$

where the first inequality follows from (3), and the second inequality holds because $f^{(\mathcal{B}_s)}(\mathbf{x}^*) \le f^{(\mathcal{B}_s)}(\mathbf{x^{(t'-1)}})$. We get that $\frac{\|\nabla f^{(\mathcal{B})}(\mathbf{x^{(t'-1)}})\|_1}{f^{(\mathcal{B})}(\mathbf{x^{(t'-1)}})} \le \epsilon'$, in contradiction to our assumption that the phase does not end before the start of iteration t'. ◀

▶ **Corollary 12.** *In any phase, the number of balancing steps is at most* $O\left(\epsilon^{-2}n^8\log(wn/\epsilon)\right)$.

Proof. In the beginning of phase s the set $\mathcal{B}_s$ contains at most $n-1$ nodes. Partition the phase into intervals $[t, t')$ where $\mathcal{B}_s$ does not change during an interval, but does change between intervals. By Lemma 11, each interval consists of at most $O\left(\epsilon^{-2}n^7\log(wn/\epsilon)\right)$ balancing steps. Since nodes that are removed from $\mathcal{B}_s$ between intervals are never returned to $\mathcal{B}_s$, the number of such intervals is at most $n-1$. Hence, the total number of balancing steps in the phase is at most $O\left(\epsilon^{-2}n^8\log(wn/\epsilon)\right)$. ◀

▶ **Lemma 13.** *The total number of phases of the algorithm is* $O(n\log w/\log n)$.

Proof. Let $s > 2$ be a phase of the algorithm and $t \in [t_s, t_{s+1})$. By Lemma 4, $f^{(\mathcal{B}_{s,t})}(\mathbf{x^{(t)}}) \ge \frac{1}{w^n}\cdot\sum_{ij} a_{ij}$. On the other hand, by Lemma 8 and Corollary 9, $\tau_s \le \frac{1}{(4n^2)^{s-2}}\cdot\tau_2 \le \frac{1}{(4n^2)^{s-2}}\cdot\sum_{ij} a_{ij}$, and $f^{(\mathcal{B}_{s,t})}(\mathbf{x^{(t)}}) \le n\tau_s$. Combining these gives $\frac{1}{w^n}\cdot\sum_{ij} a_{ij} \le n\tau_s \le \frac{n}{(4n^2)^{s-2}}\cdot\sum_{ij} a_{ij}$ which implies that $s \le \frac{\log(nw^n)}{\log(4n^2)} + 2$. ◀

Proof of Theorem 6. By Lemma 13, for some $s = O(n\log w/\log n)$, StrictBalance terminates, so $\mathcal{B}_{s,t_s} = [n]$. By Corollary 12, the number of balancing steps in a phase is at most $O\left(\epsilon^{-2}n^8\log(wn/\epsilon)\right)$. Therefore, the total number of balancing steps is at most $O\left(\epsilon^{-2}n^9\log(wn/\epsilon)\log w/\log n\right)$. These steps require at most $O\left(\epsilon^{-2}n^{10}\log(wn/\epsilon)\log w\right)$ arithmetic operations. When the algorithm terminates at time t_s, all the nodes are in $\mathcal{B}_{s,t_s}$, and by Lemma 10 they are all ϵ-balanced, so the matrix is strictly ϵ-balanced.

Thus, assuming exact arithmetics with infinite precision we have shown that the algorithm converges to a strictly ϵ-balanced matrix in the claimed number of arithmetic operations. To show that the algorithm still works if all numbers are represented with only $O(n\log(w/\epsilon))$ bits, we apply an analysis similar to the one in section 3 of [11]. ◀

Abstract

We consider the problems Zero Extension and Metric Labelling under the paradigm of parameterized complexity. These are natural, well-studied problems with important applications, but have previously not received much attention from this area.

Depending on the chosen cost function μ, we find that different algorithmic approaches can be applied to design FPT-algorithms: for arbitrary μ we parameterize by the number of edges that cross the cut (not the cost) and show how to solve Zero Extension in time $O(|D|^{O(k^2)}n^4 \log n)$ using randomized contractions. We improve this running time with respect to both parameter and input size to $O(|D|^{O(k)}m)$ in the case where μ is a metric. We further show that the problem admits a polynomial *sparsifier*, that is, a kernel of size $O(k^{|D|+1})$ that is *independent of the metric* μ.

With the stronger condition that μ is described by the distances of leaves in a tree, we parameterize by a *gap parameter* $(q-p)$ between the cost of a true solution q and a 'discrete relaxation' p and achieve a running time of $O(|D|^{q-p}|T|m + |T|\phi(n,m))$ where T is the size of the tree over which μ is defined and $\phi(n,m)$ is the running time of a max-flow computation. We achieve a similar result for the more general Metric Labelling, while also allowing μ to be the distance metric between an arbitrary subset of nodes in a tree using tools from the theory of VCSPs. We expect the methods used in the latter result to have further applications.

1 Introduction

The task of extending a partial labelling of data points to a full data set while minimizing an error function is a natural step for many scientific and engineering tasks. For the particular case of data imposed with a binary relationship, we find the problems Zero Extension and Metric Labelling to be well-suited for optimization in image processing [1], social network classification [24], or sentiment analysis [25]. The problems are as follow. For Zero Extension, we are given a graph G and a partial labelling $\tau\colon S \to D$, for terminals $S \subseteq V(G)$, and a cost function $\mu\colon D \times D \to \mathbb{R}^+$. Our task is to compute a labelling $\lambda\colon V(G) \to D$ which agrees with τ on S, subject to the following cost: for each edge $uv \in G$ we pay $\mu(\lambda(u), \lambda(v))$. In Metric Labelling, we are given G, μ as above, and a *labelling cost* $\sigma\colon V(G) \times D \to \mathbb{R}^+$.

Again we are asked to compute a labelling λ and in addition to the above edge-costs we now also pay $\sigma(v, \lambda(v))$. This model allows us to emulate terminals by making the cost $\sigma(v, \lambda(v))$ prohibitive for all but the required label $\lambda(v)$. Both problems are generalizations of Multiway Cut (we simply let μ be identically one for all distinct pairs), which has garnered considerable attention from the FPT community and formed a crystallization nucleus for the very fruitful research of cut-based problems (see e.g. [20, 17, 3, 11, 22]).
We apply most of these tools in the following, but we wish to highlight the use of tools and relaxations from *Valued CSPs* (VCSPs) for designing FPT algorithms under gap parameters. VCSPs are a general framework for expressing optimisation problems, via the specification of a set Γ of *cost functions* (aka *constraint language*). Many important problems correspond to VCSP for a specific language, including every choice of a specific metric for the problems above. Thapper and Živný [30] characterized the languages Γ for which the resulting VCSP is tractable.

The use of a tractable VCSP as a *discrete relaxation* of an NP-hard optimisation problem has led to powerful FPT algorithms [11] (see also related improvements [12, 32]). In this paper, we advance this research in two ways. First, previous approaches have required the relaxation to have a *persistence* property, which allows an optimum to be found by sequentially fixing variables. Here, we relax this condition to a weaker *domain consistency* property. Second, we use a folklore result from VCSP research to restrict the behaviour of an instance's optimal solutions in order to facilitate the proof that the domain consistency property holds for the relevant VCSPs. See Section 5 for details.

Related work. Zero Extension and Metric Labelling have been researched primarily from the perspective of efficient and approximation algorithms (see [19] for an overview and hardness results). Kleinberg and Tardos [29] introduced Metric Labelling and provided a $O(\log |S| \log \log |S|)$ approximation. A result by Fakcharoenphol *et al.* regarding embedding general metrics into tree metrics [7] improves the ratio of this algorithm to $O(\log |S|)$ and a lower bound of $O((\log |S|)^{1/2-\varepsilon})$ was proved by Chuzhoy and Naor [4]. Karzanov [14] introduced Zero Extension with the specific case of μ being a graph metric, that is, equal to the distance metric of some graph H. His central question—for which graphs H the problem is tractable—was recently fully answered by Hirai [9]. Picard and Ratliff earlier showed that an equivalent problem is tractable on trees [26]. Fakcharoenphol *et al.* showed that the problem can be approximated to within a factor of $O(\log |S| / \log \log |S|)$ [6]. Karloff *et al.* used the approach by Chuzhoy and Naor to show that no factor of $O((\log |S|)^{1/4-\varepsilon})$ for any $\varepsilon > 0$ is possible unless NP $\subseteq$ QP [13]. More recently, Hirai and Pap [8, 10] studied the problem from a more structural angle and we make use of their duality result.

Our results. We study both problems from the perspective of parameterized complexity. As the choice of metric has a strong effect on the problem complexity, we give a range of results, from the more generally applicable to the algorithmically stronger, both in terms of running time and parameterization. When μ is a general cost function or a metric, we will parametrize not by the *cost* of a solution but by the number of *crossing edges*, i.e., bichromatic edges under a labelling λ. This lets us consider μ with zero-cost pairs. For general cost functions, we employ the technique of randomized contractions [3] and prove:

▶ **Theorem 1** ($\star$[1]). Zero Extension *can be solved in time* $O(|D|^{O(k^2)} n^4 \log n)$ *where* k *is a given upper bound on the number of crossing edges in the solution.*

[1] Results marked by $\star$ are found in the full version of the paper [27]

When μ is a metric, we are able to give a linear-time FPT algorithm, while also improving the dependency on the parameter, using important separators [20]:

▶ **Theorem 2.** Zero Extension *with metric cost functions can be solved in time* $O(|D|^{O(k)} \cdot m)$ *where* k *is a given upper bound on the number of crossing edges in the solution.*

For the general metric setting, we also have our most surprising result, demonstrating that Zero Extension admits a *sparsifier*; that is, we prove that it admits a polynomial kernel *independent of the metric* μ. This result crucially builds on the technique of *representative sets* [17, 21, 18]. The exact formulation of the result is somewhat technical and we defer it to Section 4.2, but roughly, we obtain a kernel of size $O(k^{|S|+1})$, independent of μ, where k is again the number of crossing edges. This result is a direct, seemingly far-reaching generalization of the polynomial kernel for s-Multiway Cut [17].

Next, we consider the case when $\mu\colon D \times D \to \mathbb{Z}^+$ is induced by the distance in a tree T with $D \subset V(T)$. Here, relaxing the problem to allow all labels $V(T)$ as vertex values defines a tractable discrete relaxation, in the sense discussed above. In particular, we can compute a *relaxed solution cost* p in polynomial time which lower-bounds the optimal integral solution q. Using techniques from VCSP, we design a gap-parameter algorithm:

▶ **Theorem 3.** *Let* $I = (G, \tau, \mu, q)$ *be an instance of* Zero Extension *where* μ *is an induced tree metric on a set of labels* D *in a tree* T*, and let* $\hat{I} = (G, \tau, \hat{\mu}, q)$ *be the relaxed instance. Let* $p = \mathbf{cost}(\hat{I})$*. Then we can solve* I *in time* $O(|D|^{q-p}|T||D|nm)$*.*

For the further restriction when μ corresponds to the distances of the leaves D of a tree T, we obtain an algorithm with a slightly better polynomial dependence. Moreover, it uses only elementary operations like computing cuts and flows:

▶ **Theorem 4.** *Let* $I = (G, \tau, \mu, q)$ *be an instance of* Zero Extension *where* μ *is a leaf metric on a set of labels* D *in a tree* T*, and let* $\hat{I} = (G, \tau, \hat{\mu}, q)$ *be the relaxed instance. Let* $p = \mathbf{cost}(\hat{I})$*. Then we can solve* I *in time* $O(|D|^{q-p}|T|m + |T|\phi(n, m))$*, where* ϕ *is the time needed to run a max-flow algorithm.*

Finally, we apply the VCSP toolkit to Metric Labelling and obtain a similar gap algorithm (see Section 5 for undefined terms).

▶ **Theorem 5.** *Let* $I = (G, \sigma, \mu, q)$ *be an instance of* Metric Labelling *where* μ *is an induced tree metric for a tree* T *and a set of nodes* $D \subseteq V(T)$*, and where every unary cost* $\sigma(v, \cdot)$ *admits an interpolation on* T*. Let* $\hat{I} = (G, \hat{\sigma}, \hat{\mu}, q)$ *be the relaxed instance, and let* $p = \mathbf{cost}(\hat{I})$*. Then the instance* I *can be solved in time* $O^*(|D|^{q-p})$*. In particular, this applies for any* σ *if* D *is the set of leaves of* T*.*

2 Preliminaries

For a graph $G = (V, E)$ we will use $n_G = |V|$ and $m_G = |E|$ to denote the number of vertices and edges, respectively. For two disjoint vertex sets $A, B \subseteq V$ we write $E(A, B)$ to denote the edges that have one endpoint in A and the other in B. We write d_G for the distance-metric induced by G, that is, $\mathrm{d}_G(u, v)$ is the length of a shortest path between vertices $u, v \in V(G)$. We denote by $N_G(v)$ and $N_G[v]$ the open and closed neighbourhood of a vertex. For a vertex set $S \subseteq V(G)$ we write $\delta_G(S)$ to denote the set of edges with exactly one endpoint in S. We omit the subscript G, if clear from the context, in all these notations.

Let T be a tree and $xy \in T$ an edge, then we use the notation T_x to denote the component of $T - xy$ that contains x. We call a sequence of nodes $x_1 x_2 \dots x_p$ in T a *monotone sequence*

if $x_1 \leqslant_P x_2 \leqslant_P \ldots \leqslant_P x_p$ where P is a path in T and $\leqslant_P$ is the linear order induced by P. Note that $x_i = x_{i+1}$ is explicitly allowed. For two nodes $x, y \in T$ we will denote the unique x-y-path in T by $T[x, y]$. For a vertex set S, an *S-path packing* is a collection of edge-disjoint paths $\mathcal{P}$ that connect pairs of vertices in S. We will also consider *half-integral* path packings where every edge is allowed to be used by at most two paths.

Let D be a set of labels. For a graph G we call a function $\tau \colon S \to D$ for $S \subseteq V(G)$ a *partial labelling* and a function $\lambda \colon V(G) \to D$ a *labelling*. The labelling λ is an *extension* of τ if λ and τ agree on S, that is, for every vertex $u \in S$ we have that $\lambda(u) = \tau(u)$. Given a graph G and a labelling λ we call an edge $uv \in E(G)$ *crossing* if $\lambda(u) \neq \lambda(v)$. A *$\tau$-path packing* is a collection $\mathcal{P}$ of edge-disjoint paths such that every path $P \in \mathcal{P}$ connects two vertices that receive distinct labels under τ (and both are labelled).

A *cost function* over D is a symmetric positive function $\mu \colon D \times D \to \mathbb{R}^+$. We call it *simple* if $\mu(x, x) = 0$. A cost function is a *metric* if it is simple and further obeys the triangle inequality; it is a *tree metric* if it corresponds to the distance metric of a tree. We derive an *induced tree metric* from a tree metric by restricting its domain to a subset D of the nodes of the underlying tree. A *leaf metric* is an induced tree metric where D is the set of leaves of the tree. Given a cost function μ, we define the cost of a labelling λ of a graph G as $\mathbf{cost}_\mu(\lambda, G) = \sum_{uv \in G} \mu(\lambda(u), \lambda(v))$.

3 Cost functions: Randomized Contractions

We apply the framework by Chitnis *et al.* [3] to show that the general case of Zero Extension is in FPT when parameterized by the number of crossing edges. Note that crossing edges could incur an arbitrary cost, including zero. The stronger parameterization of only counting the number of crossing edges at non-zero cost makes for an intractable problem: With zero-cost edges, we can express the problem H-Retraction for reflexive graphs H, which asks us to find a retraction of a graph G into a fixed graph H. This problem is already NP-complete for H being the reflexive 4-cycle [31] and thus Zero Extension is paraNP-complete for $k = 0$ when parameterized by the number of non-zero crossing edges or the total cost.

A (σ, κ)-*good* separation is a partition (L, R) of $V(G)$ such that $|L|, |R| > \sigma$, $|E(L, R)| \leqslant \kappa$, and both $G[L]$ and $G[R]$ are connected. There exists an algorithm that finds a (σ, κ)-good separation in time $O((\sigma+\kappa)^{O(\min(\sigma,\kappa))} n^3 \log n)$ (Lemma 2.2 in [3]) or concludes that the graph is (σ, κ)-*connected*, that is, no such separation exists. The following lemma is a slight reformulation of Lemma 1.1 in [3] which in turn is based on splitters as defined by Naor *et al.* [23]:

▶ **Lemma 6** (Edge splitter). *Given a set E of size m and integers $0 \leqslant a, b \leqslant m$ one can in time $O((a+b)^{O(\min\{a,b\})} m \log m)$ construct a set family $\mathcal{F}$ over E of size at most $O((a+b)^{O(\min\{a,b\})} \log m)$ with the following property: for any disjoint sets $A, B \subseteq E$ with $|A| \leqslant a$ and $|B| \leqslant b$ there exists a set $H \in \mathcal{F}$ with $A \subseteq H$ and $B \cap H = \emptyset$.*

We first prove that Zero Extension can be solved on such highly connected instances and then apply the 'recursive understanding' framework to handle graphs with good separations.

▶ **Lemma 7.** *Let G be (σ, k)-connected for some $\sigma > k$. Then we can find an optimal solution in time $O((|D| + 2\sigma k + k)^{O(k)}(n+m) \log n)$.*

Proof sketch. Let $\lambda \in \mathbf{opt}(I)$ and let E_λ be the crossing edges with endpoints $V(E_\lambda)$. Let $C_0, C_1, \ldots, C_\ell$ be the connected components of $G - E_\lambda$ with C_0 being the largest one. Since G is (σ, k)-connected, we know that $\ell \leqslant k$ and that all components $C_1, \ldots, C_\ell$ have size at most σ (*cf.* Lemma 3.6 in [3]). We will assume that $|C_0| > \sigma$, otherwise $|V(G)| \leqslant \sigma k$ vertices and we find E_λ by brute-force.

We proceed by colouring $E(G)$. Such a colouring is *successful* if 1) E_λ is red, 2) each C_i, $i \geqslant 1$, contains a blue spanning tree, and 3) each vertex $u \in C_0 \cap V(E_\lambda)$ is contained in a blue tree of size $\geqslant \sigma + 1$. It is easy to verify that we need to correctly colour a set $B \subseteq E(G)$, $|B| \leqslant (\sigma - 1)\ell + \sigma k \leqslant 2\sigma k$ edges blue while colouring a set $R \subseteq E(G)$, $|R| \leqslant k$, edges red. We construct an edge-splitter $\mathcal{F}$ with $a = 2\sigma k$ and $b = k$ according to Lemma 6 of size $O((2\sigma k + k)^{O(k)} \log m)$. By construction, at least one colouring in $\mathcal{F}$ will be successful.

Fix a successful colouring. Let G_B be the graph on the blue edges. Call a component of G_B *small* if it contains $\leqslant \sigma$ vertices and *big* otherwise. Our task is to recover $C_0, C_1, \ldots, C_\ell$. Every C_i, $i \geqslant 1$ is small in G_B and all components reachable from C_i via red edges must either be a solution component C_j, $j \geqslant 1$, *or* a big component in G_B. Thus, we can 'discover' the sets $C_1, \ldots, C_\ell$ by marking small components that contain a terminal and then successively mark small components with red edges into already marked components. Afterwards we identify the crossing edges E_λ and λ. The total running time to identify E_λ is $(2\sigma k + k)^{O(k)}(n + m) \log n$. Given E_λ, the final step is to find an optimal assignment. We simply try all possible assignments for non-terminal components in time $O(|D|^\ell k) = O(|D|^k k)$ and the claimed running time follows. ◀

With the well-connected cases handled, the theorem follows by a straightforward application of recursive understandings [3].

▶ **Theorem 1** ($\star$[2]). Zero Extension *can be solved in time* $O(|D|^{O(k^2)} n^4 \log n)$ *where* k *is a given upper bound on the number of crossing edges in the solution.*

4 General metrics: Pushing separators

We now consider the more restricted, but reasonable case that μ is a metric, observing the triangle inequality. We find that this allows a 'greedy' operation of *pushing* in a solution λ, which allows both the design of a faster algorithm (Section 4.1) and the computation of a *metric sparsifier* (Section 4.2). Throughout the section, let $I = (G = (V, E), \tau, \mu, q)$ be an instance of Zero Extension for an arbitrary metric μ, let S be the set of terminals of G, and let D be the set of labels. We assume that the following reductions have been performed on G: For every label ℓ used by τ there is a terminal t_ℓ, and every vertex v such that $\tau(v) = \ell$ has been identified with this terminal t_ℓ.

We first prove a useful lemma. Let $\lambda \colon V \to D$ be an extension of τ, and let $U = \lambda^{-1}(\ell)$ for some $\ell \in D$. By *pushing from* ℓ *in* λ we refer to the operation of relabelling vertices to grow the set U "as large as possible", without increasing the number of crossing edges. Formally, this refers to the following operation: Let C be the furthest min-cut between vertex sets U and $S - t_\ell$, respectively S if there is no terminal t_ℓ (cf. [20, Lemma 3]); let U' be the vertices reachable from U in $G - C$; and let λ' be the labelling where $\lambda'(v) = \ell$ for $v \in U'$ and $\lambda'(v) = \lambda(v)$ otherwise. Clearly, λ' is an extension of τ. We show that as long as μ is a metric (observing the triangle inequality), pushing does not increase the cost of the solution.

▶ **Lemma 8** (Pushing Lemma). *For any* τ*-extension* λ *and every label* $\ell \in D$*, pushing from* ℓ *in* λ *yields a* τ*-extension* λ' *with* $\mathbf{cost}_\mu(\lambda', G) \leqslant \mathbf{cost}_\mu(\lambda, G)$.

Proof sketch. Since C is a min-cut there is a set of paths that begin in $\delta(U)$, saturate C, and end in terminals $S - t_\ell$. By the triangle inequality, the cost incurred by λ on these paths is at least as large as that incurred by λ', and no other edge increases its cost in λ'. ◀

[2] Results marked by $\star$ are found in the full version of the paper [27]

An immediate consequence of the above lemma is the following reduction rule.

▶ **Corollary 9** (⋆). *We can reduce to the case where for every terminal $t_\ell \in S$, $\delta(t_\ell)$ is the unique $(t_\ell, S - t_\ell)$-min cut in G.*

4.1 An FPT algorithm

We now show that Zero Extension is FPT for a metric μ parameterized by $k + |D|$, where k is a bound on the number of crossing edges of an optimum λ. The algorithm uses Lemma 8 to guess a solution λ using the classical technique of *important separators*, pioneered by Marx [20] as an important technique for FPT algorithms solving cut problems. Our algorithm roughly follows the algorithm for Multiway Cut of Chen, Liu and Lu [2], with two complications. First, unlike in Multiway Cut, there may be crossing edges in λ that are not reachable by a terminal, which makes the branching more expensive; second, even after all crossing edges have been found, it still remains to find an optimal labelling λ.

Since these complications can be present or absent for different metrics μ, we describe the algorithm in stages, where the first stage identifies all crossing edges reachable from a terminal, the second stage identifies the remaining crossing edges, and the third stage finds an assignment λ. For specific metrics μ, it may then be possible to speed this up by skipping some steps. In summary, we show the following.

▶ **Theorem 2.** Zero Extension *with metric cost functions can be solved in time $O(|D|^{O(k)} \cdot m)$ where k is a given upper bound on the number of crossing edges in the solution.*

We begin by providing the running time for the first stage. This is analysed in terms of a lower bound p on the crossing number of any labelling λ. This may be defined as follows: First apply Corollary 9, then compute $p = \sum_{t \in S} |\delta(t)|/2$. It is known that p is a lower bound on the multiway cut number of (G, S) [28], hence also on the number of crossing edges of λ, making $k - p$ a valid gap parameter. (Note that p does not measure the *cost* of a crossing edge or path; such results are shown in Section 5.)

▶ **Lemma 10** (⋆). *Let p be the lower bound as above. In $O(4^{k-p}km)$ time and 4^{k-p} guesses, we can reduce to the case where every edge of $\delta(t)$ is a crossing edge in the optimal solution for every $t \in S$.*

A similar result (without a lower bound) finds the remaining crossing edges of a solution.

▶ **Lemma 11** (⋆). *Given an input from stage 1, with p edges already marked as crossing, in $O(4^{2k-p}m)$ time and 4^{2k-p} guesses we can reduce to the case where every edge of G is crossing in the optimal solution.*

After stage 2, the remaining graph contains at most k edges, hence at most $O(k)$ vertices, and it only remains to find the min-cost labelling of the non-terminal vertices. In the absence of any stronger structural properties of the metric μ, this last phase can be completed in $|D|^{O(k)}O(m)$ time. Theorem 2 follows.

4.2 A kernel for any metric

We next show that Zero Extension has a kernel of $O(k^{s+1})$ vertices for any metric μ, where k is a bound on the number of crossing edges of a solution and s is the number of labels of μ. Moreover, the kernel can be computed without access to μ. This gives us a kind of *metric sparsifier* for (G, S), up to parameters k and s, as follows. The result is an adaptation of the kernel for s-Multiway Cut of Kratsch and Wahlström [17]. For an instance I, let $\mathbf{cost}(I, k)$ be the minimum cost of a labelling with at most k crossing edges (otherwise ∞).

▶ **Theorem 12** (⋆). *Let $s \geqslant 3$ be a constant. For every graph $G = (V, E)$ with a set S of terminals, $|S| \leqslant s$, and integer k, there is a randomized polynomial-time computable set $Z \subseteq E$ with $|Z| = O(k^{s+1})$ such that for any instance $I = (G, \tau, \mu, q)$ of* Zero Extension *with S being the set of terminals in I and μ having at most s labels, if $\mathbf{cost}(I, k) < \infty$ then there is a τ-extension λ with crossing number at most k and cost $\mathbf{cost}(I, k)$ such that every crossing edge of λ is contained in Z.*

By contracting any edges not in $\bigcup_{t \in S} \delta(t) \cup Z$ we then get the kernelized instance (G', S).

5 Tree metrics: Gap algorithms and VCSP relaxations

In this section we present more powerful algorithms parameterized by the gap parameter for problems where the metric embeds into a tree metric. We begin by a purely combinatorial algorithm for Zero Extension on leaf metrics, then we move on to the more general Zero Extension and Metric Labelling problems for general induced tree metrics. The algorithms for the latter problems rely on the *domain consistency* property of the relaxation, which allows us to solve the problem by simply branching on the value of a single variable at a time. This property is shown by way of a detour into an analysis of properties of VCSP instances whose cost functions are *weakly tree submodular*, which is a tractable problem class containing tree metrics. The algorithms for these problems are then straight-forward.

At this point, we need to address a subtlety regarding the input cost function μ. So far, the cost function only had to obey basic properties that are easily verifiable or could be seen as a 'promise'. However, some of our arguments below will explictly need the tree T that induces the metric. Luckily this issue has been solved already: given a induced tree metric μ over D in matrix form, one can in time $O(|D|^2)$ compute a tree that induces μ [5]. If μ is a leaf metric, the output will obviously have D as the leaves of T. In conclusion, we will tacitly assume that we have access to the tree T in the following.

5.1 Leaf metrics: A duality approach

The μ-Edge Disjoint Packing problem asks to find an edge-disjoint packing $\mathcal{P}$ of paths whose endpoints both lie in a terminal set $S \subseteq V(G)$ that maximizes $\mathrm{pack}(\mu, G, S) := \sum_{P \in \mathcal{P}} \mu(s_P, t_P)$ (where s_P, t_P denote start- and endpoint of P). Hirai and Pap [10] show that if μ is a tree metric then $\mathrm{pack}(\mu, G, S) = \min_\lambda \max_{F \subseteq E} \sum_{uv \in E \setminus F} \mu(\lambda(u), \lambda(v))$, where λ is a zero-extension of the terminal-set S and the sets $F \subseteq E$ are edges whose deletion leaves every non-terminal vertex with an even degree. It follows that the maximum value of a half-integral τ-path packing is just the minimum cost of a τ-extension λ, since a half-integral path-packing is just a path-packing in the graph where every edge of G has been duplicated.

Let in the following $I = (G, \tau, \mu, q)$ be an instance of Zero Leaf Extension, where μ is a leaf metric over a tree T with leaves D. Let $\hat{\mu} = \mathrm{d}_T$ be the underlying tree metric. We define the *relaxed instance* $\hat{I} = (G, \tau, \hat{\mu}, q)$. Let $\mathbf{opt}(I)$, $\mathbf{opt}(\hat{I})$ denote the set of optimal solutions for the integral and the relaxed instance, respectively. Using this notation, we can summarize the duality: Given a relaxed instance $\hat{I}$, there exists a half-integral τ-path-packing $\mathcal{P}$ of cost precisely $\mathbf{cost}(\hat{I})$. In the following we will assume, by the usual identification argument, that τ is a bijection and a τ-path packing is equivalent to an S-path packing.

▶ **Lemma 13** (⋆). *Let $\mathcal{P}$ be an half-integral τ-path packing with $\frac{1}{2} \sum_{P \in \mathcal{P}} \mu(\tau(s_P), \tau(t_P)) = \mathbf{cost}(\hat{I})$. Let $\lambda \in \mathbf{opt}(\hat{I})$ be a relaxed optimum and let $P \in \mathcal{P}$ with endpoints s, t. Then $\mathbf{cost}_{\hat{\mu}}(\lambda, P) = \mu(\tau(s), \tau(t))$.*

A direct consequence is that if we trace an s-t-path $P \in \mathcal{P}$, then the labels assigned by any relaxed optimum λ to P induce a monotone sequence from s to t in T. That is, not only will we only encounter those labels that lie on $T[s,t]$, we also will encounter them 'in order'.

Consider an edge $xy \in E(T)$. Then, as a consequence of Lemma 13 the set of edges $C_{xy}(\lambda) = \{uv \in E(G) \mid \lambda(u) \in T_x, \lambda(v) \in T_y\}$ between the vertex sets with labels in T_x and T_y, respectively, must be saturated by paths of the packing $\mathcal{P}$. For cuts right above leafs of T, this implies the following.

▶ **Lemma 14** ($\star$). *Let S be the vertices labelled by τ in G and assume that τ is a bijection. Let C be any minimum $(x, S-x)$-cut for some terminal $x \in S$. Then every optimal, half-integral S-path-packing in G will saturate C.*

▶ **Theorem 4.** *Let $I = (G, \tau, \mu, q)$ be an instance of* Zero Extension *where μ is a leaf metric on a set of labels D in a tree T, and let $\hat{I} = (G, \tau, \hat{\mu}, q)$ be the relaxed instance. Let $p = \mathbf{cost}(\hat{I})$. Then we can solve I in time $O(|D|^{q-p}|T|m + |T|\phi(n,m))$, where ϕ is the time needed to run a max-flow algorithm.*

Proof sketch. We first construct for every edge $ij \in T$ a flow network H_{ij} from G as follows: let D_i be those leaves that lie in the same component as i in $T - ij$ and D_j all others. Then H_{ij} is obtained from G by identifying all terminals $\tau^{-1}(D_i)$ into a source s and all terminals $\tau^{-1}(D_j)$ into a sink t. For each H_{ij} we compute a maximum flow f_{ij} in time $\phi(n,m)$. We can show that for every $\lambda \in \mathbf{opt}(\hat{I})$ it holds that $\sum_{xy \in T} |f_{ij}| = \sum_{xy \in T} |C_{xy}(\lambda)| = \mathbf{cost}_\mu(\hat{I})$. Note that we can also, in linear time, find the furthest cuts $\mathrm{C}_{\max}(x)$ for terminals $x \in S$ using the residual network of (H_{ij}, f_{ij}) with $i = \tau(x)$ and j the parent of i in T.

Next, we test whether G contains a vertex u that is not part of a furthest min-cut $\mathrm{C}_{\max}(x)$ for any $x \in S$; such a vertex cannot take an integral value in any relaxed optimum. We then branch on the $|D|$ possible integral values for u: for $x \in S$ with $\tau(x) \in D$ being the chosen integral value, we update the networks (H_{ij}, f_{ij}) by adding an edge xu of infinite capacity, then augment the flow. The number of augmentations is $\leqslant k - p$, as each augmentation witnesses the increase of p and thus the decrease of the parameter. We charge each augmentation to a level of the search tree and thus spend only $O(m)$ time per flow f_{ij}, for a total of $O(|T|m)$.

Otherwise, we find that every vertex of the current graph G is contained in at least one furthest min-cut. It can be shown (see full version) that the intersection of three or more such cuts is empty. Consequently, the graph decomposes into sets whose label is either fixed or is one of two possible values. A simple cut argument shows that we can fix one of the two labels greedily for the latter, and we construct an integral solution that matches the relaxed optimum. ◀

5.2 VCSP toolkit

Given a set of cost functions Γ over a domain D, an instance I of VCSP(Γ) is defined by a set of variables V and a sum of valued constraints $f_i(\bar{v}_i)$, where for each i, $f_i \in \Gamma$ and $\bar{v}_i$ is a tuple of variables over V. We write $f_i(\bar{v}) \in I$ to signify that $f_i(\bar{v})$ is a valued constraint in I. It is known that the tractability of a VCSP is characterized by certain algebraic properties of the set of cost functions. In full generality, such conditions are known as *fractional polymorphisms* for the finite-valued case and more general *weighted polymorphisms* in the general-valued case. Dichotomies are known in these terms both for the finite-valued [30] and general case of VCSP [16], i.e., characterizations of each VCSP as being either in P or NP-hard. We will only need a less general term.

A *binary multimorphism* $\langle \circ, \bullet \rangle$ of a language Γ over a domain D is a pair of binary operators that satisfy $f(\bar{x}) + f(\bar{y}) \geqslant f(\bar{x} \circ \bar{y}) + f(\bar{x} \bullet \bar{y})$, for all $f \in \Gamma, \bar{x}, \bar{y} \in D^{\mathbf{ar}(f)}$, where

$\mathbf{ar}(f)$ is the arity of f and where we extend the binary operators to vectors by applying them coordinate-wise. An operator $\circ$ is *idempotent* if $x \circ x = x$ for every $x \in D$, and *commutative* if $x \circ y = y \circ x$. A (finite, finite-valued) language Γ with a binary multimorphism where both operators are idempotent and commutative is solvable in polynomial time via an LP-relaxation [30]. The most basic example is the Boolean domain $D = \{0, 1\}$, in which case the multimorphism $\langle \wedge, \vee \rangle$ corresponds to the well-known class of *submodular functions*, which is a tractable class that generalizes cut functions in graphs.

The following is folklore, but will be important to our investigations. Again, the corresponding statements apply for arbitrary fractional polymorphisms, but we only give the version we need in the present paper.

▶ **Definition 15** (Preserved under equality)**.** Let f be a function that admits a multimorphism $\langle \circ, \bullet \rangle$. We say that two tuples $\bar{x}, \bar{y} \in D^{\mathbf{ar}(f)}$ are *preserved under equality* if $f(\bar{x}) + f(\bar{y}) = f(\bar{x} \circ \bar{y}) + f(\bar{x} \bullet \bar{y})$. For a relation $R \subseteq D^{\mathbf{ar}(r)}$, we say that f is *preserved under equality in* R if every pair of tuples $\bar{x}, \bar{y} \in R$ is preserved under equality and $\bar{x} \circ \bar{y}, \bar{x} \bullet \bar{y} \in R$.

▶ **Lemma 16** ($\star$)**.** *Let Γ be a language of cost functions that admit a multimorphism $\langle \circ, \bullet \rangle$ and let $\lambda_1, \lambda_2 \in \mathbf{opt}(I)$ for some instance I of* VSCP(Γ)*. Then for every valued constraint $f(\bar{v}) \in I$ it holds that $f(\lambda_1(\bar{v})) + f(\lambda_2(\bar{v})) = f((\lambda_1 \circ \lambda_2)(\bar{v})) + f((\lambda_1 \bullet \lambda_2)(\bar{v}))$, where $f(\lambda(\bar{v})) = f(\lambda(v_1), \ldots, \lambda(v_r))$ for $\bar{v} = v_1, \ldots, v_r$ is the value of $f(\bar{v})$ under λ. In other words, every valued constraint $f(\bar{v}) \in I$ is preserved under equality in $\mathbf{opt}(I)$.*

To illustrate, let us return again to the case of graph cut functions and submodularity over the Boolean domain. Let $G = (V, E)$ be an undirected graph, and define the cut function $f_G \colon 2^V \to \mathbb{Z}$ as $f_G(S) = |\delta(S)|$. Then f_G is the sum over binary valued constraints $f(u, v) = [u \neq v]$ over all edges $uv \in E$, in Iverson bracket notation. Since a single valued constraint $f(u, v)$ is submodular, the same holds for the cut function as a whole. Then Lemma 16 specialises into the statement that for two sets $A, B \subset V$ such that $\delta(A), \delta(B)$ are minimum s-t-cuts in G for some $s, t \in V$, there is no edge between $A \setminus B$ and $B \setminus A$. This kind of observation is a common tool in, e.g., graph theory and approximation algorithms.

The above lemma will be very useful when reasoning about the structure of $\mathbf{opt}(I)$ subject to more complex multimorphisms, as we will define next.

5.3 Submodularity on trees

Let $\preceq_T$ denote the ancestor relationship in a rooted tree T. For a path $P[x, y] \subseteq T$, let z_1, z_2 be the middle vertices of $P[x, y]$ (allowing $z_1 = z_2$ in case $P[x, y]$ has odd length) such that $z_1 \preceq_T z_2$. Define the commutative operators $\curvearrowleft, \curvearrowright$ as returning exactly those two mid vertices, e.g. $x \curvearrowleft y = y \curvearrowleft x = z_1$ and $x \curvearrowright y = y \curvearrowright x = z_2$. Languages admitting the multimorphism $\langle \curvearrowleft, \curvearrowright \rangle$ are called *strongly tree-submodular*.

Define the commutative operator $\uparrow$ to return the common ancestor of two nodes x, y in a rooted tree T. Define $x \nearrow y$ to be the vertex z on $P[x, y]$ which satisfies $\mathrm{d}_T(x, z) = \mathrm{d}_T(y, x \uparrow y)$. In other words, to find $z = x \nearrow y$, we measure the distance from y to the common ancestor of x and y and walk the same distance from x along $P[x, y]$. Languages that admit $\langle \uparrow, \nearrow \rangle$ as a multimorphism are called *weakly tree-submodular*. In particular, all strongly tree-submodular languages are weakly tree-submodular [15]. Tree-metric are, not very surprisingly, strongly tree-submodular:

▶ **Lemma 17** ($\star$)**.** *Every tree-metric is strongly (and thus also weakly) tree-submodular for every rooted version of the tree.*

We will need the following characterization of which value-pairs are preserved under equality by strong tree submodularity for tree distance functions. The proof follows from a long case analysis which we omit here.

▶ **Lemma 18 (⋆).** *Two tuples $(a,b),(x,y) \in V(T) \times V(T)$ are preserved under equality by d_T with multimorphism $\langle \curvearrowleft, \curvearrowright \rangle$ iff all four nodes lie on a single path P in T* and *either $a,b \leqslant_P x,y$ or $a,x \leqslant_P b,y$.*

▶ **Corollary 19 (⋆).** *Let d_T be preserved under equality in R for some $R \subseteq V_T \times V_T$, with at least one pair $(a,b) \in R$ with $a \neq b$. Then there is a path P in T which can be oriented as a directed path such that for every pair $(a,b) \in R$ the nodes a and b lie on P with $a \preceq_P b$.*

5.4 The domain consistency property

Consider a problem VCSP(Γ) over a domain D_I and a discrete relaxation VCSP(Γ') of VCSP(Γ) over a domain $D \supseteq D_I$. We say that the relaxation has the *domain consistency property* if the following holds: for any instance I of VCSP(Γ'), if for every variable v there is an optimal solution to I where v takes a value in D_I, then there is an optimal solution where all variables take values in D_I, i.e. an optimal solution to the original problem at the same cost. We show that the discrete relaxations of Zero Extension and Metric Labelling on induced tree metrics have the domain consistency property, allowing for FPT algorithms under the gap parameter via simple branching algorithms.

The result builds on a careful investigation of the binary constraints that $\mathbf{opt}(I)$ can induce on a pair of vertices $u,v \in V$, starting from Corollary 19. For the rest of the section, let us fix a relaxed instance $I = (G = (V,E), \tau, \mu, q)$ of Zero Extension where μ is a tree metric defined by a tree T, and the original (non-relaxed) metric is the restriction of μ to a set of nodes D_I. Note that I can be expressed as a VCSP instance using assignments and the cost function μ. Let $\mathbf{opt}$ be the set of optimal labellings. For a vertex $v \in V$, let $D(v)$ denote the set $\{\lambda(v) \mid \lambda \in \mathbf{opt}\}$, and let $D_I(v) = D_I \cap D(v)$. Furthermore, for a pair of vertices $u,v \in V$, let $R(u,v) = \{(\lambda(u),\lambda(v)) \mid \lambda \in \mathbf{opt}\}$ be the projection of $\mathbf{opt}$ onto (u,v), and $R_I(u,v) = R(u,v) \cap (D_I \times D_I)$ the integral part of this projection. We begin by observing that the "path property" of Corollary 19 applies to all vertices and edges in $\mathbf{opt}$.

▶ **Lemma 20 (⋆).** *For every vertex v that lies in a connected component of G containing at least one terminal, $D(v)$ is a path in T. Furthermore, for every edge $uv \in E$, $R(u,v)$ embeds into the transitive closure of a directed path in T.*

Next, we show the main result of this section: if u and v is a pair of variables, then whether or not there is an edge uv in E, the constraint $R(u,v)$ induced on u and v by $\mathbf{opt}$ is only non-trivial on values in $D(u) \cap D(v)$.

▶ **Lemma 21 (⋆).** *Let u and v be a pair of variables and $a \in D(u)$, $b \in D(v)$ a pair of values. If $(a,b) \notin R(u,v)$, then $a,b \in D(u) \cap D(v)$ and $a \neq b$.*

This gives us the following algorithmic consequence.

▶ **Lemma 22.** *There is a labelling $\lambda \in \mathbf{opt}$ such that for every variable v with $D_I(v)$ non-empty, we have $\lambda(v) \in D_I$.*

Proof sketch. Order $V(T)$ such that the values D_I come first, and assign to every variable v the value of $D(v)$ that is earliest in this ordering. By Lemma 21, this gives an assignment that is consistent with $R(u,v)$ for every pair of variables $u,v \in V$, and since $\mathbf{opt}$ has a majority polymorphism, this implies that the resulting assignment is in $\mathbf{opt}$. ◀

Let us for reusability spell out the explicit assumptions and requirements made until now.

▶ **Theorem 23** (⋆). *Let $I = (G = (V, E), \tau, \mu, q)$ be an instance of* Zero Extension *with no isolated vertices and where every connected component of G contains at least two terminals, and where μ is an induced tree metric for some tree T and integral nodes $D_I \subseteq T$. Additionally, assume a collection of cost functions $\mathcal{F} = (f_i(\bar{v}_i))_{i=1}^m$ has been given, where for every f_i the scope is contained in V and where f_i is weakly tree submodular for every rooted version of T. Let I' be the VCSP instance created from the sum of the cost functions of I and $\mathcal{F}$. Then I' has the domain consistency property, i.e., there is an integral relaxed optimum if and only if every vertex v is integral in at least one relaxed optimum of I'.*

5.5 Gap algorithms for general induced tree metrics

By Theorem 23, we get FPT algorithms parameterized by the gap parameter $q - p$.

▶ **Theorem 3.** *Let $I = (G, \tau, \mu, q)$ be an instance of* Zero Extension *where μ is an induced tree metric on a set of labels D in a tree T, and let $\hat{I} = (G, \tau, \hat{\mu}, q)$ be the relaxed instance. Let $p = \mathbf{cost}(\hat{I})$. Then we can solve I in time $O(|D|^{q-p}|T||D|nm)$.*

Proof. This algorithm is similar to the algorithm for a leaf metric, except that we are not as easily able to test whether every variable has an integral value in **opt**. By the results of Section 5.1, the value of **opt** is witnessed by the collection of min-cuts for edges in T; we will use this as a value oracle for I. We initially compute a max-flow across every edge of T, then for every assignment made we can compute the new value of **opt** using $O(|T|)$ calls to augmenting path algorithms. This allows us to test for optimality of an assignment in $O(|T|m)$ time. The branching step then in general iterates over at most n variables, testing at most $|D|$ assigned values for each, and testing for optimality each time. Hence the local work in a single node of the branching tree is $O(|T||D|nm)$. This either produces a variable for branching on or (by Theorem 23) produces an integral assignment, and in each branching step the value of p increases but q does not. The time for the initial max-flow computation is eaten by the factor $|T|nm$. The result follows. ◀

For Metric Labelling, we first need to restrict the unary cost functions. Intuitively, the property is analogous to linear interpolation or convexity, applied along paths of the tree. The precise definition is as follows.

▶ **Lemma 24** (⋆). *Let $f\colon V(T) \to \mathbb{R}$ be a unary function on a tree T. Then f is weakly tree submodular on T for every choice of root $r \in V_T$ if and only if it observes the following* interpolation property*: for any nodes $u, v \in V(T)$, at distance $\mathrm{d}_T(u, v) = d$, and every $i \in [d-1]$, let w_i be the node on $T[u, v]$ satisfying $d_T(u, w_i) = i$. Then for any such choice of u, v and i, it holds that $f(w_i) \leqslant ((d-i)/d)f(u) + (i/d)f(v)$.*

Let $f_0\colon U \to \mathbb{Z}^+$ be a non-negative function defined on a subset U of the nodes of a tree T. We say that f_0 *admits an interpolation on* T if there is an extension $f\colon V(T) \to \mathbb{Z}^+$ with the interpolation property such that $f(v) = f_0(v)$ for every $v \in U$. Note that this only restricts the values $f_0(u)$ for nodes $u \in U$ that lie on a tree path between two other nodes $u_1, u_2 \in U$. In particular, if U is the set of leaves of T, then every function f_0 admits an interpolation by simply padding with zero values (although stronger interpolations are in general both possible and desirable).

We get the following.

▶ **Theorem 5.** *Let $I = (G, \sigma, \mu, q)$ be an instance of* Metric Labelling *where μ is an induced tree metric for a tree T and a set of nodes $D \subseteq V(T)$, and where every unary cost $\sigma(v, \cdot)$ admits an interpolation on T. Let $\hat{I} = (G, \hat{\sigma}, \hat{\mu}, q)$ be the relaxed instance, and let $p = \mathbf{cost}(\hat{I})$. Then the instance I can be solved in time $O^*(|D|^{q-p})$. In particular, this applies for any σ if D is the set of leaves of T.*

Proof. Assume that G is connected, or else repeat the below for every connected component of G. Select two arbitrary vertices $u, v \in V$ and exhaustively guess their labels; in the case that you guess them to have the same label, identify the vertices in I (adding up their costs in σ) and select a new pair to guess on. Note that this takes at most $O(|D|^2 n)$ time, terminating whenever you have guessed more than one label in a branch or when you have guessed that all vertices are to be identical. This guessing phase can only increase the value of p. We may now treat u and v as terminals, and the instance I as the sum of a Zero Extension instance on those two terminals and a collection of additional unary cost functions $\sigma(v', \cdot)$, as in Theorem 23. Note that the resulting VCSP is tractable, i.e., the value of an optimal solution can be computed in polynomial time. The running time from this point on consists of iterating through all variables verifying whether each one has an integral value in some optimal assignment, and branching exhaustively on its value if not. ◀

In particular, as noted, for a leaf metric μ the algorithm applies without any assumptions on σ (and without T being explicitly provided).

6 Conclusion

We have given a range of algorithmic results for the Zero Extension and Metric Labelling problems from a perspective of parameterized complexity. Most generally, we showed that Zero Extension is FPT parameterized by the number of *crossing edges* of an optimal solution, i.e. the number of edges whose endpoints receive distinct labels, for a very general class of cost functions μ that need not even be metrics. This is a relatively straight-forward application of the technique of recursive understanding [3].

For the case that μ is a metric we gave two stronger results for the same parameter. First, we showed a linear-time FPT algorithm, with a better parameter dependency, using an important separators-based algorithm. Second, and highly surprisingly, we show that every graph G with a terminal set S admits a polynomial-time computable, polynomial-sized *metric sparsifier* G', with $O(k^{s+1})$ edges, such that (G', S) mimics the behaviour of (G, S) over *any* metric on at most s labels (up to solutions with crossing number k). This is a direct and seemingly far-reaching generalization of the polynomial kernel for s-Multiway Cut [17], which corresponds to the special case of the uniform metric.

Finally, we further developed the toolkit of discrete relaxations to design FPT algorithms under a *gap parameter* for Zero Extension and Metric Labelling where the metric is an induced tree metric. This in particular involves a more general FPT algorithm approach, supported by an applicability condition of *domain consistency*, relaxing the previously used persistence condition.

Let us highlight some questions. First, is there a lower bound on the size of a metric sparsifier for s labels for Zero Extension? This is particularly relevant since the existence of a polynomial kernel for s-Multiway Cut whose degree does not scale with s is an important open problem, and since the metric sparsifier is a more general result.

Second, can the FPT algorithms for induced tree metrics parameterized by the relaxation gap be generalised to restrictions of other tractable metrics, such as graph metrics for median

graphs or the most general tractable class of orientable modular graphs [9]? Complementing this, what are the strongest possible gap parameters that allow FPT algorithms for metrics that are either arbitrary, or do not explicitly provide their relaxation?

Abstract

We show that the mutual information, in the sense of Kolmogorov complexity, of any pair of strings x and y is equal, up to logarithmic precision, to the length of the longest shared secret key that two parties, one having x and the complexity profile of the pair and the other one having y and the complexity profile of the pair, can establish via a probabilistic protocol with interaction on a public channel. For $\ell > 2$, the longest shared secret that can be established from a tuple of strings $(x_1, ..., x_\ell)$ by ℓ parties, each one having one component of the tuple and the complexity profile of the tuple, is equal, up to logarithmic precision, to the complexity of the tuple minus the minimum communication necessary for distributing the tuple to all parties. We establish the communication complexity of secret key agreement protocols that produce a secret key of maximal length, for protocols with public randomness. We also show that if the communication complexity drops below the established threshold then only very short secret keys can be obtained.

1 Introduction

Mutual information is a concept of central importance in both information theory (IT) and algorithmic information theory (AIT), also known as Kolmogorov complexity. We show an interpretation of mutual information in AIT, which links it to a basic concept from cryptography. Even though a similar interpretation was known in the IT framework, an operational characterization of mutual information in AIT has been elusive till now.

To present our result, let us consider two strings x and y. It is common to draw a Venn-like diagram such as the one in Figure 1 to visualize the information relations between

them. As explained in the figure legend there are six important regions. The regions (1) to

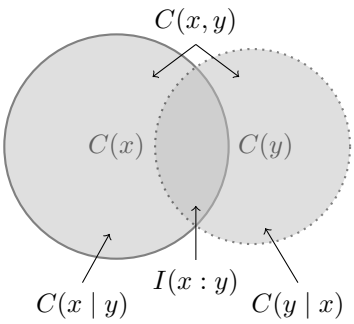

Figure 1 Two strings x and y, and their information. There are six regions that we distinguish: (1) The left solid circle represents the information in x, as given by its Kolmogorov complexity, denoted $C(x)$; (2) The right dotted circle represents the information in y, denoted $C(y)$; (3) The entire grey region (the two circles taken together) represents the information in x and y, denoted $C(x,y)$; (4) The light-grey region in the first circle represents the information in x conditioned by y, denoted $C(x \mid y)$; (5) The light-grey region in the second circle represents the information of y conditioned by x, denoted $C(y \mid x)$; and (6) the dark-grey region in the middle represents the mutual information of x and y, denoted $I(x:y)$.

(5) have a clear operational meaning. For instance, $C(x)$ is the length of a shortest program that prints x, $C(x \mid y)$ is the length of a shortest program that prints x when y is given to it, and so on. On the other hand, the mutual information $I(x:y)$ from region (6) is defined by a formula: $I(x:y) = C(x) + C(y) - C(x,y)$. Intuitively, it is the information shared by x and y. But is there an operational interpretation of the mutual information? As mentioned above, we give a positive answer: The mutual information of x and y is essentially equal to the length of a longest shared secret key that two parties, one having x and the other one having y, and both parties also possessing the complexity profile of the two strings, can establish via a probabilistic protocol.

The following simple example illustrates the above concepts. Suppose that Alice and Bob want to agree on a common secret key. If they could meet face-to-face, they could just generate such a key by, say, flipping a coin. Unfortunately, they cannot meet in person and what makes the situation really troublesome is that they can only communicate through a public channel. There is however a gleam of hope because Alice knows a random line x in the affine plane over the finite field with 2^n elements, and Bob knows a random point y on this line. The line x is specified by the slope a and the intercept b and the point y by its two coordinates c and d. Therefore each of x and y has $2n$ bits of information, but, because of the geometrical correlation, together they have $3n$ bits of information. Thus, in principle, Alice and Bob share n bits. Can they use them to obtain a common secret key? The answer is yes: Alice sends a to Bob, Bob, knowing that his point is on the line, finds x, and now they can use b as the secret key, because the adversary has only seen a, and a and b are independent.

It may appear that the geometrical relation between x and y is crucial for the above solution. In fact it is just a red herring and Alice and Bob can agree on a common secret key in a very general setting. To describe it, we consider the scenario in which Alice has a random string x and Bob has a random string y. If $x = y$, then Alice and Bob can use their common string as a secret key in an encryption scheme (such as the one-time pad) and achieve perfect information-theoretical security. What happens if x and y are not equal,

but only correlated? Somewhat surprisingly, for many interpretations of "correlated," they can still agree on a shared secret key via interaction on a public channel (for instances of this assertion, see [15, 3, 17, 1]). In this paper, we look at this phenomenon using the very general framework of algorithmic information theory to measure the correlation of strings.

1.1 Our contributions

Characterization of mutual information. In a secret key agreement protocol, Alice and Bob, on input x and respectively y, exchange messages and compute a common string that is random conditioned by the transcript of the protocol. Such a string is said to be a *shared secret key*. Unless specified otherwise, we use protocols having the following features:

(1) We assume that Alice and Bob also know how their x and y are correlated. In our setting this means that Alice and Bob know the complexity profile of x and y, which, by definition, is the tuple $(C(x), C(y), C(x, y))$.

(2) The protocols are effective and randomized, meaning that Alice and Bob use probabilistic algorithms to compute their messages.

▶ **Theorem 1** (Main Result, informal statement)**.**

1. *There is a secret key agreement protocol that, for every n-bit strings x and y, allows Alice and Bob to compute with high probability a shared secret key of length equal to the mutual information of x and y (up to an $O(\log n)$ additive term).*
2. *No protocol can produce a longer shared secret key (up to an $O(\log n)$ additive term).*

Secret key agreement for three or more parties. Mutual information is only defined for two strings, but secret key agreement can be explored for the case of more strings. Let us consider again an example. Suppose that each of Alice, Bob, and Charles have a point in the affine plane over the finite field with 2^n elements, and that the three points, which we call A, B, C, are collinear. Thus each party has $2n$ bits of information, but together they have $5n$ bits of information, because given two points, the third one can be described with n bits. The parties want to establish a common secret key, but they can only communicate by broadcasting messages over a public channel. They can proceed as follows. Alice will broadcast a string p_A, Bob a string p_B, and Charles a string p_C, such that each party using his/her point and the received information will reconstruct the three collinear points A, B, C. A protocol that achieves this is called an *omniscience protocol* because it spreads to everyone the information possessed at the beginning individually by each party. In the next step, each party will compress the $5n$ bits, comprising the three points, to a string that is random given p_A, p_B, p_C. The compressed string is the common secret key. We will see that up to logarithmic precision it has length $5n - (|p_A| + |p_B| + |p_C|)$. Assuming we know how to do the omniscience protocol and the compression step, this protocol produces a common secret key of length $5n - \mathrm{CO}(A, B, C)$, where $\mathrm{CO}(A, B, C)$ is the minimum communication for the omniscience task for the points A, B, C. In our example, it is clear that each one of p_A, p_B, p_C must be at least n bits long, and that any two of these strings must contain together at least $3n$ bits. Using some recent results from the reference [28], it can be shown that any numbers satisfying these constraints can be used for the omniscience task. It follows that the smallest communication for omniscience is achieved when $|p_A| = |p_B| = |p_C| = 1.5n$, and thus the key has $5n - 4.5n = 0.5n$ bits (Warning: we have ignored in the entire discussion some $O(\log n)$ terms). We show that this holds in general. If ℓ parties have, respectively, one component of a tuple $(x_1, \ldots, x_\ell)$ of n-bit strings, then up to $O(\log n)$ precision, they can produce a common secret key of length $C(x_1, \ldots, x_\ell) - \mathrm{CO}(x_1, \ldots, x_\ell)$, where $\mathrm{CO}(x_1, \ldots, x_\ell)$ is the

minimum communication for the omniscience task. The protocol that produces such a key is probabilistic, and, as was the case for two strings, assumes that each party i has at the beginning of the protocol besides its input string x_i also the complexity profile of the entire tuple $(x_1, \ldots, x_\ell)$. We also show a matching (up to $O(\log n)$) upper bound: no probabilistic protocol can produce a longer secret key.

▶ Remark. The value $\mathrm{CO}(A, B, C)$ is understood as the communication complexity of the *omniscience problem*. However, it can be computed as a function of the Kolmogorov complexities of the involved strings, see Definition 4 below. This fact (the communication complexity of the optimal omniscience protocol depends only on the complexity profile of the inputs) is not trivial and requires a proof.

Communication complexity for secret key agreement. In the protocol in Theorem 1, Alice and Bob exchange $\min(C(x \mid y), C(y \mid x)) + O(\log n)$ bits and obtain with high probability a shared secret key of length $I(x : y) - O(\log n)$. In this protocol we can assume that Alice and Bob use either private random bits, or public random bits. We show that for the model with public random bits, the communication complexity of the protocol is optimal, in the sense that in any protocol with public random bits there are input strings x and y, on which Alice and Bob have to exchange at least $\min(C(x \mid y), C(y \mid x))$ bits. In fact our lower bound is stronger: we show that, for any constants $\delta_1, \delta_2 > 0$, if Alice and Bob use a protocol with communication complexity $(1 - \delta_1) \min(C(x \mid y), C(y \mid x))$ for every input pair x, y, then there are inputs for which the shared secret key that they obtain has length at most $\delta_2 I(x : y)$. That is, if the communication complexity sinks below the threshold $\min(C(x \mid y), C(y \mid x))$, then the size of the common secret key drops to virtually zero. To determine the optimal communication complexity for the model with private random bits remains an open problem.

1.2 Related previous work.

IT vs. AIT. Before reviewing existing related results in the IT and the AIT frameworks, it is useful to understand the distinction between the two theories. In computer science the attribute *random* is mainly used in two (fairly different) contexts: *random processes* and *random objects*. In short, IT, which we also call Shannon's framework, focuses on the former, whereas AIT, which we also call Kolmogorov's framework, focuses on the latter. On the one hand, we may think of an uncertain physical process with unpredictable outcomes, and employ the framework of the classic probability theory (distributions, random variables, etc.). The notion of a *random variable* formalizes the idea of a process like coin tossing. In this context we can measure the uncertainty of a random variable as a whole (by its Shannon's entropy, its min-entropy, etc.), but we can not ask whether one specific outcome is random or not. On the other hand, people use *tables of random numbers*, which are available as specific sequences of digits, written on a disc or printed on a paper. The usefulness of such a table depends on its individual properties: frequencies of digits, presence or absence of hidden regularities, compressibility, etc. The usual way to measure the uncertainty of an individual string of digits is Kolmogorov complexity. In both contexts the formal measures of randomness may or may not involve computational complexity (see, e.g., different versions of pseudoentropy for distributions and the resource bounded variants of Kolmogorov complexity for individual strings). These two formalizations of randomness are connected but not interchangeable.

Both notions of randomness appear in cryptography. For example, in the one-time pad scheme, two parties share a "random" key that remains "secret" for the attacker. It is

common to use Shannon's framework, and therefore the notions of randomness and secrecy are defined in terms of random processes. In the ideal situation both parties should have access to a common source of randomness, e.g., to the results of tossing an unbiased coin (hidden from the adversary). By tossing this coin n times we get a random variable with maximal possible entropy, and thus, in Shannon's framework, the quality of randomness is perfect. But if by chance we obtain a sequence of n zeros, then this specific one-time pad looks pretty useless in any practical application. However, Shannon's information theory provides no vocabulary to complain about this apparently non-random individual key. Antunes *et al.* [2] suggested to use Kolmogorov complexity to measure the "secrecy" of individual instances of a one-time pad or a secret sharing schemes. We have in mind a similar motivation, and in this work a "secret key" is an individual string that is random in the sense of Kolmogorov complexity.

Related work. We start with a brief account of works on secret key agreement in the IT setting. The secret key agreement is a relatively well-studied problem in information theory, motivated, as the name suggests, by applications in information-theoretically secure cryptography. Wyner [27] and Csiszár and Körner [7] have analyzed the possibility of obtaining a shared secret key in the case when one party sends to the other party a single message on a channel from which the eavesdropper can obtain partial information. Maurer [16, 17] considered the case of protocols with several rounds of communication and showed that interaction can be more powerful than one-way transmission. Ahlswede and Csiszár [1] and Maurer [17] have established the tight relation between interactive secret key agreement and mutual information for *memoryless sources*. In the memoryless model, the input data is given by two random variables (X_1, X_2) obtained by n independent draws from a joint distribution, where Alice observes X_1 and Bob observes X_2. Informally stated, the references [17, 1] show that the longest shared secret key that Alice and Bob can establish via an interactive protocol with an arbitrary number of rounds is equal to the mutual information of X_1 and X_2. Csiszár and Narayan [8] go beyond the scenario with two parties, and consider the case of an ℓ-memoryless source $(X_1, \ldots, X_\ell)$ and ℓ parties, each one observing one component of the tuple. They show that the longest shared secret key the ℓ parties can establish via an interactive protocol with an arbitrary number of rounds is equal to the entropy $H(X_1, \ldots, X_\ell)$ of the ℓ-memoryless source from which one subtracts the minimum communication for omniscience. Their result holds also for stationary ergodic sources, which generalize memoryless sources. As one can see, our results are very similar. They have been inspired by the papers [1, 17, 8] and represent the AIT analogue of the results presented above. Our results imply their IT analogues, and can be viewed as more general because they do not require the memoryless or ergodicity properties of sources (in fact they do not require any generative model at all). Regarding the communication complexity of secret key agreement protocols, we only note here that Tiyagi [26] has shown that for memoryless sources it is equal to the difference between interactive common information in Wyner's sense and mutual information. In the full version of this paper we explain how Tyagi's result compares to our results on communication complexity in the AIT framework.

Let us now say a few words about related results from the AIT world. To the best of our knowledge, in AIT there has been no previous works on secret key agreement. However, the general idea of "materialization" of mutual information was studied extensively. Motivated by the intuition that mutual information represents the amount of shared information in two strings, researchers have explored the extent to which mutual information can be materialized more or less effectively. The relevant concept is that of *common information.* Informally, a

string z is a common information string extracted from strings x and y, if z can be "computed" from x, and also from y, where "computed" is taken in a more liberal sense that allows the utilization of a few help bits. In the most common setting of parameters, we require that $C(z \mid x) = O(\log n)$ and $C(z \mid y) = O(\log n)$, where n is the length of x and y and the constant hidden in the $O(\cdot)$ notation depends only on the universal machine. Informally, the common information of x and y is the length of a longest common information string that can be extracted from x and y. It can be shown that up to logarithmic precision common information is upper bounded by mutual information. In an influential paper, Gács and Körner [9] have constructed strings x and y for which the common information is much smaller than the mutual information. Moreover, the property of a pair (x, y) of having common information equal to mutual information does not depend solely on the complexity profile of x and y: There exist pairs (x_1, y_1) and (x_2, y_2) having the same complexity profile, and for (x_1, y_1) the common information and mutual information are equal, whereas for (x_2, y_2) they are not. Muchnik [19] and Romashchenko [22] have strengthened the Gács-Körner theorem in significant ways, by allowing a larger amount of help bits, parameterizing the mutual information of the constructed pair (x, y), and other ways. Chernov et al. [6] presents alternative constructions of strings for which the common information is smaller than mutual information for several regimes of parameters. A nice, self-contained and accessible exposition of this research line can be found in the book of Shen, Vereshchagin and Uspensky [23, Chapter 11].

Thus, previous works have shown negative results regarding the "materialization" of mutual information in AIT. As far as we know, ours is the first positive result. In summary, we now know that computation without communication, even enhanced with help bits, fails to extract the mutual information of two strings, while interactive computation succeeds.

1.3 The basics of algorithmic information theory

Given a Turing machine M, a string p is said to be a *program* (or a *description*) of a string x, if M on input p prints x. We denote the length of a binary string x by $|x|$. The *Kolmogorov complexity* of x relative to the Turing machine M is

$$C_M(x) = \min\{|p| \mid \ p \text{ is a program for } x \text{ relative to } M\}.$$

If U is universal Turing machine, then for every other Turing machine M there exists a string m such that $U(m, p) = M(p)$ for all p, and therefore for every string x, $C_U(x) \leq C_M(x) + |m|$. Thus, if we ignore the additive constant $|m|$, the Kolmogorov complexity of x relative to U is minimal. We fix a universal Turing machine U, drop the subscript U in $C_U(\cdot)$, and denote the complexity of x by $C(x)$. Similarly to the complexity of x, we define the complexity of x conditioned by y as $C(x \mid y) = \min\{|p| \mid \ U \text{ on input } p \text{ and } y \text{ prints } x\}$. We list below a few basic facts about Kolmogorov complexity and introduce some notation:

- For every string x, $C(x) \leq |x| + O(1)$, because a string x is trivially described by itself. (Formally, there is a Turing machine M that, for every x, on input x prints x.)
- Using some standard computable pairing function $\langle \cdot, \cdot \rangle$ that maps pairs of strings into single strings, we define the complexity of a pair of strings by $C(x, y) = C(\langle x, y \rangle)$. Then we can extend this notation to tuples of larger arity.
- We use the convenient shorthand notation $a \leq^+ b$ to mean that $a \leq b + O(\log n)$, where n is a parameter that is clear from the context and the constant hidden in the $O(\cdot)$ notation only depends on the universal machine U. Similarly, $a \geq^+ b$ means $a \geq b - O(\log n)$, and $a =^+ b$ means ($a \leq^+ b$ and $a \geq^+ b$).

- The chain rule (a.k.a. the Kolmogorov–Levin theorem) claims that for all sufficiently long strings x and y, $\big|C(x,y) - (C(x) + C(y \mid x))\big| \le 3(\log C(x) + \log C(y))$.
- The mutual information of two strings x and y is denoted $I(x : y)$, and is defined as $I(x : y) = C(x) + C(y) - C(x, y)$.
- The complexity profile of a tuple of strings $(x_1, \ldots, x_\ell)$ is given by the tuple consisting of the complexities of all non-empty subsets of the strings in the tuple, i.e., it is the tuple $(C(x_V) \mid V \subseteq [\ell], V \neq \emptyset)$. Here x_V denotes the subtuple obtained by taking the components with indices in V (for example if $V = \{1, 2, 7\}$ then $x_V = (x_1, x_2, x_7)$).

1.4 Shared secret keys and protocols for secret key agreement

Let k be a positive integer. A k-rounds two-party protocol for secret key agreement uses two computable functions A and B and runs as follows. The first party has as input a string x_A and uses private randomness r_A, the second party has as input a string x_B and uses private randomness r_B. We assume that the length of r_A (r_B) is determined by x_A (respectively, x_B). The protocol consists of the following calculations:

$$\begin{array}{lll} x_1 &= A(x_A, r_A), & y_1 = B(x_B, r_B, x_1) \\ x_2 &= A(x_A, r_A, y_1), & y_2 = B(x_B, r_B, x_1, x_2) \\ \vdots & & \\ x_k &= A(x_A, r_A, y_1, \ldots, y_{k-1}), & y_k = B(x_B, r_B, x_1, \ldots, x_k). \end{array}$$

The algorithms A and B can handle inputs of different lengths. We also allow them to be partial (i.e., it is possible that the protocol does not converge for some pairs of inputs). Let us fix parameters ϵ and $\delta(n)$. (We assume ϵ is a positive constant and $\delta(n)$ is a constant or a slow growing function, e.g., $O(\log n)$). A protocol *succeeds* with error probability ϵ and randomness deficiency $\delta(n)$ on a pair (x_A, x_B) of n-bit strings if with probability $(1 - \epsilon)$ over r_A, r_B,

$$A(x_A, r_A, t) = B(x_B, r_B, t) \stackrel{def.}{=} z, \tag{1}$$

and

$$C(z \mid t) \ge |z| - \delta(n), \tag{2}$$

where $t = (x_1, y_1, \ldots, x_k, y_k)$ is the transcript of the protocol.

The string z satisfying equation (1) and inequality (2) is called a *shared secret key* output by the protocol on input (x_A, x_B). Note that the shared secret key z is a random variable since it depends not only on the inputs x_A and x_B, but also on the randomness r_A and r_B.

In words, Alice and Bob start with input strings x_A and respectively x_B, use private randomness r_A, and respectively r_B and execute a protocol in which at round i, first Alice sends to Bob the string x_i, and next Bob sends to Alice the string y_i, and at the end Alice and Bob separately compute with high probability a common string z (equation (1)) such that z is random even conditioned by the transcript of the protocol (inequality (2)). Thus, z is secret to an adversary that has observed the protocol and consequently knows the transcript.

The number of rounds in a protocol (parameter k) may depend on the length of the inputs.

2 Main results

We present here our main results. We first show that there exists a secret key agreement protocol which produces a shared secret key of length equal (up to logarithmic precision) to the mutual information of the inputs, provided the two parties know the complexity profile. Next we show that no protocol can produce a longer shared secret key. The formal statements are as follows.

▶ **Theorem 2** (Lower bound). *There exists a secret key agreement protocol with the following property: For every n-bit strings x and y, for every constant $\epsilon > 0$, if Alice's input x_A consists of x, the complexity profile of (x, y) and ϵ, and Bob's input x_B consists of y, the complexity profile of (x, y) and ϵ, then, with probability $1 - \epsilon$, the shared secret key is a string z such that, $C(z \mid t) \geq |z| - O(\log(1/\epsilon))$ and $|z| \geq I(x : y) - O(\log(n/\epsilon))$, where t is the transcript of the protocol. Moreover, the communication consists of a single message sent by Alice to Bob of length $C(x \mid y) + O(\log(n/\epsilon))$, Alice uses $O(\log(n/\epsilon))$ random bits, and Bob does not use any random bits.*

▶ **Theorem 3** (Upper bound). *Let us consider a protocol for secret key agreement, let x_A and x_B be input strings of length n on which the protocol succeeds with error probability ϵ and randomness deficiency $\delta(n)$, and let z be the random string that is the shared secret key output by the protocol, i.e., a string satisfying relations (1) and (2). Then with probability at least $1 - O(\epsilon)$, if n is sufficiently large, $|z| \leq I(x_A : x_B) + \delta(n) + O(\log(n/\epsilon))$, where the constants in the $O(\cdot)$ notation depend on the universal machine, but not on x_A and x_B.*

Theorem 3 establishes the upper bound claimed in the Introduction. Indeed, for any pair of n-bit strings (x, y), suppose that Alice's input x_A consists of x and the complexity profile of (x, y) and Bob's input x_B consists of y and the complexity profile of (x, y). Note that $I(x_A : x_B) =^+ I(x : y)$, because the length of the complexity profile is bounded by $O(\log n)$. Hence, Theorem 3 implies that secret key agreement protocols in which the two parties, besides x and respectively y, are additionally given the complexity profile of their inputs can not produce a secret key that is longer than $I(x : y) + O(\log n)$ (provided the randomness deficiency of the key satisfies $\delta(n) = O(\log n)$).

▶ Remark. In our secret key agreement protocols, the inputs x_A and x_B have two components: $x_A = (x, h_A)$ and $x_B = (y, h_B)$, where the strings x and y are the main components, while h_A and h_B are short helping strings (for example, containing information about how x and y are correlated). The protocols designed in this paper succeed for all input pairs x_A and x_B in which $h_A = h_B =$ (the complexity profile of x and y). In case one or both of h_A and h_B are not equal to the complexity profile, the protocols still halt on every input, but the outputs may be meaningless. However, the proof of Theorem 2 can be adapted to the situation where Alice and Bob are not given the exact value of the complexity profile of (x, y) but only an approximation of this profile. If Alice and Bob are given upper and lower bounds for each component of the complexity profile of (x, y) with precision $\leq \sigma$, for some integer σ, then with probability $1 - O(\epsilon)$ Alice and Bob agree on a common secret z that is incompressible (i.e., $C(z \mid t) \geq |z| - O(\log(1/\epsilon))$ where t is the transcript of the protocol), and the length of z is greater than $I(x : y) - \sigma - O(\log(n/\epsilon))$.

3 Secret key agreement for three or more parties

In this section we analyze secret key agreement for 3 parties, which we call Alice, Bob, and Charles. Alice has a string x_A, Bob has a string x_B, and Charles has a string x_C. They

also have private random bits r_A, respectively r_B and r_C. They run a k-round protocol. In each of the k rounds, each party broadcasts a message to the other two parties, where the message is a string computed from the party's input string and private random bits, and the messages from the previous rounds. After the completion of the k rounds, each party computes a string. The requirement is that with probability at least $1-\epsilon$, they compute the same string, and that this string is random conditioned by the transcript of the protocol.

Formally, a k-round 3-party protocol for secret key agreement uses three computable functions A, B, C, and runs as follows. The first party has as input an n-bit string x_A and uses private randomness r_A, the second party has as input an n-bit string x_B and uses private randomness r_B, and the third party has as input an n-bit string x_C and uses private randomness r_C. The protocol consists of the following calculations:

$$\left.\begin{array}{lll} t_1 = A(x_A, r_A), & t_2 = B(x_B, r_B), & t_3 = C(x_C, r_C), \\ t_4 = A(x_A, r_A, t[1:3]), & t_5 = B(x_B, r_B, t[1:3]), & t_6 = C(x_C, r_C, t[1:3]), \\ t_7 = A(x_A, r_A, t[1:6]), & t_8 = B(x_B, r_B, t[1:6]), & t_9 = C(x_C, r_C, t[1:6]), \\ \vdots & & \end{array}\right\} k \text{ rounds}$$

Each row corresponds to one round and shows the messages that are broadcast in that round, and we use the notation $t[i:j]$ to denote the tuple of messages $(t_i, \ldots, t_j)$. We also denote $t = t[1:3k]$, the entire transcript of the protocol. The protocol succeeds with probability error ϵ and randomness deficiency $\delta(n)$ on the 3-tuple input (x_A, x_B, x_C) if with probability $(1-\epsilon)$ over r_A, r_B, r_C,

$$A(x_A, r_A, t) = B(x_B, r_B, t) = C(x_C, r_C, t) \stackrel{def.}{=} z, \tag{3}$$

and $C(z \mid t) \geq |z| - \delta(n)$.

▶ **Definition 4.**

(1) For each triple of strings (x_1, x_2, x_3), we denote by $S(x_1, x_2, x_3)$ the set of all triples of integers (n_1, n_2, n_3) that satisfy the following inequalities:

$$\begin{array}{ccc} n_1 \geq C(x_1 \mid x_2, x_3), & n_2 \geq C(x_2 \mid x_1, x_3), & n_3 \geq C(x_3 \mid x_1, x_2), \\ n_1 + n_2 \geq C(x_1, x_2 \mid x_3), & n_1 + n_3 \geq C(x_1, x_3 \mid x_2), & n_2 + n_3 \geq C(x_2, x_3 \mid x_1). \end{array}$$

The constraints defining $S(x_1, x_2, x_3)$ will be referred as the *Slepian-Wolf* constraints.

(2) We define $\mathrm{CO}(x_1, x_2, x_3)$ to be the minimal value of $n_1 + n_2 + n_3$ subject to n_1, n_2, n_3 satisfying the Slepian-Wolf constraints. (CO stands for *communication for omniscience.*)

We show that there exists a protocol that on every input tuple (x_A, x_B, x_C) produces with high probability a secret key of length $C(x_A, x_B, x_C) - \mathrm{CO}(x_A, x_B, x_C) - O(\log n)$ (provided the parties have the complexity profile of the input tuple), and that no protocol can produce a secret key of length larger than $C(x_A, x_B, x_C) - \mathrm{CO}(x_A, x_B, x_C) + O(\log n)$.

▶ **Theorem 5** (Upper bound). *Let us consider a 3-party protocol for secret key agreement with error probability ϵ, where the number of random bits is bounded polynomially in the input length. Let (x_A, x_B, x_C) be a 3-tuple of n-bit strings on which the protocol succeeds. Let z be the random variable which represents the secret key computed from the input (x_A, x_B, x_C) and let t be the transcript of the protocol that produces z. Then, for sufficiently large n, with probability $1 - O(\epsilon)$ we have $C(z \mid t) \leq C(x_A, x_B, x_C) - \mathrm{CO}(x_A, x_B, x_C) + O(\log(n/\epsilon))$.*

▶ **Theorem 6** (Lower bound). *There exists a 3-party protocol for secret key agreement with the following characteristics. For every n, for every tuple (x_1, x_2, x_3) of n-bit strings, for*

every $\epsilon > 0$, if Alice's input x_A consists of x_1, the complexity profile of the tuple and ϵ, Bob's input x_B consists x_2, the complexity profile of the tuple and ϵ, and Charles's input x_C consists of x_3, the complexity profile of the tuple and ϵ, then at the end the three parties compute with probability $1 - O(\epsilon)$ a common string z such that

$$C(z \mid t) \geq |z| - O(\log(1/\epsilon)) \text{ and } |z| \geq C(x_1, x_2, x_3) - \mathrm{CO}(x_1, x_2, x_3) - O(\log(n/\epsilon)),$$

where t is the transcript of the protocol.

▶ Remark. Theorem 5 and Theorem 6 remain valid for any constant number $\ell \geq 3$ of parties, with a suitable generalization of the omniscience $\mathrm{CO}(x_1, \ldots, x_\ell)$, see the full version of the paper.

4 Communication complexity of secret key agreement

It is of interest to find the communication complexity for the task of finding a shared secret key having the optimal length of $I(x : y)$. We solve this problem in the model of randomized protocols with *public random bits*, visible to Alice, Bob, and the adversary. This model is obtained by modifying slightly the definition from Section 1.4 (in which the random bits are private): we require that $r_A = r_B = r$ and we change equation (2) to $C(z \mid t, r) \geq |z| - \delta(n)$.

The protocol presented in the proof of Theorem 2 solves the task with communication $\min(C(x \mid y), C(y \mid x)) + O(\log n)$. This protocol can be easily modified to work in the model with public randomness. We argue that within the model with public randomness the communication complexity of this protocol is optimal, up to the $O(\log n)$ term. In what follows we assume as usual that Alice is given a string x and Bob is given a string y, and both parties know the complexity profile of (x, y).

▶ **Theorem 7.** *Let $\epsilon, \delta_1, \delta_2$ be arbitrary positive real constants. There is no secret key agreement protocol with public random bits such that for all inputs x and y,*

1. *the communication complexity of the protocol (the total number of all bits sent by Alice and Bob) is less than $(1 - \delta_1) \min\{C(x \mid y), C(y \mid x)\}$,*
2. *Alice and Bob agree with probability $> \epsilon$ on a common key z such that $C(z \mid t, r) > \delta_2 I(x : y)$, where r is the public randomness and $t = t(x, y, r)$ is the transcript of the protocol.*

5 Our techniques.

It is common for statements in IT (in the Shannon's entropy framework) to have an analogue version in AIT (in the Kolmogorov complexity framework). However, there is no canonical way to translate a result from one setting to the other, and proofs of homologous results in these two frameworks can be drastically different. A textbook example of this phenomenon is the chain rule: it is valid for Shannon's entropy and for Kolmogorov complexity, and the formal expressions of this rule in both frameworks look very similar. However, in Shannon's case this fact is an easy corollary of the definition, while in Kolmogorov's version it requires a nontrivial argument (which is known as the Kolmogorov–Levin theorem). There are more advanced examples of parallel properties (from IT and AIT respectively), where the discrepancy between their proofs is even more striking.

This phenomenon manifests itself in this work as well. Our main results are motivated by similar ones in IT, and there is a close resemblance of statements. As discussed above, this is not surprising. In what follows we explain the relation between our proofs and the proofs of similar statements in Shannon's framework.

The positive results (the existence of communication protocols) use constructions that at the high level are akin to those from their IT counterparts [17, 1, 8]. We employ a similar intuitive idea – manipulations with "fingerprints" of inputs of appropriate lengths[2]. However, the technical machinery is different. In the AIT framework, for communication-efficient protocols, we need quite explicit constructions, while homologous results in IT are usually proven by choosing random encodings. Our constructions are based on a combination of extractors and universal hashing. Our general protocols are not time-efficient and this is to be expected given the high generality of the type of data correlation in the AIT setting. However, for some particular types of correlation (e.g., for a pair of inputs with a bounded Hamming distance), our protocols can be modified to run in polynomial-time. In this case we use the reconciliation technique from [25, 10, 11].

In the negative results (upper bounds for the size of the common secret key, Theorems 2 and 5) the ideas from IT do not help. The reason is that in the AIT framework, the mutual information of various strings is not exactly zero, but only close to zero within some slack terms. The slack terms are small, but during the rounds of a protocol, the errors can accumulate and grow beyond control (for more detail see the discussion of the limits of the "weak" upper bound int he full version of the paper). To overcome this obstacle we come up with a new type of inequalities for Kolmogorov complexity. These inequalities are substantially different from the classic information inequalities used in the analogous results in IT. This technique is based on ideas similar to the *conditional information inequalities* in [13, 14]. We believe that this technique can be helpful in other cases, including applications in IT (see the discussion in the full version of the paper).

In the proof of a lower bound for communication complexity (Theorem 7), we use methods specific for AIT, with no apparent parallel in IT. We adapt the technique of bounds for the size of common information that goes back to An. Muchnik and use deep results regarding stochastic strings [24, 20, 21], which have not been previously employed in information theory and communication complexity.

6 Final comments

On time-efficient secret key agreement protocols. The secret key agreement protocol in the proof of Theorem 2 is computable but highly non-efficient. The only slow stage is when Bob reconstructs x given his input string y and the fingerprint of x obtained from Alice. At this stage Bob has to simulate all programs of size $C(x \mid y)$ until he obtains a string matching the fingerprint. All other stages of the protocol can be implemented in polynomial time (to this end we need to use an effective version of an extractor in the definition of fingerprints; this increases the overhead in communication complexity from $O(\log n)$ to $\mathrm{poly}(\log n)$, but this is still negligible compared to the size of the fingerprint, which is the dominating term in the communication complexity of the protocol; for details see [28]).

We cannot make Bob's computation effective in general, but we can do it for some specific pairs of inputs (x, y). Actually we can make the entire communication protocol fast, if there is a way to communicate x from Alice to Bob so that (i) communication complexity of this stage (and therefore the information revealed to the adversary) remains about $C(x \mid y)$, and (ii) all computations are performed by Alice and Bob in time $\mathrm{poly}(n)$.

[2] On the high level this protocol consists of three stages: (i) Alice sends to Bob a suitable "fingerprint" of her input $p_1(x)$; (ii) Bob uses y and $p_1(x)$ to recover x; (iii) then both Alice and Bob independently compute another fingerprint $p_2(x)$, which is used as a common secret key. The construction of the fingerprints guarantees that the adversary (who eavesdrops p_1) obtains virtually no information about p_2.

Example 1. (Discussed in Introduction, p. 2.) Let Alice get a random line x in the affine plane over the finite field with 2^n elements, and Bob get a random point y on this line. For *most* inputs of this type we have $C(x \mid y) = n \pm O(\log n)$, and there exists a simple way to transfer x from Alice to Bob with communication complexity n (Alice just sends to Bob the slope of her affine line, and Bob draws a line with this slope incident to his point). Thus, we see once again that for this simple example there exists an effective (polynomial-time) communication protocol to agree on common secret key of size $\approx n$ bits.

Example 2. Let Alice and Bob get n-bits strings x and y respectively, and the Hamming distance between these strings is at most δn for some constant $\delta < 1/2$. For most inputs of this type we have $C(x \mid y) = h(\delta)n \pm O(\log n)$ and $I(x : y) = (1 - h(\delta))n \pm O(\log n)$, where $h(\delta) = \delta \log \frac{1}{\delta} + (1 - \delta) \log \frac{1}{1-\delta}$. Can we transfer x from Alice to Bob with communication complexity $h(\delta)n + o(n)$? It turns out that such a protocol exists; moreover, there exists a communication protocol with asymptotically optimal communication complexity and polynomial time computations, see [25, 10, 11]. Plugging this protocol in our proof of Theorem 3 we conclude that on most pairs of inputs (x, y) of this type Alice and Bob can agree on a common secret key of size $(1 - h(\delta))n - o(n)$, with poly-time computations for both parties.

On using our approach for "one-shot" sources. Most known results for secret key agreement in Shannon's framework are proven under the assumption that the input data available to Alice and Bob is generated by i.i.d. or at least stationary ergodic sources. These results can be derived from Theorem 2 and Theorem 3, using the well-known relation between Shannon entropy and Kolmogorov complexity for the above type of sources [18, 12]. But actually Theorem 2 and Theorem 3 apply in more general settings. We can prove similar bounds for random inputs obtained *in one shot*, without the property of ergodicity.

This is useful because in many natural instances of the secret key agreement problem the input data are far from being ergodic, and therefore the classic technique does not apply. For instance, *Example 1* and *Example 2* discussed above illustrate this situation if we reformulate them in the probabilistic setting (i.e., we introduce the uniform distribution on the set of all valid pairs of inputs). For the probabilistic versions of these examples the matching upper and lower bounds on the size of the common secret key can be easily deduced from Theorem 2 and Theorem 3.

On the error probability. The standard results on secret key agreement deal with the paradigm that the protocol works properly for most randomly chosen inputs (which is typical for the information theory), while in our approach we prove a somewhat stronger statement: for each valid pair of input data the protocol works properly with high probability (which is typical for the theory of communication complexity).

7 Open problems and acknowledgements

▶ **Open Question 1.** *In Theorem 7 we establish a lower bound on how many bits Alice and Bob must communicate to agree on a common secret key. Our proof is valid only for communication protocols with public randomness. Is the same bound true for protocols with private sources of random bits?*

▶ **Open Question 2.** *Our communication protocols are randomized. On the other hand they use unusually few random bits, only $O(\log n)$. It is natural to ask whether we can get rid of external randomness. We conjecture that for $(O(\log n), O(\log n))$-stochastic tuples of inputs the protocol can be made purely deterministic (though it would require very high computational complexity), but this cannot be done in the general case. The proof of this fact likely requires a better understanding of the nature of non-stochastic objects (such as Chaitin's Omega number, [4], see also [24] and [23]).*

Abstract

The k-center problem is a classical combinatorial optimization problem which asks to find k centers such that the maximum distance of any input point in a set P to its assigned center is minimized. The problem allows for elegant 2-approximations. However, the situation becomes significantly more difficult when constraints are added to the problem. We raise the question whether general methods can be derived to turn an approximation algorithm for a clustering problem with some constraints into an approximation algorithm that respects one constraint more. Our constraint of choice is privacy: Here, we are asked to only open a center when at least ℓ clients will be assigned to it. We show how to combine privacy with several other constraints.

1 Introduction

Clustering is a fundamental unsupervised learning task: Given a set of objects, partition them into clusters, such that objects in the same cluster are well matched, while different clusters have something that clearly differentiates them. The three classical clustering objectives studied in combinatorial optimization are *k-center*, *k-median* and *facility location*. Given a point set P, k-center and k-median ask for a set of k centers and an assignment of the points in P to the selected centers that minimize an objective. For k-center, the objective is the maximum distance of any point to its assigned center. For k-median, it is the sum of the distances of all points to their assigned center (this is called connection cost). Facility location does not restrict the number of centers. Instead, every center (here called facility) has an opening cost. The goal is to find a set of centers such that the connection cost plus the opening cost of all chosen facilities is minimized. In the unconstrained versions each point will be assigned to its closest center. With the addition of constraints a different assignment is often necessary in order to satisfy the constraints.

A lot of research has been devoted to developing approximation algorithms for these three. The earliest success story is that of k-center: Gonzalez [21] as well as Hochbaum and Shmoys [23] gave a 2-approximation algorithm for the problem, while Hsu and Nemhauser [24] showed that finding a better approximation is NP-hard.

Since then, much effort has been made to approximate the other two objectives. Typically, facility location will be first, and transferring new techniques to k-median poses additional challenges. Significant techniques developed during the cause of many decades are LP rounding

techniques [11, 34], greedy and primal dual methods [25, 26], local search algorithms [6, 29], and, more recently, the use of pseudo-approximation [32]. The currently best approximation ratio for facility location is 1.488 [31], while the best lower bound is 1.463 [22]. For k-median, the currently best approximation algorithm achieves a ratio of $2.675+\epsilon$ [9], while the best lower bound is $1 + \frac{2}{e} \approx 1.736$ [25].

While the basic approximability of the objectives is well studied, a lot less is known once constraints are added to the picture. Constraints come naturally with many applications of clustering, and since machine learning and unsupervised learning methods become more and more popular, there is an increasing interest in this research topic. It is one of the troubles with approximation algorithms that they are often less easy to adapt to a different scenario than some easy heuristic for the problem, which was easier to understand and implement in the first place. Indeed, it turns out that adding constraints to clustering often requires fundamentally different techniques for the design of approximation algorithms and is a very new challenge altogether.

A good example for this is the *capacity* constraint: Each center c is now equipped with a capacity $u(c)$, and can only serve $u(c)$ points. This natural constraint is notoriously difficult to cope with; indeed, the standard LP formulations for the problems have an unbounded integrality gap. Capacitated k-center was first approximated with uniform upper bounds [8, 28]. Local search provides a way out for facility location, leading to 3- and 5-approximations for uniform [1] and non-uniform capacities [7], and preprocessing together with involved rounding proved sufficient for k-center to obtain a 9-approximation [15, 5]. However, the choice of techniques that turned out to work for capacitated clustering problems is still very limited, and indeed *no* constant factor approximation is known to date for k-median.

And all the while, new constraints for clustering problems are proposed and studied. In *private* clustering [3], we demand a lower bound on the number of points assigned to a center. As stated in [2, 3] this ensures a certain anonymity and is motivated through the need to obtain data privacy. The more general form where each cluster has an individual lower bound is called clustering *with lower bounds* [4]. *Fair* clustering [14] assumes that points have a protected feature (like gender), modeled by a color, and that we want clusters to be fair in the sense that the ratios between points of different colors is the same for every cluster. Clustering *with outliers* [12] assumes that our data contains measurement errors and searches for a solution where a prespecified number of points may be excluded from the cost computation. Other constraints include fault tolerance [27], matroid or knapsack constraints [13], must-link and cannot-link constraints [35], diversity [30] and chromatic clustering constraints [18, 19].

The abundance of constraints and the difficulty to adjust methods for all of them individually asks for ways to *add* a constraint to an approximation algorithm in an oblivious way. Instead of adjusting and reproving known algorithms, we would much rather like to take an algorithm as a black box and ensure that the solution satisfies one more constraint in addition. This is a challenging request. We start the investigation of such add-on algorithms by studying the privacy constraint. Indeed, we develop a method to add the privacy constraint to approximation algorithms for constraint k-center problems. That means that we use an approximation algorithm as a subroutine and ensure that the final solution will additionally respect a given lower bound. The method has to be adjusted depending on the constraint, but it is oblivious to the underlying approximation algorithm used for that constraint.

This works for the basic k-center problem (giving an algorithm for the private k-center problem), but we also show how to use the method when the underlying approximation algorithm is for k-center with outliers, fair k-center and capacitated k-center. We also demonstrate that our method suffices to approximate *strongly private* k-center, where we

assume a protected feature like in fair clustering, but instead of fairness, now demand that a minimum number of points of each color is assigned to each open center to ensure anonymity for each class individually.

Our Technique. The general structure of the algorithm is based on standard thresholding [23], i.e., the algorithm tests all possible thresholds and chooses the smallest for which it finds a feasible solution. For each threshold, it starts with the underlying algorithm and computes a non private solution. Then it builds a suitable network to shift points to satisfy the lower bounds. The approximation ratio of the method depends on the underlying algorithm and on the structure of this network.

The shifting does not necessarily work right away. If it does not produce a feasible solution, then using the max flow min cut theorem, we obtain a set of points for which we can show that the clustering uses too many clusters (and can thus not satisfy the lower bounds). The algorithm then recomputes the solution in this part. Depending on the objective function, we have to overcome different hurdles to ensure that the recomputation works in the sense that it a) makes sufficient progress towards finding a feasible solution and b) does not increase the approximation factor. The process is then iterated until we find a feasible solution.

Results. We obtain the following results for multiple combinations of privacy with other constraints. Note that our definition of k-center (see §2) distinguishes between the set of points P and the set of possible center locations L. This general case is also called the *k-supplier problem*, while classical k-center often assumes that $P = L$. Our reductions can handle the general case (with a slight increase in approximation ratio); whether the resulting algorithm is then for k-center or k-supplier thus depends on the evoked underlying algorithm.

- We obtain a 4-approximation for private k-center with outliers (5 for the supplier version). This matches the best known bounds [3] ([4] for the supplier version (this also holds for non-uniform lower bounds)).
- We compute an 11-approximation for private capacitated k-center (i.e., centers have a lower bound *and* an upper bound), and a 8-approximation for private uniform capacitated k-center (where the upper bounds are uniform, as well). The best known bounds for these two problems are 9 and 6 [17]. For the supplier version we obtain a 13-approximation which matches the best known bound [17] (for uniform upper bounds a 9-approximation-algorithm is known [17]).
- We achieve constant factor approximations for private capacitated/uncapacitated and fair k-center/k-supplier clustering. The approximation factor depends on the *balance* of the input point set and the type of upper bounds, it ranges between 10 in the uncapacitated case where for each color c the number of points with color c is an integer multiple of the number of points with the rarest color and 325 in the general supplier version with non-uniform upper bounds. To the best of our knowledge, all these combinations have not been studied before.
- Along the way, we propose constant factor algorithms for general cases of fair clustering. While [14] introduces a pretty general model of fairness, it only derives approximation algorithms for inputs with two colors and a balance of $1/t$ for an integer t. We achieve ratios of 14 and 15 for the general fair k-center and supplier problem, respectively.
- Finally, we propose the *strongly private k-center problem*. As in the fair clustering problem, the input here has a protected feature like gender, modeled by colors. Now instead of a fair clustering, we aim for anonymity for each color, meaning that we have a lower bound for each color. Each open center needs to be assigned this minimum number

Table 1 An overview on the approximation results that we combine with privacy.

	Vanilla	Capacities		Outlier	Fair Subset Partition	
		uniform	non-uniform		$\frac{r}{b} \in \mathbb{N}$	general
k-center	2 [23]	6 [28]	9 [5]	2 [10]	2 [14]	12 (full version Thm.22 [33])
k-supplier	3 [23]		11 [5]	3 [12]		

of points for each color. To the best of our knowledge, this problem has not been studied before; we obtain a 4-approximation as well as a 5-approximation for the supplier version.

Since our method does not require knowledge of the underlying approximation algorithm, the approximation guarantees improve if better approximation algorithms for the underlying problems are found. There is also hope that our method could be used for new, not yet studied constraints, with not too much adjustment.

Related Work. The unconstrained k-center problem can be 2-approximated [21, 23], and it is NP-hard to approximate it better [24]. The k-supplier problem can be 3-approximated [23], and this is also tight.

Capacitated k-center was first approximated with uniform upper bounds [8, 28]. Two decades after the first algorithms for the uniform case, [15] provided the first constant factor approximation for non-uniform capacities. The algorithm was improved and applied to the k-supplier problem in [5]. In contrast to capacities, *lower* bounds are less studied. The private k-center problem is introduced and 2-approximated in [3], and non-uniform lower bounds are studied in [4]. The k-center/k-supplier problem with outliers is 3-approximated in [12] alongside approximations to other robust variants of the k-center problem. The approximation factor for the k-center problem with outliers was improved to 2 in [10].

The fair k-center problem was introduced in [14]. The paper describes how to approximate the problem by using an approximation for a subproblem that we call fair subset partition problem. Algorithms for this subproblem are derived for two special cases where the number of colors is two, and the points are either perfectly balanced or the number of points of one color is an integer multiple of the number of points of the other color.

These are the constraints for which we make use of known results. We state the best known bounds and their references in Table 1. Approximation algorithms are also e.g. known for fault tolerant k-center [27] and k-center with matroid or knapsack constraints [13].

Relatively little is known about the combination of constraints. Cygan and Kociumaka [16] give a 25-approximation for the capacitated k-center problem with outliers. Aggarwal et. al [3] give a 4-approximation for the private k-center problem with outliers. Ahmadian and Swamy [4] consider the combination of k-supplier with outliers with (non-uniform) lower bounds and derive a 5-approximation. The paper also studies the k-supplier problem with outliers (without lower bounds), and the min-sum-of-radii problem with lower bounds and outliers. Their algorithms are based on the Lagrangian multiplier preserving primal dual method due to Jain and Vazirani [26].

Ding et. al [17] study the combination of capacities and lower bounds as well as capacities, lower bounds and outliers by generalizing the LP algorithms from [5] and [16] to handle lower bounds. They give results for several variations, including a 6-approximation for private capacitated k-center and a 9-approximation for private capacitated k-supplier.

Friggstad, Rezapour, Salavatipour [20] consider the combination of uniform capacities and non-uniform lower bounds for *facility location* and obtain bicriteria approximations.

Outline. In §2, we introduce necessary notation. §3 then presents our method, applied to the private k-center problem with outliers. We choose the outlier version since it is non-trivial but still intuitive and does thus give a good impression on the application of our method. In §4, we then briefly explain how to adjust the method to approximate private and fair k-center, private and capacitated k-center, k-center with all three constraints as well as the strongly private k-center problem. §5 provides a conclusion.

2 Preliminaries

Let (X, d) be a finite metric space, i.e., X is a finite set and $d : X \times X \to \mathbb{R}_{\geq 0}$ is a metric. We use $d(x, T) = \min_{y \in T} d(x, y)$ for the smallest distance between $x \in X$ and a set $T \subseteq X$. For two sets $S, T \subseteq X$, we use $d(S, T) = \min_{x \in S, y \in T} d(x, y)$ for the smallest distance between any pair $x \in S, y \in T$.

Let $P \subseteq X$ be a subset of X called *points* and let $L \subseteq X$ be a subset of X called *locations*. An instance of a private *assignment constrained* k-center problem consists of P, L, an integer $k \in \mathbb{N}$, a lower bound $\ell \in \mathbb{N}$ and possibly more parameters. Given the input, the problem is to compute a set of centers $C \subseteq L$ with $|C| \leq k$ and an *assignment* $\phi : P \to C$ of the points to the selected centers that satisfies $\ell \leq |\phi^{-1}(c)|$ for every selected center $c \in C$, and some specific *assignment restriction*. The solution C, ϕ shall be chosen such that

$$\max_{x \in P} d(x, \phi(x))$$

is minimized. Different assignment restrictions lead to different constrained private k-center problems. The *capacity* assignment restriction comes with an upper bound function $u : L \to \mathbb{N}$ for which we require $\ell \leq u(x)$ for all $x \in L$, and then demands $|\phi^{-1}(c)| \leq u(c)$. When we have $u(x) = u$ for all $x \in L$ and some $u \in \mathbb{N}$, then we say that the capacities are *uniform*, otherwise, we say they are *non-uniform*. The *fairness* assignment restriction provides a mapping $\chi : P \to Col$ of points to colors and then requires that each cluster has the same ratio between the numbers of points with different colors (see §4.2 in the full version [33] for specifics). The *strongly private k-center problem* can also be cast as a k-center problem with an assignment restriction. Again, the input now additionally contains a mapping χ of points to colors. Now the assignment is restricted to ensure that it satisfies the lower bound for the points of each color. We even consider the slight generalization where each color has its own lower bound, and call this problem the strongly private k-center problem.

An instance of the *private k-center problem with outliers* consists of P, L, an integer $k \in \mathbb{N}$, a lower bound ℓ, and a parameter o for the maximum number of outliers. The problem is to compute a set of centers $C \subseteq L$ with $|C| \leq k$ and an assignment $\phi : P \to C \cup \{out\}$, with $|\phi^{-1}(out)| \leq o$, which assigns each point to a center in C or to be an outlier. The choice of C, ϕ shall minimize

$$\max_{x \in P \setminus \phi^{-1}(out)} d(x, \phi(x)).$$

3 Private k-center with Outliers

▶ **Theorem 1.** *Assume that there exists an approximation algorithm A for the k-center problem with outliers with approximation factor α.*

Then for instances P, L, k, ℓ, o of the private k-center problem with outliers, we can compute an $(\alpha + 2)$-approximation in polynomial time.

Proof. Below, we describe an algorithm that uses a threshold graph with threshold τ. We show that for any given $\tau \in \mathbb{R}$, the algorithm has polynomial runtime and, if τ is equal to opt, the value of the optimal solution, computes an $(\alpha + 2)$-approximation. Since we know that the value of every solution is equal to the distance between a point and a location, we test all $O(|P||L|)$ possible distances for τ and return the best feasible clustering returned by any of them. The main proof is the proof of Lemma 2 below, which concludes this proof. ◀

Let us start with a general idea on how the algorithm works for a fixed τ. If $\tau < \mathsf{opt}$, then the algorithm will detect this, so assume that $\tau \geq \mathsf{opt}$ for now. We first use the approximation algorithm to obtain a clustering which does not necessarily satisfy the privacy constraint. Then we try to reassign points to establish the lower bounds. A point p may be reassigned to any cluster which contains at least one point which is within distance 2τ of p. (Note that any point in p's optimum cluster is at distance $\leq 2\tau$). If it is possible to reassign points like that and obtain a feasible clustering, we can compute such a reassignment with a maximum flow algorithm. Otherwise we find a set of points $P(V')$ for which we can show that the optimal clustering uses less clusters to cover all of them. We add all outliers to $P(V')$ to account for the fact that $P(V')$ may already contain outliers of the optimum solution. We then use the approximation algorithm on $P(V')$ to compute a new clustering with outliers. The output will contain fewer clusters or the same number of clusters and fewer outliers. We repeat the process until we find a feasible solution.

▶ **Lemma 2.** *Assume that there exists an approximation algorithm A for the k-center problem with outliers with approximation factor α. Let P, L, k, ℓ, o be an instance of the private k-center problem with outliers, let $\tau > 0$ and let opt denote the maximum radius in the optimal feasible clustering for P, L, k, ℓ, o. We can in polynomial time compute a feasible clustering with a maximum radius of at most $(\alpha + 2)\tau$ or determine $\tau < \mathsf{opt}$.*

Proof. We first use A to compute a solution without the lower bound. Let $\mathcal{C} = (C, \phi)$ be an α-approximate solution for the k-center problem with outliers on P, L, k, o. Note that $\mathcal{C}$ may contain clusters with less than ℓ points. Let $k' = |C|$ (note that $k' < k$ is possible), $C = \{c_1, \ldots, c_{k'}\}$, and let $C_1, \ldots, C_{k'}$ be the clusters that $\mathcal{C}$ induces, i.e., $C_j := \phi^{-1}(c_j)$. Finally, let $r = \max_{x \in P} d(x, \phi(x))$ be the largest distance of any point to its center. Observe that an optimal solution to the k-center problem with outliers can only have a lower objective value than the optimal solution to our problem because we only dropped a condition. Therefore, $\tau \geq \mathsf{opt}$ implies that $r \leq \alpha \cdot \mathsf{opt} \leq \alpha \cdot \tau$. If we have $r > \alpha \cdot \tau$, we return $\tau < \mathsf{opt}$.

We use $\mathcal{C}$ and τ to create a threshold graph which we use to either reassign points between the clusters to obtain a feasible solution or to find a set of points P' for which we can show that every feasible clustering with maximum radius τ uses less clusters than our current solution to cover it. In the latter case we compute another α-approximate solution which uses fewer clusters on P' and repeat the process. Note that for $\tau < \mathsf{opt}$ such a clustering does not necessarily exist, but for $\tau \geq \mathsf{opt}$ the optimal clustering provides a solution for P' with fewer clusters. If we do not find such a clustering with maximum radius at most $\alpha \cdot \tau$, we return $\tau < \mathsf{opt}$.

We show that every iteration of the process reduces the number of clusters or the number of outliers, therefore the process stops after at most $k \cdot o$ iterations. It may happen that our final solution contains much less clusters than the optimal solution (but it will be an approximate solution for the optimal solution with k centers).

We will use a network flow computation to move points from clusters with more than ℓ points to clusters with less than ℓ points. Moving a point to another cluster can increase the radius of the cluster. We only want to move points between clusters such that the radius

does not increase by too much. More precisely, we only allow a point p to be moved to another cluster C_i if the distance $d(p, C_i)$ between the point and the clusters is at most 2τ. This is ensured by the structure of the network described in the next paragraph. Unless stated otherwise, when we refer to distances between a point and a cluster in the following, we mean the distance between the point and the cluster in its original state before any points have been reassigned.

Given $\mathcal{C}$ and τ, we create the threshold graph $G_\tau = (V_\tau, E_\tau)$ as follows. V_τ consists of a source s, a sink t, a node v_i for each cluster C_i, a node v_{out} for the set of outliers and a node w_p for each point $p \in P$. For all $i \in [k']$, we connect s to v_i if the cluster C_i contains more than ℓ points and set the capacity of (s, v_i) to $|C_i| - \ell$. If the cluster C_i contains fewer than ℓ points, we connect v_i with t and set the capacity of (v_i, t) to $\ell - |C_i|$. Furthermore, we connect v_i with w_p for all $p \in C_i$ and set the capacity of (v_i, w_p) to 1. We also connect s to v_{out} with capacity o and v_{out} with w_p for all $p \in \phi^{-1}(out)$ with capacity 1. Whenever a point p and a cluster C_i with $p \notin C_i$ satisfy $d(p, C_i) \leq 2\tau$ (i.e., there is a point $q \in C_i$ that satisfies $d(p, q) \leq 2\tau$), we connect w_p with v_i with capacity 1.

Formally the graph $G_\tau = (V_\tau, E_\tau)$ is defined by

$$V_\tau = \{v_{out}\} \cup \{v_i \mid 1 \leq i \leq k'\} \cup \{w_p \mid p \in P\} \cup \{s, t\} \text{ and} \tag{1}$$

$$E_\tau = \{(v_i, w_p) \mid p \in C_i\} \cup \{(w_p, v_i) \mid p \notin C_i \wedge d(p, C_i) \leq 2\tau\} \tag{2}$$

$$\cup \{(v_{out}, w_p) \mid \phi(p) = out\} \tag{3}$$

$$\cup \{(s, v_{out})\} \cup \{(s, v_i) \mid |C_i| - \ell > 0\} \cup \{(v_i, t) \mid |C_i| - \ell < 0\}. \tag{4}$$

We define the capacity function $cap : E_\tau \to \mathbb{R}$ by

$$cap(e) = \begin{cases} \ell - |C_i|, & \text{if } e = (v_i, t) \\ |C_i| - \ell, & \text{if } e = (s, v_i) \\ o, & \text{if } e = (s, v_{out}) \\ 1 & \text{otherwise.} \end{cases} \tag{5}$$

We use $G = (V, E)$ to refer to G_τ as τ is clear from context. We now compute an integral maximum s-t-flow f on G. According to f we can reassign points different clusters.

▶ **Lemma 3.** *Let f be an integral maximal s-t-flow on G. It is possible to reassign p to C_i for all edges (w_p, v_i) with $f((w_p, v_i)) = 1$.*

The resulting solution has a maximum radius of at most $r + 2\tau$. If f saturates all edges of the form (v_i, t), then the solution is feasible.

Proof. Let $p \in C_i$. The choice of capacity 1 on (v_i, w_p) and flow conservation ensure $\sum_{(w_p, v_j) \in E} f((w_p, v_j)) \leq 1$ for p. Therefore no point would have to be reassigned to more than one cluster. Note that for every point $p \in C_i$ that would be reassigned we must have $f((v_i, w_p)) = 1$ and for every edge (v_i, w_p) with $f((v_i, w_p)) = 1$ the point p would be reassigned.

For any $1 \leq j \leq k'$, let $p \in C_i$ be any point which we want to reassign to C_j. Then we must have $(w_p, v_j) \in E$ and therefore there must be a point $q \in C_j$ with $d(p, q) \leq 2\tau$. Thus we have

$$d(p, c_j) \leq d(p, q) + d(q, c_j) \leq 2\tau + r = r + 2\tau.$$

Now assume that f saturates all edges of the form (v_i, t) and let $1 \leq i \leq k'$. If E contains the edge (v_i, t), then it can not contain the edge (s, v_i) and therefore all incoming edges of v_i

are of the form (w_p, v_i). Flow conservation then implies that the number of points reassigned to C_i minus the points reassigned away from C_i is equal to $f((v_i, t))$, which increases the number of points in C_i to ℓ.

If E contains the edge (s, v_i), then it can not contain the edge (v_i, t) and therefore all outgoing edges of v_i are of the form (v_i, w_p). Flow conservation then implies that the number of points reassigned away from C_i minus the points reassigned to C_i is equal to $f((s, v_i))$, which reduces the number of points in C_i to at least ℓ.

If E contains neither (s, v_i) nor (v_i, t), then the number of points in C_i is equal to ℓ and does not change (the points may change, but their number does not).

In all three cases C_i contains at least ℓ points after the reassignment. ◀

If f saturates all edges of the form (v_i, t) in G, then we reassign points according to Lemma 3 and return the new clustering.

Otherwise we look at the residual network G_f of f on G. Let V' be the set of nodes in G_f which can not be reached from s. V' contains all nodes representing clusters which would not satisfy the privacy constraint after the reassignment. We say cluster C_i *belongs* to V' if $v_i \in V'$, and a point $p \in C_i$ is *adjacent* to V' if $w_p \in V'$ and $v_i \notin V'$. Let $C(V')$ denote the set of clusters belonging to V'. Let $k'' = |C(V')|$. We say a point p belongs to V' if the cluster C_i with $p \in C_i$ belongs to V'. Let $P(V')$ and $P_A(V')$ denote the set of points that belong to V' and the set of points adjacent to V'.

▶ **Lemma 4.** *Any clustering on P with maximum radius at most τ that contains at least ℓ points in every cluster uses fewer than k'' clusters to cover all points in $P(V')$.*

Proof. We first observe that V' must have the following properties:

- $v_i \in V'$ and $(w_p, v_i) \in E$ implies $w_p \in V'$.
- $w_p \in V'$, $(w_p, v_i) \in E$ and $f((w_p, v_i)) > 0$ implies $v_i \in V'$.
- $w_p \in V'$ for some $p \in C_i$ and $v_i \notin V'$ implies $f((v_i, w_p)) = 1$.

The first property follows from the fact that f can only saturate (w_p, v_i) if f also saturates (v_j, w_p) for $p \in C_j$. So, either (w_p, v_i) is not saturated, which means that v_i can be reached from any vertex that reaches w_p, or (w_p, v_i) *is* saturated, which means that the only incoming edge of w_p in G_f is (v_i, w_p). In both cases, if $v_i \in V'$, then $w_p \in V'$. The second property follows since $f((w_p, v_i)) > 0$ implies $(v_i, w_p) \in E(G_f)$. The third property is true since we defined $cap((v_i, w_p)) = 1$.

This implies that a reassignment due to Lemma 3 would reassign all points adjacent to V' to clusters in $C(V')$ and moreover all reassignments from points in $P(V') \cup P_A(V')$ would be to clusters in $C(V')$. Let n_i denote the number of points that would be assigned to C_i after the reassignment. Then $|P(V')| + |P_A(V')| = \sum_{C_i \in C(V')} n_i$.

Now we argue that this sum is smaller than $k'' \cdot \ell$ by observing that each $n_i \leq \ell$ and at least one n_i is strictly smaller than ℓ.

Let C_i be a cluster with more than ℓ points after the reassignment. Then (s, v_i) is not saturated by f and v_i can be reached from s in G_f. Therefore after the reassignment no cluster $C_i \in C(V')$ would contain more than ℓ points; in other words, $n_i > \ell$ implies $C_i \notin C(V')$.

Let C_i be a cluster which would still contain fewer than ℓ points after the reassignment. This implies that f does not saturate the edge (v_i, t). Therefore t can be reached from v_i and since f is a maximum s-t flow, v_i can not be reached from s. We must have $v_i \in V'$.

Because we assumed that the reassignment does not satisfy all lower bounds, at least one such cluster has to exist. This implies

$$|P(V')| + |P_A(V')| = \sum_{C_i \in C(V')} n_i < k'' \cdot \ell.$$

Which means that the clusters in $C(V')$ and $P_A(V')$ do not contain enough points to satisfy the lower bound in k'' clusters.

By definition of G and V', for two points p, q with $p \in P(V')$ and $d(p,q) \leq 2\tau$ we must have $q \in P(V') \cup P_A(V')$. Let $\mathcal{C}'$ be a clustering that abides the lower bounds and has a maximal radius of at most τ. Then every cluster C' in $\mathcal{C}'$ that contains at least one point from $P(V')$ can only contain points from $P(V') \cup P_A(V')$. Therefore $\mathcal{C}'$ must contain fewer than k'' clusters which contain at least one point from $P(V')$. ◀

If we have $\tau \geq \mathsf{opt}$, then Lemma 4 implies that the optimal solution covers all points in $P(V')$ with fewer than k'' clusters. An α-approximative solution on the point set $P(V')$ with at most $k'' - 1$ clusters which contains at most o outliers is then α-approximative for $P(V')$.

Unfortunately, we do not know how many outliers an optimal clustering has in $P(V')$. We therefore involve the outliers $\phi^{-1}(out)$ in our new computation as well. Let $o' = |\phi^{-1}(out)|$ denote the current number of outliers. We obtain the following Lemma through a counting argument.

▶ **Lemma 5.** *We call a cluster special if it contains at least one point from $P(V')$ or only contains points from $\phi^{-1}(out)$. Let $\mathcal{C}'$ be a clustering on P with a maximum radius of at most τ on all special clusters that respects the lower bounds, has at most o outliers and consists of at most k clusters out of which at most k'' are special. If $\mathcal{C}'$ has exactly k'' special clusters, then $\mathcal{C}'$ has at most $o' - 1$ outliers in $P(V') \cup \phi^{-1}(out)$.*

Proof. Assume the clustering contains exactly special k'' clusters. Each of these clusters has to contain at least ℓ points from $P(V') \cup P_A(V') \cup \phi^{-1}(out)$. We know

$$|P(V') \cup P_A(V') \cup \phi^{-1}(out)| \leq |P(V') \cup P_A(V')| + o' < k''\ell + o'.$$

So there remain at most $o' - 1$ unclustered points in $P(V') \cup \phi^{-1}(out)$. ◀

Now we need to show that such a clustering exists if $\tau \geq opt$ is the case.

▶ **Lemma 6.** *If $\tau \geq opt$, then there exists a clustering $\mathcal{C}'$ on P with a maximum radius at most τ on all special clusters that respects the lower bounds, has at most o outliers and consists of at most k clusters out of which at most k'' are special.*

Proof. We look at an optimal clustering $\mathcal{C}_{opt}$. The only way $\mathcal{C}_{opt}$ can violate a condition is if it contains $k''' > k''$ special clusters. Lemma 4 implies that $\mathcal{C}_{opt}$ contains at least $k''' - k''$ clusters that contain only points in $\phi^{-1}(out)$. If all clusters in $\mathcal{C}_{opt}$ are special we know $P = P_A(V') \cup P(V') \cup \phi^{-1}(out)$. We arbitrarily select $k''' - k''$ clusters from $\mathcal{C}_{opt}$ that contain only points in $\phi^{-1}(out)$, declaring all points in them as outliers and closing the corresponding centers. This leaves us with k'' clusters which contain at least $k'' \cdot \ell$ points. Since $P = P_A(V') \cup P(V') \cup \phi^{-1}(out)$ this leaves at most $o' - 1$ outliers. Otherwise, if $\mathcal{C}_{opt}$ contains at least one cluster C which is not special, we add all outliers from $P \setminus (P_A(V') \cup P(V') \cup \phi^{-1}(out)$ to C. Again we arbitrarily select $k''' - k''$ clusters from $\mathcal{C}_{opt}$ that contain only points in $\phi^{-1}(out)$, declaring all points in them as outliers and closing the corresponding centers. By creation there are no unclustered points in $P \setminus (P_A(V') \cup P(V') \cup \phi^{-1}(out)$ and exactly k'' special clusters with radius at most τ. Therefore this clustering contains at most $o' - 1$ outliers and has at most k clusters. ◀

We now use A again to compute new solutions without the lower bound: Let $\mathcal{C}'_1 = (C'_1, \phi'_1)$ be an α-approximate solution for the k-center problem with outliers on $P(V') \cup \phi^{-1}(out)$, L, $k'' - 1$, o and let $\mathcal{C}'_2 = (C'_2, \phi'_2)$ be an α-approximate solution for the k-center problem with outliers on $P(V') \cup \phi^{-1}(out)$, L, k'', $o' - 1$. Let $r'_i = \max_{x \in P(V') \cup \phi^{-1}(out)} d(x, \phi'_i(x))$.

Note that in case $\tau < \mathsf{opt}$, it can happen that no such clustering exists or that we obtain $r'_i > \alpha \cdot \tau$ for both $i = 1$ and $i = 2$. We then return $\tau < \mathsf{opt}$. Otherwise for at least one $i \in \{1, 2\}$ $\mathcal{C}'_i$ must exist together with $r'_i \leq \alpha \cdot \tau$.

If $\mathcal{C}'_2$ exists and we have $r'_2 \leq \alpha \cdot \tau$ we replace $C(V')$ by C'_2 in $\mathcal{C}$ and adjust ϕ accordingly to obtain $\mathcal{C}_1 = (C_1, \phi_1)$ with $C_1 = (C \setminus C(V')) \cup C'_2$ and

$$\phi_1(p) = \begin{cases} \phi'_2(p) & \text{if } p \in P(V') \cup \phi^{-1}(out) \\ \phi(p) & \text{otherwise.} \end{cases} \tag{6}$$

Otherwise, if $\mathcal{C}'_1$ exists, we have $r'_1 \leq \alpha \cdot \tau$ and either $\mathcal{C}'_2$ does not exist or we have $r'_2 > \alpha \cdot \tau$, we analogous replace $C(V')$ by C'_1 to obtain $\mathcal{C}_1$.

▶ **Lemma 7.** *If we did not return $\tau < \mathsf{opt}$, then $\mathcal{C}_1$ is a solution for the k-center problem with outliers on P, L, k, o and we have $r_1 = \max_{x \in P} d(x, \phi_1(x)) \leq \alpha \cdot \tau$.*

Proof. $\mathcal{C}$ is a solution for the k-center problem with outlier on P, L, k, o with $r < \alpha \cdot \tau$ and since we did not return $\tau < \mathsf{opt}$, we must have $r'_i \leq \alpha\tau$ for the chosen $i \in \{1, 2\}$. ◀

We iterate the previous process with the new clustering $\mathcal{C}_1$ until we either determine $\tau < \mathsf{opt}$ or the reassignment of points according to Lemma 3 yields a feasible solution. Since each iteration reduces the number of clusters or keeps the same number of clusters and reduces the number of outliers, the process terminates after at most $k \cdot o$ iterations. ◀

▶ **Corollary 8.** *We can compute a 4-approximation for instances of the private k-center problem with outliers and a 5-approximation for instances of the private k-supplier problem in polynomial time.*

Proof. Follows from Theorem 1 together with the 2-approximation for k-center with outliers in [10] and the 3-approximation for k-supplier with outliers in [12]. ◀

4 Combining Privacy with other Constraints

In this section, we take the general idea from §3 and instead of outliers use it to combine privacy with other restrictions on the clusters. Given a specific restriction $\mathcal{R}$ and an approximation algorithm A for the k-center problem with restriction $\mathcal{R}$ with approximation factor α we ask: Can we similar to §3 extend A to compute an $O(\alpha)$-approximation for the private k-center problem with restriction $\mathcal{R}$?

In §3, we made use of two properties of a clustering with outliers. In Lemma 3 we used that reassigning points to another cluster never increases the number of outliers and in Lemma 4 we used that outliers have the somewhat local property that computing a new clustering on the points V' from a subset of the clusters together with the set of outliers can not create more outliers on the remaining points.

We use this section to briefly explain how the proofs with other restriction properties differ from §3 and state our results for the general cases (for the complete proofs as well as the approximation factors for all different cases, see §4+§5 in the full version [33]).

As new restrictions we study capacities, fairness and multiple lower bounds for different types of points. For the private capacitated k-center problem, the proof is easier than for

private k-center with outliers. The threshold graph $G_\tau = (V_\tau, E_\tau)$ does not need to contain nodes for the outliers anymore. It is defined by

$$V_\tau = \{v_i \mid 1 \leq i \leq k'\} \cup \{w_p \mid p \in P\} \cup \{s, t\} \text{ and} \tag{7}$$

$$E_\tau = \{(v_i, w_p) \mid p \in C_i\} \cup \{(w_p, v_i) \mid p \notin C_i \wedge d(p, C_i) \leq 2\tau\} \tag{8}$$

$$\cup \{(s, v_i) \mid |C_i| - \ell > 0\} \cup \{(v_i, t) \mid |C_i| - \ell < 0\}, \tag{9}$$

together with the capacity function $cap : E_\tau \to \mathbb{R}$

$$cap(e) = \begin{cases} \ell - |C_i|, & \text{if } e = (v_i, t) \\ |C_i| - \ell, & \text{if } e = (s, v_i) \\ 1 & \text{otherwise.} \end{cases} \tag{10}$$

The capacities on the clusters do not influence the threshold graph; they are handled by the underlying approximation algorithm. Since we never increase the number of points of a cluster to more than ℓ, our method will not introduce any capacity violation. We obtain the following results.

▶ **Theorem 9.** *Assume that there exists an approximation algorithm A for the capacitated k-center problem with approximation factor α. Then we can compute an $(\alpha + 2)$-approximation for the private capacitated k-center problem in polynomial time.*

In order to combine privacy with fairness, we first develop an approximation algorithm for general cases of the fair k-center problem. [14] show how to solve fair k-center based on approximating a subproblem that we call *fair subset partitioning problem* (it's called fairlet decomposition in [14]), and which consists of partitioning the input into fair subsets such that the maximum diameter of any subset is minimal. They give an exact algorithm for two colors with perfect balance and a 2-approximation for two colors with balance $1/t$ for an integer t. We propose an algorithm for multiple colors and general balance values. It separates the points into the different colors, computes a capacitated clustering on the points for one of the colors and uses a matching algorithm on threshold graphs in order to add the points of the other colors.

▶ **Theorem 10.** *A 12-approximation for the fair subset partition problem can be computed in polynomial time. If $b_c = 1$ for at least one color $c \in Col$, then a 2-approximation for the fair subset partition problem can be computed in polynomial time (even if $|Col| > 2$).*

With that we obtain the first approximation algorithm for the general fair k-center problem. For the private and fair k-center problem we then use a partitioning into fair subsets and let these be the nodes of the threshold graph instead of single points. When establishing the lower bounds, we move fair subsets as a whole. Let $F = \{F_1, \ldots\}$ denote the fair subsets. Then we define $G_\tau = (V_\tau, E_\tau)$ by

$$V_\tau = \{v_{out}\} \cup \{v_i \mid 1 \leq i \leq k'\} \cup \{f_i \mid F_i \in F\} \cup \{s, t\} \text{ and} \tag{11}$$

$$E_\tau = \{(v_i, f_j) \mid F_j \subseteq C_i\} \cup \{(f_j, v_i) \mid F_j \cap C_i = \emptyset \wedge d(C_i, F_j) \leq 2\tau\} \tag{12}$$

$$\cup \{(s, v_i) \mid |C_i| - \ell > 0\} \cup \{(v_i, t) \mid |C_i| - \ell < 0\} \tag{13}$$

with the capacity function $cap : E_\tau \to \mathbb{R}$

$$cap(e) = \begin{cases} \left\lceil \frac{\ell - |C_i|}{b} \right\rceil, & \text{if } e = (v_i, t) \\ \left\lceil \frac{|C_i| - \ell}{b} \right\rceil, & \text{if } e = (s, v_i) \\ 1 & \text{otherwise.} \end{cases} \tag{14}$$

We obtain the following results.

▶ **Theorem 11.** *Assume that there exists an approximation algorithm A for the fair subset partition problem with approximation factor α. Then we can compute a $(3\alpha+4)/(3\alpha+5)$-approximation for the private fair k-center/supplier problem in polynomial time.*

We also adjust our method to approximate the private fair and capacitated k-center problem, and combine it with our results on approximating the fair subset partitioning problem. The approximation ratio now becomes $\alpha(2\beta+1)$, where α is the approximation ratio for the capacitated k-center problem, and β is the approximation ratio for the fair subset partitioning problem (see Lemma 29 in the full version [33]).

For the strongly private k-center problem (see §5 in the full version [33]) we create a separate threshold graph for each color and separately try to satisfy the lower bound for each color. For a color $i \in Col$ we let P^i denote the points in P with color i and let C_j^i denote the points in C_j with color i. We create the threshold graph $G_{\tau,i} = (V_{\tau,i}, E_{\tau,i})$ by

$$V_{\tau,i} = \{v_j \mid 1 \le j \le k'\} \cup \{w_p \mid p \in P^i\} \cup \{s,t\} \text{ and} \tag{15}$$

$$E_{\tau,i} = \{(v_j, w_p) \mid p \in C_j^i\} \cup \{(w_p, v_j) \mid p \in P^i \setminus C_j \wedge d(p, C_j) \le 2\tau\} \tag{16}$$

$$\cup \{(s, v_j) \mid |C_j \cap \chi^{-1}(i)| - \ell_i > 0\} \cup \{(v_j, t) \mid |C_j \cap \chi^{-1}(i)| - \ell_i < 0\}. \tag{17}$$

We define the capacity functions $cap_i : E_{\tau,i} \to \mathbb{R}$ by

$$cap(e) = \begin{cases} \ell_i - |C_j \cap \chi^{-1}(i)|, & \text{if } e = (v_j, t) \\ |C_j \cap \chi^{-1}(i)| - \ell_i, & \text{if } e = (s, v_j) \\ 1 & \text{otherwise.} \end{cases} \tag{18}$$

We obtain the following result.

▶ **Theorem 12.** *Assume that there exists an approximation algorithm A for the k-center problem with approximation factor α. Then we can compute an $(\alpha+2)$-approximation for the strongly private k-center problem in polynomial time.*

The following corollary summarizes the remaining results in the full version [33] for the different constrained private k-center problems, and fair k-center clustering.

▶ **Corollary 13.** *There are polynomial approximation algorithms that compute*

- *an 11/13-approximation for the private capacitated k-center/supplier problem (Cor. 14 + 15),*
- *a 14/15-approximation for the fair k-center/supplier problem (Cor. 23),*
- *a 40/41-approximation for the private and fair k-center/supplier problem (Cor. 25),*
- *a 225/325-approximation for the private fair capacitated k-center/supplier problem (C. 30),*
- *improved approximations for the last three problems in special cases, and*
- *a 4/5-approximation for the strong private k-center/supplier problem (Cor. 36).*

5 Conclusion and open questions

We studied k-center with capacities, fairness and outliers and have coupled these constraints with privacy, and we proposed strongly private k-center. In addition to improving the approximation guarantee of the presented coupling process, open questions include extending it to arbitrary lower bounds, and to different objective functions. In Appendix A of the full

version [33], we present a bicriteria result for facility location that violates the lower bounds. For k-median, a similar procedure is not known at all so far. Finally, the question how to obliviously add other constraints than privacy is completely open, too.

NC Algorithms for Weighted Planar Perfect Matching and Related Problems

Abstract

Consider a planar graph $G = (V, E)$ with polynomially bounded edge weight function $w : E \to [0, \mathsf{poly}(n)]$. The main results of this paper are NC algorithms for finding minimum weight perfect matching in G. In order to solve this problems we develop a new relatively simple but versatile framework that is combinatorial in spirit. It handles the combinatorial structure of matchings directly and needs to only know weights of appropriately defined matchings from algebraic subroutines.

Moreover, using novel planarity preserving reductions, we show how to find: maximum weight matching in G when G is bipartite; maximum multiple-source multiple-sink flow in G where $c : E \to [1, \mathsf{poly}(n)]$ is a polynomially bounded edge capacity function; minimum weight f-factor in G where $f : V \to [1, \mathsf{poly}(n)]$; min-cost flow in G where $c : E \to [1, \mathsf{poly}(n)]$ is a polynomially bounded edge capacity function and $b : V \to [1, \mathsf{poly}(n)]$ is a polynomially bounded vertex demand function. There have been no known NC algorithms for these problems previously.

1 Introduction

In this paper we study deterministic parallel algorithms for the maximum planar matching problem. In particular, we concentrate our attention on the NC class where we are given polynomially many processors which need to solve the problem in polylogarithmic time. The fundamental algorithmic challenge is to compute a maximum cardinality matching, or a maximum weight matching, or a minimum weight perfect matching.

So far in the case of NC algorithms for planar graphs there seemed to be no tools to attack the most general case and we were only able to find perfect matchings in planar bipartite graphs [30, 29]. This might be bit surprising as in non-planar graph, perfect matchings are essentially as powerful as maximum cardinality matchings, see e.g., [34] for a reduction. Such reductions either make two copies of the graph, where each vertex is connected with its copy, or add a set of vertices that are connected to every vertex in the graph. However,

there exists no similar planarity preserving reduction, and so the usefulness of algorithms for planar perfect matchings is limited. Hence, in order to find a maximum cardinality matching we needed to retool to less efficient polynomial time algorithms [14, 18, 19] that are limited to bipartite case only. Or, alternatively, we could find a 2-approximate solution [21]. The lack of such planarity preserving reduction is one of the reasons why computing maximum cardinality matchings in almost linear time was recognized as one of the core problems in planar graph algorithms [4]. This despite the fact that almost linear time algorithms for the perfect matching problem existed before [31, 11].

Formally speaking, our results are as follows. Consider a planar graph $G = (V, E)$ with polynomially bounded edge weight (cost) function $w : E \to [0, \mathsf{poly}(n)]$. A *matching* in G is an independent set of edges, whereas a *perfect matching* is a matching that is incident to every vertex in G. We start by giving a relatively simple NC algorithm for finding a perfect matching in G. Then we extend this algorithm to finding *minimum weight perfect matching*, i.e., a perfect matching M of G with minimum total weight $w(M)$. Our algorithm is combinatorial in spirit as it does not manipulate a fractional matching, but only requires to know weights of appropriately defined minimum weight perfect matchings. These weights can be computed using Kasteleyn's Pfaffian orientation of planar graphs and standard algebraic techniques. The algorithm is based on the fundamental notion of balanced duals that was developed in [7] as well as in [16]. This idea allows to define and construct a dual solution in a unique way. In particular, a very simple NC algorithm for constructing a family of blossoms of this dual follows by a direct application of the algorithm given in [7].

The next problem we consider is the *minimum weight f-factor problem*, where for a given $f : V \to [1, \mathsf{poly}(n)]$ we need to find a set of edges F of minimum total cost $w(F)$ such that $\deg_F(v) = f(v)$ for all $v \in V$. Typically, this problem is reduced to the perfect matching problem via vertex splitting [15, 3]. These reductions, however, do not preserve planarity. Our contribution, is to show a new planarity preserving reduction, that allows to solve the f-factor problem in NC. Due do space limitations of this paper, this reduction and the next ones are given in the full version of this paper available on arXiv [36].

The following implication of this result was rather surprising (at least for the author). We show that the maximum weight bipartite planar matching problem can be efficiently reduced to the minimum weight non-bipartite planar perfect matching problem. Thus implying the first known NC algorithm for finding maximum weight matching in bipartite planar graphs. Moreover, our reduction preserves the size of the graph, thus any further development for weighted perfect matching in planar graphs will imply similar results for maximum weight bipartite matchings. There seem to be no easy way to extend this result to non-bipartite case, and we note that finding NC algorithms for this problem remains open. Still, we report partial progress on this problem by showing the first $o(n)$ time PRAM algorithm for maximum cardinality matching – again available in the full version of this paper.

Finally, we consider directed flow networks where capacity of edges is given by a polynomially bounded capacity function $c : E \to [1, \mathsf{poly}(n)]$ and vertex demand is given by a polynomially bounded demand function $b : V \to [1, \mathsf{poly}(n)]$. Our aim is to compute a min-cost flow that obeys edge capacities and satisfies all vertex demands. We give the first known NC algorithm for this problem resolving the long standing open problem from [31]. This result is further extended to finding maximum multiple-source multiple-sink flow in planar graphs.

Related Work

The key result that allowed development of NC algorithms for the perfect matching problems in planar graph is Kasteleyn's idea [25]. He showed that the problem of counting perfect matchings in planar graphs is reducible to determinant computation. Thus [6] implied an NC algorithm checking whether a planar graph contains a perfect matching. In [41] this result was extended to $K_{3,3}$-free graphs. Counting, however, does not allow to construct a perfect matching. The first algorithm for constructing perfect matchings was given in [31] but only in the bipartite case. Another solution that is based on different principles was developed in [29]. A partial solution for the non-bipartite case was given in [27] where an algorithm for computing half integral solution was shown. Finally, an algorithm for non-bipartite planar graphs has been proposed in [2]. The result of [2] extends to finding minimum weight perfect matchings as well. Here, we give an independent proof of this result.[1] In comparison to [2], our paper gives a simpler algorithm for constructing a perfect matchings in NC than the one in [2]. Moreover, we show several nontrivial extension of this results, i.e., to maximum weight bipartite matching, to minimum weight f-factor, or min-cost flow. We note that previously we knew how to solve only (non-weighted) maximum cardinality matching in bipartite graphs in NC [22]. However, this result contains a gap in the argument, as is based on [9] which embeds planar graph into a grid graph what does not preserve the size of maximum matchings. This problem can be solved by using [26] or [8, 40]. Moreover, in [1] it was shown how to construct perfect and weighed perfect matchings in NC when the number of perfect matchings is polynomially bounded.

When allowing randomization (i.e., when considering RNC complexity) the problem can be solved even in general non-planar graphs [24, 17, 33, 35]. All of these Monte Carlo algorithms can be turned into Las Vegas ones using [23]. Finally, we note that we are unaware of any previous parallel deterministic algorithms for weighted non-bipartite problems like minimum weight perfect matching or f-factor problems. Bipartite versions of these problem have some solutions that require at least polynomial $\Omega(n^{2/3})$ time [14, 18, 19]. Finally, we note that very recently it was shown that the general problem is solvable in quasi-NC, i.e., in polylogarithmic time using quasi-polynomially many processors [12, 38]. Moreover, the bipartite problem can be solved in pseudo-NC, i.e., in polylogarithmic time, using polynomially many processors and polylogarithmically many random bits [20].

2 Preliminaries

$G = (V, E)$ denotes an n-vertex, embedded, undirected graph. This embedding partitions the plane into maximal open connected sets and we refer to the closures of these sets as the *faces* of G. The *dual* G^* of G is a multigraph having a vertex for each face of G. For each edge e in G, there is an edge e^* in G^* between the vertices corresponding to the two faces of G adjacent to e. We identify faces of G with vertices of G^* and since there is a one-to-one correspondence between edges of G and edges of G^*, we identify an edge of G with the corresponding edge in G^*.

[1] Our framework was developed independently from [2] and was posted on arXiv on the same day [36]. Nevertheless, the author's initial write-up was very "crude" and contained some gaps. In particular, Algorithm 1 was described in a confusing way without stating which parts should happen in parallel. Moreover, we aimed to give, an alternative to [7], construction of matching duals that was incorrect. This, however, is a known result, so in this paper we just cite [7] instead. Finally, the presentation of this paper was greatly improved with respect to [36], while keeping the original framework. Moreover, consequences for more general problems have been added.

The number of faces is denoted by f. For a subset of vertices $U \subseteq V$, $\delta(U)$ denotes all edges $uv \in E$ having $|\{u, v\} \cap U| = 1$. We write $\delta(u)$ for $\delta(\{u\})$, $x(F)$ for $\sum_{e \in F} x_e$ and $\deg_F(u) = |F \cap \delta(u)|$.

The linear programming formulation of the minimum weight perfect matching problem and its dual is as follows [10]. An *odd set* has odd size; Ω is the collection of odd subsets of V of size ≥ 3.

LP of minimum weight perfect matching

$$\min \sum_{e \in E} w(e)x_e$$
$$x(\delta(v)) = 1, \forall v \in V$$
$$x(\delta(U)) \geq 1, \forall U \in \Omega$$
$$x_e \geq 0, \forall e \in E$$

LP of the dual prolem

$$\max \sum_{v \in V} \pi_v + \sum_{U \in \Omega} \pi_U$$
$$\pi_u + \pi_v + \sum_{U \in \Omega,\ uv \in \delta(U)} \pi_U \leq w(uv), \quad \forall uv \in E \quad (*)$$
$$\pi_U \geq 0, \qquad \forall U \in \Omega$$

The variables x_e in the primal indicate when an edge is included in the solution. The dual problem has variables π_v for each vertex v and π_U for each odd set U.

Moreover, a graph G is *factor critical* if for all $v \in V$ after removing v the graph has a perfect matching. A *laminar family* is a collection $\mathcal{B}$ of subsets of V such that for every pair $X, Y \in \mathcal{B}$ either $X \cap Y = \emptyset$, or $X \subseteq Y$, or $Y \subseteq X$. We use the existence of the following dual.

▶ **Lemma 1** (implicitly in [10]). *If the dual LP is feasible, then there exists an optimal dual solution $\pi : V \cup \Omega \to \mathbb{R}$ that:*

1. *the set system $\{U \in \Omega : \pi_U > 0\}$ forms a laminar family,*
2. *for each $U \in \Omega$ with $\pi_U > 0$, the graph denoted by G_U obtained by contracting each set $\{S \in \Omega : S \subset U, \pi_S > 0\}$ to a point is factor critical.*

An optimum dual solution π satisfying the above conditions is a *critical dual solution*. A set $U \in \Omega$ such that $\pi_U > 0$ is a *blossom* w.r.t. π. An important idea that is used in almost all algorithms for weighted matching is that after computing the dual we can work with a non-weighted problem. This non-weighted problem is defined in the following way: leave only *tight* edges in the graph, i.e., there is equality in (*); find a perfect matching *respecting* all blossoms $\mathcal{B}$, i.e., such that for all $B \in \mathcal{B}$ we have $|M \cap \delta(B)| = 1$. By duality slackness any matching obtained this way is a minimum weight perfect matching.

Laminar family of sets is equipped with a natural parent-child relation and can be seen as a forest. We assume this tree is rooted at V and call the resulting tree the *laminar tree*. We note that given a laminar family it is straightforward to deduce the parent-child relation, i.e., parent of a set B is the minimal set containing B, whereas children of B are maximal sets contained in B. Hence, whenever working with a laminar family we assume that the laminar tree is available as well as it can be easily computed in NC. A useful property of this view is that tree T has a *vertex separator*, i.e., there exists a vertex v such that the size of every connected component of $T - x$ is at most $\frac{|T|}{2}$.

Basic NC Algorithms

Our algorithm builds upon the following NC algorithms for computing:

- components and a spanning forest of an undirected graph [37, 5],
- paths in a directed graph – this can be done by repetitive matrix squaring,
- a maximal independent set in a graph [28],
- a vertex separator of a tree – by computing the numbers of vertices in each subtree using any of the standard techniques [32, 39].

Consider a graph G with an edge weight function $w : E \to [0, \mathsf{poly}(n)]$. For a vertex v we denote by G_v the graph $G - v$. If G has an even number of vertices then M_v denotes some *minimum weight almost perfect matching* in G_v, i.e., a minimum weight matching that misses exactly one vertex. If G has an odd number of vertices then M_v denotes some minimum weight perfect matching in G_v. M_v is not defined in a unique way, but its weight $w(M_v)$ is. In our algorithms we will only use these weights that can be computed using standard techniques (see full version for the proof).

▶ **Corollary 2.** *For a graph $G = (V, E)$ with edge weights $w : E \to [0, \mathsf{poly}(n)]$ we can in NC:*
- *for a given vertex $v \in V$, compute the weight $w(M_v)$,*
- *for a given edge $e \in E$, check whether e is* allowed*, i.e., belongs to some minimum weight perfect matching.*

Observe that the set of allowed edge is a subset of tight edges. Hence, when we remove all not allowed edges only tight edges are left in the graph.

Let us now state the following implication of the results in [7]. Basically, assuming that all $w(M_v)$ are given, Algorithm 5 from [7] gives an NC procedure for computing the blossoms of the critical dual solution.

▶ **Lemma 3** (based on Lemma 6.19 [7])**.** *Let $G = (V, E)$ be undirected connected graph where edge weights are given by $w : E \to \mathbb{Z}$ and where every edge is allowed. Given all values $w(M_v)$ for $v \in V$, the blossoms of the critical dual solution can be computed in NC.*

Algorithm 5 from [7] actually constructs a critical dual with an additional property which is called balanced. In a *balanced dual* the root of the laminar tree is required to be the central vertex of this tree as well. This makes balanced duals unique. Thus when one constructs them in parallel, all processors construct the same solution, and it can be implemented in NC.

3 The High Level Idea: Walks and Blossoms

This section aims to introduce two core ideas of our algorithm that allow us to reduce the size of the graph for the recursion, as well as a high level idea that reveals around them. We will first give an algorithm for finding a perfect matching in a graph. However, we will view the problem as weighted and seek a minimum weight perfect matching. The weighed view is useful as we will find even length walks in the graph and introduce weights on them. These weights will either cause some edges to become not allowed, or induce a blossom as shown by the following lemma. Hence, till Section 7, where we show how to handle weighted case, $w : E \to [0, \mathsf{poly}(n)]$ denotes weights defined by the algorithm as the graph considered is unweighted.

To make it more precise we say that a closed walk C in graph G is *semi-simple* if it contains an edge that appears on C only once. By e_C we denote arbitrary such edge on C.

▶ **Lemma 4.** *Consider $G = (V, E)$ with edge weight function $w : E \to [0, \mathsf{poly}(n)]$. Let C be an even semi-simple closed walk in G. Let $w(e_C) = 1$ and let $w(e) = 0$ for all $e \in C - e_C$. Then, either some edge of C is not allowed or some edge of C is in $\delta(B)$ for some blossom B.*

Proof. Assume by a contradiction that all edges of C are allowed and there is no blossom intersecting C. Hence, by complementary slackness conditions we have that $\pi_x + \pi_z = w(xz)$ for all edges $xz \in C$. In particular, for the edge $u_C v_C = e_C$ we need to have $\pi_{u_C} + \pi_{v_C} = 1$, whereas for all other edges $uv \in C - e_C$ we have $\pi_u + \pi_v = 0$. Now consider edge $zy \in C$ which is next to xz. By subtracting equalities for edge xz and zy we obtain $\pi_x - \pi_y = w(xz) - w(zy)$.

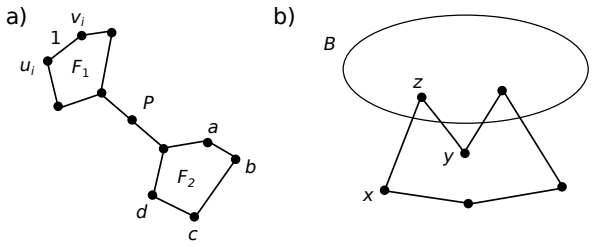

Figure 1 Figure a) shows a non-simple even length closed walk composed out of two faces F_1, F_2 and a path P. We have $\pi_a + \pi_b = 0$, $\pi_b + \pi_c = 0$ and $\pi_c + \pi_d = 0$, what gives $\pi_a - \pi_c = 0$ and $\pi_a + \pi_d = 0$. In Figure b) even length closed cycle does not contain an edge inside a blossom. In such a case $\pi_z + \pi_x + \pi_B = 0$ and $\pi_z + \pi_y + \pi_B = 0$, so $\pi_x - \pi_y = 0$.

If yz and xz are not equal to e_C we have $\pi_x - \pi_y = 0$. In general, we have $\pi_x - \pi_y = 0$ for any two vertices at even distance along path $C - e_C$. And $\pi_x + \pi_y = 0$ for any two vertices at odd distance along path $C - e_C$. Note that the distance from u_C to v_C along $C - e_C$ is odd, so we obtain $\pi_{u_C} + \pi_{v_C} = 0$, what leads to contradiction. See Figure 1 a) for an illustration. ◀

Blossoms are natural objects to recurse on, as by duality slackness there must be exactly one edge of any perfect matching M that belongs to $\delta(B)$ for any blossom B. Thus, in the recursion, we can find an almost perfect matching outside of B, an almost perfect matching inside of B and then combine them by matching one edge in $\delta(B)$ – see Section 6. However, having an edge in $\delta(B)$ does not directly guarantee that the size of the graph reduces in the recursion, as the same blossom can intersect many closed walks. We need the following stronger observation for this.

▶ **Lemma 5.** *Consider $G = (V, E)$ with edge weight function $w : E \to [0, \mathsf{poly}(n)]$. Let C be an even semi-simple closed walk in G and assume that all edges on C are allowed. Let $w(e_C) = 1$ and let $w(e) = 0$ for all $e \in C - e_C$. Then there exist edges $e_1, e_2 \in C$, such that $e_1 \in E(G \setminus B)$ and $e_2 \in E(B)$ for some blossom B.*

Proof. For contradiction assume that no edge of C is in $E(B)$ – the other case is symmetric. Hence, there can only be vertices z in $E(B)$ such that their both incident edges xz and zy on C are in $\delta(B)$. In such a case we have $\pi_x + \pi_z + \pi_B = w(xz)$ and $\pi_z + \pi_y + \pi_B = w(zy)$. Thus $\pi_x - \pi_y = w(xz) - w(zy)$, i.e., the contribution of π_B when subtracting these equalities cancels. See Figure 1 b) for illustration. Thus B does not contribute anything to the telescoping sum along $C - e_C$ and we reach similar contradiction as in the previous lemma. ◀

Hence, when recursing on the inside of the blossom or on the outside of the blossom we reduce the graph size as well. However, to obtain an NC algorithm we need to reduce the size of the graph by a constant factor, so we need to have $\Omega(n)$ edge disjoint even closed walks. The following lemma, that was implicitly proven in [27], becomes handy now.

▶ **Lemma 6.** *In a 2-connected planar graph G with f faces we can find $\Omega(f)$ edge disjoint even semi-simple closed walks in NC.*

Intuitively, the proof of this lemma puts faces into pairs that are incident. Now, either a pair contains an even face and thus this face is semi-simple, or both faces are odd. In the later case we can build an even semi-simple closed walk by walking around both faces.

The above lemma shows that in order to have many even semi-simple closed walks we just need to guarantee that the graph has many faces. Let us say that a planar graph G is *simplified*, if there are no degree 1 vertices and no two vertices of degree 2 are incident. The next lemma shows that such graphs have many faces.

▶ **Lemma 7.** *Let $G = (V, E)$ be a simplified planar graph with a perfect matching, then G has at least $\frac{n}{4} + 2$ faces.*

Proof. By Euler's formula $n - m + f = 2$, where m is the number of edges, and f is the number of faces. Let V_2 be the set of degree 2 vertices in G. Consequently, the vertices in $V \setminus V_2$ have degree at least 3. As G has a perfect matching and no two degree 2 vertices are incident, all vertices in V_2 need to be matched to vertices in $V \setminus V_2$, i.e., $|V_2| \leq |V \setminus V_2|$. By using this inequality we have.

$$2m = \sum_{v \in V} \deg(v) = \sum_{v \in V_2} \deg(v) + \sum_{v \in V \setminus V_2} \deg(v) \geq 2|V_2| + 3|V \setminus V_2| \geq \frac{5}{2}|V_2| + \frac{5}{2}|V \setminus V_2| = \frac{5n}{2}.$$

By plugging this inequality into Euler's formula we obtain $f = 2 + m - n \geq 2 + \frac{5n}{4} - n = 2 + \frac{n}{4}$. ◀

A simplified graph has many faces and thus many edge disjoint even length closed walks. We can assign weights to each of these closed walks separately. This way either many edges become not allowed, or there exists a family of blossoms containing many edges inside. The main technical part of the algorithm is to handle this family of blossoms. The algorithm has the following steps.

1. Simplify the graph as shown in Section 4. First, we take care of degree 1 vertices, by removing not allowed edges and matching edges incident to degree 1 vertices. Next, we contract paths composed of degree 2 vertices. Finally, we find perfect matchings in each connected component separately. Due to removal of not allowed edges each connected component is 2-connected as well.
2. Using Lemma 6 we find many edge disjoint even length closed walks. We assign weights to even closed walks using Lemma 4 and we remove not allowed edges. Next, we find blossoms of the critical dual using Lemma 3. These steps are described in Section 5.
3. Finally, we recurse on a critical dual as explained in Section 6, where we show how to construct a perfect matching that respects all blossoms in the dual. This construction is recursive and calls back step 1 for subgraphs of G that do not have any blossoms.

The recursion depth in this procedure is $O(\log n)$ as either $\Omega(n)$ edges become not allowed, or there are many edges separated by blossoms. In the second case for each blossom B_e there is an edge e_1 inside and an edge e_2 outside of it – see Figure 2 a). We observe that blossom divide the graph into regions and each lowest level recursive call goes to one of these regions, i.e., we recourse on inside and outside of some blossom as long as there are some blossoms intersecting the current subgraph. As visualized on Figure 2 b) there are many edges that are not incident to each region, as one of the edges from each pair (e_1, e_2) needs be outside of this region. Hence, the size of each of these regions decreases by a constant factor with respect to the original graph. This will be proven more formally in Section 5 where we analyze the running time of the algorithm.

4 Simplifying the Graph

The first ingredient of our algorithm is the following entry procedure – Algorithm 1 that simplifies the graph and assures that we are working with 2-connected graphs.

The following lemma proves the correctness of this algorithm.

▶ **Lemma 8.** *Algorithm 1 executes Algorithm 2 on a simplified 2-connected graph.*

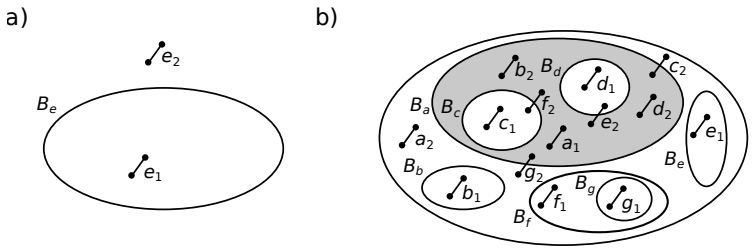

Figure 2 For each blossom B_e there needs to be a pair of edges: e_1 inside and edge e_2 outside of B_e – Figure a). Figure b): when we recurse from Algorithm 4 to Algorithm 1 the blossom tree is empty, and we are recursing on one of the regions into which blossoms divide the plane – marked with gray. Observe that at least one edge from each pair is not incident to this region.

Algorithm 1 Simplifies graph G and seeks perfect matchings in its 2-connected components.

Remove all not-allowed edges from G.
Add edges incident to degree 1 vertices to M and remove them from G.
for all maximal paths p composed out of degree 2 vertices **do** ▷ In parallel
    if p has odd length **then**
        remove p and connect vertices incident to p with an edge e_p.
    else
        remove p and add a single vertex v_p connected to vertices incident to p.
for all connected components $C \in \mathcal{C}$ of G **do** ▷ In parallel
    find perfect matching M_C using Algorithm 2.
Extend matching M on paths of degree 2 vertices.
return $M \cup \bigcup_{C \in \mathcal{C}} M_C$.

Proof. We first observe that after removing not allowed edges, an edge e incident to a vertex of with degree 1 needs to belong to all perfect matchings. Hence, it's both endpoints need to be of degree 1. After matching such edges all vertices have degree 2 or higher. Now note that the manipulation of the path p does not change degrees of other vertices. In the algorithm such path is either replaced by an edge, or single vertex. Hence, afterwards degree 2 vertices cannot be incident. Thus G is simplified and its all connected components are simplified.

Now, for contradiction assume that a connected component C is not 2-connected, i.e., there exists an articulation point v. Consider the connected components obtained from C after removal of v. Only one of them can be matched in the perfect matching to v. Thus only this one has odd number of vertices. The remaining components must have even number of vertices and no perfect matching can match them to v. Hence, their edges incident to v are not allowed. However, all not allowed edges were removed by the algorithm, so we reach a contradiction. ◀

Finally, we note that the above algorithm can be implemented in NC. First of all, in order to compute maximal paths composed out of degree 2 vertices, we just need to compute connected components of the subgraph induced by degree 2 vertices. In the final step of the algorithm we need to expand all paths that were replaced during the execution of Algorithm 1. Observe that the matching M in the simplified graph can be extended to the matching in the original graph in a straight-forward way. If p was odd, then depending on whether e_p is matched we either match even or odd edges of p. If p was even, then v_p has degree 2 and it can be matched in one of two possible ways. In these two cases the matching can be extended to the whole path.

Algorithm 2 Finds a perfect matching M in a connected graph G.

1: Find a set $\mathcal{F}$ of $\Omega(n)$ edge disjoint even semi-simple closed walks using Lemma 6.
2: Set $w(e) = 0$ for all $e \in E$.
3: **for all** $C \in \mathcal{F}$ **do** ▷ In parallel
4: Set $w(e_C) = 1$.
5: Remove all not-allowed edges from G.
6: Compute blossoms of a critical dual $\mathcal{B}$ with respect to w using Lemma 3.
7: Compute a matching M that respects $\mathcal{B}$ using Algorithm 4.
8: Return M.

5 The Main Routine

Algorithm 2 implements our main procedure. First, we find $\Omega(n)$ even semi-simple closed walks and introduce weights on them. Next, in order to reduce the size of the graph we remove not allowed edges. We then find blossoms of the critical dual solution with respect to these weights and call Algorithm 4 to find a perfect matching that respects all blossoms.

6 Finding a Perfect Matching that Respects a Family of Blossoms

Let $G = (V, E)$ be a graph and let M be a matching in G. An *alternating path* p is a path in G such that edges on p alternate between matched and unmatched. Assume that G is factor critical (e.g., inside of a blossom) and that M_s is an almost perfect matching that misses vertex s. We start by showing how using M_s we construct an almost perfect matching M_v for any v. To this end, we need to find a simple alternating path starting in s and ending in v. Denote by w_M a weight function assigning 0 to edges in M_s and 1 to edges not in M_s.

▶ **Lemma 9.** *Let M_v be the minimum weight almost perfect matching in G_v with respect to w_M, then $2w_M(M_v)$ is the length of the shortest alternating path with respect to M_s from s to v.*

Proof. Observe that the symmetric difference $M_s \oplus M_v$ contains an alternating path with respect to M_s that needs to start at s and end at v. The weight of this path is equal to the number of edges from M_s on it. As this path is alternating, the number of edges of M_v is the same. Thus minimizing $w_M(M_v)$ we minimize the length of an alternating path with respect to M_s from s to v. ◀

Now, we want to construct a graph G_L that will represent all shortest alternating paths from s with respect to M. G_L will be a layered graph, where layer l contains vertices at distance l from s — the distance is measured along alternating paths. For each $v \in V$, let G_L contain two copies v^o and v^e of v. We define $l(v^e) = 2w_M(M_v)$ for all $v \in V$, and $l(v^o) = l(u^e) - 1$ for all $uv \in M$. We add edges of G to G_L only if they connect two consecutive layers given by l – see Figure 3. Every shortest alternating path from s is contained in G_L by Lemma 9. Alteratively, if a path in G_L represents a simple path in G then it is a shortest alternating path in G. However, there are paths in G_L that do not correspond to simple paths in G, i.e., they contain both v^o and v^e for some $v \in V$ – see Figure 3 b). Nevertheless, as every vertex in G is reachable via alternating path, we can modify G_L in such a way that only paths corresponding to simple paths in G remain. This is done using Algorithm 3.

The correctness of this algorithm is established by the next lemma.

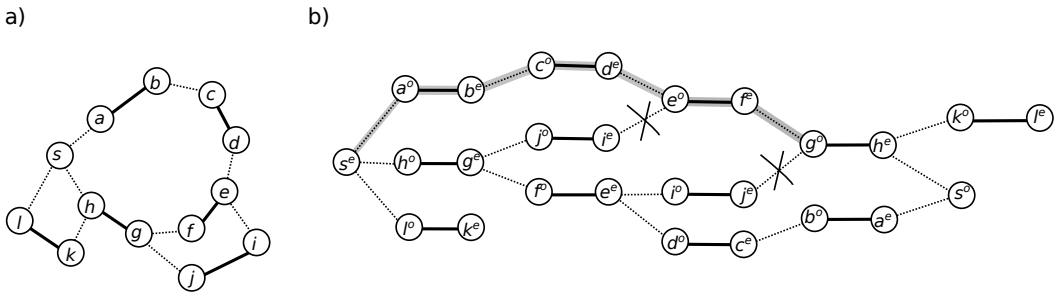

Figure 3 Figure a) shows a factor-critical graph, matched edges are marked with solid lines and s is the free vertex. Figure b) presents layered graph G_L from Algorithm 3. There are two non-simple paths represented by this graph that go from g^e to g^o. These paths are destroyed by the algorithm as g^o is reachable via a simple path p marked with grey.

Algorithm 3 Finds an alternating path with respect to M_s in G from a vertex s to vertex t.

1: For all $v \in V$ compute $w_M(M_v)$.
2: Let G_L be a graph where v has two copies v^o and v^e.
3: For all $v \in V$ set $l(v^e) = 2w_M(M_v)$.
4: For all $vu \in M$ set $l(v^o) = l(u^e) - 1$.
5: Add edges of G to G_L only if they connect vertices in consecutive layers l.
6: **for all** $v \in V$ **do** ▷ In parallel
7: **for all** u^z on some v^x-v^y path in G_L, where $x, y, z \in \{e, o\}$, $x \neq y$ **do** ▷ In parallel
8: **if** there exists s^e-u^z path p avoiding v^x in G_L **then**
9: remove all edges entering u^z but the edge on p.
10: Return any path from s^e to t^e in G_L.

▶ **Lemma 10.** *Let G be a factor critical graph and let M_s be an almost perfect matching missing vertex s. An almost perfect matching M_t missing vertex t can be found in NC using Algorithm 3.*

Proof. We first observe that the removal of edges entering u^z from G_L does not affect reachability from s, as the path p from s^e to u^z is left in the graph. Now, by contradiction, assume that at the end of the algorithm there is a path q in G_L that contains both v^e and v^o for some $v \in V$. Without loss of generality assume v^e precedes v^o. As G_L contains all simple alternating paths, there exists an s^e-v^o path p avoiding v^e. Hence, the edge of q entering the first shared vertex with p was removed by the algorithm – see Figure 3 b).[2] ◀

Algorithm 4 constructs a perfect matching M that respects a family of blossoms. Here, we explicitly consider $\mathcal{B}$ as a tree $T_{\mathcal{B}}$, i.e., the vertices of $T_{\mathcal{B}}$ are sets in $\mathcal{B}$ whereas edges in $T_{\mathcal{B}}$ represent child parent relationship. See Figure 4 for an example and an illustration of the recursion. It calls Algorithm 1 that handles the case without blossoms. The next theorem argues about the correctness of this algorithm.

▶ **Lemma 11.** *Algorithm 4 finds a perfect matching M respecting $\mathcal{B}$. The recursion depth of the internal calls of the algorithm to itself is $O(\log n)$.*

[2] The graph constructed in this algorithm can be seen as an extended version of generalized shortest path tree [13]. Alternatively, such tree could be constructed using Algorithm 5 from [7]. This, however, would result in a slightly more complicated solution.

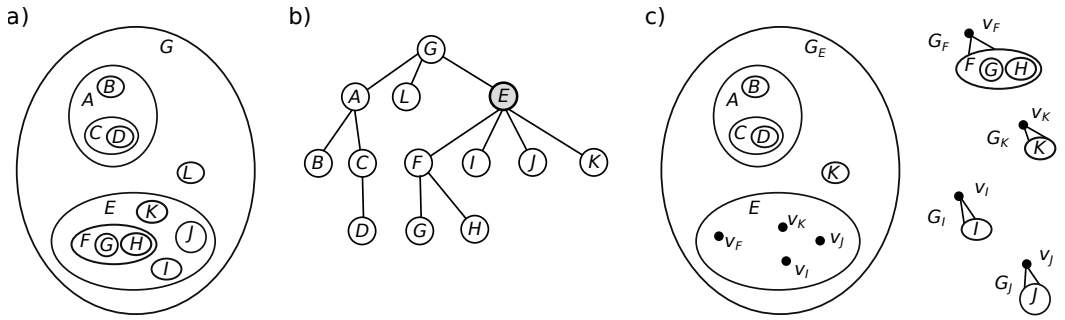

Figure 4 Figure a) shows a laminar family of sets. Figure b) gives the same family using laminar tree. Vertex separator – node E is marked with grey. Figure c) shows the graphs on which we recurse in Algorithm 4 using the marked separator E.

Algorithm 4 Computes a perfect matching M of G respecting family of blossoms $\mathcal{B}$.

if $\mathcal{B} = \emptyset$ **then**
  Return the matching M computed by Algorithm 1 on G.
Let B be a vertex separator of $T_{\mathcal{B}}$.
Begin ▷ In parallel with the next loop
  Let G_B be the graph with all children of B contracted.
  Let T_B be $T_{\mathcal{B}}$ with children of B removed.
  Recurse on G_B, T_B to obtain matching M_B.
End
for all children C of B in $T_{\mathcal{B}}$ **do** ▷ In parallel
  Let G_C be G with all vertices not in C contracted to a vertex denoted by v_C.
  Let T_C be subtree of $T_{\mathcal{B}}$ rooted at C.
  Recurse on G_C, T_C to obtain matching M_C.
for all children C of B in $T_{\mathcal{B}}$ **do** ▷ In parallel
  Remove from G_C vertex v_C and let u_C be the resulting free vertex in G_C.
  Let e_B be the edge of M_B incident to G_C.
  Let v_B be the endpoint of e_B in G_C after expanding G_C.
  Apply to M_C an alternating path from u_C to v_B found using Algorithm 3
Return $M_B \cup \bigcup_{C \text{ child of } B} M_C$.

Proof. We need to argue that M_B can be extended to a perfect matching in the whole graph. Consider a child blossom C of B. By Lemma 3 we know that C is factor-critical, so there exists an almost perfect matching M'_C in C that together with M_B forms a perfect matching. This matching differs from M_C by a single alternating path. Hence, for each child blossom the algorithm is able to combine M_B with M_C by finding a single alternating path.

As we do not recompute the family of blossoms while recursing, we need to argue that the blossoms remain intact. Observe that after contraction of a given blossom all nonintersecting blossoms remain blossoms and the graph remains planar, so we can continue recursing on subtrees of $T_{\mathcal{B}}$.

Finally, the recursion depth of the algorithm to itself is $\Omega(\log n)$, because we recurse on a vertex separator of a tree $T_{\mathcal{B}}$, so the size of the subtrees decreases by a constant factor. ◀

Lemma 11 leads to the correctness of Algorithm 2 and Algorithm 1 as well.

▶ **Theorem 12.** *Algorithm 1 finds a perfect matching in G.*

Algorithm 5 Finds a minimum weight perfect matching in $G = (V, E)$ with respect to the edge weight function $w : E \to [0, \mathsf{poly}(n)]$.

Remove all not allowed edges from G.
Compute blossoms of a critical dual $\mathcal{B}$ with respect to w using Lemma 3.
Find a perfect matching M respecting $\mathcal{B}$ using Algorithm 4.
Return M.

We now can turn our attention to arguing about the running time of our algorithm. In this section we are going to quantify the progress related to perturbing weights on each semi-simple closed walks. The entry point to our procedures is Algorithm 1. This algorithm calls Algorithm 2, which constructs a family of blossoms. Now, Algorithm 4 is used to recurse on this family till subgraphs with no blossoms are obtained. At this moment Algorithm 1 is called back. We will argue that each time Algorithm 1 is called in this recursion, the size of the graph decreases by a constant factor.

▶ **Lemma 13.** *The number of edges in G decreases by a constant factor in each recursive call to Algorithm 1.*

Proof. By Lemma 6 and Lemma 7, after graph simplification we have $\Omega(n)$ even semi-simple closed walks in the graph G. Now, by Lemma 4, for each semi-simple closed walks, either one edge becomes not-allowed, or there exists a blossom $B \in \mathcal{B}$ that intersects this closed walk. Hence, either $\Omega(n)$ edges become not-allowed, or we have $\Omega(n)$ closed walks intersected by some blossom. Lemma 5 implies that for each such intersection there exists an edge e_1 inside B and an edge e_2 outside B – see Figure 2 a). Consider a plane embedding of G and of dual graph G^*. Mark boundaries of each blossom $\delta(B)$ in G^* on the plane, thus dividing the plane into maximal open connected sets. We call these sets regions $\mathcal{R}$.

The outside of each region $R \in \mathcal{R}$ contains at least one edge from e_1 and e_2, i.e., there are $\Omega(n)$ edges not incident to a region – see Figure 2 b). We note that when we call Algorithm 1 from Algorithm 4, we recurse onto some region $R \in \mathcal{R}$ with parts of G not in R contracted to vertices. This graph contains only edges incident to a region R, so it does not contain $\Omega(n)$ edges. By Euler's formula the total numer of edges is $\leq 3n - 6$, so when recursing on each region it decreases by a constant factor. ◀

By Lemmas 11 and 13 the recursion depth in Algorithm 2 is $O(\log^2 n)$, thus:

▶ **Corollary 14.** *A perfect matching in a planar graph can be computed in NC.*

7 Minimum Weight Perfect Matching

So far we have assumed that the graph is unweighed and we have coped with the problem of constructing any perfect matching. However, our approach is versatile enough to handle weighted case in a rather straightforward way using Algorithm 5.

Hence, we obtain the following.

▶ **Lemma 15.** *A minimum weight perfect matching in a planar graph $G = (V, E)$ with edge weight function $w : E \to [0, \mathsf{poly}(n)]$ can be computed in NC.*

Proof. Observe that all allowed edges in G need to be tight. By complementary slackness conditions, a perfect matching that is composed out of allowed edges and that respects all blossoms is a minimum weight perfect matching. ◀

We note that maximum weight perfect matching can be computed by using redefined weight function $w'(e) = -w(e) + \max_{g \in E} w(g)$.

8 Planarity Preserving Reductions

Let $G = (V, E)$ be a multi-graph, i.e., we allow parallel edges as well as self-loops. For a function $f : V \to [1, \mathsf{poly}(n)]$, an *$f$-factor* is a set of edges $F \subseteq E$ such that $\deg_F(v) = f(v)$ for every $v \in V$. Without loss of generality we assume that any edge uv has multiplicity at most $\min\{f(u), f(v)\}$. A *minimum f-factor* is an f-factor F with minimum weight $w(F)$. The f-factor problem can be reduced via planarity preserving reduction to minimum weight perfect matching problem.

▶ **Lemma 16.** *Let $G = (V, E)$ be a planar multigraph with edge weight function $w : E \to [0, \mathsf{poly}(n)]$. For a function $f : V \to [1, \mathsf{poly}(n)]$, minimum f-factor can be computed in NC.*

Now consider, a graph $G = (V, E)$ be a bipartite planar graph with edge weight function $w : E \to [0, \mathsf{poly}(n)]$, and a problem of computing a maximum matching in graph G, i.e., a matching of maximum total weight. This problem in turn can be reduced to f-factor problem.

▶ **Lemma 17.** *A maximum matching in a planar bipartite graph $G = (V, E)$ with edge weight function $w : E \to [0, \mathsf{poly}(n)]$ can be computed in NC.*

In the min-cost planar flow problem, we are given a directed planar network $N = (V, E)$. The edges have integral capacities given by $c : E \to [1, \mathsf{poly}(n)]$ and integral costs $a : E \to [0, \mathsf{poly}(n)]$. Moreover, each vertex has integral demand $b : V \to [-\mathsf{poly}(n), \mathsf{poly}(n)]$. Again there exists planarity preserving reduction to f-factor problem.

▶ **Theorem 18.** *Let $N = (V, E)$ be a planar flow network with integral capacities $c : E \to [1, \mathsf{poly}(n)]$, integral costs $a : E \to [0, \mathsf{poly}(n)]$ and integral demands $b : V \to [-\mathsf{poly}(n), \mathsf{poly}(n)]$. The minimum cost flow in N can be computed in NC.*

We can modify the above reduction to handle the case when source and sink demands are not fixed but need to be maximized. We are given a directed planar network $N = (V, E)$ with integral edge capacities given by $c : E \to [1, \mathsf{poly}(n)]$. Moreover, each vertex has integral demand $b : V \to [-\mathsf{poly}(n), \mathsf{poly}(n)]$. Vertices $v \in V$ such that $b(v) \geq 0$ are called *sources* and we require for them $0 \leq f(v) \leq b(v)$. Vertices $v \in V$ such that $b(v) \leq 0$ are called *sinks* and we require $b(v) \leq f(v) \leq 0$. For remaining vertices v, i.e., when $b(V) = 0$ we need to have $f(v) = 0$. The *maximum multiple-source multiple-sink flow* in N is the flow that maximizes value $f(S)$, where S is the set of all sources.

▶ **Theorem 19.** *Let $N = (V, E)$ be a planar flow network with integral capacities $c : E \to [1, \mathsf{poly}(n)]$, integral costs $a : E \to [0, \mathsf{poly}(n)]$ and integral demands $b : V \to [-\mathsf{poly}(n), \mathsf{poly}(n)]$. The minimum cost flow in N can be computed in NC.*

Abstract

Tutte paths are one of the most successful tools for attacking problems on long cycles in planar graphs. Unfortunately, results based on them are non-constructive, as their proofs inherently use an induction on overlapping subgraphs and these overlaps prevent any attempt to bound the running time by a polynomial.

For special cases however, computational results of Tutte paths are known: For 4-connected planar graphs, Tutte paths are in fact Hamiltonian paths and Chiba and Nishizeki [5] showed how to compute such paths in linear time. For 3-connected planar graphs, Tutte paths have a significantly more complicated structure, and it has only recently been shown that they can be computed in polynomial time [24]. However, Tutte paths are defined for general 2-connected planar graphs and this is what most applications need. In this unrestricted setting, no computational results for Tutte paths are known.

We give the first efficient algorithm that computes a Tutte path (in this unrestricted setting). One of the strongest existence results about such Tutte paths is due to Sanders [23], which allows one to prescribe the end vertices and an intermediate edge of the desired path. Encompassing and strengthening all previous computational results on Tutte paths, we show how to compute such a special Tutte path efficiently. Our method refines both, the existence results of Thomassen [29] and Sanders [23], and avoids that the subgraphs arising in the inductive proof intersect in more than one edge by using a novel iterative decomposition along 2-separators. Finally, we show that our algorithm runs in time $O(n^2)$.

1 Introduction

The question whether a graph $G = (V, E)$ is *Hamiltonian*, i.e. contains a cycle of length $n := |V|$, is among the most fundamental graph problems. For planar graphs and graphs embeddable on higher surfaces, *Tutte paths* have proven to be one of the most successful tools for attacking Hamiltonicity problems and problems on long cycles. For this reason, there is a wealth of existential results in which Tutte paths serve as main ingredient; in chronological order, these are [31, 29, 26, 4, 22, 23, 27, 33, 16, 28, 11, 13, 18, 21, 20, 17, 24, 7, 2].

As a historical starting point to these results, Whitney [32] proved that every 4-connected maximal planar graph is Hamiltonian. Tutte extended this to arbitrary 4-connected planar graphs by showing that every 2-connected planar graph G contains a Tutte path [30, 31]

[1] This research is supported by the grant SCHM 3186/1-1 (270450205) from the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation).

(for a definition of Tutte paths, see Section 2). Thomassen [29] in turn proved the following generalization, which also implies that every 4-connected planar graph is Hamiltonian-connected, i.e. contains a path of length $n-1$ between any two vertices. For a plane graph G, let C_G be its outer face.

▶ **Theorem 1** (Thomassen [29]). *Let G be a 2-connected plane graph, $x \in V(C_G)$, $\alpha \in E(C_G)$ and $y \in V(G) - x$. Then G contains a Tutte path from x to y through α.*

Sanders [23] then generalized Thomassen's result further by allowing to choose the start vertex x of the Tutte path arbitrarily.

▶ **Theorem 2** (Sanders [23]). *Let G be a 2-connected plane graph, $x \in V(G)$, $\alpha \in E(C_G)$ and $y \in V(G) - x$. Then G contains a Tutte path from x to y through α.*

On top of the above series of fundamental results, Tutte paths have been used in two research branches: While the first deals with the existence of Tutte paths on graphs embeddable on higher surfaces [26, 3, 27, 33, 28, 17], the second [15, 9, 3, 10, 16, 11, 19] investigates generalizations or specializations of Hamiltonicity such as *k-walks*, *long cycles* and *Hamiltonian connectedness*.

Unfortunately, in all the results mentioned so far, very little is known about the complexity of finding a Tutte path. This is crucial, as the task of finding Tutte paths is almost always the only reason that hinders the computational tractability of the problem. The main obstruction so far is that Tutte paths are found by decomposing the input graph into overlapping subgraphs, on which induction is applied. Although this is enough to prove existence results, these overlapping subgraphs do not allow to bound the running time polynomially (as argued in [12, 24]). The only known computational results on Tutte paths [12, 1, 5, 21, 24] deal therefore with very restricted settings, such as the case that Tutte paths are just Hamiltonian paths: While it is known how to compute Tutte paths for planar 4-connected graphs [5] efficiently (in which case Tutte paths are just Hamiltonian paths), for planar 3-connected graphs a first polynomial-time algorithm was only recently shown [24].

However, no efficient algorithm is published so far that computes Tutte paths in general 2-connected planar graphs (i.e. the ones of Theorem 1 or 2). In fact, the claimed algorithmic results in [26, 27] require polynomial running times for computing such Tutte paths, without giving proofs that such algorithms exist. Given the subtlety of the arguments inherent to Tutte paths, we feel that giving such a proof is necessary. Indeed, history shows that even for the much easier setting that Tutte paths are Hamiltonian paths, an existence result for Tutte paths has been incorrectly claimed to imply a polynomial-time algorithm [29, 4] (again, due to overlapping subgraphs). For finding Tutte paths in certain restrictions of 2-connected and 3-connected planar graphs, the related results in [22, 17] claim polynomial running times as well.

Our Results

Our motivation is two-fold. First, we want to make Tutte paths accessible to algorithms. We will show that Tutte paths can be computed in time $O(n^2)$. This has impact on almost all the applications using Tutte paths listed above.

For several of them, e.g. [26, 22, 27, 17], we immediately obtain polynomial-time algorithms where no efficient algorithms were published before. In addition, Tutte paths were also used in [7, 8] to show that every essentially 4-connected polyhedral graph contains a cycle of length proportional to n. As the existence proofs in this paper are constructive, our result directly implies a efficient (in fact, an $O(n^2)$-time) algorithm for the computation of these

cycles. Furthermore, [2] showed that every 3-connected planar graph having at most three 3-separators is Hamiltonian. If a 3-connected planar graph contains at most one 3-separator, our algorithm shows that a Hamiltonian cycle can be computed in $O(n^2)$ time, by using a suitable choice of the intermediate edge α.

Second, we aim for computing the strongest possible known variant of Tutte paths, encompassing the many incremental improvements on Tutte paths made over the years. We will therefore develop an algorithm for Sander's existence result [23], which was proven to be best possible in many aspects. Sanders result has also an immediate extension to connected planar graphs [20], which can be computed simply and efficiently from our result by using block-cut trees.

We will first give a decomposition that refines the original ones used for Theorems 1 and 2, and allows to decompose G into graphs that pairwise intersect in at most one edge. We then show that this small overlap does not prevent us from achieving a polynomial running time. All graphs will be simple. We proceed by showing how this decomposition can be computed efficiently in order to find the Tutte paths of Theorem 2. Our main result is hence the following, giving the first polynomial-time algorithm for computing Tutte paths.

▶ **Theorem 3.** *Let G be a 2-connected plane graph, $x \in V(G)$, $\alpha \in E(C_G)$ and $y \in V(G) - x$. Then a Tutte path of G from x to y through α can be computed in time $O(n^2)$.*

Section 3 presents the decomposition with small overlap that proves the existence of Tutte paths. On the way to our main result, we give full algorithmic counterparts of the approaches of Thomassen and Sanders; for example, we describe small overlap variants of Theorem 1 and of the *Three Edge Lemma* [26, 22], which was used in the purely existential result of Sanders [23] as a black box.

Our Techniques

We broadly follow the idea of [5] and construct a Tutte path that is based on certain 2-separators of the graphs constructed during our decomposition. This depends on many structural properties of the given graph. In [5], the necessary properties follow from the restriction to the class of internally 4-connected planar graphs, the restriction on the endpoints of the desired Tutte path, and the fact that the Tutte paths computed recursively are actually Hamiltonian. In contrast, here we give new insights into the much wilder structure of Tutte paths of 2-connected planar graphs, allow $x, y \notin C_G$, and hence extend this technique. We show that based on the prescribed vertices and edge, there are always unique non-interlacing 2-separators that are contained in every possible Tutte path of the given graph. We then use this set of 2-separators to iteratively construct a preliminary Tutte path and use this iterative procedure to avoid overlaps of more than one edge in the decomposition of the input graph.

2 Preliminaries

We assume familiarity with standard graph theoretic notations as in [6]. Let $deg(v)$ be the degree of a vertex v. We denote the subtraction of a graph H from a graph G by $G - H$, and the subtraction of a vertex or edge x from G by $G - x$.

A *k-separator* of a graph $G = (V, E)$ is a subset $S \subseteq V$ of size k such that $G - S$ is disconnected. A graph G is *k-connected* if $|V| > k$ and G contains no $(k-1)$-separator. For a path P and two vertices $x, y \in P$, let xPy be the smallest subpath of P that contains x and y. For a path P from x to y, let $inner(P) := V(P) - \{x, y\}$ be the set of its inner vertices. Paths that intersect pairwise at most at their endvertices are called *independent*.

A connected graph without a 1-separator is called a *block*. A *block of a graph* G is an inclusion-wise maximal subgraph that is a block. Every block of a graph is thus either 2-connected or has at most two vertices. It is well-known that the blocks of a graph partition its edge-set. A graph G is called a *chain of blocks* if it consists of blocks $B_1, B_2, \ldots, B_k$ such that $V(B_i) \cap V(B_{i+1})$, $1 \leq i < k$, are pairwise distinct 1-separators of G and G contains no other 1-separator. In other words, a chain of blocks is a graph, whose block-cut tree [14] is a path.

A *plane* graph is a planar embedding of a graph. Let C be a cycle of a plane graph G. For two vertices x, y of C, let xCy be the clockwise path from x to y in C. For a vertex x and an edge e of C, let xCe be the clockwise path in C from x to the endvertex of e such that $e \notin xCe$ (define eCx analogously). Let the subgraph of G *inside* C consist of $E(C)$ and all edges that intersect the open set inside C into which C divides the plane. For a plane graph G, let C_G be its outer face.

A central concept for Tutte paths is the notion of H-bridges (see [31] for some of their properties): For a subgraph H of a 2-connected plane graph G, an *H-bridge* of G is either an edge that has both endvertices in H but is not itself in H or a component K of $G - H$ together with all edges (and the endvertices of these edges) that join vertices of K with vertices of H. An H-bridge is called *trivial* if it is just one edge. A vertex of an H-bridge L is an *attachment* of L if it is in H, and an *internal* vertex of L otherwise. An *outer* H-bridge of G is an H-bridge that contains an edge of C_G.

A *Tutte path* (*Tutte cycle*) of a plane graph G is a path (a *cycle*) P of G such that every outer P-bridge of G has at most two attachments and every P-bridge at most three attachments. In most of the cases we consider, G will be 2-connected, so that every P-bridge has at least two attachments. For vertices x, y and an edge $\alpha \in C_G$, let an *x-α-y-path* be a Tutte path from x to y that contains α. An *x-y-path* is an *x-α-y-path* for an arbitrarily chosen edge $\alpha \in C_G$.

3 Decomposition with Small Overlap

After excluding several easy cases of the decomposition, we prove Thomassen's Theorem 1 constructively and then show how to use this for a proof of the Three Edge Lemma. The Three Edge Lemma, in turn, allows us to give a constructive proof of Sander's Theorem 2 in which only small overlaps occur in the induction. Due to space constraints, we have to omit this proof, it however derived from [23] in a similar way as Theorem 1 from [29].

We will use induction on the number of vertices. In all proofs about Tutte paths of this section, the induction base is a triangle, in which the desired Tutte path can be found trivially; thus, we will assume in these proofs by the induction hypothesis that graphs with fewer vertices contain Tutte paths. All graphs in the induction will be simple.

The following sections cover different cases of the induction steps of the three statements to prove, starting with some easy cases for which a decomposition into edge disjoint subgraphs was already given [29]. For the remainder of the article, let G be a simple plane 2-connected graph with outer face C_G and let $x \in V(G)$, $\alpha \in E(C_G)$ and $y \in V(G) - x$. If $\alpha = xy$, the desired path is simply xy; thus, assume $\alpha \neq xy$. Since G is 2-connected, C_G is a cycle.

3.1 The Easy Cases

We say that G is *decomposable into G_L and G_R* if it contains subgraphs G_L and G_R such that $G_L \cup G_R = G$, $V(G_L) \cap V(G_R) = \{c, d\}$, $x \in V(G_L)$, $\alpha \in E(G_R)$, $V(G_L) \neq \{x, c, d\}$ and $V(G_R) \neq \{c, d\}$ (or the analogous setting with y taking the role of x) (see Figure 1). In

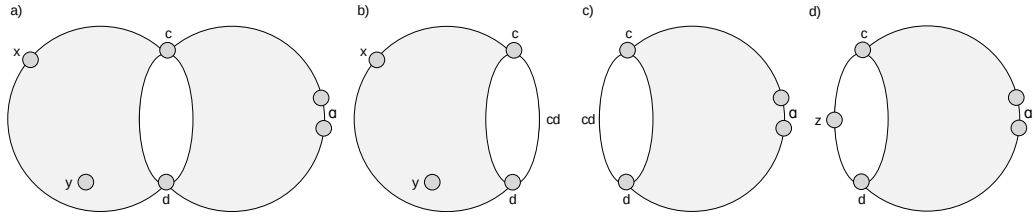

Figure 1 a) shows a graph G that is decomposable into G_L and G_R. The figures b) to d) show the graphs G'_L, G'_R and G^*_R (in this order) that are constructed to process G in [29] .

particular, $G_L \neq \{c, d\}$, even if $x \in \{c, d\}$. Hence $\{c, d\}$ is a 2-separator of G. There might exist multiple pairs (G_L, G_R) into which G is decomposable; we will always choose a pair that minimizes $|V(G_R)|$. Note that G_R intersects C_G (for example, in α), but G_L does not have to intersect C_G. In [29], it was shown that every decomposable graph G contains a Tutte path, without using recursion on overlapping subgraphs.

▶ **Lemma 4** ([29]). *If G is decomposable into G_L and G_R, then G contains an x-α-y-path.*

Even if G is not decomposable into G_L and G_R, G may contain other 2-separators $\{c, d\}$ that allow for a similar reduction as in Lemma 4 (for example, when modifying its prerequisites to satisfy $\{x, \alpha, y\} \subseteq G_R - \{c, d\}$).

▶ **Lemma 5** ([29]). *Let $\{c, d\}$ be a 2-separator of G and let J be a $\{c, d\}$-bridge of G having an internal vertex in C_G such that x, y and α are not in J. Then G contains an x-α-y-path.*

3.2 Proof of Theorem 1

We now prove that G contains a Tutte path from $x \in V(C_G)$ to $y \in V(G) - x$ through $\alpha \in E(C_G)$. For simplicity, if y is not in $V(C_G)$ but has degree two and both of its neighbors are in $V(C_G)$, then we change the embedding of G (and therefore C_G) such that y belongs to the outer face. If Lemma 4 or 5 can be applied, we obtain such a Tutte path directly, so assume their prerequisites are not met. Let l_α be the endvertex of α that appears first when we traverse C_G in clockwise order starting from x, and let r_α be the other endvertex of α. If $y \in xC_G l_\alpha$, we interchange x and y (this does not change l_α); hence, we have $y \notin xC_G l_\alpha$. If $y = r_\alpha$, we mirror the embedding such that y becomes l_α and proceed as in the previous case; hence, $y \notin xC_G r_\alpha$.

We define two paths P and Q in G, whose union will, step by step, be modified into a Tutte path of G. Let $Q := xC_G l_\alpha$ and let $H := G - V(Q)$; in particular, $y \notin Q$ and, if x is an endvertex of α, $Q = \{x\}$. Since G is not decomposable, we have $deg(r_\alpha) \geq 3$, as otherwise the neighborhood of r_α would be the 2-separator of such a decomposition. Since $deg(r_\alpha) \geq 3$, r_α is incident to an edge $e \notin C_G$ that shares a face with α. Let B_1 be the block of H that contains e. It is straight-forward to prove the following about B_1 (see Thomassen [29]), which shows that every vertex of C_G is either in Q or in B_1.

▶ **Lemma 6** ([29]). *B_1 contains $C_G - V(Q)$ and is the only block of H containing r_α.*

Consider a component A of H that does not contain B_1. Then the neighborhood of A in G is in Q and must contain a 2-separator of G due to planarity. Hence, either $y \in A$ and we can apply Lemma 4 or $y \notin A$ and we can apply Lemma 5. Since both contradicts our assumptions, H is connected and contains B_1 and y. Let K be the minimal plane chain of blocks $B_1, \ldots, B_l$ of H that contains B_1 and y (hence, $y \in B_l$). Let v_i be the intersection of B_i and B_{i+1} for $1 \leq i \leq l - 1$; in addition, we set $v_0 := r_\alpha$ and $v_l := y$.

Consider any $(K \cup C_G)$-bridge J. Since Lemma 5 cannot be applied, J has an attachment $v_J \in K$. Further, J cannot have two attachments in K, as this would contradict the maximality of the blocks in K. Let $C(J)$ be the shortest path in C_G that contains all vertices in $J \cap C_G$ and does not contain r_α as inner vertex (here, r_α serves as a *reference vertex* of C_G that ensures that the paths $C(J)$ are chosen consistently on C_G). Let l_J be the endvertex of $C(J)$ whose counterclockwise incident edge in C_G is not in $C(J)$ and let r_J be the other endvertex of $C(J)$.

3.2.1 Decomposing along Maximal 2-Separators

At this point we will deviate from the original proof of Theorem 1 in [29], which continues with an induction on every block of K that leads to overlapping subgraphs in a later step of the proof. Instead, we will show that a v_0-v_l-path P of K can be found iteratively such that the graphs in the induction have only small overlap.

For every block $B_i \neq B_1$ of K, we choose an arbitrary edge $\alpha_i = l_{\alpha_i} r_{\alpha_i}$ in C_{B_i}. In B_1 we choose α_1 such that α_1 is incident to the endvertex of $C_{B_1} \cap C_G$ that is not r_α. As done for G, we may assume for every B_i that l_{α_i} is the endvertex of α_i that is contained in $v_{i-1}C_{B_i}\alpha_i$ and that $v_i \notin v_{i-1}C_{B_i}r_{\alpha_i}$ and (by mirroring the planar embedding and interchanging v_i and v_{i-1} if necessary). However, unlike G, every B_i may satisfy the prerequisites of Lemmas 4 and 5. By the induction hypothesis of Theorem 1, B_i contains a v_{i-1}-α_i-v_i-path P_i. In [29], the outer P_i-bridges of B_i are not only being processed during this induction step, but also in a later induction step when modifying Q. We avoid such overlapping subgraphs by using a new iterative structural decomposition of B_i along certain 2-separators on C_{B_i}. This decomposition allows us to construct P_i iteratively such that the outer P_i-bridges of B_i are not part of the induction applied on B_i. Eventually, $P := \bigcup_{1 \leq i \leq l} P_i$ will be the desired v_0-v_l-path of K.

The outline is as follows. After explaining the basic split operation that is used by our decomposition, we give new insights into the structure of the Tutte paths P_i of the blocks B_i. These are used in Section 3.2.2 to define the iterative decomposition of every block B_i into a modified block $\eta(B_i)$, which will in turn allow to compute every P_i step-by-step. This gives the first part P of the desired Tutte path x-α-y of G. Subsequently, we will show how the remaining path Q can be modified to obtain the second part.

For a 2-separator $\{c, d\} \subseteq C_B$ of a block B, let B^+_{cd} be the $\{c, d\}$-bridge of B that contains cC_Bd and let B^-_{cd} be the union of all other $\{c, d\}$-bridges of B (note that B^+_{cd} contains the edge cd if and only if B^+_{cd} is trivial). For a 2-separator $\{c, d\} \subseteq C_B$, let *splitting off* B^+_{cd} (from B) be the operation that deletes all internal vertices of B^+_{cd} from B and adds the edge cd if cd does not already exist in B. Our decomposition proceeds by iteratively splitting off bridges B^+_{cd} from the blocks B_i of K for suitable 2-separators $\{c, d\} \subseteq C_{B_i}$ (we omit the subscript i in such bridges B^+_{cd}, as it is determined by c and d). The following lemma restricts these 2-separators to be contained in specific parts of the outer face.

▶ **Lemma 7.** *Let P' be a Tutte path of a block B such that P' contains an edge α' and two vertices $a, b \in C_B$. Then every outer P'-bridge J of B has both attachments in aC_Bb or both in bC_Ba. If additionally J is non-trivial and $P' \neq \alpha'$, the attachments of J form a 2-separator of B.*

Proof. Let e be an edge in $J \cap C_B$ and assume without loss of generalization that $e \in aC_Bb$. Let c and d be the last and first vertices of the paths aC_Be and eC_Bb, respectively, that are contained in P' (these exist, as a and b are in P'). Then J has attachments c and d and no further attachment, as P' is a Tutte path. This gives the first claim. For the second claim, let z be an internal vertex of J. Since $P' \neq \alpha'$, P' contains a third vertex $c \notin \{a, b\}$. As c is not contained in J, $\{c, d\}$ separates z and c and is thus a 2-separator of B. ◀

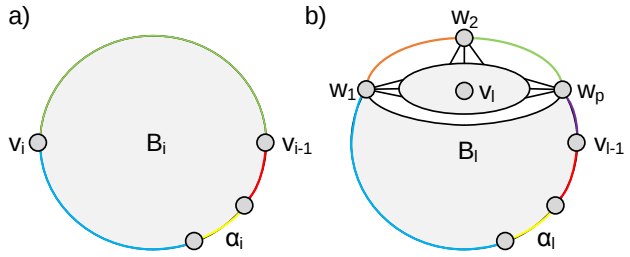

Figure 2 a) The boundary points and -parts of a block $B_i \neq B_l$. b) An instance in which the block B_l contains a 2-separator $\{w_1, w_p\}$ that splits off v_l.

For every block $B_i \neq B_l$ of K, let the *boundary points* of B_i be the vertices $v_{i-1}, l_{\alpha_i}, r_{\alpha_i}, v_i$ and let the *boundary parts* of B_i be the inclusion-wise maximal paths of C_{B_i} that do not contain any boundary point as inner vertex (see Figure 2a; note that boundary parts may be single vertices). Hence, every boundary point will be contained in any possible v_{i-1}-α_i-v_i-path P_i, and there are exactly four boundary parts, one of which is α_i. Now, if $P_i \neq \alpha_i$, applying Lemma 7 for all boundary points $a, b \in \{v_{i-1}, l_{\alpha_i}, r_{\alpha_i}, v_i\}$ and $\alpha' := \alpha_i$ implies that the two attachments of every outer non-trivial P_i-bridge of B_i form a 2-separator that is contained in one boundary part of B_i. For this reason, our decomposition will split off only 2-separators that are contained in boundary parts.

In principle, we will do the same for the block B_l. If $v_l \in C_{B_l}$, we define the boundary points of B_l just as before for $i < l$. However, B_l is special in the sense that v_l may not be in C_{B_l}. Then we have to ensure that we do not loose v_l when splitting off a 2-separator, as v_l is supposed to be contained in P_l (see Figure 2b). To this end, consider for $v_l \notin C_{B_l}$ the 2-separator $\{w_1, w_p\} \subseteq C_{B_l}$ of B_l such that $B^+_{w_1,w_p}$ contains v_l, the path $w_1 C_{B_l} w_p$ is contained in one of the paths in $\{v_{l-1} C_{B_l} \alpha_l, \alpha_l, \alpha_l C_{B_l} v_{l-1}\}$ and $w_1 C_{B_l} w_p$ is of minimal length if such a 2-separator exists. The restriction to these three parts of the boundary is again motivated by Lemma 7: If $P_l \neq \alpha_l$ and there is an outer non-trivial P_l-bridge of B_l, its two attachments are in P_l and thus we only have to split off 2-separators that are in one of these three paths to avoid these P_l-bridges in the induction. If the 2-separator $\{w_1, w_p\}$ exists, let $w_1, \dots, w_p$ be the $p \geq 2$ attachments of the $w_1 C_{B_l} w_p$-bridge of B_l that contains v_l, in the order of appearance in $w_1 C_{B_l} w_p$; otherwise, let for notational convenience $w_1 := \cdots := w_p := l_{\alpha_l}$. In the case $v_l \notin C_{B_l}$, let the *boundary points* of B_l be $v_{l-1}, l_{\alpha_l}, r_{\alpha_l}, w_1, \dots, w_p$ and let the *boundary parts* of B_l be the inclusion-wise maximal paths of C_{B_l} that do not contain any boundary point as inner vertex.

▶ **Lemma 8.** *If the 2-separator $\{w_1, w_p\}$ exists, it is unique and every v_{l-1}-α_l-v_l-path P_l of B_l contains the vertices $w_1, \dots, w_p$.*

Proof. Let $J \subset B^+_{w_1,w_p}$ be the $w_1 C_{B_l} w_p$-bridge of B_l that contains v_l and has attachments $w_1, \dots, w_p$. For the first claim, assume to the contrary that there is a 2-separator $\{w'_1, w'_{p'}\} \neq \{w_1, w_p\}$ of B_l having the same properties as $\{w_1, w_p\}$. By the connectivity of J and the property that restricts $\{w'_1, w'_{p'}\}$ to the three parts of the boundary of B_l, $\{w'_1, w'_{p'}\}$ may only split off a subgraph containing v_l if $w_1 C_{B_l} w_p \subset w'_1 C_{B_l} w'_{p'}$. This however contradicts the minimality of the length of $w'_1 C_{B_l} w'_{p'}$.

For the second claim, let P_l be any v_{l-1}-α_l-v_l-path of B_l. Assume to the contrary that $w_j \notin P_l$ for some $j \in \{1, \dots, p\}$. Then w_j is an internal vertex of an outer P_l-bridge J' of B_l. By Lemma 7, both attachments of J' are in C_{B_l}. However, since J contains a path from $w_j \notin P_l$ to $v_l \in P_l$ in which only w_j is in C_{B_l}, at least one attachment of J' is not in C_{B_l}, which gives a contradiction. ◀

Lemma 8 ensures that the boundary points of any B_i are contained in every Tutte path P_i of B_i. Every block $B_i \neq B_l$ has exactly four boundary parts and B_l has at least three boundary parts (three if $v_l \notin C_{B_l}$ and $\{w_1, w_p\}$ does not exist), some of which may have length zero. For every $1 \leq i \leq l$, the boundary parts of B_i partition C_{B_i}, and one of them consists of α_i. This implies in particular that B_i has at least two boundary parts of length at least one unless $B_i = \alpha_i$. We need some notation to break symmetries on boundary parts. For a boundary part Z of a block B, let $\{c, d\}^* \subseteq Z$ denote two elements c and d (vertices or edges) such that cC_Bd is contained in Z (this notation orders c and d consistently to the clockwise orientation of C_B); if cC_Bd is contained in some boundary part of B that is not specified, we just write $\{c, d\}^* \subseteq C_B$.

We now define which 2-separators are split off in our decomposition. Let a 2-separator $\{c, d\}^* \subseteq C_B$ of B be *maximal in a boundary part Z of B* if $\{c, d\} \subseteq Z$ and Z does not contain a 2-separator $\{c', d'\}$ of B such that $cC_Bd \subset c'C_Bd'$. Let a 2-separator $\{c, d\}^* \subseteq C_B$ of B be *maximal* if $\{c, d\}^*$ is maximal with respect to at least one boundary part of B. Hence, every maximal 2-separator is contained in a boundary part, and 2-separators that are contained in a boundary part are maximal if they are not properly "enclosed" by other 2-separators on the same boundary part.

Let two maximal 2-separators $\{c, d\}^*$ and $\{c', d'\}^*$ of B *interlace* if $\{c, d\} \cap \{c', d'\} = \emptyset$ and their vertices appear in the order c, c', d, d' or c', c, d', d on C_B (in particular, both 2-separators are contained in the same boundary part of B). In general, maximal 2-separators of a block B_i of K may interlace; for example, consider the two maximal 2-separators when B_i is a cycle on four vertices in which v_{i-1} and v_i are adjacent. However, the following lemma shows that such interlacing is only possible for very specific configurations.

▶ **Lemma 9.** *Let $\{c, d\}^*$ and $\{c', d'\}^*$ be interlacing 2-separators of B_i in a boundary part Z such that $c' \in cC_{B_i}d$ and at least one of them is maximal. Then $d'C_{B_i}c = v_{i-1}v_i = \alpha_i$.*

Proof. Since $\{c, d\}$ is a 2-separator, $B_i - \{c, d\}$ has at least two components. We argue that there are exactly two. Otherwise, $B_i - \{c, d\}$ has a component that contains the inner vertices of a path P' from c to d in $B_i - (C_{B_i} - \{c, d\})$. Then $B_i - \{c', d'\}$ has a component containing $(P' \cup C_{B_i}) - \{c', d'\}$ and no second component, as this would contain the inner vertices of a path from c' to d' in $B_i - ((P' \cup C_{B_i}) - \{c', d'\})$, which does not exist due to planarity. Since this contradicts that $\{c', d'\}$ is a 2-separator, we conclude that $B_i - \{c, d\}$, and by symmetry $B_i - \{c', d'\}$, have exactly two components.

By the same argument, $inner(cC_{B_i}d)$ and $inner(dC_{B_i}c)$ are contained in different components of $B_i - \{c, d\}$ and the same holds for $inner(c'C_{B_i}d')$ and $inner(d'C_{B_i}c')$ in $B_i - \{c', d'\}$. Hence, the component of $B_i - \{c, d'\}$ that contains $inner(cC_{B_i}d') \neq \emptyset$ does not intersect $inner(d'C_{B_i}c)$. If $inner(d'C_{B_i}c) \neq \emptyset$, this implies that $\{c, d'\} \subseteq Z$ is a 2-separator of B_i, which contradicts the maximality of $\{c, d\}$ or of $\{c', d'\}$. Hence, $inner(d'C_{B_i}c) = \emptyset$, which implies that $d'C_{B_i}c$ is an edge. As Z is not an edge, $d'C_{B_i}c = \alpha_i$. Since c and d' are the only boundary points of B_i, either $\{c, d'\} = \{v_{i-1}, v_i\}$ or $B_i = B_l$, $v_l \notin C_{B_l}$, $\{c, d'\} = \{v_{i-1}, w_2\}$, $v_{i-1} = w_1$ and $w_2 = w_p$. However, the latter case is impossible, as then $\{c, d'\}$ would be a 2-separator that separates $inner(cC_{B_i}d') \neq \emptyset$ and v_l, which contradicts the maximality of $\{c, d\}$ or of $\{c', d'\}$. This gives the claim. ◀

If two maximal 2-separators interlace, Lemma 9 thus ensures that these two are the only maximal 2-separators that may contain v_{i-1} and v_i, respectively. This gives the following direct corollary.

▶ **Corollary 10.** *Every block of K has at most two maximal 2-separators that interlace.*

Note that any boundary part may nevertheless contain arbitrarily many (pairwise non-interlacing) maximal 2-separators. The next lemma strengthens Lemma 7.

▶ **Lemma 11.** *Let P_i be a v_{i-1}-α_i-v_i-path of B_i. Let J be a non-trivial outer P_i-bridge of B_i and let e be an edge in $J \cap C_{B_i}$. Then the attachments of J are contained in the boundary part of B_i that contains e.*

Proof. Let c and d be the attachments of J such that $e \in cC_{B_i}d$ and let Z be the boundary part of B_i that contains e. If $P_i = \alpha_i$, $v_{i-1} = l_{\alpha_i}$ and $v_i = r_{\alpha_i}$ are the only boundary points of B_i. Then c and d are the endvertices of $Z = v_iC_{B_i}v_{i-1} \ni e$, which gives the claim.

Otherwise, let $P_i \neq \alpha_i$. By applying Lemma 7 with $a = l_{\alpha_i}$ and $b = r_{\alpha_i}$, $\{c, d\}$ is a 2-separator of B_i that is contained in C_{B_i}. By definition of $w_1, \dots, w_p$, there are at least three independent paths between every two of these vertices in B_i; thus, $\{c, d\}$ does not separate two vertices of $\{w_1, \dots, w_p\}$. Since all other possible boundary points $(v_{i-1}, l_{\alpha_i}, r_{\alpha_i}, v_i)$ are contained in P_i, applying Lemma 7 on these implies that $\{c, d\}$ does not separate two vertices of these remaining boundary points. Hence, if $\{c, d\} \not\subseteq Z$, we have $B_i = B_l$ and $v_l \notin C_{B_l}$ such that $\{c, d\}$ separates $\{w_1, \dots, w_p\}$ from the remaining boundary points. Since the P_i-bridge J does not contain $\alpha_l \in P_i$, $cC_{B_l}d \subseteq J$ contains $\{w_1, \dots, w_p\}$, but $inner(cC_{B_l}d)$ does not contain any other boundary point. As $v_l \in P_i$, at least one of $\{w_1, w_p\}$ must be in P_i, say w_p by symmetry. Then $d = w_p$, as $w_p \in P_i$ cannot be an internal vertex of J. Now, in both cases $p = 2$ (which implies $c \neq w_1$, as $\{c, d\} \not\subseteq Z = w_1C_{B_l}w_2$) and $p \geq 3$, J contains the edge of P_i that is incident to v_l. As this contradicts that J is a P_i-bridge, we conclude $\{c, d\} \subseteq Z$. ◀

Now we relate non-trivial outer P_i-bridges of B_i to maximal 2-separators of B_i. In the next section, we will use this lemma as a fundamental tool for a decomposition into subgraphs having only small overlaps, which will eventually construct P.

▶ **Lemma 12.** *Let P_i be a v_{i-1}-α_i-v_i-path of B_i such that $P_i \neq \alpha_i$. Then the maximal 2-separators of B_i are contained in P_i and do not interlace pairwise. If J is a non-trivial outer P_i-bridge of B_i, there is a maximal 2-separator $\{c, d\}^*$ of B_i such that $J \subseteq B^+_{cd}$.*

3.2.2 Construction of P

We do not know P_i in advance. However, Lemma 12 ensures under the condition $P_i \neq \alpha_i$ that we can split off every non-trivial outer bridge J of P_i by a maximal 2-separator, no matter how P_i looks like. This allows us to construct P_i iteratively by decomposing B_i along its maximal 2-separators. Since maximal 2-separators only depend on the graph B_i (in contrast to the paths P_i, which depend for example on the $K \cup C_G$-bridges), we can access them without knowing P_i itself. We now give the details of such a decomposition.

▶ **Definition 13.** For every $1 \leq i \leq l$, let $\eta(B_i)$ be α_i if $\alpha_i = v_{i-1}v_i$ and otherwise the graph obtained from B_i as follows: For every maximal 2-separator $\{c, d\}^*$ of B_i, split off B^+_{cd}. Moreover, let $\eta(K) := \eta(B_1) \cup \dots \cup \eta(B_l)$.

If $\alpha_i \neq v_{i-1}v_i$, α_i cannot be a v_{i-1}-α_i-v_i-path of B_i; hence, the maximal 2-separators of K that were split in this definition do not interlace due to Lemma 12. This implies that the order of the performed splits is irrelevant. In any case, we have $V(C_{\eta(B_i)}) \subseteq V(C_{B_i})$ and the only 2-separators of $\eta(B_i)$ must be contained in some boundary part of B_i, as there would have been another split otherwise. See Figure 3 for an illustration of $\eta(B_l)$. The following lemma highlights two important properties of every $\eta(B_i)$.

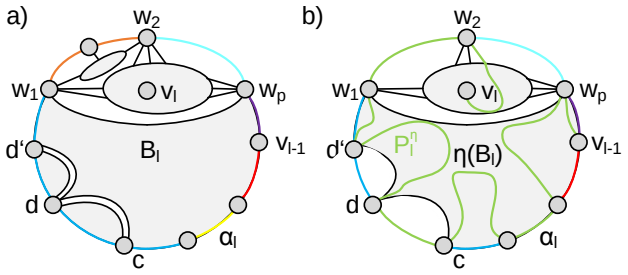

Figure 3 a) A block B_l with boundary points $v_{l-1}, l_{\alpha_l}, r_{\alpha_l}, w_1, \ldots, w_3$ that has two maximal 2-separators on the same boundary part. b) The graph $\eta(B_l)$.

▶ **Lemma 14.** *Every $\eta(B_i)$ is a block. Let P_i^η be a v_{i-1}-α_i-v_i-path of some $\eta(B_i)$ such that $P_i^\eta \neq \alpha_i$. Then every outer P_i^η-bridge of $\eta(B_i)$ is trivial.*

The next lemma shows how we can construct a Tutte path P of K iteratively using maximal 2-separators. We will provide the details of an efficient implementation in Section 4.

▶ **Lemma 15** (Construction of P)**.** *For every $1 \leq i \leq l$, a v_{i-1}-α_i-v_i-path P_i of B_i can be constructed such that no non-trivial outer P_i-bridge of B_i is part of an inductive call of Theorem 1.*

Proof. The proof proceeds by induction on the number of vertices in B_i. If B_i is just an edge or a triangle, the claim follows directly. For the induction step, we therefore assume that B_i contains at least four vertices. If $\alpha_i = v_{i-1}v_i$, we set $P_i := \alpha_i$, so assume $\alpha_i \neq v_{i-1}v_i$. In particular, $\eta(B_i) \neq \alpha_i$ and α_i is no v_{i-1}-α_i-v_i-path of $\eta(B_i)$. As $|V(\eta(B_i))| < n$, we may apply an inductive call of Theorem 1 to $\eta(B_i)$, which returns a v_{i-1}-α_i-v_i-path $P_i^\eta \neq \alpha_i$ of $\eta(B_i)$. This does not violate the claim, since $\eta(B_i)$ does not contain any non-trivial outer P_i^η-bridge by Lemma 14.

Now we extend P_i^η iteratively to the desired v_{i-1}-α_i-v_i-path P_i of B_i by restoring the subgraphs that were split off along maximal 2-separators one by one. For every edge $cd \in C_{\eta(B_i)}$ such that $\{c, d\}^*$ is a maximal 2-separator of B_i (in arbitrary order), we distinguish the following two cases: If $cd \notin P_i^\eta$, we do not modify P_i^η, as in B_i the subgraph B_{cd}^+ will be a valid outer bridge. If otherwise $cd \in P_i^\eta$, we consider the subgraph B_{cd}^+ of B_i. Clearly, $B := B_{cd}^+ \cup \{cd\}$ is a block. Define that the *boundary points* of B are c, d and the two endpoints of some arbitrary edge $\alpha_B \neq cd$ in C_B. This introduces the boundary parts of B in the standard way, and hence defines $\eta(B)$. Note that B may contain several maximal 2-separators in cC_Bd that in B_i were suppressed by $\{c, d\}^*$, as $\{c, d\}^*$ is not a 2-separator of B. In consistency with Lemma 12, which ensures that no two maximal 2-separators of B_i interlace, we have to ensure that no two maximal 2-separators of B interlace in our case $\alpha_i \neq v_{i-1}v_i$, as otherwise $\eta(B)$ would be ill-defined. This is however implied by Lemma 9, as $\alpha_B \neq cd$. Since $|V(\eta(B))| < |V(B_i)|$, a c-α_B-d-path P_B of B can be constructed such that no non-trivial outer P_B-bridge of B is part of an inductive call of Theorem 1. Since $\alpha_B \neq cd$, P_B does not contain cd. We now replace the edge cd in P_i^η by P_B. This gives the desired path P_i after having restored all subgraphs B_{cd}^+. ◀

Applying Lemma 15 on all blocks of K and taking the union of the resulting paths gives P. In the next step, we will modify Q such that $P \cup \{\alpha\} \cup Q$ becomes the desired Tutte path of G. By Lemma 15, no non-trivial outer P-bridge of K was part of any inductive call of Theorem 1 so far, which allows us to use these bridges inductively for the following modification of Q (the existence proof in [29] used these arbitrarily large bridges in inductive calls for both constructing P and modifying Q).

3.2.3 Modification of Q

We show how to modify Q such that $P \cup \{\alpha\} \cup Q$ is an x-α-y-path of G. To this end, consider a $(P \cup \{\alpha\} \cup Q)$-bridge J of G. Since Lemma 5 cannot be applied, J does not have all of its attachments in Q. On the other hand, if J has all of its attachments in $P \subseteq K$, $J \subseteq K$ follows from the maximality of blocks and therefore J satisfies all conditions for a Tutte path of G. Hence, it suffices to consider $(P \cup \{\alpha\} \cup Q)$-bridges that have attachments in both P and Q. The following lemma showcases some of their properties.

▶ **Lemma 16.** *Let J be a $(P \cup \{\alpha\} \cup Q)$-bridge of G that has an attachment in P. Then $J \cap K$ is either exactly one vertex in P or exactly one non-trivial outer P-bridge L of K. In particular, J has at most two attachments in P.*

Let J be a $(P \cup \{\alpha\} \cup Q)$-bridge of G that has attachments in both P and Q and recall that $C(J) = l_J C_G r_J$. Because Lemma 5 is not applicable to G, there is no other $(P \cup \{\alpha\} \cup Q)$-bridge than J that intersects $(J \cup C(J)) - P - \{l_J, r_J\}$; in other words, $J \cup C(J)$ is everything that is enclosed by the attachments of J in G. In order to obtain the Tutte path of Theorem 1, we will thus replace the subpath $C(J)$ with a path $Q_J \subseteq (J \cup C(J)) - P$ from l_J to r_J such that any $(Q_J \cup P)$-bridge of G that intersects $(J \cup C(J)) - P - \{l_J, r_J\}$ has at most three attachments and at most two if it contains an edge of C_G. Since l_J and r_J are contained in Q, no other $(P \cup \{\alpha\} \cup Q)$-bridge of G than J is affected by this "local" replacement, which proves its sufficiency for obtaining the desired Tutte path.

We next show how to obtain Q_J. If $C(J)$ is a single vertex, we do not need to modify Q at all (hence, $Q_J := C(J)$), as then $J \cup C(J)$ does not contain an edge of C_G and has at most three attachments in total (one in Q and at most two in P by Lemma 16). If $C(J)$ is not a single vertex, we have the following lemma.

▶ **Lemma 17** ([29, 4])**.** *Let J be a $(P \cup \{\alpha\} \cup Q)$-bridge of G that has an attachment in P and at least two in Q. Then $(J \cup C(J)) - P$ contains a path Q_J from l_J to r_J such that any $(Q_J \cup P)$-bridge of G that intersects $(J \cup C(J)) - P - \{l_J, r_J\}$ has at most three attachments and at most two if it contains an edge of C_G.*

By Lemma 16, any $(P \cup \{\alpha\} \cup Q)$-bridge J of G intersects K in at most one non-trivial P-bridge of K having attachments c and d. By Lemma 15, this non-trivial P-bridge was never part of an inductive call of Theorem 1 before (in fact, at most its edge cd was). Replacing $C(J)$ with Q_J for every such J, as described in Lemma 17 and before, therefore concludes the constructive proof of Theorem 1.

4 A Quadratic Time Algorithm

In this section, we give an algorithm based on the decomposition shown in Section 3 (see Algorithm 1). It is well known that there are algorithms that compute the blocks of a graph and the block-cut tree of G in linear time, see [25] for a very simple one. Using this on $G - Q$, we can compute the blocks $B_1, \dots, B_l$ of K in time $O(n)$.

We now check if Lemma 4 or 5 is applicable at least once to G; if so, we stop and apply the construction of either Lemma 4 or 5. Checking applicability involves the computation of special 2-separators $\{c, d\}$ of G that are in C_G (e.g., we did assume minimality of $|V(G_R)|$ in Lemma 4). In order to find such a $\{c, d\}$ in time $O(n)$, we first compute the *weak dual* G^* of G, which is obtained from the dual of G by deleting its outer face vertex, and note that such pairs $\{c, d\}$ are exactly contained in the faces that correspond to 1-separators of G^*. Once more, these faces can be found by the block-cut tree of G^* in time $O(n)$ using the above

Algorithm 1 TPATH(G, x, α, y) ▷ method, running time without induction

if G is a triangle or $\alpha = xy$ **then return** the trivial x-α-y path of G ▷ $O(1)$
if Lemma 4 or 5 is applicable at least once to G **then** ▷ weak dual block-cut tree, $O(n)$
    apply TPATH on G_L and G_R as described and **return** the resulting path ▷ $O(1)$
if there is a 2-separator $\{c, d\} \in C_G$ of G **then**
    do simple case 2
Compute the minimal plane chain K of blocks of G ▷ block-cut tree of $G - Q$, $O(n)$
Compute $\eta(K)$ ▷ dyn. progr. on weak dual block-cut tree, $O(n)$
Compute P by the induction of Lemma 15 ▷ dyn. prog. precomputes all possible B^+_{cd}, $O(n)$
Modify Q by the induction of Lemma 17 ▷ traversing outer faces of bridges, $O(n)$
return $P \cup \{\alpha\} \cup Q$

algorithm. Since the block-cut tree is a tree, we can perform dynamic programming on all these 1-separators bottom-up the tree in linear total time, in order to find one desired $\{c, d\}$ that satisfies the respective constraints (e.g. minimizing $|V(G_R)|$, or separating x and α).

Now we compute $\eta(K)$. Since the boundary points of every B_i are known from K, all *maximal* 2-separators can be computed in time $O(n)$ by dynamic programming as described above. We compute in fact the nested tree structure of all 2-separators on boundary parts due to Lemma 12, on which we then apply the induction described in Lemma 15. Hence, no non-trivial outer P-bridge of K is touched in the induction, which allows to modify Q along the induction of Lemma 17.

In our decomposition, every inductive call is invoked on a graph having less vertices than the current graph. The key insight is now to show a good bound on the total number of inductive calls to Theorem 2. In order to obtain good upper bounds, we will restrict the choice of α_i for every block B_i of K such that α_i is an edge of $C_{B_i} - v_{i-1}v_i$. This prevents several situations in which the recursion stops because of the case $\alpha = xy$, which would unease the following arguments. The next lemma shows that only $O(n)$ inductive calls are performed. Its argument is, similarly to one in [5], based on a subtle summation of the Tutte path differences that occur in the recursion tree.

▶ **Lemma 18.** *The number of inductive calls for TPATH(G, x, α, y) is at most $2n - 3$.*

Hence, Algorithm 1 has overall running time $O(n^2)$, which proves our main Theorem 3.

▶ **Corollary 19.** *Let G be a 2-connected plane graph and let α, β, γ be edges of C_G. Then a Tutte cycle of G that contains α, β and γ can be computed in time $O(n^2)$.*

Abstract

In monotone submodular function maximization, approximation guarantees based on the curvature of the objective function have been extensively studied in the literature. However, the notion of curvature is often pessimistic, and we rarely obtain improved approximation guarantees, even for very simple objective functions.

In this paper, we provide a novel approximation guarantee by extracting an $\mathrm{M}^\natural$-concave function $h : 2^E \to \mathbb{R}_+$, a notion in discrete convex analysis, from the objective function $f : 2^E \to \mathbb{R}_+$. We introduce a novel notion called the $\mathrm{M}^\natural$-concave curvature of a given set function f, which measures how much f deviates from an $\mathrm{M}^\natural$-concave function, and show that we can obtain a $(1 - \gamma/e - \epsilon)$-approximation to the problem of maximizing f under a cardinality constraint in polynomial time, where γ is the value of the $\mathrm{M}^\natural$-concave curvature and $\epsilon > 0$ is an arbitrary constant. Then, we show that we can obtain nontrivial approximation guarantees for various problems by applying the proposed algorithm.

1 Introduction

A set function $f : 2^E \to \mathbb{R}$ is called *monotone* if $f(X) \leq f(Y)$ for any $X \subseteq Y \subseteq E$ and called *submodular* if $f(X) + f(Y) \geq f(X \cap Y) + f(X \cup Y)$ for any $X, Y \subseteq E$. In monotone submodular function maximization under a cardinality constraint, given a nonnegative

monotone submodular function $f : 2^E \to \mathbb{R}_+$ and $k \in \mathbb{Z}_+$, we want to compute a set $S \subseteq E$ with $|S| \leq k$ that maximizes $f(S)$. This simple problem includes various optimization problems in theory and practice, such as facility location, combinatorial auctions [7, 14], viral marketing in social networks [11], and sensor placement [13, 12].

Although monotone submodular function maximization is an NP-hard problem, the greedy algorithm achieves a $(1 - 1/e)$-approximation, and this approximation ratio is known to be tight [20]. In practice, however, the greedy algorithm exhibits an approximation ratio much better than $1 - 1/e$, sometimes close to one [13]. This gap between the theoretical guarantee and the practical performance in "real-world" instances has been a major mystery in submodular function maximization. The first attempt to explain this gap goes back to Conforti and Cornuéjols [6]. They introduced a parameter called the (total) *curvature* of a monotone submodular function, with which we can derive a tighter approximation ratio.

▶ **Definition 1** (Curvature)**.** The curvature c of a monotone submodular function $f : 2^E \to \mathbb{R}_+$ is

$$c := 1 - \min_{i \in E} \frac{f(i \mid E - i)}{f(i)}.$$

Here, $f(i)$ and $f(i \mid E - i)$ are shorthand for $f(\{i\})$ and $f(E) - f(E - i)$, respectively. We note that $f(i \mid E - i) \leq f(i)$ holds from the submodularity of f; hence, $c \in [0, 1]$ holds. Roughly speaking, the curvature of a function measures how close it is to a modular function, where a set function $g : 2^E \to \mathbb{R}$ is called *modular* if $g(X) + g(Y) = g(X \cap Y) + g(X \cup Y)$ for every $X, Y \subseteq E$. Indeed, we can easily observe that $c = 0$ if and only if f is modular.

It is shown in [6] that the greedy method achieves a $(1 - e^{-c})/c$-approximation, which is at least $1 - 1/e$ and tends to 1 as $c \to 0$. This approximation has recently improved to $1 - c/e - \epsilon$ for any $\epsilon > 0$ using a more sophisticated algorithm by Sviridenko, Vondrák, and Ward [24]. Since the curvature is easy to analyze, it has been shown that we can obtain refined approximation guarantees for various settings by exploiting the curvature [10, 1].

However, we might ask *does the curvature explain the gap completely?* The answer seems to be negative. The concept of curvature is still unsatisfactory because monotone submodular functions in practical applications are often far from modular functions, and the curvature does not explain why we can obtain high approximation ratios. For instance, let us consider a very simple function $f(X) = \sqrt{|X|}$. Since this function has a curvature of $1 - O(1/\sqrt{n})$ for $n = |E|$, the approximation guarantee is (roughly) $1 - 1/e$, while the greedy algorithm obviously finds an optimal solution!

1.1 Our contributions

To narrow the gap discussed above, in this work we consider a larger and richer class of functions that are easy to maximize. For such a class of functions, we exploit $\mathrm{M}^\natural$-concave functions, introduced in the discrete convex analysis literature [18]. A set function $f : 2^E \to \mathbb{R}$ is called *$M^\natural$-concave*[3] if, for any $X, Y \subseteq E$ and $i \in X \setminus Y$, either (i) $f(X) + f(Y) \leq f(X - i) + f(Y + i)$ or (ii) there exists $j \in Y \setminus X$ such that $f(X) + f(Y) \leq f(X - i + j) + f(Y + i - j)$. Intuitively speaking, we can increase the sum $f(X) + f(Y)$ by making X and Y closer, which resembles concave functions. We note that an $\mathrm{M}^\natural$-concave function is submodular, and an $\mathrm{M}^\natural$-concave function can be maximized in polynomial time with the greedy algorithm (see,

[3] For a set function, $\mathrm{M}^\natural$-concave functions are essentially equivalent to *valuated matroids*.

e.g., [16]). Hence, $\mathrm{M}^\natural$-concave functions can be regarded as a class of "easy" submodular functions.

Now, we start with the following observation. For a monotone submodular function $f : 2^E \to \mathbb{R}_+$, we define a modular function h as $h(X) := \sum_{i \in X} f(i \mid E - i)$. Then, f can be decomposed as $f = g + h$, where g is another monotone submodular function. One can show that $h(X) \geq (1-c)f(X)$ for any $X \subseteq E$, where c is the curvature of f. The modular function h can be regarded as an "easy" part of f and g as a "difficult" part, and the curvature measures the contribution of the modular part h to the entire function f. Observing that any modular function is $\mathrm{M}^\natural$-concave, we can think of decompositions into a monotone submodular function and an $\mathrm{M}^\natural$-concave function, which gives the following definition:

▶ **Definition 2** ($\mathrm{M}^\natural$-concave curvature)**.** Suppose that a monotone submodular function $f : 2^E \to \mathbb{R}_+$ is decomposed as $g + h$, where $g : 2^E \to \mathbb{R}_+$ is monotone submodular, and $h : 2^E \to \mathbb{R}_+$ is $\mathrm{M}^\natural$-concave. Then, the *$M^\natural$-concave curvature* $\gamma(g, h)$ of f is the minimum value of γ such that $h(X) \geq (1 - \gamma)f(X)$ for every $X \subseteq E$, or equivalently

$$\gamma(g, h) = 1 - \min_{X \subseteq E} \frac{h(X)}{f(X)} = \max_{X \subseteq E} \frac{g(X)}{f(X)},$$

where we conventionally assume that $\frac{0}{0} := \infty$.

We abbreviate $\gamma(g, h)$ by γ if g and h are clear from the context. We note that the $\mathrm{M}^\natural$-concave curvature is defined for a decomposition $f = g + h$, whereas the standard curvature is defined for the function f itself. By the argument above, we can always find a decomposition $f = g + h$ such that the $\mathrm{M}^\natural$-concave curvature is no greater than the standard curvature.

Our main contribution is the following generalization of the results of [24, 16] in terms of the $\mathrm{M}^\natural$-concave curvature.

▶ **Theorem 3.** *Let $f : 2^E \to \mathbb{R}_+$ be a monotone submodular function that can be decomposed as $f = g + h$, where g is monotone submodular, and h is $M^\natural$-concave. Assume that we have value oracles of g and h. Then, for an integer $k \in \mathbb{Z}_+$ and a constant $\epsilon > 0$, we can find a random subset X of size k such that $\mathbf{E}[f(X)] \geq (1 - \gamma(g, h)/e - \epsilon)f(O)$ in polynomial time, where O is an optimal solution.*

Applications. $\mathrm{M}^\natural$-concave functions include many nontrivial functions such as (weighted) matroid rank functions and laminar concave functions, which are far from modular functions. Our result immediately implies that if the significant part of $f = g + h$ is due to the $\mathrm{M}^\natural$-concave part h, we can obtain a better approximation ratio, although it might not be straightforward to find such a decomposition of f into g and h even if f is a compactly represented function. In Section 4, we provide a general algorithm for finding a decomposition from the value oracle of f. This algorithm always finds a decomposition that is at least as good as the decomposition via the standard curvature. In Section 5, we provide problem-specific decompositions for several problems such as facility location, which yield improved approximation guarantees.

1.2 Proof technique

Our main result (Theorem 3) is proved by modifying the *continuous greedy algorithm*. The continuous greedy algorithm is a powerful and flexible framework for submodular function maximization, which has been applied to a matroid constraint, a knapsack constraint, and even combinations of various constraints [2, 4, 5]. At a high level, the continuous greedy

algorithm generates a sequence $\boldsymbol{x}(t)$ in the convex hull of feasible solutions for $t \in [0,1]$ by the following differential equation: $\frac{d\boldsymbol{x}}{dt} = \boldsymbol{v}(t)$ and $\boldsymbol{x}(0) = \mathbf{0}$, where $\boldsymbol{v}$ is a prescribed velocity vector. Then, we round the final point $\boldsymbol{x}(1)$ into a feasible solution X via a rounding algorithm. The previous result of [24] relies on the property that for a modular function $h = \boldsymbol{w}(X)$, if $\boldsymbol{w}^\top \boldsymbol{v}(t) \geq \alpha$ holds for $t \in [0,1]$, then $\boldsymbol{w}^\top \boldsymbol{x}(1) \geq \alpha$. This property enables us to find a fractional solution $\boldsymbol{x}(1)$ that simultaneously optimizes h and g; that is, $\boldsymbol{x}(1)$ achieves the optimal value for the modular part h and a $(1-1/e)$-approximation for the remaining monotone submodular part g.

Continuous greedy algorithm with a multilinear extension and concave closure. To run the continuous greedy algorithm, we require continuous extensions of set functions. For submodular functions, the *multilinear extension* is typically used. In addition, a modular function is trivially extendable. However, for $\mathrm{M}^\natural$-concave functions, it is nontrivial to choose a continuous extension because if we just use the multilinear extension, we end up with a $(1-1/e)$-approximation. To remedy this, we use a different continuous extension, namely, the *concave closure*. The concave closure is difficult to evaluate in general, but for $\mathrm{M}^\natural$-concave functions, we can evaluate their concave closures in polynomial time thanks to the results of discrete convex analysis. This property enables us to run a modified continuous greedy algorithm with the following strong guarantee; that is, our continuous greedy algorithm finds a fractional solution that achieves the optimal value for the $\mathrm{M}^\natural$-concave part and a $(1-1/e)$-approximation for the remaining monotone submodular part.

Rounding algorithm preserving the values of a multilinear extension and concave closure. A difficulty also arises in the rounding phase. Typically, a rounding algorithm finds a feasible subset that preserves the value of the multilinear extension. However, since our modified continuous greedy algorithm also involves a concave closure, we need to design a rounding algorithm that preserves the values of the multilinear extension and concave closure. To this end, we extend the *swap rounding* [4] algorithm for $\mathrm{M}^\natural$-concave functions. The original swap rounding algorithm is designed for rounding a fractional solution in a matroid base polytope into a matroid base without losing the value of a multilinear extension. We prove that almost the same strategy works for our purpose by exploiting the combinatorial structures of $\mathrm{M}^\natural$-concave functions.

1.3 Related work

The concept of curvature was introduced by Conforti and Cornuéjols, and they proved that the classical greedy algorithm of [20] achieves a $(1-e^{-c})/c$-approximation for a cardinality constraint. In [25], Vondrák introduced a slightly relaxed variant of the curvature, namely, the *curvature with respect to the optimum*. He obtained the same approximation guarantee $(1-e^{-c^*})/c^*$ for a matroid constraint, where c^* is the curvature with respect to the optimum, and also showed that the approximation guarantee is tight for general submodular functions. Later, this result was refined with the total curvature by Sviridenko, Vondrák, and Ward [24]. For a knapsack constraint, Yoshida [26] proved a better approximation ratio of $1-c/e$. Iyer and Bilmes [10] studied a general reduction between submodular function maximization and a *submodular cover*, and they proved that if the curvature of the functions involved is small, the two problems reduce to each other.

Discrete convex analysis originated with Murota [16]. We note that discrete convex functions are usually defined on the integer lattice $\mathbb{Z}^E$, although we focus on set functions in this paper. Discrete convex functions admit various attractive properties such as Fenchel

duality, the separation theorem, and descent-type algorithms, which are analogous to convex analysis in the Euclidean space. The applications of discrete convex analysis include economics, system analysis for electrical circuits, phylogenetic analysis, etc. Shioura [22] studied maximization of the sum of $\mathrm{M}^\natural$-concave set functions subject to a matroid constraint. He showed that pipage rounding [2] can be explained from the viewpoint of discrete convexity. For details, the reader is referred to a monograph [16] or recent survey [17].

The $\mathrm{M}^\natural$-natural concavity is equivalent to the *gross-substitutability* [17], a central concept in economics. Roughgarden, Talgam-Cohen, and Vondrák [21] studied approximation for maximizing set functions that are close to the gross-substitute functions and others. Recently, Chatziafratis, Roughgarden, and Vondrák [3] provided improved approximation guarantees via a different concept called *perturbation stability*. They proved that the greedy and local search algorithms achieve a better approximation for submodular function maximization for various set systems under a stability assumption.

1.4 Organization

In Section 2, we introduce the notation and basic concepts for submodular function maximization and discrete convex analysis. Our main theorem and continuous greedy algorithms are presented in Section 3. We describe a general algorithm for finding a decomposition of a given monotone submodular function into a monotone submodular function and an $\mathrm{M}^\natural$-concave function in Section 4. In Section 5, we provide several examples of problem-specific decompositions and the theoretical bounds of the $\mathrm{M}^\natural$-concave curvature.

2 Preliminaries

For a set $S \subseteq E$, $\mathbf{1}_S$ denotes the characteristic vector of S; that is, $\mathbf{1}_S(i) = 1$ if $i \in S$, and $\mathbf{1}_S(i) = 0$ otherwise. The dimension of the ambient space should be clear from the context. For $a \in \mathbb{R}$, we define $[a]^+ := \max\{a, 0\}$. For a vector $\boldsymbol{x} \in \mathbb{R}^E$ and $X \subseteq E$, we use the shorthand notation: $\boldsymbol{x}(X) := \sum_{i \in X} \boldsymbol{x}(i)$.

A pair consisting of a finite set E and a set family of $\mathcal{I} \subseteq 2^E$ is called a *matroid* if (i) $\varnothing \in \mathcal{I}$; (ii) if $X \in \mathcal{I}$, then any subset of X also belongs to $\mathcal{I}$; and (iii) if $X, Y \in \mathcal{I}$ and $|X| < |Y|$, then there exists $i \in Y \setminus X$ such that $X + i \in \mathcal{I}$. A member of $\mathcal{I}$ is called an *independent set*. A maximal independent set is called a *base*. The *base polytope* of a matroid is the convex hull of all characteristic vectors of its bases. The *rank function* of a matroid is the following set function: $r(X) = \max\{|I| : I \subseteq X, I \in \mathcal{I}\}$. Although it is well-known that matroid rank functions are monotone and submodular, they are indeed included in the more tractable class called $\mathrm{M}^\natural$-concave functions.

▶ **Definition 4** ($\mathrm{M}^\natural$-concave function [19]). A set function $f : 2^E \to \mathbb{R}$ is *$M^\natural$-concave* if for $X, Y \subseteq E$ and $i \in X \setminus Y$, either

$$f(X) + f(Y) \leq f(X - i) + f(Y + i), \tag{1}$$

or there exists $j \in Y \setminus X$ such that

$$f(X) + f(Y) \leq f(X - i + j) + f(Y - i + j). \tag{2}$$

It is known that $\mathrm{M}^\natural$-concave functions are submodular. Note that $\mathrm{M}^\natural$-concave functions are not necessarily monotone. We give several examples of $\mathrm{M}^\natural$-concave functions below.

▶ **Example 5** ($\mathrm{M}^\natural$-concave functions from univariate concave functions)**.** Let $\phi : \mathbb{R}_+ \to \mathbb{R}$ be a concave function. Then, $f(X) := \phi(|X|)$ is an $\mathrm{M}^\natural$-concave function. For example, $X \mapsto \sqrt{|X|}$ and $X \mapsto \min\{|X|, \alpha\}$ $(\alpha > 0)$ are $\mathrm{M}^\natural$-concave. More generally, let $\mathcal{L}$ be a laminar family on E and $\phi_L : \mathbb{R}_+ \to \mathbb{R}$ be a concave function for $L \in \mathcal{L}$. Then, $f(X) := \sum_{L\in\mathcal{L}} \phi_L(|X \cap L|)$ is an $\mathrm{M}^\natural$-concave function. Here, as a special case, a separable concave function $f(X) = \sum_{i\in E} \phi_i(|X \cap \{i\}|)$ is $\mathrm{M}^\natural$-concave.

▶ **Example 6** ($\mathrm{M}^\natural$-concave functions from matroids)**.** Let $\mathbf{M} = (E, \mathcal{I})$ be a matroid and $\boldsymbol{w} \in \mathbb{R}^E_+$. The *weighted matroid rank function* is the following set function: $f(X) = \max\{\boldsymbol{w}(I) : I \subseteq X, I \in \mathcal{I}\}$. That is, $f(X)$ is the maximum weight of independent sets in X. In particular, the matroid rank function is $\mathrm{M}^\natural$-concave.

If we restrict the domain of an $\mathrm{M}^\natural$-concave function to all subsets of the same cardinality, the condition in (1) can be omitted. Such functions are called *M-concave functions*.

For exploiting continuous greedy algorithms, we require continuous extensions of set functions.

▶ **Definition 7** (Multilinear extension)**.** The *multilinear extension* $F : [0,1]^E \to \mathbb{R}$ of a set function $f : 2^E \to \mathbb{R}$ is defined as

$$F(\boldsymbol{x}) = \sum_{X\subseteq E} f(X) \prod_{i\in X} \boldsymbol{x}(i) \prod_{i\in E\setminus X} (1 - \boldsymbol{x}(i)).$$

▶ **Definition 8** (Concave closure)**.** The *concave closure* $\bar{f} : [0,1]^E \to \mathbb{R}$ of a set function $f : 2^E \to \mathbb{R}$ is defined as

$$\bar{f}(\boldsymbol{x}) := \max\left\{ \sum_{Y\subseteq E} \lambda_Y f(Y) : \sum_Y \lambda_Y \mathbf{1}_Y = \boldsymbol{x}, \sum_Y \lambda_Y = 1, \lambda_Y \geq 0 \, (Y \subseteq E) \right\}. \tag{3}$$

If f is an $\mathrm{M}^\natural$-concave function, then $\bar{f}(\boldsymbol{x})$ can be computed in polynomial time for any $\boldsymbol{x} \in [0,1]^E$ [23]. Furthermore, the subgradients of $\bar{f}$ can be computed in polynomial time [23]. This yields a separation oracle for the constraint of the form $\bar{f}(\boldsymbol{x}) \geq \alpha$.

3 Algorithms

In this section, we prove Theorem 3. To this end, we show the following, which simultaneously optimizes g and h:

▶ **Theorem 9.** *Let $f : 2^E \to \mathbb{R}_+$ be a monotone submodular function decomposed as $f = g + h$ for a monotone submodular function $g : 2^E \to \mathbb{R}_+$ and an $M^\natural$-concave function $h : 2^E \to \mathbb{R}$, and let k be a positive integer. Then, there exists a polynomial-time algorithm that finds a random set $X \subseteq E$ of cardinality k such that*

$$\mathbf{E}[g(X)] \geq \left(1 - \frac{1}{e}\right) g(O) - \epsilon M, \quad \mathbf{E}[h(X)] \geq h(O) - \epsilon M,$$

for any constant $\epsilon > 0$, where O is an optimal solution for $\max\{f(X) : |X| \leq k\}$ and $M = \max_{e\in E} \max\{g(e), h(e)\}$.

We note that the special case in which h is modular is proved in [24].

Before proving Theorem 9, we see that Theorem 3 is an easy consequence of Theorem 9:

Algorithm 1 Modified Continuous Greedy Algorithm

Require: $g(O), h(O) \in \mathbb{R}_+$, value oracles of $G, \bar{h} : [0,1]^E \to \mathbb{R}_+$, and a value oracle of $\nabla G : [0,1]^E \to \mathbb{R}_+^E$.

1: Set $\boldsymbol{x}(0) := \mathbf{0} \in \mathbb{R}^E$

2: From $t = 0$ to $t = 1$, compute $\boldsymbol{x}(t) \in [0,1]^E$ following the differential equation $\frac{d\boldsymbol{x}}{dt} = \boldsymbol{v}(t)$, where $\boldsymbol{v} \in [0,1]^E$ is a vector satisfying $\boldsymbol{v}(t)^\top \nabla G(\boldsymbol{x}) \geq g(O) - G(\boldsymbol{x}), \bar{h}(\boldsymbol{v}(t)) \geq h(O)$, and $\boldsymbol{v}(t) \in P_k$.

3: **return** $\boldsymbol{x}(1)$.

Proof of Theorem 3. By Theorem 9, we can compute a random $X \subseteq E$ of size k such that

$$\begin{aligned}\mathbf{E}[f(X)] &\geq \left(1 - \frac{1}{e}\right) g(O) + h(O) - 2\epsilon M = \left(1 - \frac{1}{e}\right) f(O) + \frac{1}{e} h(O) - 2\epsilon M \\ &\geq \left(1 - \frac{1}{e}\right) f(O) + \frac{1-\gamma}{e} f(O) - 2\epsilon M = \left(1 - \frac{\gamma}{e}\right) f(O) - 2\epsilon M \\ &\geq \left(1 - \frac{\gamma}{e} - O(\epsilon)\right) f(O),\end{aligned}$$

where in the last inequality, we used the fact that $M = \max_{e \in E} \max\{g(e), h(e)\} \leq g(O) + h(O)$. ◀

In the rest of this section, we fix f and its decomposition $f = g + h$, and the goal is a proof of Theorem 9.

3.1 Continuous-time algorithm for simultaneous optimization

First, we present a continuous-time version of our algorithm. Although we cannot run this version in polynomial time, it is helpful to grasp the overall idea.

Our algorithm is based on the continuous greedy framework [2]. Let $G : [0,1]^E \to \mathbb{R}_+$ be the multilinear extension of g and $\bar{h} : [0,1]^E \to \mathbb{R}_+$ be the concave closure of h, and let P_k be the convex hull of all characteristic vectors of subsets of size at most k. We assume that we have value oracles of G, ∇G, and $\bar{h}$. We also assume that we know $g(O)$ and $h(O)$, where O is the optimal solution to $\max\{f(X) : |X| \leq k\}$. We discuss how we can remove these assumptions in Section 3.2. The pseudocode of the continuous greedy algorithm is given in Algorithm 1.

▶ Remark. One can find $\boldsymbol{v}$ in Algorithm 1 in polynomial time. First, the problem of finding $\boldsymbol{v}$ is a feasible problem of a convex program. This problem is feasible because $\mathbf{1}_O \in \mathbb{R}^E$ is a feasible solution. Moreover, we have a separation oracle for $\bar{h}(\boldsymbol{v}) \geq h(O)$. Hence, we can find a feasible solution using the ellipsoid method.

The following lemma shows that Algorithm 1 provides the guarantee required in Theorem 9:

▶ **Lemma 10.** *Let $\boldsymbol{x}(t)$ be the sequence computed in Algorithm 1. Then, we have $G(\boldsymbol{x}(1)) \geq (1 - 1/e)g(O)$ and $\bar{h}(\boldsymbol{x}(1)) \geq h(O)$.*

Proof. By adopting the standard analysis of the continuous greedy algorithm, we can see that $G(\boldsymbol{x}(1)) \geq (1 - 1/e)g(O)$ (see, e.g., [2]). On the other hand, since $\bar{h}$ is a concave function, $\bar{h}(\boldsymbol{x}(1)) = \bar{h}\left(\int_0^1 \boldsymbol{v}(t)dt\right) \geq \int_0^1 \bar{h}(\boldsymbol{v}(t))dt \geq h(O)$, where the first inequality follows from Jensen's inequality. ◀

3.2 Discrete-time algorithm for simultaneous optimization

Now, we describe the discrete-time version of Algorithm 1, which can be run in polynomial time. Again, we basically follow the argument in [24] and explain the modifications to Algorithm 1. We define $M = \max_{e \in E} \max\{g(e), h(e)\}$ as the maximum marginal gain of adding a single element. The detail and proof are deferred to the full version.

▶ **Lemma 11.** *For any constant $\epsilon > 0$, there exists a polynomial-time algorithm that finds a vector $\boldsymbol{x} \in P_k$ such that $G(\boldsymbol{x}) \geq (1 - 1/e)g(O) - \epsilon M$ and $\bar{h}(\boldsymbol{x}) \geq h(O) - \epsilon M$.*

3.3 Rounding

In this section, we show the following:

▶ **Lemma 12.** *Let $\boldsymbol{x} \in P_k$ be a vector. Then, there exists a polynomial-time randomized rounding algorithm that outputs $X \subseteq E$ with $|X| \leq k$ such that $\mathbf{E}[g(X)] \geq G(\boldsymbol{x})$ and $\mathbf{E}[h(X)] \geq \bar{h}(\boldsymbol{x})$.*

Theorem 9 is obtained by combining Lemmas 11 and 12. In the following, we show a rounding method, provided that a convex combination of $\bar{h}(\boldsymbol{x})$ is known. The details on how to compute a convex combination is described in the full version.

Suppose that we have a convex combination of $\bar{h}(\boldsymbol{x})$; that is, we have $\lambda_1, \dots, \lambda_m > 0$ and $X_1, \dots, X_m \subseteq E$ of size k with $\sum_i \lambda_i = 1$, $\sum_i \lambda_i \mathbf{1}_{X_i} = \boldsymbol{x}$, and

$$\bar{h}(\boldsymbol{x}) = \sum_{i=1}^{m} \lambda_i h(X_i). \tag{4}$$

Our rounding is a random process, and the condition $|X_i| = k$ ($i \in [m]$) is always preserved throughout the process.

If $X_1 = \cdots = X_m$, then we are done, and we output the set $X := X_1 (= \cdots = X_m)$, which is of size k. Otherwise, find $1 \leq a < b \leq m$ such that $X_a \setminus X_b \neq \varnothing$ and $X_a \setminus X_b \neq \varnothing$. Then, we fix $i \in X_a \setminus X_b$ and find $j \in X_b \setminus X_a$ such that $h(X_a) + h(X_b) \leq h(X_a - i + j) + h(X_b + i - j)$, whose existence is guaranteed by the $\mathrm{M}^\natural$-concavity of h. Then, we replace X_a with $X_a - i + j$ with the probability $\lambda_b/(\lambda_a + \lambda_b)$, replace X_b with $X_b + i - j$ with the complementary probability, and repeat this process again.

We now analyze the expected value of h at the end of the rounding process.

▶ **Lemma 13.** *Let $X \subseteq E$ be the output set. Then, we have $\mathbf{E}[h(X)] \geq \bar{h}(\boldsymbol{x})$.*

Proof. Suppose that we have a chosen $i \in X_a \setminus X_b$ and $j \in X_b \setminus X_a$ in an iteration of the process. Then, the expected change in the value of $\lambda_a h(X_a) + \lambda_b h(X_b)$ at this iteration is

$$\frac{\lambda_a \lambda_b}{\lambda_a + \lambda_b}[h(X_a - i + j) - h(X_a) + h(X_b + i - j) - h(X_b)] \geq 0.$$

Therefore, the expected value of $\sum_{i=1}^{m} \lambda_i h(X_i)$ is at least $\bar{h}(\boldsymbol{x})$. The lemma holds by induction on the number of iterations. ◀

Next, we analyze the expected value of g at the end of the rounding process. Let $\boldsymbol{x}^t = \sum_i \lambda_i \mathbf{1}_{X_i}$ be the random vector after the tth exchange ($t = 0, 1, \dots$). One can check that (i) $\boldsymbol{x}^0 = \boldsymbol{x}$, (ii) $\boldsymbol{x}^{t+1} - \boldsymbol{x}^t$ has at most one positive coordinate and at most one negative coordinate, and (iii) $\mathbf{E}[\boldsymbol{x}^{t+1} \mid \boldsymbol{x}^t] = \boldsymbol{x}^t$. The following lemma establishes that such a random process preserves the value of the multilinear extension of a monotone submodular function.

▶ **Lemma 14** ([4, Lemma VI.2]). *Let $\boldsymbol{x}^t$ be a vector-valued random process satisfying the above conditions (i), (ii), and (iii). Then, for the multilinear extension F of any monotone submodular function $f : 2^E \to \mathbb{R}$, we have $\mathbf{E}[F(\boldsymbol{x}^t)] \geq F(\boldsymbol{x})$ for $t = 0, 1, \ldots$.*

By Lemmas 13 and 14, we have the following lemma.

▶ **Lemma 15.** *Let X be the output of the above rounding process. Then, we have $\mathbf{E}[g(X)] \geq G(\boldsymbol{x})$ and $\mathbf{E}[h(X)] \geq \bar{h}(\boldsymbol{x})$.*

Thus, we can round a fractional solution into an integral solution without losing the objective value (in the expectation).

▶ Remark. Although the continuous greedy step also applies to any down-closed and solvable polytope, the rounding step is able to handle only cardinality constraints. For example, if we consider a matroid constraint, we need to a rounding algorithm that preserves the value of $\bar{h}$ in a matroid polytope. Since the face of $\bar{h}(\boldsymbol{x}) \geq \alpha$ is another matroid polytope, we must essentially deal with a *matroid intersection* constraint. Unfortunately, there is no known rounding algorithm for matroid intersection preserving the value of the multilinear extensions[4]. We can use a contention resolution scheme [5] instead, but this does not preserve the of the value of the multilinear extension and results in an approximation ratio worse than $1 - 1/e$.

4 Decomposition via M$^\natural$-concave Quadratic Functions

In this section, we describe a general decomposition scheme that exploits M$^\natural$-concave quadratic functions.

For a vector $\boldsymbol{d} \in \mathbb{R}^E$, we define $\mathrm{Diag}(\boldsymbol{d}) \in \mathbb{R}^{E \times E}$ as a diagonal matrix such that $\mathrm{Diag}(\boldsymbol{d})_{ii} = \boldsymbol{d}(i)$ for every $i \in E$. The following characterization of M$^\natural$-concave quadratic set functions is known:

▶ **Lemma 16** ([9], also see [17, Theorem 4.3]). *Let $A \in \mathbb{R}^{E \times E}$ be a symmetric matrix, and define $h : 2^E \to \mathbb{R}$ as $h(X) = \frac{1}{2}\mathbf{1}_X^\top A \mathbf{1}_X = \frac{1}{2}\sum_{i \in X} a_{ii} + \sum_{i,j \in X : i \neq j} a_{ij}$. Then, $h(X)$ is M$^\natural$-concave if and only if*

$$A_{ij} \leq 0 \quad \text{for any distinct } i, j \in E, \text{and} \tag{5}$$

$$A_{ij} \leq \max\{A_{ik}, A_{jk}\} \quad \text{for any distinct } i, j, k \in E. \tag{6}$$

Note that the condition in (6) says that A_{ij} must form an *ultrametric*. The above condition is closely related to the concept of a discrete Hessian matrix:

▶ **Definition 17.** The *discrete Hessian* $\mathrm{Hess}_f(X) \in \mathbb{R}^{E \times E}$ of a set function $f : 2^E \to \mathbb{R}$ at a set $X \subseteq E$ is defined as

$$\mathrm{Hess}_f(X)_{ij} = f(X + i + j) + f(X) - f(X + i) - f(X + j). \quad (i, j \in E)$$

We note that $\mathrm{Hess}_f(X)_{ij} = 0$ when i or j belongs to X. By definition, a set function $f : 2^E \to \mathbb{R}$ is submodular if and only if $\mathrm{Hess}_f(X)_{ij} \leq 0$ for any $X \subseteq E$ and distinct $i, j \in E$. A characterization of an M$^\natural$-concave function in terms of a discrete Hessian is also known:

[4] For a special class of submodular functions, a rounding algorithm for a matroid intersection is proposed in [4].

▶ **Lemma 18** ([17, Theorem 4.3]). *A set function $f : 2^E \to \mathbb{R}$ is $M^\natural$-concave if and only if its discrete Hessian satisfies the conditions in* (5) *and* (6) *at any $X \subseteq E$.*

For a monotone submodular function $f : 2^E \to \mathbb{R}_+$, consider a decomposition $f = g + h$, where $h(X) = \frac{1}{2}\mathbf{1}_X^\top A \mathbf{1}_X$ $(X \subseteq E)$ for some matrix $A \in \mathbb{R}^{E \times E}$. In the following, we derive a sufficient condition of A that makes g nonnegative monotone submodular and makes h nonnegative M$^\natural$-concave so that we can apply Theorem 3.

For the monotonicity of g, we must have $g(i \mid X) = f(i \mid X) - h(i \mid X) \geq 0$ for any $i \in E$ and $X \subseteq E - i$. This yields

$$\sum_{k \in X} A_{ik} + \frac{1}{2} A_{ii} \leq f(i \mid X). \quad (i \in E, X \subseteq E - i) \tag{7}$$

We note that, if (7) was satisfied, g becomes automatically nonnegative as $h(\varnothing) = 0$.

For the submodularity of g, we must have $\mathrm{Hess}_g(X)_{ij} = \mathrm{Hess}_f(X)_{ij} - \mathrm{Hess}_h(X)_{ij} \leq 0$ for any distinct $i, j \in E$ and $X \subseteq E \setminus \{i, j\}$. This yields

$$A_{ij} \geq \mathrm{Hess}_f(X)_{ij}. \quad (i, j \in E, i \neq j, X \subseteq E \setminus \{i, j\}) \tag{8}$$

Finally, for the nonnegativity of h, we must have

$$\mathbf{1}_X^\top A \mathbf{1}_X \geq 0 \quad (X \subseteq E). \tag{9}$$

It is difficult to handle these conditions simultaneously. Fortunately, we can show that we need to consider only the condition in (8) and the nonpositivity constraint.

▶ **Lemma 19.** *Suppose that a matrix $A \in \mathbb{R}^{E \times E}$ satisfies the conditions in* (5), (6), *and* (8). *Then, $h(X) = \frac{1}{2}\mathbf{1}_X^\top A \mathbf{1}_X$ is nonnegative $M^\natural$-concave, and $g = f - h$ is nonnegative monotone submodular.*

Trivially, we can take $A = 2\,\mathrm{Diag}(f(i \mid E - i) : i \in E)$, which yields $h(X) = \sum_{i \in X} f(i \mid E - i)$. This decomposition corresponds to that via the standard curvature. In the following, we discuss how we can find a nontrivial matrix A satisfying the conditions in (5), (6), and (8).

4.1 Ultrametric fitting problem

Assume that we can compute H_{ij} such that $\max_{X \subseteq E - i - j} \mathrm{Hess}_f(X)_{ij} \leq H_{ij} \leq 0$ for any distinct $i, j \in E$. Once we are given such H_{ij}, finding a matrix A satisfying the conditions in (5), (6), and (8) boils down to the *ultrametric fitting problem* [8]. In this problem, given $H_{ij} \leq 0$ for distinct $i, j \in E$, we are to find $A_{ij} \in [H_{ij}, 0]$ for distinct $i, j \in E$ satisfying (6) that minimizes $\max_{i \neq j} |A_{ij} - H_{ij}|$. Farach et al. [8] gave an $O(n^2)$-time algorithm for this problem. Therefore, we can find a matrix A satisfying the conditions in (5), (6), and (8) that is close to H_{ij}. Although this method is general, it is difficult to theoretically bound the M$^\natural$-concave curvature of the resulting decomposition.

4.2 Coverage function

Let $G = (E, V; A)$ be a bipartite graph. Note that here we denote by E the one of the vertex sets (i.e., the ground set) for the sake of consistency with the other parts of this paper. The coverage function $f : 2^E \to \mathbb{R}$ associated with G is defined as $f(X) := \sum_{v \in V} \min\{1, |\Gamma(v) \cap X|\}$, where $\Gamma(v) \subseteq E$ is the set of neighbors of $v \in V$. It is well-known that f is a monotone submodular function.

Now, we consider decomposing f into a monotone submodular function and monotone $\mathrm{M}^\natural$-concave function. For each $v \in V$, we define $f_v : 2^E \to \mathbb{R}$ as $f_v(X) = \min\{1, |\Gamma(v) \cap X|\}$. Then, for distinct $i, j \in E$ and $X \subseteq E - i - j$, $\mathrm{Hess}_{f_v}(X)_{ij}$ is equal to -1 if $v \notin \Gamma(X)$ and $i, j \in \Gamma(v)$ and 0 otherwise. Thus, we have $\mathrm{Hess}_f(X)_{ij} = -|\Gamma(i) \cap \Gamma(j) - \Gamma(X)|$. Since $\mathrm{Hess}_f(X)_{ij}$ is obviously nondecreasing, we can compute the exact value of $\max_{X \subseteq E \setminus \{i,j\}} \mathrm{Hess}_f(X)_{ij} = \mathrm{Hess}_f(E - i - j)_{ij} = -c_{ij}$, where $c_{ij} = |\Gamma(i) \cap \Gamma(j) - \Gamma(E - i - j)|$. Note that the quantity c_{ij} is the number of $v \in V$ whose neighbors are exactly i and j. Then, we can run the algorithm presented in Section 4.1 with $H_{ij} = -|\Gamma(i) \cap \Gamma(j) - \Gamma(E - i - j)|$ to obtain a matrix A satisfying the conditions in (5), (6), and (8). We note that the standard curvature can only handle vertices in V that have only one neighbor in E, whereas our argument can handle vertices in V that have two neighbors in E.

5 Applications

In this section, we apply Theorem 3 to obtain better approximation guarantees for the facility location problem and the sum of weighted matroid rank functions. In these applications, we need to use the specific structures of these problems.

5.1 Facility location

In the *facility location problem*, there are a set I of customers and a set E of possible locations of facilities. Each customer $i \in I$ has a revenue $w_{ij} \geq 0$ for the facility $j \in E$. We assume that customers will select the available facility of maximum revenue. The task is to select a set $X \subseteq E$ of cardinality k that maximizes

$$f(X) = \sum_{i \in I} \max_{j \in X} w_{ij},$$

where we conventionally define $f(\varnothing) = 0$. Evidently, f is a nonnegative monotone submodular function.

We can decompose f into g and h as follows. For $i \in I$, we denote $w_{i,\min} := \min_{j \in E} w_{ij}$ and let $\bar{w}_{ij} := w_{ij} - w_{i,\min}$ $(i \in I,\, j \in E)$. Then, we can rewrite f as

$$f(X) = \sum_{i \in I} \max_{j \in X} \bar{w}_{ij} + \left(\sum_{i \in I} w_{i,\min} \right) [X \neq \varnothing],$$

where $[X \neq \varnothing]$ is the indicator function of the nonemptiness of X. Let $\tilde{f}(X) = \sum_{i \in I} \max_{j \in X} \bar{w}_{ij}$ be the first term. We further subtract a modular function $\ell(X) = \sum_{j \in X} \tilde{f}(j \mid E - j)$ from $\tilde{f}$. Note that since $f(j \mid E - j) = \sum_{i \in I} [w_{ij} - \max_{k \neq j} w_{ij}]^+ = \sum_{i \in I} [\bar{w}_{ij} - \max_{k \neq j} \bar{w}_{ij}]^+ = \tilde{f}(j \mid E - j)$ for $j \in E$, this modular term is exactly the same one in the curvature decomposition for the original function f. Then, we define $g(X) := \tilde{f}(X) - \ell(X)$ and $h(X) := \ell(X) + \left(\sum_{i \in I} w_{i,\min}\right) [X \neq \varnothing]$. One can easily check that g is monotone submodular and h is $\mathrm{M}^\natural$-concave.

We can show that $\gamma(g, h)$ is no more than the standard curvature c.

▶ **Lemma 20.** *$\gamma(g, h) \leq c - \dfrac{\sum_{i \in I} w_{i,\min}}{\sum_{i \in I} w_{i,\max}}$, where $w_{i,\max} := \max_{j \in E} w_{ij}$ $(i \in E)$.*

Proof. For any nonempty $X \subseteq E$, we have

$$\frac{h(X)}{f(X)} = \frac{\ell(X)}{f(X)} + \frac{\sum_{i \in I} w_{i,\min}}{f(X)} \geq 1 - c + \frac{\sum_{i \in I} w_{i,\min}}{f(E)} = 1 - c + \frac{\sum_{i \in I} w_{i,\min}}{\sum_{i \in I} w_{i,\max}},$$

where the inequality follows from the definition of the curvature and the monotonicity of f. Therefore, $\gamma_h = 1 - \min_{X \subseteq E} \frac{h(X)}{f(X)} \leq c - \dfrac{\sum_{i \in I} w_{i,\min}}{\sum_{i \in I} w_{i,\max}}$. ◀

5.2 Sums of weighted matroid rank functions

A weighted matroid rank function is an $\mathrm{M}^\natural$-concave function (see Example 6), and its sum is a monotone submodular function. A sum of weighted matroid rank functions includes the coverage function, the facility location function, and many others, but not all monotone submodular functions. Here, we show that if the objective function is a sum of weighted matroid rank functions, we can obtain an improved approximation guarantee.

Let $f(X) = \sum_{i\in I} f_i(X)$, where $f_i(X) = \max\{\boldsymbol{w}_i(J) : J \subseteq X, J \in \mathcal{I}_i\}$ for some vector $\boldsymbol{w}_i \in \mathbb{R}_+^E$, and $\mathcal{I}_i$ is the independent set family of a matroid ($i \in I$). For $i \in I$, let $w_{i,\min} := \min_{e\in E} \boldsymbol{w}_i(e)$. Let $\tilde{f}(X) = \sum_{i\in I} \tilde{g}_i(X)$, where $\tilde{g}_i(X)$ is the weighted matroid rank function with the reduced weight $\boldsymbol{w}_i - w_{i,\min}\mathbf{1}$ for $i \in I$. Define $\ell(X) = \sum_{j\in X} \tilde{f}(j \mid E - j) = \sum_{j\in X} f(j \mid E - j)$, where the second equality follows from the fact that all matroid bases have the same cardinality. Finally, let us define $g(X) := \tilde{f}(X) - \ell(X)$ and $h(X) := \ell(X) + (\sum_{i\in I} w_{i,\min})[X \neq \varnothing]$. The proof of the following lemma is similar to that of Lemma 20.

▶ **Lemma 21.** *$\gamma(g, h) \leq c - \frac{\sum_{i\in I} w_{i,\min}}{\sum_{i\in I} W_i}$, where c is the standard curvature, and $W_i := f_i(E)$ is the maximum weight of the bases in $(E, \mathcal{I}_i)$ for each i.*

In [15], Lin and Bilmes proposed a linear mixture model of simple monotone submodular functions. One of the most general classes in their model is a linear mixture of weighted matroid rank functions. Suppose that a function $f : 2^E \to \mathbb{R}_+$ is obtained by inference for this linear mixture model. Then, we can write $f(X) = \sum_{i\in I} \alpha_i f_i(X)$, where $\alpha_i > 0$ is a mixture coefficient, and $f_i(X)$ is a weighted matroid rank function ($i \in I$). If some coefficient α_{i^*} is dominant, one can consider the following straightforward decomposition: $g(X) = \sum_{i\neq i^*} \alpha_i f_i(X)$ and $h(X) = \alpha_{i^*} f_{i^*}(X)$. Then, we can expect the resulting curvature to be small, although the actual value depends on the form of f_i ($i \in I$).

6 Conclusion and Open Problems

We propose a new concept the $\mathrm{M}^\natural$-concave curvature, which measures how a given submodular function deviates from $\mathrm{M}^\natural$-concave functions. Based on this concept, we designed a polynomial-time algorithm given a decomposition in the form of $f = g + h$, which generalizes the result of [24]. We complemented our algorithm by devising an algorithm for finding such a decomposition, which always yields a decomposition that is as good as a decomposition based on the standard curvature. We showed examples in which the the $\mathrm{M}^\natural$-concave curvature is better than the standard curvature.

We believe that the $\mathrm{M}^\natural$-concave curvature is generally useful for analysing the performance of algorithms for submodular maximization. Although in this paper we focused on the continuous greedy algorithm, it is quite natural to analyze the performance of other algorithms, e.g., local search. Our algorithm is able to handle only a cardinality constraint due to the difficulty in the rounding step. A possible direction for future work is dealing with more complicated constraints such as matroid constraints and knapsack constraints.

Abstract

The FHEW fully homomorphic encryption scheme (Ducas and Micciancio, Eurocrypt 2015) offers very fast homomorphic NAND-gate computations (on encrypted data) and a relatively fast refreshing procedure that allows to homomorphically evaluate arbitrary NAND boolean circuits. Unfortunately, the refreshing procedure needs to be executed after every single NAND computation, and each refreshing operates on a single encrypted bit, greatly decreasing the overall throughput of the scheme. We give a new refreshing procedure that simultaneously refreshes n FHEW ciphertexts, at a cost comparable to a single-bit FHEW refreshing operation. As a result, the cost of each refreshing is amortized over n encrypted bits, improving the throughput for the homomorphic evaluation of boolean circuits roughly by a factor n.

1 Introduction

Since Gentry's first construction of a Fully Homomorphic Encryption (FHE) scheme [13], much research has been done to improve both the security and efficiency of FHE. On the security front, a line of works [14, 8, 4, 6, 19] has led to a FHE scheme of Brakerski and Vaikuntanathan [9] based on learning with errors for polynomial approximation factors and therefore essentially *as secure as* regular (non-homomorphic) lattice-based *public-key encryption* [23].

On the efficiency front, major progress has been achieved too, but we are still very far from reaching the ideal goal of an FHE scheme *as efficient as public key encryption*. Brakerski, Gentry, and Vaikuntanathan [6] give a scheme for homomorphic evaluation of circuits of depth

L and security parameter λ requiring $\tilde{O}(\lambda \cdot L^3)$ per-gate computation. Gentry, Halevi, and Smart [18] used similar techniques to achieve homomorphic evaluation of width-$\Omega(\lambda)$ circuits with only polylog(λ) per-gate computation. However, these schemes place restrictions on circuit depth or size and additionally rely on the hardness of RingLWE for quasi-polynomial approximation factors, a stronger assumption than that used for public-key encryption.

Gentry's bootstrapping technique [13] is still the only known method to achieve *fully* homomorphic encryption, i.e., an encryption scheme capable of evaluating homomorphically arbitrary circuits. We recall that Gentry's bootstrapping technique involves the homomorphic computation of the decryption function on an encryption of the decryption key, a rather complex operation, and this operation needs to be performed on all wires, for every few layers of the circuit. Therefore, improving the effectiveness of bootstrapping has been the main goal of many papers aimed at making FHE faster.

Improvements to bootstrapping have been pursued following two different approaches. The first approach, extensively studied in [5, 18, 17, 16, 15, 24, 20, 21], involves the construction of FHE schemes that can pack several messages into a single ciphertext, and operate on them in parallel. While bootstrapping such a scheme may still be very expensive, it can simultaneously refresh a large number of ciphertexts in a single bootstrapping execution. This reduces the total number of times that the bootstrapping procedure needs to be executed, and the amortized cost of bootstrapping over a large (and sufficiently wide) circuit.

A newer approach, explored in [1, 2, 12, 10], works towards reducing the cost of bootstrapping a single ciphertext as much as possible, even at the price of having to perform a bootstrapping operation for every gate of the circuit. Alperin-Sheriff and Peikert [2] introduced a bootstrapping technique requiring $\tilde{O}(\lambda)$ homomorphic operations. Building upon this technique, Ducas and Micciancio [12] brought the running time of a single bootstrapping execution down to a fraction of a second, with further improvements from Chillotti, Gama, Georgieva, and Izabachène [10]. However, it comes with the limitation that the bootstrapping procedure needs to be executed for essentially every gate of the circuit, without packing several messages into a single ciphertext. So bootstrapping is much faster than, say, in HElib [20, 21], but the amortized cost per gate is still quite high.

The goal of this work is to combine the advantages of these two approaches, and show how to simultaneously refresh $O(n)$ messages (where $n = \tilde{O}(\lambda)$), but at a cost comparable to that of [1, 2, 12, 10]. Our starting point is the FHEW bootstrapping method of [12]. We remark that FHEW has been improved in some follow-up works: [3] extended the FHEW scheme to larger gates, and [10] further reduced the running time of bootstrapping, partly at the cost of making a stronger security assumption on Ring-LWE with binary secrets.[1] However, while practically relevant, both improvements are asymptotically modest: the method of [3] is limited to gates with at most $O(\log n)$ input wires, and the speed-up achieved in [10] is at most polylogarithmic. In fact, in this paper, we will make bootstrapping even slower than [12], by a factor $O(n^\epsilon)$. The advantage is that, while the bootstrapping cost gets slightly higher, we will simultaneously refresh $O(n)$ messages, reducing the amortized bootstrapping cost per message by almost a factor of n to $\tilde{O}(3^{1/\epsilon} n^\epsilon)$ and for $\epsilon < 1/2$.

In the remainder of the introduction, we provide a detailed description of the FHEW bootstrapping problem, followed by a technical overview of the high level structure of our solution.

[1] In [10], and in this work, Ring-LWE is used with binary secrets, which may be justifiable based on the best known cryptanalysis methods, but would still benefit from more theoretical investigations.

1.1 The FHEW bootstrapping problem

The starting point of this work is the "FHEW" fully homomorphic encryption scheme of [12]. In this overview, we assume some basic familiarity with LWE encryption, and use notation $\mathsf{LWE}_n^{t/q}[m,\delta]$ for the LWE encryption of a message $m \in \mathbb{Z}_t$, with secret key in $\mathbb{Z}_q^n$ and noise level δ. Similarly, we write $\mathsf{RingLWE}_d^{t/q}[m,\delta]$ for Ring LWE ciphertexts over the dth cyclotomic ring encrypting a polynomial $m(X)$ of degree $\varphi(d)$.[2] The reader is referred to Section 2.4 for background information on LWE, and for a formal definition of the notation. In its most basic form, FHEW uses a function $\mathsf{HomNAND}\colon \mathsf{LWE}_n^{4/q}[\delta] \times \mathsf{LWE}_n^{4/q}[\delta] \to \mathsf{LWE}_n^{2/q}[\Delta]$, mapping the encryption of two bits $b_0, b_1 \in \{0,1\} \subset \mathbb{Z}_4$ (encoded as integers modulo 4), to the encryption of their logical "NAND", $b_0 \barwedge b_1 = \neg(b_0 \wedge b_1)$, but with somewhat larger noise Δ and encoded as an integer modulo 2. (We refer the reader to the full version of the paper for a formal definition and analysis of the $\mathsf{HomNAND}$ function.) Since these operations are not immediately composable, to evaluate arbitrary circuits on encrypted data, [12] also provides a refreshing procedure, $\mathsf{Refresh} : \mathsf{LWE}_n^{2/q}[\Delta] \to \mathsf{LWE}_n^{4/q}[\delta]$, that maps noisy ciphertexts modulo 2, back to ciphertexts modulo 4 with low noise δ. This refreshing involves the homomorphic computation of the decryption function, and it is rather costly: on a first approximation, it involves $\tilde{O}(n)$ homomorphic modular multiplications on data encrypted under a ring/symmetric-key variant of the GSW cryptosystem [19], which we recall in Section 2.5.

Our goal is to show that one can *simultaneously* refresh a large number of ciphertexts (say, $O(n)$) at a cost comparable to a single FHEW refreshing: approximately $O(n^{1+\epsilon})$ homomorphic modular multiplications on GSW ciphertexts. This reduces the amortized cost of refreshing to just $O(n^\epsilon)$ homomorphic (GSW) multiplications per ciphertext, rather than $O(n)$ as in the original FHEW cryptosystem.

▶ **Theorem 1.** *For every $0 < \epsilon < 1/2$, there exists an algorithm* $\mathsf{Refresh}$ *which on input $O(n)$* $\mathsf{LWE}_n^{2/q}[\Delta]$ *ciphertexts, refreshes them to* $\mathsf{LWE}_n^{4/q}[\delta]$ *ciphertexts of larger message space and smaller error, using $\tilde{O}(3^{1/\epsilon} n^{1+\epsilon})$ homomorphic operations, for $0 < \epsilon < 1/2$.*

1.2 High level outline

Our scheme involves a number of different parameters. As in the FHEW cryptosystem, we will use a "small" modulus q and dimension $n = 2^{l-1}$ as parameters for the input ciphertexts. (We write $n = 2^{l-1}$ as we will frequently need to refer to $l = \log n + 1$). A larger modulus Q is used by intermediate ciphertexts. We will give a procedure to simultaneously refresh $\varphi(d) = 2 \cdot 3^{k-1}$ FHEW ciphertexts, where $Q > q > n > d$. Details follow.

We start with $\varphi(d)$ (high noise) ciphertexts in $\mathsf{LWE}_n^{2/q}[\Delta]$, as produced by the FHEW $\mathsf{HomNAND}$ operation, working on LWE encryption in dimension n. The key idea required to simultaneously refresh all of them is to first combine them into a single RingLWE ciphertext, in a polynomial ring of degree $\varphi(d)$. Specifically, as a first step, we use a variant of the key switching technique from [8] to evaluate a function

$$\mathsf{PackLWE} : \left[\mathsf{LWE}_n^{2/q}[m_i, \Delta]\right]_{i<\varphi(d)} \to \mathsf{RingLWE}_d^{2/q}[m(X), \Delta'] \tag{1}$$

[2] We will be using primarily only two cyclotomic rings $\mathcal{R}_d = \mathbb{Z}[X]/(X^{d/2}+1) \equiv \mathbb{Z}^{\varphi(d)}$ for $d = 2^k$ and $\varphi(d) = d/2$, and $\mathcal{R}_d = \mathbb{Z}[X]/(X^{2d/3} + X^{d/3} + 1) \equiv \mathbb{Z}^{\varphi(d)}$ for $d = 3^k$ and $\varphi(d) = 2d/3$.

which maps $\varphi(d)$ *arbitrary* LWE ciphertexts (encrypting scalar messages $m_0, \ldots, m_{\varphi(d)-1}$) to a single ciphertext encrypting the polynomial $m(X) = \sum_{i<\varphi(d)} m_i \cdot X^i$. The details of this packing step are given in Section 3.

Looking ahead, the final step of the homomorphic decryption procedure will produce LWE ciphertexts of dimension equal to half the modulus of its input ciphertext. Therefore, to simplify the composition of $\mathsf{HomNAND}$ and $\mathsf{Refresh}$ operations, we use modulus switching after packing to reduce the modulus of the packed ciphertext to $2n$. We use a ring version of the modulus switching technique of [8] to compute a function

$$\mathcal{R}\text{-}\mathsf{ModSwitch}\colon \mathsf{RingLWE}_d^{2/q}[m(x), \Delta'] \to \mathsf{RingLWE}_d^{2/2n}[m(x), \frac{n}{q}\Delta' + \omega(\sqrt{d \log d}) \cdot \|z\|] \tag{2}$$

mapping ciphertexts modulo q under key $z \in \mathcal{R}_d/q$ to ciphertexts modulo $2n$, with the stated error bound (with high probability over the randomized rounding). Details of the modulus switching operation are provided in the full version.

We can now move on to homomorphically decrypt this Ring LWE ciphertext. Following the general bootstrapping framework of [13], refreshing is performed by evaluating the decryption function homomorphically, on an encryption of the secret key. The homomorphic registers encrypting the entries of the secret key are implemented using a symmetric-key/ring variant of the GSW cryptosystem, that we denote abstractly as $\mathsf{REG}^{2n/Q}[\cdot]$. Note that the message modulus $2n$ matches the ciphertext modulus of $\mathsf{RingLWE}_d^{2/2n}$, which is required for entrywise encryption of the $\mathsf{RingLWE}^{2/2n}$ decryption key.

Using this notation, we can describe the refreshing procedure as the combination of two steps. The first is the primary technical contribution of this work, the homomorphic decryption function

$$\mathsf{RingDecrypt} : \mathsf{RingLWE}_d^{2/2n}[m(x), \Delta''] \to \left[\mathsf{REG}^{2n/Q}[\tilde{m}_i, \delta']\right]_{i<\varphi(d)} \tag{3}$$

which takes (as an implicit parameter) the encryption $\mathsf{REG}^{2n/Q}[\mathsf{encode}(z)]$ of a suitably encoded version of the $\mathsf{RingLWE}^{2/2n}$ secret key $z \in \mathbb{Z}_{2n}^{\varphi(d)}$. The $\mathsf{RingDecrypt}$ function is homomorphic in z, and it is computed simply by evaluating the linear component of the $\mathsf{RingLWE}$ decryption function homomorphically on $\mathsf{REG}^{2n/Q}[\mathsf{encode}(z)]$. This entails the multiplication of an encrypted polynomial by a known polynomial, which introduces some technical challenges.

We recall that FHEW accumulators (and the cryptographic registers used in this paper) encode a message $v \in \mathbb{Z}_N$ using a ring variant of the GSW cryptosystem with, as a message space, the set of polynomials in a formal variable X of degree bounded by $\varphi(N)$. These polynomials are used to encode scalar values, mapping each $v \in \mathbb{Z}_N$ to the monomial X^v. Encoding v in the exponent limits the operations available to a candidate refreshing algorithm. Addition may be performed, using the multiplicatively homomorphic property of the GSW cryptosystem to compute $X^v \cdot X^w = X^{v+w}$, but other operations are not so straightforward. Multiplication by (known) scalars (mapping $X^v \mapsto X^{vc}$) requires homomorphic exponentiation, and even a simple subtraction or negation (mapping $X^v \mapsto X^{-v}$) would require homomorphic inversion, all operations unsupported by the GSW or any other known cryptosystem.

Standard FFT algorithms, on the other hand, require both the evaluation of addition and subtractions (in each "butterfly" of the FFT), as well as scalar multiplication by "twiddle" factors, i.e., powers of the root of unity used to compute the FFT. In order to support subtraction, we represent each register in a redundant way, holding both an encryption of X^v

and an encryption of X^{-v}. To reduce the number of scalar multiplications required by our refreshing procedure, we resort to a variant of Nussbaumer negacyclic convolution algorithm [22].

In its original formulation, the Nussbaumer algorithm operates on polynomials in X (where $X^{2^k} = 1$) by writing them as bivariate polynomials in X, Y, with both X and Y of degree at most $\sqrt{n} = \sqrt{2^k}$. Alternatively, one can look at these bivariate polynomials as univariate polynomials in X with coefficients in $\mathbb{Z}[Y]$. By taking $Y = X^{\sqrt{n}}$, the coefficients belong to the ring $R = \mathbb{Z}[Y]/(Y^{\sqrt{n}} + 1)$, which admits Y as a $2\sqrt{n}$th root of unity and can be used to compute the FFT of polynomials in $R[X]$. Multiplication by roots of unity can now be expressed simply by additions, subtractions and rotations of values in $\mathbb{Z}[Y]/(Y^{\sqrt{n}} + 1)$. Furthermore, because the FFT outputs elements of R, the algorithm can be recursively applied to each of the pointwise multiplications following the FFT.

Our refreshing procedure will require some modifications to the Nussbaumer algorithm as described above, which are detailed in Section 4.4. Most critically, if the algorithm is to be used recursively, we must be careful in bounding its recursive depth. The noise of the refreshing algorithm depends exponentially on the depth of the circuit computing it, and we must restrict ourselves to constant depth to achieve polynomial noise overhead. So rather than setting $Y = X^{\sqrt{n_i}}$ for $n_i = \sqrt[2^i]{n}$ at the ith level of recursion, we fix $Y = X^{n^\epsilon}$ for all steps. Therefore, for all ϵ, the algorithm admits at most $1/\epsilon$ recursive calls. This is the main intuition behind our bootstrapping procedure: the Nussbaumer algorithm reduces polynomial multiplication to multiplications of many lower-degree polynomials, without introducing multiplications by constants or excessive noise overhead. A naive multiplication algorithm can then be used to compute the smaller polynomial products, and the transforms inverted to give the encrypted product required for homomorphic ring decryption.

The second step of the refreshing procedure is the "rounding" of the REG ciphertexts to low-noise $\mathsf{LWE}_n^{4/Q}$ ciphertexts. Since $\mathsf{REG}[\cdot]$ encrypts each coefficient of $\tilde{m}(X)$ individually, the values $\mathsf{REG}^{2n/Q}[\tilde{m}_i, \delta']$ are already refreshed, low-noise ciphertexts of the original messages $m_0, \ldots, m_{d-1}$, but using a (noisy) input encoding $\tilde{m}_i$, a different cryptosystem and a large modulus Q. Each one of them is very similar to the intermediate output of the original FHEW refreshing procedure, as if we had computed it on each $\mathsf{LWE}_{2n}^{2/q}[m_i, \Delta]$ ciphertext individualy. So, they can be mapped to $\mathsf{LWE}_{2n}^{4/q}$ ciphertexts as in the original FHEW scheme by calling a "most-significant-bit" extraction function $\mathsf{msbExtract}\colon \mathsf{REG}^{2n/Q}[\tilde{m}_i, \delta'] \to \mathsf{LWE}_n^{4/Q}[m_i, \delta']$ and the standard modulus switching procedure

$$\mathsf{ModSwitch}\colon \mathsf{LWE}_n^{4/Q}[\delta'] \to \mathsf{LWE}_n^{4/q}[\frac{q}{Q}\delta' + \sqrt{2\pi(1 + \|\mathbf{s}\|^2)}] \tag{4}$$

for a LWE ciphertext under key $\mathbf{s} \in \mathbb{Z}_Q^{2n}$, which increases the noise by a small additive term . Parameters will be set in such a way that the resulting noise is small enough to apply the $\mathsf{HomNAND}$ function and keep computing on encrypted data. This completes the high level description of our boootstrapping method.

2 Preliminaries

2.1 Basic notation

We write column vectors over a ring $\mathcal{R}$ with bold font $\mathbf{a} \in \mathcal{R}^n$. Matrices are similarly written in capitalized bold font as $\mathbf{A} \in \mathcal{R}^{n \times m}$. The L^2 norm of a vector $\mathbf{a} = (a_1, \ldots, a_n) \in \mathcal{R}^n$ is $\|\mathbf{a}\| = \sqrt{\sum_i |a_i|^2}$. The concatenation of elements $a, b, \ldots$ into a row vector is written as $[a, b, \ldots]$. We write $(a, b, \ldots)$ for concatenation as a column vector.

2.2 Distributions

A random variable X has *subgaussian* distribution over $\mathbb{R}$ of parameter α if its tails are dominated by a Gaussian of parameter α, so that $\Pr\{|X| \geq t\} \leq 2e^{-\pi t^2/\alpha^2}$ for all $t \geq 0$. A subgaussian variable X with parameter $\alpha > 0$ satisfies $E[e^{2\pi tX}] \leq e^{\pi\alpha^2 t^2}$, for all $t \in \mathbb{R}$. We note that a centered random variable X, where $|X| \leq \beta$ always holds, is subgaussian, specifically with parameter $\beta\sqrt{2\pi}$. For example the randomized rounding function $\lceil(x)\rfloor_\$$ (which takes value $\lfloor x \rfloor$ with probability $\lceil x \rceil - x$, and equals $\lceil x \rceil$ otherwise) is $\sqrt{2\pi}$-subgaussian. A random vector $\mathbf{x}$ of dimension n is subgaussian of parameter α if for all unit vectors $\mathbf{u} \in \mathbb{R}^n$, its one-dimensional marginals $\langle \mathbf{u}, \mathbf{x} \rangle$ are also subgaussian of parameter α. This extends to random matrices, where $\mathbf{X}^{m\times n}$ is subgaussian of parameter α if for all unit vectors $\mathbf{u} \in \mathbb{R}^m, \mathbf{v} \in \mathbb{R}^n$, $\mathbf{u}^t\mathbf{X}\mathbf{v}$ is subgaussian of parameter α. It follows immediately from these definitions that the concatenation of independent subgaussian vectors, all with parameter α, interpreted as either a vector or matrix, is also subgaussian with parameter α.

2.3 Cyclotomic Rings

For any positive integer N, let $\Phi_N(X) = \prod_{j\in\mathbb{Z}_N^*}(X - \omega_N^j)$ be the Nth cyclotomic polynomial, where $\omega_N = e^{2\pi \mathsf{i}/N} \in \mathbb{C}$ is the complex Nth principal root of unity, and $\mathbb{Z}_N$ is the group of invertible integers modulo N. We recall that $\Phi_N(X) \in \mathbb{Z}[X]$ is a monic polynomial of degree $\varphi(N) = |\mathbb{Z}_N^*|$ with integer coefficients. The corresponding ring $\mathcal{R}_N = \mathbb{Z}[X]/\Phi_N(X)$ of integer polynomials modulo Φ_N is called the Nth cyclotomic ring. This ring can be identified with $\mathcal{R}_N \equiv \mathbb{Z}^{\varphi(N)}$ (as additive groups) representing each element $a \in \mathcal{R}_N$ by a polynomial of degree less than $\varphi(N)$, and mapping this polynomial $a(X) = \sum_{j<\varphi(N)} a_j \cdot X^j$ to its coefficient vector $\boldsymbol{(}a\boldsymbol{)} = (a_0, \ldots, a_{\varphi(N)-1}) \in \mathbb{Z}^{\varphi(N)}$. For any ring element $a \in \mathcal{R}_N$, $\|a\|$ is taken to mean the L^2 norm of the corresponding vector $\boldsymbol{(}a\boldsymbol{)} \in \mathbb{Z}^{\varphi(N)}$. Ring elements $a, b \in \mathcal{R}_N$ also admit a matrix representation $\mathbf{M}_a \in \mathbb{Z}^{\varphi(N)\times\varphi(N)} = [\boldsymbol{(}a \cdot X^0\boldsymbol{)}, \boldsymbol{(}a \cdot X^1\boldsymbol{)}, \ldots, \boldsymbol{(}a \cdot X^{\varphi(N)-1}\boldsymbol{)}]$ (used in Section 4.5,) such that $\mathbf{M}_a \cdot \boldsymbol{(}b\boldsymbol{)} = \boldsymbol{(}a \cdot b\boldsymbol{)}$. For any positive integer q, we write $\mathcal{R}_N/q$ for the quotient $\mathcal{R}_N/(q \cdot \mathcal{R}_N)$, i.e., the ring of polynomials $\mathcal{R}_N$ with coefficients reduced modulo q. Notice that $\mathcal{R}_N/q \equiv \mathbb{Z}_q^{\varphi(N)}$ as additive groups.

For concreteness, in this paper we only use cyclotomic rings $\mathcal{R}_N$ for two special types of the index N: $N = n = 2^l$, giving the polynomial ring $\mathcal{R}_n = \mathbb{Z}[X]/(X^{n/2} + 1)$ of degree $\varphi(n) = n/2$, and $N = d = 3^k$, giving the polynomial ring $\mathcal{R}_d = \mathbb{Z}[X]/(X^{2d/3} + X^{d/3} + 1)$ of degree $\varphi(d) = 2d/3$. In particular, $\mathcal{R}_d/q \equiv \mathbb{Z}_q^{2d/3}$ (for $d = 3^k$) and $\mathcal{R}_n/q \equiv \mathbb{Z}_q^{n/2}$ (for $n = 2^l$).

▶ **Fact 2** (Recall from [11], Fact 6)**.** *If $\mathcal{D}$ is a subgaussian distribution of parameter α over $\mathcal{R}_N$, and $\mathbf{R} \leftarrow \mathcal{D}^{w\times k}$ has independent coefficients drawn from $\mathcal{D}$, then, with overwhelming probability, we have $s_1(\mathbf{R}) \leq \alpha\sqrt{N} \cdot O(\sqrt{w} + \sqrt{k} + \omega(\sqrt{\log N}))$.*

2.4 (Ring) LWE Symmetric Encryption

In this subsection we introduce notation and working definitions for the basic LWE encryption scheme that our bootstrapping procedure operates on. For complete definitions, we refer the reader to the full version.

▶ **Definition 3** ((Ring) LWE ciphertexts)**.** The set of all (Ring) LWE ciphertexts over (cyclotomic) ring $\mathcal{R}_N$, encrypting message $m \in \mathcal{R}_N/t$, under key $\mathbf{s} \in \mathcal{R}_N^n$, modulo q and with error bound β is denoted $\mathcal{R}_N\text{-}\mathsf{LWE}_{\mathbf{s}}^{t/q}[m, \beta] = \{(\mathbf{a}, b) \mid \mathbf{a} \in \mathbb{R}_N^n/q, \|\mathbf{a} \cdot \mathbf{s} - mq/t\| \leq \beta\}$. When the value of the key $\mathbf{s} \in \mathcal{R}_N^n$ is clear from the context or unimportant, we simply write $\mathcal{R}_N\text{-}\mathsf{LWE}_n^{t/q}[m, \beta]$, where the subscript n refers to the dimension of the secret $\mathbf{s} \in \mathcal{R}_N^n$.

We use some abbreviated notation in the following important special cases: When $N = 1$, we omit $\mathcal{R}_N = \mathbb{Z}$, and write $\mathsf{LWE}^{t/q}_{\mathbf{s}}[m, \beta]$ (or $\mathsf{LWE}^{t/q}_{n}[m, \beta]$) for the set of standard ($\mathbb{Z}$-) LWE ciphertexts with n-dimensional secret $\mathbf{s} \in \mathbb{Z}^n$. When $n = 1$, and $\mathbf{s} = s \in \mathcal{R}_N$ is a single ring element, we write $\mathsf{RingLWE}^{t/q}_{N}$ as an abbreviation for $\mathcal{R}_N$-$\mathsf{LWE}^{t/q}_{1}$.

The (Ring) LWE decryption procedure plays a central role in our FHE bootstrapping process, specifically in the $\mathsf{RingDecrypt}$ procedure. The decryption of an $\mathcal{R}_N$-$\mathsf{LWE}^{t/q}_{\mathbf{s}}$ ciphertext $(\mathbf{a}, b) \in (\mathcal{R}^n_N, \mathcal{R}_N)/q$ is $\mathsf{Dec}(\mathbf{s}, (\mathbf{a}, b)) = \lfloor t(b - \mathbf{a} \cdot \mathbf{s})/q \rceil \bmod t \in \mathcal{R}_N/t \equiv \mathbb{Z}_t^{\varphi(N)}$. It is easy to check that for all $(\mathbf{a}, b) \in \mathsf{LWE}^{t/q}_{\mathbf{s}}[m, q/2t]$, the decryption procedure correctly recovers the encrypted message.

2.5 Ring-GSW encryption

The cryptographic accumulators of [12] (and the extended cryptographic registers defined in our work) make use of a ring variant of the GSW encryption scheme [19], which we now briefly describe. Let $\mathcal{R}_{N/Q}$ be the Nth cyclotomic ring, modulo some suitably large integer Q. The Ring-GSW cryptosystem, encrypts a message $m \in \mathbb{Z}_N$ under key $z \in \mathcal{R}_{N/Q}$ as $\mathsf{GSW}^{N/Q}_z(m) = [\mathbf{a}, \mathbf{a} \cdot z + \mathbf{e}] + m \cdot \mathbf{g} \otimes \mathbf{I}_2$ where $\mathbf{g} = (B^0, B^1, B^2, \ldots, Q/B)$ for some base B. Similarly as for LWE, we write $\mathsf{GSW}^{N/Q}_z[m, \beta]$ for the set of ciphertexts encrypting m under z with error at most $\|\mathbf{e}\| \leq \beta$. Decryption follows from the observation that the last row of a ciphertext is a Ring-LWE encryption of m under z.

The Ring-GSW cryptosystem supports homomorphic addition and multiplication, and we will primarily use the latter. $\mathsf{GSW}^{N/Q}_z(m_0 \cdot m_1) = C_0 \times C_1$ is computed by first expressing $C_0 = \sum_i B^i C_{0,i}$ as a sum of matrices with B-bounded (polynomial) entries, and then computing the matrix product $[C_{0,0}, \ldots, C_{0,\log Q}] \cdot C_1$. Letting $\mathbf{e}_0$ (resp. $\mathbf{e}_1$) denote the error vector of C_0 (resp. C_1), the result can be written $[\mathbf{a}, \mathbf{a} \cdot z + \mathbf{e}] + m_0 m_1 \cdot \mathbf{g} \otimes \mathbf{I}_2$, where $\mathbf{e} = \sum_i C_{0,i} e_{1,i} + m_1 \mathbf{e}_0$ depends asymmetrically on the error of the inputs. To minimize the error growth resulting from a sequence of multiplications of GSW ciphertexts (with similar initial error), then, the multiplications should be evaluated in a right-associative sequence.

3 Ciphertext Packing

We describe a variant of the LWE key-switching technique that can be used to convert a set of $\varphi(d)$ LWE ciphertexts $\{(\mathbf{a}_i, b_i)\}$, each encrypting a message m_i, to a single "packed" Ring-LWE ciphertext encrypting the message $m(X) = \sum_i m_i X^{i-1}$.

▶ **Lemma 4.** *There exists a quasi-linear time algorithm that on input $\varphi(d)$ ciphertexts $c_i \in \mathsf{LWE}^{t/q}_{\mathbf{s}}(m_i, \Delta)$ (for $i = 0, \ldots, \varphi(d) - 1$, all under the same secret key $\mathbf{s} \in \mathbb{Z}^n_q$) and a packing key consisting of Ring-LWE encryptions $K_{j,l} \in \mathsf{RingLWE}^{q/q}_{\tilde{z}}[s_l 2^j, \beta_P]$ (for $l = 0, \ldots, n-1$, $j = 0 \ldots, \lceil \log q \rceil - 1$ and key $\tilde{z} \in R_{d,q}$,) outputs a Ring-LWE encryption $c \in \mathsf{RingLWE}^{t/q}_{\tilde{z}}[m(X), \beta]$ of $m(X) = \sum_i m_i X^i$ under $\tilde{z}$ with error at most $\beta = O(\sqrt{d}\Delta + \sqrt{dn \log q}\beta_P)$.*

The proof of Lemma 4 and accompanying pseudocode may be found in the full version, but we summarize its conclusion here. Let $K_{j,l} = (\tilde{a}'_{j,l}, \tilde{b}'_{j,l})$ be the entries of the packing key and $c_i = (\mathbf{a}_i, b_i)$ be the input ciphertexts. Defining $\sum_{j < \log q} \tilde{\mathbf{a}}_j 2^j = \sum_i \mathbf{a}_i \cdot X^{i-1} \in \mathcal{R}^n_{d,q}$ and taking $\tilde{a}'' = -\sum_{j,l} \tilde{a}_{j,l} \tilde{a}'_{j,l}$ and $\tilde{b}'' = \tilde{b} - \sum_{j,l} \tilde{a}_{j,l} \cdot \tilde{b}'_{j,l}$ gives the desired packed ciphertext $(\tilde{a}'', \tilde{b}'')$ encrypting $m(X)$.

The homomorphic decryption procedure produces LWE ciphertexts of dimension $n = q/2$ equal to the modulus of the packed ciphertext. This is problematic because on subsequent refreshing operations, the resulting error bound will become larger than $q \log q$, and the

ciphertexts will no longer be decryptable. Before proceeding, we switch to a smaller modulus which we take to be $2n$ for simple composability. The details of the modulus switching procedure and its associated error bounds are omitted here, but provided in the full version of the paper.

4 Homomorphic Decryption

The homomorphic decryption procedure takes as input a single Ring-LWE ciphertext $(a, b) \in \mathsf{RingLWE}_{\tilde{z}}^{t/2n}(m, \beta) \subseteq (\mathcal{R}_d/2n)^2$ and the encryption of some function of the secret key $\tilde{z} \in \mathcal{R}_d/2n$. The decryption procedure needs to compute the ring element $b - a \cdot \tilde{z} \in \mathcal{R}_d/2n$, and then "round" the result to $\varphi(d)$ LWE ciphertexts. All this should be done homomorphically, given the encryption of (some function of) $\tilde{z}$. We can represent the computation of this ring element as an arithmetic circuit C with inputs in $\mathbb{Z}_{2n}$, but to begin designing such a circuit, we must first consider the cryptographic registers on which we will be computing. We begin this section with a description of the registers used in our ciphertext refreshing procedure, to be followed by a description and analysis of the components of our homomorphic decryption procedure.

4.1 Homomorphic Registers

We use a symmetric/ring variant of the GSW cryptosystem to implement the cryptographic registers used by the homomorphic decryption procedure, similar to the accumulators of FHEW. Registers supporting arithmetic modulo $2n$ are implemented using the $\mathsf{GSW}_N^{2n/Q}$ cryptosystem based on the Nth cyclotomic ring, for N a power of 2 with $2n|N$.

We recall that in FHEW, a value $v \in \mathbb{Z}_{2n}$ is represented by $\mathsf{GSW}_N^{2n/Q}(Y^v)$, where $Y = X^i$ is a primitive $2n$th root of unity. In this scheme we take $N = 2n$, and therefore X is our root of unity. To reduce redundancy given this choice of parameters, we omit the subscript N when referring to GSW ciphertexts, writing $\mathsf{GSW}^{2n/Q}$. This choice of parameters is more thoroughly justified in Section 4.5, but as the homomorphic decryption procedure will produce LWE ciphertexts of dimension $N/2$, taking $N/2 = n$, where n is the original dimension of the LWE ciphertexts, allows us to omit an additional step of key switching back to dimenion n.

These GSW registers support the following operations:

- Initialization $(v \leftarrow w)$: $uX^w\mathbf{G}$, with $u \in \mathbb{Z}_Q$, $u \approx Q/2t$, and invertible mod Q.
- Increment $(v \leftarrow v + c)$: $\mathbf{C} \mapsto \mathbf{C} \cdot X^c$
- Addition: $\mathsf{GSW}^{2n/Q}(uX^v) \times \mathsf{GSW}^{2n/Q}(uX^w) = \mathsf{GSW}_z^{2n/Q}(uX^{v+w})$.
- Extraction: map the accumulator to an LWE ciphertext.

To support subtraction, we represent a value $v \in \mathbb{Z}_{2n}$ as a pair $(\mathsf{GSW}(uX^v), \mathsf{GSW}(uX^{-v}))$. Addition is computed componentwise: $(C_0, C_0') + (C_1, C_1') = (C_0 \times C_1, C_0' \times C_1')$. We implement negation simply by swapping the elements of a pair, and subtraction by combining the two operations. This gives us cryptographic registers supporting all operations required by our refreshing algorithm. To avoid explicitly writing these pairs, we define

$$\mathsf{REG}_z^{q/Q}(v, \beta) = (\mathsf{GSW}_N^{q/Q}(uX^v), \mathsf{GSW}_N^{q/Q}(uX^{-v})).$$

4.2 Slow Multiplication

The use of the REG scheme restricts our arithmetic circuits to use only the operations described above. Given the asymmetric error growth of the underlying GSW operations, we must also be careful in how we design our circuit, as we don't want both inputs to any

addition or subtraction gate to have already accumulated significant error. For the rest of this section, however, we omit explicit references to the REG scheme wherever possible, to simplify the presentation of the homomorphic decryption algorithm. We instead use the notation $[\![c]\!]$ to denote a register or registers encrypting value(s) c.

Our goal, then, is to specify an efficient circuit which is parameterized by the input ciphertext (a, b), meets our restrictions, and outputs an encryption of the desired ring element $[\![b - a \cdot \tilde{z}]\!]$ that will then allow each coefficient to be homomorphically rounded to an LWE ciphertext. We discuss the rounding procedure in Section 4.5. In the next few sections, we specify an arithmetic circuit computing $[\![b - a \cdot \tilde{z}]\!]$, where this circuit takes as input a function of the secret key, $[\![f(\tilde{z})]\!]$, and computes the linear decryption step $C_{a,b}([\![f(\tilde{z})]\!]) = [\![b - a \cdot \tilde{z}]\!]$. We will start with a comparatively straightforward, but inefficient, such construction in which we compute $a \cdot \tilde{z}$ homomorphically with a slow multiplication algorithm.

Let $l = \log n + 1$ and $f(\tilde{z}) \in \mathbb{Z}_{2n}^{l \times \varphi(d)}$ be defined by $f(\tilde{z})_{j,k} = \tilde{z}_k 2^j$. Let $a_{i,j}$ be the jth bit of the binary decomposition of a_i so that $a_i = \sum_{j=0}^{l-1} a_{i,j} 2^j$. We may express multiplication of $\tilde{z}_k$ by a_i by computing $\tilde{z}_k \cdot a_i = \sum_{j=0}^{l-1} a_{i,j} \tilde{z}_k 2^j$. Then we define $C_{a_i}([\![f(\tilde{z})]\!], k) = \sum_{j=0}^{l-1} a_{i,j} [\![f(\tilde{z})_{j,k}]\!]$ to be a circuit computing this multiplication homomorphically using only additions, as the $a_{i,j}$ values are binary. We may then define a circuit C_a, computing a slow multiplication algorithm (mod Φ_d) using these C_{a_i} subcircuits, addition, and subtraction gates.

▶ **Lemma 5.** *Let B be the base of the geometric progression defining* $\mathbf{g}$ *in* GSW *encryption, and let $d_b = \lceil \log_B Q \rceil$. There is an algorithm*

$\mathsf{SlowMult} : a \in \mathcal{R}_d/2n \times (\mathsf{REG}_s(f(\tilde{z})_{j,k}, \beta))_{j,k} \to (\mathsf{REG}_s((a \cdot \tilde{z})_i, \beta'))_i$

requiring $\tilde{O}(d^2)$ homomorphic operations, and where $\beta' \leq \tilde{O}(\beta B \sqrt{n d_B d})$ with high probability.

The proof of Lemma 5 appears in the full version, and the analysis of error growth is similar to that of [11]. To briefly justify its stated complexity, we observe that SlowMult is just naive polynomial multiplication algorithm using only additions, and therefore taking time $O(l)$ per scalar multiplication. Therefore its complexity is $\tilde{O}(d^2)$. The original FHEW refreshing procedure requires only $\tilde{O}(n)$ homomorphic additions per ciphertext, so we already see this algorithm offers no improvement over sequential refreshing of d ciphertexts using FHEW. We will instead use variants of existing fast multiplication algorithms for the homomorphic computation of $a \cdot \tilde{z}$, using SlowMult as a subroutine.

4.3 Homomorphic DFT

We briefly recall and introduce notation for the discrete Fourier transform. We denote the discrete Fourier transform of a length m sequence of elements $x \in \mathcal{R}^m$, where ring $\mathcal{R}$ has mth principal root of unity ω_m, by $\bar{x}_i = DFT(x)_i = \sum_{k=0}^{m-1} x_k \omega_m^{ik}$ and its inverse $x_k = DFT^{-1}(\bar{x})_k = \sum_{i=0}^{m-1} \bar{x}_i \omega_m^{-ik}$. The polynomial product $a \cdot \tilde{z}$ for $a, \tilde{z} \in \mathcal{R}_d/2n$ may then be computed as

$$(a * \tilde{z} \mod X^m - 1) \mod \Phi_d = DFT^{-1}(\frac{1}{m} DFT(a) \cdot DFT(\tilde{z})) \mod \Phi_d$$

provided an mth principal root of unity ω_m exists in $\mathcal{R}_d/2n$ (and $m > \frac{4}{3} d \geq deg(a \cdot \tilde{z})$).

But to compute the DFT homomorphically, we need to be able to homomorphically compute multiplication by ω_m^{-ik}. If we take $\omega_m \in \mathbb{Z}_{2n}$, each multiplication by ω_m^{-ik} requires l homomorphic operations per coefficient (as described in Section 4.2). Furthermore, reducing the quadratic complexity of the DFT requires FFT techniques, recursing to depth $\log m$. At each step of recursion, then, we perform homomorphic operations on registers produced from

the last step, with some increase in error from the previous set of operations. We therefore cannot take advantage of the asymmetric error growth of the GSW scheme underlying our registers and the error growth of our algorithm will become quasi-polynomial in n, exceeding the desired polynomial bound on error overhead. This brings us to the last component of the algorithm, which avoids these scalar multiplications, and achieves efficient multiplication without sacrificing polynomial error growth.

4.4 Nussbaumer Transform

In order to efficiently compute the polynomial product $a \cdot \tilde{z} \in \mathcal{R}_d/2n$, we define a variation of the Nussbaumer transform, suited for multiplication of polynomials modulo a power of 3 cyclotomic. Informally, the transform first maps an element $a \in \mathcal{R}_d/2n$ to a bivariate polynomial in such a way that it may be represented by a coefficient vector of dimension smaller than $\varphi(d)$, over $\mathcal{R}_{d^{1-\epsilon}}/2n$. Taking the DFT of this coefficient vector allows us to reduce the computation of $a \cdot \tilde{z}$ to the pointwise multiplication of two vectors with entries in $\mathcal{R}_{d^{1-\epsilon}}/2n$. The inverse map on the inverse DFT of the smaller polynomial products yields $a \cdot \tilde{z} \in \mathcal{R}_d/2n$. We now give a more detailed description of the algorithm.

Let $d = 3^k$, $m = d^\epsilon$ with $d \geq 3m^2$, and $r = \varphi(d)/m = \varphi(d^{1-\epsilon})$. To multiply two polynomials, the transform maps each polynomial to a bivariate polynomial by the isomorphism

$$\psi : \mathbb{Z}_{2n}[X]/(\Phi_d) \to (\mathbb{Z}_{2n}[Y]/(\Phi_{d/m}(Y)))[X]/(X^m - Y)$$
$$a(X) = \sum_{i=0}^{\varphi(d)} a_i X^i \mapsto \sum_{j=0}^{m-1} \sum_{i=0}^{r-1} a_{mi+j} Y^i X^j \text{ where } Y = X^m.$$

Because $\psi(a)$ and $\psi(\tilde{z})$ have degree at most $m-1$ in X, computing $\psi(a) \cdot \psi(b)$ modulo any polynomial of degree greater than $2m-2$ in X prior to reducing by $X^m - Y$ will not change the result. We also note that Y is a principal d/mth root of unity in $\mathbb{Z}_{2n}[Y]/(\Phi_{d/m}(Y))$, and therefore $Y^{d/3m^2} = Y^{3^{k(1-2\epsilon)-1}}$ is a $3m$th root which can also be shown to be principal.

This allows us to efficiently compute $\psi(a) \cdot \psi(\tilde{z})$ first modulo $X^{3m} - 1$ by pointwise multiplication of the respective DFTs, followed by a reduction modulo $(X^m - Y)$. Since the "points" of the DFT pointwise multiplication step are elements of $\mathbb{Z}_{2n}[Y]/(\Phi_{d/m}(Y))$, these multiplications can be performed by recursive application of the transform or SlowMult.

Without recursion, this gives a key preprocessing function

$$f(\tilde{z}) = (1, 2, 4, ..., n) \otimes [\frac{1}{3m} DFT(\psi(\tilde{z}))_i]_{i<3m} \in (\mathcal{R}_{d/m}/2n)^{l \times 3m} \tag{5}$$

where the DFT evaluates $\psi(\tilde{z})$ at root of unity $\omega_{3m} = Y^{d/3m^2}$.

Let $\bar{a}_i = DFT(\psi(a))_i$ be the ith of the $3m$ degree $< r$ polynomials produced by the Nussbaumer transform. Let $C_{\bar{a}_i}$ denote a circuit computing SlowMult of known polynomial $\bar{a}_i$ (of degree $< r$) with an encrypted polynomial given as input (along with encryptions of all power of 2 multiples of the polynomial's coefficients, for $2^l \leq n$, as in Section 4.2). Let C_{F^*} be a circuit homomorphically computing the inverse DFT for length $3m$ vectors of encrypted polynomials in $\mathcal{R}_{d/m}/2n$. Then we may specify a circuit computing $[\![a \cdot \tilde{z}]\!]$

$$C_a([\![f(\tilde{z})]\!] = C_{F^*}([C_{\bar{a}_i}([\![f(\tilde{z})_{(\cdot),i}]\!])]_i) \mod X^m - Y = [\![a \cdot \tilde{z}]\!].$$

$[\![b - a \cdot \tilde{z}]\!]$ is then computed by negating each of the registers $\mathsf{REG}((a \cdot \tilde{z})_i)$ and incrementing each one by the corresponding b_i, computing $C_{a,b}([\![f(\tilde{z})]\!]) = -C_a([\![f(\tilde{z})]\!]) + b$.

The map ψ is purely representational, so requires no computation. The forward and inverse DFT steps require evaluating polynomials at the roots of unity $\omega_{3m}^i = Y^{id/3m^2}$,

which is implemented by rotation of the coefficient vectors with negation, addition, and subtraction to implement the reduction in $\mathcal{R}_{d/m}/2n$. SlowMult was defined using only the operations of addition and subtraction, and the final reduction modulo $X^m - Y$ similarly only requires additions and subtractions. This circuit then satisfies our criteria, allowing for the homomorphic computation of $a \cdot \tilde{z}$ without use of multiplication gates.

The Nussbaumer transform admits a recursive algorithm that gives tradeoffs between runtime and error growth of the cryptographic registers, but we defer consideration of the recursive formulation to Section 4.7.

▶ **Lemma 6.** *Let $\mathcal{K}^R$ be a refreshing key*

$$\mathcal{K}^R = K^R_{i,j,k} = \mathsf{REG}_z^{N/Q}([f(\tilde{z})_{i,j,k}]) = \mathsf{REG}_z^{N/Q}\left[\frac{1}{3m} DFT(\psi(\tilde{z}))_{i,k} 2^j, \beta_R\right] \text{ (from Eq. 5)}$$

where $DFT(\psi(\tilde{z}))_{i,k}$ indicates the kth coefficient of the ith polynomial output by the Nussbaumer transform (giving $i < 3m, j < l, k < r$). For every $0 < \epsilon < \frac{1}{2}$, there is an algorithm RingDecrypt *that on input $\mathcal{K}^R$ and* RingLWE *ciphertext $(a, b) \in \mathsf{RingLWE}_{\tilde{z}}^{2/2n}[m, \beta]$ under $\tilde{z} \in \mathcal{R}_d/2n$, outputs $\varphi(d)$ ciphertexts $\left[\mathsf{REG}_z^{N/Q}[\tilde{m}_i, \beta']\right]_{i<\varphi(d)}$ with $\beta' < \tilde{O}\left(\beta B^4 (n d_B)^{3.5} d^{\epsilon+.5}\right)$, and requiring $\tilde{O}(d^{2-\epsilon})$ homomorphic operations.*

The proof of Lemma 6 may be found in the full version of the paper, but the stated complexity is justified here informally. Lemma 5 states that SlowMult requires $\tilde{O}(d^2)$ operations on input polynomials of degree $O(d)$. The RingDecrypt algorithm multiplies $3m$ polynomials of degree $O(d/m)$, so these multiplications contribute $\tilde{O}(d^{2-\epsilon})$ homomorphic operations. The complexity of the DFT step, which performs $3m$ summations of $3m$ polynomials with degree $O(d/m)$, will then be dominated by that of SlowMult for all permissible ϵ, and therefore RingDecrypt will require $\tilde{O}(d^{2-\epsilon})$ many homomorphic operations.

Once we have performed the RingDecrypt procedure, it remains to round the resulting vector of ciphertexts to yield $\varphi(d)$ refreshed LWE ciphertexts.

4.5 msbExtract

Once we have computed the sequence of registers $[\mathsf{REG}_z^{2n/Q}[b_i - (a \cdot \tilde{z})_i]]_{i<\varphi(d)}$, we must homomorphically perform the rounding step of decryption and recover a sequence of reduced-error LWE ciphertexts encrypting each m_i. This can be accomplished as in FHEW, by applying the msbExtract procedure of [12] to each of the $\varphi(d)$ registers produced by RingDecrypt. As in FHEW, this procedure produces refreshed ciphertexts with the GSW modulus Q, so must be followed by ModSwitch to convert them to the smaller intial modulus q.

We note that our msbExtract procedure differs somewhat from that of FHEW, in that we omit the step of key switching. In FHEW, the procedure takes as additional input a switching key. This key enables the LWE encryptions under key (z) that are recovered at an intermediate stage of the rounding algorithm to be converted to LWE encryptions under the initial key $\mathbf{s}$. Choosing our REG key z such that $(z) = \mathbf{s}$ obviates the need for key switching, as the intermediate LWE ciphertexts will already be encrypted under the proper key. This choice of key requires assuming the security of RingLWE with binary secrets, as assumed in [10], but this assumption may be removed at the cost of the additional key switching step. The proof of Lemma 7 may be found in the full version, and is similar to that of [12].

▶ **Lemma 7.** *There is an algorithm* msbExtract *that, given a cryptographic register of the form $\mathsf{REG}_z^{2n/Q}(b_i - (a \cdot \tilde{z})_i, \beta)$ as input, with $(z) = \mathbf{s}$, outputs a LWE ciphertext $\mathsf{LWE}_{\mathbf{s}}^{4/Q}(m_i, \sqrt{n} \cdot \beta)$.*

4.6 Refreshing Algorithm

We now present the amortized bootstrapping algorithm from start to finish and give an analysis of its runtime and error growth.

The algorithm takes as input $\varphi(d)$ ciphertexts for $d = 3^k$, under the same key $s \in \mathbb{Z}_q^n$ and with error at most Δ, to be simultaneously refreshed. It also requires key material for the PackLWE and RingDecrypt procedures, described in their respective sections, but recalled here for reference. The packing key $\mathcal{K}^P = K^P_{j,l}$ is required to pack the LWE ciphertexts into a single RingLWE ciphertext under a new key $\tilde{z} \in \mathcal{R}_d/q$, and is given by $K^P_{j,l} = \mathsf{RingLWE}^{q/q}_{\tilde{z}}(s_l 2^j, \beta_P)$. The refreshing key $\mathcal{K}^R = K^R_{i,j,k}$ encrypts a function of the RingLWE secret $f(\tilde{z})$ under a REG key $z \in \mathcal{R}_{2n}/Q$, and is required for the homomorphic decryption of the resulting RLWE ciphertext. Its entries are given by $K^R_{i,j,k} = \mathsf{REG}^{2n,Q}_z\left(\frac{1}{3m} DFT(\psi(\tilde{z}))_{i,k}) 2^j, \beta_R\right)$.

▶ **Theorem 8.** *For every $0 < \epsilon < \frac{1}{2}$, there exists an algorithm* Refresh *that, on the input described above, produces $\varphi(d)$* LWE *ciphertexts with error $\tilde{O}\left(\|s\| + \frac{q}{Q} \cdot \beta_R (Bn)^4 d_B^{3.5} d^{\epsilon+.5}\right)$, and requires $\tilde{O}(d^{2-\epsilon})$ homomorphic operations.*

Proof. From Lemma 6, we already have that the homomorphic complexity of RingDecrypt is $\tilde{O}(d^{2-\epsilon})$, and this dominates the complexity of RingDecrypt.

The correctness of this refreshing scheme will rely on the error bounds at two stages of the algorithm. For msbExtract to recover the correct m_i's from the output of RingDecrypt, the error of each $\tilde{m}_i = \frac{2n}{t} m_i + e$ must not exceed $\frac{n}{t}$ (for $t = 2$, the message space of m_i).

From the error bounds of Theorem 4 and Equation 2, we have that the ciphertext output by $\mathsf{ModSwitch}_{\mathcal{R}}$ will have error bounded by $O\left(\frac{2n}{q}(\sqrt{d}\Delta + \sqrt{dn \log q}\beta_P) + \omega(\sqrt{d \log d}) \cdot \|\tilde{z}\|\right)$. To bound this by $n/2$, we restrict $\tilde{z}$ to $\|\tilde{z}\| = O(\sqrt{d})$. Then so long as the LWE ciphertext error Δ satisfies $\Delta < O(\frac{q}{\sqrt{d}})$, $d\sqrt{\log d} < O(n)$, and $d^2 n < O(\frac{q^2}{\log q})$, the packed ciphertexts will be decryptable with high probability.

We also need to guarantee that the ciphertexts output by Refresh will have error small enough that this scheme is composable. From the bounds of Lemma 6, Lemma 7, and Equation 4, this requires us to bound the error of the ciphertexts output by Refresh by $\beta' = \tilde{O}\left(\|s\| + \frac{q}{Q} \cdot \beta_R (nB)^4 d_B^{3.5} d^{\epsilon+.5}\right) < \frac{q}{\sqrt{d}}$. Letting s be a binary secret, (which does not reduce hardness of the associated LWE instance, as shown in [7]), this gives us that $\frac{Q}{(d_B)^{3.5}} > \beta_R n^4 \sqrt{\log n} B^4 d^{1+\epsilon}$, so taking $B = \Theta(1)$ and $Q > \tilde{O}(\beta_R n^4 d^{1+\epsilon} (\log d)^{3.5})$ will guarantee correct decryption with high probability. ◀

4.7 Recursive optimization

In this section we summarize a recursive formulation of the Nussbaumer transform, and how it can improve the complexity of the RingDecrypt algorithm, at the cost of an increase in the error. The proof of Theorem 9 may be found in the full version.

The Nussbaumer transform as described in Section 4.4 can be thought of as a reduction from a single multiplication of two polynomials in $\mathbb{Z}_{2n}[X]/(\Phi_d(X))$ to $3m$ multiplications of pairs of polynomials in $\mathbb{Z}_{2n}[Y]/(\Phi_{d/m}(Y))$. We may recursively apply this transformation ρ times, provided we have a $3m$th root of unity in the ring $\mathbb{Z}_{2n}[Y]/(\Phi_{d/m^\rho}(Y))$, which will be the case as long as $d/m^\rho \geq 3m$. ϵ is fixed and so this bounds the recursive depth of the algorithm by $\rho < \frac{1}{\epsilon} - 1$.

▶ **Theorem 9.** *The recursive $\mathsf{RingDecrypt}_\rho$ algorithm, with constant parameter ϵ and recursive depth $\rho < \frac{1}{\epsilon} - 2$, requires $\tilde{O}(3^\rho d^{2-\rho\epsilon} + 3^\rho d^{1+\epsilon})$ homomorphic operations and yields an error growth of $\tilde{O}(B^{3\rho+1}(nd_B)^{3\rho}\sqrt{nd_B d^{1+\rho\epsilon}})$.*

Abstract

The problem of computing the vertex expansion of a graph is an NP-hard problem. The current best worst-case approximation guarantees for computing the vertex expansion of a graph are a $\mathcal{O}\left(\sqrt{\log n}\right)$-approximation algorithm due to Feige et al. [16], and $\mathcal{O}\left(\sqrt{\mathsf{OPT}\log d}\right)$ bound in graphs having vertex degrees at most d due to Louis et al. [29].

We study a natural semi-random model of graphs with sparse vertex cuts. For certain ranges of parameters, we give an algorithm to recover the planted sparse vertex cut exactly. For a larger range of parameters, we give a constant factor bi-criteria approximation algorithm to compute the graph's balanced vertex expansion. Our algorithms are based on studying a semidefinite programming relaxation for the balanced vertex expansion of the graph.

In addition to being a family of instances that will help us to better understand the complexity of the computation of vertex expansion, our model can also be used in the study of community detection where only a few nodes from each community interact with nodes from other communities. There has been a lot of work on studying random and semi-random graphs with planted sparse edge cuts. To the best of our knowledge, our model of semi-random graphs with planted sparse vertex cuts has not been studied before.

1 Introduction

Given a graph $G = (V, E)$, the vertex expansion of a non-empty subset $S \subset V$, denoted by $\phi^{\mathsf{V}}(S)$, is defined as[2]

$$\phi^{\mathsf{V}}(S) \stackrel{\text{def}}{=} |V| \frac{|N(S)| + |N(V \setminus S)|}{|S|\,|V \setminus S|},$$

where $N(S)$, the neighborhood of S, is defined as $N(S) \stackrel{\text{def}}{=} \{j \in V \setminus S : \exists i \in S \text{ such that } \{i, j\} \in E\}$. The vertex expansion of the graph G, denoted by ϕ^{V}_G, is defined as $\phi^{\mathsf{V}}_G \stackrel{\text{def}}{=} \min_{S \subset V,\ S \neq \emptyset} \phi^{\mathsf{V}}(S)$. Computing the vertex expansion of a graph is NP-hard. The complexity of computing various graph expansion parameters are central open problems in theoretical computer science, and inspite of many decades of intensive research, they are yet to be fully understood [8, 9, 26, 10, 16, 39].

Feige et al. [16] gave a $\mathcal{O}\left(\sqrt{\log n}\right)$-approximation algorithm for computing the vertex expansion of a graph. Louis et al. [29] gave an algorithm that computes a set having vertex expansion at most $\mathcal{O}\left(\sqrt{\phi^{\mathsf{V}} \log d}\right)$ in graphs having vertex degrees at most d. We give a brief description of other related works in Section 1.3. In this work, we study a natural semi-random family of graphs, and give polynomial time exact and approximation algorithms for computing the *balanced vertex expansion* (a notion that is closely related to the vertex expansion of a graph, we define it formally in Section 1.1) w.h.p.

In many problems, there is a huge gap betwen theory and practice; the best known algorithms provide a somewhat underwhelming performance guarantee, however simple heuristics perform remarkably well in practice. Examples of this include the simplex algorithm for linear programming [25], SAT [11], sparsest cut [22, 23], among others. In many cases, the underwhelming provable approximation guarantee of an algorithm is a property (hardness of approximation) of the problem itself; even in many such cases, simple heuristics work remarkably well in practice. A possible explanation for this phenomenon could be that for many problems, the instances arising in practice tend to have some inherent structure that makes them "easier" than the worst case instances. Many attempts have been made to understand the structural properties of these instances, and to use them in designing algorithms specifically for such instances, which could perform much better than algorithms for general instances. A fruitful direction of study has been that of modelling real world instances as a family of random and semi-random instances satisfying certain properties. Our work can be viewed as the study of the computation of vertex expansion along this direction.

Often graphs with sparse cuts are used to model communities. For example, the vertices of a graph can be used to represent the members of the communities, and two vertices would have an edge between them if the members corresponding to them are *related* in some way. In such a graph, the sparse cuts indicate the presence of a small number of relations across the members corresponding to the cut, which are likely to be some form of communities within the members. The *stochastic block models* have been used to model such communities. Our model can also be viewed as model for communities where only a few members from each community have a relationship with members from another community.

[2] Other definitions of vertex expansion have been studied in the literature, see Section 1.3.

1.1 Vertex Expansion Block Models

For a graph $G = (V, E)$, its *balanced vertex expansion* $\phi^{\mathsf{V-bal}}$ is defined as

$$\phi_G^{\mathsf{V-bal}} \stackrel{\text{def}}{=} \min_{\substack{S \subset V \\ |S|=|V|/2}} \phi^{\mathsf{V}}(S)\,.$$

Another common notion of vertex expansion that has been studied in the literature is $\phi^{\mathsf{V,a}}(S) \stackrel{\text{def}}{=} (|V|\,|N(S)|\,/\,(|S|\,|V \setminus S|))$, and as before, $\phi_G^{\mathsf{V,a}} \stackrel{\text{def}}{=} \min_{S \subset V} \phi^{\mathsf{V,a}}(S)$. [29] showed that the computation ϕ_G^{V} and $\phi_G^{\mathsf{V,a}}$ is equivalent upto constant factors. In this work, we develop a semi-random model for investigating the balanced vertex expansion of graphs.

We study instances that are constructed as follows. We start with a set of n vertices, and we arbitrarily partition them into two sets S, S' of $n/2$ vertices each. Next, we choose a small subset $T \subset S$ of size εn (resp. $T' \subset S'$) to form the vertex boundary of these sets. On $S \setminus T$ (resp. $S' \setminus T'$), we add an arbitrary graph whose spectral gap[3] is at least λ (a parameter in this model), and whose vertices have roughly the same degree. We add an arbitrary low degree bipartite graph between T and T'. Between each pair of vertices in $(S \setminus T) \times T$, we add edges independently at random with probability p; this is the only part of the construction that is random. Next, we allow a *monotone adversary* to alter the graph : the monotone adversary can arbitrarily add edges that do not change the sparsity of the vertex cut (S, S'), i.e., add edges between any pair of vertices in S (resp. S'), and between any pair in $T \times T'$.

In our model, we allow the sets S and S' to be generated using different sets of parameters, i.e., we use $\varepsilon_1, \lambda_1, p_1$ for S and $\varepsilon_2, \lambda_2, p_2$ for S'. We formally define the vertex expansion block model below (see also Figure 1).

▶ **Definition 1.** An instance of $\mathsf{VBM}(n, \varepsilon_1, \varepsilon_2, p_1, p_2, c, r, \lambda_1, \lambda_2)$ is generated as follows.

1. Let V be a set of n vertices. Partition V into two sets S and S' of $n/2$ vertices each. Partition S into two sets T and $S \setminus T$ of sizes $\varepsilon_1 n$ and $(1/2 - \varepsilon_1)n$ respectively. Similarly, partition S' into two sets T' and $S' \setminus T'$ of sizes $\varepsilon_2 n$ and $(1/2 - \varepsilon_2)n$ respectively.
2. Between each pair in $(S \setminus T) \times T$ (resp. $(S' \setminus T') \times T'$), add an edge independently with probability p_1 (resp. p_2).
3. Between pairs of vertices in $S \setminus T$ (resp. $S' \setminus T'$), add edges to form an arbitrary roughly regular (formally, ratio of the maximum vertex degree and the minimum vertex degree is at most r) of spectral gap[3] at least λ.
4. Between pairs in $T \times T'$, add edges to form an arbitrary bipartite graph of vertex degrees in the range $[1, c]$ (this bipartite graph need not be connected); if $c < 1$, then add no edges in this step. We will use $\mathcal{F}$ to denote this bipartite graph.
5. (*Monotone Adversary*) Arbitrarily add edges between any pair of vertices in S (resp. S'). Arbitrarily add edges between any pair in $T \times T'$.

Output the resulting graph G.

We note that the direct analogue for vertex expansion of *Stochastic Block Models* (see related work in Section 1.3) in the regimes allowing for exact recovery is included in this setting: there, the graphs within S and S' are completely random, and so are the connections between T and T' (before the monotone adversary acts). Our model allows for a lot more adversarial action, while restricting the randomness to only a small portion of the graph.

[3] The spectral gap of a graph is defined as the second smallest eigenvalue of its normalized Laplacian matrix, see Section 1.6 for definition

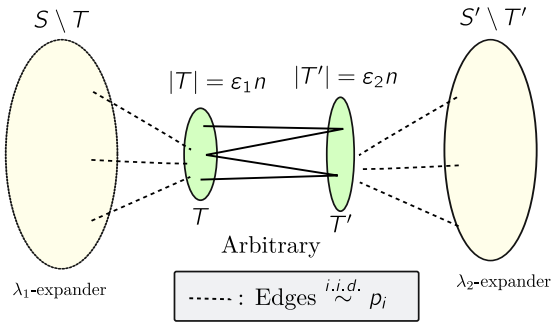

Figure 1 $\mathsf{VBM}(n, \varepsilon_1, \varepsilon_2, p_1, p_2, c, r, \lambda_1, \lambda_2)$. A monotone adversary may further add arbitrary edges within S, S' and between T, T'.

In addition to being a family of instances that will help us to better understand the complexity of the computation of vertex expansion, the vertex expansion block model can also be used in the study of community detection. In the case of two communities, the vertices in S and S' can model the members of the communities. Each community can have a few representatives who interact with the representatives from other communities; these representatives can be modelled using T and T', and their interactions can be modelled by the arbitrary graphs within T and T', and the low degree bipartite graph and the action of the monotone adversary between T and T'. Even though the connections within a community may be arbitrary, usually the members within the community are well connected with each other; this can be modelled by the choosing an appropriate values of λ_1, λ_2 plus the action of the monotone adversary. We can model the connections between community members and their representatives by a sparse random bipartite graph; our model allows the flexibility of choosing p_1 and p_2, and also the action of the monotone adversary.

1.2 Our Results

Our main result is a polynomial time algorithm for exactly recovering S and S' from a graph sampled from $\mathsf{VBM}(n, \varepsilon_1, \varepsilon_2, p_1, p_2, c, r, \lambda_1, \lambda_2)$ for certain ranges of parameters.

▶ **Theorem 2.** *There exist universal constants $c_1 \in \mathbb{R}^+, c_2 \in (0, 1/2), c_3 \in \mathbb{Z}^+, c_4 \in \mathbb{R}^+, c_5 \in (0, 1)$ satisfying the following: there exists a polynomial time algorithm which takes a graph generated from $\mathsf{VBM}(n, \varepsilon_1, \varepsilon_2, p_1, p_2, c, r, \lambda_1, \lambda_2)$, where $p_1, p_2 \in (c_1(\log n)/n, 1]$, $\varepsilon_1, \varepsilon_2 \in [1/n, c_2]$, $c \leqslant c_3$, $r \leqslant c_4$ and $\lambda_1, \lambda_2 \geqslant c_5$, and outputs the sets S and S' with probabilty at least $1 - 1/\mathsf{poly}(n)$.*

We give a description of the steps in proving Theorem 2 in Section 2; in the full version of this paper, we also observe that our proof actually shows a slightly more general result.

We also show that if the instances satisfy a few weaker requirements, then we can obtain a constant factor bi-criteria approximation algorithm for computing the balanced vertex expansion.

We study the case when $S \setminus T$ is an arbitrary graph, i.e., it does not have constant spectral gap. Note that this case is captured by setting $\lambda_1 = 0$ in our model, since the monotone adversary can create any arbitrary graph on $S \setminus T$. Our proof also allows us to let the graph induced on S' be an arbitrary graph. Again, this is captured by setting $p_2 = \lambda_2 = 0$ in our model, since the monotone adversary can create any arbitrary graph on S'. We show that we can use the underlying random bipartite graph between $S \setminus T$ and T to obtain a bi-criteria approximation algorithm in this case, that outputs an almost balanced cut with vertex expansion within a constant factor of the planted one.

▶ **Theorem 3.** *There exist universal constants $c_1 \in \mathbb{R}^+$, $c_2 \in (0,1/2), c_6 \in (0,1/2)$ satisfying the following: there exists a polynomial time algorithm which takes a graph generated from $\mathsf{VBM}(n, \varepsilon_1, \varepsilon_2, p_1, 0, 0, 0, 0, 0)$, where $\varepsilon_1, \varepsilon_2 \in [1/n, c_2]$ and $p_1(\varepsilon_1+\varepsilon_2)n \geqslant c_1 \log n$, and outputs with probability at least $1 - 1/\mathsf{poly}(n)$, a set $A \subset V$ satisfying $|A| \in [c_6 n, (1-c_6)n]$ and $\phi^{\mathsf{V}}(A) \leqslant \mathcal{O}(\varepsilon_1 + \varepsilon_2)$.*

Next, we study the case where the edges between $S \setminus T$ and T are arbitrary, but λ_1 is large. As in the previous case, our proof allows the graph induced on S' to be an arbitrary graph. Again, as before, this case is captured by setting $p_1 = p_2 = \lambda_2 = 0$. In this case, we show that for certain ranges of λ_1, we can obtain a constant factor bi-criteria approximation algorithm for computing the balanced vertex expansion.

▶ **Theorem 4.** *There exist universal constants $c_2 \in (0,1/2), c_5 \in (0,1), c_6 \in (0,1/2)$ satisfying the following: there exists a polynomial time algorithm which takes a graph generated from $\mathsf{VBM}(n, \varepsilon_1, \varepsilon_2, 0, 0, 0, r, \lambda_1, 0)$, where $\varepsilon_1, \varepsilon_2 \in [1/n, c_2]$, and $\lambda_1 \geqslant c_5 r^3(\varepsilon_1 + \varepsilon_2)$, and outputs a set $A \subset V$ satisfying $|A| \in [c_6 n, (1-c_6)n]$ and $\phi^{\mathsf{V}}(A) \leqslant \mathcal{O}(\varepsilon_1 + \varepsilon_2)$.*

In fact, we prove a stronger result: it suffices for $S \setminus T$ to contain a subgraph on $\Omega(n)$ vertices having spectral gap at least $c_5 r^3(\varepsilon_1 + \varepsilon_2)$, to obtain a constant factor bi-criteria approximation algorithm for computing the balanced vertex expansion.

Organization of the rest of the paper

We will next describe related work in Section 1.3, and give our SDP relaxation in Section 1.4. We give an overview of our proofs in Section 1.5, and present a slightly more detailed description of the proof of our main result, Theorem 2, in Section 2. For the proofs of Theorem 3 and Theorem 4, we refer the reader to the full version of the paper.

1.3 Related Work

Stochastic Block Models

Closely related to the vertex expansion of a graph is the notion of edge expansion which is defined as follows.

▶ **Definition 5.** For a weighted graph $G = (V, E, w)$, with non-negative edge weights $w : E \to \mathbb{Q}^+$, the edge expansion of a non-empty set $S \subset V$ is defined as

$$\phi_G(S) \stackrel{\text{def}}{=} \frac{\sum_{e \in E(S, V\setminus S)} w(e)}{\min\{\mathsf{vol}(S), \mathsf{vol}(V \setminus S)\}},$$

where $E(S, V \setminus S) \stackrel{\text{def}}{=} \{\{i,j\} \in E : i \in S, j \notin S\}$ and $\mathsf{vol}(S) \stackrel{\text{def}}{=} \sum_{i \in S} \sum_{j \sim i} w(\{i,j\})$. The edge expansion of the graph is defined as $\phi_G \stackrel{\text{def}}{=} \min_{S \subset V,\ S \neq \emptyset} \phi_G(S)$.

The *Stochastic Block Model* (we will refer to it as the *edge expansion stochastic block model* to differentiate it from our block model) is a randomized model for instances that are generated as follows. A set of n vertices is arbitrarily partitioned into sets S, S' of equal sizes. Between each pair of vertices in S, an edge is added independently with probability p, and between each pair of vertices in $S \times S'$, an edge is added independently with probability q (typically $p > q$).

Starting with work of Holland et al.[20], the works of Boppana [13], who gave a spectral algorithm, and of Jerrum and Sorkin [21], who gave a metropolis algorithm, contributed

significantly to the study of stochastic block models. One of the break through works in the study of SBMs is the work of McSherry [34], who gave a simple spectral algorithm for a certain range of parameters. There has been a lot of recent work related to a certain conjecture regarding SBMs, which stated the regime of parameters p, q for which it was possible to detect the presence of communities. The works [36, 37, 38, 33] have contributed to proving various aspects of the conjecture. In a recent work, Abbe et al.[3] showed that the natural SDP relaxation for balanced edge expansion is integral when there is a sufficient gap between p and q, and $p, q = \Omega(\log n/n)$; Mossel et al.[38] gave an algorithm for a larger regime of parameters which was not based on semidefinite programming. More general SBMs have been studied by Abbe and Sandon [4, 5, 6], Aggarwal et al.[7], etc.

Kim et al.[24] studied a version of SBM for hypergraphs, and gave algorithms for it based on studying a certain "adjacency tensor", the analog of the adjacency matrix for hypergraphs. They also study the sum-of-squares algorithms for this model. [27] gave a reduction from vertex expansion problems to hypergraph expansion problems. We note that applying this reduction to the instances from our models does not give the model studied by [24]: this reduction will only introduce hyperedges between the sets corresponding to T and T', whereas the model studied by [24] adds random hyperedges between S and S'. Moreover, many parts of the graph from our model are adversarially chosen.

Semi-random models for edge expansion problems

Monotone adversarial errors in SBMs are the arbitrary addition of edges between pairs of vertices within S (resp. S'), and the arbitrary deletion of existing edges between S and S'. Feige and Kilian [17] gave an algorithm for the edge expansion model with monotone adversarial errors when the gap between p and q is sufficiently large. Guedon and Vershynin [18] gave an algorithm based on semidefinite programming for partially recovering the communities for certain ranges of parameters. Moitra et al.[35] gave algorithms (based on semidefinite programming) and lower bounds for partial recovery in the stochastic block model with a monotone adversary. Makarychev et al.[32] gave an algorithm for partial recovery for the stochastic block model with a monotone adversarial errors and a small number of arbitrary errors (i.e. non-monotone errors).

Makarychev et al.[30, 31] studied some semi-random models of instances for edge expansion problems. In particular, [30] studied a model analogous to $\mathsf{VBM}(n, \varepsilon_1, \varepsilon_2, 0, 0, 0, r, \lambda_1, 0)$for edge expansion problems; they showed that if the number of edges crossing (S, S') is εm, and if there is a set of m edges E_1 such that (S, E_1) is a regular graph having spectral expansion at least $\Omega(\varepsilon)$, then there is an algorithm to recover a balanced cut of edge expansion $\mathcal{O}(\varepsilon)$. The proof of Theorem 4 and that of the corresponding result in [30] both proceed by using the expansion of the underlying subgraph to show that an $\Omega(n)$ sized subset of the SDP vectors lie in a ball of small radius. [30] use this to recover a constant factor bi-criteria approximation to balanced edge expansion; we adapt this approach to vertex expansion to prove Theorem 4.

The results cited here are only a small sample of the work on the SBMs. Since our model is very different from the edge expansion stochastic block models, we only give a brief survey of the literature here, and we refer the reader to a survey by Abbe [1] for a comprehensive discussion. In general, algorithms for edge expansion problems can not be used for our vertex expansion block model since sparse edge cuts and sparse vertex cuts can be uncorrelated. In particular, the action of the monotone adversary in VBM rules out the use of edge-expansion based algorithms for detecting S and S'. In the full version of this paper, we describe an explicit family graphs generated in the VBM model where these algorithms fail.

Vertex Expansion

There has been some work in investigating vertex expansion (balanced and non-balanced) the worst-case setting. Bobkov et al. [12] gave a Cheeger-type inequality for vertex expansion, where a parameter λ_∞ plays a role analogous to the use of the second eigenvalue λ_2 in Cheeger's inequality for edge expansion. Feige et al.[16] gave a $\mathcal{O}\left(\sqrt{\log n}\right)$-approximation algorithm for the problem of computing the vertex expansion of graphs. Louis et al.[29] gave an SDP rounding based algorithm that computes a set having vertex expansion at most $\mathcal{O}\left(\sqrt{\phi_G^{\mathsf{V}} \log d}\right)$, where d is the maximum vertex degree; they also showed a matching hardness result based on the Small-set expansion hypothesis. Louis and Makarychev [27] gave a bi-criteria approximation for Small-set vertex expansion, a problem related to vertex expansion. Chan et al. [14] studied various parameters related to hypergraphs, including parameters related to hypergraph expansion; they showed that many of their results extend to the corresponding vertex expansion analogues on graphs

Louis and Raghavendra [28] studied a model of instances for vertex expansion similar to ours. In their model, the adversary partitions the vertex set V into two equal sized sets S, S', and chooses a subset T (resp. T') of S (resp. S') of size at most εn. Next, the adversary chooses an arbitrary subset of pairs of vertices in S (resp. S') to form edges such that graph induced on S (resp. S') is an edge expander. The adversary chooses an arbitrary subset of the pairs of vertices in $T \times T'$ to form edges. [28] give an SDP rounding based algorithm to compute a set having vertex expansion $\mathcal{O}\left(\sqrt{\varepsilon}\right)$.

1.4 SDP Relaxation

We use the SDP relaxation for $\phi_G^{\mathsf{V}-\mathsf{bal}}$ (SDP 6), this SDP is very similar to that of [29]. We give the dual of this SDP in SDP 7.

▶ **SDP 6** (Primal).

$$\min \sum_{i \in V} \eta_i$$

subject to

$$\begin{aligned} U_{ii} + U_{jj} - 2U_{ij} &\leqslant \eta_i && \forall i \in V, j \in N(i) \\ U_{ii} &= 1 && \forall i \in V \\ \sum_{i \in V} \sum_{j \in V} U_{ij} &= 0 \\ U &\succeq 0 \end{aligned}$$

▶ **SDP 7** (Dual).

$$\max \sum_{i \in V} B_{ii}$$

subject to

$$\begin{aligned} \sum_{j \in N(i)} Y_{ij} &= 1 \\ Y_{ij} &\geqslant 0 && \forall \{i,j\} \in E \\ B_{ij} &= 0 && \forall i,j \in V, i \neq j \\ L(Y) + \alpha \mathbb{1}\mathbb{1}^T - B &\succeq 0 \end{aligned}$$

Here $\mathbb{1}$ denotes the all-ones vector, and $L(Y)$ denotes the Laplacian matrix of graph weight by the matrix $Y + Y^T$, i.e.

$$L(Y)_{ij} = \begin{cases} \sum_{l \in N(i)} (Y_{il} + Y_{li}) & i = j \\ -(Y_{ij} + Y_{ji}) & j \in N(i) \\ 0 & \text{otherwise} \end{cases}.$$

First, let us see why SDP 6 is a relaxation for $\phi^{\mathsf{V}-\mathsf{bal}}$. Let P be the set corresponding to $\phi_G^{\mathsf{V}-\mathsf{bal}}$, and let $\mathbb{1}_P \in \{-1, 1\}^n$ be a vector such $\mathbb{1}_P(i)$ is equal to 1 if $i \in P$ and -1 otherwise. Note that since $|P| = |V|/2$, we have $\mathbb{1}^T \mathbb{1}_P = 0$. It is easy to verify that

$U := \mathbb{1}_P \mathbb{1}_P^T$ and $\eta_i := \max_{j \in N(i)} \left(\mathbb{1}_P(i) - \mathbb{1}_P(j)\right)^2$ is a feasible solution for SDP 6, and that $\sum_{i \in V} \eta_i = 4\left(|N(P)| + |N(V \setminus P)|\right)$. Therefore, $\phi_G^{\mathsf{V-bal}} = 4\left(\sum_{i \in V} \eta_i\right)/n$. and therefore, SDP 6 is a relaxation for $\phi^{\mathsf{V-bal}}$. Henceforth, we will use $\mathbb{1}_P$ to be the ± 1-indicator vector of a set $P \subset V$, i.e., $\mathbb{1}_P(i)$ is equal to 1 if $i \in P$ and -1 otherwise. We prove the following theorem about SDP 6.

▶ **Theorem 8.** *For the regime of parameters stated in Theorem 2,* $U' \stackrel{\text{def}}{=} \mathbb{1}_S \mathbb{1}_S^T$ *and for each* i, $\eta_i' \stackrel{\text{def}}{=} \max_{j \in N(i)} \left(\mathbb{1}_S(i) - \mathbb{1}_S(j)\right)^2$ *for the set* S *defined in* $\mathsf{VBM}(n, \varepsilon_1, \varepsilon_2, p_1, p_2, c, r, \lambda_1, \lambda_2)$*, is the unique optimal solution to SDP 6 with probabilty at least* $1 - 1/\mathsf{poly}(n)$.

Theorem 8 gives an algorithm to compute the matrix $\mathbb{1}_S \mathbb{1}_S^T$. By factorizing this matrix, one can obtain the vector $\mathbb{1}_S$, using which the set S can be computed. Therefore, Theorem 8 implies Theorem 2.

1.5 Proof Overview

1.5.1 Theorem 2

It is easy to verify that (U', η_i') is a feasible solution to SDP 6. Our goal will be to construct a dual solution (i.e. a feasible solution to SDP 7) which satisfies two properties,

1. The cost of this solution should be same as the cost of this primal solution (U', η').
2. The matrix $\left(L(Y) + \alpha \mathbb{1}\mathbb{1}^T - B\right)$ should have rank $n - 1$.

Using strong duality, (1) will suffice to ensure that (U', η') is an optimal solution of the primal SDP . To show that this is the unique primal optimal solution, we will use the complementary slackness conditions which state that

$$U \cdot \left(L(Y) + \alpha \mathbb{1}\mathbb{1}^T - B\right) = 0\,. \tag{1}$$

Since, $\left(L(Y) + \alpha \mathbb{1}\mathbb{1}^T - B\right)$ will have rank $n - 1$, this will imply that all primal optimal solutions must have rank at most 1, or in other words, there is a unique primal optimal solution (see Lemma 11).

While the approach of using complementary slackness conditions for proving the integrality of the SDP relaxation has been studied for similar problems before ([15, 2, 3, 19, 7]), there is no known generic way of implementing this approach to any given problem. Usually the challenging part in implementing this approach is in constructing an appropriate dual solution, and that, like in most of the works cited above, forms the core of our proof.

We give an outline of how we construct our dual solutions. We begin by setting the Y value for each edge added by the monotone adversary to 0, thus our proof can be viewed as saying that SDP 6 "ignores" all those edges. For the sake of simplicity, let us consider the case when the bipartite graph between T and T' is a c-regular graph. We set $B_{ii} := 4$ if $i \in T \cup T'$ and 0 if $i \notin T \cup T'$. Thus, if we can choose Y such that this choice of B is a feasible solution, then this will ensure that the cost of this dual solution, and the cost of the primal solution (U', η') are both equal to $4(\varepsilon_1 + \varepsilon_2)n$, thereby fullfilling our first requirement.

If U is a rank one matrix, and $\left(L(Y) + \alpha \mathbb{1}\mathbb{1}^T - B\right)$ is a rank $n - 1$ matrix, then (1) implies that $\mathbb{1}_S$ is an eigenvector of $\left(L(Y) + \alpha \mathbb{1}\mathbb{1}^T - B\right)$ with eigenvalue 0. This fact will be extremely useful in setting the Y values for the edges in the bipartite graph between T and T' (Lemma 12). Now, we only have to choose the Y values for the edges fully contained in S (resp. S'). We first prove the following lemma which will help us to choose the Y values.

▶ **Lemma 9** (Informal statement of Lemma 10). *There exists a constant c' such that it suffices to choose Y satisfying*

$$X^T\left(L(Y)\right)X \geqslant \frac{c'}{n}\left(\sum_{i\in S\setminus T}\sum_{t\in T}\left(X_i-X_t\right)^2+\sum_{i\in S'\setminus T'}\sum_{t\in T'}\left(X_i-X_t\right)^2\right) \qquad \forall X\in\mathbb{R}^n\,.$$

The proof of this lemma follows by carefully choosing the value of α, and by exploiting the fact that $\mathbb{1}_S$ is an eigenvector of $L(Y)+\alpha\mathbb{1}\mathbb{1}^T-B$ with eigenvalue 0. Proving the condition in Lemma 9 can be viewed as the problem of choosing capacities for the edges to support the multicommodity flow where each vertex $i\in S\setminus T$ wants to send c'/n amount of flow to each $t\in T$. This idea can work when S (resp. S') is a sufficiently dense graph, but does not work when S (resp. S') is sparse (for more details, we refer the reader to the full version). Our second idea is to use the edge expansion properties of the underlying spanning subgraph. For a d-regular edge expander $H=(V',E')$ having the second smallest normalized Laplacian eigenvalue λ, we get that $\sum_{\{ij\}\in E'}\left(X_i-X_j\right)^2\geqslant(\lambda d/n)\sum_{ij\in E'}\left(X_i-X_j\right)^2$. Since $L(Y)$ is a Laplacian matrix, we get that

$$\begin{aligned}X^TL(Y)X=&\sum_{i,j\in S\{i,j\}\in E}\left(Y_{ij}+Y_{ji}\right)\left(X_i-X_j\right)^2\\&+\sum_{i,j\in S'\{i,j\}\in E}\left(Y_{ij}+Y_{ji}\right)\left(X_i-X_j\right)^2\\&+\sum_{i\in T,j\in T'\{i,j\}\in E}\left(Y_{ij}+Y_{ji}\right)\left(X_i-X_j\right)^2\,.\end{aligned}$$

Now, since S and S' contain an almost regular edge expander as a spanning subgraph, we can adapt the expander argument to this setting and obtain some lower bound on this quantity. This strategy can work in some special cases, but fails in general. Our proof shows that the desired lower bound in Lemma 9 can be obtained using a careful combination of these two ideas, in addition to exploiting the various properties of the random graph between $S\setminus T$ and T (resp. $S'\setminus T'$ and T').

1.5.2 Theorem 3 and Theorem 4

We first solve SDP 6 and obtain a matrix U such that $U\succeq 0$. Therefore, U can be factorized into $U=W^TW$ for some matrix W. Let $u_1,\ldots,u_n$ denote the columns of this matrix W. We give an algorithm to "round" these vectors into a set satisfying the guarantees in the theorem. As in the previous case, we show that we can "ignore" all the edges added by the monotone adversary, and only focus on the edges added in step 2, 3, 4 in Definition 1.

A well known fact for edge expander graphs having roughly equal vertex degrees is that if the value of $\|u_i-u_j\|^2$ averaged over all edges $\{i,j\}$ in the graph is small, then the value of $\|u_i-u_j\|^2$ averaged over all pairs of vertices i,j in the graph is also small. In the proof of Theorem 4, we use the expansion properties of the $\Omega(n)$ sized subset of S coupled with this fact to show that an $\Omega(n)$ sized subset of the vectors $\{u_i:i\in V\}$ must lie in a ball of small diameter; this step is similar to the corresponding step of [30]. We use this to construct an embedding of the graph onto a line, and recover a cut from this embedding using an algorithm of [29]; this step can be viewed as adapting the corresponding step of [30] to vertex expansion.

In the case when $\lambda_1=0$, we show that the lopsided random bipartite graph between $S\setminus T$ and T is an edge expander w.h.p. However, this graph is not close to being regular;

the degrees of the vertices in T would be much higher than the degrees of the vertices in $S \setminus T$. Therefore, we can not directly use the strategy employed in the previous case. But we show that we can use the fact that the measure of $S \setminus T$ under the stationary distribution of the random bipartite graph between $S \setminus T$ and T is $\Omega(1)$, and that the vertices in $S \setminus T$ have roughly equal vertex degrees, to show that $\|u_i - u_j\|^2$ averaged over all pairs of vertices $i, j \in S \setminus T$ is small. From here, we proceed as in the previous case.

1.6 Notation

We denote graphs by $G = (V, E)$, where the vertex set V is identified with $[n] := \{1, 2, \dots n\}$. For any $S \subseteq V$, we denote the induced subgraph on S by $G[S]$. Given $i \in V$ and $T \subseteq V$, define $N_T(i) \stackrel{\text{def}}{=} \{j \in T \ : \ \{i, j\} \in E\}$, and $N(i) = N_V(i)$. We denote $\Delta_T(i) := |N_T(i)|$, and $\Delta(i) = |N(i)|$. For a subgraph $\mathcal{F}$ of G, the degree of i within $\mathcal{F}$ is correspondingly $\Delta_{\mathcal{F}}(i)$.

Given a graph $G = (V, E)$ with a weight function $w : E \to \mathbb{R}_{\geqslant 0}$ on its edges, we define the *weighted* degree of a vertex $i \in V$ as $d(i) := \sum_{j \in N(i)} w_{\{i,j\}}$. In our theorems, following SDP 7, we will be assigning directed weights (or capacities) Y_{ij} to edges $\{i, j\} \in E$, and use $L(Y)$ to denote the Laplacian of G with weights $Y_{ij} + Y_{ji}$ on the edges.

Given the normalized Laplacian $\mathcal{L} = I - D^{-1/2} A D^{-1/2}$, the *spectral gap* of G denoted by λ, is the second-smallest eigenvalue of $\mathcal{L}$.

Typically, for a vector $X \in \mathbb{R}^n$, its i-th component is denoted by X_i, or in rare cases for clarity, by $X(i)$. As in the introduction, we use $\mathbb{1}_S$ for any $S \subseteq V$ to denote the vector in $\mathbb{R}^{|V|}$ having entries $\mathbb{1}_S(i) = 1$, if $i \in S$, and -1 otherwise.

2 Exact Recovery for VBM

2.1 A sufficient condition

In order to prove Theorem 8, we start with the following lemma, which outlines a sufficient condition for integrality of the primal optimal SDP solution. For the proof of this lemma, and all subsequent lemmas in this section, we refer the reader to the full version of the paper.

▶ **Lemma 10.** *For a* VBM$(n, \varepsilon_1, \varepsilon_2, p_1, p_2, c, r, \lambda_1, \lambda_2)$ *instance, if we can find a* $Y \in \mathbb{R}^{n \times n}$ *that satisfies the linear constraints on it (*$Y_{ij} \geqslant 0$ *and* $\sum_j Y_{ij} = 1$*), and in addition has:*
(a) $\forall X \in \mathbb{R}^n$,

$$X^T \left(L(Y)\right) X \geqslant \frac{c'}{n} \left(\sum_{i \in S \setminus T} \sum_{t \in T} (X_i - X_t)^2 + \sum_{i \in S' \setminus T'} \sum_{t \in T'} (X_i - X_t)^2 \right), \tag{2}$$

(b) *For every* $i \in T, j \in T'$, *we have* $Y_{ij} = 1/\Delta_{\mathcal{F}}(i)$ *and* $Y_{ji} = 1/\Delta_{\mathcal{F}(j)}$,
(c) *For every* $i \in T, j \in S \setminus T$ *and* $i \in T', j \in S \setminus T'$, *we have* $Y_{ij} = 0$
where $c' = 8c/(1 - \max\{\varepsilon_1, \varepsilon_2\})$, *then SDP 6 has* (U', η') *as defined in Theorem 8 as its unique optimal solution.*

▶ Remark. Along with the SDP 7 linear constraints on Y, the above conditions ensure that we can extend Y to a feasible dual solution (Y, B, α), that satisfies the positive-semidefiniteness constraint *and* is optimal.

We begin by noting a simple consequence of complementary slackness conditions.

▶ **Lemma 11.** *Let* $M := L(Y) + \alpha \mathbb{1}\mathbb{1}^T - B$ *be constructed using an optimal dual solution* (Y, B, α). *The primal optimal solution is integral and unique if* $\mathbb{1}_S$ *is a unique eigenvector of* M *with eigenvalue* 0.

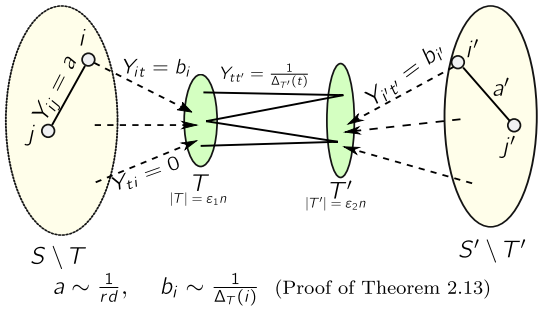

Figure 2 Outline of Y_{ij}'s used in the constructed dual solution.

It is thus sufficient to prove that the conditions in Lemma 10 imply that we can use the given Y to come up with a B and α, such that (Y, B, α) is feasible, *and* $\mathbb{1}_S$ is a unique eigenvector of M with eigenvalue 0. We first find a B (depending on Y) that yields a dual objective value of exactly $4(\varepsilon_1 + \varepsilon_2)n$ and ensures that $\mathbb{1}_S$ is an eigenvector with eigenvalue 0. We use $d_T(i) = \sum_{j \in N(i) \cap T}(Y_{ij} + Y_{ji})$ for the weighted degree of i into $T \subseteq V$.

▶ **Lemma 12.** *Fix some partial candidate dual solution (Y, α). Consider the setting of the diagonal matrix B given by:*

$$B_{ii} = \begin{cases} 2 \cdot d_{T'}(i), & \text{for } i \in T \\ 2 \cdot d_T(i), & \text{for } i \in T' \\ 0, & \text{otherwise} \end{cases} \tag{3}$$

Then $\mathbb{1}_S$ is an eigenvector of M with eigenvalue 0. Furthermore, if (Y, α) is feasible for this B and satisfies condition (c) of Lemma 10, then the dual variable assignment (Y, B, α) is optimal, with objective value $4(\varepsilon_1 + \varepsilon_2)n$.

Thus, at this point, we know how to show that a feasible (Y, α) satisfying the conditions in Lemma 10 can be extended to get the dual variable B that ensures that the primal is integral. It now remains to show that given an assignment to Y that satisfies conditions in Lemma 10, and a B constructed thereof using Lemma 12, we can find an appropriate α so that (Y, B, α) is actually feasible.

The setting of B helps us exploit the following fact in showing that (Y, B, α) is feasible for some α.

▶ **Fact 13.** *If $M \in \mathbb{R}^{n \times n}$ is a symmetric matrix with eigenvector v having eigenvalue 0, then $M \succeq 0$ and $\text{rank}(M) = n - 1 \iff \exists l > 0 \ : \ M + l \cdot vv^T \succ 0$.*

Thus, instead of showing that $M := (L + \alpha \mathbb{1}\mathbb{1}^T - B) \succeq 0$, we use the above fact with $v = \mathbb{1}_S$. By our setting for B, $\mathbb{1}_S$ is an eigenvector of M with eigenvalue 0. We show that there is an α that gives us that $M' := L + \alpha\left(\mathbb{1}\mathbb{1}^T + \mathbb{1}_S\mathbb{1}_S^T\right) - B \succ 0$ (by using condition (a) and (b) of Lemma 10).

This ensures M satisfies Lemma 11, completing the proof of Lemma 10. We leave the details to the full version of the paper.

2.2 Satisfying the sufficient condition

We are now left with the task of assigning appropriate weights Y_{ij} to the edges, so that Lemma 10's conditions are satisfied. Effectively, we only have to find weights within $G[S]$ and

$G[S']$, as Lemma 10 already fixes the rest. First, we recall that for any $X \in \mathbb{R}^n$, $X^T L(Y) X = \sum_{\{i,j\} \in E} (Y_{ij} + Y_{ji})(X_i - X_j)^2$. We drop the argument Y henceforth as it will be clear from context. The following observation is useful to keep in mind:

▶ **Observation 14.** *Given a (Y, B, α) dual solution, that satisfies all but the constraints $\sum_{j \in N(i)} Y_{ij} = 1$, having instead that $\forall i \in V \ : \ \sum_{j \in N(i)} Y_{ij} \leqslant 1$, we can produce a feasible solution (Y', B, α) of the same objective value.*

We will henceforth find values for the dual variable Y satisfying just the weaker constraint $\sum_{j \in N(i)} Y_{ij} \leqslant 1$. We first describe the following instructive case, in order to aid intuition.

▶ **Lemma 15.** *When $G[S]$ and $G[S']$ are complete graphs, there is a constant $\beta < 1$ and weights Y, such that when $\varepsilon \stackrel{\text{def}}{=} \max\{\varepsilon_1, \varepsilon_2\} \leqslant \beta$, the sufficient condition in Lemma 10 is satisfied, and hence the primal SDP is integral.*

Proof. For every pair i, j such that $i \in S \setminus T$ and $t \in T$, we set $Y_{it} = b := \frac{1}{\varepsilon n}$. The Y_{ij}'s within S' are set similarly. Let $Y_{ij} = 0$ for all other edges within $G[S]$, and $G[S']$. The constraint $\sum_{j \in N(i)} Y_{ij} \leqslant 1$ is satisfied as $b \times \Delta_T(i) \leqslant 1 \implies b\varepsilon n \leqslant 1$.

In order to prove integrality, we verify that (2) holds for the chosen value of b. Expanding out the term $X^T L X$ gives:

$$X^T L X \ \geqslant \ b \sum_{\substack{i \in S \setminus T \\ t \in T}} (X_i - X_t)^2 \ + \ b \sum_{\substack{i \in S' \setminus T' \\ t \in T'}} (X_i - X_t)^2 .$$

From the condition in Lemma 10, we get that the primal SDP is integral as long as $bn \geqslant 8c/(1-\varepsilon)$, which is true as long as $\frac{1-\varepsilon}{\varepsilon} > 8c$. This is true for ε being less than a small enough constant. ◀

Let us now consider the general case. We will focus on just S henceforth, as similar arguments will work for S' too, and the feasible solution can be constructed independently for either part. Observe that in contrast to the complete graph above, certain terms are missing in the expansion of $X^T L_{|S} X$: these terms are of the form

$$(X_i - X_t)^2 \qquad \forall i \in S \setminus T, t \in T : i \notin N(t) .$$

One way to recover these terms is to make use of the following observation:

▶ **Fact 16.** *For any $x_1, x_2, \ldots x_{l+1} \in \mathbb{R}$, we have $\sum_{i=1}^{l} (x_i - x_{i+1})^2 \geqslant \frac{1}{l}(x_1 - x_{l+1})^2$*

Flow Routing:

Fact 16 gives us a way to generate terms of the form $(X_i - X_t)^2$ using the edges present in the graph $G[S]$. In particular, we can generate a missing term of the form $(X_i - X_t)^2$, as a sum along a path $P = (i_1 = i, i_2, i_3, \ldots, i_l = t)$ in G of the terms $(X_{i_j} - X_{i_{j+1}})^2$, for every $j \in [l-1]$. Each of these terms occurs in the expansion of $X^T L X$. If we use an amount a of the weight of each edge on $\mathcal{P}$ in doing so, the final term has a coefficient of $\frac{a}{l}$, and this can be seen as i attempting to sending a 'flow' of magnitude a to t via $\mathcal{P}$.

Generating all the missing terms can now be formulated as a flow-routing problem using paths of length at most l (for some fixed l). The flows going from i to t generate the term $(X_i - X_t)^2$. Lemma 10 can therefore be restated as the problem of routing at least $c'l/n$ units of flow from every $i \in S \setminus T$ to $t \in T$. The constraint on the (directed) flow edges out of i is determined by the values Y_{ij}. The capacity of the edge $\{i, j\}$ in the direction $i \to j$ is

Y_{ij}, and the outdegree constraint states that every vertex can push out at most one unit of flow in total. Furthermore, a flow of 'a' units travelling along a path of distance l to reach t finally contributes only a/l, due to Fact 16. We state this idea formally below.

▶ **Lemma 17** (Flow routing problem). *Suppose we are given $G[S]$ and $G[S']$ with a feasible assignment Y for the edges. Consider a directed version of $G[S]$, where every edge $\{i,j\} \in E$ is replaced by the directed edges (i,j) and (j,i) with capacities Y_{ij} and Y_{ji} respectively. If for some $l \in \mathbb{N}$, and for every $i \in S \setminus T$ and $t \in T$, we can route a flow of $c'l/n$ from $i \to t$ using paths of length at most l in $G[S]$ (and similarly for $G[S']$), while obeying the (directed) capacity constraints on the edges, then we have:*

$$X^T L X \geqslant \frac{c'}{n}\left(\sum_{i\in S\setminus T}\sum_{t\in T}(X_i - X_t)^2 + \sum_{i\in S'\setminus T'}\sum_{t\in T'}(X_i - X_t)^2\right) \qquad \forall X \in \mathbb{R}^n$$

However, simply routing flows satisfying the above in an arbitrary $G[S]$ (or $G[S']$) turns out to be impossible. We carefully exploit the spectral expansion of $G[S \setminus T]$ (and $G[S' \setminus T']$), along with the randomness on the graph in $S \setminus T \times T$ while routing our flows to find our assignment for Y. Figure 2 summarizes briefly the dual values for Y that we finally use. We leave the details for the full version of the paper.

Related Version Due to size constraints, many technical details are omitted. These details will be included in a full version and can already be found in the preprint [22] (`https://arxiv.org/abs/1707.06855`) of this article.

Acknowledgements I am indebted to my advisor Martin Dietzfelbinger for drawing my attention to this problem as well as for providing a constant stream of useful literature recommendations. When discussing a preliminary version of this work at the Dagstuhl Seminar 17181 on Theory and Applications of Hashing, Michael Mitzenmacher and Konstantinos Panagiotou provided useful comments.

1 Introduction

In **standard cuckoo hashing** [20], a set $X = \{x_1, \dots, x_{cn}\}$ of objects (possibly with associated data) from a universe $\mathcal{U}$ is to be stored in a hash table indexed by $V = \{0, \dots, n-1\}$ of size n such that each object x_i resides in one of two associated memory locations $h_1(x_i), h_2(x_i)$, given by hash functions $h_1, h_2 : \mathcal{U} \to V$. In most theoretic works, these functions are modelled as fully random functions, selected uniformly and independently from $V^{\mathcal{U}}$.

The load parameter $c \in [0, 1]$ indicates the desired space efficiency, i.e. the ratio between objects and allocated table positions. Whether or not a valid placement of the objects in the table exists is well predicted by whether c is above or below the *threshold* $c^* = \frac{1}{2}$: If $c \leq c^* - \varepsilon$ for arbitrary $\varepsilon > 0$, then a placement exists with high probability (whp), i.e. with probability approaching 1 as n tends to infinity, and if $c \geq c^* + \varepsilon$ for $\varepsilon > 0$, then no placement exists whp.

If a placement is found, we obtain a dictionary data structure representing $X \subseteq \mathcal{U}$. To check whether an object $x \in U$ resides in the dictionary (and possibly retrieve associated data), only the memory locations $h_1(x)$ and $h_2(x)$ need to be computed and searched for x. Combined with results facilitating swift creation, insertion and deletion, standard cuckoo hashing has decent performance when compared to other hashing schemes at load factors around $\frac{1}{3}$ [20].

Several generalisations have been studied that allow trading rigidity of the data structure – and therefore performance of lookup operations – for load thresholds closer to 1.

- In ***k*-ary cuckoo hashing**, due to Fotakis et al. [8], a general number $k \geq 2$ of hash functions is used.
- Dietzfelbinger and Weidling [6] propose partitioning the table into $\frac{n}{\ell}$ contiguous **blocks of size ℓ** and assign two random blocks to each object via the two hash functions, allowing an object to reside anywhere within those blocks.
- By **windows of size ℓ** we mean the related idea – called "cuckoo-lp" in [6] – where x may reside anywhere in the intervals $[h_1(x), h_1(x) + \ell)$ and $[h_2(x), h_2(x) + \ell)$ (all indices understood modulo n). Compared to the block variant, the values $h_1(x), h_2(x) \in V$ need not be multiples of ℓ, so the possible intervals do not form a partition of V.

The overall performance of a cuckoo hashing scheme is a story of multidimensional trade-offs and hardware dependencies, but based on experiments in [6, 17] roughly speaking, the following empirical claims can be made:

- k-ary cuckoo hashing for $k > 2$ is slower than the other two approaches. This is because lookup operations trigger up to k evaluations of hash functions and k random memory accesses, each likely to result in a cache fault. In the other cases, only the number of key comparisons rises, which are comparatively cheap.
- Windows of size ℓ offer a better tradeoff between worst-case lookup times and space efficiency than blocks of size ℓ.

Although our results are oblivious of hardware effects, they support the second empirical observation from a mathematical perspective.

1.1 Previous Work on Thresholds

Precise thresholds are known for k-ary cuckoo hashing [4, 12, 10], cuckoo hashing with blocks of size ℓ [7, 3], and the combination of both, i.e. k-ary cuckoo hashing with blocks of size ℓ with $k \geq 3, \ell \geq 2$ [9]. The techniques in the cited papers are remarkably heterogeneous and often specific to the cases at hand. Lelarge [18] managed to unify the above results using techniques from statistical physics that, perhaps surprisingly, feel like they grasp more directly at the core phenomena. Generalising further, Leconte, Lelarge, and Massoulié [15] solved the case where each object must occupy $j \in \mathbb{N}$ incident table positions, $r \in \mathbb{N}$ of which may lie in the same block (see also [13]).

Lehman and Panigrahy [17] showed that, asymptotically, the load threshold is $1 - (2/e + o_\ell(1))^\ell$ for cuckoo hashing with blocks of size ℓ and $1 - (1/e + o_\ell(1))^{1.59\ell}$ in the case of windows, with no implication for small constant ℓ. Beyer [2] showed in his master's thesis that for $\ell = 2$ the threshold is at least 0.829 and at most 0.981. To our knowledge, this is an exhaustive list of published work concerning windows.

In a spirit similar to cuckoo hashing with windows, Porat and Shalem [21] analyse a scheme where memory is partitioned into pages and a bucket of size k is a choice of k memory positions from the same page (not necessarily contiguous). The authors provide rigorous lower bounds on the corresponding thresholds as well as empirical results.

1.2 Our Contribution

We provide precise thresholds for k-ary cuckoo hashing with windows of size ℓ for all $k, \ell \geq 2$. In particular this solves the case of $k = 2$ left open in [6, 17]. Note the pronounced improvements in space efficiency when using windows over blocks, for instance in the case of $k = \ell = 2$, where the threshold is at roughly 96.5% instead of roughly 89.7%.

Formally, for any $k, \ell \geq 2$, we identify real analytic functions $f_{k,\ell}$, $g_{k,\ell}$, such that for $\gamma_{k,\ell} = \inf_{\lambda>0}\{f_{k,\ell}(\lambda) \mid g_{k,\ell}(\lambda) < 0\}$ we have

▶ **Main Theorem.** *The threshold for k-ary cuckoo hashing with windows of size ℓ is $\gamma_{k,\ell}$, in particular for any $\varepsilon > 0$,*

(i) *if $c > \gamma_{k,\ell} + \varepsilon$, then no valid placement of objects exists whp and*

(ii) *if $c < \gamma_{k,\ell} - \varepsilon$, then a valid placement of objects exists whp.*

While $f_{k,\ell}$ and $g_{k,\ell}$ are very unwieldy, with ever more terms as ℓ increases, numerical aproximations of $\gamma_{k,\ell}$ can be attained with mathematics software. We provide some values in Table 1.

1.3 Methods

The obvious methods to model cuckoo hashing with windows either give probabilistic structures with awkward dependencies or the question to answer for the structure follows awkward rules. Our first non-trivial step is to transform a preliminary representation into a hypergraph with n vertices, cn uniformly random hyperedges of size k, an added deterministic cycle, and a question strictly about the orientability of this hypergraph.

In the new form, the problem is approachable by a combination of belief propagation methods and the objective method [1], adapted to the world of hypergraph orientability by Lelarge [18] in his insightful paper. The results were further strengthened by a Theorem in [15], which we apply at a critical point in our argument.

As the method is fundamentally about approximate sizes of incomplete orientations, it leaves open the possibility of $o(n)$ unplaced objects; a gap that can be closed in an afterthought with standard methods.

Table 1 Some thresholds $c_{k,\ell}$ as obtained by [20, 3, 7, 4, 12, 11, 9] and values of $\gamma_{k,\ell}$ as obtained from our main theorem.
In both tables, the line for $\ell = 1$ corresponds to plain k-ary cuckoo hashing, reproduced here for comparison.

Thresholds $c_{k,\ell}$ for k-ary cuckoo hashing with blocks of size ℓ:

1.4 Further Discussion

In the full version of this paper, we touch on three further issues that complement our results but are somewhat detached from our main theorem.

Numerical approximations of the thresholds. We explain how mathematics software can be used to get approximations for the values $\gamma_{k,\ell}$, which have been characterised only implicitely.

Speed of convergence. We provide experimental results with finite table sizes to demonstrate how quickly the threshold behaviour emerges.

Constructing orientations We examine the LSA algorithm by Khosla for insertion of elements, adapted to our hashing scheme. Experiments suggest an expected constant runtime per element as long as the load is bounded away from the threshold, i.e. $c < \gamma_{k,\ell} - \varepsilon$ for some $\varepsilon > 0$.

2 Definitions and Notation

A cuckoo hashing scheme specifies for each object $x \in X$ a set $A_x \subset V$ of table positions that x may be placed in. For our purposes, we may identitfy x with A_x. In this sense, $H = (V, X)$ is a hypergraph, where table positions are vertices and objects are hyperedges. The task of placing objects into admissible table positions corresponds to finding an *orientation* of H, which assigns each edge $x \in X$ to an incident vertex $v \in x$ such that no vertex has more than one edge assigned to it. If such an orientation exists, H is *orientable*.

We now restate the hashing schemes from the introduction in this hypergraph framework, switching to letters e (and E) to refer to (sets of) edges. We depart in notation, but not in substance, from definitions given previously, e.g. [8, 5, 17]. Illustrations are available in Figure 1.

Concerning ***k*-ary cuckoo hashing** the hypergraph is given as:

$$H_n = H^k_{n,cn} := (\mathbb{Z}_n, E = \{e_1, e_2, \dots, e_{cn}\}), \quad \text{for } e_i \leftarrow \tbinom{\mathbb{Z}_n}{k}, \tag{1}$$

where $\mathbb{Z}_n = \{0, 1, \dots, n-1\}$ and for a set S and $k \in \mathbb{N}$ we write $e \leftarrow \binom{S}{k}$ to indicate that $e = \{s_1, s_2, \dots, s_k\}$ is obtained by picking $s_1, \dots, s_k$ independently and uniformly at random from S.

There is a subtle difference to picking e uniformly at random from $\binom{S}{k}$, the set of all k-subsets of S, as the elements $s_1, \dots, s_k$ need not be distinct. We therefore understand e as a multiset. Also, we may have $e_i = e_j$ for $i \neq j$, so E is a multiset as well.[1]

Assuming the table size n is a multiple of ℓ, ***k*-ary cuckoo hashing with blocks of size ℓ** is modelled by the hypergraph

$$B_n = B^{k,\ell}_{n,cn} := (\mathbb{Z}_n, \{e'_1, e'_2, \dots, e'_{cn}\}), \quad \text{where } e'_i = \bigcup_{j \in e_i} [j\ell, (j+1)\ell) \text{ and } e_i \leftarrow \tbinom{\mathbb{Z}_{n/\ell}}{k}, \tag{2}$$

that is, each hyperedge is the union of k blocks chosen uniformly at random from the set of all blocks, which are the n/ℓ intervals of size ℓ in $\mathbb{Z}_n$ that start at a multiple of ℓ. Note that for $\ell = 1$ we recover H_n.

Similarly, ***k*-ary cuckoo hashing with windows of size ℓ** is modelled by

$$W_n = W^{k,\ell}_{n,cn} := (\mathbb{Z}_n, \{e'_1, e'_2, \dots, e'_{cn}\}), \quad \text{where } e'_i = \bigcup_{j \in e_i} [j, j+\ell) \text{ and } e_i \leftarrow \tbinom{\mathbb{Z}_n}{k}, \tag{3}$$

that is, each hyperedge is the union of k windows chosen uniformly at random from the set of all windows, which are the n intervals of size ℓ in $\mathbb{Z}_n$, this time without alignment

[1] While our choice for the probability space is adequate for cuckoo hashing and convenient in the proof, such details are inconsequential. Choosing H_n uniformly from the set of all hypergraphs with *cn distinct* edges all of which contain k *distinct* vertices would be equivalent for our purposes.

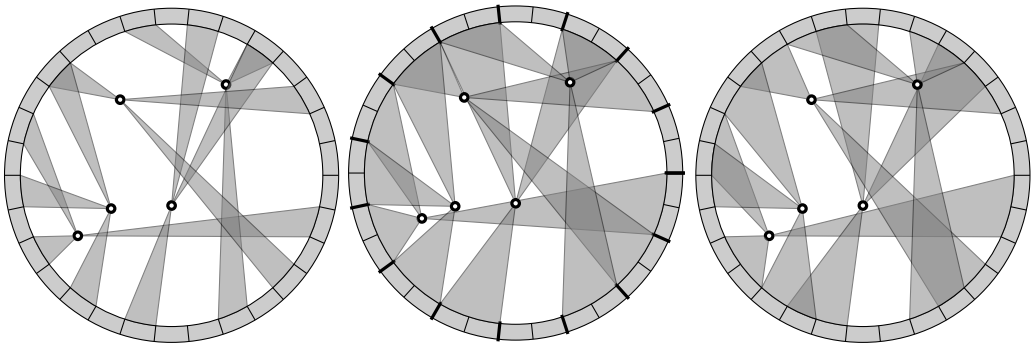

Figure 1 Drawing of possible outcomes for the hypergraphs H_n, B_n and W_n (modelling k-ary cuckoo hashing plain / with blocks / with windows) for $n = 30$, $c = \frac{1}{6}$, $k = 3$ and $\ell = 2$ (ℓ only for B and W). Each edge is drawn as a point and connected to all incident table cells, which are arranged in a circle. In the case of B, thick lines indicate the borders between blocks.

restriction. Note that intervals wrap around at the ends of the set $\{0, \dots, n-1\}$ with no awkward "border intervals". Again, for $\ell = 1$ we recover H_n.

3 Outline of the Proof

Step 1: A tidier problem. The elements of an edge e of B_n and W_n are not independent, as e is the union of k intervals of size ℓ. This poorly reflects the actual tidiness of the probabilistic object. We may obtain a model with independent elements in edges, by switching to a more general notion of what it means to orient a hypergraph.

Formally, given a weighted hypergraph $H = (V, E, \eta)$ with weight function $\eta : V \cup E \to \mathbb{N}$, an *orientation* μ of H assigns to each pair (e, v) of an edge and an incident vertex a number $\mu(e, v) \in \mathbb{N}_0$ such that

$$\forall e \in E\colon \sum_{v \in e} \mu(e, v) = \eta(e), \text{ and } \forall v \in V\colon \sum_{e \ni v} \mu(e, v) \leq \eta(v). \tag{4}$$

We will still say that an edge e *is oriented to* a vertex v (possibly several times) if $\mu(e, v) > 0$. One may be inclined to call $\eta(v)$ a *capacity* for $v \in V$ and $\eta(e)$ a *demand* for $e \in E$, but we use the same letter in both cases as the distinction is dropped later anyway.

Orientability of H, B and W from earlier is also captured in the generalised notion with implicit vertex weights of $\eta \equiv 1$.

A simplified representation of B_n is straightforward to obtain. We provide it mainly for illustration purposes, see Figure 2(a):

$$\hat{B}_n := \hat{B}^{k,\ell}_{n,cn} := (\mathbb{Z}_{n/\ell}, \{e_1, e_2, \dots, e_{cn}\}, \eta), \quad \text{where } e_i \leftarrow \tbinom{\mathbb{Z}_{n/\ell}}{k} \tag{5}$$
$$\text{and } \eta(v) = \ell \text{ for } v \in \mathbb{Z}_{n/\ell} \text{ and } \eta(e_i) = 1 \text{ for } 1 \leq i \leq cn.$$

In $\hat{B}_n$, each group of ℓ vertices of B_n representing one block is now contracted into a single vertex of weight ℓ and edges contain k independent vertices representing blocks instead of $k\ell$ dependent vertices. It is clear that B_n is orientable if and only if $\hat{B}_n$ is orientable.

In a similar spirit we identify a transformed version $\hat{W}_n$ for W_n, but this time the details are more complicated as the vertices have an intrinsic linear geometry, whereas B_n featured essentially an unordered collection of internally unordered blocks. The *ordinary edges* in $\hat{W}_n$

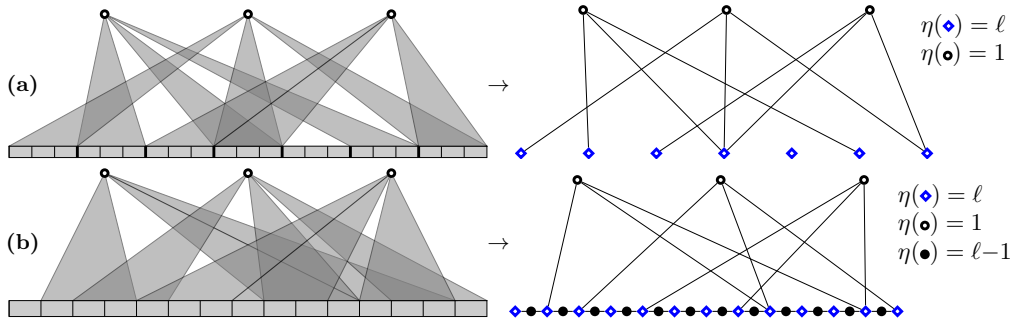

Figure 2 (a) In k-ary cuckoo hashing with blocks of size ℓ (here $k = \ell = 3$), we can contract each block into a single vertex of weight ℓ to obtain a simpler but equivalent representation of the orientation problem.
(b) In k-ary cuckoo hashing with windows of size ℓ, a similar idea can be made to work, but additional helper edges (drawn as $\bullet$) of weight $\ell - 1$ are needed (see Proposition 1).

also have size k instead of size $k\ell$, but we need to introduce additional *helper edges* that capture the linear geometry of $\mathbb{Z}_n$, see Figure 2(b). We define:

$$\begin{aligned}&\hat{W}_n := \hat{W}^{k,\ell}_{n,cn} := (\mathbb{Z}_n, C_n \cup \{e_1, \dots, e_{cn}\}, \eta) \\ &\text{with ordinary edges } e_i \leftarrow \tbinom{\mathbb{Z}_n}{k},\ \text{helper edges } C_n = \{c_i := (i, i+1) \mid i \in \mathbb{Z}_n\}, \\ &\text{and weights } \eta(w) = \ell,\ \eta(h) = \ell - 1,\ \eta(e) = 1 \quad \text{for} \quad w \in \mathbb{Z}_n, h \in C_n, e \in \{e_1, \dots, e_{cn}\}.\end{aligned} \tag{6}$$

Note that formally the graphs W_n and $\hat{W}_n$ are random variables on a common probability space. An outcome $\omega = (e_i)_{1 \le i \le cn}$ from this space determines both graphs.

The following proposition justifies the definition and is proved in the full version of this paper.

▶ **Proposition 1.** *$\hat{W}_n$ is orientable if and only if W_n is orientable.*[2]

An important merit of $\hat{W}_n$ that will be useful in Step 3 is that it is *locally tree-like*, meaning each vertex has a probability of $o(1)$ to be involved in a constant-length cycle. Here, by a cycle in a hypergraph we mean a sequence of distinct edges $e_1, e_2, \dots, e_j$ such that successive edges share a vertex and e_j and e_1 share a vertex.

Note the interesting special case $\hat{W}^{2,2}_{n,cn}$, which is a cycle of length n with cn random chords, unit edge weights and vertices of weight 2. Understanding the orientability thresholds for this graph seems interesting in its own right, not just as a means to understand $W^{2,2}_{n,cn}$.

Step 2: Incidence Graph and Allocations. The next step is by no means a difficult or creative one, we merely perform the necessary preparations needed to apply [15], introducing their concept of an allocation in the process.

This will effectively get rid of the asymmetry between the roles of vertices and edges in the problem of orienting $\hat{W}_n$, by switching perspective in two simple ways. The first is to consider the incidence graph G_n of $\hat{W}_n$ instead of $\hat{W}_n$ itself, i.e. the bipartite graph

$$G_n = G^{k,\ell}_{n,cn} = (\underbrace{C_n}_{A_C} \cup \underbrace{\{e_1, \dots, e_{cn}\}}_{A_R}, \underbrace{\mathbb{Z}_n}_{B}, \underbrace{\text{“}\ni\text{”}}_{E(G_n)}). \tag{7}$$

[2] Formally this should read: The events $\{W_n \text{ is orientable}\}$ and $\{\hat{W}_n \text{ is orientable}\}$ coincide.

We use $A = A_C \cup A_R$ to denote those vertices of G_n that were edges in $\hat{W}_n$ and B for those vertices of G_n that were vertices in $\hat{W}_n$. Vertices $a \in A$ and $b \in B$ are adjacent in G_n if $b \in a$ in $\hat{W}_n$. The weights η on vertices and edges in $\hat{W}_n$ are now vertex weights with $\eta(a_C) = \ell - 1$, $\eta(a_R) = 1$, $\eta(b) = \ell$ for $a_C \in A_C$, $a_R \in A_R$, $b \in B$. The notion of μ being an orientation translates to μ being a map $\mu : E(G_n) \to \mathbb{N}_0$ such that $\sum_{b \in N(a)} \mu(a,b) = \eta(a)$ for all $a \in A$ and $\sum_{a \in N(b)} \mu(a,b) \leq \eta(b)$ for all $b \in B$. Note that vertices from A need to be *saturated* ("$= \eta(a)$" for $a \in A$) while vertices from B need not be ("$\leq \eta(b)$" for $b \in B$). This leads to the second switch in perspective.

Dropping the saturation requirement for A, we say μ is an *allocation* if $\sum_{u \in N(v)} \mu(u,v) \leq \eta(v)$ for all $v \in A \cup B$.

Clearly, any orientation is an allocation, but not vice versa; for instance, the trivial map $\mu \equiv 0$ is an allocation. Let $|\mu|$ denote the size of an allocation, i.e. $|\mu| = \sum_{e \in E} \mu(e)$. By bipartiteness, no allocation can have a size larger than the total weight of A, i.e.

$$\text{for all allocations } \mu\colon |\mu| \leq \eta(A) = \sum_{a \in A} \eta(a) = |A_C| \cdot (\ell - 1) + |A_R| \cdot 1 = (\ell - 1 + c)n$$

and it is precisely the orientations of G_n that have size $\eta(A)$. We conclude:

▶ **Proposition 2.** *Let $M(G_n)$ denote the maximal size of an allocation of G_n. Then*

$$\tfrac{M(G_n)}{n} = \ell - 1 + c \quad \textit{if and only if} \quad G_n \textit{ is orientable} \quad \textit{if and only if} \quad \hat{W}_n \textit{ is orientable.}$$

Step 3: The Limit T of G_n. Reaping the benefits of step 1, we find G_n to have $O(1)$ cycles of length $O(1)$ whp. To capture the local appearance of G_n even more precisely, let the *r-ball* around a vertex v in a graph be the subgraph induced by the vertices of distance at most r from v. Then the r-ball around a random vertex of G_n is distributed, as n gets large, more and more like the r-ball around the root of a random infinite rooted tree $T = T_c^{k,\ell}$. It is distributed as follows, with nodes of types A_C, A_R or B.

- The root of T is of type A_C, A_R or B with probability $\frac{1}{2+c}$, $\frac{c}{2+c}$ and $\frac{1}{2+c}$, respectively.
- If the root is of type A_C, it has two children of type B. If it is of type A_R, it has k children of type B. If it is of type B, it has two children of type A_C and a random number X of children of type A_R, where $X \sim \mathrm{Po}(kc)$. Here $\mathrm{Po}(\lambda)$ denotes the Poisson distribution with parameter λ.
- A vertex of type A_C that is not the root has one child of type B. A vertex of type A_R that is not the root has $k-1$ children of type B.
- A vertex of type B that is not the root has a random number X of children of type A_R, where $X \sim \mathrm{Po}(kc)$. If its parent is of type A_C, then it has one child of type A_C, otherwise it has two children of type A_C.
- Vertices of type A_C, A_R and B have weight $\ell-1$, 1 and ℓ, respectively.

All random decisions should be understood to be independent. A type is also treated as a set containing all vertices of that type. In the full version of this paper we briefly recall the notion of *local weak convergence* and argue that the following holds:

▶ **Proposition 3.** *$(G_n)_{n \in \mathbb{N}} = (G_{n,cn}^{k,\ell})_{n \in \mathbb{N}}$ converges locally weakly to $T = T_c^{k,\ell}$.*

Step 4: The Method of [15]. We are now in a position to apply a powerful Theorem due to Leconte, Lelarge, and Massoulié [15] that characterises $\lim_{n \to \infty} \frac{M(G_n)}{n}$ in terms of solutions to belief propagation equations for T. Put abstractly: The limit of a function of G_n is a function of the limit of G_n. We elaborate on details and deal with the equations in the

full version of this paper. After condensing the results into a characterisation of $\gamma_{k,\ell} \in (0,1)$ in terms of "well-behaved" functions we obtain:

▶ **Proposition 4.**

$$\lim_{n\to\infty} \frac{M(G_{n,cn})}{n} \begin{cases} = \ell - 1 + c & \textit{almost surely} \quad \textit{if } c < \gamma_{k,\ell} \\ < \ell - 1 + c & \textit{almost surely} \quad \textit{if } c > \gamma_{k,\ell} \end{cases}$$

Step 5: Closing the Gap. It is important to note that we are not done, as

$$\lim_{n\to\infty} \frac{M(G_{n,cn})}{n} = \ell - 1 + c \text{ a.s.} \quad \text{does not imply}^3 \quad M(G_{n,cn}) = n \cdot (\ell - 1 + c) \text{ whp.} \quad (8)$$

We still have to exclude the possibility of a gap of size $o(n)$ on the right hand side, imagine for instance $M(G_{n,cn}) = (\ell - 1 + c)n - \sqrt{n}$ to appreciate the difference. In the setting of cuckoo hashing with double hashing (see [16]), it is actually the analogue of this pesky distinction that seems to be in the way of proving precise thresholds for perfect orientability, so we should treat this seriously.

Luckily the line of reasoning by Lelarge [18] can be adapted to our more general setting. The key is to prove that if not all objects can be placed into the hash table, then the configuration causing this problem has size $\Theta(n)$ (and those large overfull structures do not go unnoticed on the left side of (8)).

▶ **Lemma 1.** *There is a constant $\delta > 0$ such that whp no set of $0 < t < \delta n$ vertices in $\hat{W}_n$ (of weight ℓt) induces edges of total weight ℓt or more, provided $c \leq 1$.*

The proof of this Lemma (using first moment methods) and the final steps towards our main theorem are found in the full version of this paper.

4 Conclusion and Outlook

We established a method to determine load thresholds $\gamma_{k,\ell}$ for k-ary cuckoo hashing with (unaligned) windows of size ℓ. In particular, we resolved the cases with $k = 2$ left open in [6, 17], confirming corresponding experimental results by rigorous analysis.

The following four questions may be worthwhile starting points for further research.

Is there more in this method? It is conceivable that there is an insightful simplification of our calculations that yields a less unwieldy characterisation of $\gamma_{k,\ell}$. We also suspect that the threshold for the appearance of the $(\ell+1)$-*core* of $\hat{W}_n$ can be identified with some additional work (for cores see e.g. [19, 14]). This threshold is of interest because it is the point where the simple peeling algorithm to compute an orientation of $\hat{W}_n$ breaks down.

Can we prove efficient insertion? Given our experiments concerning the performance of Khosla's LSA algorithm for inserting elements in our hashing scheme (for details refer to the full version), it seems likely that its runtime is linear. But one could also consider approaches that do not insert elements one by one but build a hash table of load $c = \gamma_{k,\ell} - \varepsilon$ given all elements at once. Something in the spirit of the selfless algorithm [3] or excess degree reduction [4] may offer linear runtime with no performance degradation as ε gets smaller, at least for $k = 2$.

How good is it in practice? This paper does not address the competitiveness of our hashing scheme in realistic practical settings. The fact that windows give higher thresholds than (aligned) blocks for the *same* parameter ℓ may just mean that the "best" ℓ for a particular use case is lower, not precluding the possibility that the associated performance benefit is outweighed by other effects. [6] provide a few experiments in their appendix suggesting slight advantages for windows in the case of unsuccessful searches and slight disadvantages for successful searches and insert operations, in one very particular setup with $k = 2$. Further research could take into account precise knowledge of cache effects on modern machines, possibly using a mixed approach, respecting alignment only insofar as it is favoured by the caches. Ideas from Porat and Shalem [21] could prove beneficial in this regard.

What about other geometries? We analysed linear hash tables where objects are assigned random intervals. One could also consider a square hash table $(\mathbb{Z}_{\sqrt{n}})^2$ where objects are assigned random squares of size $\ell \times \ell$ (with no alignment requirement). We suspect that understanding the thresholds in such cases would require completely new techniques.

Abstract

A fundamental problem in the theory of secure multi-party computation (MPC) is to characterize functions with more than 2 parties which admit MPC protocols with information-theoretic security against passive corruption. This question has seen little progress since the work of Chor and Ishai (2001), which demonstrated difficulties in resolving it. In this work, we make significant progress towards resolving this question in the important case of aggregating functionalities, in which m parties $P_1, \ldots, P_m$ hold inputs $x_1, \ldots, x_m$ and an aggregating party P_0 must learn $f(x_1, \ldots, x_m)$.

We give a necessary condition and a slightly stronger sufficient condition for f to admit a secure protocol. Both the conditions are stated in terms of an algebraic structure we introduce called Commuting Permutations Systems (CPS), which may be of independent combinatorial interest.

When our sufficiency condition is met, we obtain a perfectly secure protocol with minimal interaction, that fits the model of Non-Interactive MPC or NIMPC (Beimel et al., 2014), but without the need for a trusted party to generate correlated randomness. We define Unassisted Non-Interactive MPC (UNIMPC) to capture this variant. We also present an NIMPC protocol for all functionalities, which is simpler and more efficient than the one given in the prior work.

A fundamental problem in the theory of secure multi-party computation (MPC) is to characterize functions with *more than 2 parties* which admit MPC protocols with information-theoretic security against passive corruption. This question has seen little progress since the work of Chor and Ishai [2], which demonstrated difficulties in resolving it.

We report an ongoing work, in which we make significant progress towards resolving this question in the important case of *aggregating functionalities*: In an aggregating functionality, there are m parties $P_1, \ldots, P_m$ with inputs $x_1, \ldots, x_m$ and an aggregating party P_0 must learn $f(x_1, \ldots, x_m)$. Aggregating functionalities form a practically and theoretically important

class. In particular, it has been the subject of an influential line of study that started with the *minimal model for secure computation* of Feige, Kilian and Naor [4]. This model – sometimes refered to as the Private Simultaneous Messages (PSM) model – served as a precursor of important concepts like randomized encodings [5] that have proven useful in a variety of cryptographic applications. Recently, a strengthening of this model, called Non-Interactive MPC (NIMPC) was introduced by Beimel et al. [1], which is closer to standard MPC in terms of the security requirements. In both these models the severe restriction on the communication pattern often leads to simple and elegant protocols. Indeed, for specialized functions (like "Remote-OT" and AND) the original protocols developed in the PSM model [4] can also be shown to be optimal (or very nearly so) in terms of communication and randomness complexity [3, 9]. Similarly, Beimel et al. discovered several elegant NIMPC protocols for special classes of functions [1]. However, these protocols do not directly translate to MPC protocols *as these models include a trusted party* which sends correlated random variables to the parties in a pre-processing phase. The term aggregating functionality was coined in [8].

Our contributions in this work fall into three broad categories: (1) minimal models of computation, (2) algebraic-combinatorial classes of aggregating functionalities, and (3) positive and negative results relating the above two.

Minimal Models of MPC. The previous minimalistic models of MPC – PSM [4] and NIMPC [1] – admit secure protocols for all functions, unlike the full-fledged MPC model. Our minimalistic models (called UNIMPC* and UNIMPC) admit secure protocols only for functions which have secure protocols in the MPC model. While the previous models were proposed in the context of studying communication complexity of information-theoretic MPC, ours is perhaps the first significant model aimed at studying the feasibility of information-theoretic MPC.

UNIMPC stands for *Unassisted NIMPC* and, as the name suggests, removes the assistance from the trusted party in NIMPC: Instead the parties should securely compute the correlated randomness by themselves, in an offline phase. Unlike PSM and NIMPC, which allow trusted parties, *UNIMPC retains the standard security model of MPC*, allowing corruption of any set of parties. While MPC and NIMPC are incomparable in the sense that an MPC protocol does not yield an NIMPC protocol (because of the general communication pattern) and an NIMPC protocol does not yield an MPC protocol (because of the use of a trusted party), UNIMPC could be seen as a common denominator of these two secure computation models.

> *A UNIMPC protocol can be directly interpreted as an MPC protocol as well as an NIMPC protocol.*

UNIMPC* corresponds to a minimalistic version of UNIMPC, with protocols which have a single round of (simultaneous) communication among the parties before they get their inputs, followed by a single message from each party to the aggregator after they receive their input. (UNIMPC allows arbitrarily many rounds of communication prior to receiving inputs.) Understanding the gap between the classes of functionalities with UNIMPC and UNIMPC* protocols is closely related to understanding the power of multiparty secure sampling [7].

Commuting Permutations Systems. We identify an algebraic-combinatorial structure called Commuting Permutations System (CPS) and a sub-class called Commuting Permutation Subgroup Systems (CPSS).

Below S_n denotes the symmetric group – the group of all permutations of n elements.

▶ **Definition 1.** An (n, m)-*Commuting Permutations System* (CPS) is a collection $(X_1, \cdots, X_m)$ where for all $i \in [m]$, $X_i \subseteq S_n$ contains the identity permutation, and for any collection $(\pi_1, \cdots .\pi_m)$ with $\pi_i \in X_i$, and $\rho \in S_m$, $\pi_1 \circ \cdots \circ \pi_m(1) = \pi_{\rho(1)} \circ \cdots \circ \pi_{\rho(m)}(1)$.[1]

It is called an (n, m)-*Commuting Permutation Subgroups System* (CPSS) if each X_i is a subgroup of S_n.

An $(m+1)$-party aggregating functionality $f : X_1 \times \cdots \times X_m \to [n]$ is said to be a *CPS functionality* (resp. CPSS functionality) if $(X_1, \cdots, X_m)$ is an (n, m)-CPS (resp. (n, m)-CPSS) and for all $(\pi_1, \cdots, \pi_m) \in X_1 \times \cdots \times X_m$, $f(\pi_1, \cdots, \pi_m) = (\prod_{i \in [m]} \pi_i)(1)$.

Results. Our main results can be summarized as follows. Writing CPS (or CPSS) for class of functionalities that "embed" into a CPS (respectively, CPSS) functionality, and UNIMPC*, UNIMPC and MPC for classes of functionalities that admit the corresponding secure protocol, we have, for any number of parties,

$$\text{CPSS} \Rightarrow \text{UNIMPC}^* \Rightarrow \text{UNIMPC} \Rightarrow \text{MPC} \Rightarrow \text{CPS}.$$

Note that we leave an intriguing gap between the necessary and sufficient conditions. In particular we leave open the possibility that the set of functionalities with UNIMPC protocols is a strict subset of the set of aggregating functionalities with MPC protocols, and is a strict superset of aggregating functionalities with UNIMPC* protocols. However, these differences disappear for small number of parties: When the number of input parties is 2, we show that UNIMPC* $\Leftrightarrow$ CPS, and when the number of input parties is 3, UNIMPC $\Leftrightarrow$ CPS.

We also obtain a characterization of all "Latin hypercube functionalities" which have an MPC protocol, and show that they all have UNIMPC* protocol. This result relies on the above results, as well as on the existence of NIMPC protocols for every CPS functionality. For the sake of being self-contained we present a simple NIMPC protocol for general functionalities, which in fact turns out to be more efficient than the prior constructions [1, 6].

Our results could be seen as a step towards fully characterizing the functionalities with information-theoretic MPC protocols in various security models. For instance, for characterizing functionalities with UC secure protocols, aggregating functionalities remain the only class to be understood [8], and the sub-classes of aggregating functionalities identified in this work can serve as a starting point for understanding UC security. Similarly, the problem of characterizing symmetric functions (when all parties get the same output) as considered in [2] is still unsolved, but our positive results do present new possibilities there (because a passive-secure MPC protocol for an aggregating functionality can be readily converted into one for a symmetric functionality computing the same function).

Abstract

We consider the Shallow-Light Steiner Network problem from a fixed-parameter perspective. Given a graph G, a distance bound L, and p pairs of vertices $\{(s_i, t_i)\}_{i\in[p]}$, the objective is to find a minimum-cost subgraph G' such that s_i and t_i have distance at most L in G' (for every $i \in [p]$). Our main result is on the fixed-parameter tractability of this problem for parameter p. We exactly characterize the demand structures that make the problem "easy", and give FPT algorithms for those cases. In all other cases, we show that the problem is W[1]-hard. We also extend our results to handle general edge lengths and costs, precisely characterizing which demands allow for good FPT approximation algorithms and which demands remain W[1]-hard even to approximate.

1 Introduction

We study *length-bounded* variants of Steiner Tree and Steiner Forest, which are related to (but still quite different from) *directed* variants. The direct setting assumes that the edges in the graph are directed. While in the length-bounded setting, we typically assume that the input graph and demands are undirected but each demand has a distance bound, and a solution is only feasible if every demand is connected within distance at most the given bound (rather than just being connected). One of the most basic problems of this form is the Shallow-Light Steiner Tree problem (SLST), where the demands $\{(s_i, t_i)\}_{i\in[p]}$ form a star with root $r = s_1 = s_2 = \cdots = s_p$ and there is a global length bound L (so in any feasible solution the distance from r to t_i is at most L for all $i \in [p]$). This problem has been studied extensively [8, 9, 6, 5], but if we generalize this problem to arbitrary demand pairs then we get the Shallow-Light Steiner Network problem, which to the best of our knowledge has received essentially no study.

▶ **Definition 1** (Shallow-Light Steiner Network)**.** Given a graph $G = (V, E)$, a cost function $c : E \to \mathbb{R}^+$, a length function $l : E \to \mathbb{R}^+$, a distance bound L, and p pairs of vertices $\{(s_i, t_i)\}_{i\in[p]}$. The objective of SLSN is to find a minimum cost subgraph $G' = (V, S)$, such that for every $i \in [p]$, there is a path between s_i and t_i in G' with length at most L.

Let H be the graph with vertex set $\{s_1, \ldots, s_p, t_1, \ldots, t_p\}$ and edge set $\{(s_i, t_i)\}_{i\in[p]}$. We call H the *demand graph* of the problem.

Both the directed and the length-bounded settings share a dichotomy between considering either star demands (Directed Steiner Tree (DST)/SLST) or totally general demands (Directed Steiner Network (DSN)/SLSN). But this gives an obvious set of questions: what demand graphs make the problem "easy" (in FPT) and what demand graphs make the problem "hard" (W[1]-hard)? Recently Feldmann and Marx [4] gave a complete characterization for this for DSN, proving that if the demand graph is transitively equivalent to an "almost-caterpillar" then the problem is in FPT, and otherwise the problem is W[1]-hard.

While *a priori* there might not seem to be much of a relationship between the directed and the length-bounded settings, there are multiple folklore results that relate them, usually by means of some sort of layered graph. For example, any FPT algorithm for the DST problem can be turned into an FPT algorithm for SLST (with unit edge lengths) and vice versa. However, such a relationship is not known for more general demand graphs.

In light of these relationships between the directed and the length-bounded settings and the recent results of [4], it is natural to attempt to characterize the demand graphs that make SLSN easy or hard. We solve this problem, giving a complete characterization of easy and hard demand graphs. Informally, we show that SLSN is significantly harder than DSN: the only "easy" demand graphs are stars (in which case the problem is just SLST) and constant-size graphs. Even tiny modifications, like a star with a single independent edge, become W[1]-hard (despite being in FPT for DSN).

Connection to Overlay Routing: SLST and SLSN are particularly interesting due to their connection to overlay routing protocols that use so-called *dissemination graphs* for routing rather than traditional paths. Routing on dissemination graphs allows these systems to be significantly more robust, and a length bound corresponds to a latency bound, which is critical for many applications. Recently, Babay et al. [1] designed and built such a system, and demonstrated that it can achieve significantly greater reliability and timeliness than traditional routing with only a slight increase in cost. Finding good solutions to $2\binom{n}{2}$ different SLST instances and $\binom{n}{2}$ different SLSN instances is a crucial piece of this system (as these are the graphs on which routing happens). The search for fast algorithms for these instances was the main motivation behind this work. We refer the interested reader to [1] for a further discussion of this routing system and how it related to SLSN and SLST.

2 Our Results

We first define SLSN with respect to a class (set) of demand graphs.

▶ **Definition 2.** The Shallow-Light Steiner Network problem with restricted demand graph class $\mathcal{C}$ (SLSN$_\mathcal{C}$) is the SLSN problem with the additional restriction that the demand graph H of the problem must be isomorphic to some graph in $\mathcal{C}$.

We define $\mathcal{C}_\lambda$ as the class of all demand graphs with at most λ edges, and $\mathcal{C}^*$ as the class of all star demand graphs (there is a central vertex called the root, and every other vertex in the demand graph is adjacent to the root and only the root). Our main result is that

these are *precisely* the easy classes: We first prove that SLSN is in XP for parameter p (i.e. solvable in $n^{f(p)}$ time for some function f), which immediately implies that $\text{SLSN}_{\mathcal{C}_\lambda}$ can be solved in polynomial time if λ is a constant. Note that $\text{SLSN}_{\mathcal{C}^*}$ is precisely the SLST problem, for which a folklore FPT algorithm exists, thus $\text{SLSN}_{\mathcal{C}^*}$ (while NP-hard) is in FPT for parameter p. We also show that, for any other class $\mathcal{C}$ (i.e., any class which is not just a subset of $\mathcal{C}^* \cup \mathcal{C}_\lambda$ for some constant λ), the problem $\text{SLSN}_{\mathcal{C}}$ is W[1]-hard for parameter p. In other words, if the class of demand graphs includes arbitrarily large non-stars, then the problem is W[1]-hard parameterized by the number of demands. More formally, we prove the following theorems.

▶ **Theorem 3.** *The unit-length arbitrary-cost* SLSN *problem with parameter p is in* XP*, and it can be solved in $n^{O(p^4)}$ time.*

To prove this theorem, we first prove a structural lemma which shows that the optimal solution must be the union of several lowest cost paths with restricted length (these paths may be between steiner nodes, but we show that there cannot be too many). Then we just need to guess all the endpoints of these paths, as well as all the lengths of these paths. We prove that there are only $n^{O(p^4)}$ possibilities, and the running time is also $n^{O(p^4)}$.

▶ **Theorem 4.** *The unit-length arbitrary-cost* $\text{SLSN}_{\mathcal{C}^*}$ *problem is* FPT *for parameter p.*

As mentioned, $\text{SLSN}_{\mathcal{C}^*}$ is exactly the same as SLST, so we use a folklore reduction between SLST and DST to prove this theorem.

▶ **Theorem 5.** *If $\mathcal{C}$ is a recursively enumerable class, and $\mathcal{C} \not\subseteq \mathcal{C}_\lambda \cup \mathcal{C}^*$ for any constant λ, then* $\text{SLSN}_{\mathcal{C}}$ *is* W[1]*-hard for parameter p, even in the unit-length and unit-cost case.*

All of the above results are in the unit-length setting. We extend both our upper bounds and hardness results to handle arbitrary lengths, but with some extra complications. Even if $p = 1$, with arbitrary lengths and arbitrary costs the SLSN problem is equivalent to the Restricted Shortest Path problem, which is known to be NP-hard [7]. Therefore we can no longer hope for an FPT algorithm (with parameter p). So we change our notion of "easy" from "solvable in FPT" to "arbitrarily approximable in FPT": we show $(1+\varepsilon)$-approximation algorithms for the easy cases, and prove that there is no $\left(\frac{5}{4} - \varepsilon\right)$-approximation algorithm for the hard cases in $f(p) \cdot poly(n)$ time for any function f.

▶ **Theorem 6.** *For any constant $\lambda > 0$, there is a fully polynomial time approximation scheme (*FPTAS*) for the arbitrary-length arbitrary-cost* $\text{SLSN}_{\mathcal{C}_\lambda}$ *problem.*

▶ **Theorem 7.** *There is a $(1+\epsilon)$-approximation algorithm in $O(4^p \cdot poly(\frac{n}{\varepsilon}))$ time for the arbitrary-length arbitrary-cost* $\text{SLSN}_{\mathcal{C}^*}$ *problem.*

Our next theorem is analogous to Theorem 5, but since costs are allowed to be arbitrary we can prove stronger hardness of approximation (under stronger assumptions).

▶ **Theorem 8.** *Assume that the (randomized) Gap-Exponential Time Hypothesis [2] (Gap-ETH) holds. Let $\varepsilon > 0$ be a small constant, and $\mathcal{C}$ be a recursively enumerable class where $\mathcal{C} \not\subseteq \mathcal{C}_\lambda \cup \mathcal{C}^*$ for any constant λ. Then there is no $\left(\frac{5}{4} - \varepsilon\right)$-approximation algorithm in $f(p) \cdot n^{O(1)}$ time for* $\text{SLSN}_{\mathcal{C}}$ *for any function f, even with unit-lengths and polynomial-costs.*

Note that this theorem uses a much stronger assumption (Gap-ETH rather than W[1] $\neq$ FPT), which assumes that there is no (possibly randomized) algorithm running in $2^{o(n)}$ time that can distinguish whether a 3SAT formula is satisfiable or at most a $(1-\varepsilon)$-fraction of its clauses can be satisfied. This enables us to utilize the hardness result for a generalized version of the MCC problem from [3], which will allow us to modify our reduction from Theorem 5 to get hardness of approximation.

Brief Announcement: Zero-Knowledge Protocols for Search Problems

Zvika Brakerski
Weizmann Institute of Science, Rehovot, Israel
zvika.brakerski@weizmann.ac.il

Abstract

We consider natural ways to extend the notion of Zero-Knowledge (ZK) Proofs beyond decision problems. Specifically, we consider *search problems*, and define zero-knowledge proofs in this context as interactive protocols in which the prover can establish the correctness of a solution to a given instance without the verifier learning anything beyond the intended solution, even if it deviates from the protocol.

The goal of this work is to initiate a study of Search Zero-Knowledge (search-ZK), the class of search problems for which such systems exist. This class trivially contains search problems where the validity of a solution can be efficiently verified (using a single message proof containing only the solution). A slightly less obvious, but still straightforward, way to obtain zero-knowledge proofs for search problems is to let the prover send a solution and prove in zero-knowledge that the instance-solution pair is valid. However, there may be other ways to obtain such zero-knowledge proofs, and they may be more advantageous.

In fact, we prove that there are search problems for which the aforementioned approach fails, but still search zero-knowledge protocols exist. On the other hand, we show sufficient conditions for search problems under which some form of zero-knowledge can be obtained using the straightforward way.

1 Introduction

The notion of Zero-Knowledge Proofs (ZK-Proofs) introduced by Goldwasser, Micali and Rackoff [15] is one of the most insightful and influential in the theory of computing. Its tremendous impact came not only from having numerous applications but maybe more importantly from changing the way we think about proofs, communication and how to formalize such intuitive claims as a party "not learning anything" from an interaction. In a nutshell, a ZK-Proof is an interactive proof of some statement, i.e. an interaction between

a prover P and a verifier V with the prover attempting to convince the verifier that some instance x belongs to a language L. In addition to the usual completeness and soundness, in the ZK scenario the prover wants to protect itself from revealing "too much information" to the verifier. Surely the verifier needs to learn that indeed $x \in L$, but nothing else beyond this fact should be revealed. Furthermore, even a *malicious* verifier that does not follow the prescribed protocol should not be able to trick the prover into revealing more information than intended. This intuitive statement is formalized using the *simulation paradigm*, the existence of a simulator machine S that takes an input $x \in L$ and a possibly cheating verifier V^* and samples from the view of V^* in the interaction (P, V^*) (up to negligible statistical or computational distance). Since the view of the verifier can essentially be produced (up to negligible distance) knowing only that $x \in L$, it clearly does not reveal anything beyond this fact.

Our Results. In this work we consider a setting where again the prover is concerned about revealing too much information to the verifier, but now in the context of *search problems*. That is, the prover would like to assist the verifier in learning a solution y to an instance x of some search problem, but would like to limit the verifier's ability to learn anything beyond the intended solution (or distribution of solutions).

While one's first intuition of a search problem is of one where it is efficient to verify a solution (i.e. searching for an NP witness), this is actually not the interesting setting here. In fact, in this case the prover can just send the witness, and the verifier verifies locally, so no additional information beyond the solution is revealed. One example one could consider is the isomorphic vertex problem: given two graphs (G_1, G_2) and a vertex v_1 in G_1, find a vertex v_2 in G_2 that is isomorphic to v_1 under *some* isomorphism.

Our first contribution is to formalize this notion using the simulation paradigm, as follows. We require that the prover for the interactive protocol is associated with a family of distributions $\{Y_x\}_x$ over solutions for each input x, intuitively corresponding to the distribution V is allowed to learn. We require that the view of any verifier can be simulated given only a sample y drawn from Y_x. To reduce the number of free parameters in the definition we propose to associate Y_x with the distribution of solutions output by an interaction of an honest prover with an honest verifier (note that importantly this refers to the distribution of solutions y output by the honest verifier and not to the honest verifier's entire view). Thus the zero-knowledge task becomes to ensure that no verifier (including the honest verifier) learns anything except the honest verifier's prescribed output. In terms of soundness, we require that V either outputs some valid solution for the search problem (if such exists), or rejects, except perhaps with small probability, even when interacting with a malicious prover.

Intuitively one could think that in order to achieve search-ZK, the prover should first sample a solution from Y_x, send it to the verifier and then prove in decision-ZK the validity of the solution (that is, that in a sense search-ZK is reducible to decision-ZK). Indeed almost all examples for protocols we have are roughly of this form. We investigate whether it is possible to provide a protocol of this form for any language in search-ZK, or whether there are some cases where other methods can achieve search-ZK but the aforementioned outline cannot. We define the class prefix-ZK to be the class of problems with protocols as above. We show that prefix-ZK has a complete problem (which we are unable to show for general search-ZK) and we show conditions under which some search-ZK systems can be transformed into prefix-ZK (for the same underlying search problem). Finally, we show that, perhaps counter-intuitively, search-ZK contains problems that are not in prefix-ZK, so at least in that sense the study of search-ZK may not be a derivative of the study of decision-ZK. Interestingly, this separation follows from showing that search-PSPACE *does not contain* search-IP, which may be of independent interest.

Lastly, we discuss the relation between search-ZK and the notion of *pseudo-deterministic* algorithms and protocols presented by Gat and Goldwasser [6] and further explored by Goldreich, Goldwasser, Grossman, Holden and Ron [7, 12, 16, 13, 14]. In a pseudo-deterministic protocol, not only should the distribution Y_x be a singleton y_x, but also the soundness requirement is that a malicious prover cannot make an honest verifier output a solution different from y_x (except with small probability). One of the advantages of pseudo-deterministic protocols is that they allow for soundness amplification for search problems. We show that the isomorphic vertex problem indeed has a pseudo-deterministic search-ZK protocol, suggesting that achieving strong soundness together with strong privacy is possible in some interesting cases.

Related Notions. The first related notion is that of secure multiparty computation (MPC) by Yao [20] and Goldreich, Micali and Wigderson [8]. For the purpose of this work, the relevant setting is of secure *two-party* computation where two parties A, B with inputs x_A, x_B wish to compute values y_A, y_B which depend on both inputs. The privacy requirement is that each party does not learn more than its intended output. It would appear that setting $A = P$, $B = V$, and defining F_B appropriately to output what the verifier is allowed to learn, should result in a search-ZK protocol. However, looking more closely, the complexity of an MPC protocol scales with the complexity of the function F_B, which in general scales with the complexity of the prover's functionality. If the prover's functionality is not in NP, then MPC cannot be used. MPC appears to be useful in the restricted case of computational search-ZK for search problems that can be computed as a function of an NP witness. Our isomorphic vertex problem falls into that category (with the NP witness being an isomorphism), however for isomorphic vertex we have a *statistical* search-ZK protocol. For statistical search-ZK, the MPC methodology does not seem to be useful, since information theoretically secure *two-party* computation is not possible [3, 2].

Another related like of work is concerned with privacy of approximation algorithms, initiated by Feigenbaum et al. [5] and Halevi et al. [17], and further studied by Beimel et al. [1]. The setting in these works is quite different from ours. Their ideal setting is where a solution to some search problem is posted without revealing the input (e.g. output a vertex cover for some graph without revealing the edges of the graphs). The problem arises when solving exactly is hard and an approximation algorithm is used instead. Their goal is to show that the approximate solution does not reveal more information than the exact solution. Note that in this setting there is no soundness requirement (in fact, a client cannot be convinced that a solution is correct since it does not have the input).

Future Directions. Our work is far from being an exhaustive study of search-ZK, and we hope to open the door for additional study. One direction of research is designing search-ZK protocols for other problems of interest, and more importantly general approaches for search-ZK for classes of problems. The question of whether search-ZK has complete problems in the computational and statistical setting remains open. Another intriguing line of inquiry, which may also be helpful for resolving the above, is whether we can translate the extensive body of work on statistical ZK protocols [4, 18, 9, 11, 10, 19] into the search regime.

Abstract

We study variants of locally decodable and locally correctable codes in computationally bounded, adversarial channels, under the assumption that collision-resistant hash functions exist, and with no public-key or private-key cryptographic setup. Specifically, we provide constructions of *relaxed locally correctable* and *relaxed locally decodable codes* over the binary alphabet, with constant information rate, and poly-logarithmic locality. Our constructions compare favorably with existing schemes built under much stronger cryptographic assumptions, and with their classical analogues in the computationally unbounded, Hamming channel. Our constructions crucially employ *collision-resistant hash functions* and *local expander graphs*, extending ideas from recent cryptographic constructions of memory-hard functions.

Introduction

An error-correcting code is a tuple $(\mathsf{Enc}, \mathsf{Dec})$, where a sender encodes a *message* m of k symbols from an alphabet Σ, into a *codeword* c of block-length n, consisting of symbols over the same alphabet, using encoding algorithm $\mathsf{Enc} : \Sigma^k \to \Sigma^n$; a receiver uses decoding algorithm $\mathsf{Dec} : \Sigma^n \to \Sigma^k$ to recover the message m from a received word $w \in \Sigma^n$. Codes with both large *information rate*, defined as k/n, and large *error rate*, which is the tolerable fraction of errors in the received word, are most desirable.

In modern uses of error-correcting codes, one may only need to recover small portions of the message, such as a single bit. Given an index $i \in [n]$, and oracle access to w, a local decoder must make only $q = o(n)$ queries into w, and output the bit m_i. The *locality* of the decoder is defined to be q. Codes that admit such fast decoders are called *locally decodable*

codes (LDCs) [12, 15]. A related notion is that of *locally correctable codes* (LCCs), where the local decoder must output bits of the codeword c, instead of bits of the message m.

Ben-Sasson *et al.* [4] propose the notion of *relaxed locally decodable codes* (RLDCs) as a way to remedy the dramatic tradeoffs of classical LDCs. In this notion the decoding algorithm is allowed to output "$\perp$" sometimes; however, it should not output an incorrect value too often. More formally, given $i \in [k]$, and oracle access to the received word w, which is assumed to be relative close to some codeword $c = \mathsf{Enc}(m) \in \Sigma^n$, the local decoder: (1) outputs m_i if $w = c$; (2) outputs either m_i or $\perp$ with probability 2/3, otherwise; and, (3) the set of indices i such that the decoder outputs m_i (the correct value) with probability 2/3, has size at least $\rho \cdot k$ for some constant $\rho > 0$. The relaxed definition allows them to achieve RLDCs with constant query complexity and blocklength $n = k^{1+\epsilon}$.

Recently, Gur *et al.* [9] introduce the analogous notion of *relaxed locally correctable codes* (RLCCs). The results in [9] obtain significantly better parameters for RLCCs than for classical LCCs; namely, they construct RLCCs with constant query complexity, polynomial block length, and constant error rate, and RLCCs with quasipolynomial query complexity, linear blocklength (constant rate), with the caveat that the error rate is subconstant. These results immediately extend to RLDCs, since their codes are *systematic*, meaning that the initial part of the encoding consists of the message itself.

Computationally bounded, adversarial channels

All the above constructions of local codes assume a channel that may introduce a bounded number of adversarial errors, and the channel has as much time as it needs to decide what positions to corrupt (i.e., the standard Hamming channel). In this work we study RLDCs and RLCCs in the *computationally bounded, adversarial channel* model, introduced by Lipton [13]. In this model we require that the adversary who determines which bits of the codeword to corrupt must run in probabilistic polynomial time. Existing constructions of locally correctable codes in the computationally bounded channel model typically require preliminary trusted setup [14, 10, 11, 7] (e.g., the sender and receiver have established cryptographic keys). By contrast, our results do not require the sender and the receiver to share a secret key for a symmetric cipher, nor do we assume the existence of a public key infrastructure (PKI). Instead our constructions are based on the existence of collision-resilient hash functions, a standard cryptographic assumption. Because the parameters of a collision-resistant hash function are public, *any* party (sender/receiver/attacker) is able to evaluate it.

Our Contributions

We now define our model. Our codes interact with an adversarial channel, so their strength is measured both in their error correction and locality capabilities (as for RLCCs/RLDCs), and in the security they provide against the channel.

▶ **Definition 1.** A *computational adversarial channel* $\mathcal{A}$ with error rate τ is an algorithm that interacts with a local code $(\mathsf{Gen}, \mathsf{Enc}, \mathsf{Dec})$ of rate k/n in rounds, as follows. In each round of the execution, given a security parameter λ,

(1) Generate $s \leftarrow \mathsf{Gen}(1^\lambda)$; s is public, so Enc, Dec, and $\mathcal{A}$ have access to s

(2) The channel $\mathcal{A}$ on input s hands a message x to the sender.

(3) The sender computes $c = \mathsf{Enc}(s, x)$ and hands it back to the channel (in fact, the channel can compute c without this interaction).

(4) The channel $\mathcal{A}$ corrupts at most τn entries of c to obtain a word $w \in \Sigma^n$; w is given to the receiver's Dec with query access, together with a challenge index $i \in [n]$

(5) The receiver outputs $b \leftarrow \mathsf{Dec}^w(s, i)$.

(6) We define $\mathcal{A}(s)$'s *probability of fooling* Dec on this round to be $p_{\mathcal{A},s} = \Pr[b \notin \{\perp, c_i\}]$, where the probability is taken only over the randomness of the $\mathsf{Dec}^w(s, i)$. We say that $\mathcal{A}(s)$ is γ-successful *at fooling* Dec if $p_{\mathcal{A},s} > \gamma$. We say that $\mathcal{A}(s)$ is ρ-successful *at limiting* Dec if $|\mathsf{Good}_{\mathcal{A},s}| < \rho \cdot n$, where $\mathsf{Good}_{\mathcal{A},s} \subseteq [n]$ is the set of indices j such that $\Pr[\mathsf{Dec}^w(s, j) = c_j] > \frac{2}{3}$. We use $\mathsf{Fool}_{\mathcal{A},s}(\gamma, \tau, \lambda)$ (resp. $\mathsf{Limit}_{\mathcal{A},s}(\rho, \tau, \lambda)$) to denote the event that the attacker was γ-successful at fooling Dec (resp. ρ-successful at limiting Dec) on this round.

▶ **Definition 2** ((Computational) Relaxed Locally Correctable Codes (CRLCC))**.** A local code $(\mathsf{Gen}, \mathsf{Enc}, \mathsf{Dec})$ is a $(q, \tau, \rho, \gamma, \mu(\cdot))$-CRLCC *against a class* $\mathbb{A}$ of adversaries, if Dec^w makes at most q queries to w and satisfies the following:

(1) For all public seeds s if $w \leftarrow \mathsf{Enc}(s, x)$ then $\mathsf{Dec}^w(s, i)$ outputs $b = (\mathsf{Enc}(s, x))_i$.

(2) For all $\mathcal{A} \in \mathbb{A}$ we have $\Pr[\mathsf{Fool}_{\mathcal{A},s}(\gamma, \tau, \lambda)] \leq \mu(\lambda)$, where the randomness is taken over the selection of $s \leftarrow \mathsf{Gen}(1^\lambda)$ as well as $\mathcal{A}$'s random coins.

(3) For all $\mathcal{A} \in \mathbb{A}$ we have $\Pr[\mathsf{Limit}_{\mathcal{A},s}(\rho, \tau, \lambda)] \leq \mu(\lambda)$, where the randomness is taken over the selection of $s \leftarrow \mathsf{Gen}(1^\lambda)$ as well as $\mathcal{A}$'s random coins.

When $\mu(\lambda) = 0$ and $\mathbb{A}$ is the set of all (computationally unbounded) channels we say that the code is a (q, τ, ρ, γ)-RLCC. When $\mu(\cdot)$ is a negligible function *and* $\mathbb{A}$ is restricted to the set of all probabilistic polynomial time (PPT) attackers we say that the code is a (q, τ, ρ, γ)-CRLCC (computational relaxed locally correctable code). We say that a code that satisfies conditions 1 and 2 is a *Weak CRLCC*, while a code satisfying 1, 2 and 3 is a *Strong CRLCC*.

Results and Techniques. At a technical level our constructions use *local expander graphs* and *collision resistant hash functions* (CRHF) as main building blocks.

Local expanders have several nice properties that have been recently exploited in the design and analysis of secure memory hard functions [8, 1, 2, 6, 3]. Given a graph $G = (V, E)$ and distinguished subsets $A, B \subseteq V$ of nodes such that A and B are disjoint and $|A| = |B|$, we say that the pair (A, B) contains a δ-*expander* if for all $X \subseteq A$ and $Y \subseteq B$ with $|X| > \delta|A|$ and $|Y| > \delta|B|$, there is an edge connecting X and Y. A δ-*local expander* is a directed acyclic graph G with n nodes $V(G) = \{1, \ldots, n\}$ with the property that for *any* radius $r > 0$ and *any* node $v \geq 2r$ the sets $A = \{v - 2r + 1, \ldots, v - r\}$ and $B = \{v - r + 1, \ldots, v\}$ contain a δ-expander. For any constant $\delta > 0$ it is possible to construct a δ-local expander with the property that $\mathsf{indeg}(G) \in \mathcal{O}(\log n)$ and $\mathsf{outdeg}(G) \in \mathcal{O}(\log n)$ [8, 3].

A CRHF function is a pair (GenH, H) of PPT algorithms, where for security parameter 1^λ, GenH outputs a public seed $s \in \{0,1\}^*$ that is passed as the first input to $H : \{0,1\}^* \times \Sigma^* \to \Sigma^{\ell(\lambda)}$. The *length* of the hash function is $\ell(\lambda)$. (GenH, H) is said to be collision-resistant if any PPT adversary can produce a collision with only negligible probability.

Using local expander graphs we first construct Weak CRLCCs and then Strong CRLCCs against PPT adversaries, under the assumption that CRHF*s* exist. Our constructions are systematic, so they immediately imply the existence of CRLDCs with the same parameters.

▶ **Theorem 3.** *Assuming the existence of a CRHF* (GenH, H) *with length* $\ell(\lambda)$*, there exist constants* $0 < \tau, \rho, \gamma < 1$ *and a negligible function* μ*, such that there exists a constant rate* $(\mathsf{polylog}\, n, \tau, \rho, \gamma, \mu(\cdot))$*-Strong CRLCC of blocklength* n *over the binary alphabet. In particular, if* $\ell(\lambda) = \mathsf{polylog}\, \lambda$ *and* $\lambda \in \Theta(n)$ *then the code is a* $(\mathsf{polylog}\, n, \tau, \rho, \gamma, \mu(\cdot))$*-Strong CRLCC.*

The classical RLCCs of [9] achieve $(\log n)^{\mathcal{O}(\log \log n)}$ query complexity, constant information rate, but subconstant error rate, in the Hamming channel.

Abstract

In this announcement, we show that the classical Maximum Coverage problem (MC) admits a PTAS via local search in essentially all cases where the corresponding instances of Set Cover (SC) admit a PTAS via the local search approach by Mustafa and Ray [7]. As a corollary, we answer an open question by Badanidiyuru, Kleinberg, and Lee [1] regarding half-spaces in $\mathbb{R}^3$ thereby settling the existence of PTASs for essentially all natural cases of geometric MC problems. As an intermediate result, we show a color-balanced version of the classical planar subdivision theorem by Frederickson [5]. We believe that some of our ideas may be useful for analyzing local search in other settings involving a hard cardinality constraint.

1 Introduction and Contribution

Let U be a set of ground elements, $\mathcal{F} \subseteq 2^U$ be a family of subsets of U and k be a positive integer. The Maximum Coverage (MC) problem asks for a k-subset $\mathcal{F}'$ of $\mathcal{F}$ such that the number $|\bigcup \mathcal{F}'|$ of ground elements covered by $\mathcal{F}'$ is maximized. In the closely related Set Cover problem (SC), the goal is to cover all ground elements using as few sets as possible. Both problems are among the most fundamental NP-hard optimization problems and their approximability is in general well understood [3, 4].

We examine the approximability of *geometric* MC problems. Badanidiyuru et al. [1] provided fixed-parameter approximation schemes for the large class of MC problems with bounded VC dimension. The running times of these schemes are polynomial in $|U|$ and $|\mathcal{F}|$ but *exponential* in k, in the VC dimension, and in the reciprocal of the error parameter $\epsilon > 0$. Prior to their work [1], Mustafa and Ray [7] had shown that local search yields PTASs for many geometric SC problems where a naturally defined *exchange graph* between a locally optimum solution and a globally optimum solution is *planar*. While the range of settings solvable by the fixed-parameter approximation approach of Badanidiyuru et al. is in principle even broader, the approach of Mustafa and Ray gives PTASs with strictly polynomial running time while still encompassing essentially all of the natural cases of (unweighted) SC that are not known to be APX-hard. It is thus an interesting question if their approach gives PTASs (with strictly polynomial running times) also for the corresponding MC problems.

A difficulty in carrying over this approach from SC to MC lies in the hard cardinality constraint in MC. For SC, Mustafa and Ray used the planar subdivision theorem by Frederickson [5] to subdivide the above-mentioned planar exchange graph into *small* pieces where each one provides a candidate swap. This subdivision may, however, be arbitrarily unbalanced with respect to the two feasible solutions forming the node set of the exchange graph. Hence a direct application of this approach would be in conflict with the cardinality constraint. Another difficulty comes from the different objective functions of MC and SC and that the analysis of Mustafa and Ray exploits that *all* ground elements are covered.

In this announcement we summarize how to overcome these issues (see [2] for the full version). A key step in our proof is that the pieces of an (unbalanced) subdivision obtained Frederickson's theorem [5] can be recombined in a careful way to obtain a *color-balanced* version of that theorem (see Theorem 2). Also the subsequent analysis of the performance guarantee requires some new ideas because of the other above-mentioned difficulties, and because our colored subdivision cannot not achieve perfect but only rough balance.

In a b-local search for MC, we start with any feasible solution. We perform a profitable *swap* of cardinality b as long as there is one. The timing is polynomial for constant b.

2 Our Results

For a graph G, a subset S of $V(G)$ is an *α-balanced separator* when its removal breaks G into two collections of connected components such that each collection contains at most an α fraction of $V(G)$ where $\alpha \in [\frac{1}{2}, 1)$ and α is a constant. The size of a separator S is the number of vertices it contains. For a non-decreasing sublinear function f, a subgraph-closed class of graphs is said to be *f-separable* if there is an $\alpha \in [\frac{1}{2}, 1)$ such that for any $n > 2$, any n-vertex graph in the class has an α-balanced separator of size at most $f(n)$.

▶ **Definition 1.** A class $\mathcal{C}$ of instances of MC is called *f-separable* if for any two disjoint feasible solutions $\mathcal{F}$ and $\mathcal{F}'$ of any instance in $\mathcal{C}$ there exists an f-separable graph G with node set $\mathcal{F} \cup \mathcal{F}'$ with the following *exchange* property. If there is a ground element $u \in U$

that is covered both by $\mathcal{F}$ and $\mathcal{F}'$ then there exists an edge (S, S') in G with $S \in \mathcal{F}$ and $S' \in \mathcal{F}'$ with $u \in S \cap S'$.

Note that a class of MC instances where each instance admits planar exchange graphs is $O(\sqrt{n})$-separable.

▶ **Theorem 2.** *Let $\mathcal{G}$ be a subgraph-closed f-separable graph class and G be a 2-colored n-vertex graph in $\mathcal{G}$ with color classes Γ_1, Γ_2 such that $|\Gamma_2| \geq |\Gamma_1|$. For any q and $r \ll n$ where r is suitably large, there is an integer $t \in \Theta(\frac{n}{q \cdot r})$ such that V can be partitioned into $t+1$ sets $\mathcal{X}, V_1, \ldots, V_t$ where c_1, c_2 are constants (depending only on f) and there is an integer $q' \in [q, 2q-1]$ satisfying the following properties.*

- **(i)** *$N(V_i) \cap V_j = \emptyset$ for each $i \neq j$ and $\mathcal{X} = \bigcup_i N(V_i)$,*
- **(ii)** *$|V_i| \geq \frac{q' \cdot r}{2}$ and $|V_i| \leq 2 \cdot (q'+1) \cdot r$ for each i,*
- **(iii)** *$|N(V_i)| \leq c_1 \cdot q \cdot f(r)$ for each i (thus, $|\mathcal{X}| \leq \sum_{i=1}^{t} |N(V_i)| \leq \frac{c_2 \cdot f(r) \cdot n}{r}$),*
- **(iv)** *$\left| |V_i \cap \Gamma_1| - \frac{|\Gamma_1|}{|\Gamma_2|} \cdot |V_i \cap \Gamma_2| \right| \leq 4 \cdot r$ for each i.*

▶ **Theorem 3.** *For any non-decreasing strictly sublinear function f, every f-separable class of MC instances (closed under removing elements and sets) admits a PTAS via local search.*

The following theorem describes several cases of MC that can be solved by our approach. Therein, we refer to several maximization versions of classical minimum covering problems (such as Vertex Cover). For example, in Maximum Vertex Cover, we are given a graph G and number k and we want to find a k vertices which *cover* as many edges as possible. The others are defined analogously. For a definition of 1.5D Terrain Guarding we refer to Krohn et al. [6].

▶ **Theorem 4.** *Local search gives a PTAS for:*

(V) *the* Maximum Vertex Cover *problem on f-separable and subgraph-closed graph classes,*

(T) *the* Maximum 1.5D Terrain Guarding *problem.*

and the following classes of MC problems:

(C_1) *the set of ground elements is a set of points in $\mathbb{R}^3$, and the family of subsets is induced by a set of halfspaces in $\mathbb{R}^3$.*

(C_2) *the set of ground elements is a set of points in $\mathbb{R}^2$, and the family of subsets is induced by a set of convex pseudodisks (a set of convex objects where any two objects can have at most two intersections in their boundary).*

and the following Maximum Hitting Set *problems:*

(H_1) *the set of ground elements is a set of points in $\mathbb{R}^2$, and the set of ranges is induced by a set of r-admissible regions (this includes pseudodisks, same-height axis-parallel rectangles, circular disks, translates of convex objects).*

(H_2) *the set of ground elements is a set of points in $\mathbb{R}^3$, and the set of ranges is induced by a set of halfspaces in $\mathbb{R}^3$.*

and Maximum Dominating Set *problems in each of the following graph classes:*

(D_1) *intersection graphs of homothetic copies of convex objects (which includes arbitrary squares, regular k-gons, translated and scaled copies of a convex object).*

(D_2) *non-trivial minor-closed graph classes.*

Abstract

Generating good revenue is one of the most important problems in Bayesian auction design, and many (approximately) optimal dominant-strategy incentive compatible (DSIC) Bayesian mechanisms have been constructed for various auction settings. However, most existing studies do not consider the complexity for the seller to carry out the mechanism. It is assumed that the seller knows "each single bit" of the distributions and is able to optimize perfectly based on the entire distributions. Unfortunately this is a strong assumption and may not hold in reality: for example, when the value distributions have exponentially large supports or do not have succinct representations.

In this work we consider, for the first time, the *query complexity* of Bayesian mechanisms. We only allow the seller to have limited oracle accesses to the players' value distributions, via *quantile queries* and *value queries*. For a large class of auction settings, we prove *logarithmic* lower-bounds for the query complexity for any DSIC Bayesian mechanism to be of any constant approximation to the optimal revenue. For single-item auctions and multi-item auctions with unit-demand or additive valuation functions, we prove *tight* upper-bounds via efficient query schemes, without requiring the distributions to be regular or have monotone hazard rate. Thus, in those auction settings the seller needs to access much less than the full distributions in order to achieve approximately optimal revenue.

1 Introduction

An important problem in Bayesian mechanism design is to design auctions that (approximately) maximize the seller's expected revenue. More precisely, in a Bayesian multi-item auction a seller has m heterogenous items to sell to n players. Each player i has a private value for each item j, v_{ij}; and each v_{ij} is independently drawn from some prior distribution $\mathcal{D}_{ij}$. When the prior distribution $\mathcal{D} \triangleq \times_{ij}\mathcal{D}_{ij}$ is of *common knowledge* to both the seller and the players, optimal Bayesian incentive-compatible (BIC) mechanisms have been discovered for various auction settings [16, 11, 4, 5], where all players reporting their true values forms a Bayesian Nash equilibrium. When there is no common prior but the seller knows $\mathcal{D}$, many (approximately) optimal dominant-strategy incentive-compatible (DSIC) Bayesian mechanisms have been designed [16, 17, 7, 14, 19, 6], where it is each player's *dominant strategy* to report his true values.

However, the *complexity* for the seller to carry out such mechanisms is largely unconsidered in the literature. Most existing Bayesian mechanisms require that the seller has full access to the prior distribution $\mathcal{D}$ and is able to carry out all required optimizations based on $\mathcal{D}$, so as to compute the allocation and the prices. Unfortunately the seller may not be so knowledgeable or powerful in real-world scenarios. If the supports of the distributions are exponentially large (in m and n), or if the distributions are continuous and do not have succinct representations, it is hard for the seller to write out "each single bit" of the distributions or precisely carry out arbitrary optimization tasks based on them. Even with a single player and a single item, when the value distribution is irregular, computing the optimal price in time that is much smaller than the size of the support is not an easy task. Thus, a natural and important question to ask is *how much the seller should know about the distributions in order to obtain approximately optimal revenue.*

In this work we consider, for the first time, the *query complexity* of Bayesian mechanisms. In particular, the seller can only access the distributions by making oracle queries. Two types of queries are allowed, *quantile queries* and *value queries*. That is, the seller queries the oracle with specific quantiles (respectively, values), and the oracle returns the corresponding values (respectively, quantiles) in the underlying distributions. These two types of queries happen a lot in market study. Indeed, the seller may wish to know what is the price he should set so that half of the consumers would purchase his product; or if he sets the price to be 200 dollars, how many consumers would buy it. Another important scenario where such queries naturally come up is in databases. Indeed, although the seller may not know the distribution, some powerful institutes, say the Office for National Statistics, may have such information figured out and stored in its database. As in most database applications, it may be neither necessary nor feasible for the seller to download the whole distribution to his local machines. Rather, he would like to access the distribution via queries to the database. Other types of queries are of course possible, and will be considered in future works.

In this work we focus on *non-adaptive* queries. That is, the seller makes all oracle queries simultaneously, before the auction starts. This is also natural in both database and market study scenarios, and adaptive queries will be considered in future works.

2 Main Results

We would like to understand both lower- and upper-bounds for the query complexity of approximately optimal Bayesian auctions. In this work, we mainly consider three widely studied settings: single-item auctions and multi-item auctions with unit-demand or additive valuation functions. Our main results are summarized in Table 1.

Table 1 Our main results. Here $h(\cdot) < 1$ is the tail function in the small-tail assumptions. For single-item auctions, the revenue is a $(1+\epsilon)$-approximation to the optimal BIC revenue, with ϵ sufficiently small. For multi-item auctions with unit-demand or additive valuation functions, the revenue is a c-approximation for some constant c.

	Query Complexity	Distributions		
		Bounded in $[1, H]$		Unbounded & Small Tail
Auctions	Single-Item	$\Theta(n\epsilon^{-1}\log H)$		$O(-n\epsilon^{-1}\log h(\frac{2\epsilon}{3(1+\epsilon)}))$
	Unit-Demand	$\forall c > 1$: $\Omega(\frac{mn\log H}{\log c})$	$\forall c > 24$: $O(\frac{mn\log H}{\log(c/24)})$	$\forall c > 24$: $O(-\frac{mn\log h(\frac{2c-48}{3c})}{\log(c/24)})$
	Additive	$\forall c > 1$: $\Omega(\frac{mn\log H}{\log c})$	$\forall c > 8$: $O(\frac{mn\log H}{\log(c/8)})$	$\forall c > 8$: $O(-\frac{m^2 n\log h(\frac{c-8}{10c})}{\log(c/8)})$
	Single-Item	Regular Distributions: $\Omega(n\epsilon^{-1})$, $O(n\epsilon^{-1}\log\frac{n}{\epsilon})$		

Note that we allow arbitrary unbounded distributions that satisfy *small-tail assumptions*, which means the expected revenue generated from the "tail" of the distributions is negligible compared to the optimal revenue. Similar assumptions are widely adopted in sampling mechanisms [18, 12], to deal with irregular distributions with unbounded supports. Since distributions with bounded supports automatically satisfy the small-tail assumptions, the lower-bounds listed for the former apply to the latter as well.

Also note that our lower- and upper-bounds on query complexity are *tight* for bounded distributions. In the full version of the paper [9], we show that our lower-bounds allow the seller to make both value and quantile queries, and apply to any multi-player multi-item auctions where each player's valuation function is *succinct sub-additive*. The lower-bounds also allow randomized queries and randomized mechanisms.

For the upper-bounds, all our query schemes are deterministic and only make one type of queries: value queries for bounded distributions and quantile queries for unbounded ones. We show that our schemes, despite of being very efficient, only loses a small fraction of revenue compared with the cases where the seller has full access to the distributions.

3 Discussion and Future Directions

In the full version, we will elaborate on the connections between our work and related studies. For example, a closely related area is sampling mechanisms [10, 13, 15, 12, 3]. It assumes that the seller does not know $\mathcal{D}$ but observes independent samples from $\mathcal{D}$ before the auction begins. The *sample complexity* measures how many samples the seller needs so as to obtain a good approximation to the optimal Bayesian revenue. Our results show that query complexity can be exponentially smaller than sample complexity: the former is *logarithmic* in the "size" of the distributions, while the latter is known to be polynomial. We will also discuss other related studies such as [2, 1, 3, 8].

Finally, we point out some interesting further directions. As mentioned, we focus on non-adaptive queries in this work. One can imagine more powerful mechanisms using *adaptive* queries, where the seller's later queries depend on the oracle's responses to former ones. It is intriguing to design approximately optimal Bayesian mechanisms with lower query complexity using adaptive queries, or prove that even with such queries, the query complexity cannot be much better than our lower-bounds. Another interesting direction is when the answers of the oracle contain noise. In this case, the distributions learnt by the seller may be within a small distance from the "true distributions" defined by oracle answers without noise. It would be interesting to design mechanisms to handle such noise.

Abstract

We show that a broad class of $(+, \diamond)$ vector products (for binary integer functions $\diamond$) are equivalent under one-to-polylog reductions to the computation of the Hamming distance. Examples include: the dominance product, the threshold product and ℓ_{2p+1} distances for constant p. Our results imply equivalence (up to $\operatorname{poly}\log n$ factors) between complexity of computation of All Pairs: Hamming Distances, ℓ_{2p+1} Distances, Dominance Products and Threshold Products. As a consequence, Yuster's (SODA'09) algorithm improves not only Matoušek's (IPL'91), but also the results of Indyk, Lewenstein, Lipsky and Porat (ICALP'04) and Min, Kao and Zhu (COCOON'09). Furthermore, our reductions apply to the pattern matching setting, showing equivalence (up to $\operatorname{poly}\log n$ factors) between pattern matching under Hamming Distance, ℓ_{2p+1} Distance, Dominance Product and Threshold Product, with current best upperbounds due to results of Abrahamson (SICOMP'87), Amir and Farach (Ann. Math. Artif. Intell.'91), Atallah and Duket (IPL'11), Clifford, Clifford and Iliopoulous (CPM'05) and Amir, Lipsky, Porat and Umanski (CPM'05). The resulting algorithms for ℓ_{2p+1} Pattern Matching and All Pairs ℓ_{2p+1}, for $2p+1 = 3, 5, 7, \ldots$ are new.

Additionally, we show that the complexity of AllPairsHammingDistances (and thus of other aforementioned AllPairs- problems) is within $\operatorname{poly}\log n$ from the time it takes to multiply matrices $n \times (n \cdot d)$ and $(n \cdot d) \times n$, each with $(n \cdot d)$ non-zero entries. This means that the current upperbounds by Yuster (SODA'09) cannot be improved without improving the sparse matrix multiplication algorithm by Yuster and Zwick (ACM TALG'05) and vice versa.

1 Introduction

Many classical algorithmic problems received new attention when formulated as algebraic problems. In pattern matching we can define a similarity score between two strings and ask for this score between the pattern $\mathbf{P}$ of length m and every m-substring of the text $\mathbf{T}$ of length $n \geq m$. For example, scores of Hamming distance or L_1 distance between numerical strings generalize the classical pattern matching. All those problems share an additive structure, i.e. for an input pattern $\mathbf{P}$ and text $\mathbf{T}$, the score vector $\mathbf{O}$ is such that $\mathbf{O}[i] = \sum_j \mathbf{P}[j] \diamond \mathbf{T}[i+j]$

Table 1 Summary of different score functions and the corresponding problems. $\mathbf{1}[\varphi]$ is 1 iff φ and 0 otherwise.

Name	Score function	Pattern Matching problem	All Pairs problem
Hamming	$\mathbf{1}[x \neq y]$	$\mathbf{O}[i] = \lvert\{j : \mathbf{P}[j] \neq \mathbf{T}[i+j]\}\rvert$	$O[i][j] = \lvert\{k : \mathbf{A}_i[k] \neq \mathbf{B}_j[k]\}\rvert$
Dominance	$\mathbf{1}[x \leq y]$	$\mathbf{O}[i] = \lvert\{j : \mathbf{P}[j] \leq \mathbf{T}[i+j]\}\rvert$	$O[i][j] = \lvert\{k : \mathbf{A}_i[k] \leq \mathbf{B}_j[k]\}\rvert$
δ-Threshold	$\mathbf{1}[\lvert x-y\rvert \geq \delta]$	$\mathbf{O}[i] = \lvert\{j : \lvert\mathbf{P}[j] - \mathbf{T}[i+j]\rvert > \delta\}\rvert$	$O[i][j] = \lvert\{k : \lvert\mathbf{A}_i[k] - \mathbf{B}_j[k]\rvert > \delta\}\rvert$
ℓ_1 distance	$\lvert x-y\rvert$	$\mathbf{O}[i] = \sum_j \lvert\mathbf{P}[j] - \mathbf{T}[i+j]\rvert$	$O[i][j] = \sum_{k=1}^{n} \lvert\mathbf{A}_i[k] - \mathbf{B}_j[k]\rvert$

for some binary function $\diamond$. Just as those pattern matching generalizations are based on *convolution*, there is a family of problems based on *matrix multiplication*, varying in flavour according to the vector product used. There, we are given two matrices A and B and the output is the matrix $O[i][j] = \sum_k A[i][k] \diamond B[k][j]$. This is equivalent to the computation of all pairwise $(+, \diamond)$-vector products for two vector families, the so called AllPairs- problems. For a certain class of score functions, pattern matching generalizations admit independently algorithms of identical complexity $\mathcal{O}(n\sqrt{m \log m})$ (c.f. [1–3, 8]). For the same score functions, the best algorithms for corresponding AllPairs- problems are of complexity $\mathcal{O}(n^{(\omega+3)/2})$ or similar (c.f. [6, 8, 11]).

Our contribution:

We show that for a wide class of $(+, \diamond)$ products, the corresponding problems are of (almost) equivalent hardness. This class includes Hamming distance or Dominance, but also any piecewise polynomial function of two variables (for appropriate definition of piecewise polynomiality, c.f. Definition 2) excluding certain degenerate forms (e.g. polynomials). Thus we should not expect the problems based on $(+, \diamond)$ products to be significantly harder to compute than e.g. ones based on Hamming distance. The reduction applies both to Pattern Matching setting and to All Pairs- setting alike. We refer to Table 1 for a summary of considered problems and to Figure 1 for a summary of the old and new reductions. It implies that Yuster's [11] improvement to the exponent of AllPairsDominanceProducts applies to all other AllPairs- problems considered here. Additionally, any tradeoffs between vectors dimension and runtime (c.f. [5, 8]), or input sparsity and runtime (c.f. [4, 9, 10]) translates between problems. Additionally, we link the complexity of AllPairsHammingDistances (and thus to other AllPairs- problems) to one of a sparse rectangular matrix multiplication (c.f. Theorem 4): an instance of APHam can be expanded to an instance of sparse matrix multiplication of rectangular matrices, and any matrix multiplication instance with those parameters can be contracted back to APHam. It is interesting to observe that applying the fastest existing sparse matrix multiplication algorithm (c.f. [12]) to the resulting instance results in the same runtime as solving APHam directly.

2 Preliminaries

For vectors $\mathbf{A}, \mathbf{B}$ and matrices $\mathcal{A}, \mathcal{B}$, we denote the $(+, \diamond)$ vector product as $\textsc{vprod}(\diamond, \mathbf{A}, \mathbf{B}) \stackrel{\text{def}}{=} \sum_i \mathbf{A}[i] \diamond \mathbf{B}[i]$, the $(+, \diamond)$ convolution as $\textsc{conv}(\diamond, \mathbf{A}, \mathbf{B}) = \mathbf{C}$ where $\mathbf{C}[k] = \sum_{i+j=k} \mathbf{A}[i] \diamond \mathbf{B}[j]$ and the $(+, \diamond)$ matrix product as $\textsc{mprod}(\diamond, \mathcal{A}, \mathcal{B}) = \mathcal{C}$ where $\mathcal{C}[i, j] = \sum_k \mathcal{A}[i, k] \diamond \mathcal{B}[k, j]$.

Thus, e.g. defining $\mathsf{Ham}(x, y) \stackrel{\text{def}}{=} \mathbf{1}[x \neq y]$, then $\textsc{vprod}(\mathsf{Ham}, \cdot, \cdot)$, $\textsc{conv}(\mathsf{Ham}, \cdot, \cdot)$ and $\textsc{mprod}(\mathsf{Ham}, \cdot, \cdot)$ correspond to Hamming Distance between vectors, HamPM and APHam.

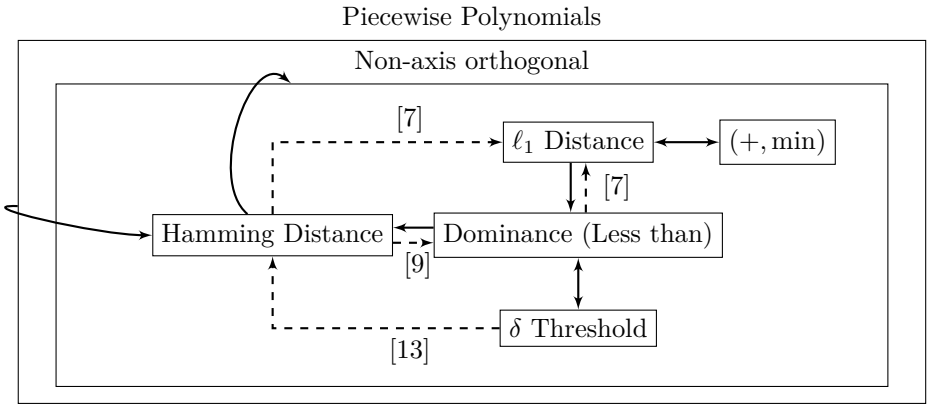

Figure 1 Existing and new reductions between problems, together with problem classes.

▶ **Definition 1.** We say that $\diamond$ reduces preserving linearity to instances of $\square_1, \ldots, \square_K$, if there are functions $f_1, \ldots, f_K$ and $g_1, \ldots, g_K$ and coefficients $\alpha_1, \ldots, \alpha_K$, such that for any x, y:[1] $x \diamond y = \sum_i \alpha_i \cdot \big(f_i(x) \mathbin{\square_i} g_i(y)\big)$.

Given Definition 1, we have for any vectors $\mathbf{A}, \mathbf{B}$ and matrices $\mathcal{A}, \mathcal{B}$: $\textsc{vprod}(\diamond, \mathbf{A}, \mathbf{B}) = \sum_i \alpha_i \cdot \textsc{vprod}(\square_i, f_i(\mathbf{A}), g_i(\mathbf{B}))$, $\textsc{conv}(\diamond, \mathbf{A}, \mathbf{B}) = \sum_i \alpha_i \cdot \textsc{conv}(\square_i, f_i(\mathbf{A}), g_i(\mathbf{B}))$ and $\textsc{mprod}(\diamond, \mathcal{A}, \mathcal{B}) = \sum_i \alpha_i \cdot \textsc{mprod}(\square_i, f_i(\mathcal{A}), g_i(\mathcal{B}))$, where $f(\mathbf{A})$ and $f(\mathcal{A})$ denotes a coordinate-wise application of f to vector $\mathbf{A}$ and matrix $\mathcal{A}$, respectively.

3 Main results

▶ Remark. We assume that all input values and coefficients are integers bounded in absolute value by $\mathrm{poly}(n)$.

▶ **Definition 2.** For integers A, B, C and polynomial $P(x, y)$ we say that the function $P(x, y) \cdot \mathbf{1}[Ax + By + C > 0]$ is *halfplane polynomial*. We call a sum of halfplane polynomial functions a *piecewise polynomial*. We say that a function is *axis-orthogonal piecewise polynomial*, if it is piecewise polynomial and for every i, $A_i = 0$ or $B_i = 0$.

Observe that $\mathsf{Ham}(x, y) = \mathbf{1}[x > y] + \mathbf{1}[x < y]$, $\max(x, y) = x \cdot \mathbf{1}[x \geq y] + y \cdot \mathbf{1}[x < y]$, $|x - y|^{2p+1} = (x - y)^{2p+1} \cdot \mathbf{1}[x > y] + (y - x)^{2p+1} \cdot \mathbf{1}[x < y]$, and $\mathsf{Thr}_\delta(x, y) \stackrel{\text{def}}{=} \mathbf{1}[|x - y| \geq \delta] = \mathbf{1}[x \leq y - \delta] + \mathbf{1}[x \geq y + \delta]$.

▶ **Theorem 3.** *Let $\diamond$ be a piecewise polynomial of constant degree and $\mathrm{poly}\log n$ number of summands.*

- *If $\diamond$ is axis orthogonal, then $\diamond$ is "easy": $(+, \diamond)$ convolution takes $\widetilde{O}(n)$ time, $(+, \diamond)$ matrix multiplication takes $\widetilde{O}(n^\omega)$ time.*
- *Otherwise, $\diamond$ is* Hamming distance complete*: under one-to-polylog reductions, $(+, \diamond)$ product is equivalent to Hamming distance, $(+, \diamond)$ convolution is equivalent to* HamPM *and $(+, \diamond)$ matrix multiplication is equivalent to* APHam.

[1] For the sake of simplicity, we are omitting in the definition the post-processing function necessary e.g. $(\,\cdot\,)^{1/p}$ for L_p norms.

▶ **Theorem 4.** *The time complexity of* APHam *on n vectors of dimension d is (under randomized Las Vegas reductions) within* $\operatorname{poly}\log n$ *from time it takes to multiply matrices $n \times (n \cdot d)$ and $(n \cdot d) \times n$, each with $(n \cdot d)$ non-zero entries.*

Abstract

In the Directed Feedback Vertex Set (DFVS) problem, we are given as input a directed graph D and an integer k, and the objective is to check whether there exists a set S of at most k vertices such that $F = D - S$ is a directed acyclic graph (DAG). Determining whether DFVS admits a polynomial kernel (parameterized by the solution size) is one of the most important open problems in parameterized complexity. In this article, we give a polynomial kernel for DFVS parameterized by the solution size plus the size of any treewidth-η modulator, for any positive integer η. We also give a polynomial kernel for the problem, which we call Vertex Deletion to treewidth-η DAG, where given as input a directed graph D and a positive integer k, the objective is to decide whether there exists a set of at most k vertices, say S, such that $D - S$ is a DAG and the treewidth[1] of $D - S$ is at most η.

1 Introduction and Overview of Our Results

In the Directed Feedback Vertex Set (DFVS) problem, the input consists of a directed graph D on n vertices, and an integer k. The parameter is k, and the objective is to check whether there exists a set of at most k vertices, say S, such that $F = D - S$ is a directed acyclic graph (DAG). The question whether DFVS is fixed-parameter tractable was posed as an open problem in the first few papers on fixed-parameter tractability (FPT) [8, 9].

[1] Throughout the article, by treewidth of a directed graph we mean the treewidth of its underlying undirected graph.

This remained an open problem for over a decade until, in a breakthrough paper, DFVS was shown to be fixed-parameter tractable by Chen et al. [5] in 2008. Specifically, they gave an algorithm that runs in time $\mathcal{O}(4^k \cdot k! \cdot k^4 \cdot n^4)$. Following the resolution of the fixed-parameter tractability status of DFVS, one of the most natural follow-up questions in parameterized complexity, that has been raised several times, and has become one of the most fundamental questions, is "does DFVS admit a polynomial kernel?" A polynomial kernel is essentially a polynomial-time preprocessing algorithm that transforms the given instance of the problem into an equivalent one whose size is bounded polynomially in the specified parameter. Whenever the parameter is not specified, it is implied that the parameter is the solution size (in our case, the integer k in the input of the DFVS problem). In an attempt to develop an understanding on what makes this problem hard, and to move closer to answering this open question, several routes have been taken. These include:

1. enriching the parameterization to encompass not only solution size but also additional structural parameters,
2. restricting the input instances,
3. restricting the structure of the resulting DAG (F).

In this article, we give two results concerning DFVS that contribute to progress along all these three routes. We begin by first stating our results formally. For a directed graph D, a subset $M \subseteq V(D)$ is called a *treewidth η-modulator* if $D - M$ has treewidth at most η. For a fixed positive integer $\eta > 0$, let $\mathcal{F}_\eta$ be the family of digraphs of treewidth at most η. Formally, our first problem is the following.

DFVS/DFVS+Treewidth-η Modulator (DFVS/DFVS+Tw-η Mod) **Parameter:** $k + \ell$
Input: A digraph D, an integer k, $M \subseteq V(D)$ such that $|M| = \ell$ and $D - M \in \mathcal{F}_\eta$.
Question: Does there exist $S \subseteq V(D)$ such that $|S| \leq k$ and $D - S$ is a DAG?

Our first result is the following.

▶ **Theorem 1.** DFVS/DFVS+Tw-η Mod *admits a polynomial kernel of size* $(k \cdot \ell)^{\mathcal{O}(\eta^2)}$.

Our second problem is the following.

Vertex Deletion to treewidth-η DAG **Parameter:** k
Input: A digraph D, an integer k.
Question: Does there exist $S \subseteq V(D)$ such that $|S| \leq k$ and $D - S$ is a DAG and $D - S \in \mathcal{F}_\eta$?

The next theorem states our second result.

▶ **Theorem 2.** *For any fixed positive integer η,* Vertex Deletion to treewidth-η DAG *has polynomial kernel.*

Let us now see how both our results make progress along all the three routes described above. Along the first route, Bergougnoux et al. [4] studied DFVS parameterized by the feedback vertex set (**fvs**) number of the underlying undirected graph, and gave a polynomial kernel for this problem. Our first result gives a polynomial kernel for DFVS when the parameter is solution size (k) plus the size of any treewidth-η modulator in D (say ℓ), for any fixed positive integer η. Note that the parameter $k + \ell$ is not only upper bounded by $\mathcal{O}(\mathbf{fvs})$, where **fvs** is the feedback vertex set number of the underlying undirected graph of D, but it can be arbitrarily smaller than **fvs**. Thus, studying such a parameter brings us closer to

the problem of the existence of a polynomial kernel for DFVS. (Note that the question of the existence of a polynomial kernel for DFVS parameterized by the size of a treewidth-η modulator, for $\eta \geq 2$, alone has a negative answer because Vertex Cover parameterized by the size of any treewidth-2 modulator cannot have a polynomial kernel, unless $\mathsf{NP} \subseteq \frac{\text{co-NP}}{\text{poly}}$ [6].) Moreover, the ideas harnessed during the construction of our polynomial kernel utilizes the tool of important separators in a novel fashion. To the best of our knowledge, this is the first time that the power of important separators has been harnessed to develop a polynomial kernel. Furthermore, to derive this result, we need to embed this tool in state-of-the-art machinery such as the use of protrusion replacers where the replacement is a minor of the part of the graph that is replaced.

Along the second route (that is, studying DFVS by restricting the input instance), there have been several results for polynomial kernels for DFVS when the input graph is a tournament or some generalization of it (like a bipartite tournament etc.) [1, 3, 7, 10]. However, the existence of a polynomial kernel for DFVS is open even when the input digraph is a planar digraph. From our first result (Theorem 1), we can conclude that we have a polynomial kernel for DFVS when the treewidth of the input graph is polynomial in the solution size ($k^{\mathcal{O}(1)}$).

Along the third route, Mnich and van Leeuwen [11] studied the problem, where they considered DFVS with an additional restriction on the output DAG rather than the input instance. They inspected this question by considering k vertex deletion to the classes of out-forests, out-trees and (directed) pumpkins. They obtained polynomial kernels for all these problems. Observe that for all these classes, the treewidth of the graphs in these classes is constant (at most 2). In a follow-up paper [2], the kernel sizes given by Mnich and van Leeuwen [11] were reduced. Our second result generalizes this approach by demanding that the resulting DAG has bounded treewidth (bounded by any fixed constant η).

Our Methods. We now give a very brief overview of the methods used to prove our results. In fact, here, we only focus on our first result.

Proof Idea of Theorem 1. Our kernelization algorithm can be divided into three main phases. Recall that the input is a directed graph D, an integer k and a treewidth-η modulator M of size ℓ. In the first phase, we decompose the graph into $\mathcal{O}(k\ell^2)$ parts (which we call *zones*), each of which have constant treewidth and a "controlled" neighbourhood in the rest of the graph. In the next step, we mark $(k\ell)^{\mathcal{O}(\eta^2)}$ vertices inside each zone, which have the property that in the case of a YES-instance, there is also a solution that does not use any of the unmarked vertices in these zones. Getting such a set of marked vertices of polynomial size is the core of our algorithm. Having such a set of marked vertices at our disposal, we then design reduction rules that partition the unmarked vertices in each zone into disjoint protrusions that are then replaced by constant size graphs, such that the modulator M remains a treewidth-η modulator in the resulting graph too. Note that this is done (over a standard protrusion replacement) to ensure that our parameter does not increase in the resulting instance. If one does not care about the parameter increase in the resulting instance, then some of the steps in this algorithm can be simplified.

nvarma@bu.edu

Abstract

We describe work in progress on providing a separation between erasure-resilient and tolerant property testing. Specifically, we are able to exhibit a property which is testable (with the number of queries independent of the length of the input) in the presence of erasures, but is not testable tolerantly.

1 Description

In this brief announcement, we describe our recent investigation of the effects of adversarial corruption to inputs on the complexity of sublinear-time algorithms. Input corruption occurs either in the form of errors (when some values get changed) or in the form of erasures (when some values go missing). Understanding the relative difficulty of designing algorithms that work in the presence of different forms of corruption is a problem of fundamental importance. It is with this motivation in mind that property testing [5, 7], one of the most widely studied models of sublinear-time algorithms, was generalized to erasure-resilient testing [3] and (error) tolerant testing [6].

Erasure-resilient property testing falls between (standard) property testing and tolerant testing. Specifically, an erasure-resilient tester for a property, in the special case when no erasures occur, is a standard tester for this property. Also, a tolerant tester for a property implies the existence of an erasure-resilient tester with comparable parameters for the same property. Dixit, Raskhodnikova, Thakurta and Varma [3] separate standard and erasure-resilient testing by describing a property that is *easy* to test in the standard model and *hard* to test in the erasure-resilient model. Their separation is based on an earlier result by Fischer and Fortnow [4] that separates standard property testing from tolerant property testing in the same sense. Their main tool is PCPs of proximity (also known as assignment testers) defined by Ben-Sasson, Goldreich, Harsha, Sudan and Vadhan [1] and by Dinur and Reingold [2]. Dixit et al. [3] asked whether it is possible to obtain a separation between erasure-resilient and tolerant testing. Here, we announce such a separation. Specifically,

45th International Colloquium on Automata, Languages, and Programming (ICALP 2018).

we are able to describe a property testable in the erasure-resilient model with the query complexity independent of the input size, but for which the query complexity of tolerant testing grows with the input size.

1.1 Erasure-Resilient and Tolerant Testing: Definitions

We now describe the erasure-resilient and tolerant models of testing. A *property* $\mathcal{P}$ is a set of strings. A string is *α-erased* for $\alpha \in [0,1)$ if at most an α fraction of its values are erasures (denoted by $\perp$). A *completion* of an α-erased string $x \in \{0,1,\perp\}^n$ is a string $y \in \{0,1\}^n$ that agrees with x on all the positions where x is nonerased. An *α-erasure-resilient ε-tester* [3] for a property $\mathcal{P}$ is a randomized algorithm that, given parameters $\alpha \in [0,1), \varepsilon \in (0,1)$ and oracle access to an α-erased string x, accepts with probability at least $2/3$ if x has a completion in $\mathcal{P}$ and rejects with probability at least $2/3$ if, in every completion of x, at least an ε fraction of the **nonerased** positions has to be changed to get a string in $\mathcal{P}$. The property $\mathcal{P}$ is *α-erasure-resiliently ε-testable* if there exists an α-erasure-resilient ε-tester for $\mathcal{P}$ with query complexity that depends only on the parameters α and ε (but not on the length of the input string).

A string $x \in \{0,1\}^n$ is ε'-far (α-close) from (to, respectively) a property $\mathcal{P}$, if the normalized Hamming distance of x from $\mathcal{P}$ is at least ε' (at most α, respectively). An *(α,ε')-tolerant tester* [6] for $\mathcal{P}$ is a randomized algorithm that, given parameters $\alpha \in (0,1), \varepsilon' \in (\alpha,1)$ and oracle access to a string x, accepts with probability at least $\frac{2}{3}$, if x is α-close to $\mathcal{P}$ and rejects with probability at least $\frac{2}{3}$, if x is ε'-far from $\mathcal{P}$. The property $\mathcal{P}$ is *(α,ε')-tolerantly testable* if there exists an (α,ε')-tolerant tester for $\mathcal{P}$ with query complexity that depends only on the parameters α and ε' (but not on the length of the input string).

1.2 Comparison of parameters

We remark that, while comparing the above two models, it is appropriate to compare $(\alpha, \alpha+\varepsilon(1-\alpha))$-tolerant testing of a property $\mathcal{P}$ with α-erasure-resilient ε-testing of $\mathcal{P}$ for the same values of α and ε. The parameter α in both the models is an upper bound on the fraction of corruptions (erasures, or errors) that an adversary can make to an input. An α-erasure-resilient ε-tester rejects with probability at least $\frac{2}{3}$ if, for for every way of completing an input string, one needs to change at least an ε fraction of the remaining part of the input to make it satisfy $\mathcal{P}$. Similarly, an $(\alpha, \alpha+\varepsilon(1-\alpha))$-tolerant tester rejects with probability at least $\frac{2}{3}$ if, for every way of *correcting* α fraction of the input values, one needs to change at least an ε fraction of the remaining $(1-\alpha)$ fraction of the input to make it satisfy $\mathcal{P}$.

1.3 Our Results

Our main contribution is the following theorem which states that there exists a property that is erasure-resiliently testable and is not tolerantly testable. This proves that tolerant testing is, in general, a harder problem than erasure-resilient testing.

▶ **Theorem 1** (Main Theorem). *There exists a property $\mathcal{P}$ and constants $\varepsilon, \alpha \in (0,1)$ such that*

- *$\mathcal{P}$ is α-erasure-resiliently ε-testable;*
- *$\mathcal{P}$ is not $(\alpha, \alpha+\varepsilon(1-\alpha))$-tolerantly testable.*

2 Conclusions

To summarize, we solve an open question proposed by Dixit et al. [3] and prove that tolerant testing is harder than erasure-resilient testing.

Abstract

In the bounded-degree cut problem, we are given a multigraph $G = (V, E)$, two disjoint vertex subsets $A, B \subseteq V$, two functions $\mathrm{u}_A, \mathrm{u}_B : V \to \{0, 1, \ldots, |E|\}$ on V, and an integer $k \geq 0$. The task is to determine whether there is a minimal (A, B)-cut (V_A, V_B) of size at most k such that the degree of each vertex $v \in V_A$ in the induced subgraph $G[V_A]$ is at most $\mathrm{u}_A(v)$ and the degree of each vertex $v \in V_B$ in the induced subgraph $G[V_B]$ is at most $\mathrm{u}_B(v)$. In this paper, we show that the bounded-degree cut problem is fixed-parameter tractable by giving a $2^{18k}|G|^{O(1)}$-time algorithm. This is the first single exponential FPT algorithm for this problem. The core of the algorithm lies two new lemmas based on important cuts, which give some upper bounds on the number of candidates for vertex subsets in one part of a minimal cut satisfying some properties. These lemmas can be used to design fixed-parameter tractable algorithms for more related problems.

1 Introduction

A *cut* of a graph is a partition of the vertices of the graph into two disjoint subsets. Graph cuts play an important role in combinatorial optimization and graph theory. The classical *minimum cut problem* is well known to be polynomially solvable [13]. Due to the rich application realm of this problem, many variants and extensions have been investigated. Some problems ask to partition the graph into more than two parts to disconnect some vertices such as the *k-way cut problem* (the *k-cut problem*) [14, 15], the *multiterminal cut problem* [9, 21] and the *multicut problem* [5, 19]. Some problems are still going to partition the graph into two parts, but with some additional requirements beyond the disconnectivity. One of the most extensively studied additional requirements is the constraint on the numbers of vertices or edges in each of the two parts. For examples, the *balanced cut problem* [1, 12, 16] and the *minimum bisection problem* [7, 10, 11] require the numbers of vertices in the two parts of the cut as close as possible. The (*balanced*) *judicious bipartition problem* [17] has

conditions on the numbers of edges in the two parts. Some other well studied additional requirements include conditions on the connectivity of the two parts such as the *2-disjoint connected subgraphs problem* [8], and conditions on the degree of the two parts, such as the series of bipartition problems with degree constraints [2, 3, 4, 20, 22].

In this paper, we study the *bounded-degree cut* problem, which belongs to the latter kind of the extensions: to partition a given graph into two parts with some degree constraints on the induced subgraphs of the two parts. We mainly consider the upper bounds of the degree. An (S,T)-cut (V_1,V_2) is minimal if $E_G(V_1)$ does not contain $E_G(V_1')$ or $E_G(V_2')$ as a subset for any $S \subseteq V_1' \subsetneqq V_1$ and $T \subseteq V_2' \subsetneqq V_2$. Our problem is defined as follows.

BOUNDED-DEGREE CUT (with parameter: k)
Instance: A multigraph $G=(V,E)$, two disjoint nonempty vertex subsets $A,B \subseteq V$, two functions u_A and u_B from V to $\{0,1,\ldots,|E|\}$ and an integer $k \geq 0$.
Question: Does there exist a minimal (A,B)-cut (V_A,V_B) such that
the number of edges with one endpoint in V_A and one endpoint in V_B is at most k,
for each vertex $v \in V_A$, the degree of it in the induced graph $G[V_A]$ is at most $\mathrm{u}_A(v)$, and
for each vertex $v \in V_B$, the degree of it in the induced graph $G[V_B]$ is at most $\mathrm{u}_B(v)$?

During the last decade, cut related problems were extensively studied from the viewpoint of parameterized algorithms [12, 18, 7, 17, 15, 19, 21, 6]. In this paper, we will study BOUNDED-DEGREE CUT from the viewpoint of parameterized algorithms. Our main result is the first single-exponential FPT algorithm for BOUNDED-DEGREE CUT, which implies that BOUNDED-DEGREE CUT can be solved in polynomial time for $k = O(\log |G|)$.

▶ **Theorem 1.** BOUNDED-DEGREE CUT *can be solved in* $2^{18k} \cdot |G|^{O(1)}$ *time.*

2 The main idea

The most crucial techniques in this paper are: to use important cuts introduced by Marx [18] to obtain the following two general lemmas for bounded sets related to cuts; and then based on these two lemmas, to construct from a given instance a set of at most 2^{18k} new "easy" instances such that the original instance is feasible if and only if at least one of the "easy" instances is feasible.

▶ **Lemma 2.** *Let $A,B,C \subseteq V$ be non-empty subsets in a graph $G=(V,E)$ and k and ℓ be nonnegative integers. Then one can find in $2^{3(k+\ell)}(n+m)^{O(1)}$ time a family $\mathcal{X}$ of at most $2^{3(k+\ell)}$ subsets of C with a property that $C \cap V_1 \in \mathcal{X}$ for any minimal (A,B)-cut (V_1,V_2) with size at most k such that $|C \cap V_1| \leq \ell$.*

▶ **Lemma 3.** *Let $A,B,B' \subseteq V$ be non-empty subsets in a graph $G=(V,E)$, where $B' \subseteq B$, and k be a nonnegative integer. Then one can find in $2^{3k}(n+m)^{O(1)}$ time a family $\mathcal{Y}$ of at most 2^{3k} subsets of $N_G(B')$ with a property that $N_G(B') \cap V_1 \in \mathcal{Y}$ for any minimal (A,B)-cut (V_1,V_2) with size at most k.*

We will use $I=(G=(V,E),A,B)$ to denote an instance of the problem, where u_A, u_B and k are omitted since they remain unchanged throughout our argument. We use Z_A and Z_B to denote the sets of *A-unsatisfied vertices* and *B-unsatisfied vertices*, respectively, i.e., $Z_A \triangleq \{v \in V \mid \deg_G(v) > \mathrm{u}_A(v)\}$ and $Z_B \triangleq \{v \in V \mid \deg_G(v) > \mathrm{u}_B(v)\}$. We call I an *easy instance* if it holds that $Z_A \cup Z_B \subseteq A \cup B$, $N_G(Z_A \cap A) \subseteq A \cup B$, and $N_G(Z_B \cap B) \subseteq A \cup B$. We can see that an easy instance can be solved in polynomial time.

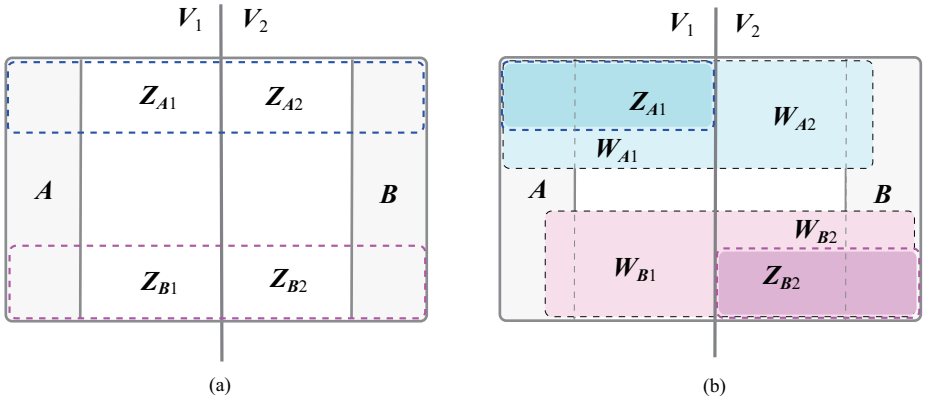

Figure 1 (a) An (A, B)-cut $\pi = (V_A, V_B)$ to I and the partitions $\{Z_{A1}, Z_{A2}\}$ of Z_A and $\{Z_{B1}, Z_{B2}\}$ of Z_B by π, where possibly $Z_A \cap Z_B \neq \emptyset$, (b) The partitions $\{W_{B1}, W_{B2}\}$ of $W_B = N_G(Z_{B2})$ and $\{W_{A1}, W_{A2}\}$ of $W_A = N_G(Z_{A1})$ by π, where possibly $W_A \cap W_B \neq \emptyset$.

For a given instance I with a feasible (A, B)-cut (V_1, V_2), we try to guess some subsets $V_1' \subseteq V_1 \setminus A$ and $V_2' \subseteq V_2 \setminus B$ so that the new instance $(G, A^* = A \cup V_1', B^* = B \cup V_2', \mathrm{u}_A, \mathrm{u}_B, k)$ remains feasible and is an easy. We will generate at most 2^{18k} easy instances.

3 Constructing Easy Instances

For a minimal (A, B)-cut $\pi = (V_1, V_2)$ (not necessarily feasible) in a given instance $I = (G = (V, E), A, B)$, we define the following notation on vertex subsets:
$Z_{Ai} \triangleq Z_A \cap V_i$ and $Z_{Bi} \triangleq Z_B \cap V_i$, $i = 1, 2$;
$W_A \triangleq N_G(Z_{A1})$ and $W_B \triangleq N_G(Z_{B2})$; $W_{Ai} \triangleq W_A \cap V_i$, and $W_{Bi} \triangleq W_B \cap V_i$, $i = 1, 2$;
$A_\pi \triangleq A \cup Z_{A1} \cup Z_{B1} \cup W_{A1} \cup W_{B1}$ and $B_\pi \triangleq B \cup Z_{A2} \cup Z_{B2} \cup W_{A2} \cup W_{B2}$.
See in Fig. 1 for an illustration on these subsets. Observe that the resulting instance (G, A_π, B_π) is an easy instance. The (A, B)-cut $\pi = (V_1, V_2)$ is feasible if and only if the corresponding instance (G, A_π, B_π) is feasible.

3.1 Partitioning Unsatisfied Vertices

For a minimal (A, B)-cut (V_1, V_2) to an instance I, let Z_{A1} and Z_{B2} be the subsets defined in the above. We observe that if the cut is feasible, then

$$|Z_{A1}|, |Z_{B2}| \leq k$$

since each vertex in $Z_{A1} \cup Z_{B2}$ has at least one incident edge included in $E_G(V_1, V_2)$ so that the degree constraint on the vertex holds.

By applying Lemma 2 to $(A, B, C = Z_A, k, \ell = k)$, we can construct in $2^{6k}(n+m)^{O(1)}$ time a family $\mathcal{X}_1$ of at most 2^{6k} subsets of Z_A such that $\mathcal{X}_1$ contains the set Z_{A1} defined to each feasible (A, B)-cut (V_1, V_2) in the instance $I = (G, A, B)$. Symmetrically it takes $2^{6k}(n+m)^{O(1)}$ time to find a family $\mathcal{X}_2$ of at most 2^{6k} subsets of Z_B such that $\mathcal{X}_2$ contains the set Z_{B2} defined to each feasible (A, B)-cut (V_1, V_2) in the instance $I = (G, A, B)$. Then the set $\mathcal{X}_{1,2}$ of all pairs (X_1, X_2) of disjoint sets $X_i \in \mathcal{X}_i$, $i = 1, 2$ contains the pair (Z_{A1}, Z_{B2}) defined to each feasible (A, B)-cut (V_1, V_2) in I. By noting that $|\mathcal{X}_{1,2}| \leq 2^{6k} 2^{6k} = 2^{12k}$, we obtain the next.

▶ **Lemma 4.** *Given an instance $I = (G, A, B)$, one can construct in $2^{12k}(n+m)^{O(1)}$ time at most 2^{12k} new instances $I' = (G, A', B')$ with $Z_A \cup Z_B \subseteq A' \cup B'$, one of which is equal to $(G, A \cup Z_{A1} \cup Z_{B1}, B \cup Z_{A2} \cup Z_{B2})$ for each feasible (A, B)-cut (V_1, V_2) to I.*

3.2 Partitioning Neighbors of Unsatisfied Vertices

For a minimal (A, B)-cut (V_1, V_2) to an instance I, let W_{A2} and W_{B1} be the subsets defined in the above. We observe that if the cut is feasible, then

$$|W_{B1}|, |W_{A2}| \leq k$$

since each of $|N_G(Z_{B2}) \cap V_1|$ and $|N_G(Z_{A1}) \cap V_2|$ is at most $|E_G(V_1, V_2)| \leq k$ to the feasible (A, B)-cut (V_1, V_2).

By applying Lemma 3 to $(A \cup Z_{A1} \cup Z_{B1}, B \cup Z_{A2} \cup Z_{B2}, B' = Z_{B2}, k)$, we can construct in $2^{3k}n^{O(1)}$ time a family $\mathcal{Y}_1$ of at most 2^{3k} subsets of $N_G(Z_{B2})$ such that $\mathcal{Y}_1$ contains the set $W_{B1} = N_G(Z_{B2}) \cap V_1$ defined to each feasible (A, B)-cut (V_1, V_2) in the instance $I = (G, A, B)$. Symmetrically it takes $2^{3k}(n+m)^{O(1)}$ time to find a family $\mathcal{Y}_2$ of at most 2^{3k} subsets of $N_G(Z_{A1})$ such that $\mathcal{Y}_2$ contains the set $W_{A2} = N_G(Z_{A1}) \cap V_2$ defined to each feasible (A, B)-cut (V_1, V_2) in I. Then the set $\mathcal{Y}_{1,2}$ of all pairs (Y_1, Y_2) of disjoint sets $Y_i \in \mathcal{Y}_i$, $i = 1, 2$ contains the pair (W_{B1}, W_{A2}) defined to each feasible (A, B)-cut (V_1, V_2) in the instance $I = (G, A, B)$. By noting that $|\mathcal{Y}_{1,2}| \leq 2^{6k}$, we obtain the next.

▶ **Lemma 5.** *Given an instance $I = (G, A, B)$ and the subsets Z_{A1} and Z_{B2} defined to a feasible (A, B)-cut (V_1, V_2) in I, one can construct in $2^{6k}(n+m)^{O(1)}$ time at most 2^{6k} new easy instances $I' = (G, A', B')$, one of which is equal to (G, A_π, B_π) defined to the feasible (A, B)-cut $\pi = (V_1, V_2)$.*

By Lemmas 4 and 5, we obtain the next, which can imply Theorem 1.

▶ **Lemma 6.** *Given an instance $I = (G, A, B)$, one can construct in $2^{18k}(n+m)^{O(1)}$ time at most 2^{18k} new easy instances $I' = (G, A', B')$, one of which is equal to (G, A_π, B_π) for each feasible (A, B)-cut $\pi = (V_1, V_2)$ to I.*

Abstract

We introduce *Almost Sure Productivity (ASP)*, a probabilistic generalization of the productivity condition for coinductively defined structures. Intuitively, a probabilistic coinductive stream or tree is ASP if it produces infinitely many outputs with probability 1. Formally, we define ASP using a final coalgebra semantics of programs inspired by Kerstan and König. Then, we introduce a core language for probabilistic streams and trees, and provide two approaches to verify ASP: a syntactic sufficient criterion, and a decision procedure by reduction to model-checking LTL formulas on probabilistic pushdown automata.

1 Introduction

The study of probabilistic programs has a long history, especially in connection with semantics [22] and verification [23, 17, 28]. Over the last decade the field of probabilistic programming has attracted renewed attention with the emergence of practical probabilistic programming languages and novel applications in machine learning, privacy-preserving data mining, and modeling of complex systems. On the more theoretical side, many semantical and syntactic tools have been developed for verifying probabilistic properties. For instance, significant attention has been devoted to termination of probabilistic programs, focusing on the complexity of the different termination classes [19], and on practical methods for proving that a program terminates [16, 25, 2, 27]. The latter class of works generally focuses on *almost sure termination*, which guarantees that a program terminates with probability 1.

Coinductive probabilistic programming is a new computational paradigm that extends probabilistic programming to infinite objects, such as streams and infinite trees, providing a natural setting for programming and reasoning about probabilistic infinite processes such as Markov chains or Markov decision processes. Rather surprisingly, the study of coinductive probabilistic programming was initiated only recently [3], and little is known about generalizations of coinductive concepts and methods to the probabilistic setting. In this paper we consider *productivity*, which informally ensures that one can compute arbitrarily precise approximations of infinite objects in finite time. Productivity has been studied extensively for standard, non-probabilistic coinductive languages [18, 14, 1, 12, 7], but the probabilistic setting introduces new subtleties and challenges.

Contributions

Our first contribution is conceptual. We introduce *almost sure productivity* (ASP), a probabilistic counterpart to productivity. A probabilistic stream computation is almost surely productive if it produces an infinite stream of outputs with probability 1. For instance, consider the stream defined by the equation

$$\sigma = (a : \sigma) \oplus_p \sigma$$

Viewed as a program, this stream repeatedly flips a coin with bias $p \in (0, 1)$, producing the value a if the coin comes up heads and retrying if the coin comes up tails. This computation is almost surely productive since the probability it fails to produce outputs for n consecutive steps is $(1 - p)^n$, which tends to zero as n increases. In contrast, consider the stream

$$\sigma = \bar{a} \oplus_p \epsilon$$

This computation flips a single biased coin and returns an infinite stream of a's if the coin comes up heads, and the empty stream ϵ if the coin comes up tails. This process is *not* almost surely productive since its probability of outputting an infinite stream is only p, which is strictly less than 1.

We define almost sure productivity for any system that can be equipped with a final coalgebra semantics in the style of Kerstan and König [20] (Section 3). We instantiate our semantics on a core probabilistic language for computing over streams and trees (Section 4). Then, we consider two methods for proving almost sure productivity.

1. We begin with a syntactic method that assigns a real-valued measure to each expression e (Section 5). Intuitively, the measure represents the expected difference between the number of outputs produced and consumed per evaluation step of the expression. For instance, the computation that repeatedly flips a fair coin and outputs a value if the coin is heads has measure $\frac{1}{2}$ – with probability $1/2$ it produces an output, with probability 0 it produces no outputs. More complex terms in our language can also consume outputs internally, leading to possibly negative values for the productivity measure.
   We show that every expression whose measure is strictly positive is almost surely productive; the proof of soundness of the method uses concentration results from martingale theory. While simple to carry out, our syntactic method is incomplete – it does not yield any information for expressions with non-positive measure.
2. To give a more sophisticated analysis, we reduce the problem of deciding ASP to probabilistic model-checking (Section 6). We translate our programs to probabilistic pushdown automata and show that almost sure productivity is characterized by a logical formula in LTL. This fragment is known to be decidable [6], giving a sound and complete procedure for deciding ASP.

We consider more advanced generalizations and extensions in Section 7, survey related work in Section 8, and conclude in Section 9.

2 Mathematical Preliminaries

This section reviews basic notation and definitions from measure theory and category theory. Given a set A we will denote by $A_\perp$ the coproduct of A with a one-element set containing a distinguished element $\perp$, i.e., $A_\perp = A + \{\perp\}$.

Coalgebra, Monads, Kleisli categories

We assume that the reader is familiar with the notions of objects, morphisms, functors and natural transformations (see, for instance, [5]). Given an endofunctor $F : \mathcal{C} \to \mathcal{C}$, a *coalgebra* of F is a pair (X, f) of an object $X \in \mathcal{C}$ and a morphism $f : X \to F(x)$ in $\mathcal{C}$. A *monad* is a triple (T, η, μ) of an endofunctor $T : \mathcal{C} \to \mathcal{C}$ and two natural transformations $\eta : 1_\mathcal{C} \to T$ (the *unit*) and $\mu : T^2 \to T$ (the *multiplication*) such that $\mu \circ \mu_T = \mu \circ T\mu$ and $\mu \circ \eta_T = 1_T = \mu \circ T\eta$. Given a category $\mathcal{C}$ and a monad (T, η, μ), the *Kleisli category* $\mathcal{K}\ell(T)$ of T has as objects the objects of $\mathcal{C}$ and as morphisms $X \to Y$ the morphisms $X \to T(Y)$ in $\mathcal{C}$.

Streams, Trees, Final Coalgebra

We will denote by O^ω the set of infinite streams of elements of O (alternatively characterized as functions $\mathbb{N} \to O$). We have functions $\mathsf{head} \colon O^\omega \to O$ and $\mathsf{tail} \colon O^\omega \to O^\omega$ that enable observation of the elements of the stream. In fact, they provide O^ω with a one-step structure that is canonical: given any set S and any two functions $h \colon S \to O$ and $t \colon S \to S$ (i.e., a coalgebra $(S, \langle h, t\rangle)$ of the functor $F(X) = O \times X$) there exists a *unique* stream function associating semantics to elements of S:

$$\begin{array}{ccc} S & \overset{[\![-]\!]}{\dashrightarrow} & O^\omega \\ {\scriptstyle \langle h,t\rangle}\downarrow & & \downarrow{\scriptstyle \langle \mathsf{head},\mathsf{tail}\rangle} \\ O \times S & \overset{id\times[\![-]\!]}{\dashrightarrow} & O \times O^\omega \end{array}$$

Formally, this uniqueness property is known as *finality*: O^ω is the *final coalgebra* of the functor $F(X) = O \times X$ and the above diagram gives rise to a coinductive definition principle. A similar principle can be obtained for infinite binary trees and other algebraic datatypes. The above diagrams are in the category of sets and functions, but infinite streams and trees have a very rich algebraic structure and they are also the carrier of final coalgebras in other categories. For the purpose of this paper, we will be particularly interested in a category where the maps are probabilistic – the Kleisli category of the distribution (or *Giry*) monad.

Probability Distributions, σ-algebras, Measurable Spaces

To model probabilistic behavior, we need some basic concepts from measure theory (see, e.g., [30]). Given an arbitrary set X we call a set Σ of subsets of X a *σ-algebra* if it contains the empty set and is closed under complement and countable union. A *measurable space* is a pair (X, Σ). A *probability measure* or distribution μ over a measurable space is a function $\mu : \Sigma \to [0, 1]$ assigning probabilities $\mu(A) \in [0, 1]$ to the *measurable sets* $A \in \Sigma$ such that $\mu(X) = 1$ and $\mu(\bigcup_{i\in I} A_i) = \sum_{i\in I} \mu(A_i)$ whenever $\{A_i\}_{i\in I}$ is a countable collection of disjoint measurable sets. The collection $\mathcal{D}(X)$ of probability distributions over a measurable space

X forms the so-called Giry monad. The monad unit $\eta\colon X \to \mathcal{D}(X)$ maps $a \in X$ to the point mass (or Dirac measure) δ_a, i.e., the measure assigning 1 to any set containing a and 0 to any set not containing a. The monad multiplication $m\colon \mathcal{D}\mathcal{D}(X) \to \mathcal{D}(X)$ is given by integration:

$$m(P)(S) = \int ev_S dP, \text{ where } ev_S(\mu) = \mu(S).$$

Given measurable spaces (X, Σ_X) and (Y, Σ_Y), a *Markov kernel* is a function $P : X \times \Sigma_Y \to [0,1]$ (equivalently, $X \to \Sigma_Y \to [0,1]$) that maps each source state $x \in X$ to a distribution over target states $P(x,-) : \Sigma_Y \to [0,1]$.

Markov kernels form the arrows in the Kleisli category $\mathcal{K}\ell(\mathcal{D})$ of the $\mathcal{D}$ monad; we denote such arrows by $X \xrightarrow{P} Y$. Composition in the Kleisli category is given by integration:

$$X \xrightarrow{P} Y \xrightarrow{Q} Z \qquad (P \circ Q)(x, A) = \int_{y \in Y} P(x, dy) \cdot Q(y, A)$$

Associativity of composition is essentially Fubini's theorem.

3 Defining Almost Sure Productivity

We will consider programs that denote probability distributions over coinductive types, such as infinite streams or trees. In this section, we focus on the definitions for programs producing streams and binary trees for simplicity, but our results should extend to arbitrary polynomial functors (see Section 7).

First, we introduce the semantics of programs. Rather than fix a concrete programming language at this point, we let $\mathbb{T}$ denote an abstract state space (e.g., the terms of a programming language or the space of program memories). The state evolves over an infinite sequence of discrete time steps. At each step, we will probabilistic observe either a concrete output ($a \in A$) or nothing ($\bot$), along with a resulting state. Intuitively, $p \in \mathbb{T}$ is ASP if its probability of producing unboundedly many outputs is 1. Formally, we give states in $\mathbb{T}$ a denotational semantics $[\![-]\!]\colon \mathbb{T} \to \mathcal{D}((A_\bot)^\omega)$ defined coinductively, starting from a given one-step semantics function that maps each term to an output in $A_\bot$ and the resulting term. Since the step function is probabilistic, we work in the Kleisli category for the distribution monad; this introduces some complications when computing the final coalgebras in this category. We take the work on probabilistic streams by Kerstan and König [20] as our starting point, and then generalize to probabilistic trees.

▶ **Theorem 1** (Finality for streams [20]). *Given a set $\mathbb{T}$ of programs endowed with a probabilistic step function $\mathsf{st}\colon \mathbb{T} \to \mathcal{D}(A_\bot \times \mathbb{T})$, there is a* unique *semantics function $[\![-]\!]$ assigning to each program a probability distribution of output streams such that the following diagram commutes in the Kleisli category $\mathcal{K}\ell(\mathcal{D})$:*

$$\begin{array}{ccc} \mathbb{T} & \xrightarrow{[\![-]\!]} & (A_\bot)^\omega \\ {\scriptstyle \mathsf{st}}\downarrow & & \downarrow{\scriptstyle <\mathsf{head},\mathsf{tail}>} \\ A_\bot \times \mathbb{T} & \xrightarrow{id \times [\![-]\!]} & A_\bot \times (A_\bot)^\omega \end{array}$$

▶ **Definition 2** (ASP for streams). A stream program $p \in \mathbb{T}$ is *almost surely productive* (ASP) if

$$\Pr_{\sigma \sim [\![p]\!]}[\sigma \text{ has infinitely many concrete output elements } a \in A] = 1.$$

For this to be a sensible definition, the event "σ has infinitely many concrete output elements $a \in A$" must be a measurable set in some σ-algebra on $(A_\perp)^\omega$. Following Kerstan and König, we take the σ-algebra generated by *cones*, sets of the form $uA^\omega = \{v \in (A_\perp)^\omega \mid u \text{ prefix of } v, u \in (A_\perp)^*\}$. Our definition evidently depends on the definition of $[\![-]\!] \colon \mathbb{T} \to \mathcal{D}(A_\perp)^\omega$; our coinductively defined semantics will be useful later for showing soundness when verifying ASP, but our definition of ASP is sensible for any semantics $[\![-]\!]$.

▶ **Example 3.** Let us consider the following program defining a stream σ recursively, in which each recursion step is determined by a coin flip with bias p:

$$\sigma = (a : \sigma) \oplus_p \mathsf{tail}(\sigma)$$

In the next section we will formally introduce this programming language, but intuitively the program repeatedly flips a coin. If the coin flip results in heads the program produces an element a. Otherwise the program tries to compute the tail of the recursive call; the first element produced by the recursive call is dropped (consumed), while subsequent elements produced (if any) are emitted as output.

To analyze the productivity behavior of this probabilistic program, we can reason intuitively. Each time the second branch is chosen, the program must choose the first branch strictly more than once in order to produce one output (since, e.g., $\mathsf{tail}(a : \sigma) = \sigma$). Accordingly, the productivity behavior of this program depends on the value of p. When p is less than $1/2$, the program chooses the first branch less often than the second branch and the program is not ASP. On the other hand, when $p > 1/2$ the program will tend to produce more elements a than are consumed by the destructors, and the above program is ASP. In the sequel, we will show two methods to formally prove this fact.

It will be convenient to represent the functor as $F(X) = A_\perp \times X$ as $A \times X + X$. In the rest of this paper we will often use the latter representation and refer to the final coalgebra as *observation streams* $\mathsf{OS} = (A_\perp)^\omega$ with structure $\mathsf{OS} \xleftarrow[\cong]{\langle \mathsf{out},\mathsf{unf}\rangle} A \times \mathsf{OS} + \mathsf{OS}$ given by $\mathsf{out}(a, \sigma) = a : \sigma$ and $\mathsf{unf}(\sigma) = \perp : \sigma$.

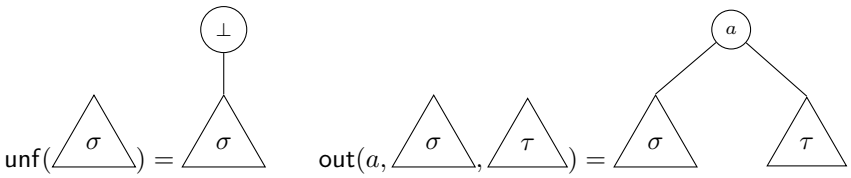
Streams are not the only coinductively defined data; infinite binary trees are another classical example. To generate trees, we can imagine that a program produces an output value – labeling the root node – and two child programs, which then generate the left and right child of a tree of outputs. Much like we saw for streams, probabilistic programs generating these trees may sometimes step to a single new program without producing outputs. Accordingly we will work with the functor $F(X) = A \times X \times X + X$, where the left summand can be thought of as the result of an output step, while the right summand gives the result of a non-output step.

▶ **Theorem 4** (Finality for trees). *Given a set of programs $\mathbb{T}$ endowed with a probabilistic step function $\mathsf{st} \colon \mathbb{T} \to \mathcal{D}(A \times \mathbb{T} \times \mathbb{T} + \mathbb{T})$, there is a* unique *semantics function $[\![-]\!]$ assigning to each program a probability distribution of output trees such that the following diagram commutes in the Kleisli category $\mathcal{K}\ell(\mathcal{D})$.*

$$\begin{array}{ccc} \mathbb{T} & \xrightarrow{\quad [\![-]\!] \quad} & \mathsf{Trees}(A_\perp) \\ {\scriptstyle \mathsf{st}}\downarrow & & \downarrow{\scriptstyle \langle \mathsf{out},\mathsf{unf}\rangle^{-1}} \\ A \times \mathbb{T} \times \mathbb{T} + \mathbb{T} & \xrightarrow{id \times [\![-]\!] \times [\![-]\!] + [\![-]\!]} & A \times \mathsf{Trees}(A_\perp) \times \mathsf{Trees}(A_\perp) + \mathsf{Trees}(A_\perp) \end{array}$$

$\mathsf{Trees}(A_\perp)$ are infinite trees where the nodes are either elements of A or $\perp$. An a-node has two children whereas a $\perp$-node only has one child. Formally, we can construct these trees

with the two maps out and unf:



Defining ASP for trees is a bit more subtle than for streams. Due to measurability issues, we can only refer to the probability of infinitely many outputs along one path at a time in the tree. A bit more formally, let $w \in \{L, R\}^\omega$ be an infinite word on alphabet $\{L, R\}$. Given any tree $t \in \mathsf{Trees}(A_\perp)$, w induces a single path t_w in the tree: from the root, the path follows the left/right child of a-nodes as indicated by w, and the single child of $\perp$-nodes.

▶ **Definition 5** (ASP for trees)**.** A tree program $p \in \mathbb{T}$ is *almost surely productive* (ASP) if

$$\forall w \in \{L, R\}^\omega.\ \Pr_{t \sim [\![p]\!]}[t_w \text{ has infinitely many concrete output nodes } a \in A] = 1.$$

We have omitted the σ-algebra structure on $\mathsf{Trees}(A_\perp)$ for lack of space, but it is quite similar to the one for streams: it is generated by the cones $u\mathsf{Trees}(A_\perp) = \{t \in \mathsf{Trees}(A_\perp) \mid t \text{ is an extension of the finite tree } u\}$.

▶ **Example 6.** Consider the probabilistic tree defined by the following equation:

$$\tau = \mathsf{mk}(a, \tau, \tau) \oplus_p \mathsf{left}(\tau)$$

The $\mathsf{mk}(a, t_1, t_2)$ constructor produces a tree with the root labeled by a and children t_1 and t_2, while the $\mathsf{left}(t)$ destructor consumes the output at the root of t and steps to the left child of t. While this example is more difficult to work out informally, it has similar ASP behavior as the previous example we saw for streams: when $p > 1/2$ this program is ASP, since it has strictly higher probability of constructing a node (and producing an output) than destructing a node (and consuming an output).

4 A Calculus for Probabilistic Streams and Trees

Now that we have introduced almost sure productivity, we consider how to verify this property. We work with two variants of a simple calculus for probabilistic coinductive programming, for producing streams and trees respectively. We suppose that outputs are drawn from some finite alphabet A. The language for streams considers terms of the following form:

$$e \in \mathbb{T} ::= \sigma \mid e \oplus_p e \mid a : e\ (a \in A) \mid \mathsf{tail}(e)$$

The distinguished variable σ represents a recursive occurrence of the stream so that streams can be defined via equations $\sigma = e$. The operation $e_1 \oplus_p e_2$ selects e_1 with probability p and e_2 with probability $1 - p$. The constructor $a : e$ builds a stream with head a and tail e. The destructor $\mathsf{tail}(e)$ computes the tail of a stream, discarding the head.

The language for trees is similar, with terms of the following form:

$$e \in \mathbb{T} ::= \tau \mid e \oplus_p e \mid \mathsf{mk}(a, e, e)\ (a \in A) \mid \mathsf{left}(e) \mid \mathsf{right}(e)$$

The variable τ represents a recursive occurrence of the tree, so that trees are defined as $\tau = e$. The constructor $\mathsf{mk}(a, e_1, e_2)$ builds a tree with root labeled a and children e_1 and e_2. The destructors $\mathsf{left}(e)$ and $\mathsf{right}(e)$ extract the left and right children of e, respectively.

We interpret these terms coalgebraically by first giving a step function from $\mathsf{st}_e : \mathbb{T} \to \mathcal{D}(F(\mathbb{T}))$ for an appropriate functor, and then taking the semantics as the map to the final coalgebra. For streams, we take the functor $F(X) = A \times X + X$: a term steps to a distribution over either an output in A and a resulting term, or just a resulting term (with no output). To describe how the recursive occurrence σ steps, we parametrize the step function st_e by the top level stream term e; this term remains fixed throughout the evaluation. This choice restricts recursion to be global in nature, i.e., our language does not support mutual or nested recursion. Supporting more advanced recursion is also possible, but we stick with the simpler setting here; we return to this point in Section 7.

The step relation is defined by case analysis on the syntax of terms. Probabilistic choice terms reduce by scaling the result of stepping e and the result of stepping e' by p and $1-p$ respectively, and then combining the distributions:

$$\mathsf{st}_e(e_1 \oplus_p e_2) \triangleq p \cdot \mathsf{st}_e(e_1) + (1-p) \cdot \mathsf{st}_e(e_2)$$

The next cases push destructors into terms:

$$\mathsf{st}_e(\mathsf{tail}^k(a : e)) \triangleq \mathsf{st}_e(\mathsf{tail}^{k-1}(e))$$
$$\mathsf{st}_e(\mathsf{tail}^k(e_1 \oplus_p e_2)) \triangleq \mathsf{st}_e(\mathsf{tail}^k(e_1) \oplus_p \mathsf{tail}^k(e_2))$$

Here and below, we write tail^k as a shorthand for $k > 0$ applications of tail.

The remaining cases return point distributions. If we have reached a constructor then we produce a single output. Otherwise, we replace σ by the top level stream term, unfolding a recursive occurrence.

$$\mathsf{st}_e(a : e') \triangleq \delta(inl(a, e'))$$
$$\mathsf{st}_e(e') \triangleq \delta(inr(e'[e/\sigma])) \quad \text{otherwise}$$

Note that a single evaluation step of a stream may lead to multiple constructors at top level of the term, but only one output can be recorded each step – the remaining constructors are preserved in the term and will give rise to outputs in subsequent steps.

The semantics is similar for trees. We take the functor $F(X) = (A \times X \times X) + X$: a term reduces to a distribution over either an output in A and two child terms, or a resulting term and no output. The main changes to the step relation are for constructors and destructors. The constructor $\mathsf{mk}(a, e_1, e_2)$ reduces to $\delta(inl(a, e_1, e_2))$, representing an output a this step. Destructors are handle like tail for streams, where $\mathsf{left}(\mathsf{mk}(a, e_1, e_2))$ reduces to e_1 and $\mathsf{right}(\mathsf{mk}(a, e_1, e_2))$ reduces to e_2, and $\mathsf{tail}^k(-)$ is generalized to any finite combination of $\mathsf{left}(-)$ and $\mathsf{right}(-)$.

Concretely, let $C[e]$ be any (possibly empty) combination of left and right applied to e. We have the following step rules:

$$\mathsf{st}_e(C[\mathsf{left}(\mathsf{mk}(a, e_l, e_r))]) \triangleq \mathsf{st}_e(C[e_l])$$
$$\mathsf{st}_e(C[\mathsf{right}(\mathsf{mk}(a, e_l, e_r))]) \triangleq \mathsf{st}_e(C[e_r])$$
$$\mathsf{st}_e(C[e_1 \oplus_p e_2]) \triangleq p \cdot \mathsf{st}_e(C[e_1]) + (1-p) \cdot \mathsf{st}_e(C[e_2])$$
$$\mathsf{st}_e(\mathsf{mk}(a, e_l, e_r)) \triangleq \delta(inl(a, e_l, e_r))$$
$$\mathsf{st}_e(C[\tau]) \triangleq \delta(inr(C[e]))$$

5 Syntactic Conditions for ASP

With the language and semantics in hand, we now turn to proving ASP. While it is theoretically possible to reason directly on the semantics using our definitions from Section 3, in practice it

is much easier to reason about the language. In this section we present a syntactic sufficient condition for ASP. Intuitively, the idea is to approximate the expected number of outputs every step; if this measure is strictly positive, then the program is ASP.

5.1 A Syntactic Measure

We define a syntactic measure $\#(-) : \mathbb{T} \to \mathbb{R}$ by induction on stream terms:

$$\begin{aligned} \#(\sigma) &\triangleq 0 \\ \#(e_1 \oplus_p e_2) &\triangleq p \cdot \#(e_1) + (1-p) \cdot \#(e_2) \\ \#(a : e) &\triangleq \#(e) + 1 \\ \#(\mathsf{tail}(e)) &\triangleq \#(e) - 1 \end{aligned}$$

The measure # describes the expected difference between the number of outputs produced (by constructors) and the number of outputs consumed (by destructors) in each unfolding of the term. We can define a similar measure for tree terms:

$$\begin{aligned} \#(\tau) &\triangleq 0 \\ \#(e_1 \oplus_p e_2) &\triangleq p \cdot \#(e_1) + (1-p) \cdot \#(e_2) \\ \#(\mathsf{mk}(a, e_1, e_2)) &\triangleq \min(\#(e_1), \#(e_2)) + 1 \\ \#(\mathsf{left}(e)) = \#(\mathsf{right}(e)) &\triangleq \#(e) - 1 \end{aligned}$$

We can now state conditions for ASP for streams and trees.

▶ **Theorem 7.** *Let e be a stream term with $\gamma = \#(e)$. If $\gamma > 0$, e is ASP.*

▶ **Theorem 8.** *Let e be a tree term with $\gamma = \#(e)$. If $\gamma > 0$, e is ASP.*

The main idea behind the proof for streams is that by construction of the step relation, each step either produces an output or unfolds a fixed point (if there is no output). In unfolding steps, the expected measure of the term plus the number of outputs increases by γ. By defining an appropriate martingale and applying the Azuma-Hoeffding inequality, the sum of the measure and the number of outputs must increase linearly as the term steps when $\gamma > 0$. Since the measure is bounded above – when the measure is large the stream outputs instead of unfolding – the number of outputs must increase linearly and the stream is ASP.

The proof for trees is similar, showing that on any path through the observation tree there are infinitely many output steps with probability 1. We present detailed proofs in the full version of this paper.

5.2 Examples

We consider a few examples of our analysis. The alphabet A does not affect the ASP property; without loss of generality, we can let the alphabet A be the singleton $\{\star\}$.

▶ **Example 9.** Consider the stream definition $\sigma = (\star : \sigma) \oplus_p \mathsf{tail}(\sigma)$. The # measure of the stream term is $p \cdot 1 + (1-p) \cdot (-1) = 2p - 1$. By Theorem 7, the stream is ASP when $p > 1/2$.

The measure does not give useful information when # is not positive.

▶ **Example 10.** Consider the stream definition $\sigma = (\star : \sigma) \oplus_{1/2} \mathsf{tail}(\sigma)$; the # measure of the term is 0. The number of outputs can be modeled by a simple random walk on a line, where

the maximum position is the number of outputs produced by the stream. Since a simple random walk has probability 1 of reaching every $n \in \mathbb{N}$ [26], the stream term is ASP.

In contrast, $\#(\sigma)$ is 0 but the stream definition $\sigma = \sigma$ is clearly non-productive.

We can give similar examples for tree terms.

▶ **Example 11.** Consider the tree definitions $\tau = e_i$, where

- $e_1 \triangleq \mathsf{left}(\tau) \oplus_{1/4} \mathsf{mk}(\star, \tau, \tau)$
- $e_2 \triangleq \mathsf{left}(\tau) \oplus_{1/4} \mathsf{mk}(\star, \tau, \mathsf{left}(\tau))$.

We apply Theorem 8 to deduce ASP. We have $\#(e_1) = (1/4) \cdot (-1) + (3/4) \cdot (+1) = 1/2$, so the first term is ASP. For the second term, $\#(e_2) = (1/4) \cdot (-1) + (3/4) \cdot 0 = -1/4$, so our analysis does not give any information.

6 Probabilistic Model-Checking for ASP

The syntactic analysis for ASP is simple, but it is not complete – no information is given if the measure is not positive. In this section we give a more sophisticated, complete analysis by first modeling the operational semantics of a term by a *Probabilistic Pushdown Automaton* (pPDA), then deciding ASP by reduction to model-checking.

6.1 Probabilistic Pushdown Automata and LTL

A pPDA is a tuple $\mathcal{A} = (S, \Gamma, \mathcal{T})$ where S is a finite set of states and Γ is a finite *stack alphabet*. The *transition function* $\mathcal{T} : S \times (\Gamma \cup \{\bot\}) \times S \times \Gamma^* \to [0, 1]$ looks at the top symbol on the stack (which might be empty, denoted $\bot$), consumes it, and pushes a (possibly empty, denoted ε) string of symbols onto the stack, before transitioning to the next state. A *configuration* of $\mathcal{A}$ is an element of $\mathcal{C} = S \times \Gamma^*$, and represents the state of the pPDA and the contents of its stack (with the top on the left) at some point of its execution. Given a configuration, the transition function $\mathcal{T}$ specifies a distribution over configurations in the next step. Given an initial state s and an initial stack $\gamma \in \Gamma^*$, $\mathcal{T}$ induces a distribution $\mathrm{Paths}(s, \gamma)$ over the infinite sequence of configurations starting in (s, γ).

Linear Temporal Logic (LTL) [29] is a linear-time temporal logic that describes runs of a transition system, which in a pPDA correspond to infinite sequences of configurations. Propositions in LTL are defined by the syntax

$$\phi, \psi ::= Q \mid \neg\phi \mid \mathcal{X}\phi \mid \phi \,\mathcal{U}\, \psi \mid \Diamond\phi \mid \Box\phi$$

where ϕ, ψ are *path formulas*, which describe a particular path, and Q is a set of atomic propositions. The validity of an LTL formula on a run π of pPDA $\mathcal{A}$ is defined as follows:

$$\pi \models \Phi \Leftrightarrow \pi[0] \in Q \qquad \pi \models \phi \,\mathcal{U}\, \psi \Leftrightarrow \exists i. \pi_i \models \psi \wedge \forall j < i. \pi_j \models \phi$$
$$\pi \models \neg\phi \Leftrightarrow \pi \not\models \phi \qquad \pi \models \Diamond\phi \Leftrightarrow \exists i. \pi_i \models \phi$$
$$\pi \models \mathcal{X}\phi \Leftrightarrow \pi_1 \models \phi \qquad \pi \models \Box\phi \Leftrightarrow \forall i. \pi_i \models \phi$$

where atomic propositions q are interpreted as $[\![q]\!] \subseteq \mathcal{C}$. As expected, path formulas are interpreted in traces of configurations $\pi \in \mathcal{C}^\omega$; $\pi[i]$ is the ith element in the path π, and π_i is the suffix of π from $\pi[i]$.

Given a pPDA $\mathcal{A}$, a starting configuration $(s, \gamma) \in \mathcal{C}$ and a LTL formula ϕ, the *qualitative model-checking problem* is to decide whether runs starting from (s, γ) satisfy ϕ almost surely, i.e., whether $\Pr_{\pi \in \mathrm{Paths}(s,\gamma)}[\pi \models \phi] = 1$. The following is known.

▶ **Theorem 12** (Brázdil, et al. [6]). *The quantitative model-checking problem for pPDAs against LTL specifications is decidable.*

Almost sure productivity states that an event – namely, producing an output – occurs infinitely often with probability 1. Such properties can be expressed in LTL.

▶ **Lemma 13.** *Let $(s,\gamma) \in \mathcal{C}$ be an initial configuration and $\mathcal{B} \subseteq \mathcal{C}$ be a set of configurations. Then $\Pr_{\pi \in \mathrm{Paths}(s,\gamma)}[\pi$ visits $\mathcal{B}$ infinitely often$] = 1$ iff $\Pr_{\pi \in \mathrm{Paths}(s,\gamma)}[\pi \models \Box\Diamond\mathcal{B}] = 1$.*

We will encode language terms as pPDAs and cast almost sure productivity as an LTL property stating that configurations representing output steps are reached infinitely often with probability 1. Theorem 12 then gives a decision procedure for ASP. In general, this algorithm[1] is in **PSPACE**.

6.2 Modeling streams with pPDAs

The idea behind our encoding from terms to pPDAs is simple to describe. The states of the pPDA will represent subterms of the original term, and transitions will model steps. In the original step relation, the only way a subterm can step to a non-subterm is by accumulating destructors. We use a single-letter stack alphabet to track the number of destructors so that a term like $\mathsf{tail}^k(e)$ can be modeled by the state corresponding to e and k counters on the stack. More formally, given a stream term e we define a pPDA $\mathcal{A}_e = (\mathcal{S}_e, \{tl\}, \mathcal{T}_e)$, where $\mathcal{S}_e$ is the set of syntactic subterms of e and $\mathcal{T}_e$ is the following transition function:

$$\begin{aligned}
\mathcal{T}_e((\sigma,a),(e,a)) &= 1 & \mathcal{T}_e((a':e',\bot),(e',\varepsilon)) &= 1\\
\mathcal{T}_e((e_1 \oplus_p e_2,a),(e_1,a)) &= p & \mathcal{T}_e((a':e',tl),(e',\varepsilon)) &= 1\\
\mathcal{T}_e((e_1 \oplus_p e_2,a),(e_2,a)) &= 1-p & \mathcal{T}_e((\mathsf{tail}(e'),a),(e',tl\cdot a) &= 1
\end{aligned}$$

Above, $\cdot$ concatenates strings and we implicitly treat a as alphabet symbol or a singleton string. All non-specified transitions have zero probability. We define the set of *outputting configurations* as $\mathcal{O} \triangleq \{s \in \mathcal{C} \mid \exists a', e'.\, s = (a' : e', \bot)\}$, that is, configurations where the current term is a constructor and there are no pending destructors. Our main result states that this set is visited infinitely often with probability 1 if and only if e is ASP. In fact, we prove something stronger:

▶ **Theorem 14.** *Let e be a stream term and let $\mathcal{A}_e$ be the corresponding pPDA. Then,*

$$\Pr_{t\sim[\![e]\!]}[t \text{ has infinitely many output nodes}] = \Pr_{\pi\sim\mathrm{Paths}(e,\varepsilon)}[\pi \models \Box\Diamond\,\mathcal{O}].$$

In particular, e is ASP if and only if for almost all runs π starting in (e,ε), $\pi \models \Box\Diamond\mathcal{O}$.

By Theorem 12, ASP is decidable for stream terms. In fact, it is also possible to decide whether a stream term is almost surely *not* productive, i.e., the probability of producing infinitely many outputs is zero.

[1] Technically, this algorithm requires first encoding the LTL formula into a Deterministic Rabin Automaton (DRA). Even though this encoding can in general blow up the problem size exponentially, this is not the case for the simple conditions we consider.

6.3 Extending to trees

Now, we extend our approach to trees. The main difficulty can be seen in the constructors. For streams, we can encode the term $a : e$ by proceeding to the tail e. For trees, however, how can we encode $\mathsf{mk}(a, e_1, e_2)$? The pPDA cannot step to both e_1 and e_2. Since the failure of ASP may occur down either path, we cannot directly translate the ASP property on trees to LTL – ASP is a property of *all* paths down the tree. Instead, on constructors our pPDA encoding will choose a path at random to simulate. As we will show, if the probability of choosing a path that outputs infinitely often is 1, then every path will output infinitely often. Notice that in general, properties that happen with probability 1 do not necessarily happen for every path, but the structure of our problem allows us to make this generalization.

More formally, the stack alphabet will now be $\{rt, lt\}$, and on constructors we transition to each child with probability $1/2$:

$$\begin{aligned}
\mathcal{T}_e((\tau, a), (e, a)) &= 1 \\
\mathcal{T}_e((e_1 \oplus_p e_2, a), (e_1, a)) &= p \\
\mathcal{T}_e((e_1 \oplus_p e_2, a), (e_2, a)) &= 1 - p \\
\mathcal{T}_e((\mathsf{mk}(a', e_l, e_r), \bot), (e_l, \varepsilon)) &= 1/2 \\
\mathcal{T}_e((\mathsf{mk}(a', e_l, e_r), \bot), (e_r, \varepsilon)) &= 1/2
\end{aligned}$$

$$\begin{aligned}
\mathcal{T}_e((\mathsf{mk}(a', e_l, e_r), lt), (e_l, \varepsilon)) &= 1 \\
\mathcal{T}_e((\mathsf{mk}(a', e_l, e_r), rt), (e_r, \varepsilon)) &= 1 \\
\mathcal{T}_e((\mathsf{left}(e'), a), (e', lt \cdot a)) &= 1 \\
\mathcal{T}_e((\mathsf{right}(e'), a), (e', rt \cdot a)) &= 1
\end{aligned}$$

We define $\mathcal{O} \triangleq \{s \in \mathcal{C} \mid \exists a', e_l, e_r.\, s = (\mathsf{mk}(a', e_l, e_r), \varepsilon)\}$ to be the set of outputting configurations, and we can characterize ASP with the following theorem.

▶ **Theorem 15.** *Let e be a tree term and $\mathcal{A}_e$ be the corresponding probabilistic PDA. Then $\Pr_{\pi \sim \mathrm{Paths}(e,\bot)}[\pi \models \Box\Diamond\, \mathcal{O}] = 1$ if and only if for every $w \in \{L, R\}^\omega$,*

$$\Pr_{t \sim [\![e]\!]}[t \text{ has infinitely many output nodes along } w] = 1.$$

Thus we can decide ASP by deciding a LTL formula.

7 Possible Generalizations and Extensions

Our definition of ASP and our verification approaches suggest several natural directions.

Handling Richer Languages. The most concrete direction is to consider richer languages for coinductive probabilistic programming. Starting from our core language, one might consider allowing more operations on coinductive terms, mutually recursive definitions, or conditional tests of some kind. It should also be possible to develop languages for more complex coinductive types associated with general polynomial functors (see, e.g., Kozen [24]). Note that adding more operations, e.g. pointwise + of streams would increase the expressivity of the language but raise additional challenges from the perspective of the semantics – we would have to add extra structure to the base category and re-check that the finality proof.

Developing new languages for coinductive probabilistic programming – perhaps an imperative language or a higher-order language – would also be interesting. From the semantics side, our development in Section 3 should support any language equipped with a small-step semantics producing output values, allowing ASP to be defined for many kinds of languages. The verification side appears more challenging. Natural extensions, like a pointwise addition operation, already seem to pose challenges for the analyses. We know of no general method to reasoning about ASP. This stands in contrast to almost sure termination, which can be established by where flexible criteria like decreasing probabilistic variants [17]. Considering counterparts of these methods for ASP is an interesting avenue of research.

Exploring Other Definitions. Our definition of ASP is natural, but other definitions are possible. For trees (and possibly more complex coinductive structures), we could instead require that there *exists* a path producing infinitely many outputs, rather than requiring that *all* paths produce infinitely many outputs. This weaker notion of ASP can be defined in our semantics, but it is currently unclear how to verify this kind of ASP.

Our notion of ASP also describes just the probability of generating infinitely many outputs, and does not impose any requirement on the generation rate. Quantitative strengthenings of ASP – say, requiring bounds on the expected number of steps between outputs – could give more useful information.

Understanding Dependence on Step Relation. Our coalgebraic semantics supporting our verification methods are based on a small-step semantics for programs. A natural question is whether this dependence is necessary, or if one could verify ASP with a less step-dependent semantics. Again drawing an analogy, it appears that fixing a reduction strategy is important in order to give a well-defined notion of almost sure termination for probabilistic higher-order languages (see, e.g., [25]). The situation for almost sure productivity is less clear.

8 Related Work

Our work is inspired by two previously independent lines of research: probabilistic termination and productivity of coalgebraic definitions.

Probabilistic Termination. There are a broad range of techniques for proving termination of probabilistic programs. Many of the most powerful criteria use advanced tools from probability theory [27], especially martingale theory [8, 16, 9, 10, 11]. Other works adopt more pragmatic approaches, generally with the goal of achieving automation. Arons, Pnueli and Zuck [4] reduce almost sure termination of a program P to termination of a non-deterministic program Q, using a planner that must be produced by the verifier. Esparza, Gaiser and Kiefer [15] give a CEGAR-like approach for building patterns (which play a role similar to planners) and prove that their approach is complete for a natural class of programs.

Productivity of Corecursive Definitions. There has been a significant amount of work on verifying productivity of corecursive definitions without probabilistic choice. Endrullis and collaborators [14] give a procedure for deciding productivity of an expressive class of stream definitions. In a companion work [13], they study the strength of data oblivious criteria, i.e., criteria that do not depend on values. More recently, Komendantskaya and collaborators [21] introduce observational productivity and give a semi-decision procedure for logic programs.

9 Conclusion

We introduce almost sure productivity, a counterpart to almost sure termination for probabilistic coinductive programs. In addition, we propose two methods for proving ASP for a core language for streams and infinite trees. Our results demonstrate that verification of ASP is feasible and can even be decidable for simple languages.

Abstract

The termination analysis of linear loops plays a key rôle in several areas of computer science, including program verification and abstract interpretation. Such deceptively simple questions also relate to a number of deep open problems, such as the decidability of the Skolem and Positivity Problems for linear recurrence sequences, or equivalently reachability questions for discrete-time linear dynamical systems. In this paper, we introduce the class of *o-minimal invariants*, which is broader than any previously considered, and study the decidability of the existence and algorithmic synthesis of such invariants as certificates of non-termination for linear loops equipped with a large class of halting conditions. We establish two main decidability results, one of them conditional on Schanuel's conjecture in transcendental number theory.

1 Introduction

This paper is concerned with the existence and algorithmic synthesis of suitable *invariants* for linear loops, or equivalently for discrete-time linear dynamical systems. Invariants are one of the most fundamental and useful notions in the quantitative sciences, and within computer science play a central rôle in areas such as program analysis and verification, abstract

interpretation, static analysis, and theorem proving. To this day, automated invariant synthesis remains a topic of active research; see, e.g., [17], and particularly Sec. 8 therein.

In program analysis, invariants are often invaluable tools enabling one to establish various properties of interest. Our focus here is on simple linear loops, of the following form:

$$P: \quad x \leftarrow s; \;\; \texttt{while } x \notin F \texttt{ do } x \leftarrow Ax\,, \tag{1}$$

where x is a d-dimensional column vector of variables, s is a d-dimensional vector of integer, rational, or real numbers, $A \in \mathbb{Q}^{d\times d}$ is a square rational matrix of dimension d, and $F \subseteq \mathbb{R}^d$ represents the halting condition.

Much research has been devoted to the termination analysis of such loops (and variants thereof); see, e.g., [3, 2, 25]. For $S \subseteq \mathbb{R}^d$, we say that P *terminates* on S if it terminates for all initial vectors $s \in S$. One of the earliest and most famous results in this line of work is due to Kannan and Lipton, who showed polynomial-time decidability of termination in the case where S and F are both singleton vectors with rational entries [15, 16]. This work was subsequently extended to instances in which F is a low-dimensional vector space [6, 8] or a low-dimensional polyhedron [7]. Still starting from a fixed initial vector, the case in which the halting set F is a hyperplane is equivalent to the famous Skolem Problem for linear recurrence sequences, whose decidability has been open for many decades [29, §3.9], although once again positive results are known in low dimensions [20, 32]. The case in which F is a half-space corresponds to the Positivity Problem for linear recurrence sequences, likewise famously open in general but for which some partial results also exist [23, 22].

Cases in which the starting set S is infinite have also been extensively studied, usually in conjunction with a halting set F consisting of a half-space. For example, decidability of termination for $S = \mathbb{R}^d$ and $S = \mathbb{Q}^d$ are known [31, 4]; see also [21]. In the vast majority of cases, however, termination is a hard problem (and often undecidable [34]), which has led researchers to turn to semi-algorithms and heuristics. One of the most popular and successful approaches to establishing termination is the use of ranking functions, on which there is a substantial body of work; see, e.g., [2], which includes a broad survey on the subject.

Observe, for a loop P such as that given in (1), that failure to terminate on a set S corresponds to the existence of some vector $s \in S$ from which P loops forever. It is important to note, however, that the absence of a suitable ranking function does not necessarily entail non-termination, owing to the non-completeness of the method. Yet surprisingly, as pointed out in [14], there has been significantly less research in methods seeking to establish *non-termination* than in methods aimed at proving termination. Most existing efforts for the former have focused on the synthesis of appropriate invariants; see, e.g., [11, 9, 28, 26, 10, 27, 13].

In order to make this notion more precise, let us associate with our loop P a *discrete-time linear dynamical system* (A, s). The *orbit* of this dynamical system is the set $\mathcal{O} = \{A^n s \mid n \geq 0\}$. It is clear that P fails to terminate from s iff $\mathcal{O}$ is disjoint from F. A possible method to establish the latter is therefore to exhibit a set $\mathcal{I} \subseteq \mathbb{R}^d$ such that:

1. $\mathcal{I}$ contains the initial vector s, i.e., $s \in \mathcal{I}$;
2. $\mathcal{I}$ is invariant under A, i.e., $A\mathcal{I} \subseteq \mathcal{I}$; and
3. $\mathcal{I}$ is disjoint from F, i.e., $\mathcal{I} \cap F = \emptyset$.

Indeed, the first two conditions ensure that $\mathcal{I}$ contains the entire orbit $\mathcal{O}$, from which the desired claim follows thanks to the third condition.

In instances of non-termination, one notes that the orbit $\mathcal{O}$ itself is always an invariant meeting the above conditions. However, since in general one does not know how to algorithmically check Condition (3), such an invariant is of little use. One therefore usually first fixes a suitable class of candidate sets for which the above conditions can be mechanically verified,

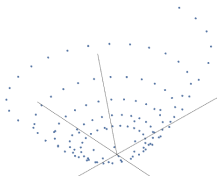

Figure 1 The orbit $\mathcal{O}$ of (A, s)

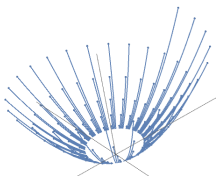

Figure 2 Trajectory rays of $\mathcal{O}$.

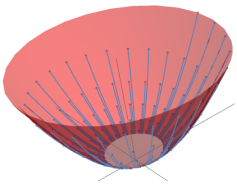

Figure 3 Trajectory cone for $\mathcal{O}$.

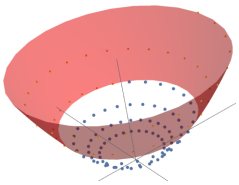

Figure 4 Invariant for $\mathcal{O}$.

and within that class, one seeks to determine if an invariant can be found. Examples of such classes include polyhedra [11], algebraic sets [27], and semi-algebraic sets [13].

Main contributions. We focus on loops of the form given in (1) above. We introduce the class of *o-minimal invariants*, which, to the best of our knowledge, is significantly broader than any of the classes previously considered. We also consider two large classes of halting sets, namely semi-algebraic sets, as well as sets definable in the first-order theory of the reals with exponentiation, denoted $\mathfrak{R}_{\exp}$. Given $s \in \mathbb{Q}^d$, $A \in \mathbb{Q}^{d\times d}$, and $F \subseteq \mathbb{R}^d$, our main results are the following: if F is a semi-algebraic set, it is decidable whether there exists an o-minimal invariant $\mathcal{I}$ containing s and disjoint from F, and moreover in positive instances such an invariant can be defined explicitly in $\mathfrak{R}_{\exp}$; for the more general case in which F is $\mathfrak{R}_{\exp}$-definable, the same holds assuming Schanuel's conjecture.

We illustrate below some of the key ideas from our approach. Consider a linear dynamical system (A, s) with $A \in \mathbb{Q}^{3\times 3}$ whose orbit $\mathcal{O}$ is depicted in Figure 1. In our example, $\mathcal{O}$ spirals outward at some rate ρ_1 in the x, y-plane, and increases along the z-axis at some rate ρ_2. Intuitively, ρ_1 and ρ_2 are the moduli of the eigenvalues of A.

We now consider a 'normalised' version of A, with both moduli set to 1. We then connect every point on the normalised orbit with a *trajectory ray* to its corresponding point on $\mathcal{O}$, while respecting the rates ρ_1 and ρ_2 (see Figure 2). One can observe that the normalised orbit is dense in the unit circle. We prove that *any* o-minimal invariant for (A, s) must in fact eventually contain every trajectory ray for every point on the unit circle; we depict the union of these rays, referred to as the *trajectory cone*, in Figure 3. Finally, we show that any o-minimal invariant must in fact contain some truncation of the trajectory cone from below, starting from some height. That is, there is a uniform bound from which all the rays must belong to the invariant. Moreover, we can now synthesise an $\mathfrak{R}_{\exp}$-definable o-minimal invariant by simply adjoining a finite number of orbit points to the truncated trajectory cone, as depicted in Figure 4.

It is worth emphasising that, whilst in general there cannot exist a smallest o-minimal invariant, the family of truncated cones that we define plays the rôle of a 'minimal class', in the sense that *any* o-minimal invariant must necessarily contain some truncated cone. We make all of these notions precise in the main body of the paper.

The work that is closest to ours in the literature is [13], which considers the same kind of loops as we do here, but restricted to the case in which the halting set F is always a rational singleton. The authors then exhibit a procedure for deciding the existence of semi-algebraic invariants. The present paper has a considerably broader scope, in that we deal with much wider classes both of invariants and halting sets. From a technical standpoint, the present paper correspondingly makes heavy use of model-theoretic and number-theoretic tools that are entirely absent from [13]. It is interesting to note, however, that the question of the existence of semi-algebraic (rather than o-minimal) invariants in the present setting appears to be a challenging open problem.

2 Preliminaries

The *first-order theory of the reals*, denoted $\mathfrak{R}_0$, is the collection of true sentences in the first-order logic of the structure $\langle \mathbb{R}, 0, 1, +, \cdot, < \rangle$. Sentences in $\mathfrak{R}_0$ are quantified Boolean combinations of atomic propositions of the form $P(x_1, \ldots, x_n) > 0$ where P is a polynomial with integer coefficients, and $x_1, \ldots, x_n$ are variables. Tarski famously showed that this theory admits quantifier elimination [30] and is therefore decidable. In addition to $\mathfrak{R}_0$, we also consider the *first-order theory of the reals with exponentiation*, denoted $\mathfrak{R}_{\exp}$, which augments $\mathfrak{R}_0$ with the exponentiation function $x \mapsto e^x$.

A set $S \subseteq \mathbb{R}^d$ is *definable* in a theory $\mathfrak{R}$ if there exists a formula $\varphi(x_1, \ldots, x_d)$ in $\mathfrak{R}$ with free variables $x_1, \ldots, x_d$ such that $S = \{(c_1, \ldots, c_d) \in \mathbb{R}^d \mid \varphi(c_1, \ldots, c_d) \text{ is true}\}$. A function $f \colon B \to \mathbb{R}^m$ with $B \subseteq \mathbb{R}^n$ is *definable* in $\mathfrak{R}$ if its graph $\Gamma(f) = \{(x, f(x)) \mid x \in B\} \subseteq \mathbb{R}^{n+m}$ is an $\mathfrak{R}$-definable set. For $\mathfrak{R} = \mathfrak{R}_0$, the first-order theory of the reals, $\mathfrak{R}_0$-definable sets (resp. functions) are known as *semi-algebraic* sets (resp. functions).

▶ Remark. Our usage of the terms "definable" and "semi-algebraic" corresponds to "definable without parameters" and "semi-algebraic without parameters" in model theory.

A theory $\mathfrak{R}$ is said to be *o-minimal* if every $\mathfrak{R}$-definable subset of the reals $S \subseteq \mathbb{R}$ is a finite union of points and (possibly unbounded) intervals.

▶ **Definition 1.** A set $S \subseteq \mathbb{R}^d$ is *o-minimal* if it is definable in some o-minimal theory that extends $\mathfrak{R}_{\exp}$.

Tarski's result on quantifier elimination [30] also implies that $\mathfrak{R}_0$ is o-minimal. The o-minimality of $\mathfrak{R}_{\exp}$, on the other hand, is due to Wilkie [33]. O-minimal theories enjoy many useful properties, some of which we list below, referring the reader to [12] for precise definitions and proofs. In what follows, $\mathfrak{R}$ is a fixed o-minimal theory.

1. For an $\mathfrak{R}$-definable set $S \subseteq \mathbb{R}^d$, its topological closure $\overline{S}$ is also $\mathfrak{R}$-definable.
2. For an $\mathfrak{R}$-definable function $f \colon S \to \mathbb{R}$, the number $\inf\{f(x) \mid x \in S\}$ is $\mathfrak{R}$-definable (as a singleton set).
3. O-minimal theories admit *cell decomposition*: every $\mathfrak{R}$-definable set $S \subseteq \mathbb{R}^d$ can be written as a finite union of connected components called *cells*. Moreover, each cell is $\mathfrak{R}$-definable and homeomorphic to $(0,1)^m$ for some $m \in \{0, 1, \ldots, d\}$. The *dimension* of S is defined as the maximal such m occurring in the cell decomposition of S.
4. For an $\mathfrak{R}$-definable function $f \colon S \to \mathbb{R}^m$, the dimension of its graph $\Gamma(f)$ is the same as the dimension of S.

As mentioned above, $\mathfrak{R}_0$ is decidable thanks to its effective quantifier elimination procedure. Equivalently, given a semi-algberaic set, we can effectively compute its cell decomposition. Unfortunately, few more expressive theories are known to be decidable. The theory $\mathfrak{R}_{\exp}$ is decidable provided that Schanuel's conjecture, an assertion in transcendental number theory, holds [18]. Our decidability result in Theorem 12 is subject to Schanuel's conjecture; somewhat surprisingly, however, we exhibit in Theorem 13 an unconditional decidability result.

▶ Remark. While all our $\mathfrak{R}$-definable sets live in $\mathbb{R}^d$, it is often convenient or necessary to consider sets in $\mathbb{C}^d$. To this end, by identifying $\mathbb{C}$ with $\mathbb{R}^2$, we define a set $S \subseteq \mathbb{C}^d$ to be $\mathfrak{R}$-definable if the set $\{(x, y) \in \mathbb{R}^d \times \mathbb{R}^d \mid x + iy \in S\}$ in $\mathbb{R}^{2d}$ is $\mathfrak{R}$-definable.

A *discrete-time linear dynamical system* (LDS) consists of a pair (A, s), where $A \in \mathbb{Q}^{d \times d}$ and $s \in \mathbb{Q}^d$. Its *orbit* $\mathcal{O}$ is the set $\{A^n s \mid n \in \mathbb{N}\}$. An *invariant* for (A, s) is a set $\mathcal{I} \subseteq \mathbb{R}^d$ that contains s and is stable under applications of A, i.e., $A\mathcal{I} \subseteq \mathcal{I}$. Given a set $F \subseteq \mathbb{R}^d$, we say that the invariant $\mathcal{I}$ *avoids* F if the two sets are disjoint.

3 From the Orbit to Trajectory Cones and Rays

Let (A, s) be an LDS with $A \in \mathbb{Q}^{d\times d}$ and $s \in \mathbb{Q}^d$. We consider the orbit $\mathcal{O} = \{A^n s \mid n \in \mathbb{N}\}$. Write A in Jordan form as $A = PJP^{-1}$ where P is an invertible matrix, and J is a block diagonal matrix of the form $J = \mathrm{diag}(B_1, \ldots, B_k)$, where for every $1 \le i \le k$, $B_i \in \mathbb{C}^{d_i \times d_i}$ is a Jordan block corresponding to an eigenvalue $\rho_i\lambda_i$:

$$B_i = \begin{pmatrix} \rho_i\lambda_i & 1 & & \\ & \ddots & \ddots & \\ & & \ddots & 1 \\ & & & \rho_i\lambda_i \end{pmatrix}.$$

Here $\rho_1, \ldots, \rho_k \in \mathbb{R}_{\ge 0}$, the numbers $\lambda_1, \ldots, \lambda_k$ are algebraic and have modulus 1, and $\sum_{i=1}^{k} d_i = d$. To reflect the block structure of J, we often range over $\{1, \ldots, d\}$ via a pair (i, j), with $1 \le i \le k$ and $1 \le j \le d_i$, which denotes the index corresponding to row j in block i; we refer to this notation as *block-row indexing*.

▶ Remark. Henceforth, we assume that for all $1 \le i \le k$ we have that $\rho_i > 0$ (i.e., that the matrices A and J are invertible). Indeed, if $\rho_i = 0$, then B_i is a nilpotent block and therefore, for the purpose of invariant synthesis, we can ignore finitely many points of the orbit under A until B_i^n is the 0 block. We can then restrict our attention to the image of A^n, by identifying it with $\mathbb{R}^{d-d_i}$.

Observe that now, for every set $F \subseteq \mathbb{R}^d$, we have that $A^n s \in F$ iff $J^n s' \in P^{-1}F$ where $s' = P^{-1}s$.

For every $n > d$, $J^n = \mathrm{diag}(B_1^n, \ldots, B_k^n)$ with

$$B_i^n = \begin{pmatrix} (\rho_i\lambda_i)^n & \frac{n}{\rho_i\lambda_i}(\rho_i\lambda_i)^n & \cdots & \frac{\binom{n}{d_i-1}}{(\rho_i\lambda_i)^{d_i-1}}(\rho_i\lambda_i)^n \\ & \ddots & & \vdots \\ & & & (\rho_i\lambda_i)^n \end{pmatrix}.$$

Every coordinate of $J^n s'$ is of the form $(\rho_i\lambda_i)^n Q_{i,j}(n) = \rho_i^n \lambda_i^n Q_{i,j}(n)$ for some $1 \le i \le k$ and $1 \le j \le d_i$, where $Q_{i,j}$ is a polynomial (possibly with complex coefficients) that depends on J and s'.

Let $R = \mathrm{diag}(\rho_1, \ldots, \rho_k)$ and $L = \mathrm{diag}(\lambda_1, \ldots, \lambda_k)$. We define $\mathbb{T}$ to be the subgroup of the torus in $\mathbb{C}^k$ generated by the multiplicative relations of the normalised eigenvalues $\lambda_1, \ldots, \lambda_k$. That is, consider the subgroup $G = \{v = (v_1, \ldots, v_k) \in \mathbb{Z}^k \mid \lambda_1^{v_1} \cdots \lambda_k^{v_k} = 1\}$ of $\mathbb{Z}^k$, and let

$$\mathbb{T} = \{(\alpha_1, \ldots, \alpha_k) \in \mathbb{C}^k \mid |\alpha_i| = 1 \text{ for all } i, \text{ and for every } v \in G,\ \alpha_1^{v_1} \cdots \alpha_k^{v_k} = 1\}.$$

A result by Masser [19] allows to compute in polynomial time a basis for G, and hence a representation of $\mathbb{T}$. Using Kronecker's theorem on inhomogeneous simultaneous Diophantine approximation [5] it is shown in [24] that $\{L^n \mid n \in \mathbb{N}\}$ is a dense subset of $\{\mathrm{diag}(\alpha_1, \ldots, \alpha_k) \mid (\alpha_1, \ldots, \alpha_k) \in \mathbb{T}\}$.

Thus, for every $n \in \mathbb{N}$, we have

$$J^n s' \in \left\{ \left(\rho_1^n p_1 Q_{1,1}(n), \ldots, \rho_k^n p_k Q_{k,d_k}(n)\right)^{\intercal} \mid (p_1, \ldots, p_k) \in \mathbb{T} \right\}.$$

We now define a continuous over-approximation of the expressions ρ_i^n. To this end, if there exists some modulus ρ_i larger than 1 (in which case, without loss of generality, assume that $\rho_k > 1$), then for every $1 \le i \le k$ let $b_i = \log_{\rho_k} \rho_i$, and observe that $\rho_i^n = (\rho_k^n)^{b_i}$. We

then replace the expression ρ_k^n with a continuous variable t, so that ρ_i^n becomes t^{b_i}, and n is replaced by $\log_{\rho_k} t$. If all moduli are at most 1 and some are strictly smaller than 1 (in which case, without loss of generality, $\rho_k < 1$), then replace the expression ρ_k^n with $1/t$. Note that in both cases, t grows unboundedly large as n tends to infinity. In the full version of this paper we handle the special (and simpler) case in which all eigenvalues have modulus exactly 1. Henceforth, we assume that $\rho_k > 1$. If $\rho_k < 1$, the proofs are carried out *mutatis mutandis*.

This over-approximation leads to the following definition, which is central to our approach.

▶ **Definition 2.** For every $t_0 \geq 1$, we define the *trajectory cone*[3] for the orbit $\mathcal{O}$ as

$$\mathcal{C}_{t_0} = \left\{ \left(t^{b_1} p_1 Q_{1,1}(\log_{\rho_k} t), \ldots, t^{b_k} p_k Q_{k,d_k}(\log_{\rho_k} t)\right)^\intercal \;\middle|\; (p_1, \ldots, p_d) \in \mathbb{T},\ t \geq t_0 \right\}.$$

In particular, we have that $J^n s' \in \mathcal{C}_1$.

In order to analyse invariants, we require a finer-grained notion than the entire trajectory cone. To this end, we introduce the following.

▶ **Definition 3.** For every $p = (p_1, \ldots, p_k) \in \mathbb{T}$ and every $t_0 \geq 1$, we define the *(trajectory) ray*[4] $\mathsf{r}(p, t_0) = \left\{ \left(t^{b_1} p_1 Q_{1,1}(\log_{\rho_k} t), \ldots, t^{b_k} p_k Q_{k,d_k}(\log_{\rho_k} t)\right)^\intercal \mid t \geq t_0 \right\}$.

Observe that we have $\mathcal{C}_{t_0} = \bigcup_{p \in \mathbb{T}} \mathsf{r}(p, t_0)$.

▶ **Example 4.** Consider the matrix $A = \mathrm{diag}(5, 2)$ and the initial point $s = (1, 1)^\intercal$. We then have $\mathbb{T} = \{(1, 1)\}$ and $\mathcal{C}_{t_0} = \left\{ \left(t^{\log_2 5}, t\right)^\intercal \mid t \geq t_0 \right\}$. Observe that this is not an $\mathfrak{R}_0$-definable set, as the exponent $\log_2 5$ is not rational. This shows that even for diagonalizable matrices (where $\mathcal{C}_{t_0}$ has a simple form, devoid of the polynomials $Q_{i,j}$), $\mathfrak{R}_0$ might not be enough to recover definability of the orbit (in the sense of Theorem 5 below).

4 Constructing Invariants from Trajectory Cones

We now proceed to show that the trajectory cones defined in Section 3 can be used to characterise o-minimal invariants. More precisely, we show that for an LDS (A, s) with $A = PJP^{-1}$, the image under P of every trajectory cone $\mathcal{C}_{t_0}$, augmented with finitely many points from $\mathcal{O}$, is an invariant. Moreover, we show that such invariants are $\mathfrak{R}_{\exp}$-definable, and hence o-minimal. Complementing this, we show in Section 5 that *every* o-minimal invariant must contain some trajectory cone.

In what follows, let $A = PJP^{-1}$, s, as well as the real numbers $b_1, \ldots, b_d$ be defined as in Section 3.

▶ **Theorem 5.** *For every $t_0 \geq 1$, the set $P \cdot \mathcal{C}_{t_0} \cup \left\{A^n s \mid n < \log_{\rho_k} t_0\right\}$ is an $\mathfrak{R}_{\exp}$-definable invariant for the LDS (A, s).*

The intuition behind Theorem 5 is as follows. Clearly, the orbit $\mathcal{O}$ itself is always an invariant for (A, s). However, it is generally not definable in any o-minimal theory (in particular, since it has infinitely many connected components). In order to recover definability

[3] These sets are, of course, not really cones. Nevertheless, if for all i we have $b_i = 1$ and the polynomials $Q_{i,j}$ are constant, then the set $\mathcal{C}_{t_0}$ is a conical surface formed by the union of rays going from the origin through all points of $\mathbb{T}$. The initial segments of the rays, of length determined by the parameter t_0, are removed.

[4] Likewise, this set is not, strictly speaking, a straight half-line.

in $\mathfrak{R}_{\exp}$ while maintaining stability under A, the invariants constructed in Theorem 5 over-approximate the orbit by the image of the trajectory cone $\mathcal{C}_{t_0}$ under the linear transformation P. Finally, a finite set of points from $\mathcal{O}$ is added to this image of the trajectory cone, to fill in the missing points in case t_0 is too large.

The proof of Theorem 5 has several parts. First, recall that the trajectory cone itself, $\mathcal{C}_{t_0}$, is an over-approximation of the set $\left\{J^n P^{-1} s \mid n \in \mathbb{N}\right\}$. As such, clearly $\mathcal{C}_{t_0} \subseteq \mathbb{C}^d$. In comparison, the orbit can be written as $\mathcal{O} = \left\{P J^n P^{-1} s \mid n \in \mathbb{N}\right\} \subseteq \mathbb{R}^d$. We prove in the full version of the paper the following lemma, from which it follows that the entire set $P \cdot \mathcal{C}_{t_0}$ is also a subset of $\mathbb{R}^d$.

▶ **Lemma 6.** *For every $p \in \mathbb{T}$ and $t_0 \geq 1$, we have $P \cdot \mathsf{r}(p, t_0) \subseteq \mathbb{R}^d$.*

Let us simply remark here that by analysing the structure of the matrices involved in defining $P \cdot \mathsf{r}(p, t_0)$, and using the facts that the columns of P are generalised eigenvectors of A, and that conjugate pairs of eigenvalues correspond to conjugate pairs of generalised eigenvectors, it is not hard to see that the above product does indeed yield only real values. However, a formal proof of this involves fairly tedious calculations. In the full version of the paper, we proceed instead via an analytic argument.

In the second part of the proof of Theorem 5, we show that $P \cdot \mathcal{C}_{t_0}$ is stable under A. The key ingredient is the following lemma, which characterises the action of J on rays and is proved in Section 4.1.

▶ **Lemma 7.** *For every $p = (p_1, \ldots, p_k) \in \mathbb{T}$ and $t_0 \geq 1$, we have $J \cdot \mathsf{r}(p, t_0) = \mathsf{r}(Lp, \rho_k t_0)$.*

The next lemma then lifts Lemma 7 to the entire trajectory cone.

▶ **Lemma 8.** *For every $t_0 \geq 1$, we have $J \cdot \mathcal{C}_{t_0} \subseteq \mathcal{C}_{t_0}$.*

Proof. Recall that $\mathcal{C}_{t_0} = \bigcup_{p \in \mathbb{T}} \mathsf{r}(p, t_0)$. By Lemma 7 we have that $J \cdot \mathcal{C}_{t_0} = \bigcup_{p \in \mathbb{T}} \mathsf{r}(Lp, \rho_k t_0)$. Since $\rho_k > 1$, it follows that $\rho_k t_0 \geq t_0$. In addition, $p \in \mathbb{T}$ iff $Lp \in \mathbb{T}$. Hence we have that $\mathsf{r}(Lp, \rho_k t_0) \subseteq \mathsf{r}(Lp, t_0)$, from which we conclude that $J \cdot \mathcal{C}_{t_0} \subseteq \bigcup_{p \in \mathbb{T}} \mathsf{r}(Lp, t_0) = \bigcup_{p \in \mathbb{T}} \mathsf{r}(p, t_0) = \mathcal{C}_{t_0}$. ◀

The proof of Theorem 5 combines all these ingredients together and is given in subsection 4.2.

4.1 Proof of Lemma 7

Let $y = \begin{pmatrix} t^{b_1} p_1 Q_{1,1}(\log_{\rho_k} t) \\ \vdots \\ t^{b_k} p_k Q_{k,d_k}(\log_{\rho_k} t) \end{pmatrix} \in \mathsf{r}(p, t_0)$. We claim that $Jy = \begin{pmatrix} (\rho_k t)^{b_1} \lambda_1 p_1 Q_{1,1}(\log_{\rho_k}(\rho_k t)) \\ \vdots \\ (\rho_k t)^{b_k} \lambda_k p_k Q_{k,d_k}(\log_{\rho_k}(\rho_k t)) \end{pmatrix}$.
Note that since $Lp = (\lambda_1 p_1, \ldots, \lambda_k p_k)$, the above suffices to conclude the proof.

Consider a coordinate $m = (i, j)$ of Jy in block-row index, with $j < d_i$. The case of $j = d_i$ is similar and simpler. To simplify notation, we write λ, ρ, and d instead of λ_i, ρ_i, and d_i, respectively. Then we have

$$(Jy)_m = \lambda \rho t^{b_i} p_i Q_{i,j}(\log_{\rho_k} t) + t^{b_i} p_i Q_{i,j+1}(\log_{\rho_k} t)\,.$$

Recall that[5]

$$Q_{i,j}(\log_{\rho_k} t) = \sum_{c=0}^{d-j} \frac{\binom{\log_{\rho_k} t}{c}}{(\rho\lambda)^c} s'_{i,j+c}\,,$$

[5] Here, for $w \in \mathbb{R}$ and $m \in \mathbb{N}$, one defines $\binom{w}{m} = \frac{1}{m!} \prod_{i=0}^{m-1} (w - i)$, which maintains consistency with the original definition of $Q_{i,j}$ in Section 3.

with $(i, j+c)$ in block-row index. We can then write

$$(Jy)_m = \lambda\rho t^{b_i} p_i \sum_{c=0}^{d-j} \frac{\binom{\log_{\rho_k} t}{c}}{(\rho\lambda)^c} s'_{i,j+c} + t^{b_i} p_i \sum_{c=0}^{d-j-1} \frac{\binom{\log_{\rho_k} t}{c}}{(\rho\lambda)^c} s'_{i,j+c+1}\,. \tag{2}$$

We now compare this to coordinate m of our claim, namely

$$(\rho_k t)^{b_i} \lambda p_i Q_{i,j}(\log_{\rho_k}(\rho_k t)) = (\rho_k t)^{b_i} \lambda p_i \sum_{c=0}^{d-j} \frac{\binom{\log_{\rho_k}(\rho_k t)}{c}}{(\rho\lambda)^c} s'_{i,j+c}\,. \tag{3}$$

We compare the right-hand sides of Equations (2) and (3) by comparing the coefficients of $s'_{i,q}$ for $q \in \{j, \dots, d\}$ (these being the only ones that appear in the expressions). For $q = j$ we see that in (2) the number $s'_{i,j}$ occurs in the first summand only, and its coefficient is thus $\lambda\rho t^{b_i} p_i$, while in (3) it is $(\rho_k t)^{b_i} \lambda p_i = \rho_k^{b_i} t^{b_i} \lambda p_i = \rho t^{b_i} \lambda p_i$, since $b_i = \log_{\rho_k} \rho$. Thus, the coefficients are equal.

For $q > j$, write $q = j + c$ with $c \geq 1$; the coefficient at $s'_{i,j+c}$ in (2) is then

$$\lambda\rho t^{b_i} p_i \frac{\binom{\log_{\rho_k} t}{c}}{(\rho\lambda)^c} + t^{b_i} p_i \frac{\binom{\log_{\rho_k} t}{c-1}}{(\rho\lambda)^{c-1}} = \frac{t^{b_i}\rho\lambda p_i}{(\rho\lambda)^c} \left(\binom{\log_{\rho_k} t}{c} + \binom{\log_{\rho_k} t}{c-1} \right) = \frac{t^{b_i}\lambda\rho p_i}{\lambda^c} \binom{\log_{\rho_k} t + 1}{c}$$

where the last equality follows from a continuous version of Pascal's identity. Finally, by noticing that $\log_{\rho_k} t + 1 = \log_{\rho_k}(\rho_k t)$, it is easy to see that this is the same coefficient as in (3).

4.2 Proof of Theorem 5

Let $t_0 \geq 1$. By applying Lemma 6 to every $p \in \mathbb{T}$, we conclude that $P \cdot \mathcal{C}_{t_0} \subseteq \mathbb{R}^d$. It is then easy to see that $P \cdot \mathcal{C}_{t_0}$ is definable in $\mathfrak{R}_{\exp}$ (note that the only reason the set $\mathcal{C}_{t_0}$ might fail to be $\mathfrak{R}_{\exp}$-definable is that the underlying domain should be $\mathbb{R}$ and not $\mathbb{C}$).

Next, by Lemma 8 we have that $J \cdot \mathcal{C}_{t_0} \subseteq \mathcal{C}_{t_0}$. Applying P from the left, we get $PJ \cdot \mathcal{C}_{t_0} \subseteq P \cdot \mathcal{C}_{t_0}$. Thus, we have $AP \cdot \mathcal{C}_{t_0} = PJP^{-1}P \cdot \mathcal{C}_{t_0} = PJ \cdot \mathcal{C}_{t_0} \subseteq P \cdot \mathcal{C}_{t_0}$.

Finally, observe that $\{A^n s \mid n \geq \log_{\rho_k} t_0\} \subseteq P \cdot \mathcal{C}_{t_0}$. Since any finite subset of $\mathcal{O}$ can be described in $\mathfrak{R}_0$, we conclude that the set $\{A^n s \mid n < \log_{\rho_k} t_0\} \cup P \cdot \mathcal{C}_{t_0}$ is an $\mathfrak{R}_{\exp}$-definable invariant for (A, s).

5 O-Minimal Invariants Must Contain Trajectory Cones

In this section we consider invariants definable in o-minimal extensions of $\mathfrak{R}_{\exp}$. Fix such an extension $\mathfrak{R}$ for the remainder of this section.

▶ **Theorem 9.** *Consider an $\mathfrak{R}$-definable invariant $\mathcal{I}$ for the LDS (A, s). Then there exists $t_0 \geq 1$ such that $P \cdot \mathcal{C}_{t_0} \subseteq \mathcal{I}$.*

To prove Theorem 9, we begin by making following claims of increasing strength:

▶ **Claim 1.** *For every $p \in \mathbb{T}$ there exists $t_0 \geq 1$ such that $P \cdot \mathsf{r}(p, t_0) \subseteq \mathcal{I}$ or $P \cdot \mathsf{r}(p, t_0) \cap \mathcal{I} = \emptyset$.*

▶ **Claim 2.** *For every $p \in \mathbb{T}$ there exists $t_0 \geq 1$ such that $P \cdot \mathsf{r}(p, t_0) \subseteq \mathcal{I}$.*

▶ **Claim 3.** *There exists $t_0 \geq 1$ such that for every $p \in \mathbb{T}$ we have $P \cdot \mathsf{r}(p, t_0) \subseteq \mathcal{I}$.*

Proof of Claim 1. Fix $p \in \mathbb{T}$. Observe that by Lemma 6, $P \cdot \mathsf{r}(p,1)$ is $\mathfrak{R}$-definable. Further note that $P \cdot \mathsf{r}(p,1)$ is of dimension 1 (as it is homeomorphic to $[1,\infty)$). Thus, the dimension of $P \cdot \mathsf{r}(p,1) \cap \mathcal{I}$ is at most 1, so its cell decomposition contains finitely many connected components of dimensions 0 or 1. In particular, either one component is unbounded, in which case there exists a t_0 such that $P \cdot \mathsf{r}(p,t_0) \subseteq \mathcal{I}$, or all the components are bounded, in which case there exists a t_0 such that $P \cdot \mathsf{r}(p,t_0) \cap \mathcal{I} = \emptyset$. ◀

Before proceeding to Claim 2, we prove an auxiliary lemma, which is an adaptation of a similar result from [13]. For a set X, we write $\overline{X}$ to refer to the topological closure of X. We use the usual topology on $\mathbb{R}^n$, $\mathbb{C}^n$, and the (usual) subspace topology on their subsets.

▶ **Lemma 10.** *Let $S, F \subseteq \mathbb{T}$ be $\mathfrak{R}$-definable[6] sets such that $\overline{S} = \overline{F} = \mathbb{T}$. Then $F \cap S \neq \emptyset$.*

Proof. We start by stating two properties of the dimension of a definable set in an o-minimal theory $\mathfrak{R}$. First, for any $\mathfrak{R}$-definable set $X \subseteq \mathbb{R}^n$ we have $\dim(X) = \dim(\overline{X})$ [12, Chapter 4, Theorem 1.8]. Secondly, if $X \subseteq Y$ are $\mathfrak{R}$-definable subsets of $\mathbb{R}^n$ that have the same dimension, then X has non-empty interior in Y [12, Chapter 4, Corollary 1.9]. In the situation at hand, since $\dim(F) = \dim(\overline{F})$, it follows that F has non-empty interior with respect to the subspace topology on $\overline{F} = \overline{S}$. But then S is dense in $\overline{S}$ while F has non-empty interior in $\overline{S}$, and thus $S \cap F \neq \emptyset$. ◀

Proof of Claim 2. We strengthen Claim 1. Assume by way of contradiction that there exist $p \in \mathbb{T}$ and $t_0 \in \mathbb{R}$ such that $P \cdot \mathsf{r}(p,t_0) \cap \mathcal{I} = \emptyset$, and consider $J^{-1} \cdot \mathsf{r}(p,t_0)$. Let $q \in \mathbb{T}$ be $L^{-1}p = (\frac{p_1}{\lambda_1}, \ldots, \frac{p_k}{\lambda_k})$ and let $t_1 = \frac{t_0}{\rho_k}$. Then $p = Lq$ and $t_0 = \rho_k t_1$ and, by Lemma 7, $J\mathsf{r}(q,t_1) = \mathsf{r}(Lq, \rho_k t_1) = \mathsf{r}(p,t_0)$. Since J is invertible, we conclude that $J^{-1}\mathsf{r}(p,t_0) = \mathsf{r}(q,t_1)$.

We now claim that $P \cdot \mathsf{r}(q,t_1) \cap \mathcal{I} = \emptyset$. Recall that $P \cdot \mathsf{r}(p,t_0) \cap \mathcal{I} = \emptyset$. Applying $A^{-1} = PJ^{-1}P^{-1}$, we have by the above that $P \cdot \mathsf{r}(q,t_1) \cap A^{-1}\mathcal{I} = \emptyset$. Since $A\mathcal{I} \subseteq \mathcal{I}$, then $\mathcal{I} \subseteq A^{-1}\mathcal{I}$, so we have $P \cdot \mathsf{r}(q,t_1) \cap \mathcal{I} \subseteq P \cdot \mathsf{r}(q,t_1) \cap A^{-1}\mathcal{I} = \emptyset$.

Recall that, following the discussion in section 3, we have $\rho_k > 1$. This implies $t_1 \leq t_0$ and $\mathsf{r}(q,t_0) \subseteq \mathsf{r}(q,t_1)$, so in particular $P \cdot \mathsf{r}(q,t_0) \cap \mathcal{I} = \emptyset$. Thus, assuming $P \cdot \mathsf{r}(p,t_0) \cap \mathcal{I} = \emptyset$, we have just proved that $P \cdot \mathsf{r}(L^{-1}p,t_0) \cap \mathcal{I} = \emptyset$; repeating this argument, we get that for every $n \in \mathbb{N}$, the point $s = L^{-n}p$ satisfies $P \cdot \mathsf{r}(s,t_0) \cap \mathcal{I} = \emptyset$.

Let $S = \{L^{-n}p \mid n \in \mathbb{N}\}$. Then S is dense in $\mathbb{T}$, since the group of multiplicative relations defined by the eigenvalues of L^{-1} is the same as the one defined by those of L. Define $S' = \{s \in \mathbb{T} \mid P \cdot \mathsf{r}(s,t_0) \cap \mathcal{I} = \emptyset\}$. Then S' is $\mathfrak{R}$-definable, and we have $S \subseteq S' \subseteq \mathbb{T}$. Moreover, $\overline{S} = \mathbb{T}$, so $\overline{S'} = \mathbb{T}$.

We now prove that, in fact, $S' = \mathbb{T}$. Assuming (again by way of contradiction) that there exists $q \in \mathbb{T} \setminus S'$, then by the definition of S' we have $P \cdot \mathsf{r}(q,t_0) \cap \mathcal{I} \neq \emptyset$. It follows that for every $n \in \mathbb{N}$, the point $q' = L^n q$ also satisfies $P \cdot \mathsf{r}(q',t_0) \cap \mathcal{I} \neq \emptyset$. Define $F = \{L^n q \mid n \in \mathbb{N}\}$, then F is dense in $\mathbb{T}$. But then the set $F' = \{q \in \mathbb{T} \mid P \cdot \mathsf{r}(q,t_0) \cap \mathcal{I} \neq \emptyset\}$ satisfies $F \subseteq F' \subseteq \mathbb{T}$ and $\overline{F'} = \mathbb{T}$. Now the sets S' and F' are both definable in $\mathfrak{R}$, and the topological closure of each of them is $\mathbb{T}$. It follows from Lemma 10 that $F' \cap S' \neq \emptyset$, which is clearly a contradiction. Therefore, there is no $q \in \mathbb{T} \setminus S'$; that is, $S' = \mathbb{T}$.

From this, however, it follows that $P \cdot \mathcal{C}_{t_0} \cap \mathcal{I} = \emptyset$, which is again a contradiction, since $P \cdot \mathcal{C}_{t_0} \cap \mathcal{O} \neq \emptyset$ and $\mathcal{O} \subseteq \mathcal{I}$, so we are done. ◀

Proof of Claim 3. Consider the function $f\colon \mathbb{T} \to \mathbb{R}$ defined by $f(p) = \inf\{t \in \mathbb{R} \mid P \cdot \mathsf{r}(p,t) \subseteq \mathcal{I}\}$. By Claim 2 this function is well-defined. Since $P \cdot \mathsf{r}(p,t)$ is $\mathfrak{R}$-definable, then so is f.

[6] Recall that, in order to reason about $\mathbb{T} \subseteq \mathbb{C}^k$ in $\mathfrak{R}$, we identify $\mathbb{C}$ with $\mathbb{R}^2$.

Moreover, its graph $\Gamma(f)$ has finitely many connected components, and the same dimension as $\mathbb{T}$. Thus, there exists an open set $K \subseteq \mathbb{T}$ (in the induced topology on $\mathbb{T}$) such that f is continuous on K. Furthermore, K is homeomorphic to $(0,1)^m$ for some $0 \leq m \leq k$, and thus we can find sets $K'' \subseteq K' \subseteq K$ such that K'' is open, and K' is closed.[7] Since f is continuous on K, it attains a maximum on K'. Consider the set $\{L^n \cdot K'' \mid n \in \mathbb{N}\}$. By the density of $\{L^n \mid n \in \mathbb{N}\}$ in $\mathbb{T}$, this is an open cover of $\mathbb{T}$, and hence there is a finite subcover $\{L^{n_1}K'', \ldots, L^{n_m}K''\}$. Since $K'' \subseteq K'$, it follows that $\{L^{n_1}K', \ldots, L^{n_m}K'\}$ is a finite closed cover of $\mathbb{T}$.

We now show that, for all $p \in \mathbb{T}$, we have $f(Lp) \leq \rho_k \cdot f(p)$. Indeed, consider any $p \in \mathbb{T}$ and $t > 0$ such that $P \cdot \mathsf{r}(p,t) \subseteq \mathcal{I}$. Applying $A = PJP^{-1}$, we get $PJ \cdot \mathsf{r}(p,t) \subseteq A\mathcal{I} \subseteq \mathcal{I}$. By Lemma 7, $J \cdot \mathsf{r}(p,t) = \mathsf{r}(Lp, \rho_k t)$, so we can conclude that $P \cdot \mathsf{r}(Lp, \rho_k t) \subseteq \mathcal{I}$. This means that $P \cdot \mathsf{r}(p,t) \subseteq \mathcal{I}$ implies $P \cdot \mathsf{r}(Lp, \rho_k t) \subseteq \mathcal{I}$; therefore, $f(Lp) \leq \rho_k \cdot f(p)$.

Now denote $s_0 = \max_{p \in K'} f(p)$. Then for every $1 \leq i \leq m$ we have $\max_{p \in L^{n_i}K'} f(p) \leq \rho_k^{n_i} s_0$; so $f(p)$ is indeed bounded on $\mathbb{T}$. ◀

Finally, we conclude from Claim 3 that there exists $t_0 \geq 1$ such that $P \cdot \mathcal{C}_{t_0} \subseteq \mathcal{I}$. This completes the proof of Theorem 9.

6 Deciding the Existence of O-Minimal Invariants

We now turn to the algorithmic aspects of invariants and present our two main results, Theorems 12 and 13.

Let $\mathfrak{R}$ be either $\mathfrak{R}_0$ or $\mathfrak{R}_{\exp}$. We consider the following problem: given an LDS (A, s), with $A \in \mathbb{Q}^{d \times d}$ and $s \in \mathbb{Q}^d$, and given an $\mathfrak{R}$-definable halting set $F \subseteq \mathbb{R}^d$, we wish to decide whether there exists an o-minimal invariant $\mathcal{I}$ for (A, s) that avoids F, and to compute such an invariant if it exists. We term this question the *O-Minimal Invariant Synthesis Problem for $\mathfrak{R}$-Definable Halting Sets*.

The following is a consequence of Theorems 5 and 9.

▶ **Lemma 11.** *Let (A, s) and $\mathfrak{R}$ be as above, and let F be $\mathfrak{R}$-definable. Then there exists an o-minimal invariant $\mathcal{I}$ for (A, s) that avoids F iff there is some $t_0 \geq 1$ such that $P \cdot \mathcal{C}_{t_0} \cap F = \emptyset$ and such that $A^n s \notin F$ for every $0 \leq n \leq \log_{\rho_k} t_0$.*

Proof. By Theorem 9, if an o-minimal invariant $\mathcal{I}$ for (A, s) exists, then there exists $t_0 \geq 1$ such that $P \cdot \mathcal{C}_{t_0} \subseteq \mathcal{I}$. Moreover, $\mathcal{I} \cap F = \emptyset$ implies $\mathcal{O} \cap F = \emptyset$, so that $A^n s \notin F$ for every $n \in \mathbb{N}$, and in particular for $0 \leq n \leq \log_{\rho_k} t_0$.

Conversely, let there be $t_0 \geq 1$ such that $P \cdot \mathcal{C}_{t_0} \cap F = \emptyset$ and, for every $0 \leq n \leq \log_{\rho_k} t_0$, it holds that $A^n s \notin F$. Let $t_0' \in \mathbb{Q}$ be such that $t_0' \geq t_0$. By Theorem 5, the set $\mathcal{I} = P \cdot \mathcal{C}_{t_0'} \cup \left\{A^n s \mid 0 \leq n \leq \log_{\rho_k} t_0'\right\}$ is an $\mathfrak{R}_{\exp}$-definable invariant that avoids F. ◀

Observe that the formula $\exists t_0 \geq 1 : P \cdot \mathcal{C}_{t_0} \cap F = \emptyset$ is a sentence in $\mathfrak{R}_{\exp}$, and by Lemma 11, deciding the existence of an invariant amounts to determining the truth value of this sentence.

Decidability for $\mathfrak{R}_{\exp}$-definable halting sets assuming Schanuel's conjecture. Applying Theorem 5, we note that an invariant for (A, s) that avoids F—if one exists—can always be defined in $\mathfrak{R}_{\exp}$.

[7] In case $m = 0$, the proof actually follows immediately from Claim 2, since $\mathbb{T}$ is finite.

▶ **Theorem 12.** *The O-Minimal Invariant Synthesis Problem for $\mathfrak{R}_{\exp}$-Definable Halting Sets is decidable, assuming Schanuel's conjecture. Moreover, in positive instances, we can explicitly define such an invariant in $\mathfrak{R}_{\exp}$.*

Proof. Assume Schanuel's conjecture. Then by [18], the theory $\mathfrak{R}_{\exp}$ is decidable. Thus we can decide whether there exists $t_0 \geq 1$ such that $P \cdot \mathcal{C}_{t_0} \cap F = \emptyset$. If the sentence is false, then by Lemma 11 there is no invariant, and we are done. If the sentence is true, however, it still remains to check whether $A^n s \notin F$ for every $0 \leq n \leq \log_{\rho_k} t_0$. While we can decide whether $A^n s \in F$ for a fixed n, observe that we do not have an *a priori* bound on t_0. Hence we proceed as follows: For every $n \in 1, 2, \ldots$, check both whether $A^n s \in F$ and, for $t_0 = \rho_k^n$, whether $PC_{t_0} \cap F = \emptyset$. In case $A^n s \in F$, then clearly there is no invariant, since $\mathcal{O} \cap F \neq \emptyset$, and we are done. On the other hand, if $PC_{t_0} \cap F = \emptyset$, then return the $\mathfrak{R}_{\exp}$-definable invariant as per Lemma 11.

We claim that the above procedure always halts. Indeed, we know that there exists t_0 for which $P \cdot \mathcal{C}_{t_0} \cap F = \emptyset$. Thus, either for some $n < \log_{\rho_k} t_0$, it holds that $A^n s \in F$, in which case there is no invariant and we halt when we reach n, or we proceed until we reach $n \geq \log_{\rho_k} t_0$, in which case we halt and return the invariant. ◀

▶ Remark. It is interesting to note that, should Schanuel's conjecture turn out to be false, the above procedure could still never return a 'wrong' invariant. The worst that could happen is that decidability of $\mathfrak{R}_{\exp}$ fails in that the putative algorithm of [18] simply never halts, so no verdict is ever returned.

Unconditional decidability for semi-algebraic halting sets.

▶ **Theorem 13.** *The O-Minimal Invariant Synthesis Problem for Semi-Algebraic Halting Sets is decidable. Moreover, in positive instances, we can explicitly define such an invariant in $\mathfrak{R}_{\exp}$.*

By Lemma 11, in order to prove Theorem 13, it is enough to decide the truth value of the $\mathfrak{R}_{\exp}$-sentence $\exists t_0 \geq 1 : P \cdot \mathcal{C}_{t_0} \cap F = \emptyset$. Indeed, as $A^n s \in \mathbb{Q}^d$, one can always check unconditionally whether for a given n the vector $A^n s$ belongs to the semi-algebraic set F. The algorithm is then otherwise the same as that presented in the proof of Theorem 12. The proof of Theorem 13 therefore boils down to the following lemma.

▶ **Lemma 14.** *For F a semi-algebraic set, it is decidable whether there exists $t_0 \geq 1$ such that $P \cdot \mathcal{C}_{t_0} \cap F = \emptyset$.*

Our key tool is the following celebrated result from transcendental number theory:

▶ **Theorem 15** (Baker's theorem [1])**.** *Let $\alpha_1, \ldots, \alpha_m \in \mathbb{C}$ be algebraic numbers different from 0 and let $b_1, \ldots, b_m \in \mathbb{Z}$ be integers. Write $\Lambda = b_1 \log \alpha_1 + \ldots + b_m \log \alpha_m$. There exists a number C effectively computable from $b_1, \ldots, b_m, \alpha_1, \ldots, \alpha_m$ such that if $\Lambda \neq 0$ then $|\Lambda| > H^{-C}$, where H is the maximum height of $\alpha_1, \ldots, \alpha_m$.*

As in Section 3, we assume that $\rho_k > 1$ (with the cases of $\rho_k < 1$ and $\rho_k = 1$ being analogous and easier, respectively). Recall that the subgroup $\mathbb{T}$ of the torus defined by the multiplicative relations of the eigenvalues of A is a semi-algebraic set. Write $\vec{\tau}(t) = (t^{b_1} Q_{1,1}(\log_{\rho_k} t), \ldots, t^{b_k} Q_{k,d_k}(\log_{\rho_k} t))$, and consider the set

$$U = \left\{ (z_1, \ldots, z_d)^\intercal \in \mathbb{C}^d \mid \forall (p_1, \ldots, p_d) \in \mathbb{T},\ P\,(z_1 p_1, \ldots, z_d p_d)^\intercal \in \mathbb{R}^d \setminus F \right\}.$$

It is enough to decide whether there exists $t_0 \geq 1$ such that for all $t \geq t_0$, $\vec{\tau}(t) \in U$.

Observe that U is a semi-algebraic set (see Remark on Page 4). In the full version of the paper, we reduce our analysis to the case where U is of the form $\bigwedge_{l=1}^{m} R_l(u_1, \ldots, u_d, v_1, \ldots, v_d) \sim_l 0$. Here, for every $1 \leq l \leq m$, $\sim_l \in \{>, =\}$ and R_l is a polynomial with integer coefficients in variables $u_1, \ldots, u_d, v_1, \ldots, v_d$; for each i, the variables u_i and v_i represent $\operatorname{Re} z_i$ and $\operatorname{Im} z_i$, the real and imaginary parts of z_i, respectively.

Thus, we now need to decide whether we can find $t_0 \geq 1$ such that for every $t \geq t_0$ it holds that $R_l(\vec{\tau}(t)) \sim_l 0$ for every $1 \leq l \leq m$. Fix $1 \leq l \leq m$. Recall that we consider every vector in $\mathbb{C}^d$ as a vector in $\mathbb{R}^{2d}$; thus, the polynomial R_l has the form

$$\sum_i a_i \cdot u_1^{n'_{i,1}} \cdot \ldots \cdot u_d^{n'_{i,d}} \cdot v_1^{n''_{i,1}} \cdot \ldots \cdot v_d^{n''_{i,d}},$$

with $a_i \in \mathbb{Z}$ and $n'_{i,s}, n''_{i,s} \in \mathbb{Z}_{\geq 0}$. Therefore, $R_l(\vec{\tau}(t))$ is the sum of terms of the form

$$a_i \cdot t^{(n'_{i,1}+n''_{i,1})\cdot b_1 + \ldots + (n'_{i,d}+n''_{i,d})\cdot b_k} \cdot (\operatorname{Re} Q_{1,1}(\log_{\rho_k} t))^{n'_{i,1}} \cdot \ldots \cdot (\operatorname{Re} Q_{k,d_k}(\log_{\rho_k} t))^{n'_{i,k}} \cdot (\operatorname{Im} Q_{1,1}(\log_{\rho_k} t))^{n''_{i,1}} \cdot \ldots \cdot (\operatorname{Im} Q_{k,d_k}(\log_{\rho_k} t))^{n''_{i,k}}$$

where $Q_{i,j}(\cdot)$, as above, are polynomials from the definition of trajectory cones. Note that all $Q_{i,j}$ are only evaluated at real points, and hence it is easy for us to refer to $\operatorname{Re} Q_{i,j}$ and $\operatorname{Im} Q_{i,j}$; these are polynomials in one real variable with real algebraic coefficients. We rewrite $R_l(\vec{\tau}(t))$ in the form

$$\sum_i t^{n_{i,1}\cdot b_1 + \ldots + n_{i,k}\cdot b_k} \cdot f_i(\log_{\rho_k} t)$$

where each $f_i(\cdot)$ is also a polynomial with real algebraic coefficients, and $b_1, \ldots, b_k$ are distinct logarithms of the moduli of the eigenvalues of A. We can compute all these polynomials f_i, eliminating from the sum all terms that have $f_i \equiv 0$.

Observe that $R_l(\vec{\tau}(t))$ is a function of a single variable $t > 0$. In order to reason about the sign of this expression as $t \to \infty$, we need to determine its leading term. To that end, we first need to decide for every $i \neq j$ whether the two new exponents $n_{i,1}b_1 + \ldots + n_{i,k}b_k$ and $n_{j,1}b_1 + \ldots + n_{j,k}b_k$ are equal and, if not, which is larger. (If the exponents are equal, we aggregate the polynomials f_i and f_j accordingly.) By rearranging the terms, it's enough to decide whether $n_1b_1 + \ldots + n_kb_k > 0$ for some $n_1, \ldots, n_k \in \mathbb{Z}$. Recall that $b_j = \log_{\rho_k} \rho_j = \log \rho_j / \log \rho_k$ where log denotes the natural logarithm. By Baker's theorem, there exists an effectively computable $\epsilon > 0$ such that either $n_1b_1 + \ldots + n_kb_k = 0$, or $|n_1b_1 + \ldots + n_kb_k| > \epsilon$.

We now proceed by computing an approximation Δ of $n_1b_1 + \ldots + n_kb_k$ with additive error at most $\frac{\epsilon}{3}$. This is easily done, as we are dealing with computable quantities. We then have that $\Delta \in [-\frac{\epsilon}{3}, \frac{\epsilon}{3}]$ iff $n_1b_1 + \ldots + n_kb_k = 0$, and otherwise we have $\operatorname{sign}(\Delta) = \operatorname{sign}(n_1b_1 + \ldots + n_kb_k)$. Thus we can sort the exponents $n_{i,1} \cdot b_1 + \ldots + n_{i,k} \cdot b_k$ in descending order and, using the same procedure, compare each of them to 0.

Now consider the term that has the largest exponent, m; suppose this term is $t^m \cdot f_i(\log_{\rho_k} t)$. Then the sign of $R_l(\vec{\tau}(t))$ as $t \to \infty$ is determined by the sign of the leading term of the polynomial $f_i(\cdot)$; only if the sum is empty can the sign of $R_l(\vec{\tau}(t))$ be 0 for all sufficiently large t.

The argument above shows that we can compute the leading terms of the expressions $R_l(\vec{\tau}(t))$ and decide whether the conjunction $\bigwedge_{l=1}^{m} R_l \sim_l 0$ holds for all $t \geq t_0$ starting from some t_0. This completes the proof.

Topological Sorting with Regular Constraints

Abstract

We introduce the *constrained topological sorting problem* (CTS): given a regular language K and a directed acyclic graph G with labeled vertices, determine if G has a topological sort that forms a word in K. This natural problem applies to several settings, e.g., scheduling with costs or verifying concurrent programs. We consider the problem CTS[K] where the target language K is fixed, and study its complexity depending on K. We show that CTS[K] is tractable when K falls in several language families, e.g., *unions of monomials*, which can be used for pattern matching. However, we show that CTS[K] is NP-hard for $K = (ab)^*$ and introduce a *shuffle reduction* technique to show hardness for more languages. We also study the special case of the *constrained shuffle problem* (CSh), where the input graph is a disjoint union of strings, and show that CSh[K] is additionally tractable when K is a group language or a union of district group monomials. We conjecture that a dichotomy should hold on the complexity of CTS[K] or CSh[K] depending on K, and substantiate this by proving a coarser dichotomy under a different problem phrasing which ensures that tractable languages are closed under common operators.

1 Introduction

Many scheduling or ordering problems amount to computing a *topological sort* of a directed acyclic graph (DAG), i.e., a totally ordered sequence of the vertices that is compatible with the edge relation: when we enumerate a vertex, all its predecessors must have been enumerated first. However, in some settings, we need a topological sort satisfying additional constraints that cannot be expressed as edges. We formalize this problem as follows: the vertices of the DAG are labeled with some symbols from a finite alphabet A, and we want to find a topological sort that falls into a specific regular language. We call this the *constrained topological sort problem*, or CTS. For instance, if we fix the language $K = ab^*c$, and consider the example DAGs of Figure 1, then G_1 and G_2 have a topological sort that falls in K.

CTS relates to many applications. For instance, many *scheduling* applications use a dependency graph [1] of tasks, and it is often useful to express other constraints, e.g., some tasks must be performed by specific workers and we should not assign more than p successive tasks to the same worker. We can express this as a CTS-problem: label each task by the worker which can perform it, and consider the target regular language K containing all words where the same symbol is not repeated more than p times. In *concurrency* applications,

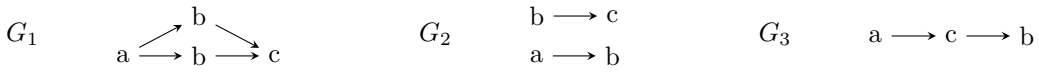

Figure 1 Example labeled DAGs on the alphabet $A = \{a, b, c\}$

we may consider a program with multiple threads, and want to verify that there is no linearization of its instructions that exhibits some unsafe behavior, e.g., executing a read before a write. To search for such a linearization, we can label each instruction with its type, and consider CTS with a target language describing the behavior that we wish to detect. CTS can also be used in uncertain data management tasks, to reason about the possible answers of aggregate queries on uncertain ordered data [4]. It can also be equivalently phrased in the language of partial order theory: seeing the labeled DAG as a *labeled partial order* $<$, we ask if some *linear extension* achieves a word in K.

We thus believe that the CTS-problem is useful, and natural, but we are not aware of previous work studying it, except for a special case called the *shuffle problem*. This problem deals with the *interleaving* of strings, as studied, e.g., in concurrent programming languages [18, 21], computational biology [17], and formal languages [10, 8, 26]. Specifically, we are given a tuple of strings, and we must decide if they have some interleaving that falls in the target language K. This problem was known to be NP-complete [19, 32, 16] when the target language K is given as input (in addition to the tuple of strings), even when K consists of just one target string. To rephrase this shuffle problem in our context, we call *constrained shuffle problem* (CSh) the special case of CTS where we require input DAGs to be a union of directed path graphs (corresponding to the strings).

Our goal in this paper is to study the complexity of CTS and CSh. We assume that the target regular language K is fixed, and call CTS[K] and CSh[K] the corresponding problems, whose complexity is only a function of the input DAG (labeled on the alphabet A of K). Our central question is: *for which regular languages K are the problems* CTS[K] *or* CSh[K] *tractable?* More precisely, for each of these problems, we conjecture a dichotomy on K: the problem is either in NL or it is NP-complete. However, the tractability boundary is challenging to chart out, and we have not been able to prove these conjectures in full generality. In this paper, we present the results that we have obtained towards this end.

Paper structure. We formally define the CTS and CSh problems in Section 2 and state the conjecture. We then show the following results:

- In Section 3, we present our hardness results. We recall the results of [32] on the shuffle problem, and present a general *shuffle reduction* technique to show hardness for more languages. We use it in particular to show that CSh[$(ab)^*$], hence CTS[$(ab)^*$], are NP-hard, and extend this to several other languages.
- In Section 4, we present tractability results. We show that CTS[K], hence CSh[K], is in non-deterministic logspace (NL) when K is a union of *monomial languages*, i.e., of languages of the form $A_1^* a_1 \cdots A_{n-1}^* a_{n-1} A_n^*$, with the a_i being letters and the A_i being subalphabets. Such languages can be used for applications such as pattern matching, e.g., with the language $A^* u A^*$ for a fixed pattern $u \in A^*$. We also show tractability for other languages that are not of this form, e.g. $(ab)^* + A^* aa A^*$ and variants thereof, using different techniques such as Dilworth's theorem [9].
- In Section 5, we use our hardness and tractability results to show a coarser dichotomy result. Specifically, we give an alternative phrasing of the CTS and CSh problems using

semiautomata and DAGs with *multi-letter* labels: this amounts to closing the tractable languages under intersection, inverse morphism, complement, and quotients. In this phrasing, when the semiautomaton is counter-free, we can show that the problems are either in NL or NP-complete. This dichotomy is effective, i.e., the criterion on the semiautomaton is decidable, and it turns out to be the same for CTS and CSh.

- In Section 6, we focus on the constrained shuffle problem, and lift the counter-free assumption of the previous section. We show that CSh$[K]$ is tractable when K is a *group language* or more generally a union of *district group monomials*. This tractability result is the main technical contribution of the paper, with a rather involved proof. It implies, e.g., that the following problem is in NL for any fixed finite group H: given $g \in H$ and words $w_1, \ldots, w_n$ of elements of H, decide whether there is an interleaving of the w_i which evaluates to g according to the group operation.

2 Problem Statement and Main Results

We give some preliminaries and define the two problems that we study. We fix a finite alphabet A, and call A^* the set of all finite words on A. For $w \in A^*$, we write $|w|$ for the *length* of w, and write $|w|_a$ for the number of occurrences of $a \in A$ in w. We denote the empty word by ϵ. A *labeled DAG* on the alphabet A, or A-*DAG*, is a triple $G = (V, E, \lambda)$ where (V, E) is a directed acyclic graph with vertex set $V = \{1, \ldots, n\}$ and edge set $E \subseteq V \times V$, and where $\lambda : V \to A$ is a function giving a label in A to each vertex in V. For $u \neq v$ in V, we say that u is an *ancestor* of v if there is a directed path from u to v in G, we say that u is a *descendant* of v if v is an ancestor of u, and otherwise we call u and v *incomparable*. A *topological sort* of G is a bijective function σ from $\{1, \ldots, n\}$ to V such that, for all $(u, v) \in E$, we have $\sigma^{-1}(u) < \sigma^{-1}(v)$. The word *achieved* by σ is $\lambda(\sigma) := \lambda(\sigma(1)) \cdots \lambda(\sigma(n)) \in A^*$.

The *constrained topological sort problem* CTS$[K]$ for a fixed language $K \subseteq A^*$ (described, e.g., by a regular expression) is defined as follows: given an A-DAG G, determine if there is a topological sort σ of G such that $\lambda(\sigma) \in K$ (in which case we say that σ *achieves* K).

We now define the *constrained shuffle problem* (CSh). Given two words $u, v \in A^*$, the *shuffle* [32] of u and v, written $u \sqcup\!\sqcup v$, is the set of words that can be obtained by interleaving them. Formally, a word $w \in A^*$ is in $u \sqcup\!\sqcup v$ iff there is a partition $P \sqcup Q$ of $\{1, \ldots, |w|\}$ such that $w_P = u$ and $w_Q = v$, where w_P denotes the sub-word of w where we keep the letters at positions in P, and likewise for w_Q. The *shuffle* $\sqcup\!\sqcup(U)$ of a tuple of words U is defined by induction as follows: we set $\sqcup\!\sqcup() := \{\epsilon\}$, set $\sqcup\!\sqcup(u) := \{u\}$, and set $\sqcup\!\sqcup(u_1, \ldots, u_n, u_{n+1}) := \bigcup_{v \in \sqcup\!\sqcup(u_1, \ldots, u_n)} v \sqcup\!\sqcup u_{n+1}$. The *constrained shuffle problem* CSh$[K]$ for a fixed language $K \subseteq A^*$ is defined as follows: given a tuple of words U, determine if $K \cap \sqcup\!\sqcup(U)$ is nonempty. Of course, CSh$[K]$ is a special case of CTS$[K]$: we can code any tuple of words U as an A-DAG G_U by coding each $u \in U$ as a directed path graph $v_1 \to \cdots \to v_{|u|}$ with $\lambda(v_i) = u_i$ for all $1 \leq i \leq |u|$. Thus, we will equivalently see inputs to CSh as tuples of words (called *strings* in this context) or as A-DAGs that are unions of directed path graphs.

▶ **Example 2.1.** The problem CTS$[(ab)^*]$ on an input $\{a, b\}$-DAG G asks if G has a topological sort starting with an a, ending with a b, and alternating between elements of each label. The problem CSh$[(aa + b)^*]$ on a tuple U of strings on $\{a, b\}$ asks if there is an interleaving $w \in \sqcup\!\sqcup(U)$ such that all a^*-factors in w are of even length (e.g., *bbaabaaaa*, but not *baaabb*).

In this work, we study the complexity of the problems CTS$[K]$ and CSh$[K]$ depending on the language K. Clearly we can always solve these problems by guessing a topological sort (or an interleaving), and verifying that it achieves a word in K. Hence, the complexity

is always in NP^K, that is, in non-deterministic PTIME with an oracle for the *word problem* of K, which we can call to test if an input word in is K:

▶ **Proposition 2.2.** *For any language K, the problems* $\mathrm{CTS}[K]$ *and* $\mathrm{CSh}[K]$ *are in* NP^K.

In particular, the problems are in NP when the language K is regular, because the word problem for regular languages is in PTIME. We will study regular languages in this work. We believe that regular languages can be classified depending on the complexity of these problems, and make the following *dichotomy conjecture*:

▶ **Conjecture 2.3.** *For every regular language K, the problem* $\mathrm{CTS}[K]$ *is either in NL or NP-complete. Likewise, the problem* $\mathrm{CSh}[K]$ *is either in NL or NP-complete.*

Towards this conjecture, we determine in this paper the complexity of CTS and CSh for several languages and classes. We first show in the next section that these problems are hard for some languages such as $(ab)^*$, and we then show tractability results in Section 4, and a coarser dichotomy result in Section 5 under an alternative phrasing of our problems.

3 Hardness Results

Our hardness results are based on the *shuffle problem* of formal language theory which asks, given a word $w \in A^*$ and a tuple U of words of A^*, whether $w \in \sqcup\!\sqcup(U)$. This problem is known to be NP-hard already on the alphabet $\{a, b\}$ (see [32]). The shuffle problem is different from CSh, because the target word of the shuffle problem is given as input, whereas the target regular language of CSh is fixed. However, the hardness of the shuffle problem directly implies the hardness of CSh, hence of CTS, for a well-chosen target language:

▶ **Proposition 3.1.** *Let $K_0 := (a_1a_2 + b_1b_2)^*$. The problem* $\mathrm{CSh}[K_0]$ *is NP-hard.*

Proof sketch. We can reduce a shuffle instance (w, U) to the instance $I := w_1 \cup U_2$ for $\mathrm{CSh}[K_0]$, where w_1 is w but adding the subscript 1 to all labels, and U_2 is defined analogously. A topological sort of I achieving K_0 must then alternate between w_1 and U_2, and enumerate letters with the same label (up to the subscript), witnessing that $w \in \sqcup\!\sqcup(U)$. ◀

In this section, we will refine this approach to show hardness for more languages. We first recall another initial hardness result from [32]. We then introduce a general *shuffle reduction* technique to show the hardness of languages by reducing from other hard languages. Last, we show that CTS and CSh are hard for the language $(ab)^*$ and for other languages.

Initial hard family. To bootstrap the hardness results of [32] on the shuffle problem (on input words) to our CSh-problem (on fixed languages), we generalize the definition of CSh to a *regular language family* $\mathcal{K}$, i.e., a (generally infinite) family of regular languages, each of which is described as a regular expression. The CSh-problem for $\mathcal{K}$, written $\mathrm{CSh}[\mathcal{K}]$, asks, given a regular expression $K \in \mathcal{K}$ and a set of strings U, whether $K \cap \sqcup\!\sqcup(U)$ is nonempty. In other words, we no longer fix one single target language but a family $\mathcal{K}$ of target languages, and the input chooses one target language from the family $\mathcal{K}$. The following is then shown in [32] by reducing from UNARY-3-PARTITION [13]:

▶ **Lemma 3.2. ([32], Lemma 3.2)** *Let $\mathcal{K} := \{(a^ib^i)^* \mid i \in \mathbb{N}\}$. Then* $\mathrm{CSh}[\mathcal{K}]$ *is NP-hard.*

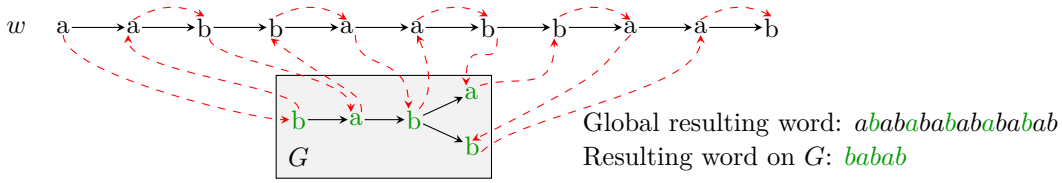

Figure 2 Example of a shuffle reduction from $K := (ba)^*b$ to $K' := (ab)^*$

Shuffle reduction. Our goal in this section is to show the hardness of CTS and CSh for more languages, but we do not wish to prove hardness for every language from scratch. Instead, we will introduce a general tool called the *shuffle reduction* that allows us to leverage the hardness of a language K to show that another language K' is also hard. Specifically, if a language K shuffle-reduces to a language K', this will imply that there is a PTIME reduction from CTS[K] to CTS[K'], and from CSh[K] to CSh[K'].

The intuition for the shuffle reduction is as follows: to reduce from K to K', given an input A-DAG G, we build an A-DAG G' formed of G plus an additional directed path labeled by a word w. Thus, any topological sort σ' of G' must be the interleaving of w and of a topological sort σ of G. Now, if we require that σ' achieves K', the presence of w can impose specific conditions on σ. Intuitively, if w is sufficiently long and "far away" from all words of K', then σ' must "repair" w to a word of K' by inserting symbols from G, so the insertions performed by σ may need to be in a specific order, i.e., σ may be forced to achieve a word of K. This means that solving CTS[K'] on G' allows us to solve CTS[K] on G. This intuition is illustrated on Figure 2: to achieve a word of $K' := (ab)^*$ on the DAG G', a topological sort must enumerate elements from G to insert them at the appropriate positions in w, achieving a word of $K := (ba)^*b$. We call *filter sequence* a family of words like w that allow us to reduce any CTS[K]-instance to CTS[K']. Formally:

▶ **Definition 3.3 (Filter sequence).** Let K and K' be languages on an alphabet A. A *filter sequence* for K and K' is an infinite sequence (f_n) of words of A^* having the following property: for every $n \in \mathbb{N}$, for every word $v \in A^*$ such that $|v| = n$, we have $v \in K$ iff $(v \sqcup\!\sqcup f_n) \cap K' \neq \emptyset$.

In Figure 2, we can choose $f_5 := w$ when defining a filter sequence for $(ba)^*b$ and $(ab)^*$: indeed, if we interleave w with any DAG G of 5 vertices, then a topological sort σ of G achieves K iff some interleaving σ' of σ with w achieves K'. We can now define our reduction:

▶ **Definition 3.4 (Shuffle reduction).** We say that a language K *shuffle-reduces* to a language K' if there is a filter sequence (f_n) for K and K' such that the function $i \mapsto f_i$ is computable in PTIME (where i is given in unary).

We say that a regular language family $\mathcal{K}$ *shuffle-reduces* to K' if each K does, and if we can compute in PTIME the function $(K, i) \mapsto f_i^K$, which maps a regular expression K of $\mathcal{K}$ and an integer i in unary to the i-th word in a filter sequence (f_n^K) for K and K'.

▶ **Theorem 3.5.** *For any regular language family $\mathcal{K}$ and language K', if $\mathcal{K}$ shuffle-reduces to K' then we can reduce in PTIME from* CTS[$\mathcal{K}$] *to* CTS[K']*, and from* CSh[$\mathcal{K}$] *to* CSh[K'].

Hardness for $(ab)^*$. We now use the shuffle reduction and the language family of Lemma 3.2 to show the hardness of $(ab)^*$. This will be instrumental for our coarser dichotomy in Section 5:

▶ **Theorem 3.6.** *The problem* CSh[$(ab)^*$] *(hence* CTS[$(ab)^*$]*) is NP-hard.*

Proof sketch. We shuffle-reduce from the language family $\mathcal{K}$ of Lemma 3.2: for the language $K_B = (a^B b^B)^*$ of $\mathcal{K}$, we define the filter sequence for words of length $2Bn$ by $f^B_{2Bn} := (b^B a^B ab)^n$. This ensures that, when interleaving f^B_{2Bn} with a word v of length $2Bn$ to achieve a word of $(ab)^*$, we must use v to insert in f^B_{2Bn} the letters written in bold: $((\mathbf{a}b)^B(a\mathbf{b})^B ab)^n$. This can be done iff $v = (a^B b^B)^n$, i.e., iff $v \in K_B$. We conclude by Theorem 3.5. ◀

Other hard languages. From the hardness of $(ab)^*$, we can use the shuffle reduction to show hardness for many other languages. For instance, we can show hardness for any language u^*, where $u \in A^*$ is a word with two different letters:

▶ **Proposition 3.7.** *Let $u \in A^*$ such that $|u|_a > 0$ and $|u|_b > 0$ for $a \neq b$ in A. Then* CSh$[u^*]$ *(hence* CTS$[u^*]$*) is NP-hard.*

Proof sketch. We shuffle-reduce from $(ab)^*$ with the filter sequence $f_{2n} := (uu_{-a}uu_{-b}u)^n$, where u_{-a} (resp. u_{-b}) is u but removing one occurrence of a (resp. of b). If a word v with $|v| = 2n$ has an interleaving w with f_{2n} that falls in u^*, then in w we must intuitively insert one a from v in each u_{-a} and one b from v in each u_{-b}, so that $v = (ab)^n$. To formalize this, we first rotate u to ensure that its first and last letters are different. We then observe that, as w is in u^*, any factor w' of length $|u|$ of w must be such that $|w'|_a = |u|_a$ and $|w'|_b = |u|_b$. We then consider factors of w of length $|u|$ centered on the u_{-a} and u_{-b} in f_{2n}: we argue that in w we must have inserted at least one a in or around each u_{-a}, and at least one b in or around each u_{-b}, otherwise these factors do not have enough a's and enough b's. ◀

We can also use the shuffle reduction to show hardness for other languages, e.g., $(aa+bb)^*$:

▶ **Proposition 3.8.** *Let $L := (aa + bb)^*$. The problem* CSh$[L]$ *(hence* CTS$[L]$*) is NP-hard.*

Proof sketch. We do again a shuffle reduction from $(ab)^*$, with the filter sequence $f_{2n} = (ab)^n$. If a word v with $|v| = 2n$ is such that $v \sqcup\!\sqcup f_{2n}$ intersects $(aa + bb)^*$ nontrivially, it must intuitively insert a's and b's in f_{2n} alternatively, so it must be $(ab)^n$. Note that a similar proof would also show hardness for the language $(a^i + b^j)^*$ for any choice of $i, j \geq 2$. ◀

We show a last result that does not use the shuffle reduction but an easy consideration on the number of letter occurrences. This result will be useful in Section 5:

▶ **Proposition 3.9.** *The problem* CSh$[(ab + b)^*]$ *(hence* CTS$[(ab + b)^*]$*) is NP-hard.*

Proof. We describe an easy PTIME reduction from CSh$[(ab)^*]$ to CSh$[(ab + b)^*]$. Given an instance I, check if the number of a-labeled and b-labeled vertices is the same, and fail if it is not. Otherwise, then I achieves a word of $(ab + b)^*$ iff it achieves one of $(ab)^*$, because we must enumerate one a-labeled vertex with each b-labeled vertex. ◀

We believe that the shuffle reduction applies to many other languages, though we do not know how to characterize them. In particular, we believe that the following could be shown with the shuffle reduction, generalizing all the above hardness results except Proposition 3.8:

▶ **Conjecture 3.10.** *Let F be a finite language such that, for some letter $a \in A$, the language F contains no power of a but contains a word which contains a. Then* CSh$[F^*]$ *is NP-hard.*

4 Tractability Results

Having shown hardness for several languages, we now present our tractability results. We will also rely on some of these results to show our coarser dichotomy result in the next section.

Closure under union. The first observation on tractable languages is that they are closed under union, as follows (recalling the definition of CTS and CSh for language *families*):

▶ **Lemma 4.1.** *For any finite family of languages $\mathcal{K}$, there is a logspace reduction from* CTS$[\bigcup \mathcal{K}]$ *to* CTS$[\mathcal{K}]$*, and likewise from* CSh$[\bigcup \mathcal{K}]$ *to* CSh$[\mathcal{K}]$*.*

Proof. To solve a problem for the language $\bigcup \mathcal{K}$ on an input instance I, simply enumerate the languages $K' \in \mathcal{K}$, and solve the problem on I for each K'. Clearly I is a positive instance of the problem for $\bigcup \mathcal{K}$ iff I is a positive instance of the problem for one of the K'. ◀

▶ **Corollary 4.2.** *For any finite family of languages $\mathcal{K}$, if* CTS$[K']$ *is in NL for each $K' \in \mathcal{K}$, then so is* CTS$[\bigcup \mathcal{K}]$*. The same is true of the CSh-problem.*

Clearly, tractability is also preserved under the *reverse operator*, i.e., reversing the order of words in a language; however tractable languages are *not* closed under many usual operators, as we will show in Section 5. Still, closure under union will often be useful in the sequel.

Monomials. We will now show that CTS is tractable for an important family of languages (and unions of such languages): the *monomial* languages. Having fixed the alphabet A, a *monomial* is a language of the form $A_1^* a_1 A_2^* a_2 \cdots a_n A_{n+1}^*$ with $a_i \in A$ and $A_i \subseteq A$ for all i. In particular, we may have $A_i = \emptyset$ so that $A_i^* = \epsilon$: hence, for every word $u \in A^*$, the language $A^* u A^*$ is a monomial language, which intuitively tests whether a word contains the pattern u. Several decidable algebraic and logical characterizations of these languages are known; in particular, unions of monomials are exactly the languages that are definable in the first-order logic fragment $\Sigma_2[<]$ of formulas with quantifier prefix $\exists^* \forall^*$, and it is decidable to check if a regular language is in this class [24, 22]. We show:

▶ **Theorem 4.3.** *For any monomial language K, the problem* CTS$[K]$ *is in NL.*

Proof sketch. Let K be $A_1^* a_1 A_2^* a_2 \cdots A_n^* a_n A_{n+1}^*$. We can first guess in NL the vertices $v_1, \ldots, v_n$ to which the $a_1, \ldots, a_n$ are mapped, so all that remains is to check, for each such guess, whether we can match the remaining vertices to the A_i. We proceed by induction on n. The base case of $n = 0$ (i.e., $K = A_1^*$) is trivial. For the induction step, using the fact that NL = co-NL (see [15, 28]), we check that the descendants of the last element v_n are all in A_{n+1}^*, and then we compute the set S of vertices that *must* be enumerated before v_n: they are the ancestors of the v_i, and the ancestors of any vertex labeled by a letter in $A \setminus A_{n+1}$. We then use the induction hypothesis to check in NL whether S has a topological sort that achieves a word in $A_1^* a_1 \ldots A_{n-1}^* a_{n-1} A_n^*$. ◀

Tractability based on width. While unions of monomials are a natural class, it turns out that they do not cover all tractable languages. In particular, we can show:

▶ **Proposition 4.4.** *Let $A := \{a, b\}$ and $K := (ab)^* + A^* aa A^*$. The problem* CTS$[K]$ *(hence* CSh$[K]$*) is in NL.*

This result is not covered by Theorem 4.3, because we can show that K cannot be expressed as a union of monomials (see the long version [5]); and the proof technique is different.

Proof. Let G be an input A-DAG. We first check in NL if G contains two incomparable vertices $v_1 \neq v_2$ such that $\lambda(v_1) = \lambda(v_2) = a$. If yes, we conclude that G is a positive instance, as we can clearly achieve K by enumerating v_1 and v_2 contiguously.

If there are no two such vertices, we check in NL if there are two comparable a-labeled vertices $v_1 \neq v_2$ that can be enumerated contiguously, i.e., there is an edge $v_1 \to v_2$ but no vertex w that is *between* v_1 and v_2, i.e., is a descendant of v_1 and an ancestor of v_2. If there are two such vertices v_1 and v_2, we conclude again that G is a positive instance.

Otherwise, our first test implies that G induces a total order on the a-labeled vertices, and our second test implies that any two consecutive a-labeled vertices in this order must have at least one b-labeled vertex between them. This ensures that no topological sort achieves A^*aaA^*, so it suffices to test whether one can achieve $(ab)^*$. Clearly this is the case iff all consecutive pairs of a-labeled vertices have exactly one b-labeled vertex between them, and there is exactly one additional b-labeled vertex that can be enumerated after the last a-labeled vertex. We can test this in NL, which concludes the proof. ◀

Intuitively, the language of Proposition 4.4 is tractable because it is easy to solve unless the input instance has a very restricted structure, namely, all a's are comparable. We do not know whether this result generalizes to $(ab)^* + A^*a^iA^*$ for $i > 2$. However, following the intuition of this proof, we can show the tractability of a similar kind of regular languages:

▶ **Proposition 4.5.** *Let $A := \{a, b\}$, let K' be a regular language, let $i \in \mathbb{N}$, and let $K := K' + A^*(a^i + b^i)A^*$. The problem* CTS$[K]$ *(hence* CSh$[K]$*) is in NL.*

As in Proposition 4.4, CTS is trivial for the languages in this proposition unless the input A-DAG G has a restricted shape. Here, the requirement is on the *width* of G, i.e., the maximal cardinality of a subset of pairwise incomparable vertices (called an *antichain*), so we can show Proposition 4.5 by distinguishing two cases depending on the width of G:

Proof sketch. We test in NL whether the input A-DAG G contains an antichain C of size $2i$: if it does, then at least i vertices in C must have the same label, and we can enumerate them in succession to achieve $A^*a^iA^*$ or $A^*b^iA^*$, so G is a positive instance. Otherwise, G has width $< 2i$, and Dilworth's theorem [9] implies that its elements can be partitioned into chains, so that CTS can be solved in NL following a dynamic algorithm on them. ◀

Other tractable case. We close the section with another example of a regular language which is tractable for the CSh-problem for what appears to be a unrelated reason.

▶ **Proposition 4.6.** *Let $A := \{a, b\}$ and $K := (aa + b)^*$. The problem* CSh$[K]$ *is in NL.*

This is in contrast to $(aa + bb)^*$, for which we showed intractability (Proposition 3.8). We do not know the complexity of the CTS-problem for $(aa + b)^*$, or the complexity for either problem of languages of the form $(a^i + b)^*$ for $i > 2$.

Proof sketch. We show that the existence of a suitable topological sort can be rephrased to an NL-testable equivalent condition, namely, there is no string in the input instance whose number of odd "blocks" of a-labeled elements dominates the total number of a-labeled elements available in the other strings. If the condition fails, then we easily establish that no suitable topological sort can be constructed: indeed, eliminating each odd block of a's in the dominating string requires one a from the other strings. If the condition holds, we can simplify the input strings and show that a greedy algorithm can find a topological sort by picking pairs of a's in the two current heaviest strings. ◀

5 A Coarser Dichotomy Theorem

In the two previous sections, we have established some intractability and tractability results about the constrained topological sort and constrained shuffle problems for various languages. Remember that our end goal would be to characterize the tractable and intractable languages, and show a dichotomy (Conjecture 2.3). This is difficult, and one reason is that the class of tractable languages is not "well-behaved": while it is closed under the union operator (Corollary 4.2), it is is *not* closed under intersection, complement, and other common operations. This makes it difficult to study tractable languages using algebraic language theory [23].

▶ **Proposition 5.1.** *We have the following counterexamples to closure:*

- ***Quotient.*** *There exists a word $u \in A^*$ and a regular language K such that* $\mathrm{CSh}[K]$ *is in NL but* $\mathrm{CSh}\left[u^{-1}K\right]$ *is NP-hard.*
- ***Intersection.*** *There exists two regular languages K_1 and K_2 such that* $\mathrm{CTS}[K_1]$ *and* $\mathrm{CTS}[K_2]$ *are both in PTIME but* $\mathrm{CSh}[K_1 \cap K_2]$ *is NP-hard*
- ***Complement.*** *There exists a regular language K such that* $\mathrm{CTS}[K]$ *is in NL, but* $\mathrm{CSh}[A^* \setminus K]$ *is NP-hard.*
- ***Inverse of morphism.*** *There exists a regular language K and morphism φ such that* $\mathrm{CTS}[K]$ *is in NL but* $\mathrm{CSh}\left[\varphi^{-1}(K)\right]$ *is NP-hard.*

The three last results of this proposition also apply to the constrained topological sort problem, but the first one does not, and in fact CTS-tractable languages *are* closed under quotients. This observation implies that there are regular languages K such that $\mathrm{CSh}[K]$ is tractable but $\mathrm{CTS}[K]$ is NP-hard; one concrete example is $K := b^*A^* + aaA^* + (ab)^*$ (see long version [5]). We sketch the proof of Proposition 5.1:

Proof sketch. For each operation, we use $(ab)^*$ as our NP-hard language (by Theorem 3.6).

For quotient, we take $K := bA^* + aaA^* + (ab)^*$, and $u := ab$. We have $u^{-1}K = (ab)^*$, but $\mathrm{CSh}[K]$ is in NL because any shuffle instance with more than one string satisfies K.

For intersection, we take $K_1 := (ab)^*(\epsilon + bA^*)$ and $K_2 := (ab)^*(\epsilon + aaA^*)$. We have $K_1 \cap K_2 = (ab)^*$, but $\mathrm{CSh}[K_1]$ and $\mathrm{CSh}[K_2]$ are in PTIME using an ad-hoc greedy algorithm.

For complement, we take $K := bA^* \cup A^*a \cup A^*aaA^* \cup A^*bbA^*$. As K is a union of monomials, we know by Theorem 4.3 that $\mathrm{CTS}[K]$ is in NL, but we have $A^* \setminus K = (ab)^*$.

For inverse of morphism, we take $A := \{a, b\}$ and $K := (ab)^* + A^*(a^3 + b^3)A^*$. We know that $\mathrm{CTS}[K]$ is in PTIME by Proposition 4.5. Now, defining $\varphi : A^* \to A^*$ by $\varphi(a) := aba$ and $\varphi(b) := bab$, we have $\varphi^{-1}(K) = (ab)^*$ because no word in the image of φ has three identical consecutive symbols. ◀

Proposition 5.1 suggests that tractable languages would be easier to study algebraically if we ensured that they were closed under all these operations, i.e., if they formed a variety [23]. In this section, we enforce this by moving to an alternative phrasing of the CTS and CSh problems. This allows us to leverage algebraic techniques and show a dichotomy theorem in this alternative phrasing, under an additional *counter-free* assumption. We first present the alternative phrasing, and then present the additional assumption and our dichotomy result.

Alternative phrasing. The first change in our alternative phrasing is that the input DAG G will now be an A^*-*DAG*, i.e., a DAG labeled with words of A^* rather than letters of A. As before, a topological sort σ of G *achieves* a word $\lambda(\sigma) \in A^*$ obtained by concatenating the λ-images of the vertices of G in the order of σ: but vertex labels are now "atomic" words

whose letters cannot be interleaved with anything else. The *multi-letter* CTS and CSh problems are the variants defined with A^*-DAGs; intuitively, this ensures that tractable languages are closed under inverse morphisms.

The second change is that we will not fix one single target language, but a *semiautomaton* [14], i.e., an automaton where initial and final states are not specified. Formally, a semiautomaton is a tuple (Q, A, δ) where Q is the set of states, A is the alphabet, and $\delta : Q \times A \to Q$ is the transition function; we extend δ to words as usual by setting $\delta(q, \epsilon) := q$ and $\delta(q, u_1 \cdots u_{n+1}) := \delta(\delta(q, u_1), u_2 \cdots u_{n+1})$. We will fix the target semiautomaton, and the initial and final states will be given in the input instance (in addition to the DAG). This enforces closure under quotients (by choosing the initial and final states) and complement (by toggling the final states). Further, to impose closure under intersection, the input instance will specify a *set* of pairs of initial-final states, with a logical AND over them. The question is to determine whether the input DAG achieves a word accepted by *all* the corresponding automata; and this enforces closure under intersection.

We can now summarize the formal definition of our problem variants. The *multi-letter* CTS-*problem for a fixed semiautomaton* $S = (Q, A, \delta)$ takes as input an A^*-DAG and a set $\{(i_1, F_1), \ldots, (i_k, F_k)\}$ of initial-final state pairs, where $i_j \in Q$ and $F_j \subseteq Q$ for all $1 \leq j \leq k$. The input is accepted if there is a topological sort σ of G such that, for all $1 \leq j \leq k$, the word $\lambda(\sigma)$ is accepted by the automaton (Q, A, δ, i_j, F_j), i.e., $\delta(i_j, \lambda(\sigma)) \in F_j$. The *multi-letter* CSh-*problem for a fixed semiautomaton* is defined in the same way, imposing that the input A^*-DAG is a union of directed path graphs.

Dichotomy result Our dichotomy will apply to the multi-letter CTS and CSh problem for semiautomata. However, we will need to make an additional assumption, namely, that the semiautomaton is *counter-free*. This assumption means that our dichotomy will only apply to a well-known subset of regular languages, namely, the *star-free languages*, that are better understood algebraically; it excludes in particular the tricky case of *group languages* that we will study separately in Section 6. Formally, a semiautomaton is *counter-free* if, for every state q and word $u \in A^*$, if $\delta(q, u^n) = q$ for some $n > 1$, then we have $\delta(q, u) = q$. Under the counter-free assumption, we can prove the following dichotomy, using our hardness and tractability results in Sections 3 and 4:

▶ **Theorem 5.2.** *Let S be a counter-free semiautomaton. Then the multi-letter CSh-problem and CTS-problem for S are either both in NL, or both NP-complete. The dichotomy is effective: given S, it is PSPACE-complete to decide which case applies.*

We conclude the section by introducing some technical tools used for this result and for Section 6, and by giving a proof sketch. The criterion of the dichotomy on S is phrased in terms of the *transition monoid* of S, which we now define (see, e.g., [23] for details). Remember that a monoid is a set that has an associative binary operation and a neutral element. The *transition monoid* $T(S)$ of a semiautomaton $S = (Q, A, \delta)$ is the set of functions $f : Q \to Q$ that are "achieved" by S in the following sense: there is a word $u \in A^*$ such that $\delta(q, u) = f(q)$ for all $q \in Q$. In particular, the neutral element is the identity function, which is achieved by taking $u := \epsilon$; and the binary operation on $T(S)$ is function composition, which is associative. Note that the transition monoid is finite and can be computed from S.

We assumed that S is counter-free, and this is equivalent [20] to saying that $T(S)$ is in the class $\mathbf{A}$ of *aperiodic* finite monoids (formally defined by the equation $x^{\omega+1} = x^\omega$ where ω is the idempotent power [23] of the monoid). Within $\mathbf{A}$, our dichotomy criterion on $T(S)$ is based on a certain subclass of $\mathbf{A}$, called $\mathbf{DA}$ (see [30]): S is tractable iff $T(S)$ is in $\mathbf{DA}$, and it is PSPACE-complete [31] to test whether this holds (using the formal definition of $\mathbf{DA}$ by the equation $(xy)^\omega x (xy)^\omega = (xy)^\omega$). We can now sketch the proof of Theorem 5.2:

Proof sketch. We first show that if $T(S)$ is in **DA** then the multi-letter CTS and CSh problems for S are in NL. For this, we rely on one characterization of **DA** (from [30]): if $T(S)$ is in **DA** then the regular languages recognized by S (for any set of initial-final states) are unions of *unambiguous monomials*, in particular they are unions of monomials, so we have tractability by Corollary 4.2 and Theorem 4.3.

For the converse direction, we use a second characterization of **DA** (from [29]): if $T(S)$ is *not* in **DA** then there is a choice of initial-final state pairs for which S computes a language K whose inverse image by some morphism is either $(ab)^*$ or $(ab+b)^*$. We know that these languages are intractable (Theorem 3.6 and Proposition 3.9) so we conclude by showing a PTIME reduction from one of these two languages: this is possible in our alternative problem phrasing, in particular using the multi-letter labels to invert the morphism. ◀

6 Lifting the Counter-Free Assumption for CSh

Our dichotomy theorem in the previous section (Theorem 5.2) was shown for an alternative phrasing of our problems (with semiautomata and multi-letter inputs), and made the additional assumption that the input semiautomaton is counter-free. In this section, we study how to lift the counter-free assumption. In exchange for this, we restrict our study to the constrained shuffle problem (CSh) rather than CTS.

To extend Theorem 5.2 for the CSh-problem, we will again classify the semiautomata S based on their transition monoid $T(S)$. However, instead of **DA**, we will use the two classes **DO** and **DS** introduced in [27] (formally **DO** is defined by the equation $(xy)^\omega(yx)^\omega(xy)^\omega = (xy)^\omega$ and **DS** by the equation $((xy)^\omega(yx)^\omega(xy)^\omega)^\omega = (xy)^\omega$ for ω the idempotent power). Both **DO** and **DS** are supersets of **DA**, specifically we have $\mathbf{DA} \subseteq \mathbf{DO} \subseteq \mathbf{DS}$, and we can test in PSPACE in S whether $T(S)$ is in each of these classes [31]. Our main result is then:

▶ **Theorem 6.1.** *Let S be a semiautomaton. If $T(S)$ is in **DO**, then the multi-letter CSh-problem for S is in NL. If $T(S)$ is not in **DS**, then it is NP-complete.*

This result generalizes Theorem 5.2 for the CSh-problem, because both **DO** and **DS** collapse to **DA** for aperiodic monoids (see [27] and [2, Chapter 8]); formally, $\mathbf{DO} \cap \mathbf{A} = \mathbf{DS} \cap \mathbf{A} = \mathbf{DA}$. However, **DO** covers more languages than **DA**: the main technical challenge to prove Theorem 6.1 is to show that CSh is tractable for these languages. One important example are the *group languages* over A: these are the regular languages recognized, for some choice of initial-final state pairs, by a semiautomaton S over A such that $T(S)$ is a group. A more general example are *district group monomials*, which are the languages of the form $K_1a_1 \cdots K_na_nK_{n+1}$ where, for all i, we have $a_i \in A$ and K_i is a group language over some alphabet $A_i \subseteq A$. Note that district group monomials are more expressive than the *group monomials* defined in earlier work [25] (which set $A_i := A$ for all i), and they also generalize the monomials that we studied in Section 4 (any A_i^* is trivially a group language over A_i, even though it is not a group language over A). In fact, to prove Theorem 6.1, what we need is to generalize Theorem 4.3 (for CSh) from monomials to district group monomials:

▶ **Theorem 6.2.** *Let K be a district group monomial. Then* CSh$[K]$ *is in NL.*

Note that this theorem, like Theorem 4.3, applies to the original phrasing of CSh, not the alternative phrasing with semiautomata and multi-letter DAGs. Thus, Theorem 6.2 implies that the original CSh-problem is tractable for many languages that we had not covered previously, e.g., $(ab^*a+b)^*c(ba^*b+a)^*$, the language testing whether there is one c preceded by an even number of a and followed by an even number of b. The proof of Theorem 6.2 is our main technical achievement, and we sketch it below (see the long version [5] for details):

Proof sketch. We focus on the simpler case of a group language, for a finite group H. The problem can be rephrased directly in terms of H: given a tuple I of strings over H and a target element $g \in H$, determine if there is an interleaving of I that evaluates to g under the group operation. Our approach partitions H into the *rare* elements H_{rare}, that occur in a constant number of strings, and the *frequent* elements H_{freq}, that occur in sufficiently many strings. For the frequent elements, we can build a large antichain C from the strings where they occur, with each element of H_{freq} occuring many times in C. Now, as topological sorts can choose any order on C, they can intuitively achieve all elements of the subgroup $\langle H_{\text{freq}} \rangle$ generated by H_{freq}, except that they cannot change "commutative information", e.g., the parity of the number of elements. We formalize the notion of "commutative information" using relational morphisms, and prove an *antichain lemma* that captures our intuition that all elements of $\langle H_{\text{freq}} \rangle$ with the right commutative information can be achieved.

For the rare elements, we can simply follow a dynamic algorithm on the constantly many strings where they occur. However, we must account for the possibility of inserting elements of $\langle H_{\text{freq}} \rangle$ from the other strings, and we must show that it suffices to do constantly many insertions, so that it was sufficient to impose a constant lower bound on $|C|$. We formalize this as an *insertion lemma*, which we prove using Ramsey's theorem. ◀

We close the section by commenting on the two main limitations of Theorem 6.1. The first limitation is that it is not a dichotomy: it does not cover the semiautomata with transition monoid in $\mathbf{DS} \setminus \mathbf{DO}$. We do not know if the corresponding languages are tractable or not; we have not identified intractable cases, but we can show tractability, e.g., for $(a^+b^+a^+b^+)^*$, the language of words with an even number of subfactors of the form a^+b^+.

▶ **Proposition 6.3.** *Let* $K = (a^+b^+a^+b^+)^*$. *Then* $\mathrm{CSh}[K]$ *is in NL.*

However, it would be difficult to show tractability for all of **DS**, because **DS** is still poorly understood in algebraic language theory. For instance, characterizing the languages with a syntactic monoid in **DS** has been open for over 20 years [2, Open problem 14, page 442].

The second limitation of Theorems 6.1 and 6.2 is that they only apply to CSh. New problems arise with CTS: for instance, an $\{a, b\}$-DAG G may contain large antichains C_a and C_b of a-labeled and b-labeled vertices, and yet contain no antichain with many a-labeled and b-labeled vertices (e.g., if G is the series composition of C_a and C_b). The missing proof ingredient seems to be an analogue of Dilworth's theorem for *labeled* DAGs (see also [3]).

7 Conclusion and Open Problems

We have studied the complexity of two problems, constrained topological sort (CTS) and constrained shuffle (CSh): fixing a regular language K, given a labeled DAG (for CTS) or a tuple of strings (for CSh), we ask if the input DAG has a topological sort achieving K. We have shown tractability and intractability for several regular languages using a variety of techniques. These results yield a coarser dichotomy (Theorem 5.2) in an alternate problem phrasing that imposes some closure assumptions.

Our work leaves the main dichotomy conjecture open (Conjecture 2.3). Even in the alternate problem phrasing of Theorem 5.2, our dichotomy only covers counter-free semiautomata: the restriction is lifted in Section 6 but only for CSh, and with a gap between tractability and intractability. In the original phrasing, there are many concrete languages that we do not understand: Does Proposition 4.4 extend to $(ab)^* + A^*a^iA^*$ for $i > 2$? Does Proposition 4.6 extend to $(a^i + b)^*$ for $i > 2$, or to CTS rather than CSh? Can we show Conjecture 3.10?

Another direction would be to connect CSh and CTS to the framework of *constraint satisfaction problems* (CSP) [11], which studies the complexity of homomorphism problems for fixed "constraints" (right-hand-side of the homomorphism). If this were possible, it could lead to a better understanding of our tractable and hard cases. However, CTS does not seem easy to rephrase in CSP terms: topological sorts and regular language constraints seems hard to express in terms of homomorphisms, even in extensions such as *temporal* CSPs [6, 7].

One last question would be to investigate CTS and CSh for *non-regular* languages. The simplest example is the Dyck language, which appears to be NP-hard for CTS (at least in the multi-letter setting), but tractable for CSh, via a connection to scheduling; see [12], problem SS7. More generally, CTS and CSh could be studied, e.g., for context-free languages, where the complexity landscape may be equally enigmatic.

Abstract

We show that for no surface except for the plane does monadic second-order logic (MSO) have a zero-one-law – and not even a convergence law – on the class of (connected) graphs embeddable on the surface. In addition we show that every rational in [0,1] is the limiting probability of some MSO formula. This strongly refutes a conjecture by Heinig et al. (2014) who proved a convergence law for planar graphs, and a zero-one law for connected planar graphs, and also identified the so-called gaps of [0,1]: the subintervals that are not limiting probabilities of any MSO formula. The proof relies on a combination of methods from structural graph theory, especially large face-width embeddings of graphs on surfaces, analytic combinatorics, and finite model theory, and several parts of the proof may be of independent interest. In particular, we identify precisely the properties that make the zero-one law work on planar graphs but fail for every other surface.

1 Introduction

We consider classes of labelled graphs with the uniform distribution on graphs with a fixed number of vertices. Let S be a closed compact surface, and let $\mathcal{G}_S$ be the class of graphs embeddable on S. Heinig et al. [9] studied limiting probabilities of first order (FO) and monadic second order (MSO) properties of graphs in the classes $\mathcal{G}_S$. They showed that a convergence law in FO holds for all surfaces S, and that a convergence law holds in MSO when S is the sphere, so that $\mathcal{G}_S$ is the class of planar graphs. They also showed that a zero-one law in FO holds for *connected* graphs in $\mathcal{G}_S$, and a zero-one law in MSO for connected planar graphs. They conjectured that these results extend to MSO properties on

an arbitrary surface. We strongly refute these conjectures. For each surface S other than the sphere we construct an MSO formula φ such that the probability that φ is satisfied in $\mathcal{G}_S$ does not converge when the number of vertices n tends to infinity, not even on connected graphs. In addition, telling whether the probability of a given MSO formula φ converges is an undecidable problem. We also show that every rational number in [0,1] is the limiting probability of some MSO formula for connected graphs in $\mathcal{G}_S$.

We sketch next the main ingredients in the proofs of our results. We fix a surface S different from the sphere. Embeddings of graphs on surfaces can be defined in purely combinatorial terms. If S is orientable, an embedding of a graph on S is given by a rotation system consisting, for each vertex v, of a cyclic orientation of the edges incident with v. If S is non-orientable one has to consider also signed edges [10]. Given a graph G embedded in S the *face-width* of the embedding is the minimum number of intersections of G with a non-contractible curve in S. In what follows, we say that a graph property holds with high probability (w.h.p.), or asymptotically almost surely (a.a.s.), if it holds with probability tending to 1 as n tends to infinity. It is known [10] that if the face-width of a 3-connected graph G is at least $2g$, where g is the genus of G (orientable or not), then G has a unique embedding in S. We also need the fact that the face-width of a random 3-connected graph G embedded on S is $\Omega(\log n)$ w.h.p. [1].

It is shown in [2] that w.h.p. a random graph G in $\mathcal{G}_S$ has a unique non-planar 3-connected component C. Since planarity is MSO expressible and 3-connected components are MSO definable, so is C. Using the fact that w.h.p. the face-width of C is large, we show the existence of an MSO definable grid structure M in G of size $\Omega(\log\log n)$. This is obtained starting with a non-contractible cycle, which is MSO definable, and extending it to a grid structure. Inspired by the capacity of MSO to emulate Turing machine computations on grid graphs, we are then able to define an MSO formula φ expressing the property that $\log^\dagger |M|$ is in $\{0,1,2,3\}$ modulo 8, where $\log^\dagger n$ is a variant of $\log^* n$ (see Section 5). Given that $\log\log n \leq |M| \leq n$, the value of $\log^\dagger |M|$ modulo 8 oscillates and, as a consequence, the probability that φ holds does not converge as n goes to infinity.

The non-converging formula φ, combined with the abovementioned capacity of MSO to emulate Turing machine computations on grid graphs, also gives the undecidability of the decision problem for converging probabilities. For each Turing machine M, we find an MSO formula φ_M that simulates partial runs of M along the definable growing grids. The formula φ_M has asymptotic probability 1 if M halts, and asymptotic probability 0 otherwise, and the probability of the conjunction $\varphi \wedge \varphi_M$ is thus converging if and only if M halts.

To prove that each rational in $[0,1]$ is the limiting probability of some MSO formula, we use the following facts. (a) A 3-connected graph in a surface of genus g has a spanning tree with maximum degree at most $4g$ [7]. (b) For the class $\mathcal{G}_S$, every property in MSO_2 (quantification over vertices and edges) is also expressible in MSO [5]. (c) The size X_n of the unique non-planar component obeys a limit local law related to a stable law [8]. Consider now a random graph G in $\mathcal{G}_S$ with n vertices, let C be the unique non-planar component, and let $X_n = |C|$. From properties (a) and (b) it follows that, for each integers a and b, we can express in MSO the property $\varphi_{a,b}$ that X_n is equal to a modulo b. Using property (c) we show that the probability that $\varphi_{a,b}$ is satisfied tends to $1/b$. Now given any rational non-negative $a/b \leq 1$, the property that X_n is less than a modulo b tends to a/b.

The key fact that makes MSO properties of graphs on non-planar surfaces so different from the plane is that w.h.p. there is a unique *non-planar* 3-connected component, which also happens to be the only one of linear size. For random planar graphs there is a unique 3-connected component of linear size as well, but it is indistinguishable in MSO from the smaller ones.

2 Graphs and Surfaces

In this section we present the background from graph theory and surface topology we need for our main result. We refer to [10, 6] for background on graphs and surfaces. Our notation on surfaces and embeddings follows [10].

Graphs. All graphs in this paper are finite, undirected, and simple, i.e. no parallel edges or self-loops. We denote the vertex and edge set of a graph G by $V(G)$ and $E(G)$, resp. For $d \geq 0$, a graph G is *d-degenerate* if every subgraph $H \subseteq G$ contains a vertex of degree at most d.

We need the concept of 3-connected components of a graph G. For $k > 0$, a graph G is *k-connected* if $|V(G)| > k$ and $G - S$ is connected for all $S \subseteq V(G)$ with $|S| < k$. A *connected component* of G is an inclusion-wise maximal connected subgraph $C \subseteq G$. A *2-connected component* of G is an inclusion-wise maximal 2-connected subgraph $C \subseteq G$. For defining *3-connected components* of G we need some preparation.

Let G be a 2-connected graph. A *separator of order* 2 in G is a set $X = \{u, v\}$ of distinct vertices such that $G - X$ is not connected. Let C be an inclusion-wise maximal subgraph of G such that for all 2-separations X of G there is one connected component of $G - X$ which contains all vertices of $C - X$. For any such 2-separation X of G, if $X \subseteq V(C)$ then we add an edge between the two vertices of X in C if it is not already there. This produces a new graph $\widetilde{C}$. For a 2-connected graph G, the graphs $\widetilde{C}$ obtained in this way which are not cycles are called the 3-connected components of G. Tutte proved that every 2-connected graph has a decomposition into a tree whose nodes are cycles or 3-connected components.

Surfaces and Graph Embeddings. We now present some fundamental properties of surfaces and embedded graphs. We refer to [10] for background.

A *surface* is a compact connected Hausdorff topological space in which every point has a neighbourhood homeomorphic to the plane. A surface can be constructed from the sphere by cutting a number of holes and pairs of holes into the sphere, each homeomorphic to an open disc. Every pair of holes is then closed by adding a *handle* – an open cylinder – connecting the boundary of the holes. The remaining holes are closed by adding a *crosscap*, that is, by identifying each point on the boundary of the hole with the corresponding point on the opposite side. The surface classification theorem shows that every surface is homeomorphic to a surface constructed in this way. Any surface obtained in this way that includes a crosscap is called *non-orientable*, otherwise it is called *orientable*. Our main result holds for orientable and non-orientable surfaces. Due to space constraints, we only explain the orientable case. The surface obtained from the sphere by adding k handles is denoted by $\mathbb{S}_k$. The number k is called the *genus* of $\mathbb{S}_k$.

Let $S = \mathbb{S}_k$ be a surface. The way we constructed S implies that we can reduce it to the plane by taking for each handle a closed curve that goes around the handle and cut the surface along the curves, closing the appearing holes by disks. This way, every handle is cut open and the resulting surface is homeomorphic to the plane. We call curves which cut a handle in this way *noncontractible*. There are two types of non-contractible curves: if we cut along a curve, we may either disconnect the surface or not. Curves which do not disconnect the surface when we cut along them are called *non-separating*.

Following [10], a graph G' is *embedded* on a surface S if its vertices are distinct points on S and every edge e of G' with endpoints u, v is a simple closed arc connecting u and v in S such that the interior of e is disjoint from other edges and vertices of G'. A graph G is

embeddable on S if it is isomorphic to an embedded graph G' on S. Let Π be an embedding of a graph G in S. The connected components of $S - \Pi$ are called the *faces* of Π.

An embedding of a graph in a surface S can be uniquely represented by an object called an *embedding scheme* or *rotation system*. If v is a vertex of G then the embedding of G embeds the edges incident with v in some order in clockwise orientation around v. That is, for any v the embedding defines a cyclic permutation of the incident edges, or a linear order on the edges that have v as an endpoint. We call this order the *clockwise order* around v. A *rotation system* is a set of clockwise orderings containing one order for every vertex.

Such a rotation system uniquely determines an embedding of G in S. Given a rotation system π of a graph G, we can construct the facial cycles of the embedding as follows. Let v be a vertex and let $e = \{u, v\}$ be an incident edge. Then v and e determine a walk in G where we start at v, follow the edge e to its other endpoint and then proceed with the next edge in clockwise order until we return to v. In this way we obtain exactly the facial cycles of the embedding. In particular, we can represent any face of the embedding by orienting an edge in its boundary cycle, which fixes the start vertex v and the edge e to choose first. This will be used in the MSO definition in the next section.

One of the main challenges in proving our main result is that we need to define MSO-formulas that encode in a given graph an embedding of it in a fixed surface S. Whitney proved that a planar graph G that is 3-connected has a unique embedding into the plane. In [3], Courcelle proved that there are MSO-formulas defining the rotation system for planar graphs.

To prove that rotation systems are also definable for graphs on other surfaces we will reduce the problem to the planar case as follows. As mentioned above, any surface can be reduced to the plane by cutting the surface along a finite set of closed curves each of which cuts a handle. We can generalize this concept of *cutting along a cycle* to cycles in embedded graphs.

In the sequel, let S be a surface. If we refer to a Π-*embedded graph* G we implicitly define Π to be an embedding of the graph G on S. Let $C = (v_0 e_1 v_1 e_2 .... v_k = v_0)$ be a cycle in G. For $i > 0$, let L_i be the set of edges incident to v_i which in the clockwise ordering around v_i appear after e_i but before e_{i+1} the R_i be the set of edges appearing after e_{i+1} and e_i. The edges in any L_i are called the *left* edges of the cycle C and the edges in any R_i are called the *right* edges of C.

▶ **Definition 2.1.** Let $C = (v_0 e_1 v_1 \dots v_k)$ be a surface nonseparating cycle of a Π-embedded graph G. Let G' be the graph obtained from G by replacing C by two isomorphic copies $C_r = (v_0^r e_1^r v_1^r \dots v_k^r)$ and $C_l = (v_0^r e_1^l v_1^l \dots v_k^l)$ such that all edges $e = \{u, v_i\}$ on the right of C are replaced by edges $\{u, v_i^r\}$ incident to the corresponding vertices on C_r and all edges $e = \{u, v_i\}$ on the left of C are replaced by edges $\{u, v_i^l\}$ incident to the corresponding vertices on C_l. We say that G' is obtained from G by *cutting along the cycle* C. The embedding Π defines an embedding Π' of G' in the surface obtained from S by cutting along C and closing the resulting holes by discs in the obvious way. Note that the two copies C_1, C_2 of C are now facial cycles. We now add two new vertices f_1, f_2 such that f_i has an edge to every vertex of C_i. This means that f_i is drawn in the face bounded by C_i. We call the resulting graph the *augmented graph obtained by cutting along* C.

This motivates the following definition.

▶ **Definition 2.2** (Planarizing set of cycles)**.** Let G be a Π-embedded graph. A *planarizing set of cycles* is a set $C_1, \dots, C_k$ of pairwise disjoint cycles in G such that cutting along all cycles $C_1, \dots, C_k$ results in a connected graph embedded in the sphere.

We will see below that for certain graphs embedded on a surface such sets of cycles always exist. For this, we need the concept of face-width.

▶ **Definition 2.3.** Let Π be an embedding of a graph G on S. The *face-width* $\mathrm{fw}(G,\Pi)$ of G is the smallest number k such that S contains a noncontractible closed curve that intersects G in k points, or ∞ if no noncontractible curve exists (i.e. S is the plane).

We prove next that the connectivity between two Π-noncontractible and Π-nonseparating cycles is at least as high as the face-width of Π.

▶ **Lemma 2.4.** *Let G be a 2-connected Π-embedded graph and let C and C' be two disjoint Π-noncontractible, Π-nonseparating cycles. Let $2 \leq k = \mathrm{fw}(G,\Pi) < \infty$. Then there are at least k pairwise vertex disjoint paths linking C and C'. Furthermore, if G is 3-connected with $3 \leq \mathrm{fw}(G,\Pi) < \infty$ and C is a Π-nonseparating cycle then be the augmented graph $\widetilde{G}$ obtained from G by cutting along C is 3-connected.*

See [10, Theorem 5.11.2] for a proof of the following theorem.

▶ **Theorem 2.5.** *Let G be a graph that is Π-embedded in a surface with Euler genus g and let d be a positive integer. If $\mathrm{fw}(G,\Pi) \geq 8(d+1)(2^g-1)$, then G contains a planarizing collection of induced cycles $C_1,\ldots,C_k$, for some $g/2 \leq k \leq g$, such that the distance between C_i and C_j, $i \neq j$, is at least d.*

The previous theorem and the lemma preceding it show that starting from a graph that is 3-connected and has an embedding of face-width at least 3, we can reduce it to a 3-connected planar graph by cutting along a constant number of cycles. Combining this with Whitney's theorem of unique embeddings of 3-connected planar graphs implies the following result which will be important later.

▶ **Theorem 2.6.** *Let G be a 3-connected graph that is Π-embedded in a surface with Euler genus g such that $3 \leq 8(d+1)(2^g-1) \leq \mathrm{fw}(G,\Pi) < \infty$. Let G' be the augmented graph obtained by cutting along a set of planarizing cycles. Then the facial cycles of Π are precisely the facial cycles of the unique plane embedding of G'. Moreover, an embedding scheme which is equivalent to Π can be deduced from the rotation system of the plane embedding of G'.*

The following definition captures the abstract properties of planarizing sets of cycles.

▶ **Definition 2.7.** Let G be a graph and let $k \geq 0$. A *potential system of planarizing cycles of order k* is a sequence $\big((C_i,L_i,R_i)\big)_{i=1}^k$ such that $C_1,\ldots,C_k$ are pairwise vertex disjoint cycles in G and L_i,R_i form a partition of the set of edges $e \notin E(C_i)$ incident with a vertex on C_i, for all i.

Note that the procedure of cutting along a cycle in a graph G and the augmented graph obtained from G in this way as defined above can be applied to any cycle C with a given partition L,R of the edges $e \notin E(C)$ incident with a vertex on C. Of course it may not always lead to the intended effect, e.g. if the sets L and R of left and right edges are chosen wrongly. But in any case it will produce a graph G' and if G and Π satisfy the conditions of Theorem 2.5, then G' will be the augmented graph obtained by cutting along the cycles $C_1,\ldots,C_k$.

Let G' be the graph obtained in this way. We call G' the graph *obtained from G by cutting along $\mathcal{S}$*. If G' is planar and Π' is a plane embedding of G' then we can obtain an embedding Π'' of G on some surface as follows. Let $f_1,\ldots,f_k$ be the extra vertices in G'. If we delete $f_1,\ldots,f_k$ from G' and Π' then we obtain a plane embedding Π'' which, for each i,

has two facial cycles corresponding to the two copies of C_i. We cut two holes, each having a copy of C_i as boundary cycle, and then identify the corresponding points on the two copies of C_i in the obvious way. In this way we obtain a surface S defined by an embedding Π''' of G. We call S, Π''' the surface and embedding *obtained from* G' *and* Π' *by* gluing *along* $\mathcal{S}$.

The results and constructions proved in this subsection imply the next theorem.

▶ **Theorem 2.8.** *Let S be a surface of genus g and let G be a 3-connected graph embedded in S by an embedding Π such that $8(d+1)(2^g-1) \leq \mathrm{fw}(G,\Pi) < \infty$.*

1. *Then, there exists a potential system of planarizing cycles $\mathcal{S}$ of order at most g such that the graph G' obtained from G by cutting along $\mathcal{S}$ is 3-connected and planar, and if Π' is the (uniquely determined) plane embedding of G', then S and Π are the surface and the embedding obtained from G' and Π' by gluing along $\mathcal{S}$.*
2. *Furthermore, for every potential system of planarizing cycles $\mathcal{S}$ of order at most g such that the graph G' obtained from G by cutting along $\mathcal{S}$ is 3-connected and planar, if Π' is the (uniquely determined) plane embedding of G', then S and Π are the surface and the embedding obtained from G' and Π' by gluing along $\mathcal{S}$.*

This theorem is the main tool for defining embeddings in monadic second-order logic later on. In the next section we exploit face-width for finding grids of controlled size.

Grid-like Structures in High-Face Width Embeddings. In this section we establish some graph theoretical properties of embedded graphs that will allow us to define grids in embedded graphs whose order is proportional to the face-width.

▶ **Definition 2.9.** Let G be a 2-connected Π-embedded graph such that $\mathrm{fw}(G,\Pi) \geq 2$ and let $F = F(G,\Pi)$ be the set of Π-faces. The *vertex-face graph* is the bipartite graph $\Gamma = \Gamma(G,\Pi)$ with vertex set $V(G) \cup F(G,\Pi)$ and an edge between $u \in V(G)$ and $f \in F(G,\Pi)$ if u is contained in the facial cycle bounding f.

Note that any closed curve on a surface corresponds to a cycle in the vertex-face graph in the obvious way. From now on, we will therefore consider cycles in the $\Gamma(G,\Pi)$. The length of such a cycle is the number of faces (or vertices) on it.

▶ **Lemma 2.10** (Prop. 5.5.10 of [10])**.** *Let G be a Π-embedded graph such that $2 < \mathrm{fw}(G,\Pi) < \infty$, and let $k := \lfloor \frac{\mathrm{fw}(G,\Pi)}{2} \rfloor - 1$. Let v be a Π-face and let $B_0(v)$ be the Π-boundary walk of v. For $i > 0$ we define $B_i(v)$ as the union of $B_{i-1}(v)$ and all Π-facial walks that have a vertex in $B_{i-1}(v)$. Then there exist $k+1$ disjoint Π-contractible cycles $C_0, \ldots, C_k$ such that for all $i = 0, 1, ..., k$, $C_i \subseteq \partial B_i(v)$ and $B_i(v) \subseteq Int(C_i)$.*

We are now ready to prove the graph theoretical properties we will use later to show that any 3-connected graph embedded by a face-width k embedding, for some $3 \leq k < \infty$, contains a $\frac{k}{4} \times \frac{k}{4}$-grid which, moreover, is *controlled* by a noncontractible cycle.

Let Π be an embedding of a graph G on a surface S of Euler genus g such that $\mathrm{fw}(G,\Pi) \geq 3$. Let $\Gamma = \Gamma(G,\Pi)$. Let $k := \lfloor \frac{\mathrm{fw}(G,\Pi)}{2} \rfloor - 1$.

▶ **Definition 2.11.** Let C be a Π-nonseparating, Π-non-contractible cycle of Γ of minimal length. Hence, the number of vertices and faces on C is exactly $\mathrm{fw}(G,\Pi)$. Let v be a face on C. A set $\mathcal{P} = \{P_0, \ldots, P_k\}$ of pairwise vertex disjoint cycles is *controlled by C and v*, if for all $0 \leq i \leq k$,

- P_i intersects C in exactly two vertices p_i, p'_i,
- for all $1 \leq i \leq k$, p_i and p_{i-1} and also p'_i and p'_{i-1} have a common neighbour on C, which is a face, and p_0 and p'_0 are the neighbours of the face v on C, and
- if $i < j$ then P_i is contained in the component of $G - P_j$, called the *interior* of P_j, that contains v.

Let C and v be as before and let $\mathcal{P} = \{P_0, \ldots, P_k\}$ be a set of pairwise vertex disjoint cycles controlled by C and v. Then either there is exactly one face $\bar{v}$ on C not in the interior of P_k or there is exactly one vertex $\bar{v}$ on C which is neither in the interior of P_k nor on P_k itself. We call the node $\bar{v}$ in the previous claim the *opposite node of v on C* and denote it by $\bar{v}$.

Let $C, v, \bar{v}$ and $\mathcal{P}$ be as before. Let a be a face on C and let $\mathcal{Q} = \{Q_1, \ldots, Q_k\}$ be a set of pairwise disjoint cycles controlled by C and a. Let $\bar{a}$ be the opposite node of a on C.

Let $s := \lceil \frac{k+1}{2} \rceil$ and let $s' := k - s$. If $\mathrm{fw}(G, \Pi)$ is odd then a is a face of facial distance s from v on C if, and only if, the cycle $Q \in \mathcal{Q}$ which contains the vertex $\bar{v}$ has v on its exterior but v is adjacent to a vertex on Q. If $\mathrm{fw}(G, \Pi)$ is even then a is a face of facial distance s from v on C if, and only if, v and $\bar{v}$ are adjacent to vertices on the same two cycles in $\mathcal{Q}$. If a and v satisfy these conditions, then we say that v and a *match*.

This observation will allow us to define $a, \bar{a}, \bar{v}$ from C and v. What is left is to give a topological condition for C to be a noncontractible cycle of minimal length. But this can easily be done using Lemma 2.4. Finally, it can be shown that $C, v, \bar{v}, a, \bar{a}$ uniquely determine a grid structure in $C \cup \mathcal{P} \cup \mathcal{Q}$ of size s'. The previous claims together establish the following theorem.

▶ **Theorem 2.12.** *Let C be a noncontractible, nonseparating cycle of length $\mathrm{fw}(G, \Pi)$ and let v be a face on C. Let $\mathcal{P}$ be a set of pairwise disjoint cycles controlled by C and v and let $\bar{v}$ be the node on the opposite of v on C. Let x be a face on C and let $\mathcal{Q}$ be a set of pairwise disjoint cycles controlled by C and x and let $\bar{x}$ be the node opposite of x on C. Finally, suppose v and x match as defined in the previous claim. Then $C, v, x, \bar{x}, \bar{v}$ determine an $s' \times s'$ grid.*

3 Monadic Second-Order Logic

In this section we introduce monadic second-order logic (MSO), and develop the MSO definability of embedding schemes and grids in large face-width embeddings.

Logic. A *vocabulary* is a set of relation symbols with associate arities. If L is a vocabulary, a *finite L-structure M* is given by a finite *domain* or *universe* $D(M)$ and a relation $R(M) \subseteq M^r$ for each relation symbol $R \in L$ of arity r

The class of formulas of monadic second-order logic (MSO) is the smallest class of formulas that contains the atomic formulas and is closed under negations, conjunctions, disjunctions, and existential and universal quantification of individual and set variables. An individual variable ranges over the domain, and a set variable ranges over the subsets of the domain. If X is a set variable and x is an individual variable, then $X(x)$ is the atomic formula that says that x is in the set X. Given a structure M, the relation defined by a formula $\varphi(\bar{x}, \bar{X})$ with individual and set free-variables $\bar{x}$ and $\bar{X}$, respectively, is the set of pairs of tuples $(\bar{a}, \bar{A})$ such that M makes $\varphi(\bar{a}, \bar{A})$ true. A formula without free variables is called a *sentence*.

Logic on Graphs, MSO_1 and MSO_2. There are two natural encodings of graphs G as structures. In the *standard encoding* the vocabulary has a single binary relation symbol E, the domain of the structure is $V(G)$, and the binary relation E is interpreted by $E(G)$. In the *incidence encoding* the vocabulary has two unary relation symbols V and E, one binary relation symbol I, the domain is $V(G) \cup E(G)$, and I is the incidence relation between vertices and their incident edges. The unary relations V and E are interpreted by $V(G)$ and $E(G)$. Whereas for FO it is irrelevant which encoding is used, the two encodings behave

differently for MSO: on the standard encoding the set quantifiers range over sets of vertices whereas on the incidence encoding they range also over sets of edges, e.g., over paths. MSO on the standard encoding is often referred to as MSO_1 and on the incidence encoding it is referred to as MSO_2. For graphs of bounded genus, and even more generally, for classes of graphs that are p-degenerate for some fixed $p > 0$, the two logics MSO_1 and MSO_2 are equivalent: see Theorem 5.22 in [5]. Since we only consider classes of graphs of bounded genus we will assume from now on that graphs are given by their incidence encoding.

MSO-definitions and interpretations. For an integer $k \geq 1$, an MSO-definition of L-structures of *order* k is a collection of formulas $\varphi_{D,1}(x), \ldots, \varphi_{D,k}(x)$ and $\varphi_{R,t}(\bar{x})$ for $R \in L$ and $t \in [k]^r$, where r is the arity of R, and x in $\varphi_{D,i}(x)$ is an individual variable, and $\bar{x}$ in $\varphi_{R,t}(\bar{x})$ is a tuple of individual variables of length r. If Ψ is such an MSO-definition and M is a structure of the vocabulary of the formulas in Ψ, then the structure defined by Ψ on M is the L-structure N with $D(N) = \{(a,i) \in D(M) \times [k] : M \models \varphi_{D,i}(a)\}$ and $R(N) = \{((a_1,i_1),\ldots,(a_r,i_r)) \in (D(M) \times [k])^r : M \models \varphi_{R,(i_1,\ldots,i_r)}(a_1,\ldots,a_r)\}$. An MSO-definition of order k with parameters is defined analogously, with each formula carrying additional parameter variables $\bar{z}$ and $\bar{Z}$, and an additional formula $\pi(\bar{z},\bar{Z})$ to tell if a choice of parameters $\bar{b},\bar{B}$ is *good*. We say that Ψ takes the structure M as input and produces the structure N as output, for the good choice of parameters $\bar{b}$ and $\bar{B}$, if the defining formulas produce N when $\bar{z}$ and $\bar{Z}$ are replaced by the parameters. If there is as least one good choice of parameters in M and the same structure N is produced under all good choices of parameters, then we omit any reference to them and say that Ψ takes M as input and produces N as output.

Finally, MSO-interpretations extend MSO-definitions to allow *factor structures*. Concretely, an MSO-interpretation (without parameters, of order 1) includes an additional *equality-defining* formula $\varphi_{\equiv}(x,y)$, that is required to define an equivalence relation on the domain defined by $\varphi_D(x)$ that is a congruence of the relations defined by the $\varphi_R(\bar{x})$'s. On a structure M as input, the MSO-interpretation produces the structure whose domain is the set of equivalence classes of the equivalence relation $\equiv$ defined by $\varphi_{\equiv}(x,y)$ on the domain defined by $\varphi_D(x)$, and whose relations are the relations that are defined by the $\varphi_R(\bar{x})$'s factored by $\equiv$. MSO-interpretations with parameters and of order $k > 1$ are defined analogously.

The composition of two MSO-interpretations is defined in the obvious way and is again an MSO-interpretation. As an example of MSO-interpretation we state the following easily derived consequence of Theorem 4.7 in [3].

▶ **Theorem 3.1.** *There is an MSO-definition Ψ that, for every graph G given as input and every 3-connected component C of G, there is a good choice of parameters for Ψ on which it produces C.*

Logic Representation of Embedding Schemes. Embedding schemes will be represented as graphs expanded by two relations that represent the cyclic orderings around the vertices. Concretely, the vocabulary has two unary relation symbols V and E for vertices and edges, one binary relation symbol I for the incidence relation between vertices and edges and one ternary relation symbol R for cyclic orderings. The predicate $R(v,e_1,e_2)$ holds if e_1 and e_2 are edges that are incident to vertex v, and e_1 is the immediate predecessor of e_2 in the cyclic ordering of the edges that are incident to v.

This encoding was used by Courcelle [4] to show that there is an MSO-definition that takes a 3-connected planar graph as input and produces an embedding in the plane as output, which is unique by Whitney's Theorem.

▶ **Theorem 3.2** ([4]). *There is an MSO-definition that, given a 3-connected planar graph G as input, produces an embedding scheme as output.*

It will be convenient to extend the embedding schemes to include the faces of the embedding. Accordingly, extended embedding schemes will include a set F of faces in their domain and store the incidence relation between edges and faces through the incidence relation I.

We aim at an MSO-interpretation that given an embedding scheme produces its extension with faces. A face is determined by one of its bounding edges together with an orientation. Specifying the orientation directly by specifying one of its endpoints would take us beyond the syntax of MSO-interpretations. Instead of that, we use a proper k-coloring of the graph with a small number k of colors and specify the orientation of the edge by specifying the colors of the left and right endpoints. The k-coloring is provided through k many parameter set variables, and we choose k large enough so that any graph in the surface under consideration has chromatic number at most k. It is well-known that the chromatic number of all graphs embeddable in a fixed surface is bounded (see [10]). In the case of planar graphs $k = 5$ suffices (and even $k = 4$ does).

▶ **Lemma 3.3.** *For every $k \geq 2$, there is an MSO-interpretation that, given an embedding scheme for a graph that is k-colorable, produces its extension by faces as an extended embedding scheme.*

Embeddings by Reduction to Planar Case. Our next goal is to prove the analogue of Theorem 3.2 for higher genus surfaces. We proceed by reduction to the planar case via Theorem 2.8. Let S be an orientable surface of genus g. For simplicity we start with the orientable case.

We start with two MSO-interpretations that implement the operations of cutting a graph along a potential system of planarizing cycles, and its reverse operation of gluing along it; cf. Definition 2.7 and the discussion immediately following it. Systems are represented most simply by a sequence of $3k$ set variables.

▶ **Lemma 3.4.** *There is an MSO-interpretation Ξ that, given a graph G and potential system of planarizing cycles $\mathcal{S}$, produces the graph G' obtained from G by cutting along $\mathcal{S}$. Conversely, there is an MSO-interpretation Ξ' that, given a graph G, a potential system of planarizing cycles $\mathcal{S}$, and a plane embedding scheme Π' for the output of Ξ on G and $\mathcal{S}$, produces the graph G'' and the embedding scheme Π'' that is obtained from G' and Π' by gluing along $\mathcal{S}$.*

With these objects at hand we are ready to prove the analogue of Theorem 3.2.

▶ **Theorem 3.5.** *Let S be a surface of genus g. There is an MSO-interpretation that, given a 3-connected graph G that has an embedding in S of finite face-width at least $8(d+1)(2^g-1)$ (which must be unique), produces such an embedding Π.*

We need to show that the conditions of Theorem 2.8 can be defined in MSO.

Defining Grids in High Face-Width Embeddings. Our final goal of this section is to develop an MSO-interpretation γ which defines large grids in 3-connected Π-embedded graphs.

▶ **Theorem 3.6.** *There is an* MSO*-interpretation γ that, given an extended embedding scheme for a graph G of finite face-width $k \geq 3$, produces a grid of order $\lfloor \frac{k}{4} \rfloor$.*

To define γ, we need to show that the conditions of Theorem 2.12 can be defined in MSO.

4 Size and face-width for random graphs

Fix a surface S of genus $g \geq 0$. It was shown in [2] that, a.a.s., a random graph G from $\mathcal{G}_S$ has genus g, and in particular it is not planar if $g > 0$. Moreover, a.a.s., G has a unique non-planar connected component, as well as a unique non-planar 2-connected and 3-connected components. Moreover, these components are all *giant*, i.e., of size linear in the number of vertices. Indeed the probability distributions of their sizes is well-understood. In the following, if f_n and g_n are sequences of positive real numbers, we use the notation $f_n \sim g_n$ to mean that $\lim_{n\to\infty} f_n/g_n = 1$.

Sizes of the components. Let L_n denote the size (i.e., number of vertices) of the largest connected component in a random n-vertex graph G from $\mathcal{G}_S$, and let $M_n = n - L_n$. Theorem 5.3 in [2] determines the distribution of M_n, and hence of L_n: for every fixed integer $k \geq 0$ we have $\Pr[M_n = k] \sim p \cdot g_k \frac{\gamma^{-k}}{k!}$ where p, g_k and γ are constants that do not depend on n, nor on the surface S. Moreover there exists constants $a > 0$ and $b > 0$ such that $\mathrm{E}(M_n) \sim a$ and $\mathrm{Var}(M_n) \sim b$. In particular, by Chebyshev's inequality this means that, for any $a(n)$ that grows to infinity however slowly, we have $M_n \leq a(n)$ a.a.s., and hence $L_n \geq n - a(n)$ a.a.s. Theorem 5.4 and 5.5 also in [2] determine the distributions of the sizes of the largest 2-connected and 3-connected components, but only for random *connected* graphs from $\mathcal{G}_S$. However, by composing the results it is still possible to determine the sizes for random arbitrary graphs from $\mathcal{G}_S$, as we do next.

A sequence of integer random variables $X_0, X_1, \ldots$ is said to admit a local limit law of the Airy type with parameters α and c if for every real finite interval $[a, b]$ it holds that $\Pr\left[X_n = \lfloor \alpha n + x n^{2/3} \rfloor\right] \sim n^{-2/3} c g(cx)$ uniformly for every $x \in [a, b]$, where $g(x) = 2e^{-2x^3/3}(x\mathrm{Ai}(x^2) - \mathrm{Ai}'(x^2))$ and $\mathrm{Ai}(x)$ is the Airy function. Here, uniformly for every $x \in [a, b]$ means that for every positive real $\varepsilon > 0$ and every large enough n the ratio is ε-close to 1 simultanesouly for all $x \in [a, b]$.

▶ **Theorem 4.1.** *Let X_n and Y_n denote the sizes of the largest 2-connected and 3-connected components of a random n-vertex graph in $\mathcal{G}_S$. Then X_n and Y_n admit local limit laws of the Airy type (with different parameters). Moreover, a.a.s., the largest connected, 2-connected and 3-connected components are unique and have maximal possible genus, and all other connected, 2-connected and 3-connected components are planar.*

Face-width of the components. For this section we assume that the genus of S is $g > 0$. Our goal is to show that the face-width of the largest 3-connected component of the random graph grows logarithmically. We will need the following facts:

Almost all 3-connected maps on S with m edges have face-width greater than $\delta \log m$ for some constant $\delta > 0$. This is proved in [1] for rooted maps. Since almost all 3-connected maps have no non-trivial automorphisms [12] this is also true for unrooted maps. Moreover, the largest 3-connected component of a random graph G from $\mathcal{G}_S$ is unique and non-planar by Theorem 4.1 a.a.s., and has face-width greater than any fixed constant also a.a.s. [2]. As a consequence it has a unique embedding in S, and it can be considered as an unrooted map [13].

▶ **Theorem 4.2.** *Let S be a surface of genus $g > 0$ and let F_n denote the face-width of the largest 3-connected component of a random n-vertex graph in $\mathcal{G}_S$. Then there exists γ such that $F_n \geq \gamma \log n$ asymptotically almost surely.*

Proof. Let G denote a random n-vertex graph in $\mathcal{G}_S$. Let L and T denote the largest 2-connected and 3-connected components of G. We start by arguing that, conditioned on the number of edges of L and T, the distribution of T is uniform over the 3-connected graphs in $\mathcal{G}_S$ with its number of edges. Indeed, L is obtained from T by (possibly) replacing each edge of T with a 2-connected graph, so each T with m edges gives rise to the same number L with k edges. For $m \geq k$, let $B_{m,k}$ denote the event that $e(T) = m$ and $e(L) = k$. By Theorem 4.1, the sizes of T and L are at least cn a.a.s., for some constant $c > 0$. Since they are at least 2-connected, also $e(T) \geq cn$ and $e(L) \geq cn$ a.a.s.. Now we combine the previous paragraph with the one just before the theorem: In the distribution conditioned on $B_{m,k}$, the 3-connected component T can be considered as a random m-edge 3-connected map embedded in S, and its facewidth is at least $\delta \log m$ if m is large enough. We conclude that the facewidth of T is indeed at least $\delta \log(cn)$ a.a.s. Precisely, if A denotes the event that T has facewidth at least $\delta \log(cn)$, then $\Pr[\, A \,] \geq \sum_{m \geq k \geq cn} \Pr[\, A \mid B_{m,k} \,] \Pr[\, B_{m,k} \,]$. For fixed $\varepsilon > 0$, if n is large enough, then $\Pr[\, A \mid B_{m,k} \,] \geq 1 - \varepsilon$ for any $m \geq k \geq cn$. It follows that, if n is large enough, then $\Pr[\, A \,] \geq (1-\varepsilon) \sum_{m \geq k \geq cn} \Pr[\, B_{m,k} \,] \geq (1-\varepsilon)^2$. Since $\varepsilon > 0$ was arbitrary, the claim is proved by choosing any $\gamma > 0$ smaller than δ. ◀

5 Limiting probabilities of MSO-sentences

In this section we put everything together. Let S be a surface of genus $g > 0$. The results so far show that a random n-vertex graph in $\mathcal{G}_S$ will have facewidth $\Omega(\log n)$ with high probability, and that on such graphs an $m \times m$ grid is MSO-definable, for some $m \geq \log \log n$. More precisely:

▶ **Theorem 5.1.** *Let S be a surface other than the sphere. There is an MSO-interpretation that, on a given n-vertex graph G from $\mathcal{G}_S$, produces an $m \times m$ grid for some $m \geq \log \log n$ for every and at least one good choice of parameters, asymptotically almost surely when G is a random n-vertex graph in $\mathcal{G}_S$.*

We use this to build MSO-sentences with non-converging probabilities. We use it also for proving the undecidability of the problem of determining the asymptotic probabilities of MSO-sentences. For building MSO-sentences whose probabilities converge to any given rational number in the interval $[0, 1]$ we use Theorem 4.1 from the previous section.

MSO-sentences with non-converging probabilities. For every base $b \geq 2$ and every natural number n, define $\mathrm{tow}_b(n)$ recursively by $\mathrm{tow}_b(0) = 1$ and $\mathrm{tow}_b(i+1) = b^{\mathrm{tow}_b(i)}$. For every real $x \geq 0$, let $\log_b^*(x)$ denote the smallest integer k such that $\mathrm{tow}_b(i) \geq x$, and let $\log_b^\dagger(x)$ denote the smallest integer k such that $\sum_{i=0}^{k} \mathrm{tow}_b(i) \geq x$. By induction on k one proves that $\sum_{i=0}^{k} \mathrm{tow}_b(i) \leq 2\mathrm{tow}_b(k)$, and hence $\log_b^*(x/2) \leq \log_b^\dagger(x) \leq \log_b^*(x)$ for every $b \geq 2$ and every real $x \geq 0$. Both $\log_b^*(n)$ and $\log_b^\dagger(n)$ are monotone non-decreasing functions of n that have all natural numbers in their range. When the base is 2 we omit b from the notation.

The source of divergence in our example is the following easily verified arithmetic fact:

▶ **Lemma 5.2.** *If $m_1, m_2, \ldots$ is an integer sequence such that $\log \log(n) \leq m_n \leq n$ for every large enough n, then the sequence given by $\log^\dagger(m_n) \bmod 8$ is not eventually always in $\{0,1,2,3\}$ and not eventually always in $\{4,5,6,7\}$.*

For the next technical lemma it will be more convenient to move, temporarily, to the vocabulary of directed grids. For every $i \in \{0, \ldots, 7\}$, we want an MSO-sentence $\mathtt{strange}_i$ that holds in the $n \times n$ directed grid if and only if $\log^\dagger(n)$ is congruent to i mod 8. We use the notation $G^{\mathrm{d}}_{n \times n}$ to denote the $n \times n$ directed grid.

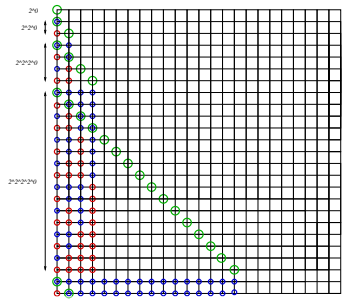

Figure 5.1 The red-green-blue pattern for the proof of Lemma 5.3.

▶ **Lemma 5.3.** *For every $i \in \{0,\dots,7\}$ there exists an MSO-sentence $\texttt{strange}_i$ in the vocabulary of directed grids such that, for every natural number $n \geq 1$, the sentence $\texttt{strange}_i$ is true in $G^{\mathrm{d}}_{n\times n}$ if and only if $\log^\dagger(n)$ is congruent to i mod 8.*

Proof. The sentence uses three existentially quantified monadic second-order variables R, G, and B, for red, green and blue. First it verifies that the colors satisfy the pattern of Figure 5.1. Once this is verified, the sentence states that the number of green vertices in the leftmost column is congruent to $i+1$ mod 8. The number of green vertices in the leftmost column is the smallest k such that $\sum_{i=0}^{k-1} \mathrm{tow}(i) \geq n$; i.e. $k = \log^\dagger(n)+1$, so the statement states that $\log^\dagger(n)+1 \equiv i+1 \bmod 8$, which is the same as $\log^\dagger(n) \equiv i \bmod 8$. ◀

We need to find a way of defining directed grids in the $\{\texttt{right},\texttt{down}\}$-vocabulary from undirected ones. One way to do this via MSO-interpretations can be extracted from Section 5.2.3 in [5].

▶ **Theorem 5.4.** *Let S be a surface other than the sphere. There is an MSO-sentence whose asymptotic probability on $\mathcal{G}_S$ does not converge.*

Proof. Let Θ be the composition of Ψ from Theorem 5.1 with interpretation that produces directed grids from undirected ones. For every $T \subseteq \{0,\dots,7\}$, let φ_T say that there is a good choice of the parameters for Θ that make it define a directed square grid on which the disjunction $\bigvee_{i\in T} \texttt{strange}_i$ holds. If $\varphi_{\{0,1,2,3\}}$ has probability 0, then $\varphi_{\{4,5,6,7\}}$ has probability 1 by Lemma 5.3. Let $T \in \{\{0,1,2,3\},\{4,5,6,7\}\}$ be such that φ_T does not have asymptotic probability 0.

We claim that the asymptotic probability of φ_T does not converge. Otherwise, it converges to a positive real, and a positive fraction of the n-vertex graphs in $\mathcal{G}_S$ satisfy φ_T. Therefore, for n there is a least one n-vertex graph in $\mathcal{G}_S$ for which there is a good choice of parameters that makes Ψ define a directed $m\times m$ grid with $\log^\dagger(m)$ mod 8 in T and such that at the same time $m \geq \log\log n$. In other words, we find a sequence m_n that contradicts Lemma 5.2. ◀

Undecidability of the decision problem. We proceed by reduction from the halting problem for Turing machines, which is of course undecidable. For every 1-tape Turing machine M we want an MSO sentence $\texttt{halts}_M$ of the vocabulary of directed grids, that holds in the $n \times n$ directed grid if and only if the computation of M on the empty input halts in time at most n using space at most n. This construction is standard.

▶ **Lemma 5.5.** *For every two-sided 1-tape Turing machine M there exists an MSO-sentence $\texttt{halts}_M$ of the vocabulary of directed grids such that, for every natural number $n \geq 1$, the sentence halts_M is true in $G^{\mathrm{d}}_{n\times n}$ if and only if the computation of M on the empty input halts in time at most n using space at most n.*

We combine the non-converging formula of Theorem 5.4 with Lemma 5.5.

▶ **Theorem 5.6.** *Let S be a surface other than the sphere. The problem of determining whether a given MSO-sentence has a converging asymptotic probability on $\mathcal{G}_S$ is undecidable.*

Proof. Let φ be the MSO-sentence with non-converging asymptotic probability from Theorem 5.4. As in the proof of Theorem 5.4, let Ψ be the MSO-interpretation in Theorem 5.1, and let Θ be the composition of Ψ with the MSO-interpretation that produces a directed grid from an undirected one. For every two-sided 1-tape Turing machine M, let ψ_M be the sentence that says that there is a good choice of parameters for Θ that makes it define a square grid, and the sentence $\texttt{halts}_M$ holds on some principal square subgrid of this grid. It is easy to see that ψ_M has asymptotic probability one if M halts, and probability zero otherwise. This $\varphi \wedge \psi_M$ converges if and only if M halts. ◀

All rationals in [0,1] as limiting probabilities. Our goal in this section is to construct an MSO sentence whose asymptotic probability over $\mathcal{G}_S$, for any fixed surface S other than the sphere, converges to any given rational number in the interval $[0, 1]$. The idea of the construction is the following. Let us say that we want to achieve the rational p/q as limiting probability. Suppose that we succeed to write a sentence that says that the unique non-planar 3-connected component of the random n-vertex graph has size that is congruent to some $a \in \{0, \ldots, p-1\}$ mod q. If we do, then by Theorem 4.1 the probability that this sentence holds on the random n-vertex graph is the probability that an integer random variable that admits a local limit law of the Airy type is congruent to some $a \in \{0, \ldots, p-1\}$ mod q. It turns out that this probability approaches p/q as n approaches infinity:

▶ **Lemma 5.7.** *Let $X_0, X_1, \ldots$ be a sequence of integer random variables that admits a local limit law of the Airy type with parameters α and c. Then for every integer $q \geq 1$ and every $a \in \{0, \ldots, q-1\}$ it holds that $\lim_{n\to\infty} \Pr\left[X_n \equiv a \pmod q\right] = 1/q$.*

For saying that the unique non-planar 3-connected component has a size that is congruent to a mod q we use the fact every 3-connected graph of bounded Euler characteristic $\chi \leq 0$ has a spanning tree of degree at most $\lceil (8 - 2\chi)/3 \rceil$ [7, 11]. Thus, the unique non-planar 3-connected component, which is embeddable in the surface S, has such a spanning tree, which can be guessed in MSO_2. Once available, the spanning tree of bounded degree can be used to define a linear order on the vertices of the 3-connected component, and MSO over the linear order can say that its length is congruent to a mod q. Taking the disjunction over all $a \in \{0, \ldots, p-1\}$, the asymptotic probability of the resulting sentence will be p/q.

▶ **Theorem 5.8.** *Let S be a surface other than the sphere. For every rational number $r \in [0, 1]$, there exists an MSO sentence whose asymptotic probability on $\mathcal{G}_S$ converges to r.*

Abstract

We consider bisimulation-invariant monadic second-order logic over various classes of finite transition systems. We present several combinatorial characterisations of when the expressive power of this fragment coincides with that of the modal μ-calculus. Using these characterisations we prove for some simple classes of transition systems that this is indeed the case. In particular, we show that, over the class of all finite transition systems with Cantor–Bendixson rank at most k, bisimulation-invariant MSO coincides with L_μ.

1 Introduction

A characterisation of the bisimulation-invariant fragment of a given classical logic relates this logic to a suitable modal logic. In this way, one obtains a correspondence between a family of classical logics and a family of modal logics. Such characterisation results therefore help with ordering the zoo of logics introduced (on both sides) over the years and with distinguishing between natural and artificial instances of such logics.

The study of bisimulation-invariant fragments of classical logics was initiated by a result of van Benthem [2] who proved that the bisimulation-invariant fragment of first-order logic coincides with standard modal logic. Inspired by this work, several other characterisations have been obtained. The table below summarises the results known so far.

bisimulation-invariant fragment	modal logic	reference
first-order logic	modal logic	[2]
monadic second-order logic	modal μ-calculus	[10]
monadic path logic	CTL*	[12, 13]
weak monadic second-order logic	continuous μ-calculus	[4]
weak chain logic	PDL	[4]

There are also similar characterisations for various variants of bisimulation like *guarded bisimulation* [1, 7] or bisimulation for *inquisitive modal logic* [5].

Researchers in finite model theory started to investigate to which extent these correspondences also hold when only considering *finite* structures, that is, whether every formula of a given classical logic that is bisimulation-invariant over the class of all finite transition systems is equivalent, over that class, to the corresponding modal logic. For first-order logic, a corresponding characterisation does indeed hold. Its proof by Rosen [15] uses tools from finite model theory and is very different to the proof by van Benthem.

The above mentioned result by Janin and Walukiewicz on bisimulation-invariant monadic second-order logic has so far defied all attempts at a similar transfer to the realm of finite structures. The main reason is that the original proof is based on automata-theoretic techniques and an essential ingredient is a reduction to trees, via the unravelling operation. As this operation produces infinite trees, we cannot use it for formulae that are only bisimulation-invariant over finite transition systems.

In this paper we start a fresh attempt at a finitary version of the result of Janin and Walukiewicz. Instead of automata-theoretic techniques we employ the composition method. For certain classes of very simple, finite transition systems we characterise the bisimulation-invariant fragments of monadic second-order logic over these classes. We hope that some day our techniques can be extended to the general case of *all* finite structures, but currently there are still a few technical obstacles to overcome.

We start in Section 2 by recalling the needed material on bisimulation and by listing all known results on bisimulation-invariant monadic second-order logic. We also collect some low-hanging fruit by proving two new results concerning (i) finite classes and (ii) the class of all finite trees. Finally, we lay the groundwork for the more involved proofs to follow by characterising bisimulation-invariance in terms of a combinatorial property called the *unravelling property.* In Section 3, we collect some tools from logic we will need. The emphasis in on so-called *composition lemmas.* Nothing in this section is new.

Finally we start in Section 4 in earnest by developing the technical machinery our proofs are based on. Sections 5 and 6 contain our first two applications: characterisations of bisimulation-invariant monadic second-order logic over (i) the class of lassos and (ii) certain classes of what we call *hierarchical* lassos. The former is already known and simply serves as an example of our techniques and to fix our notation for the second result, which is new.

Before presenting our last characterisation result, we develop in Section 7 some additional technical tools that allow us to reduce one characterisation result to another. This is then applied in Section 8 to the most complex of our results. We characterise bisimulation-invariant monadic second-order logic over the class of all transition systems of a given Cantor–Bendixson rank.

2 Bisimulation-invariance

We consider two logics in this paper: (i) *monadic second-order logic* (MSO), which is the extension of first-order logic by set variables and set quantifiers, and (ii) the *modal μ-calculus* (L_μ), which is the fixed-point extension of modal logic. A detailed introduction can be found, e.g., in [8]. Concerning the μ-calculus and bisimulation, we also refer to the survey [17]. *Transition systems* are directed graphs where the edges are labelled by elements of a given set A and vertices by elements of some set I. Formally, we consider a transition system as a structure of the form $\mathfrak{S} = \langle S, (E_a)_{a\in A}, (P_i)_{i\in I}, s_0\rangle$ where the $E_a \subseteq S \times S$ are (disjoint) binary edge relations, the $P_i \subseteq S$ are (disjoint) unary predicates, and s_0 is the initial state.

We write $\mathfrak{S}, s$ to denote the transition system obtained from $\mathfrak{S}$ by declaring s to be the initial state.

A central notion in modal logic is *bisimilarity* since modal logics cannot distinguish between bisimilar systems.

▶ **Definition 2.1.** Let $\mathfrak{S}$ and $\mathfrak{T}$ be transition systems.

(a) A *bisimulation* between $\mathfrak{S}$ and $\mathfrak{T}$ is a binary relation $Z \subseteq S \times T$ such that all pairs $\langle s,t\rangle \in Z$ satisfy the following conditions.

(prop) $s \in P_i^{\mathfrak{S}}$ iff $t \in P_i^{\mathfrak{T}}$, for all $i \in I$.

(forth) For each edge $\langle s,s'\rangle \in E_a^{\mathfrak{S}}$, there is some $\langle t,t'\rangle \in E_a^{\mathfrak{T}}$ such that $\langle s',t'\rangle \in Z$.

(back) For each edge $\langle t,t'\rangle \in E_a^{\mathfrak{T}}$, there is some $\langle s,s'\rangle \in E_a^{\mathfrak{S}}$ such that $\langle s',t'\rangle \in Z$.

(b) Let s_0 and t_0 be the initial states of, respectively, $\mathfrak{S}$ and $\mathfrak{T}$. We say that $\mathfrak{S}$ and $\mathfrak{T}$ are *bisimilar* if there exists a bisimulation Z between $\mathfrak{S}$ and $\mathfrak{T}$ with $\langle s_0,t_0\rangle \in Z$. We denote this fact by $\mathfrak{S} \sim \mathfrak{T}$.

(c) We denote by $\mathcal{U}(\mathfrak{S})$ the *unravelling* of a transition system $\mathfrak{S}$. ⌟

The next two observations show that the unravelling operation is closely related to bisimilarity. In fact, having the same unravelling can be seen as a poor man's version of bisimilarity.

▶ **Lemma 2.2.** *Let $\mathfrak{S}$ and $\mathfrak{T}$ be transition systems.*

(a) $\mathcal{U}(\mathfrak{S}) \sim \mathfrak{S}$.

(b) $\mathfrak{S} \sim \mathfrak{T}$ *implies* $\mathcal{U}(\mathfrak{S}) \sim \mathcal{U}(\mathfrak{T})$.

As already mentioned modal logics cannot distinguish between bisimilar systems. They are *bisimulation-invariant* in the sense of the following definition.

▶ **Definition 2.3.** Let $\mathcal{C}$ be a class of transition systems.

(a) An MSO-formula φ is *bisimulation-invariant* over $\mathcal{C}$ if

$$\mathfrak{S} \sim \mathfrak{T} \quad \text{implies} \quad \mathfrak{S} \models \varphi \;\Leftrightarrow\; \mathfrak{T} \models \varphi, \quad \text{for all } \mathfrak{S},\mathfrak{T} \in \mathcal{C}.$$

(b) We say that, *over the class $\mathcal{C}$, bisimulation-invariant* MSO *coincides with* L_μ if, for every MSO-formula φ that is bisimulation-invariant over the class $\mathcal{C}$, there exists an L_μ-formula ψ such that

$$\mathfrak{S} \models \varphi \quad \text{iff} \quad \mathfrak{S} \models \psi, \quad \text{for all } \mathfrak{S} \in \mathcal{C}. \qquad ⌟$$

A straightforward induction over the structure of formulae shows that every L_μ-formula is bisimulation-invariant over all transition systems. Hence, bisimulation-invariance is a necessary condition for an MSO-formula to be equivalent to an L_μ-formula.

The following characterisations of bisimulation-invariant MSO have been obtained so far. We start with the result of Janin and Walukiewicz.

▶ **Theorem 2.4** (Janin, Walukiewicz [10])**.** *Over the class of all transition systems, bisimulation-invariant* MSO *coincides with* L_μ.

The main part of the proof consists in proving the following variant, which implies the case of all structures by a simple reduction.

▶ **Theorem 2.5** (Janin, Walukiewicz)**.** *Over the class of all trees, bisimulation-invariant* MSO *coincides with* L_μ.

There have already been two attempts at a finitary version. The first one is by Hirsch who considered the class of all regular trees, i.e., unravellings of finite transition systems. The proof is based on the fact that a formula is bisimulation-invariant over all trees if, and only if, it is bisimulation-invariant over regular trees.

▶ **Theorem 2.6** (Hirsch [9]). *Over the class of all regular trees, bisimulation-invariant* MSO *coincides with* L_μ.

The second result is by Dawar and Janin who considered the class of finite lassos, i.e., finite paths leading to a cycle. We will present a proof in Section 5 below.

▶ **Theorem 2.7** (Dawar, Janin [6]). *Over the class of all lassos, bisimulation-invariant* MSO *coincides with* L_μ.

In this paper, we will extend this last result to larger classes. We start with two easy observations. The first one is nearly trivial.

▶ **Theorem 2.8.** *Over every finite class $\mathcal{C}$ of finite transition systems, bisimulation-invariant* MSO *coincides with* L_μ.

The second observation is much deeper, but fortunately nearly all of the work has already been done by Janin and Walukiewicz.

▶ **Theorem 2.9.** *Over the class of all finite trees, bisimulation-invariant* MSO *coincides with* L_μ.

As a preparation for the more involved characterisation results to follow, we simplify our task by introducing the following property of a class $\mathcal{C}$ of transition systems, which will turn out to be equivalent to having a characterisation result for bisimulation-invariant MSO over $\mathcal{C}$.

▶ **Definition 2.10.** We say that a class $\mathcal{C}$ of transition systems has the *unravelling property* if, for every MSO-formula φ that is bisimulation-invariant over $\mathcal{C}$, there exists an MSO-formula $\hat{\varphi}$ that is bisimulation-invariant over trees such that

$$\mathfrak{S} \models \varphi \quad \text{iff} \quad \mathcal{U}(\mathfrak{S}) \models \hat{\varphi}\,, \quad \text{for all } \mathfrak{S} \in \mathcal{C}\,. \qquad \lrcorner$$

Using Theorem 2.5, we can reformulate this definition as follows. This version will be our main tool to prove characterisation results for bisimulation-invariant MSO: it is sufficient to prove that the given class has the unravelling property.

▶ **Theorem 2.11.** *A class $\mathcal{C}$ of transition systems has the unravelling property if, and only if, over $\mathcal{C}$ bisimulation-invariant* MSO *coincides with* L_μ.

Let us also note the following result, which allows us to extend the unravelling property from a given class to certain superclasses.

▶ **Lemma 2.12.** *Let $\mathcal{C}_0 \subseteq \mathcal{C}$ be classes such that every system in $\mathcal{C}$ is bisimilar to one in $\mathcal{C}_0$. If $\mathcal{C}_0$ has the unravelling property, then so does $\mathcal{C}$.*

3 Composition lemmas

We have mentioned above that automata-theoretic methods have so far been unsuccessful at attacking the finite version of the Janin–Walukiewicz result. Therefore, we rely on the composition method instead. Let us recall how this method works.

▶ **Definition 3.1.** Let $\mathfrak{S}$ and $\mathfrak{T}$ be transition systems (or general structures) and $m < \omega$ a number. The *m-theory* $\mathrm{Th}_m(\mathfrak{S})$ of $\mathfrak{S}$ is the set of all MSO-formulae of quantifier-rank m that are satisfied by $\mathfrak{S}$. (The quantifier-rank of a formula is its nesting depths of (first-order and second-order) quantifiers.) We write

$$\mathfrak{S} \equiv_m \mathfrak{T} \quad :\text{iff} \quad \mathrm{Th}_m(\mathfrak{S}) = \mathrm{Th}_m(\mathfrak{T}) .$$ ⌟

Roughly speaking the composition method provides some machinery that allows us to compute the m-theory of a given transition system by breaking it down into several components and looking at the m-theories of these components separately. This approach is based on the realisation that several operations on transition systems are compatible with m-theories in the sense that the m-theory of the result can be computed from the m-theories of the arguments. Statements to that effect are known as *composition theorems*. For an overview we refer the reader to [3] and [11]. The following basic operations and their composition theorems will be used below. We start with disjoint unions.

▶ **Definition 3.2.** The *disjoint union* of two structures $\mathfrak{A} = \langle A, R_0^{\mathfrak{A}}, \dots, R_m^{\mathfrak{A}} \rangle$ and $\mathfrak{B} = \langle B, R_0^{\mathfrak{B}}, \dots, R_m^{\mathfrak{B}} \rangle$ is the structure

$$\mathfrak{A} \oplus \mathfrak{B} := \big\langle A \cup B,\ R_0^{\mathfrak{A}} \cup R_0^{\mathfrak{B}}, \dots,\ R_m^{\mathfrak{A}} \cup R_m^{\mathfrak{B}},\ \mathrm{Left},\ \mathrm{Right} \big\rangle$$

obtained by forming the disjoint union of the universes and relations of $\mathfrak{A}$ and $\mathfrak{B}$ and adding two unary predicates $\mathrm{Left} := A$ and $\mathrm{Right} := B$ that mark whether an element belongs to $\mathfrak{A}$ or to $\mathfrak{B}$. If $\mathfrak{A}$ and $\mathfrak{B}$ are transition systems, the initial state of $\mathfrak{A} \oplus \mathfrak{B}$ is that of $\mathfrak{A}$. ⌟

The corresponding composition theorem looks as follows. It can be proved by a simple induction on m.

▶ **Lemma 3.3.** $\mathfrak{A} \equiv_m \mathfrak{A}'$ *and* $\mathfrak{B} \equiv_m \mathfrak{B}'$ *implies* $\mathfrak{A} \oplus \mathfrak{B} \equiv_m \mathfrak{A}' \oplus \mathfrak{B}'$.

Two other operations we need are interpretations and fusion operations.

▶ **Definition 3.4.** An *interpretation* is an operation τ on structures that is given by a list $\langle \delta(x), (\varphi_R(\bar{x}))_{R \in \Sigma} \rangle$ of MSO-formulae. Given a structure $\mathfrak{A}$, it produces the structure $\tau(\mathfrak{A})$ whose universe consists of all elements of $\mathfrak{A}$ satisfying the formula δ and whose relations are those defined by the formulae φ_R. The *quantifier-rank* of an interpretation is the maximal quantifier-rank of a formula in the list. An interpretation is *quantifier-free* if its quantifier-rank is 0. ⌟

▶ **Lemma 3.5.** *Let τ be an interpretation of quantifier-rank k. Then*

$$\mathfrak{A} \equiv_{m+k} \mathfrak{A}' \quad \textit{implies} \quad \tau(\mathfrak{A}) \equiv_m \tau(\mathfrak{A}') .$$

▶ **Definition 3.6.** Let P be a predicate symbol. The *fusion operation* fuse_P merges in a given structure all elements of the set P into a single element, i.e., all elements of P are replaced by a single new element and all edges incident with one of the old elements are attached to the new one instead. ⌟

▶ **Lemma 3.7.** $\mathfrak{A} \equiv_m \mathfrak{A}'$ *implies* $\mathrm{fuse}_P(\mathfrak{A}) = \mathrm{fuse}_P(\mathfrak{A}')$.

Using the composition theorems for these basic operations we can prove new theorems for derived operations. As an example let us consider *pointed paths,* i.e., paths where both end-points are marked by special colours.

▶ **Definition 3.8.** We denote the *concatenation* of two paths $\mathfrak{A}$ and $\mathfrak{B}$ by $\mathfrak{A} + \mathfrak{B}$. And we write $\mathfrak{A}^\bullet$ for the expansion of a path $\mathfrak{A}$ by two new constants for the end-points. ⌟

▶ **Corollary 3.9.** *Let* $\mathfrak{A}, \mathfrak{A}', \mathfrak{B}, \mathfrak{B}'$ *be paths. Then* $\mathfrak{A}^\bullet \equiv_m \mathfrak{A}'^\bullet$ *and* $\mathfrak{B}^\bullet \equiv_m \mathfrak{B}'^\bullet$ *implies* $(\mathfrak{A} + \mathfrak{B})^\bullet \equiv_m (\mathfrak{A}' + \mathfrak{B}')^\bullet$.

Proof. As the end-points are given by constants, we can construct a quantifier-free interpretation τ mapping $\mathfrak{A}^\bullet \oplus \mathfrak{B}^\bullet$ to $(\mathfrak{A} + \mathfrak{B})^\bullet$. ◀

Note that, since the concatenation operation is associative, it in particular follows that the set of m-theories of paths forms a semigroup.

Finally let us mention one more involved operation with a composition theorem. Let $\mathfrak{S}$ be a transition system and $\mathfrak{C} \subseteq \mathfrak{S}$ a subsystem. We say that $\mathfrak{C}$ is *attached* at the state $s \in S$ if there is a unique edge (in either direction) between a state in $S \setminus C$ and a state in C and this edge leads from s to the initial state of $\mathfrak{C}$.

▶ **Proposition 3.10.** *Let* $\mathfrak{S}$ *be a (possibly infinite) transition system and let* $\mathfrak{S}'$ *be the system obtained from* $\mathfrak{S}$ *by replacing an arbitrary number of attached subsystems by subsystems with the same* m*-theories (as the corresponding replaced ones). Then* $\mathfrak{S} \equiv_m \mathfrak{S}'$.

For a finite system $\mathfrak{S}$ this statement can be proved in the same way as Corollary 3.9 by expressing $\mathfrak{S}$ as a disjoint union followed by a quantifier-free interpretation. For infinite systems, we need a more powerful version of the disjoint union operation called a *generalised sum* (see [16]).

As presented above these tools work with m-theories, which is not quite what we need since we have to also account for bisimulation-invariance. To do so we modify the definitions as follows.

▶ **Definition 3.11.** Let $\mathcal{C}$ be a class of transition systems and $m < \omega$ a number.

(a) We denote by $\simeq^m_{\mathcal{C}}$ the transitive closure of the union $\equiv_m \cup \sim$ restricted to the class $\mathcal{C}$. Formally, we define $\mathfrak{S} \simeq^m_{\mathcal{C}} \mathfrak{T}$ if there exist systems $\mathfrak{C}_0, \dots, \mathfrak{C}_n \in \mathcal{C}$ such that

$$\mathfrak{C}_0 = \mathfrak{S}\,, \quad \mathfrak{C}_n = \mathfrak{T}\,, \quad \text{and} \quad \mathfrak{C}_i \equiv_m \mathfrak{C}_{i+1} \quad \text{or} \quad \mathfrak{C}_i \sim \mathfrak{C}_{i+1}\,, \qquad \text{for all } i < n\,.$$

(b) We denote by $\mathrm{Th}^m_{\mathcal{C}}(\mathfrak{S})$ the set of all MSO-formulae of quantifier-rank m that are bisimulation-invariant over $\mathcal{C}$ and that are satisfied by $\mathfrak{S}$, and we define

$$\mathfrak{S} \equiv^m_{\mathcal{C}} \mathfrak{S}' \quad :\text{iff} \quad \mathrm{Th}^m_{\mathcal{C}}(\mathfrak{S}) = \mathrm{Th}^m_{\mathcal{C}}(\mathfrak{S}')\,.$$

We also set $\mathrm{TH}^m_{\mathcal{C}} := \{\, \mathrm{Th}^m_{\mathcal{C}}(\mathfrak{S}) \mid \mathfrak{S} \in \mathcal{C} \,\}$. ⌟

Note that, up to logical equivalence, there are only finitely many formulae of a given quantifier-rank. Hence, each set $\mathrm{TH}^m_{\mathcal{C}}$ is finite and the relations $\equiv_m$, $\equiv^m_{\mathcal{C}}$ and $\simeq^m_{\mathcal{C}}$ have finite index.

▶ **Lemma 3.12.** *If* φ *is a* MSO*-formula of quantifier-rank* m *that is bisimulation-invariant over* $\mathcal{C}$*, then* $\mathfrak{S} \simeq^m_{\mathcal{C}} \mathfrak{T}$ *implies* $\mathfrak{S} \models \varphi \Leftrightarrow \mathfrak{T} \models \varphi$.

Some of the above composition theorems also hold for the relation $\simeq^m_{\mathcal{C}}$. This is immediate if the operation in question also preserves bisimilarity. We mention only two such results. The second one will be needed below.

▶ **Lemma 3.13.** *Let* $\mathcal{C}$ *be a class that is closed under disjoint unions.*

$$\mathfrak{A} \simeq^m_{\mathcal{C}} \mathfrak{A}' \quad \textit{and} \quad \mathfrak{B} \simeq^m_{\mathcal{C}} \mathfrak{B}' \quad \textit{implies} \quad \mathfrak{A} \oplus \mathfrak{B} \simeq^m_{\mathcal{C}} \mathfrak{A}' \oplus \mathfrak{B}'\,.$$

▶ **Proposition 3.14.** *Let $\mathcal{C}$ and $\mathcal{D}$ be two classes, $\mathfrak{S} \in \mathcal{C}$ a (possibly infinite) transition system and let $\mathfrak{S}'$ be the system obtained from $\mathfrak{S}$ by replacing an arbitrary number of attached subsystems by subsystems which are $\simeq^m_{\mathcal{D}}$-equivalent. Then $\mathfrak{S} \simeq^m_{\mathcal{C}} \mathfrak{S}'$ provided that the class $\mathcal{C}$ is closed under the operation of replacing attached subsystems in $\mathcal{D}$.*

4 Types

Our strategy to prove the unravelling property for a class $\mathcal{C}$ is as follows. For every quantifier-rank m, we assign to each tree $\mathfrak{T}$ a so-called *m-type* $\tau_m(\mathfrak{T})$. We choose the functions τ_m such that we can compute the theory $\mathrm{Th}^m_{\mathcal{C}}(\mathfrak{C})$ of a system $\mathfrak{C} \in \mathcal{C}$ from the m-type $\tau_m(\mathcal{U}(\mathfrak{C}))$ of its unravelling. Furthermore, we need to find MSO-formulae checking whether a tree has a given m-type. The formal definition is as follows.

▶ **Definition 4.1.** Let $\mathcal{C}$ be a class of transition systems and $\mathcal{T}$ the class of all trees.

(a) A *family of type functions* for $\mathcal{C}$ is a family of functions $\tau_m : \mathcal{T} \to \Theta_m$, for $m < \omega$, where the co-domains Θ_m are finite sets and each τ_m satisfies the following two axioms.

(S1) $\tau_m(\mathcal{U}(\mathfrak{C})) = \tau_m(\mathcal{U}(\mathfrak{C}'))$ implies $\mathrm{Th}^m_{\mathcal{C}}(\mathfrak{C}) = \mathrm{Th}^m_{\mathcal{C}}(\mathfrak{C}')$, for $\mathfrak{C}, \mathfrak{C}' \in \mathcal{C}$.

(S2) $\mathfrak{T} \sim \mathfrak{T}'$ implies $\tau_m(\mathfrak{T}) = \tau_m(\mathfrak{T}')$, for all $\mathfrak{T}, \mathfrak{T}' \in \mathcal{T}$.

(b) A family $(\tau_m)_m$ of type functions is *definable* if, for every $\theta \in \Theta_m$, there exists an MSO-formula ψ_θ such that

(S3) $\mathfrak{T} \models \psi_\theta$ iff $\tau_m(\mathfrak{T}) = \theta$, for all trees $\mathfrak{T}$. ⌟

Let us start by showing how to prove the unravelling property using type functions. The following characterisation theorem can be considered to be the main theoretical result of this article.

▶ **Theorem 4.2.** *Let $\mathcal{C}$ be a class of transition systems and $\mathcal{T}$ the class of all trees. The following statements are equivalent.*

(1) *Over $\mathcal{C}$, bisimulation-invariant* MSO *coincides with* L_μ.

(2) *$\mathcal{C}$ has the unravelling property.*

(3) *There exists a definable family $(\tau_m)_m$ of type functions for $\mathcal{C}$.*

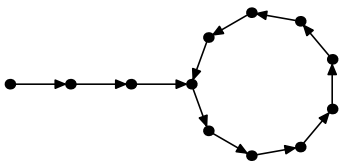
(4) *There exist functions $g : \omega \to \omega$ and $h_m : \mathrm{TH}^{g(m)}_{\mathcal{T}} \to \mathrm{TH}^m_{\mathcal{C}}$, for $m < \omega$, such that*

$$h_m\big(\mathrm{Th}^{g(m)}_{\mathcal{T}}(\mathcal{U}(\mathfrak{C}))\big) = \mathrm{Th}^m_{\mathcal{C}}(\mathfrak{C}), \quad \text{for all } \mathfrak{C} \in \mathcal{C}$$

(in other words, the $g(m)$-theory of $\mathcal{U}(\mathfrak{C})$ determines the m-theory of $\mathfrak{C}$).

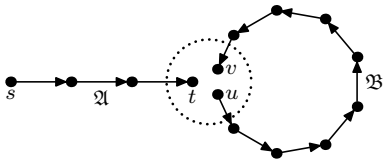
5 Lassos

As an application of type functions, we consider a very simple example, the class of *lassos*. Our proof is based on more or less the same arguments as that by Dawar and Janin [6], just the presentation differs. A lasso is a transition system consisting of a directed path ending in a cycle.



We allow the borderline cases where the initial path has length 0 or the cycle consists of only a single edge.

To define the type of a lasso, note that we can construct every lasso $\mathfrak{L}$ from two finite paths $\mathfrak{A}$ and $\mathfrak{B}$ by identifying three of their end-points.



The paths $\mathfrak{A}$ and $\mathfrak{B}$ are uniquely determined by $\mathfrak{L}$. We will refer to $\mathfrak{A}$ as the *tail* of the lasso and to $\mathfrak{B}$ as the *loop.* We introduce two kinds of types for lassos, a strong one and a weak one.

▶ **Definition 5.1.** The *strong m-type* of a lasso $\mathfrak{L}$ with tail $\mathfrak{A}$ and loop $\mathfrak{B}$ is the pair

$$\mathrm{stp}_m(\mathfrak{L}) := \langle \alpha, \beta \rangle\,, \quad \text{where} \quad \alpha := \mathrm{Th}_m(\mathfrak{A}^\bullet) \quad \text{and} \quad \beta := \mathrm{Th}_m(\mathfrak{B}^\bullet)\,. \qquad \lrcorner$$

The strong m-type of a lasso uniquely determines its m-theory.

▶ **Lemma 5.2.** *Let* $\mathfrak{L}_0$ *and* $\mathfrak{L}_1$ *be lassos.*

$$\mathrm{stp}_m(\mathfrak{L}_0) = \mathrm{stp}_m(\mathfrak{L}_1) \quad \textit{implies} \quad \mathfrak{L}_0 \equiv_m \mathfrak{L}_1\,.$$

The problem with the strong type of a lasso $\mathfrak{L}$ is that we cannot recover it from the unravelling of $\mathfrak{L}$ as the decomposition of $\mathcal{U}(\mathfrak{L})$ into the parts of $\mathfrak{L}$ is uncertain. Therefore we introduce another notion of a type where this recovery is possible. For this we recall some facts from the theory of ω-semigroups.

Recall that we have noted in Corollary 3.9 that the m-theories of pointed paths form a finite semigroup with respect to concatenation. Furthermore, every element a of a finite semigroup has an *idempotent power* a^π, which is defined as the value a^n where n is the least natural number such that $a^n \cdot a^n = a^n$.

▶ **Definition 5.3.** (a) A *factorisation* of an infinite path $\mathfrak{A}$ is a sequence $(\mathfrak{A}_i)_{i<\omega}$ of finite paths whose concatenation is $\mathfrak{A}$. Such a factorisation has *m-type* $\langle \alpha, \beta \rangle$ if

$$\alpha := \mathrm{Th}_m(\mathfrak{A}_0^\bullet) \quad \text{and} \quad \beta := \mathrm{Th}_m(\mathfrak{A}_i^\bullet)\,, \quad \text{for } i > 0\,.$$

(b) Two pairs $\langle \alpha, \beta \rangle$ and $\langle \gamma, \delta \rangle$ of m-theories are *conjugate* if there are m-theories ξ and η such that

$$\gamma\delta^\pi = \alpha\beta^\pi\xi\,, \quad \beta^\pi = \xi\eta\,, \quad \text{and} \quad \delta^\pi = \eta\xi\,.$$

Being conjugate is an equivalence relation. We denote the equivalence class of a pair $\langle \alpha, \beta \rangle$ by $[\alpha, \beta]$.

(c) The *weak m-type* of a lasso $\mathfrak{L}$ with parts $\mathfrak{A}$ and $\mathfrak{B}$ is

$$\mathrm{wtp}_m(\mathfrak{L}) := [\alpha, \beta]\,, \quad \text{where} \quad \alpha := \mathrm{Th}_m(\mathfrak{A}^\bullet) \quad \text{and} \quad \beta := \mathrm{Th}_m(\mathfrak{B}^\bullet)\,.$$

(d) The *m-type* of an infinite tree $\mathfrak{T}$ is

$$\tau_m(\mathfrak{T}) := [\alpha, \beta]\,,$$

where α and β is an arbitrary pair of m-theories such that every branch of $\mathfrak{T}$ has a factorisation of m-type $\langle \alpha, \beta \rangle$. If there is no such pair, we set $\tau_m(\mathfrak{T}) := \bot$. $\lrcorner$

▶ **Lemma 5.4.** *Let $\mathcal{L}$ be the class of all lassos and let $\mathfrak{L}_0, \mathfrak{L}_1 \in \mathcal{L}$.*

$$\mathrm{wtp}_m(\mathfrak{L}_0) = \mathrm{wtp}_m(\mathfrak{L}_1) \quad \textit{implies} \quad \mathfrak{L}_0 \simeq^m_{\mathcal{L}} \mathfrak{L}_1 \,.$$

To show that the functions $(\tau_m)_m$ form a family of type functions, we need the following standard facts about factorisations and their types (see, e.g., Section II.2 of [14]).

▶ **Proposition 5.5.** *Let $\mathfrak{A}$ be an infinite path.*
(a) *$\mathfrak{A}$ has a factorisation of type $\langle \alpha, \beta \rangle$, for some α and β.*
(b) *If $\mathfrak{A}$ has factorisations of type $\langle \alpha, \beta \rangle$ and $\langle \gamma, \delta \rangle$, then $\langle \alpha, \beta \rangle$ and $\langle \gamma, \delta \rangle$ are conjugate.*
Note that these two statements imply in particular that the type $\tau_m(\mathfrak{T})$ of a tree $\mathfrak{T}$ is well-defined.

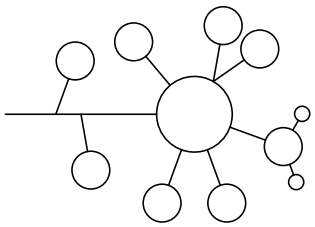
▶ **Lemma 5.6.** *The functions $(\tau_m)_m$ defined above form a definable family of type functions for the class of all lassos.*

By Theorem 4.2, it therefore follows that the class of lassos has the unravelling property.

▶ **Theorem 5.7.** *The class of all lassos has the unravelling property.*

6 Hierarchical Lassos

After the simple example in the previous section, let us give a more substantial application of the type machinery. We consider *hierarchical* (or *nested*) lassos. These are obtained from a lasso by repeatedly attaching sublassos to some states. More precisely, a 1-lasso is just an ordinary lasso, while inductively a $(k+1)$-lasso is obtained from a k-lasso by attaching one or more lassos to some of the states. (Each state may have several sublassos attached.)



Alternatively, we can obtain a $(k+1)$-lasso $\mathfrak{M}$ from a 1-lasso $\mathfrak{L}$ by attaching k-lassos. We will call this lasso $\mathfrak{L}$ the *main lasso* of $\mathfrak{M}$.

The types we use for k-lassos are based on the same principles as those for simple lassos, but we have to nest them in order to take the branching of a hierarchical lasso into account.

▶ **Definition 6.1.** Let $t : \mathrm{dom}(t) \to C$ be a labelled tree and $m < \omega$.
(a) For a branch β of t, we set

$$\mathrm{wtp}_m(\beta) := [\sigma, \tau] \,,$$

if β has a factorisation of m-type $\langle \sigma, \tau \rangle$. (By Proposition 5.5, this is well-defined.)
(b) For $k < \omega$, we define

$$\mathrm{tp}^0_m(t) := \big\{\, \mathrm{wtp}_m(\beta) \;\big|\; \beta \text{ a branch of } t \,\big\} \,,$$
$$\mathrm{tp}^{k+1}_m(t) := \mathrm{tp}^0_m(\mathrm{TP}^k_m(t)) \,,$$

where $\mathrm{TP}^k_m(t) : T \to C \times \mathcal{P}(\Theta^k_m)$ is the tree with labelling

$$\mathrm{TP}^k_m(t)(v) := \big\langle t(v),\ \{\, \mathrm{tp}^k_m(t|_u) \mid u \text{ a successor of } v \,\} \big\rangle \,. \qquad \lrcorner$$

We will prove that the functions tp_m^k form a family of type functions. Note that it follows immediately from the definition that they satisfy Properties (S2) and (S3). Hence, it only remains to check (S1).

▶ **Lemma 6.2.** (a) *Let $\mathfrak{M}$ be a k-lasso and $\mathfrak{N}$ a k'-lasso. Then*

$$\mathcal{U}(\mathfrak{M}) \sim \mathcal{U}(\mathfrak{N}) \quad \textit{implies} \quad \mathrm{tp}_m^k(\mathfrak{M}) = \mathrm{tp}_m^k(\mathfrak{N})\,.$$

(b) *For every type τ, there exists an* MSO*-formula φ such that*

$$\mathcal{U}(\mathfrak{M}) \models \varphi \quad \text{iff} \quad \mathrm{tp}_m^k(\mathfrak{M}) = \tau\,.$$

Thus, to prove that the class of k-lassos has the unravelling property it is sufficient to show that tp_m^k also satisfies Property (S1). We will do so by induction on k. The base case of this induction rests on the following lemma.

▶ **Lemma 6.3.** *Let $\mathcal{L}_k$ be the class of all k-lassos and let $\mathfrak{M}$ be a k-lasso such that, for every vertex v and all branches β and γ starting at a successor of v, we have $\mathrm{wtp}_m(\beta) = \mathrm{wtp}_m(\gamma)$. Then $\mathfrak{M} \simeq^m_{\mathcal{L}_k} \mathfrak{N}$, for some 1-lasso $\mathfrak{N}$.*

▶ **Proposition 6.4.** *Let $\mathfrak{M}$ be a k-lasso and $\mathfrak{N}$ a k'-lasso. For $m \geq 1$,*

$$\mathrm{tp}_m^k(\mathfrak{M}) = \mathrm{tp}_m^k(\mathfrak{N}) \quad \textit{implies} \quad \mathfrak{M} \simeq^m_{\mathcal{L}_K} \mathfrak{N}\,,$$

where $\mathcal{L}_K$ is the class of all K-lassos with $K := \max(k, k')$.

Using Theorem 4.2 we now immediately obtain the following statement.

▶ **Theorem 6.5.** *For every k, the class of all k-lassos has the unravelling property.*

7 Reductions

We would like to define reductions that allow us to prove that a certain class has the unravelling property when we already know that some other class has this property. To do so, we encode every transition system of the first class by some system in the second one. The main example we will be working with is a function ϱ that removes certain attached subsystems and uses additional vertex labels to remember the m-theories of all deleted system. Up to equivalence of m-theories, we can undo this operation by a function η that attaches to each vertex labelled by some m-theory θ some fixed system with theory θ. Let us give a general definition of such pairs of maps.

▶ **Definition 7.1.** Let $\mathcal{C}$ and $\mathcal{D}$ be classes of transition systems and $k, m < \omega$. A function $\varrho : \mathcal{C} \to \mathcal{D}$ is a (k, m)-*encoding map* if there exists a function $\eta : \mathcal{D} \to \mathcal{C}$ such that

(E1) $\varrho(\eta(\mathfrak{D})) \simeq^k_{\mathcal{D}} \mathfrak{D}\,, \quad$ for all $\mathfrak{D} \in \mathcal{D}\,.$

(E2) $\varrho(\mathfrak{C}) \simeq^k_{\mathcal{D}} \varrho(\mathfrak{C}') \quad$ implies $\quad \mathfrak{C} \simeq^m_{\mathcal{C}} \mathfrak{C}'\,, \quad$ for all $\mathfrak{C}, \mathfrak{C}' \in \mathcal{C}\,.$

In this case, we call the function η a (k, m)-*decoding map* for ϱ. ⌟

These two axioms imply dual axioms with the functions ϱ and η exchanged.

▶ **Lemma 7.2.** *Let $\eta : \mathcal{D} \to \mathcal{C}$ be a (k, m)-decoding map for $\varrho : \mathcal{C} \to \mathcal{D}$.*

(E3) $\eta(\varrho(\mathfrak{C})) \simeq^m_{\mathcal{C}} \mathfrak{C}\,, \quad$ *for all* $\mathfrak{C} \in \mathcal{C}\,.$

(E4) $\mathfrak{D} \simeq^k_{\mathcal{D}} \mathfrak{D}' \quad$ *implies* $\quad \eta(\mathfrak{D}) \simeq^m_{\mathcal{C}} \eta(\mathfrak{D}')\,, \quad$ *for all* $\mathfrak{D}, \mathfrak{D}' \in \mathcal{D}\,.$

The axioms of an encoding map were chosen to guarantee the property stated in the following lemma. It will be used below to prove that encoding maps can be used to transfer the unravelling property from one class to another.

▶ **Lemma 7.3.** *Let $\varrho : \mathcal{C} \to \mathcal{D}$ a (k, m)-encoding map and $\eta : \mathcal{D} \to \mathcal{C}$ a (k, m)-decoding map for ϱ. For every* MSO*-formula φ of quantifier-rank m that is bisimulation-invariant over $\mathcal{C}$, there exists an* MSO*-formula $\hat{\varphi}$ of quantifier-rank k that is bisimulation-invariant over $\mathcal{D}$ such that*

$$\mathfrak{C} \models \varphi \quad \text{iff} \quad \varrho(\mathfrak{C}) \models \hat{\varphi}\,, \quad \textit{for all } \mathfrak{C} \in \mathcal{C}\,.$$

It remains to show how to use encoding maps to transfer the unravelling property. Just the existence of such a map is not sufficient. It also has to be what we call definable.

▶ **Definition 7.4.** Let $\mathcal{C}$ be a class of transition systems.

(a) A (k, m)-encoding map $\varrho : \mathcal{C} \to \mathcal{D}$ is *definable* if, for every MSO-formula φ that is bisimulation-invariant over trees, there exists an MSO-formula $\hat{\varphi}$ that is bisimulation-invariant over trees such that

$$\mathcal{U}(\varrho(\mathfrak{C})) \models \varphi \quad \text{iff} \quad \mathcal{U}(\mathfrak{C}) \models \hat{\varphi}\,, \quad \text{for all } \mathfrak{C} \in \mathcal{C}\,.$$

(b) We say that $\mathcal{C}$ is *reducible* to a family $(\mathcal{D}_m)_{m<\omega}$ of classes if there exist a map $g : \omega \to \omega$ and, for each $m < \omega$, functions $\varrho_m : \mathcal{C} \to \mathcal{D}_m$ and $\eta_m : \mathcal{D}_m \to \mathcal{C}$ such that ϱ_m is a definable $(g(m), m)$-encoding map and η_m a corresponding $(g(m), m)$-decoding map. ⌟

(The only reason why we use a family of classes to reduce to, instead of a single one is so that we can have the labellings of systems in $\mathcal{D}_m$ depend on the quantifier-rank m.)

▶ **Theorem 7.5.** *Suppose that $\mathcal{C}$ is reducible to $(\mathcal{D}_m)_{m<\omega}$. If every class $\mathcal{D}_m$ has the unravelling property, so does $\mathcal{C}$.*

8 Finite Cantor–Bendixson rank

One common property of k-lassos is that the trees we obtain by unravelling them all have finite Cantor–Bendixson rank. In this section we will generalise our results to cover transition systems with this more general property. The proof below consists in a two-step reduction to the class of k-lassos.

▶ **Definition 8.1.** Let $\mathfrak{T}$ be a finitely branching tree. The *Cantor–Bendixson derivative* of $\mathfrak{T}$ is the tree $\mathfrak{T}'$ obtained from $\mathfrak{T}$ by removing all subtrees that have only finitely many infinite branches. The *Cantor-Bendixson rank* of a tree $\mathfrak{T}$ is the least ordinal α such that applying $\alpha + 1$ Cantor–Bendixson derivatives to $\mathfrak{T}$ results in an empty tree. The *Cantor–Bendixson rank* of a transition system $\mathfrak{S}$ is equal to the Cantor–Bendixson rank of its unravelling. ⌟

We can go from the class of k-lassos to that of systems with bounded Cantor–Bendixson rank in two steps.

▶ **Definition 8.2.** (a) A transition system is a *generalised k-lasso* if it is obtained from a finite tree by attaching (one or several) k-lassos to every leaf.

(b) A transition system $\mathfrak{T}$ is a *tree extension* of $\mathfrak{S}$ if $\mathfrak{T}$ is obtained from $\mathfrak{S}$ by attaching an arbitrary number of finite trees to some of the vertices. ⌟

With these two notions we can characterise the property of having bounded Cantor–Bendixson rank as follows.

▶ **Proposition 8.3.** *Let $\mathfrak{S}$ be a finite transition system.*

(a) *For every $k < \omega$, the following statements are equivalent.*

(1) *$\mathfrak{S}$ has Cantor–Bendixson rank at most k.*

(2) *$\mathfrak{S}$ is bisimilar to a tree extension of a generalised $(k+1)$-lasso.*

(b) *The following statements are equivalent.*

(1) *$\mathfrak{S}$ has finite Cantor–Bendixson rank.*

(2) *$\mathfrak{S}$ is bisimilar to a tree extension of a generalised k-lasso, for some $k < \omega$.*

(3) *Every strongly connected component of $\mathfrak{S}$ is either a singleton or a cycle.*

To prove the unravelling property for the transition systems of bounded Cantor–Bendixson rank, we proceed in two steps. First we consider generalised k-lassos and then their tree extensions.

▶ **Theorem 8.4.** *For fixed k, the class of all generalised k-lassos has the unravelling property.*

Using this intermediate step, we obtain the following proof for transition systems with bounded Cantor–Bendixson rank.

▶ **Theorem 8.5.** *The class of all finite transition systems of Cantor–Bendixson rank at most k has the unravelling property.*

▶ **Corollary 8.6.** *Over the class of all finite transition systems with Cantor–Bendixson rank at most k, bisimulation-invariant* MSO *coincides with* L_μ.

9 Conclusion

We have shown in several simple examples how to characterise bisimulation-invariant MSO in the finite. In particular, we have proved that it coincides with L_μ over

- every finite class (Theorem 2.8),
- the class of all finite trees (Theorem 2.9),
- the classes of all lassos, k-lassos, and generalised k-lassos (Theorems 5.7, 6.5, and 8.4),
- the class of all systems of Cantor–Bendixson rank at most k (Theorem 8.5).

Our main tool in these proofs was the unravelling property (Theorem 2.11). It will be interesting to see how far our methods can be extended to more complicated classes. For instance, can they be used to prove the following conjecture?

Conjecture. *If a class $\mathcal{C}$ of transition systems has the unravelling property, then so does the class of all subdivisions of systems in $\mathcal{C}$.*

A good first step seems to be the class of all finite transition systems that have Cantor–Bendixson rank k, for some $k < \omega$ that is not fixed.

In this paper we have considered only transition systems made out of paths with very limited branching. To extend our techniques to classes allowing for more branching seems to require new ideas. A simple test case that looks promising is the class of systems with a 'lasso-decomposition' of width k, i.e., something like a tree decomposition but where the pieces are indexed by a lasso instead of a tree.

Abstract

We study an expressive model of timed pushdown automata extended with modular and fractional clock constraints. We show that the binary reachability relation is effectively expressible in hybrid linear arithmetic with a rational and an integer sort. This subsumes analogous expressibility results previously known for finite and pushdown timed automata with untimed stack. As key technical tools, we use quantifier elimination for a fragment of hybrid linear arithmetic and for cyclic order atoms, and a reduction to register pushdown automata over cyclic order atoms.

1 Introduction

Timed automata (TA) are one of the most studied models of reactive timed systems. The fundamental result that paved the way to automatic verification of timed systems is decidability (and PSPACE-completeness) of the reachability problem for TA [2]. However, in certain applications, such as in parametric verification, deciding reachability is insufficient, and one needs to construct the more general *binary reachability relation*, i.e., the entire (possibly infinite) set of of pairs of configurations (c_i, c_f) s.t. there is an execution from c_i to c_f. The reachability relation for TA has been shown to be effectively expressible in hybrid linear arithmetic with rational and integer sorts [11, 13, 15, 18]. Since hybrid logic is decidable, this yields an alternative proof of decidability of the reachability problem.

In this paper, we compute the reachability relation for timed automata extended with a stack. An early model of *pushdown timed automata* (PTDA) extending TA with a (classical, untimed) stack has been considered by Bouajjani *et al.* [5]. More recently, *dense-timed pushdown automata* (dtPDA) have been proposed by Abdulla *et al.* [1] as an extension of PTDA. In dtPDA, stack symbols are equipped with rational *ages*, which initially are 0 and increase with the elapse of time at the same rate as global clocks; when a symbol is popped,

its age is tested for membership in an interval. While dtPDA syntactically extend PTDA by considering a timed stack, timed constraints can in fact be removed while preserving the timed language recognised by the dtPDA, and thus they semantically collapse to PTDA [8]. This motivates the quest for a strictly more expressive generalisation of PTDA and dtPDA with a truly timed stack. It has been observed in [21] that adding fractional stack constraints prevents the stack from being untimed, and thus strictly enriches the expressive power[3].

We embrace this observation and propose the model of *timed pushdown automata* (TPDA), which extends timed automata with a timed stack and integer, fractional, and modulo diagonal/non-diagonal constraints. The model features local clocks and stack clocks. As time elapses, all clocks increase their values, and they do so at the same rate. Local clocks can be reset and compared according to the generalised constraints above. At the time of a push operation, new stack clocks are created whose values are initialised, possibly non-deterministically, as to satisfy a given push constraint between stack clocks and local clocks; similarly, a pop operation requires that stack clocks to be popped satisfy a given pop constraint of analogous form. Stack push/pop constraints are also of the form of diagonal/non-diagonal integer, modulo, and fractional constraints.

Contributions. We compute the *binary reachability relation* of TPDA, i.e., the family of binary relations $\{\rightsquigarrow_{\ell r}\} \subseteq \mathbb{Q}^X_{\geq 0} \times \mathbb{Q}^X_{\geq 0}$ for control locations ℓ, r s.t. from the initial clock valuation $\mu \in \mathbb{Q}^X_{\geq 0}$ and control location ℓ we can reach the final clock valuation $\nu \in \mathbb{Q}^X_{\geq 0}$ and control location r, written $\mu \rightsquigarrow_{\ell r} \nu$. The stack is empty at the beginning and at the end of the computation. The main contribution of the paper is the effective computation of the TPDA reachability relation in the existential fragment of *linear arithmetic* $\mathcal{L}_{\mathbb{Z},\mathbb{Q}}$, a two-sorted logic combining Presburger arithmetic $(\mathbb{Z}, \leq, (\equiv_m)_{m\in\mathbb{N}}, +, 0)$ and linear rational arithmetic $(\mathbb{Q}, \leq, +, 0)$. As a byproduct of our constructions, we actually characterise the more general *ternary reachability relation* $\mu \overset{\pi}{\rightsquigarrow}_{\ell r} \nu$, where μ, ν are as above and $\pi : \mathbb{N}^\Sigma$ additionally counts the number of occurrences of input letters over a finite alphabet Σ, i.e., the Parikh image of the run. To our knowledge, the ternary reachability relation was not previously considered. As an application of ternary reachability, we can model, for instance, letter counts of initial and final, possibly non-empty, stack contents. Thus, ternary reachability is an expressive extension of binary reachability.

The computation of the ternary reachability relation is achieved by two consecutive translations. First, we transform a TPDA into a *fractional* TPDA, which uses only fractional constraints. In this step we exploit *quantifier elimination* for a fragment of linear arithmetic corresponding to clock constraints. Quantifier elimination is a pivotal tool in this work, and to our knowledge its use in the study of timed models is novel. The final integer value of clocks is reconstructed by letting the automaton input special tick symbol $\checkmark_x$ every time clock x reaches an integer value (provided it is not reset anymore later); it is here that ternary reachability is more suitable than binary reachability.

Secondly, a fractional TPDA is transformed into a PDA with registers (RPDA) over the so called *cyclic order atoms* $(\mathbb{Q} \cap [0,1), K)$ [7], where K is the ternary cyclic order relation

$$K(a,b,c) \equiv a < b < c \vee b < c < a \vee c < a < b, \qquad \text{for } a,b,c \in \mathbb{Q} \cap [0,1). \tag{1}$$

In other words, $K(a,b,c)$ holds if, distributing a, b, c on the unit circle and going clockwise from a, then we fist visit b and afterwards c. Since fractional values are wrapped around 0 when time increases, K is invariant under time elapse. We use registers to store the fractional

[3] For TA, fractional constraints can be handled by the original region construction and do not make the model harder to analyse [2].

parts of absolute times of last clock resets; fractional constraints on clocks are simulated by constraints on registers using K. In order to compute the reachability relation for RPDA we use again quantifier elimination, this time over cyclic order atoms. The latter property holds since cyclic order atoms constitute a homogeneous structure [16]. Therefore, another contribution of this work is the solution of a nontrivial problem such as computing the reachability relation for TPDA, which is a clock model, as an application of RPDA, which is a register model. The analysis of RPDA is substantially easier than a direct analysis of (fractional) TPDA.

From the complexity standpoint, the formula characterising the reachability relation of a TPDA is computable in double exponential time. However, when cast down to TA or TPDA with timeless stack (which subsume PTDA and, a posteriori, dtPDA), the complexity drops to singly exponential, matching the previously known complexity for TA [18]. For PTDA, no complexity was previously given in [12], and thus the result is new. For TPDA, the binary reachability problem has not been studied before. Since the existential fragment of $\mathcal{L}_{\mathbb{Z},\mathbb{Q}}$ is decidable in NP (because so is existential linear rational arithmetic [19] and existential Presburger arithmetic [23]), we can solve the reachability problem of TPDA in 2NEXP by reduction to satisfiability for $\mathcal{L}_{\mathbb{Z},\mathbb{Q}}$. Since our constructions preserve the languages of all the models involved, untimed TPDA languages are context-free.

Discussion. From a syntactic point of view, TPDA significantly lifts the restrictions of dtPDA– which allow only classical non-diagonal constraints, i.e., interval tests, and thus has neither diagonal, nor modulo, nor fractional constraints – and of the model of [21] – which additionally allows diagonal/non-diagonal fractional tests, and thus does not have modulo constraints. Since classical diagonal constraints reduce to classical non-diagonal constraints, and, *in the presence of fractional constraints*, integer and modulo constraints can be removed altogether (cf. Sec. 4), TPDA are expressively equivalent to [21]. However, while [21] solves the control state reachability problem, we solve the more general problem of computing the binary reachability relation. Our reduction technique not only preserves reachability, like [21], but additionally enables the reconstruction of the reachability relation.

Our expressivity result generalises analogous results for TA [11, 13, 15, 18] and PTDA [12]. The proof of [11] for TA has high technical difficulty and does not yield complexity bounds. The proof of [13] for TA uses an automata representation for sets of clock valuations; the idea of *reset-point semantics* employed in [13] is analogous to using registers instead of clocks. The paper [15] elegantly expresses the reachability relation for TA with *clock difference relations* (CDR) over the fractional values of clocks. It is remarkable that the formulas expressing the reachability relations that we obtain are of the same shape as CDR. The recent paper [18] shows that the TA binary reachability relation can be expressed in the same fragment of hybrid linear arithmetic that we use for TPDA, which we find very intriguing. Their proof converts the integer value of clocks into counters, and then observes that, thanks to the specific reset policy of clocks, these counter machines have a semilinear reachability relation; the latter is proved by encoding the value of counters into the language. In our proof, we bring the encoding of the integer value of clocks into the language to the forefront, via the introduction of the ternary reachability relation. The proof of [12] for PTDA also separates clocks into their integer and fractional part. It is not clear how any of the previous approaches could handle a timed stack.

Another approach for computing the reachability relation for TPDA would be to reduce it directly to a more expressive register model, such as *timed register pushdown automata* (TRPDA) [8, 9], which considers both integer $(\mathbb{Z}, \leq, +1)$ and rational registers $(\mathbb{Q}_{\geq 0}, \leq)$. While

such a reduction for the reachability problem is possible since (the integer part of) large clock values can be "forgotten", e.g., along the lines of [8], this does not hold anymore if we want to preserve the reachability relation. For this reason, in the present work we first remove the integer part of clocks (by encoding it in the untimed language) and then we reduce to RPDA, which have only fractional registers and no integer register, and are thus easier to analyse than TRPDA[4]. The method of quantifier elimination was recently applied to the analysis of another timed model, namely *timed communicating automata* [6].

Finally, another expressive extension of TA, called *recursive timed automata* (RTA), has been proposed [20, 3]. RTA use a timed stack to store the current clock valuation, which does not evolve as time elapses and can be restored at the time of pop. This facility makes RTA expressively incomparable to all models previously mentioned.

Missing proofs can be found in the technical report [10].

Notations. Let $\mathbb{Q}$, $\mathbb{Q}_{\geq 0}$, $\mathbb{Z}$, and $\mathbb{N}$ denote the rationals, the non-negative rationals, the integers, and the natural numbers; let $\mathbb{I} = \mathbb{Q}_{\geq 0} \cap [0, 1)$ be the unit rational interval. Let $\equiv_m$ denote the congruence modulo $m \in \mathbb{N} \setminus \{0\}$ in $\mathbb{Z}$. For $a \in \mathbb{Q}$, let $\lfloor a \rfloor \in \mathbb{Z}$ denote the largest integer k s.t. $k \leq a$, and let $\{a\} = a - \lfloor a \rfloor$ denote its fractional part. Let $\mathbb{1}_{C?}$, for a condition C, be 1 if C holds, and 0 otherwise.

2 Linear arithmetic and quantifier elimination

Consider the two-sorted structure $\mathcal{A} = \mathcal{A}_{\mathbb{Z}} \uplus \mathcal{A}_{\mathbb{Q}}$, where $\mathcal{A}_{\mathbb{Z}} = (\mathbb{Z}, \leq, (\equiv_m)_{m\in\mathbb{N}}, +, (k)_{k\in\mathbb{Z}})$ and $\mathcal{A}_{\mathbb{Q}} = (\mathbb{Q}, \leq, +, (k)_{k\in\mathbb{Q}})$. We consider "+" as a binary function, and we have a constant k for every integer/rational number. By *linear arithmetic*, denoted $\mathcal{L}_{\mathbb{Z},\mathbb{Q}}$, we mean the two-sorted first-order language in the vocabulary of $\mathcal{A}$. Restriction to the integer sort yields Presburger arithmetic $\mathcal{L}_{\mathbb{Z}}$ (*integer formulas*), and restriction to the rational sort yields linear rational arithmetic $\mathcal{L}_{\mathbb{Q}}$ (*rational formulas*). We assume constants are encoded in binary.

Two formulas are *equivalent* if they are satisfied by the same valuations. It is well-known that the theories of $\mathcal{A}_{\mathbb{Z}}$ [17] and $\mathcal{A}_{\mathbb{Q}}$ [14] admit effective elimination of quantifiers: Every formula can effectively be transformed in an equivalent quantifier-free one. Therefore, the theory of $\mathcal{A}$ also admits quantifier elimination, by the virtue of the following general fact (when speaking of a structure admitting quantifier elimination, we have in mind its theory).

▶ **Lemma 1.** *If the structures $\mathcal{A}_1$ and $\mathcal{A}_2$ admit (effective) elimination of quantifiers, then the two-sorted structure $\mathcal{A}_1 \uplus \mathcal{A}_2$ also does so. For conjunctive formulas, the complexity is the maximum of the two complexities.*

For clock constraints, we will use the first-order language over the two sorted structure $\mathcal{A}^{\mathrm{c}} = \mathcal{A}^{\mathrm{c}}_{\mathbb{N}} \uplus \mathcal{A}^{\mathrm{c}}_{\mathbb{I}}$, where the integer sort is restricted to $\mathcal{A}^{\mathrm{c}}_{\mathbb{N}} = (\mathbb{N}, \leq, (\equiv_m)_{m\in\mathbb{N}}, +1, 0)$ – the domain is now $\mathbb{N}$ and full addition "+" is replaced by the unary successor operation "+1") – and the rational sort to $\mathcal{A}^{\mathrm{c}}_{\mathbb{I}} = (\mathbb{I}, \leq, 0)$ – the domain is now the unit interval, there is no addition, and the only constant is 0. Let $\mathcal{L}^{\mathrm{c}}_{\mathbb{N},\mathbb{I}}$ be such a sub-logic. (As syntactic sugar we allow to use addition of arbitrary, even negative, integer constants in integer formulas, e.g. $x - 4 \leq y + 2$.) As before, $\mathcal{L}^{\mathrm{c}}_{\mathbb{N}}$ and $\mathcal{L}^{\mathrm{c}}_{\mathbb{I}}$ are the restrictions to the respective sorts. All the sub-logics above admit effective elimination of quantifiers.

[4] TRPDA are more general than RPDA– cyclic order atoms can be interpreted into $(\mathbb{Q}_{\geq 0}, \leq)$. The binary reachability relation for TRPDA can be computed by refining the reductions of [9] used for deciding the reachability problem. However, we do not know how to use the reachability relation of TRPDA to compute that of TPDA.

▶ **Lemma 2.** *The structures $\mathcal{A}^{\mathrm{c}}_{\mathbb{N}}$ and $\mathcal{A}^{\mathrm{c}}_{\mathbb{I}}$ admit effective elimination of quantifiers. For $\mathcal{A}^{\mathrm{c}}_{\mathbb{N}}$ the complexity is singly exponential for conjunctive formulas, while for $\mathcal{A}^{\mathrm{c}}_{\mathbb{I}}$ is quadratic.*

Notice that since $\mathcal{L}^{\mathrm{c}}_{\mathbb{N}}$ is a fragment of Presburger arithmetic $\mathcal{L}_{\mathbb{Z}}$, we could apply the quantifier elimination for $\mathcal{L}_{\mathbb{Z}}$ to get a quantifier-free $\mathcal{L}_{\mathbb{Z}}$ formula. Our result is stronger since we get a quantifier-free formula of the more restrictive fragment $\mathcal{L}^{\mathrm{c}}_{\mathbb{N}}$.

▶ **Corollary 3.** *The structure $\mathcal{A}^{\mathrm{c}}$ admits effective quantifier elimination. The complexity is exponential for conjunctive formulas.*

3 Timed pushdown automata

Clock constraints. Let X be a finite set of clocks. We consider constraints which can separately speak about the integer $\lfloor x \rfloor$ and fractional value $\{x\}$ of a clock $x \in X$. A *clock constraint* over X is a boolean combination of *atomic clock constraints* of one of the forms

	(integer)	(modular)	(fractional)
(non-diagonal)	$\lfloor x \rfloor \leq k$	$\lfloor x \rfloor \equiv_m k$	$\{x\} = 0$
(diagonal)	$\lfloor x \rfloor - \lfloor y \rfloor \leq k$	$\lfloor x \rfloor - \lfloor y \rfloor \equiv_m k$	$\{x\} \leq \{y\}$

where $x, y \in X$, $m \in \mathbb{N}$,a and $k \in \mathbb{Z}$. Since we allow arbitrary boolean combinations, we consider also the constraint **true**, which is always satisfied, and variants with any $\sim \in \{\leq, <, \geq, >\}$ in place of $\leq$. A *clock valuation* is a mapping $\mu \in \mathbb{Q}^X_{\geq 0}$ assigning a non-negative rational number to every clock in X; we write $\lfloor \mu \rfloor$ for the valuation in $\mathbb{N}^X$ s.t. $\lfloor \mu \rfloor(x) := \lfloor \mu(x) \rfloor$ and $\{\mu\}$ for the valuation in $\mathbb{I}^X$ s.t. $\{\mu\}(x) := \{\mu(x)\}$. For a valuation μ and a clock constraint φ we say that μ *satisfies* φ if φ is satisfied when integer clock values $\lfloor x \rfloor$ are evaluated according to $\lfloor \mu \rfloor$ and fractional values $\{x\}$ according to $\{\mu\}$.

▶ Remark (Clock constraints as quantifier-free $\mathcal{L}^{\mathrm{c}}_{\mathbb{N},\mathbb{I}}$ formulas). Up to syntactic sugar, a clock constraint over clocks $\{x_1, \ldots, x_n\}$ is the same as a quantifier-free $\mathcal{L}^{\mathrm{c}}_{\mathbb{N},\mathbb{I}}$ formula $\varphi(\lfloor x_1 \rfloor, \ldots, \lfloor x_n \rfloor, \{x_1\}, \ldots, \{x_n\})$ over n integer and n rationals variables.

▶ Remark (Classical clock constraints). Integer and fractional constraints subsume classical ones. For clocks x, y, since $x = \lfloor x \rfloor + \{x\}$ (and similarly for y)[5], $x - y \leq k$ for an integer k is equivalent to $(\lfloor x \rfloor - \lfloor y \rfloor \leq k \wedge \{x\} \leq \{y\}) \vee \lfloor x \rfloor - \lfloor y \rfloor \leq k - 1$, and similarly for $x \leq k$. On the other hand, the fractional constraint $\{x\} = 0$ is not expressible as a classical constraint.

▶ Remark ($\lfloor x \rfloor - \lfloor y \rfloor$ versus $\lfloor x - y \rfloor$). In the presence of fractional constraints, the expressive power would not change if, instead of atomic constraints $\lfloor x \rfloor - \lfloor y \rfloor \equiv_m k$ and $\lfloor x \rfloor - \lfloor y \rfloor \leq k$ speaking of the *difference of the integer parts*, we would choose $\lfloor x - y \rfloor \equiv_m k$ and $\lfloor x - y \rfloor \leq k$ speaking of the *integer part of the difference*, since the two are inter-expressible:

$$\lfloor x - y \rfloor = \lfloor x \rfloor - \lfloor y \rfloor - \mathbb{1}_{\{x\} < \{y\}?} \qquad \text{and} \qquad \{x - y\} = \{x\} - \{y\} + \mathbb{1}_{\{x\} < \{y\}?}. \tag{2}$$

The model. A *timed pushdown automaton* (TPDA) is a tuple $\mathcal{P} = \langle \Sigma, \Gamma, L, X, Z, \Delta \rangle$ where Σ is a finite input alphabet, Γ is a finite stack alphabet, L is a finite set of control locations, X is a finite set of *global clocks*, and Z is a finite set of *stack clocks* disjoint from X. The last item Δ is a set of transition rules $\langle \ell, \mathsf{op}, r \rangle$ with $\ell, r \in L$ control locations, where op determines the type of transition:

[5] We often identify a clock x with its value for simplicity of notation.

- *time elapse* $\mathsf{op} = \mathsf{elapse}$,
- *input* $\mathsf{op} = a \in \Sigma_\varepsilon := \Sigma \cup \{\varepsilon\}$ an input letter,
- *test* $\mathsf{op} = \varphi$ a *transition constraint* over clocks X,
- *reset* $\mathsf{op} = \mathsf{reset}(Y)$ with $Y \subseteq X$ a set of clocks to be reset,
- *push* $\mathsf{op} = \mathsf{push}(\alpha : \psi)$ with $\alpha \in \Gamma$ a stack symbol to be pushed on the stack under the *stack constraint* ψ over clocks $X \cup Z$, or
- *pop* $\mathsf{op} = \mathsf{pop}(\alpha : \psi)$ similarly as push.

We assume that every atomic constraint in a stack constraint contains some stack variable from Z. Throughout the paper, let x_0 be a global clock that is never reset (and thus measures the total elapsed time), and let z_0 be a stack clock that is 0 when pushed. A TPDA has *untimed stack* if the only stack constraint is **true**. Without push/pop operations, we obtain nondeterministic timed automata (TA).

▶ Remark (Complexity). For complexity estimations, we assume that constraints are conjunctions of atomic constraints, that constants therein are encoded in binary, that M is the maximal constant, and that all modular constraints use the same modulus M.

▶ Remark (Time elapse). The standard semantics of timed automata where time can elapse freely in every control location is simulated by adding explicit time elapse transitions $\langle \ell, \mathsf{elapse}, \ell \rangle$ for suitable locations ℓ. Our explicit modelling of the elapse of time will simplify the constructions in Sec. 4.

▶ Remark (Comparison with dtPDA). The dtPDA model [1] allows only one stack clock $Z = \{z\}$ and stack constraints of the form $z \sim k$. As shown in [8], this model is equivalent to TPDA with untimed stack. Our extension is two-fold. First, our definition of stack constraint is more liberal, since we allow more general *diagonal stack constraints* of the form $z - x \sim k$. Second, we also allow *modular* $\lfloor y \rfloor - \lfloor x \rfloor \equiv_m k$ and *fractional constraints* $\{x\} \sim \{y\}$, where clocks x, y can be either global or stack clocks. As demonstrated in Example 4 below, this model is not reducible to untimed stack, and thus TPDA are more expressive than dtPDA.

Semantics. Every stack symbol is equipped with a fresh copy of clocks from Z. At the time of $\mathsf{push}(\alpha : \psi)$, the push constraint ψ specifies possibly nondeterministically the initial value of all clocks in Z w.r.t. global clocks in X. Both global and stack clocks evolve at the same rate when a time elapse transition is executed. At the time of $\mathsf{pop}(\alpha : \psi)$, the pop constraint ψ specifies the final value of all clocks in Z w.r.t. global clocks in X. A *timed stack* is a sequence $w \in (\Gamma \times \mathbb{Q}_{\geq 0}^Z)^*$ of pairs (γ, μ), where γ is a stack symbol and μ is a valuation for stack clocks in Z. For a clock valuation μ and a set of clocks Y, let $\mu[Y \mapsto 0]$ be the same as μ except that clocks in Y are mapped to 0. For $\delta \in \mathbb{Q}_{\geq 0}$, let $\mu + \delta$ be the clock valuation which adds δ to the value of every clock, i.e., $(\mu + \delta)(x) := \mu(x) + \delta$, and for a timed stack $w = (\gamma_1, \mu_1) \cdots (\gamma_k, \mu_k)$, let $w + \delta$ be $(\gamma_1, \mu_1 + \delta) \cdots (\gamma_k, \mu_k + \delta)$. A *configuration* is a triple $\langle \ell, \mu, w \rangle \in L \times \mathbb{Q}_{\geq 0}^X \times (\Gamma \times \mathbb{Q}_{\geq 0}^Z)^*$ where ℓ is a control location, μ is a clock valuation over the global clocks X, and w is a timed stack. Let $\langle \ell, \mu, u \rangle, \langle r, \nu, v \rangle$ be two configurations. For every input symbol or time increment $a \in (\Sigma_\varepsilon \cup \mathbb{Q}_{\geq 0})$ we have a transition $\langle \ell, \mu, u \rangle \xrightarrow{a} \langle r, \nu, v \rangle$ whenever there exists a rule $\langle \ell, \mathsf{op}, r \rangle \in \Delta$ s.t. one of the following holds:

- $\mathsf{op} = \mathsf{elapse}$, $a \in \mathbb{Q}_{\geq 0}$, $\nu = \mu + a$, $v = u + a$.
- $\mathsf{op} = a \in \Sigma_\varepsilon$, $\nu = \mu$, $u = v$.
- $\mathsf{op} = \varphi$, $a = \varepsilon$, $\mu \models \varphi$, $\nu = \mu$, $u = v$.
- $\mathsf{op} = \mathsf{reset}(Y)$, $a = \varepsilon$, $\nu = \mu[Y \mapsto 0]$, $v = u$.
- $\mathsf{op} = \mathsf{push}(\gamma : \psi)$, $a = \varepsilon$, $\mu = \nu$, $v = u \cdot \langle \gamma, \mu_1 \rangle$ if $\mu_1 \in \mathbb{Q}_{\geq 0}^Z$ satisfies $(\mu, \mu_1) \models \psi$, where $(\mu, \mu_1) \in \mathbb{Q}_{\geq 0}^{X \cup Z}$ is the unique clock valuation that agrees with μ on X and with μ_1 on Z.
- $\mathsf{op} = \mathsf{pop}(\gamma : \psi)$, $a = \varepsilon$, $\mu = \nu$, $u = v \cdot \langle \gamma, \mu_1 \rangle$ provided that $\mu_1 \in \mathbb{Q}_{\geq 0}^Z$ satisfies $(\mu, \mu_1) \models \psi$.

A *timed word* is a sequence $w = \delta_1 a_1 \cdots \delta_n a_n \in (\mathbb{Q}_{\geq 0}\Sigma_\varepsilon)^*$ of alternating time elapses and input symbols; the one-step transition relation $\langle \ell, \mu, u\rangle \xrightarrow{a} \langle r, \nu, v\rangle$ is extended on timed words w as $\langle \ell, \mu, u\rangle \xrightarrow{w} \langle r, \nu, v\rangle$ in the natural way. The *timed language* from location ℓ to r is $L(\ell, r) := \left\{ \pi_\varepsilon(w) \in (\mathbb{Q}_{\geq 0}\Sigma)^* \;\middle|\; \langle \ell, \mu_0, \varepsilon\rangle \xrightarrow{w} \langle r, \mu_0, \varepsilon\rangle \right\}$ where $\pi_\varepsilon(w)$ removes the ε's from w and μ_0 is the valuation that assigns $\mu_0(x) = 0$ to every clock x. The corresponding *untimed language* $L^{\text{un}}(\ell, r)$ is obtained by removing the time elapses from $L(\ell, r)$.

▶ **Example 4.** Let L be the timed language of even length palindromes s.t. the time distance between every pair of matching symbols is an integer:

$$L = \{\delta_1 a_1 \cdots \delta_{2n} a_{2n} \mid \forall (1 \leq i \leq n) \cdot a_i = a_{2n-i+1} \wedge \delta_{i+1} + \cdots + \delta_{2n-i+1} \in \mathbb{N}\}\,.$$

L can be recognised by a TPDA over input and stack alphabet $\Sigma = \Gamma = \{a, b\}$, with locations ℓ, r, no global clock, one stack clock $Z = \{z\}$, and the following transition rules (omitting some intermediate states), where α ranges over $\{a, b\}$:

$$\langle \ell, \alpha; \mathsf{push}(\alpha : \{z\} = 0), \ell\rangle \qquad \langle \ell, \varepsilon, r\rangle$$
$$\langle r, \alpha; \mathsf{pop}(\alpha : \{z\} = 0), r\rangle \qquad \langle \ell, \mathsf{elapse}, \ell\rangle, \langle r, \mathsf{elapse}, r\rangle$$

We have $L = L(\ell, r)$. Since L cannot be recognised by TPDA with untimed stack (cf. [21]), fractional stack constraints strictly increase the expressive power of the model.

The reachability relation. The *Parikh image* of a timed word w is the mapping $\text{PI}_w \in \mathbb{N}^\Sigma$ s.t. $\text{PI}_w(a)$ is the number of a's in w, ignoring the elapse of time and ε's. For two control locations ℓ, r, clock valuations $\mu, \nu \in \mathbb{Q}^X_{\geq 0}$, and a timed word $w \in (\mathbb{Q}_{\geq 0}\Sigma_\varepsilon)^*$, we write $\mu \overset{w}{\rightsquigarrow}_{\ell r} \nu$ if $\langle \ell, \mu, \varepsilon\rangle \xrightarrow{w} \langle r, \nu, \varepsilon\rangle$. We overload the notation and, for $\pi \in \mathbb{N}^\Sigma$, we write $\mu \overset{\pi}{\rightsquigarrow}_{\ell r} \nu$ if there exists a timed word w s.t. $\mu \overset{w}{\rightsquigarrow}_{\ell r} \nu$ and $\pi = \text{PI}_w$. We see $\{\rightsquigarrow_{\ell r}\}_{\ell, r \in L}$ as a family of subsets of $\mathbb{Q}^X_{\geq 0} \times \mathbb{N}^\Sigma \times \mathbb{Q}^X_{\geq 0}$ and we call it the *ternary reachability relation*.

Let $\left\{\psi_{\ell r}(\lfloor \overline{x}\rfloor, \{\overline{x}\}, \overline{f}, \lfloor \overline{y}\rfloor, \{\overline{y}\})\right\}_{\ell, r \in L}$ be a family of $\mathcal{L}_{\mathbb{Z},\mathbb{Q}}$ formulas, where $\lfloor \overline{x}\rfloor, \lfloor \overline{y}\rfloor$ represent the integer values of initial and final clocks, $\{\overline{x}\}, \{\overline{y}\}$ their fractional values, and $\overline{f}$ letter counts. The reachability relation $\{\rightsquigarrow_{\ell r}\}_{\ell, r \in L}$ is *expressed* by the family of formulas $\{\psi_{\ell r}\}_{\ell, r \in L}$ if the following holds: For every control locations $\ell, r \in L$, clock valuations $\mu, \nu \in \mathbb{Q}^X_{\geq 0}$ and $\pi \in \mathbb{N}^\Sigma$, $\mu \overset{\pi}{\rightsquigarrow}_{\ell r} \nu$ holds, if, and only if, $(\lfloor \mu\rfloor, \{\mu\}, \pi, \lfloor \nu\rfloor, \{\nu\}) \models \psi_{\ell r}$ holds.

Main results. As the main result of the paper we show that the reachability relation of TPDA and TA is expressible in linear arithmetic $\mathcal{L}_{\mathbb{Z},\mathbb{Q}}$.

▶ **Theorem 5.** *The reachability relation of a* TPDA *is expressed by a family of existential $\mathcal{L}_{\mathbb{Z},\mathbb{Q}}$ formulas computable in double exponential time. For* TA*, the complexity is exponential.*

This is a strengthening of analogous results for TA [11, 18] since our model, even without stack, is more expressive than classical TA due to fractional constraints. As a side effect of the proofs we get:

▶ **Theorem 6.** *Untimed* TPDA *languages $L^{un}(\ell, r)$ are effectively context-free.*

The following two sections are devoted to proving the two theorem above.

4 Fractional TPDA

A TPDA is *fractional* if it contains only fractional constraints. We show that computing the reachability relation reduces to the same problem for fractional TPDA. Our transformation is done in three steps, each one further restricting the set of allowed constraints.

A The TPDA is *push-copy*, that is, push operations can only copy global clocks into stack clocks. There is one stack clock z_x for each global clock x, and the only push constraint is

$$\psi_{\mathsf{copy}}(\overline{x}, \overline{z}_{\overline{x}}) \equiv \bigwedge_{x \in X} \lfloor z_x \rfloor = \lfloor x \rfloor \wedge \{z_x\} = \{x\}\,. \tag{3}$$

By pushing copies of global clocks into the stack, we can postpone checking all non-trivial stack constraints to the time of pop. This steps uses quantifier elimination. The blowup of the number of pop constraints and stack alphabet is exponential.

B The TPDA is *pop-integer-free*, that is, pop transitions do not contain integer constraints. The construction is similar to a construction from [8] and is presented in the technical report [10]. Removing pop integer constraints is crucial towards removing all integer clocks (modulo constraints will be removed by the next step). This step strongly relies on the fact that stack clocks are copies of global clocks, which allows one to remove integer pop constraints by reasoning about analogous constraints between global clocks at the time of push and their future values at the time of pop, thus bypassing the stack altogether. We introduce one global clock for each integer pop constraint, exponentially many locations in the number of clocks and pop constraints, and exponentially many stack symbols in the number of pop constraints. When combined with the previous step, altogether exponentially many new clocks are introduced, and doubly exponentially many locations/stack symbols. It is remarkable that pop integer constraints can be removed by translating them into finitely many transition constraints on global clocks.

C The TPDA is fractional. All integer clocks are removed. In order to recover their values (which are needed to express the reachability relation), a special symbol $\checkmark_x$ is produced when an integer clock elapses one time unit. This step introduces a further exponential blowup of control locations w.r.t. global clocks and polynomial in the maximal constant M. The overall complexity of control locations thus stays double exponential.

By **A**+**B**+**C** (in this order, since the latter properties are ensured assuming the previous ones), we get the following theorem.

▶ **Theorem 7.** *A* TPDA $\mathcal{P}$ *can be effectively transformed into a fractional* TPDA $\mathcal{Q}$ *s.t. a family of* $\mathcal{L}_{\mathbb{Z},\mathbb{Q}}$ *formulas* $\{\varphi_{\ell r}\}$ *expressing the reachability relation of* $\mathcal{P}$ *can effectively be computed from a family of* $\mathcal{L}_{\mathbb{Z},\mathbb{Q}}$ *formulas* $\{\varphi'_{\ell' r'}\}$ *expressing the reachability relation of* $\mathcal{Q}$*. The number of control locations and the size of the stack alphabet in* $\mathcal{Q}$ *have a double exponential blowup, and the number of clocks has an exponential blowup.*

If there is no stack, then we do not need the first two steps, and we can do directly **C**.

▶ **Corollary 8.** *The reachability relation of push-copy* TPDA/TA *effectively reduces to the reachability relation of fractional* TPDA/TA *with an exponential blowup in control locations.*

(A) The TPDA is push-copy

Let $K_{\leq}$ be the non-strict variant of the ternary cyclic order K from (1), defined as $K_{\leq}(a,b,c) \equiv K(a,b,c) \vee a = b \vee b = c$ for $a, b, c \in \mathbb{I}$. Let $\psi_{\mathsf{push}}(\overline{x}, \overline{z})$ be a push constraint, and let $\psi_{\mathsf{pop}}(\overline{x}', \overline{z}')$ be the corresponding pop constraint. Since stack clock z_0 is 0 when pushed

on the stack, z'_0 is the total time elapsed between push and pop; let $\overline{z}'_0 = (z'_0, \dots, z'_0)$ (the length of which depends on the context). Let $\overline{z}'_{\overline{x}}$ be a vector of stack variables representing the value of *global clocks* at the time of pop, provided they were not reset since the matching push. Since all clocks evolve at the same rate, for every global clock x and stack clock z, we have

$$x = z'_x - z'_0 \qquad \text{and} \qquad z = z' - z'_0. \tag{4}$$

If at the time of push, instead of pushing $\overline{z}$, we push on the stack a copy of global clocks $\overline{x}$, then at the time of pop it suffices to check that the following formula holds

$$\psi'_{\mathsf{pop}}(\overline{x}', \overline{z}'_{\overline{x}}) \;\equiv\; \exists \overline{z}' \geq \overline{0} \cdot \psi_{\mathsf{push}}(\overline{z}'_{\overline{x}} - \overline{z}'_0, \overline{z}' - \overline{z}'_0) \wedge \psi_{\mathsf{pop}}(\overline{x}', \overline{z}'). \tag{5}$$

Note that the assumption that $z_0 = 0$ at the time of push makes the existential quantification satisfiable by exactly one value of z'_0, namely the total time elapsed between push and pop. However, $\psi_{\mathsf{push}}(\overline{z}'_{\overline{x}} - \overline{z}'_0, \overline{z}' - \overline{z}'_0)$ is not a constraint anymore, since variables are replaced by differences of variables. We resolve this issue by showing that the latter is in fact equivalent to a clock constraint. Thanks to (4), for every clock x we have $\lfloor x \rfloor = \lfloor z'_x - z'_0 \rfloor, \{x\} = \{z'_x - z'_0\}$, and $\lfloor z \rfloor = \lfloor z' - z'_0 \rfloor, \{z\} = \{z' - z'_0\}$. Thus, a fractional constraint $\{y\} \leq \{z\}$ in ψ_{push} is equivalent to $\{z'_y - z'_0\} \leq \{z' - z'_0\}$, which is in turn equivalent to $C = K_{\leq}(\{z'_0\}, \{z'_y\}, \{z'\})$, which is definable from $\leq$. Moreover, $\lfloor y \rfloor - \lfloor z \rfloor = \lfloor z'_y - z'_0 \rfloor - \lfloor z' - z'_0 \rfloor = (z'_y - z'_0 - \{z'_y - z'_0\}) - (z' - z'_0 - \{z' - z'_0\}) = (z'_y - z') - \{z'_y - z'_0\} + \{z' - z'_0\} = (z'_y - z') - \{z'_y - z'\} + \mathbb{1}_{D?} = \lfloor z'_y - z' \rfloor + \mathbb{1}_{D?}$, with $D = C \wedge \{z'_y\} \neq \{z'\}$. (Notice that $\lfloor z'_0 \rfloor$ disappears in this process: This is not a coincidence, since diagonal integer/modular/fractional constraints are invariant under the elapse of an *integer* amount of time.) Thus by (2) we obtain a constraint $\psi'_{\mathsf{push}}(\overline{z}'_{\overline{x}}, \overline{z}')$ logically equivalent to $\psi_{\mathsf{push}}(\overline{z}'_{\overline{x}} - \overline{z}'_0, \overline{z}' - \overline{z}'_0)$, and, by separating the fractional and integer constraints (cf. Remark 3), $\psi'_{\mathsf{pop}}(\overline{x}', \overline{z}'_{\overline{x}}) \equiv \exists \lfloor \overline{z}' \rfloor, \{\overline{z}'\} \cdot \psi'_{\mathsf{push}}(\lfloor \overline{z}'_{\overline{x}} \rfloor, \{\overline{z}'_{\overline{x}}\}, \lfloor \overline{z}' \rfloor, \{\overline{z}'\}) \wedge \psi_{\mathsf{pop}}(\lfloor \overline{x}' \rfloor, \{\overline{x}'\}, \lfloor \overline{z}' \rfloor, \{\overline{z}'\})$. By Corollary 3, we can perform quantifier elimination and we obtain a logically equivalent clock constraint of exponential size (in DNF) $\xi_{\psi_{\mathsf{push}}, \psi_{\mathsf{pop}}}(\lfloor \overline{x}' \rfloor, \{\overline{x}'\}, \lfloor \overline{z}'_{\overline{x}} \rfloor, \{\overline{z}'_{\overline{x}}\})$, where the subscript indicates that this formula depends on the pair $(\psi_{\mathsf{push}}, \psi_{\mathsf{pop}})$ of push and pop constraints. The construction of $\mathcal{P}'$ consists in checking $\xi_{\psi_{\mathsf{push}}, \psi_{\mathsf{pop}}}$ in place of ψ_{pop}, assuming that the push constraint was ψ_{push}. The latter is replaced by ψ_{copy}. Control states are the same in the two automata; we can break down the $\xi_{\psi_{\mathsf{push}}, \psi_{\mathsf{pop}}}$ in DNF and record each conjunct in the stack, yielding a new stack alphabet of exponential size.

▶ **Lemma 9.** *Let $\{\rightsquigarrow_{\ell r}\}_{\ell, r \in L}$, $\{\rightsquigarrow'_{\ell r}\}_{\ell, r \in L}$ be the reachability relations of $\mathcal{P}$, resp., $\mathcal{P}'$. Then, $\rightsquigarrow_{\ell r} = \rightsquigarrow'_{\ell r}$ for every $\ell, r \in L$, and $\mathcal{P}'$ has stack alphabet exponential in the size of $\mathcal{P}$.*

(C) The TPDA is fractional

Assume that the TPDA $\mathcal{P}$ is both push-copy (**A**) and pop-integer-free (**B**). We remove diagonal integer $\lfloor y \rfloor - \lfloor x \rfloor \sim k$ and modulo $\lfloor y \rfloor - \lfloor x \rfloor \equiv_m k$ constraints on global clocks x, y as in TA [2]. In the rest of the section, transition and stack constraints of $\mathcal{P}$ are of the form

$$\begin{array}{lllll}
\text{(trans.)} & \lfloor x \rfloor \leq k, & \lfloor x \rfloor \equiv_m k, & \{x\} = 0, & \{x\} \leq \{y\}, \quad (6) \\
\text{(push)} & \lfloor z_x \rfloor = \lfloor x \rfloor, & & & \{z_x\} = \{x\}, \quad (7) \\
\text{(pop)} & & \lfloor y \rfloor - \lfloor z_x \rfloor \equiv_m k, & \{z_x\} = 0, & \{y\} \leq \{z_x\}, \quad (8) \\
 & & \lfloor z_y \rfloor - \lfloor z_x \rfloor \equiv_m k, & & \{z_y\} \leq \{z_x\}.
\end{array}$$

Unary abstraction. We replace the integer value of clocks by their *unary abstraction*: Valuations $\mu, \nu \in \mathbb{Q}_{\geq 0}^X$ are *M-unary equivalent*, written $\mu \approx_M \nu$, if, for every clock $x \in X$, $\lfloor \mu(x) \rfloor \equiv_M \lfloor \nu(x) \rfloor$ and $\lfloor \mu(x) \rfloor \leq M \Leftrightarrow \lfloor \nu(x) \rfloor \leq M$. Let Λ_M be the (finite) set of M-unary equivalence classes of clock valuations. For $\lambda \in \Lambda_M$ we abuse notation and write $\lambda(x)$ to indicate $\mu(x)$ for some $\mu \in \lambda$, where the choice of representative μ does not matter. We write $\lambda[Y \mapsto 0]$ for the equivalence class of $\nu[Y \mapsto 0]$ and we write $\lambda[x \mapsto x+1]$ for the equivalence class of $\nu[x \mapsto \nu(x)+1]$, for some $\nu \in \lambda$ (whose choice is irrelevant). Let $\varphi_\lambda(\overline{x}) \equiv \bigwedge_{x \in X} \lfloor x \rfloor \equiv_M \lambda(x) \wedge (\lfloor x \rfloor < M \Leftrightarrow \lambda(x) < M)$ say that clocks belong to λ. For φ containing transition constraints of the form (6), $\varphi|_\lambda$ is φ where every integer $\lfloor x \rfloor \leq k$ or modulo constraint $\lfloor x \rfloor \equiv_M k$ is uniquely resolved to be **true** or **false** by replacing every occurrence of $\lfloor x \rfloor$ with $\lambda(x)$. Similarly, for ψ a pop constraint of the form (8), $\psi|_{\lambda_{\mathsf{push}}, \lambda_{\mathsf{pop}}}$ is obtained by resolving modulo constraints $\lfloor y \rfloor - \lfloor z_x \rfloor \equiv_M k$ and $\lfloor z_y \rfloor - \lfloor z_x \rfloor \equiv_M k$ to be **true** or **false** by replacing every occurrence of $\lfloor y \rfloor$ by its abstraction at the time of pop $\lambda_{\mathsf{pop}}(y)$, and every occurrence of $\lfloor z_x \rfloor$ by $\lambda_{\mathsf{push}}(x) + \Delta(\lambda_{\mathsf{push}}, \lambda_{\mathsf{pop}})$, i.e., the initial value of clock x plus the total integer time elapsed until the pop, defined as $\Delta(\lambda_{\mathsf{push}}, \lambda_{\mathsf{pop}}) = \lambda_{\mathsf{pop}}(x_0) - \lambda_{\mathsf{push}}(x_0) - \mathbb{1}_{\{z_0\} > \{x_0\}?}$, i.e., we take the difference of x_0 (which is never reset) between push and pop, possibly corrected by "-1" if the last time unit only partially elapsed; the substitution for $\lfloor z_y \rfloor$ is analogous. Fractional constraints are unchanged.

Sketch of the construction. Given a push-copy and pop-integer-free TPDA $\mathcal{P}$, we build a fractional TPDA $\mathcal{Q}$ over the extended alphabet $\Sigma' = \Sigma \cup \{\checkmark_x \mid x \in X\}$ as follows. We eliminate integer $\lfloor x \rfloor \leq k$ and modulo constraints $\lfloor x \rfloor \equiv_M k$ by storing in the control the M-unary abstraction λ. To reconstruct the reachability relation of $\mathcal{P}$, we store the set of clocks Y which will not be reset anymore in the future. Thus, control locations L' of $\mathcal{Q}$ are of the form $\langle \ell, \lambda, Y \rangle$. In order to properly update the M-unary abstraction λ, the automaton checks how much time elapses by looking at the fractional values of clocks. When λ is updated to $\lambda[x \mapsto x+1]$, a symbol $\checkmark_x$ is optionally produced if $x \in Y$ was guessed not to be reset anymore in the future. A test transition $\langle \ell, \varphi, r \rangle$ is simulated by $\langle \langle \ell, \lambda, Y \rangle, \varphi|_\lambda, \langle r, \lambda, Y \rangle \rangle$. A push-copy transition $\langle \ell, \mathsf{push}(\alpha : \psi_{\mathsf{copy}}), r \rangle$ is simulated by $\langle \langle \ell, \lambda, Y \rangle, \mathsf{push}(\langle \alpha, \lambda \rangle : \bigwedge_{x \in X} \{z_0\} = 0 \wedge \{z_x\} = \{x\}), \langle r, \lambda, Y \rangle \rangle$ copying only the fractional parts and the unary class of global clocks. A pop-integer-free transition $\langle \ell, \mathsf{pop}(\alpha : \psi), r \rangle$ is simulated by $\langle \langle \ell, \lambda_{\mathsf{pop}}, Y \rangle, \mathsf{pop}(\langle \alpha, \lambda_{\mathsf{push}} \rangle : \psi|_{\lambda_{\mathsf{push}}, \lambda_{\mathsf{pop}}}), \langle r, \lambda_{\mathsf{pop}}, Y \rangle \rangle$. The reachability formula $\varphi_{\ell r}$ for $\mathcal{P}$ can be expressed by guessing the initial and final abstractions λ, μ, and the set of clocks Y which is never reset in the run. For clocks $x \in Y$, we must observe precisely $\lfloor x' \rfloor - \lfloor x \rfloor$ ticks $\checkmark_x$, and for the others, $\lfloor x' \rfloor$, where x is the initial and x' the final value. Let $g_x^Y = \lfloor x' \rfloor - \lfloor x \rfloor$ if $x \in Y$, and $\lfloor x' \rfloor$ otherwise.

▶ **Lemma 10.** *Let $\{\psi_{\ell' r'}(\{\overline{x}\}, (\overline{f}, \overline{g}), \{\overline{x}'\})\}_{\ell', r' \in L'}$ express the reachability relation of the fractional $\mathcal{Q}$ where $\{\overline{x}\}, \{\overline{x}'\}$ are the fractional values of clocks (we ignore integer values), $\overline{f}$ is the Parikh image of the original input letters from Σ, and $\overline{g}$ of the new input letters $\checkmark_x$'s. The reachability relation of $\mathcal{P}$ is expressed by $\varphi_{\ell r}(\lfloor \overline{x} \rfloor, \{\overline{x}\}, \overline{f}, \lfloor \overline{x}' \rfloor, \{\overline{x}'\}) \equiv \bigvee_{\lambda, Y, \mu} \varphi_\lambda(\lfloor \overline{x} \rfloor) \wedge \psi_{\langle \ell, \lambda, Y \rangle \langle r, \mu, X \rangle}(\{\overline{x}\}, (\overline{f}, \overline{g}^Y), \{\overline{x}'\})$.*

5 From fractional TPDA to register PDA

The aim of this section is to prove the following result which, together with Theorem 7, completes the proof of our main result Theorem 5.

Figure 1 (a) Relation K. (b) The cyclic difference $b \ominus a$.

▶ **Theorem 11.** *The fractional reachability relation of a fractional* TPDA $\mathcal{P}$ *is expressed by existential* $\mathcal{L}_{\mathbb{Z},\mathbb{Q}}$ *formulas, computable in time exponential in the number of clocks and polynomial in the number of control locations and stack alphabet.*

Cyclic atoms. We model fractional clock values by the *cyclic atoms* structure $(\mathbb{I}, K)$ with universe $\mathbb{I} = \mathbb{Q} \cap [0, 1)$, where K is the ternary cyclic order (1). Since K is invariant under cyclic shift, it is convenient to think of elements of $\mathbb{I}$ as placed clockwise on a circle of unit perimeter; cf. Fig. 1(a). An *automorphism* is a bijection α that preserves and reflects K, i.e., $K(a, b, c)$ iff $K(\alpha(a), \alpha(b), \alpha(c))$; automorphisms are extended to tuples $\mathbb{I}^n$ point-wise. Cyclic atoms are homogeneous [16] and thus $\mathbb{I}^n$ splits into exponentially many *orbits* $\mathrm{Orb}(\mathbb{I}^n)$, where $u, v \in \mathbb{I}^n$ are in the same orbit if some automorphism maps u to v. An orbit is an equivalence class of indistinguishable tuples, similarly as regions for clock valuations, but in a different logical structure: For instance $(0.2, 0.3, 0.7)$, $(0.7, 0.2, 0.3)$, and $(0.8, 0.2, 0.3)$ belong to the same orbit, while $(0.2, 0.3, 0.3)$ belongs to a different orbit.

Register PDA. We extend classical pushdown automata with additional $\mathbb{I}$-valued *registers*, both in the finite control (i.e., global registers) and in the stack. Registers can be compared by quantifier-free formulas with equality and K, called K*-constraints*. For simplicity, we assume that there are the same number of global and stack registers. A *register pushdown automaton* (RPDA) is a tuple $\mathcal{Q} = \langle \Sigma, \Gamma, L, X, Z, \Delta \rangle$ where Σ is a finite input alphabet, Γ is a finite stack alphabet, L is a finite set of control locations, X is a finite set of *global registers*, Z is a finite set of *stack registers*, and the last item Δ is a set of transition rules $\langle \ell, \mathsf{op}, r \rangle$ with $\ell, r \in L$ control locations, where op is either: 1) an input letter $a \in \Sigma_\varepsilon$, 2) a $2k$-ary K-constraint $\psi(\overline{x}, \overline{x}')$ relating pre- and post-values of global registers, 3) a push operation $\mathsf{push}(\alpha : \psi(\overline{x}, \overline{z}))$ with $\alpha \in \Gamma$ a stack symbol to be pushed on the stack under the $2k$-ary K-constraint ψ relating global $\overline{x}$ and stack $\overline{z}$ registers, or 4) a pop operation $\mathsf{pop}(\alpha : \psi(\overline{x}, \overline{z}))$, similarly as push. We consider RPDA as symbolic representations of classical PDA with infinite sets of control states $\widetilde{L} = L \times \mathbb{I}^X$ and infinite stack alphabet $\widetilde{\Gamma} = \Gamma \times \mathbb{I}^Z$. A *configuration* is thus a tuple $\langle \ell, \mu, w \rangle \in L \times \mathbb{I}^X \times \widetilde{\Gamma}^*$ where ℓ is a control location, μ is a valuation of the global registers, and w is the current content of the stack. Let $\langle \ell, \mu, u \rangle, \langle r, \nu, v \rangle$ be two configurations. For every input symbol $a \in \Sigma_\varepsilon$ we have a transition $\langle \ell, \mu, u \rangle \xrightarrow{a} \langle r, \nu, v \rangle$ whenever there exists a rule $\langle \ell, \mathsf{op}, r \rangle \in \Delta$ s.t. one of the following holds: 1) $\mathsf{op} = a \in \Sigma_\varepsilon$, $\mu = \nu$, $u = v$, or 2) $\mathsf{op} = \varphi$, $a = \varepsilon$, $(\mu, \nu) \models \varphi$, $u = v$, or 3) $\mathsf{op} = \mathsf{push}(\gamma : \psi)$, $a = \varepsilon$, $\mu = \nu$, $v = u \cdot \langle \gamma, \mu_1 \rangle$ if $\mu_1 \in \mathbb{I}^Z$ satisfies $(\mu, \mu_1) \models \psi$, or 4) $\mathsf{op} = \mathsf{pop}(\gamma : \psi)$, $a = \varepsilon$, $\mu = \nu$, $u = v \cdot \langle \gamma, \mu_1 \rangle$ if $\mu_1 \in \mathbb{I}^Z$ satisfies $(\mu, \mu_1) \models \psi$.

Reachability relation. The reachability relations $\mu \overset{w}{\rightsquigarrow}_{\ell r} \nu$ and $\mu \overset{f}{\rightsquigarrow}_{\ell r} \nu$ are defined as for TPDA by extending one-step transitions $\langle \ell, \mu, u \rangle \xrightarrow{a} \langle r, \nu, v \rangle$ to words $w \in \Sigma^*$ and their Parikh images $f = \mathrm{PI}_w \in \mathbb{N}^\Sigma$. Thus, $\mu \overset{f}{\rightsquigarrow}_{\ell r} \nu$ is a subset of $\mathbb{I}^X \times \mathbb{N}^\Sigma \times \mathbb{I}^X$, which is furthermore

invariant under orbits. In the following let X' be a copy of global clocks. An initial valuation μ belongs to $\mathbb{I}^X$, a final valuation ν to $\mathbb{I}^{X'}$, and the joint valuation (μ,ν) belongs to $\mathbb{I}^{X\times X'}$. The following two lemmas hold for RPDA with homogeneous atoms; cf. [7], or Sec. 9 in [4].

▶ **Lemma 12.** *If $(\mu,\nu),(\mu',\nu')$ belong to the same orbit of $\mathbb{I}^{X\times X'}$, then $\mu \overset{f}{\rightsquigarrow}_{\ell r} \nu$ iff $\mu' \overset{f}{\rightsquigarrow}_{\ell r} \nu'$.*

▶ **Lemma 13.** *Given a RPDA $\mathcal{Q}$ one can construct a context-free grammar G of exponential size with nonterminals of the form $X_{\ell ro}$, for control locations ℓ, r and an orbit $o \in \mathrm{Orb}(\mathbb{I}^{X\times X'})$, recognising the language $L(X_{\ell ro}) = \left\{ \pi_\Sigma(w) \in \Sigma^* \;\middle|\; \exists (\mu,\nu) \in o \cdot \mu \overset{w}{\rightsquigarrow}_{\ell r} \nu \right\}$, where $\pi_\Sigma(w)$ is w without the ε's. Consequently, RPDA recognise context-free languages.*

▶ **Lemma 14** (Theorem 4 of [22])**.** *The Parikh image of $L(X_{\ell ro})$ is expressed by an existential Presburger formula $\varphi^{\mathbb{Z}}_{\ell ro}$ computable in time linear in the size of the grammar.*

▶ **Corollary 15.** *Let $\varphi^{\mathbb{I}}_o$ be the characteristic K-constraint of the orbit $o \in \mathrm{Orb}(\mathbb{I}^{X\times X'})$. The reachability relation $\rightsquigarrow_{\ell r}$ of an RPDA $\mathcal{Q}$ is expressed by $\varphi_{\ell r}(\overline{x},\overline{f},\overline{x}') \equiv \bigvee_{o\in \mathrm{Orb}(\mathbb{I}^{X\times X'})} \varphi^{\mathbb{Z}}_{\ell ro}(\overline{f}) \wedge \varphi^{\mathbb{I}}_o(\overline{x},\overline{x}')$. The size of $\varphi_{\ell r}$ is exponential in the size of $\mathcal{Q}$.*

Proof of Theorem 11. Define *cyclic sum* and *difference* of $a,b \in \mathbb{Q}$ to be $a \oplus b = \{a+b\}$, resp., $a \ominus b := \{a-b\}$. For a set of clocks X, let $X_{x_0} = X \cup \{x_0\}$ be its extension with an extra clock $x_0 \notin X$ which is never reset, and let $\hat{X}_{x_0} = \{\hat{x} \mid x \in X_{x_0}\}$ be a corresponding set of registers. The special register $\hat{x}_0$ stores the (fractional part of the) current timestamp, and register $\hat{x}$ stores the (fractional part of the) timestamp of the last reset of x. In this way we can recover the fractional value of x as the cyclic difference $\{x\} = \hat{x}_0 \ominus \hat{x}$. Let (cf. Fig. 1(b))

$$\varphi_\ominus(\overline{x},\overline{\hat{x}}) \equiv \bigwedge_{x\in X} \{x\} = \hat{x}_0 \ominus \hat{x}. \tag{9}$$

Resetting clocks in $Y \subseteq X$ is simulated by $\varphi_{\mathsf{reset}(Y)} \equiv \hat{x}'_0 = \hat{x}_0 \wedge \bigwedge_{x\in Y} \hat{x}' = \hat{x}_0 \wedge \bigwedge_{x\in X\setminus Y} \hat{x}' = \hat{x}$ and time elapse by $\varphi_{\mathsf{elapse}} \equiv \bigwedge_{x\in X} \hat{x}' = \hat{x}$. The equality $\hat{x}'_0 = \hat{x}_0$ in $\varphi_{\mathsf{reset}(Y)}$ says that time does not elapse, and the absence of constraints on $\hat{x}_0, \hat{x}'_0$ in $\varphi_{\mathsf{elapse}}$ allows for an arbitrary elapse of time. A clock constraint φ is converted into a K-constraint $\hat{\varphi}$ by replacing $\{x\} = 0$ with $\hat{x} = \hat{x}_0$ and $\{x\} \le \{y\}$ by $K_\le(\hat{y},\hat{x},\hat{x}_0)$, for $x,y \in X \cup Z$. For a TPDA $\mathcal{P} = \langle \Sigma,\Gamma,L,X,Z,\Delta\rangle$, we define the following RPDA $\mathcal{Q} = \left\langle \Sigma,\Gamma,L,\hat{X}_{x_0},\hat{Z},\hat{\Delta}\right\rangle$. The input rules are preserved. A reset rule $\langle \ell,\mathsf{reset}(Y),r\rangle \in \Delta$, is simulated by $\langle \ell,\varphi_{\mathsf{reset}(Y)},r\rangle \in \hat{\Delta}$, a time elapse rule $\langle \ell,\mathsf{elapse},r\rangle \in \Delta$ is simulated by $\langle \ell,\varphi_{\mathsf{elapse}},r\rangle \in \hat{\Delta}$, a push rule $\langle \ell,\mathsf{push}(\gamma:\varphi),r\rangle \in \Delta$ is simulated by $\langle \ell,\mathsf{push}(\gamma:\hat{\varphi}),r\rangle \in \hat{\Delta}$, and similarly for pop rules. By Corollary 15, let $\varphi_{\ell r}(\overline{\hat{x}},\overline{f},\overline{\hat{x}'})$ express the reachability relation of $\mathcal{Q}$, and define $\xi^{\mathbb{I}}_o(\overline{x},\overline{x}') \equiv \exists \overline{\hat{x}},\overline{\hat{x}'} \cdot \varphi^{\mathbb{I}}_o(\overline{\hat{x}},\overline{\hat{x}'}) \wedge \varphi_\ominus(\overline{x},\overline{\hat{x}}) \wedge \varphi_\ominus(\overline{x}',\overline{\hat{x}'})$. The reachability relation of $\mathcal{P}$ is recovered as

$$\psi_{\ell r}(\overline{x},\overline{f},\overline{x}') \equiv \bigvee \{\varphi^{\mathbb{Z}}_{\ell ro}(\overline{f}) \wedge \xi^{\mathbb{I}}_o(\overline{x},\overline{x}') | o \in \mathrm{Orb}(\mathbb{I}^{X\times X'})\}. \tag{10}$$

Intuitively, we guess the value for registers $\overline{\hat{x}},\overline{\hat{x}'}$ and we check that they correctly describe the fractional values of global clocks as prescribed by $\varphi_\ominus$. We now remove the quantifiers from $\xi^{\mathbb{I}}_o$ to uncover the structure of fractional value comparisons. Introduce a new variable $\delta = \hat{x}_0 \ominus \hat{x}'_0$, and perform the following substitutions in $\varphi^{\mathbb{I}}_o$ (c.f. the definition of $\varphi_\ominus$ in (9)): $\hat{x} \mapsto \hat{x}_0 \ominus \{x\}$, $\hat{x}' \mapsto (\hat{x}_0 \ominus \delta) \ominus \{x'\}$, and $\hat{x}'_0 \mapsto \hat{x}_0 \ominus \delta$. By writing $(\hat{x}_0 \ominus \delta) \ominus \{x'\}$ as $\hat{x}_0 \ominus (\delta \oplus \{x'\})$, we have only atomic constraints of the forms $K(\hat{x}_0 \ominus u, \hat{x}_0 \ominus v, \hat{x}_0 \ominus t)$ and $\hat{x}_0 \ominus u = \hat{x}_0 \ominus v$, where terms u,v,t are of one of the forms 0, $\{x\}$, $\delta \oplus \{x'\}$, δ. These constraints are equivalent, respectively, to $K(t,v,u)$ and $u = v$. By expanding the definition of K (cf. (1)), we obtain only constraints of the form $u \precsim v$ with $\precsim \in \{<,\le\}$. Since δ appears

at most once on either side, it can either be eliminated if it appears on both u, v, or otherwise exactly one of u, v is of the form δ or $\delta \oplus \{x'\}$, and the other of the form 0 or $\{x\}$. By moving $\{x'\}$ on the other side of the inequality in constraints containing $\delta \oplus \{x'\}$, $\xi_o^{\mathbb{I}}$ is equivalent to $\bigwedge_i s_i \precsim t_i \ \wedge \ \exists 0 \leq \delta < 1 \cdot \bigwedge_j u_j \precsim \delta \wedge \bigwedge_k \delta \precsim v_k$, where the terms s_i, t_i, u_j, v_k's are of the form 0, $\{x\}$, or $\{x\} \ominus \{y'\}$. We can now eliminate the quantification on δ and get a constraint of the form $\bigwedge_h s_h \precsim t_h$. Finally, by expanding $b \ominus a$ as $b - a + 1$ if $b < a$ and $b - a$ otherwise (since $a, b \in \mathbb{I}$) we have $\xi_o^{\mathbb{I}}(\overline{x}, \overline{x}') \ \equiv \ \bigwedge_h s'_h \precsim t'_h$, where the s'_h, t'_h's are of one of the forms: 0, $\{x\}$, $\{x\} - \{y'\}$, or $\{x\} - \{y'\} + 1$. ◀

Abstract

A vector addition system (VAS) with an initial and a final marking and transition labels induces a language. In part because the reachability problem in VAS remains far from being well-understood, it is difficult to devise decision procedures for such languages. This is especially true for checking properties that state the existence of infinitely many words of a particular shape. Informally, we call these *unboundedness properties*.

We present a simple set of axioms for predicates that can express unboundedness properties. Our main result is that such a predicate is decidable for VAS languages as soon as it is decidable for regular languages. Among other results, this allows us to show decidability of (i) separability by bounded regular languages, (ii) unboundedness of occurring factors from a language K with mild conditions on K, and (iii) universality of the set of factors.

Acknowledgements We are indebted to Mohamed Faouzi Atig for suggesting to study separability by bounded languages, which was the starting point for this work. We are also grateful to Sławomir Lasota and Sylvain Schmitz for important discussions. This collaboration started at the Gregynog 71717 workshop organized by Ranko Lazić and Patrick Totzke.

1 Introduction

Vector addition systems (VAS) and, essentially equivalent, Petri nets are among the most widely used models of concurrent systems. Although they are used extensively in practice, there are still fundamental questions that are far from being well understood.

Part of the research was conducted when the author was supported by a fellowship within the Postdoc-Program of the German Academic Exchange Service (DAAD) and by Labex DigiCosme, Univ. Paris-Saclay, project VERICONISS.

This is reflected in what we know about decidability questions regarding the most expressive class of languages associated to VAS: The languages of (arbitrarily) labeled VAS with a given initial and final configuration, which we call *VAS languages*. In the 1970s, this class has been characterized in terms of closure properties and Dyck languages by Greibach [27] and Jantzen [36]. Almost all decidability results about these languages use a combination of these closure properties and the decidability of the reachability problem for VAS [43] (or for Reinhardt's extension [47], such as in [1, 51]). Of course, this method is confined to procedures that somehow reduce to the existence of one or finitely many runs of VAS.

There are two notable exceptions to this and they both rely on an extensions of decision procedures for reachability in VAS. The first is Hauschildt and Jantzen's result [33] from 1994 that finiteness of VAS languages is decidable, which employs Hauschildt's algorithm to decide semilinearity of reachability sets [32]. The second is the much more recent result of Habermehl, Meyer, and Wimmel from 2010 [28]. It shows computability of downward closures for VAS languages (which significantly generalizes decidability of finiteness) and involves a careful inspection of marked graph-transition sequences (MGTS) of Lambert's algorithm. (As observed in [15, 52], computability of downward closures can also be derived from [6].) This sparsity of results is due to the fact that the algorithms for the reachability problem are still quite unwieldy and have been digested by few researchers.

In particular, it currently seems difficult to decide whether there exist infinitely many words of some shape in a given language—unless the problem reduces to computing downward closures. Informally, we call problems of this type *unboundedness problems*. Such problems are important for two reasons. The first concerns *separability problems*, which have attracted attention in recent years [5, 11, 26, 44, 45]. Here, instead of deciding whether two languages are disjoint, we are looking for a (typically finite-state) certificate for disjointness, namely a set that includes one language and is disjoint from the other. For general topological reasons, inseparability is usually witnessed by a common pattern, whose presence in a language is an unboundedness property. The second reason is that unboundedness problems tend to be *decidable where exact queries are not*. This phenomenon also occurs in the theory of regular cost functions [12]. Moreover, as it turns out in this work, this is true for VAS languages as well.

Contribution. We present a simple notion of an *unboundedness predicate* on languages and show that such predicates are decidable for VAS languages as soon as they are decidable for regular languages. On the one hand, this provides an easy and general way to obtain new decidability results for VAS languages without the need to understand the details of the KLMST decomposition. On the other hand, we apply this framework to prove:

(i) Boundedness in the sense of Ginsburg and Spanier [24] is decidable. A language $L \subseteq \Sigma^*$ is *bounded* if $L \subseteq w_1^* \cdots w_n^*$ for some $w_1, \ldots, w_n \in \Sigma^*$. Moreover, it is decidable whether two given VAS languages are separable by a bounded regular language.

(ii) Computability of downward closures can be recovered as well.

(iii) Suppose that $K \subseteq \Sigma^*$ is chosen so that it is decidable whether K intersects a given regular language. Then, it is decidable for a given VAS language L whether L contains words with arbitrarily many factors from K. Moreover, in case the number of factor occurrences in L is bounded, we can even compute an upper bound.

(iv) Under the same assumptions as above on $K \subseteq \Sigma^*$, one can decide if every word from K^* appears as a factor of a given VAS language $L \subseteq \Sigma^*$. In particular, it is decidable whether L contains every word from Σ^* as a factor.

It should be stressed that results (iii) and (iv) came deeply unexpected to the authors for two reasons. First, the assumptions are already satisfied when K is induced by a system model as powerful as well-structured transition systems (WSTS) or higher-order recursion schemes. In these cases, it is in general *undecidable* whether a given VAS language contains a factor from K *at least once*, because intersection emptiness easily reduces to this problem (see the remarks after Theorem 4.8). We therefore believe that these results might lead to new approaches to verifying systems with concurrency and (higher-order) recursion, where the latter undecidability (or the unknown status in the case of simple recursion [40]) is usually a barrier for decision procedures. Secondly, the problems in (iii) and (iv) are undecidable as soon as L is just slightly beyond the realm of VAS: Already for one-counter languages L, both (iii) and (iv) become undecidable. Thus, compared to other infinite-state systems, VAS languages turn out to be extraordinarily amenable to unboundedness problems.

Related work. Other authors have investigated general notions of unboundedness properties for VAS [2, 4, 16, 50], usually with the goal of obtaining EXPSPACE upper bounds. However, those properties a priori concern the state space itself. While they can sometimes be used to reason about languages [4, 16], this has been confined to coverability languages, which are significantly less expressive than the reachability languages studied here. Specifically, every problem we consider here is hard for the reachability problem (see Remark 3.2).

An early attempt was Yen's work [50], which claimed an EXPSPACE upper bound for a powerful logic concerning paths in VAS. Unfortunately, a serious flaw in the latter was discovered by Atig and Habermehl [2], who presented a corrected proof for a restricted version of Yen's logic. Demri [16] then introduced a notion of *generalized unboundedness properties*, which covers more properties from Yen's logic and proved an EXPSPACE procedure to check them. Examples include reversal-boundedness, place boundedness, and regularity of firing sequences of unlabeled VAS. Finally, Blockelet and Schmitz [4] introduce an extension of computation tree logic (CTL) that can express "coverability-like properties" of VAS. The authors prove an EXPSPACE upper bound for model checking this logic on VAS.

2 Preliminaries

Let Σ be a finite alphabet. For $w \in \Sigma^*$, we denote its length by $|w|$. The i-th letter of w, for $i \in [1, |w|]$ is denoted $w[i]$. Moreover, we write $\Sigma_\varepsilon = \Sigma \cup \{\varepsilon\}$. A *(d-dimensional) vector addition system* (VAS) V consists of finite set of *transitions* $T \subseteq \mathbb{Z}^d$, *source* and *target* vectors $s, t \in \mathbb{N}^d$ and a *labeling* $h\colon T \to \Sigma_\varepsilon$, whose extension to a morphism $T^* \to \Sigma^*$ is also denoted h. Vectors $v \in \mathbb{N}^d$ are also called *configurations*. A transition $t \in T$ can be *fired* in a configuration $v \in \mathbb{N}^d$ if $v + t \in \mathbb{N}^d$. Then, the result of firing t is the configuration $v + t$ and we write $v \xrightarrow{h(t)} v'$ for $v' = v + t$. For $w \in \Sigma^*$, we write $v \xrightarrow{w} v'$ if there exist $v_1, \ldots, v_k \in \mathbb{N}^d$ such that $v = v_0 \xrightarrow{x_1} v_1 \xrightarrow{x_2} \ldots \xrightarrow{x_k} v_k \xrightarrow{x_{k+1}} v_{k+1} = v'$, where $w = x_1 \cdots x_{k+1}$ for some $x_1, \ldots, x_{k+1} \in \Sigma_\varepsilon$. The *language* of V, denoted $L(V)$, is the set of all labels of runs from source to target, i.e. $L(V) = \{w \in \Sigma^* \mid s \xrightarrow{w} t\}$. The languages of the form $L(V)$ for VAS V are called *VAS languages*. A word $u = a_1 \cdots a_n$ with $a_i \in \Sigma$ is a *subword* of a word $v \in \Sigma^*$ if $v \in \Sigma^* a_1 \Sigma^* \cdots \Sigma^* a_n \Sigma^*$, which is denoted $u \preceq v$. For a language $L \subseteq \Sigma^*$ its *downward closure* is the language $L{\downarrow} = \{u \in \Sigma^* \mid \exists v \in L\colon u \preceq v\}$. It is known that $L{\downarrow}$ is regular for every $L \subseteq \Sigma^*$ [34, 31]. A *language class* is a collection of languages, together with some way of finitely describing these languages (such as by grammars, automata, etc.). If $\mathcal{C}$ is a language class so that given a description of a language L from $\mathcal{C}$, we can compute an automaton for $L{\downarrow}$, we say that *downward closures are computable* for $\mathcal{C}$.

A *full trio* is a language class that is effectively closed under rational transductions [3], which are relations defined by nondeterministic two-tape automata. Equivalently, a full trio is a class that is effectively closed under morphisms, inverse morphisms, and regular intersection [3]. Full trios are abundant among infinite-state models: If a nondeterministic machine model involves a finite-state control, the resulting language class is a full trio. Examples include *VAS languages* [36], *coverability languages of WSTS* [23], *one-counter languages* (which are accepted by one-counter automata *with zero tests*) [35], and languages of *higher-order pushdown automata* [42] and *higher-order recursion schemes* [30]. The context-sensitive languages do not constitute a full trio, as they are not closed under erasing morphisms.

3 Main result

Here, we introduce our notion of unboundedness predicates and present our main result.

For didactic purposes, we begin our exposition of unboundedness predicates with a simplified (but already useful) version. An important aspect of the definition is that technically, an unboundedness predicates is not a property of the language $L \subseteq \Sigma^*$ we want to analyze, but of the set of its factors. In other words, we have a unary predicate $\mathfrak{p}$ on languages and we want to decide whether $\mathfrak{p}(F(L))$, where $F(L) = \{w \in \Sigma^* \mid L \cap \Sigma^* w \Sigma^* \neq \emptyset\}$ is the set of factors of L. For the definition, it is helpful to keep in mind the simplest example of an unboundedness predicate, the *infinity predicate* $\mathfrak{p}_{\mathsf{inf}}$, where $\mathfrak{p}_{\mathsf{inf}}(K)$ if and only if K is infinite. Then, $\mathfrak{p}_{\mathsf{inf}}(F(L))$ if and only if L is infinite. A unary predicate $\mathfrak{p}$ on languages over Σ^* is called *1-dimensional unboundedness predicate* if for every $K, L \subseteq \Sigma^*$, we have:

(i*) if $\mathfrak{p}(K)$ and $K \subseteq L$, then $\mathfrak{p}(L)$.
(ii*) if $\mathfrak{p}(K \cup L)$, then either $\mathfrak{p}(L)$ or $\mathfrak{p}(K)$.
(iii*) if $\mathfrak{p}(F(KL))$, then either $\mathfrak{p}(F(K))$ or $\mathfrak{p}(F(L))$.

Part of our result will be that for such predicates, if we can decide whether $\mathfrak{p}(F(R))$ for regular languages R, we can decide whether $\mathfrak{p}(F(L))$ for VAS languages L. Before we come to that, we want to generalize a bit. There are predicates we want to decide that fail to satisfy axiom (iii*), such as the one stating $a^*b^* \subseteq L{\downarrow}$ for $L \subseteq \Sigma^*$: It is satisfied for a^*b^*, but neither for a^* nor for b^*. (Deciding such predicates is useful for computing downward closures [52] and separability by piecewise testable languages [15]) To capture such predicates, which intuitively ask for several quantities being unbounded simultaneously, we present a more general set of axioms. Here, the idea is to formulate predicates over simultaneously occurring factors. For a language $L \subseteq \Sigma^*$ and $n \in \mathbb{N}$, let

$$F_n(L) = \{(w_1, \ldots, w_n) \in (\Sigma^*)^n \mid \Sigma^* w_1 \Sigma^* \cdots w_n \Sigma^* \cap L \neq \emptyset\}.$$

We will speak of *n-dimensional* predicates, i.e., predicates $\mathfrak{p}$ on subsets of $(\Sigma^*)^n$, and we want to decide whether $\mathfrak{p}(F_n(L))$ for a given language L. The following are axioms referring to all subsets $S, T \subseteq (\Sigma^*)^n$, languages $L_i \subseteq \Sigma^*$, and all $k \in \mathbb{N}$. We call $\mathfrak{p}$ an *(n-dimensional) unboundedness predicate* if

(i) if $\mathfrak{p}(S)$ and $S \subseteq T$, then $\mathfrak{p}(T)$.
(ii) if $\mathfrak{p}(S \cup T)$, then $\mathfrak{p}(S)$ or $\mathfrak{p}(T)$.
(iii) if $\mathfrak{p}(F_n(L_1 \cdots L_k))$, then $n = n_1 + \cdots + n_k$ such that $\mathfrak{p}(F_{n_1}(L_1) \times \cdots \times F_{n_k}(L_k))$.

Intuitively, the last axiom says that if a concatenation satisfies the predicate, then this is already witnessed by factors in at most n participants of the concatenation. Note that for

$n = 1$, the axioms coincide with the simplified axioms (i*) to (iii*) above. An n-dimensional unboundedness predicate $\mathfrak{p}$ is *decidable for a language class* $\mathcal{C}$ if, given a language L from $\mathcal{C}$, it is decidable whether $\mathfrak{p}(F_n(L))$. The following is our main result.

▶ **Theorem 3.1.** *Given a VAS language $L \subseteq \Sigma^*$, one can compute a regular $R \subseteq \Sigma^*$ such that $L \subseteq R$ and for every n-dim. unboundedness predicate $\mathfrak{p}$, we have $\mathfrak{p}(F_n(L))$ iff $\mathfrak{p}(F_n(R))$.*

Note that this implies that decidability of $\mathfrak{p}$ for regular languages implies decidability of $\mathfrak{p}$ for VAS languages for any n-dim. unboundedness predicate $\mathfrak{p}$. In addition, when our unboundedness predicate expresses that a certain quantity is unbounded, then in the bounded case, Theorem 3.1 sometimes allows us to compute an upper bound (see, e.g. Theorem 4.8).

▶ Remark 3.2. Let us comment on the complexity of deciding whether $\mathfrak{p}(F_n(L))$ for a VAS language L. Call $\mathfrak{p}$ *non-trivial* if there is at least one $S \subseteq (\Sigma^*)^n$ that satisfies $\mathfrak{p}$ and least one $S' \subseteq (\Sigma^*)^n$ for which $\mathfrak{p}$ is not satisfied. Then, deciding whether $\mathfrak{p}(F_n(L))$ is at least as hard as the reachability problem. Indeed, in this case axiom (i) implies that $F_n(\Sigma^*) = (\Sigma^*)^n$ satisfies $\mathfrak{p}$, but $F_n(\emptyset) = \emptyset$ does not. Given a VAS V and two vectors μ_1 and μ_2, it is easy to construct a VAS V' so that $L(V') = \Sigma^*$ if V can reach μ_2 from μ_1 and $L(V') = \emptyset$ otherwise.

4 Applications

Bounded languages. Our first application concerns bounded languages. A language $L \subseteq \Sigma^*$ is *bounded* if there exist words $w_1, \ldots, w_n \in \Sigma^*$ such that $L \subseteq w_1^* \cdots w_n^*$. This notion was introduced by Ginsburg and Spanier [24]. Since a bounded language as above can be characterized by the set of vectors $(x_1, \ldots, x_n) \in \mathbb{N}^n$ for which $w_1^{x_1} \cdots w_n^{x_n} \in L$, bounded languages are quite amenable to analysis. This has led to a number of applications to concurrent recursive programs [18, 19, 20, 21, 41], but also counter systems [17] and WSTS [9].

Boundedness has been shown decidable for *context-free languages* by Ginsburg and Spanier [24] (PTIME-completeness by Gawrychowski et al. [22]) and hence also for *regular languages* (NL-completeness also in [22]), for *equal matrix languages* by Siromoney [49], and for trace languages of *complete deterministic well-structured transition systems* by Chambart et al. [9]. The latter implies that boundedness is decidable for coverability languages of deterministic vector addition systems, in which case EXPSPACE-completeness was shown by Chambart et al. [9] (the upper bound had been established by Blockelet and Schmitz [4]).

We use Theorem 3.1 to show the following.

▶ **Theorem 4.1.** *Given a VAS, it is decidable whether its language is bounded.*

The rest of this section is devoted to the proof of Theorem 4.1. Let $\mathfrak{p}_{\mathsf{notb}}$ be the 1-dimensional predicate that holds for a language $K \subseteq \Sigma^*$ if and only if K it is not bounded. We plan to apply Theorem 3.1 to $\mathfrak{p}_{\mathsf{notb}}$, but it allows us to decide only whether $\mathfrak{p}_{\mathsf{notb}}(F(L))$ for a given VAS language L. Thus we need the following fact, which we prove in a moment.

▶ **Fact 4.2.** *A language $L \subseteq \Sigma^*$ is bounded if and only if $F(L)$ is bounded.*

We also need to show that $\mathfrak{p}_{\mathsf{notb}}$ is indeed an unboundedness predicate, meaning that it satisfies axioms (i*) to (iii*). By definition of boundedness, $\mathfrak{p}_{\mathsf{notb}}$ clearly fulfills axiom (i*). Axioms (ii*) and (iii*) are implied by Fact 4.2 and the following.

▶ **Fact 4.3.** *If K and L are bounded then both $K \cup L$ and KL are bounded as well.*

Let us prove Facts 4.2 and 4.3 and begin with Fact 4.3. If K and L are bounded, then $K \subseteq w_1^* \cdots w_n^*$ and $L \subseteq w_{n+1}^* \cdots w_m^*$ for some $w_1, \ldots, w_m \in \Sigma^*$. Then we have $K \cup L, KL \subseteq w_1^* \cdots w_m^*$, which shows Fact 4.3. In order to show Fact 4.2, observe first that for each individual word $w \in \Sigma^*$, the language $F(w)$ is bounded because it is finite. Thus, if $L \subseteq w_1^* \cdots w_n^*$, then $F(L)$ is included in $F(w_1)w_1^*F(w_1) \cdots F(w_n)w_n^*F(w_n)$, which is bounded as a concatenation of bounded languages by Fact 4.3. Thus, $F(L)$ is bounded as well. Conversely, L inherits boundedness from its superset $F(L)$.

To conclude Theorem 4.1, we need to show that given regular language $R \subseteq \Sigma^*$, it is decidable whether $\mathfrak{p}_{\mathsf{notb}}(F(R))$. By Fact 4.2, this amounts to checking whether R is bounded. This is decidable even for context-free languages [24] (and in NL for regular ones [22]).

Separability. We can also use our results to decide whether two VAS languages are separable by a bounded regular language. Very generally, if $\mathcal{S}$ is a class of sets, we say that a set K is *separable from* a set L *by* a set from $\mathcal{S}$ if there is a set S in $\mathcal{S}$ so that $K \subseteq S$ and $L \cap S = \emptyset$.

The separability problem was recently investigated for VAS languages and several subclasses. In [15] it is shown that separability of VAS languages by piecewise testable languages (a subclass of regular languages) is decidable. Decidability of separability of VAS languages by regular languages is still open, but it is known for several subclasses thereof [10, 11, 13]. In [14] it is shown that any two disjoint VAS coverability languages are separable by a regular language. Here, using Theorem 4.1 we are able to show the following.

▶ **Theorem 4.4.** *Given two VAS languages K and L, it is decidable whether K is separable from L by a bounded regular language.*

Clearly, in order for that to hold, K has to be bounded, which we can decide. Moreover, by enumerating expressions $w_1^* \cdots w_n^*$, we can find one with $K \subseteq w_1^* \cdots w_n^*$. Since the bounded regular languages (BRL) are closed under intersection (recall that a subset of a bounded language is again bounded), K and L are separable by a BRL if and only if $L_0 = K$ and $L_1 = L \cap w_1^* \cdots w_n^*$ are separable by a BRL. Since now both input languages are included in $w_1^* \cdots w_n^*$, we can reformulate the problem into one over vector sets.

▶ **Lemma 4.5.** *Let $L_0, L_1 \subseteq w_1^* \cdots w_n^*$ and $U_i = \{(x_1, \ldots, x_n) \in \mathbb{N}^n \mid w_1^{x_1} \cdots w_n^{x_n} \in L_i\}$ for $i \in \{0, 1\}$. Then, L_0 is separable from L_1 by a BRL if and only if U_0 is separable from U_1 by a recognizable subset of $\mathbb{N}^n$.*

Recall that a subset $S \subseteq \mathbb{N}^n$ is *recognizable* if there is a morphism $\varphi\colon \mathbb{N}^n \to F$ into a finite monoid F with $S = \varphi^{-1}(\varphi(S))$. Lemma 4.5 is a straightforward application of Ginsburg and Spanier's characterization of BRL [25].

Since in our case, L_0 and L_1 are VAS languages, a standard construction shows that U_0 and U_1 are (effectively computable) sections of VAS reachability sets. Here, sections are defined as follows. For a subset $I \subseteq [1, n]$, let $\pi_I\colon \mathbb{N}^n \to \mathbb{N}^{|I|}$ be the projection onto the coordinates in I. Then, every set of the form $\pi_{[1,n]\setminus I}(S \cap \pi_I^{-1}(x))$ for some $I \subseteq [1, n]$ and $x \in \mathbb{N}^{|I|}$ is called a *section* of $S \subseteq \mathbb{N}^n$. Thus, the following result by Clemente et al. [11] allows us to decide separability by BRL.

▶ **Theorem 4.6** ([11])**.** *Given two sections $S_0, S_1 \subseteq \mathbb{N}^n$ of reachability sets of VAS, it is decidable whether S_0 is separable from S_1 by a recognizable subset of $\mathbb{N}^n$.*

Downward closures and simultaneous unboundedness. We now illustrate how to compute downward closures using our results. First of all, computability of downward closures for VAS languages follows directly from Theorem 3.1 because it implies $R{\downarrow} = L{\downarrow}$: For each word

$w = a_1 \cdots a_n$ with $a_1, \ldots, a_n \in \Sigma$, consider the n-dimensional predicate $\mathfrak{p}_w$ which is satisfied for $S \subseteq (\Sigma^*)^n$ iff $(a_1, \ldots, a_n) \in S$. Then $\mathfrak{p}_w(F_n(L))$ if and only if $w \in L{\downarrow}$. It is easy to check that this is an unboundedness predicate. Hence, $R{\downarrow} = L{\downarrow}$.

However, in order to illustrate how to apply unboundedness predicates, we present an alternative approach. In [52], it was shown that if a language class $\mathcal{C}$ is closed under rational transductions (which is the case for VAS languages), then downward closures are computable for $\mathcal{C}$ if and only if, given a language L from $\mathcal{C}$ and letters $a_1, \ldots, a_n$, it is decidable whether $a_1^* \cdots a_n^* \subseteq L{\downarrow}$. Let us show how to decide the latter using unboundedness predicates.

For this, we use an n-dimensional predicate. For a subset $S \subseteq (\Sigma^*)^n$, let $S{\downarrow}$ be the set of all tuples $(u_1, \ldots, u_n) \in (\Sigma^*)^n$ such that there is some $(v_1, \ldots, v_n) \in S$ with $u_i \preceq v_i$ for $i \in [1, n]$. Our predicate $\mathfrak{p}_{\mathsf{sup}}$ is satisfied for $S \subseteq (\Sigma^*)^n$ if and only if $a_1^* \times \cdots \times a_n^* \subseteq S$. Then clearly $\mathfrak{p}_{\mathsf{sup}}(F_n(L))$ if and only if $a_1^* \cdots a_n^* \subseteq L{\downarrow}$. It is easy to check that $\mathfrak{p}_{\mathsf{sup}}$ fulfills axiom (i) and axiom (ii). For the latter, note that $a_1^* \times \cdots \times a_n^* \subseteq (S_1 \cup S_2){\downarrow}$ implies that for some $j \in \{1, 2\}$, there are infinitely many $\ell \in \mathbb{N}$, with $(a_1^\ell, \ldots, a_n^\ell) \in S_j$ and hence $a_1^* \times \cdots \times a_n^* \subseteq S_j{\downarrow}$. For axiom (iii), we need a simple combinatorial argument:

▶ **Lemma 4.7.** *If $a_1^* \times \cdots \times a_n^* \subseteq F_n(L_1 \cdots L_k){\downarrow}$, then $n = n_1 + \cdots + n_k$ with $a_1^* \times \cdots \times a_n^* \subseteq (F_{n_1}(L_1) \times \cdots \times F_{n_k}(L_k)){\downarrow}$.*

It remains to show that for a regular language R, it is decidable whether $a_1^* \cdots a_n^* \subseteq R{\downarrow}$. Since it is easy to construct an automaton for $R{\downarrow}$, this amounts to a simple inclusion check.

Non-overlapping factors. Our next example shows that under very mild assumptions on a language K, one can decide whether the words in a VAS language L contain arbitrarily many factors from K. For $w \in \Sigma^*$ and $K \subseteq \Sigma^+$, let $|w|_K$ be the largest number m such that there are $w_1, \ldots, w_m \in K$ with $(w_1, \ldots, w_m) \in F_m(w)$. Note that since $\varepsilon \notin K$, there is always a maximal such m. Consider the function $f_K \colon \Sigma^* \to \mathbb{N}$, $w \mapsto |w|_K$. A function $f \colon \Sigma^* \to \mathbb{N}$ is *unbounded* on $L \subseteq \Sigma^*$ if for every $k \in \mathbb{N}$, we have $f(w) \geq k$ for some $w \in L$.

▶ **Theorem 4.8.** *If $\mathcal{C}$ is a full trio with decidable emptiness problem, then given a VAS language L and a language $K \subseteq \Sigma^+$ from $\mathcal{C}$, it is decidable whether f_K is unbounded on L. If f_K is bounded on L, we can compute an upper bound.*

Theorem 4.8 is quite unexpected because very slight variations lead to undecidability. If we ask whether f_K is non-zero on a given VAS language (as opposed to unbounded), then this is in general undecidable. Indeed, suppose $\mathcal{C}$ is a full trio for which intersection with VAS languages is undecidable (such as languages of lossy channel systems[4] or higher-order pushdown languages [29, 52]). Then given a language $K \subseteq \Sigma^*$ from $\mathcal{C}$, a VAS language L and some $c \notin \Sigma$, the function f_{cKc} is non-zero on cLc if and only if $K \cap L \neq \emptyset$.

Furthermore, the same problem becomes undecidable in general if instead of VAS languages, we want to decide the problem for a language class as simple as one-counter languages (OCL). Indeed, suppose $\mathcal{C}$ is a full trio for which intersection with OCL is undecidable (such as the class of OCL). For a given $K \subseteq \Sigma^*$ from $\mathcal{C}$, an OCL $L \subseteq \Sigma^*$, and some $c \notin \Sigma$, the set $c(Lc)^*$ is effectively an OCL and f_{cKc} is unbounded on $c(Lc)^*$ if and only if $K \cap L \neq \emptyset$.

Let us prove Theorem 4.8. Fix a language $K \subseteq \Sigma^*$ from $\mathcal{C}$. Our predicate $\mathfrak{p}_{\mathsf{nof}}$ is one-dimensional and is satisfied on a set $L \subseteq \Sigma^*$ if and only if f_K is unbounded on L. Then clearly,

[4] It seems to be folklore that intersection between languages of lossy channel systems and languages of one-dimensional VAS is undecidable (the additional counter can be used to ensure that no letter is dropped). The only reference we could find is [46].

$\mathfrak{p}_{\mathsf{nof}}(F(L))$ if and only if f_K is unbounded on L. It is immediate that axioms (i*) and (ii*) are satisfied. Furthermore, axiom (iii*) follows by contraposition: If neither $\mathfrak{p}_{\mathsf{nof}}(F(L_0))$ nor $\mathfrak{p}_{\mathsf{nof}}(F(L_1))$, then there are $B_0, B_1 \in \mathbb{N}$ such that f_K is bounded by B_i on L_i for $i = 0, 1$. That implies that f_K is bounded by $B_0 + B_1 + 1$ on L_0L_1. This rules out $\mathfrak{p}_{\mathsf{nof}}(F(L_0L_1))$, which establishes axiom (iii*). The following uses standard arguments.

▶ **Lemma 4.9.** *Let $\mathcal{C}$ be a full trio with decidable emptiness problem. Given a language K from $\mathcal{C}$ and a regular language R, it is decidable whether f_K is unbounded on R. Moreover, if f_K is bounded on R, we can compute an upper bound.*

We can deduce Theorem 4.8 from Lemma 4.9 as follows. Using Theorem 3.1, we compute the language R. Then, f_K is unbounded on R iff it is unbounded on L. Moreover, an upper bound for f_K on R is also an upper bound for f_K on L because $L \subseteq R$.

Counting automata. To illustrate how these results can be used, we formulate an extension of Theorem 4.8 in terms of automata that can count. Let $\mathcal{C}$ be a full trio. Intuitively, a $\mathcal{C}$-counting automaton can read a word produced by a VAS and can use machines corresponding to $\mathcal{C}$ as oracles. Just like the intersection of two languages that describe threads in a concurrent system signals a safety violation [7, 8, 41], a successful oracle call would signal a particular undesirable event. In such a model, it would be undecidable whether any oracle call can be successful if, for example, $\mathcal{C}$ is the class of higher-order pushdown languages. However, we show that it *is* decidable whether such an automaton can make an unbounded number of successful oracle calls and if not, compute an upper bound. Hence, we can decide if the number of undesirable events is bounded and, if so, provide a bound.

A *$\mathcal{C}$-counting automaton* is a tuple $\mathcal{A} = (Q, \Sigma, \Gamma, C, q_0, E, Q_f)$, where Q is a finite set of *states*, Σ is its *input alphabet*, Γ is its *(oracle) tape alphabet*, C is a finite set of *counters*, $q_0 \in Q$ is its *initial state*, $Q_f \subseteq Q$ is its set of *final states*, and $E \subseteq Q \times \Sigma^* \times (\Omega \cup \{\varepsilon\}) \times Q$ is a finite set of *edges*, where Ω is a set of *operations* of the following form. First, we have an operation $\mathsf{push}(a)$ for each $a \in \Gamma$, which appends a to the oracle tape. Moreover, we have $\mathsf{check}(K, c)$ for each $K \subseteq \Gamma^*$ from $\mathcal{C}$ and each $c \in C$, which first checks whether the current tape content belongs to K and if so, increments the counter c. After the oracle query, it empties the oracle tape, regardless of whether the oracle answers positively or negatively.

A *configuration* of $\mathcal{A}$ is a triple (q, u, μ), where $q \in Q$ is the current state, $u \in \Gamma^*$ is the oracle tape content, and $\mu \in \mathbb{N}^C$ describes the counter values. For a label $x \in \Sigma \cup \{\varepsilon\}$, and configurations $(q, u, \mu), (q', u', \mu')$, we write $(q, u, \mu) \xrightarrow{x} (q', u', \mu')$ if (q', u', μ') results from (q, u, μ) as described above. In the general case $w \in \Sigma^*$, $(q, u, \mu) \xrightarrow{w} (q', u', \mu')$ has the obvious meaning. We extend the set of natural numbers $\mathbb{N}$ by setting $\overline{\mathbb{N}} = \mathbb{N} \cup \{\omega\}$, where ω is the first infinite ordinal number and represents the infinity. $\mathcal{A}$ defines a function $\Sigma^* \to \overline{\mathbb{N}}$ with $\mathcal{A}(w) = \sup \left\{ \inf_{c \in C} \mu(c) \mid \mu \in \mathbb{N}^C,\ (q_0, \varepsilon, 0) \xrightarrow{w} (q, u, \mu) \text{ for some } q \in Q_f,\ u \in \Gamma^* \right\}$, where 0 is the zero vector in $\mathbb{N}^C$. Hence, $\mathcal{A}$ is unbounded on L if for every $k \in \mathbb{N}$, there is a $w \in L$ and a run of $\mathcal{A}$ on w in which for each $c \in C$, at least k of the oracle queries for c are successful. The following can be shown similarly to Theorem 4.8, but using a multi-dimensional unboundedness predicate.

▶ **Theorem 4.10.** *Let $\mathcal{C}$ be a full trio with decidable emptiness. Given a VAS language L and a $\mathcal{C}$-counting automaton $\mathcal{A}$, it is decidable whether $\mathcal{A}$ is unbounded on L. Moreover, if $\mathcal{A}$ is bounded on L, then one can compute an upper bound $B \in \mathbb{N}$ for $\mathcal{A}$ on L.*

Factor inclusion. As a last example, we show how our results can be used to decide inclusion problems. Specifically, given a VAS language $L \subseteq \Sigma^*$, it is decidable whether $\Sigma^* \subseteq F(L)$. In fact, we show a more general result:

▶ **Theorem 4.11.** *If $\mathcal{C}$ is a full trio with decidable emptiness problem, then given a VAS language L and a language K from $\mathcal{C}$, it is decidable whether $K^* \subseteq F(L)$.*

Here, $\Sigma^* \subseteq F(L)$ is the special case where $K = \Sigma$. Recall that is is undecidable whether $L = \Sigma^*$ for VAS languages and for one-counter languages (OCL) (e.g. [15, Lemma 6.1]).

Similar to Theorem 4.8, deciding whether $\Sigma^* \subseteq F(L)$ is already undecidable for OCL L: For a given OCL $L \subseteq \Sigma^*$, pick a letter $c \notin \Sigma$ and note that $L' = c(Lc)^* \subseteq (\Sigma \cup \{c\})^*$ is effectively an OCL and $(\Sigma \cup \{c\})^* \subseteq F(L')$ if and only if $L = \Sigma^*$. Also, under the assumptions of the theorem, it is undecidable whether $K \subseteq F(L)$: If $L \subseteq \Sigma^*$ and $c \notin \Sigma$, then $c\Sigma^* c \subseteq F(cLc)$ if and only if $L = \Sigma^*$ (every full trio contains the regular set $c\Sigma^* c$).

Let us see how Theorem 4.11 follows from Theorem 3.1. Fix a language K from $\mathcal{C}$. We use the 1-dim. predicate $\mathfrak{p}_{\mathsf{fu}}$, which is satisfied on a set $L \subseteq \Sigma^*$ if and only if $K^* \subseteq F(L)$. Of course, axiom (i) holds by definition. Axiom (iii) follows by contraposition: Suppose that $K^* \subseteq F(L_1 L_2)$ and $K^* \not\subseteq F(L_1)$ with some $u \in K^* \setminus F(L_1)$. Let $v \in K^*$ be arbitrary. Then, since $K^* \subseteq F(L_1 L_2)$, we have $uv \in F(L_1 L_2)$. This means, there are $x, y \in \Sigma^*$ with $xuvy \in L_1 L_2$. Hence, we have $xuvy = w_1 w_2$ for some $w_i \in L_i$ for $i = 1, 2$. Then $|w_1| < |xu|$, because otherwise u would belong to $F(L_1)$. Therefore, v is a factor of w_2 and thus $v \in F(L_2)$. Hence, $K^* \subseteq F(L_2)$. Of course, a similar argument works if $K^* \subseteq F(L_1 L_2)$ and $K^* \not\subseteq F(L_2)$. This proves axiom (iii). Axiom (ii) can be shown the same way. Thus, by Theorem 3.1, it suffices to decide whether $K^* \subseteq F(R)$ for regular R, which follows from the fact that $\mathcal{C}$ is a full trio and has decidable emptiness.

5 Proof of the main result

We prove our decidability result using the KLMST decomposition. More specifically, we show a consequence that might be interesting in its own right.

▶ **Theorem 5.1.** *Given a VAS language $L \subseteq \Sigma^*$, one can compute $m, k \in \mathbb{N}$ and regular languages $R_{i,j} \subseteq \Sigma^*$, for $i \in [1, m]$, $j \in [1, k]$ so that*

$$L \subseteq \bigcup_{i=1}^{m} R_{i,1} \cdots R_{i,k} \qquad \text{and} \qquad R_{i,1} \times \cdots \times R_{i,k} \subseteq F_k(L) \text{ for every } i \in [1, m]. \tag{1}$$

We first show how to derive Theorem 3.1 from Theorem 5.1 and then proceed with the proof of Theorem 5.1, as it is much more technically complicated.

Proof of Theorem 3.1. Suppose Theorem 5.1 holds. Then, given a VAS language L, we compute $m, k \in \mathbb{N}$ and the regular languages $R_{i,j}$ for $i \in [1, m], j \in [1, k]$. We choose $R = \bigcup_{i=1}^{m} R_{i,1} \cdots R_{i,k}$. Then we have $L \subseteq R$. Let us show that $\mathfrak{p}(F_n(L))$ if and only if $\mathfrak{p}(F_n(R))$. If $\mathfrak{p}(F_n(L))$, then clearly $\mathfrak{p}(F_n(R))$, because $L \subseteq R$ implies $F_n(L) \subseteq F_n(R)$ and by axiom (i), this implies $\mathfrak{p}(F_n(R))$. Conversely, suppose $\mathfrak{p}(F_n(R))$. Then by axiom (ii), there is an $i \in [1, m]$ such that $\mathfrak{p}(F_n(R_i))$, where $R_i = R_{i,1} \cdots R_{i,k}$. According to axiom (iii), we can write $n = n_1 + \cdots + n_k$ such that $\mathfrak{p}$ holds for $S := F_{n_1}(R_{i,1}) \times \cdots \times F_{n_k}(R_{i,k})$. Note that by the choice of $R_{i,j}$, we have $R_{i,1} \times \cdots \times R_{i,k} \subseteq F_k(L)$ and therefore $S \subseteq F_n(L)$. This implies $\mathfrak{p}(F_n(L))$ by axiom (i).

Proof of Theorem 5.1. The remainder of this section is devoted to the proof of Theorem 5.1. Like the method for computing downward closures by Habermehl, Meyer, and Wimmel [28], the construction of the sets $R_{i,j}$ is based on Lambert's proof [38] of the decidability of the reachability problem for Petri nets. In order to be compatible with Lambert's exposition, we phrase our proof in terms of Petri nets instead of vector addition systems.

A *Petri net* $N = (P, T, \text{PRE}, \text{POST})$ consists of a finite set P of *places*, a finite set T of *transitions* and two mappings $\text{PRE}, \text{POST}\colon T \to \mathbb{N}^P$. Configurations of Petri net are elements of $\mathbb{N}^P$, called *markings*. For two markings M, M' we say that M' *dominates* M, denoted $M \leq M'$, if for every place $p \in P$, we have $M[p] \leq M'[p]$. The *effect* of a transition $t \in T$ is $\text{POST}(t) - \text{PRE}(t) \in \mathbb{Z}^P$, denoted $\Delta(t)$. If a marking M dominates $\text{PRE}(t)$ for a transition $t \in T$ then t is *fireable* in M and the result of firing t in marking M is $M' = M + \Delta(t)$, we write $M \xrightarrow{t} M'$. We extend notions of fireability and firing naturally to sequences of transitions, we also write $M \xrightarrow{w} M'$ for $w \in T^*$. The *effect* of $w \in T^*$ is sum of the effects of its letters, $\Delta(w) = \sum_{i=1}^{|w|} \Delta(w[i])$. For a Petri net $N = (P, T, \text{PRE}, \text{POST})$ and markings M_0, M_1, we define the language $L(N, M_0, M_1) = \{w \in T^* \mid M_0 \xrightarrow{w} M_1\}$. Hence, $L(N, M_0, M_1)$ is the set of transition sequences leading from M_0 to M_1. Moreover, let $L(N, M_0) = \bigcup_{M \in \mathbb{N}^P} L(N, M_0, M)$, i.e. the set of all the transition sequences fireable in M_0. A *labeled Petri net* is a Petri net $N = (P, T, \text{PRE}, \text{POST})$ together with an *initial marking* M_I, a *final marking* M_F, and a *labeling*, i.e. a homomorphism $h : T^* \to \Sigma^*$. The language *recognized by* the labeled Petri net is then defined as $L_h(N, M_I, M_F) = h(L(N, M_I, M_F))$.

It is folklore (and easy to see) that a language is a VAS language if and only if it is recognized by a labeled Petri net (and the translation is effective). Thus, it suffices to show Theorem 5.1 for languages of the form $L = h(L(N, M_I, M_F))$. Moreover, it is already enough to prove Theorem 5.1 for languages of the form $L(N, M_I, M_F)$. Indeed, observe that if we have constructed $R_{i,j}$ so that Eq. (1) is satisfied, then with $S_{i,j} = h(R_{i,j})$, we have $h(L) \subseteq \bigcup_{i=1}^{m} S_{i,1} \cdots S_{i,k}$ and $S_{i,1} \times \cdots \times S_{i,k} \subseteq F_k(h(L))$ for every $i \in [1, m]$. Thus from now on, we assume $L = L(N, M_I, M_F)$ for a fixed Petri net $N = (P, T, \text{PRE}, \text{POST})$.

The KLMST decomposition. Lambert's decision procedure [38] is a refinement of the previous ones by Mayr [43] and Kosaraju [37]. Leroux and Schmitz [39] recast it as an algorithm using WQO ideals and dubbed it *KLMST decomposition* after its inventors [37, 38, 43, 48].

The idea is the following. We disregard for a moment that a transition sequence has to keep all intermediate markings non-negative and only look for a sequence that may go negative on the way. It is standard technique to express the existence of such a sequence as a linear equation system $Ax = b$. As expected, solvability of this system is not sufficient for the existence of an actual run. However, if we are in the situation that we can find (a) runs that pump up all coordinates arbitrarily high and also (b) counterpart runs that remove those excess tokens again, then solvability of the equation system is also sufficient: We first increase all coordinates high enough, then we execute our positivity-ignoring sequence, and then we pump down again. Roughly speaking, the achievement of the KLMST decomposition is to put us in the latter situation, which we informally call *perfect circumstances*.

To this end, one uses a data structure, in Lambert's version called *marked graph-transition sequence (MGTS)*, which restricts the possible runs of the Petri net. If the MGTS satisfies a condition that realizes the above perfect circumstances, then it is called *perfect*. Unsurprisingly, not every MGTS is perfect. However, part of the procedure is a decomposition of an imperfect MGTS into finitely many MGTS that are less imperfect. Moreover, this decomposition terminates in a finite set of perfect MGTS. Thus, applied to an MGTS whose restriction is merely to start in M_I and end in M_F, then the decomposition yields finitely many perfect MGTS $\mathcal{N}_1, \ldots, \mathcal{N}_n$ such that the runs from M_I to M_F are precisely those conforming to at least one of the MGTS. Moreover, checking whether $\mathcal{N}_i$ admits a run amounts to solving a linear equation system.

Basic notions. Let us introduce some notions used in Lambert's proof. We extend the set of configurations $\mathbb{N}^d$ into $\overline{\mathbb{N}}^d$. We extend the notion of transition firing into $\overline{\mathbb{N}}^d$ naturally, by defining $\omega - k = \omega = \omega + k$ for every $k \in \mathbb{N}$. For $u, v \in \overline{\mathbb{N}}^d$ we write $u \leq_\omega v$ if $u[i] = v[i]$ or $v[i] = \omega$. Intuitively reaching a configuration with ω at some places means that it is possible to reach configurations with values ω substituted by arbitrarily high values.

A key notion in [38] is that of MGTS, which formulate restrictions on paths in Petri nets. A *marked graph-transition sequence (MGTS)* for our Petri net $N = (P, T, \text{Pre}, \text{Post})$ is a finite sequence $C_0, t_1, C_1 \dots C_{n-1}, t_n, C_n$, where t_i are transitions from T and C_i are precovering graphs, which are defined next. A *precovering graph* is a quadruple $C = (G, m, m^{\text{init}}, m^{\text{fin}})$, where $G = (V, E, h)$ is a finite, strongly connected, directed graph with $V \subseteq \overline{\mathbb{N}}^P$ and labeling $h\colon E \to T$, and three vectors: a *distinguished* vector $m \in V$, an *initial* vector $m^{\text{init}} \in \overline{\mathbb{N}}^P$, and a *final* vector $m^{\text{fin}} \in \overline{\mathbb{N}}^P$. A precovering graph has to meet two conditions: First, for every edge $e = (m_1, m_2) \in E$, there is an $m_3 \in \overline{\mathbb{N}}^P$ with $m_1 \xrightarrow{h(e)} m_3 \leq_\omega m_2$. Second, we have $m^{\text{init}}, m^{\text{fin}} \leq_\omega m$. Additionally we impose the restriction on MGTS that the initial vector of C_0 equals M_I and the final vector of C_n equals M_F.

Languages of MGTS. Each precovering graph can be treated as a finite automaton. For $m_1, m_2 \in V$, we denote by $L(C, m_1, m_2)$ the set of all $w \in T^*$ read on a path from m_1 to m_2. Moreover, let $L(C) = L(C, m, m)$. MGTS have associated languages as well. Let $\mathcal{N} = C_0, t_1, C_1 \dots C_{n-1}, t_n, C_n$ be an MGTS of a Petri net N, where $C_i = (G_i, m_i, m_i^{\text{init}}, m_i^{\text{fin}})$. Its language $L(\mathcal{N})$ is the set of all words of the form $w = w_0 t_1 w_1 \cdots w_{n-1} t_n w_n \in T^*$ where: $w_i \in L(C_i)$ for each $i \in [0, n]$ and (ii) there exist markings $\mu_0, \mu_0', \mu_1, \mu_1', \dots, \mu_n, \mu_n' \in \mathbb{N}^P$ such that $\mu_i \leq_\omega m_i^{\text{init}}$ and $\mu_i' \leq_\omega m_i^{\text{fin}}$ and $\mu_0 \xrightarrow{w_0} \mu_0' \xrightarrow{t_1} \mu_1 \xrightarrow{w_1} \dots \xrightarrow{w_{n-1}} \mu_{n-1}' \xrightarrow{t_n} \mu_n \xrightarrow{w_n} \mu_n'$. Notice that by (ii) and the restriction that $m_0^{\text{init}} = M_I$ and $m_n^{\text{fin}} = M_F$, we have $L(\mathcal{N}) \subseteq L(N, M_I, M_F)$ for any MGTS $\mathcal{N}$.

Hence roughly speaking, $L(\mathcal{N})$ is the set of runs that contain the transitions $t_1, \dots, t_n$ and additionally markings before and after firing these transitions are prescribed on some places: this is exactly what the restrictions $\mu_i \leq_\omega m_i^{\text{init}}$, $\mu_i' \leq_\omega m_i^{\text{fin}}$ impose.

Notice that at the moment we do not expect that values ω occurring at $m_i, m_i^{\text{init}}, m_i^{\text{fin}}$ impose any restriction on the form of accepted runs. Meaning of ω values is reflected in the notion of *perfect* MGTS described later. As an immediate consequence of the definition, we observe that for every MGTS $\mathcal{N} = C_0, t_1, C_1 \dots C_{n-1}, t_n, C_n$ we have

$$L(\mathcal{N}) \subseteq L(C_0) \cdot \{t_1\} \cdot L(C_1) \cdots L(C_{n-1}) \cdot \{t_n\} \cdot L(C_n). \tag{2}$$

Perfect MGTS. As announced above, Lambert calls MGTS with a paricular property *perfect* [38]. Since the precise definition is involved and we do not need all the details, it is enough for us to mention a selection of properties of perfect MGTS. Intuitively, in perfect MGTSes, the value ω on place p in m_i means that inside of the component C_i, the token count in place p can be made arbitrarily high. In [38] it is shown (Theorem 4.2 (page 94) together with the preceding definition) that

▶ **Theorem 5.2** ([38]). *For a Petri net N one can compute finitely many perfect MGTS $\mathcal{N}_1, \dots, \mathcal{N}_m$ such that $L(N, M_I, M_F) = \bigcup_{i=1}^m L(\mathcal{N}_i)$.*

Moreover, by Corollary 4.1 in [38] (page 93), given a perfect MGTS $\mathcal{N}$, it is decidable whether $L(\mathcal{N}) \neq \emptyset$. Therefore, our task reduces to the following. We have a perfect MGTS $\mathcal{N}$ with $L(\mathcal{N}) \neq \emptyset$ and want to compute regular languages $R_1, \dots, R_k$ such that $L(\mathcal{N}) \subseteq R_1 \cdots R_k$ and $R_1 \times \cdots \times R_k \subseteq F_k(L(\mathcal{N}))$. (Note that if the MGTS have

different lengths, we can always fill up with $\{\varepsilon\}$). We choose $R_1, \ldots, R_k$ to be the sequence $L(C_0), \{t_1\}, L(C_1), \ldots, L(C_{n-1}), \{t_n\}, L(C_n)$. Then Eq. (2) tells us that this achieves $L(\mathcal{N}) \subseteq R_1 \cdots R_k$ and all that remains to be shown is

$$L(C_0) \times \{t_1\} \times L(C_1) \times \cdots \times L(C_{n-1}) \times \{t_n\} \times L(C_n) \subseteq F_{2n+1}(L(\mathcal{N})). \tag{3}$$

Constructing runs. In order to show Eq. (3), we employ a simplified version of Lambert's iteration lemma, which involves covering sequences. Let C be a precovering graph for a Petri net $N = (P, T, \textsc{Pre}, \textsc{Post})$ with a distinguished vector $m \in \overline{\mathbb{N}}^P$ and initial vector $m^{\text{init}} \in \overline{\mathbb{N}}^P$. A sequence $u \in L(C) \cap L(N, m^{\text{init}})$ is called a *covering sequence for* C if for every place $p \in P$ we have either 1) $m^{\text{init}}[p] = \omega$, or 2) $m[p] = m^{\text{init}}[p]$ and $\Delta(u)[p] = 0$, or 3) $m[p] = \omega$ and $\Delta(u)[p] > 0$. This corresponds intuitively to the three possible cases for the set of runs in N crossing the component C in a place p: (i) runs that can have arbitrarily high value on p when entering C, (ii) runs where, when entering C, p has a fixed value, and the tokens in p cannot be pumped inside of C, or (iii) runs where, when entering C, p has a fixed value, but it can be pumped up inside of C.

Let $\mathcal{N} = C_0, t_1, C_1 \ldots C_{n-1}, t_n, C_n$ be an MGTS, where $C_i = (V_i, E_i, h_i)$ is a precovering graph, and let the distinguished vertex be m_i and initial vertex be m_i^{init}. If $\mathcal{N}$ is a perfect MGTS then according to the definition from [38] (page 92), for every $i \in [0, n]$ there exists a covering sequence $u_i \in L(C_i) \cap L(N, m_i^{\text{init}})$. This corresponds to the mentioned intuition that ω values imply arbitrarily high values. As a direct consequence of Lemma 4.1 in [38] (page 92), Lambert's iteration lemma, we obtain:

▶ **Lemma 5.3.** *Let $\mathcal{N} = C_0, t_1, C_1 \ldots C_{n-1}, t_n, C_n$ be a perfect MGTS and let x_i be a covering sequences for C_i for $i \in [0, n]$. Then there exist words $y_i \in T^*$ for $i \in [0, n]$ such that $x_0 y_0 \cdot t_1 \cdot x_1 y_1 \cdots x_{n-1} y_{n-1} \cdot t_n \cdot x_n y_n \in L(\mathcal{N})$.*

Lemma 5.3 is obtained from Lemma 4.1 in [38] as follows. The word u_i there is our x_i and v_i there is an arbitrary covering sequence of C_i reversed. Then, our y_i is set to $u_i^{k-1} \beta_i(w_i)^k (v_i)^k$ for some $k \geq k_0$. The only technical part of the proof of Theorem 5.1 is the following lemma.

▶ **Lemma 5.4.** *Let C be a precovering graph for a Petri net $N = (P, T, \textsc{Pre}, \textsc{Post})$ with a distinguished vector $m \in \overline{\mathbb{N}}^P$ and initial vector $m^{\text{init}} \in \overline{\mathbb{N}}^P$ such that $s \in L(C) \cap L(N, m^{\text{init}})$ is a covering sequence. Then for every $v \in L(C)$ there is a covering sequence for C of the form uv, for some $u \in T^*$.*

Proof. Intuitively, we do the following. The existence of a covering sequence means that one can obtain arbitrarily high values on places p where $m[p] = \omega$. Thus, in order to construct a covering sequence containing v as a suffix, we first go very high on the ω places, so high that adding v as a suffix later will still result in a sequence with positive effect.

Let us make this precise. Executing the sequence v might have a negative effect in a place $p \in P$ with $m[p] = \omega$. Let $k \in \mathbb{N}$ be the largest possible negative effect a prefix of v can have in any coordinate. Note that since s is a covering sequence, s^k is a covering sequence as well. We claim that $s^k v$ is also a covering sequence. It is contained in $L(C)$ and fireable at m^{init}. Moreover, by choice of k, the sequence $s^k v$ has a positive effect on each p with $m[p] = \omega$. If $m[p] < \omega$, then $\Delta(s)[p] = 0 = \Delta(v)[p]$ and hence $\Delta(s^k v)[p] = 0$. ◀

Using Lemma 5.3 and Lemma 5.4, it is now easy to show Eq. (3). Given words $v_i \in T^*$ with $v_i \in L(C_i)$ for $i \in [0, n]$, we use Lemma 5.4 to choose $x_i \in T^*$ such that $x_i v_i$ is a covering sequence of C_i for $i \in [0, n]$. By Lemma 5.3, we can find $w_1, \ldots, w_n$ so that the word $x_0 v_0 w_0 \cdot t_1 \cdot x_1 v_1 w_1 \cdots x_{n-1} v_{n-1} w_{n-1} \cdot t_n \cdot x_n v_n w_n$ belongs to $L(\mathcal{N})$, and thus $(v_0, t_1, v_1, \ldots, v_{n-1}, t_n, v_n) \in F_{2n+1}(L(\mathcal{N}))$, which proves Eq. (3).

Abstract

Recently it was shown that the transitive closure of a directed graph can be updated using first-order formulas after insertions and deletions of single edges in the dynamic descriptive complexity framework by Dong, Su, and Topor, and Patnaik and Immerman. In other words, Reachability is in DynFO.

In this article we extend the framework to changes of multiple edges at a time, and study the Reachability and Distance queries under these changes. We show that the former problem can be maintained in DynFO$(+,\times)$ under changes affecting $\mathcal{O}(\frac{\log n}{\log\log n})$ nodes, for graphs with n nodes. If the update formulas may use a majority quantifier then both Reachability and Distance can be maintained under changes that affect $\mathcal{O}(\log^c n)$ nodes, for fixed $c \in \mathbb{N}$. Some preliminary results towards showing that distances are in DynFO are discussed.

1 Introduction

In today's databases, data sets are often large and subject to frequent changes. In use cases where only a fixed set of queries has to be evaluated on such data, it is not efficient to re-evaluate queries after each change, and therefore dynamic approaches have been considered. The idea is that when a database $\mathcal{D}$ is modified by changing a set $\Delta\mathcal{D}$ of tuples then the result of a query is recomputed by using its result on $\mathcal{D}$, the set $\Delta\mathcal{D}$, and possibly other previously computed auxiliary data.

One such dynamic approach is the *dynamic descriptive complexity* approach, formulated independently by Dong, Su, and Topor [8], as well as Patnaik and Immerman [19]. In their framework the query result and the auxiliary data are represented by relations, and updates of the auxiliary relations are performed by evaluating first-order formulas. The class of queries that can be maintained in this fashion constitutes the class DynFO. The motivation to use first-order logic as the vehicle for updates is that its evaluation is highly parallelizable and, in addition, that it corresponds to the relational algebra which is the core of SQL. Hence, if a query result can be maintained using a first-order update program, this program can be translated into equivalent SQL queries.

While it is desirable to understand how to update query results under complex changes $\Delta\mathcal{D}$, the focus of dynamic descriptive complexity so far has been on single tuple changes. The reason is that for many queries our techniques did not even suffice to tackle this case.

In recent years, however, we have seen several new techniques for maintaining queries. The Reachability query – one of the main objects of study in dynamic descriptive complexity – has been shown to be in DynFO using a linear algebraic method and a simulation technique [4]. The latter has been advanced into a very powerful tool: for showing that a query can be maintained in DynFO, it essentially suffices to show that it can be maintained for $\log n$ many change steps after initializing the auxiliary data by an AC^1 pre-computation[1] [5], where n is the size of the database's (active) domain. This tool has been successfully applied to show that all queries expressible in monadic second order logic can be maintained in DynFO on structures of bounded treewidth.

Those new techniques motivate a new attack on more complex changes $\Delta\mathcal{D}$. But what are reasonable changes to look at? Updating a query after a change $\Delta\mathcal{D}$ that replaces the whole database by a new database is essentially equivalent to the static evaluation problem with built-in relations: the stored auxiliary data has to be helpful for every possible new database, and therefore plays the role of built-in relations. Thus changes should be restricted in some way. Three approaches come to mind immediately: to only allow changes of restricted size; to restrict changes structurally; or to define changes in a declarative way.

In this article we focus on the first approach. Before discussing our results we shortly outline the other two approaches.

There is a wide variety of structural restrictions. For example, the change set $\Delta\mathcal{D}$ could only change the database locally or in such a way that the changes affect auxiliary relations only locally, e.g., if edges are inserted into distinct connected components it should be easier to maintain reachability. Another option is to restrict $\Delta\mathcal{D}$ to be of a certain shape, examples studied in the literature are cartesian-closed changes [8] and deletions of anti-chains [7].

A declarative mechanism for changing a database is to provide a set of parameterised rules that state which tuples should be changed depending on a parameter provided by a user. For example, a rule $\rho(x, y; z)$ could state that all edges (x, y) shall be inserted into a

[1] Readers not familiar with the circuit class AC^1 may safely think of LOGSPACE pre-computations.

graph such that x and y are connected to the parameter z. First-order logic as a declarative mean to change databases has been studied in [20], where it was shown that undirected reachability can be maintained under insertions defined by first-order formulas, and single tuple deletions.

In this article we study changes of small size with a focus on the Reachability and Distance queries. As can be seen from the discussion above, the former query has been well-studied in diverse settings of dynamic descriptive complexity, and therefore results on its maintainability under small changes serve as an important reference point.

There is another reason to study Reachability under non-constant size changes. Recall that Reachability is complete for the static complexity class NL. The result that Reachability is in DynFO does not imply NL $\subseteq$ DynFO, as DynFO is only known to be closed under very weak reductions, called bounded first-order reductions, under which Reachability is not NL-complete [19]. In short, these reductions demand that whenever a bit of an instance is changed, then only constantly many bits change in the image of the instance under the reduction. When a query such as Reachability is maintainable under larger changes, then this restriction may be relaxed and might yield new maintainability results for other queries under single edge changes.

In this work we show that Reachability can be maintained under changes of non-constant size. Since our main interest is the study of changes of non-constant size, we assume throughout the article that all classes come with built-in arithmetic and denote, e.g., by DynFO$(+,\times)$ the class of queries that can be maintained with first-order updates in the presence of a built-in linear addition and multiplication relations. How our results can be adapted to classes without built-in arithmetic is discussed towards the end of Section 3.

▶ **Theorem 1.** *Reachability can be maintained in* DynFO$(+,\times)$ *under changes that affect* $\mathcal{O}(\frac{\log n}{\log\log n})$ *nodes of a graph, where n is the number of nodes of the graph.*

The distance query was shown to be in DynFO+Maj by Hesse [13], where the class DynFO+Maj allows to specify updates with first-order formulas that may include majority quantifiers (equivalently, updates can be specified by uniform TC^0 computations). We generalize Hesse's result to changes of size polylogarithmic in the size of the domain.

▶ **Theorem 2.** *Reachability and Distance can be maintained in* DynFO+Maj$(+,\times)$ *under changes that affect* $\mathcal{O}(\log^c n)$ *nodes of a graph, where $c \in \mathbb{N}$ is fixed and n is the number of nodes of the graph.*

One of the important open questions of dynamic descriptive complexity is whether distances can be maintained in DynFO, even under single edge changes. We contribute to the solution of this question by discussing how distances can be maintained in a subclass of DynFO+Maj$(+,\times)$ that is only slightly stronger than DynFO$(+,\times)$.

Organization

After recapitulating notations in Section 2, we adapt the dynamic complexity framework to bulk changes in Section 3. Our main results, maintainability of reachability and distances under multiple changes, are proved in Section 4 and Section 5. We conclude with a discussion in Section 6.

2 Preliminaries

In this section we review basic definitions and results from finite model theory and databases.

We consider finite relational structures over relational signatures $\tau = \{R_1, \ldots, R_\ell\}$, where each R_i is a relational symbol of arity $\mathrm{Ar}(R_i)$. A τ-structure $\mathcal{D}$ consists of a finite domain D and relations $R_i^{\mathcal{D}}$ over D of arity $\mathrm{Ar}(R_i)$, for each $i \in \{1, \ldots, \ell\}$. The *active domain* $\mathrm{adom}(\mathcal{D})$ of a structure $\mathcal{D}$ contains all elements used in some tuple of $\mathcal{D}$. Since the motivation to study dynamic complexity originates from database theory, we use terminology from this area. In particular we use the terms "relational structure" and "relational database" synonymously.

We study the queries Reachability and Distance. Reachability asks, given a directed graph G, for all pairs s, t of nodes such that there is a path from s to t in G. Distance asks for the length of the shortest path between any pair of reachable nodes.

We assume familiarity with first-order logic FO and refer to [16] for an introduction. The logic FO+Maj extends FO by allowing majority quantifiers. Such quantifiers can ask whether more than half of all elements satisfy a given formula. We write FO(+,×) and FO+Maj(+,×) to denote that formulas have access to built-in relations $\leq, +, \times$ which are interpreted as linear order, addition and multiplication on the domain of the underlying structure. We note that FO(+,×) and FO+Maj(+,×) are equal to the circuit classes (DLOGTIME-)uniform AC^0 and TC^0, respectively [2].

In FO(+, ×), each tuple $(a_1, \ldots, a_c)$ encodes a number from $[n^c - 1]_0 \stackrel{\text{def}}{=} \{0, \ldots n^c - 1\}$. We will henceforth identify tuples over the domain and numbers.

It is well-known that FO(+, ×) supports arithmetic on numbers with polylog bits. Furthermore, iterated addition and multiplication for polylog many numbers with polylog bits can be expressed in FO(+, ×). More precisely:

▶ **Lemma 3** (cf. [14, Theorem 5.1]). *Suppose φ is a* FO(+, ×) *formula that defines $r \in \mathcal{O}(\log^c n)$ polylog bit numbers $a_1, \ldots, a_r$, then there are formulas ψ_+ and $\psi_\times$ that define the sum and product of $a_1, \ldots, a_r$, respectively.*

Due to these facts, many calculations can be defined in FO(+, ×). In particular, primes can be identified, and $\frac{\log n}{\log \log n}$ numbers of $\log \log n$ bits each can be encoded and decoded in $\log n$ bit numbers.

Suppose $p_1, \ldots, p_m$ are primes whose product is N. Then each number $A < N$ can be uniquely represented as a tuple $\bar{a} = (a_1, \ldots, a_m)$ where $a_i = A \mod p_i$. The tuple $\bar{a}$ is called *Chinese remainder representation* (CRR) of A. The number A can recovered from $\bar{a}$ via $A = \sum_i a_i h_i C_i - rN$, where $C_i = \frac{N}{m_i}$, h_i is the inverse of C_i modulo m_i, and $r = \sum_{i=1}^{m} \lfloor \frac{x_i h_i}{m_i} \rfloor$ [14, p. 702]. Due to Lemma 3, in FO(+, ×) one can encode and decode $\mathcal{O}(\log n)$ bit numbers into their CRR defined by $\mathcal{O}(\log n)$ primes with $\mathcal{O}(\log \log n)$ bits.

In this article we use basic notions and results from linear algebra which are introduced when they are needed. Throughout the article, a matrix with $\mathcal{O}(n^d)$ rows and columns and entries in $[n^c]_0$ will be represented by a relation R that contains a tuple $(\bar{r}, \bar{c}, \bar{v})$ if and only if the value at row $\bar{r}$ and column $\bar{c}$ is $\bar{v}$.

3 Dynamic Framework for Multiple Changes

We briefly repeat the essentials of dynamic complexity, closely following [21], and discuss generalisations due to changes of non-constant size.

The goal of a dynamic program is to answer a given query on an *input database* subjected to changes that insert or delete tuples. The program may use an auxiliary data structure represented by an *auxiliary database* over the same domain. Initially, both input and auxiliary database are empty; and the domain is fixed during each run of the program.

Changes. In previous work, changes of single tuples have been represented as explicit parameters for the formulas used to update the auxiliary relations. Non-constant size changes cannot be represented in this fashion. An alternative is to represent changes implicitly by giving update formulas access to the old input database as well as to the changed input database [11]. Here, we opt for this approach.

For a database $\mathcal{D}$ over domain D and schema τ, a change $\Delta\mathcal{D}$ consists of sets R^+ and R^- of tuples for each relation symbol $R \in \tau$. The result $\mathcal{D} + \Delta\mathcal{D}$ of an application of the change $\Delta\mathcal{D}$ to $\mathcal{D}$ is the input database where $R^{\mathcal{D}}$ is changed to $(R^{\mathcal{D}} \cup R^+) \setminus R^-$. The *size* of $\Delta\mathcal{D}$ is the total number of tuples in relations R^+ and R^- and the set of *affected elements* is the (active) domain of tuples in $\Delta\mathcal{D}$.

Dynamic Programs and Maintenance of Queries. A dynamic program consists of a set of update rules that specify how auxiliary relations are updated after changing the input database. An *update rule* for updating an ℓ-ary auxiliary relation T after a change is a first-order formula φ over schema $\tau \cup \tau_{\text{aux}}$ with ℓ free variables, where τ_{aux} is the schema of the auxiliary database. After a change $\Delta\mathcal{D}$, the new version of T is $T \stackrel{\text{def}}{=} \{\vec{a} \mid (\mathcal{D} + \Delta\mathcal{D}, \mathcal{A}) \models \varphi(\vec{a})\}$ where $\mathcal{D}$ is the old input database and $\mathcal{A}$ is the current auxiliary database. Note that a dynamic program can choose to have access to the old input database by storing it in its auxiliary relations.

For a state $\mathcal{S} = (\mathcal{D}, \mathcal{A})$ of the dynamic program $\mathcal{P}$ with input database $\mathcal{D}$ and auxiliary database $\mathcal{A}$ we denote the state of the program after applying a change sequence α and updating the auxiliary relations accordingly by $\mathcal{P}_\alpha(\mathcal{S})$.

The dynamic program *maintains* a q-ary query $\mathcal{Q}$ under changes that affect k elements (under changes of size k, respectively) if it has a q-ary auxiliary relation Q that at each point stores the result of $\mathcal{Q}$ applied to the current input database. More precisely, for each non-empty sequence α of changes that affect k elements (changes of size k, respectively), the relation Q in $\mathcal{P}_\alpha(\mathcal{S}_\emptyset)$ and $\mathcal{Q}(\alpha(\mathcal{D}_\emptyset))$ coincide, where $\mathcal{D}_\emptyset$ is an empty input structure, $\mathcal{S}_\emptyset$ is the auxiliary database with empty auxiliary relations over the domain of $\mathcal{D}_\emptyset$, and $\alpha(\mathcal{D}_\emptyset)$ is the input database after applying α.

If a dynamic program maintains a query, we say that the query is in DynFO. Similarly to DynFO one can define the class of queries DynFO$(+, \times)$ that allows for three particular auxiliary relations that are initialised as a linear order and the corresponding addition and multiplication relations. Other classes are defined accordingly.

For many natural queries $\mathcal{Q}$, in order to show that $\mathcal{Q}$ can be maintained, it is enough to show that the query can be maintained for a bounded number of steps. Intuitively, this is possible for queries for which isolated elements do not influence the query result, if there are many such elements. Formally, a query $\mathcal{Q}$ is *almost domain-independent* if there is a $c \in \mathbb{N}$ such that $\mathcal{Q}(\mathcal{A}) \restriction (\text{adom}(\mathcal{A}) \cup B) = \mathcal{Q}(\mathcal{A} \restriction (\text{adom}(\mathcal{A}) \cup B))$ for all structures $\mathcal{A}$ and sets $B \subseteq A \setminus \text{adom}(\mathcal{A})$ with $|B| \geq c$.

A query $\mathcal{Q}$ is $(\mathcal{C}, f)$-*maintainable*, for some complexity class $\mathcal{C}$ and some function $f : \mathbb{N} \to \mathbb{R}$, if there is a dynamic program $\mathcal{P}$ and a $\mathcal{C}$-algorithm $\mathbb{A}$ such that for each input database $\mathcal{D}$ over a domain of size n, each linear order $\leq$ on the domain, and each change sequence α of length $|\alpha| \leq f(n)$, the relation Q in $\mathcal{P}_\alpha(\mathcal{S})$ and $\mathcal{Q}(\alpha(\mathcal{D}))$ coincide, where $\mathcal{S} = (\mathcal{I}, \mathbb{A}(\mathcal{I}, \leq))$.

The following theorem is a slight adaption of Theorem 3 from [5] and can be proved analogously.

▶ **Theorem 4.** *Every* $(\text{AC}^i, \log^i n)$*-maintainable, almost domain-independent query is in* DynFO$(+, \times)$.

The Role of the Domain and Arithmetic. In order to focus on the study of changes of non-constant size, we choose a simplified approach and include arithmetic in our setting. We state our results for DynFO(+, ×) and according classes to make it clear that we assume the presence of a linear order, addition and multiplication relation on the whole domain at all times.[2]

We shortly discuss the consequences of not assuming built-in arithmetic on our results. For single tuple changes, the presence of built-in arithmetic essentially gives no advantage.

▶ **Proposition 5** ([4, Theorem 4], formulation from [5, Proposition 2]). *If a query* $\mathcal{Q} \in$ DynFO(+, ×) *under single-tuple changes is almost domain-independent, then also* $\mathcal{Q} \in$ DynFO.

This result relies on the fact that one can maintain a linear order and arithmetic on the activated domain in DynFO under single-tuple changes [9], that is, on all elements that were in the active domain at some point of time. Under larger changes this is a priori not possible, as then one has to express in FO a linear order and arithmetic on the elements that enter the active domain.

An alternate approach to assuming the presence of built-in arithmetic is to demand that changes *provide* additional information on the changed elements, for example, that they provide a linear order and arithmetic on the domain of the change. Using this approach, our results can be stated in terms of DynFO and DynFO+Maj with the sole modification that sizes of changes are given relative to the size of the activated domain instead of with respect to the size of the whole domain. In this fashion our results also translate to the setting of first-order incremental evaluation systems of Dong, Su, and Topor [8], where the domain can grow and shrink.

4 Reachability under Multiple Changes

In this section we prove that Reachability can be maintained under multiple changes.

▶ **Theorem 1.** *Reachability can be maintained in* DynFO(+, ×) *under changes that affect* $\mathcal{O}(\frac{\log n}{\log \log n})$ *nodes of a graph, where* n *is the number of nodes of the graph.*

The approach is to use the well-known fact that Reachability can be reduced to the computation of the inverse of a matrix, and to invoke the Sherman-Morrison-Woodbury identity (cf. [12]) to update the inverse. This identity essentially reduces the update of inverses after a change affecting k nodes to the computation of an inverse of a $k \times k$ matrix.

The challenge is to define the updates in FO(+, ×). The key ingredients here are to compute inverses with respect to many primes, and throw away primes for which the inverse does not exist. As, by Theorem 4, it suffices to maintain the inverse for $\log^c n$ many steps for some c to be fixed later (see proof of Theorem 6), some primes remain valid if one starts from sufficiently – but polynomially – many primes. We show that the inverse of $k \times k$ matrices over $\mathbb{Z}_p$ can be defined in FO(+, ×) for $k = \frac{\log n}{\log \log n}$.

Theorem 1 in particular generalizes the result that Reachability can be maintained under single edge changes [4]; our proof is an alternative to the proof presented in the latter work.

[2] Different assumptions have been made in the literature. In [18], Patnaik and Immerman assume only a linear order to be present, while full arithmetic is assumed in [19]. Etessami observed that arithmetic can be built up dynamically, and therefore subsequent work usually assumed initially empty auxiliary relations, see e.g. [4, 5]. In the setting of first-order incremental evaluation systems usually no arithmetic is assumed to be present [8].

In [4], maintenance of Reachability is reduced to the question whether a matrix A has full rank, and it was shown that the rank can be maintained by storing and updating an invertible matrix B and a matrix D from which the rank can be easily extracted, such that $B \cdot A = D$.

4.1 Reachability and Matrix Inverses

There is a path from s to t in a graph G of size n with adjacency matrix A_G if and only if the s-t-entry of the matrix $(nI - A_G)^{-1}$ is non-zero. This follows from the equation $(nI - A_G)^{-1} = \frac{1}{n}\sum_{i=0}^{\infty}(\frac{1}{n}A_G)^i$ and the fact that A_G^i counts the number of paths from s to t of length i. Notice that $A \stackrel{\text{def}}{=} nI - A_G$ is invertible as matrix over $\mathbb{Q}$ for every adjacency matrix A_G since it is strictly diagonally dominant [15, Theorem 6.1.10].

When applying a change ΔG to G that affects k nodes, the adjacency matrix of G is updated by adding a suitable change matrix ΔA with at most k non-zero rows and columns to A. Thus Theorem 1 follows from the following proposition[3].

▶ **Theorem 6.** *When $A \in \mathbb{Z}^{n\times n}$ takes values polynomial in n and is assumed to stay invertible over $\mathbb{Q}$, then non-zeroness of entries of $A^{-1} \in \mathbb{Q}^{n\times n}$ can be maintained in* DynFO$(+,\times)$ *under changes that affect $\mathcal{O}(\frac{\log n}{\log\log n})$ rows and columns.*

Each change affecting $\mathcal{O}(\frac{\log n}{\log\log n})$ rows and columns can be partitioned into constantly many changes that affect $k \stackrel{\text{def}}{=} \frac{\log n}{\log\log n}$ rows and columns. We therefore concentrate on such changes in the following.

The change matrix ΔA for a change affecting k rows and columns has at most k non-zero rows and columns and can therefore be decomposed into a product UBV of suitable matrices U, B, and V, where U, B, and V have dimensions $n \times k$, $k \times k$, and $k \times n$, respectively.

▶ **Lemma 7.** *Fix a ring R. Suppose $M \in R^{n\times n}$ with non-zero rows $r_{i_1}, \dots, r_{i_k}$ and columns $c_{j_1}, \dots, c_{j_k}$. Then $M = UBV$ with $U \in R^{n\times k}, B \in R^{k\times k}$, and $V \in R^{k\times n}$ where*

1. *B is obtained from M by removing all-zero rows and columns.*
2. $U = \begin{pmatrix} \bar{u}_1 \\ \vdots \\ \bar{u}_n \end{pmatrix}$ *where* $\bar{u}_i = \begin{cases} \bar{0}^T & \text{if } i \notin \{i_1, \dots, i_k\} \\ \bar{e}_m^T & \text{if } i = i_m \end{cases}$
3. $V = \begin{pmatrix} \bar{v}_1, \dots, v_n \end{pmatrix}$ *where* $\bar{v}_j = \begin{cases} \bar{0} & \text{if } j \notin \{j_1, \dots, j_k\} \\ \bar{e}_m & \text{if } j = j_m \end{cases}$

Here, $\bar{e}_m$ denotes the m-th unit vector.

By the Sherman-Morrison-Woodbury identity (cf. [12]), the updated inverse can therefore be written as

$$(A + \Delta A)^{-1} = (A + UBV)^{-1} = A^{-1} - A^{-1}U(I + BVA^{-1}U)^{-1}BVA^{-1} \qquad (\star)$$

The inverse of a matrix in $\mathbb{Z}^{n\times n}$ with entries that are polynomial in n is a matrix in $\mathbb{Q}^{n\times n}$ with entries $\frac{a}{b}$ that may involve numbers exponential in n. In particular computations cannot be performed in FO$(+,\times)$ directly. For this reason all computations will be done modulo many primes, and non-zeroness of entries of A^{-1} is extracted from these values.

[3] Due to lack of space some details are hidden here. The described reduction maps the empty graph to the matrix whose diagonal entries are n. Values of the inverse for this matrix cannot be determined in FO, and thus one does not immediately get the desired result for Reachability. This issue can be circumvented by mapping to matrices with only some non-zero entries on the diagonal, and studying the inverse of the matrices induced by non-zero diagonal entries.

Let us first see how to update $(A+\Delta A)^{-1}$ modulo a prime p under the assumption that both $A \pmod p$ and $A+\Delta A \pmod p$ are invertible. Observe that $(I+BVA^{-1}U)^{-1}$ is a $k \times k$ matrix and therefore an essential prerequisite to compute $(A+\Delta A)^{-1} \pmod p$ is to be able to define the inverse of such small matrices. That this is possible follows from the following lemma and the fact that $[D^{-1}]_{ij} = (-1)^{i+j}\frac{\det D_{ji}}{\det D}$ for invertible $D \in \mathbb{Z}_p^{k\times k}$. Here $[C]_{ij}$ denotes the ij-th entry of a matrix C and C_{ji} denotes the submatrix obtained by removing the j-th row and the i-th column.

▶ **Theorem 8.** *Fix a domain of size n and a prime $p \in \mathcal{O}(n^c)$. The value of the determinant of a matrix $A \in \mathbb{Z}_p^{k\times k}$ for $k = \frac{\log n}{\log\log n}$ can be defined in* $\mathrm{FO}(+,\times)$.

The technical proof of this theorem is deferred until the next Subsection 4.2.

That $(A+\Delta A)^{-1} \pmod p$ can defined in $\mathrm{FO}(+,\times)$ using Equation $(\star)$ now is a consequence of a straightforward analysis of the involved matrix operations.

▶ **Proposition 9.** *Fix a domain of size n and a prime $p \in \mathcal{O}(n^c)$. Given the inverse of a matrix $A \in \mathbb{Z}_p^{n\times n}$ and a matrix $\Delta A \in \mathbb{Z}_p^{n\times n}$ with at most $k = \frac{\log n}{\log\log n}$ non-zero rows and columns, one can determine whether $A+\Delta A$ is invertible in* $\mathrm{FO}(+,\times)$ *and, if so, the inverse can be defined.*

Proof. A decomposition of the matrix ΔA into UBV with $U \in \mathbb{Z}_p^{n\times k}, B \in \mathbb{Z}_p^{k\times k}$, and $V \in \mathbb{Z}_p^{k\times n}$ can be defined in $\mathrm{FO}(+,\times)$ using the characterization from Lemma 7. A simple analysis of the right hand side of Equation $(\star)$ – taking the dimensions of U, V, and B into account – yields that $VA^{-1}U$ and therefore $(I+BVA^{-1}U)^{-1}B$ are $k \times k$ matrices. Furthermore, $U(I+BVA^{-1}U)^{-1}BV$ is an $n \times n$ matrix that has at most k non-zero rows and columns.

The only obstacle to invertibility is that the inverse of $D \stackrel{\text{def}}{=} I+BVA^{-1}U$ may not exist in $\mathbb{Z}_p$. This is the case if and only if $\det(D) \equiv 0 \pmod p$ which can be tested using Theorem 8. If D is invertible, then its inverse can be defined by invoking Theorem 8 twice and using $[D]_{ij} = (-1)^{i+j}\frac{\det D_{ji}}{\det D}$.

Finally, if one knows how to compute $(I+BVA^{-1}U)^{-1}$, each entry in $A^{-1}U(I+BVA^{-1}U)^{-1}BV$ can be defined by adding k products of two numbers, and similarly for $(A^{-1}U(I+BVA^{-1}U)^{-1}BV)A^{-1}$. This can be done in $\mathrm{FO}(+,\times)$ due to Lemma 3. ◀

It remains to show how to maintain non-zeroness of entries of $(A+\Delta A)^{-1} \in \mathbb{Q}^{n\times n}$. Essentially a dynamic program can maintain a Chinese remainder representation of $(A+\Delta A)^{-1}$ and extract whether an entry is non-zero from this representation. An obstacle is that whenever $(I+BVA^{-1}U)^{-1} \pmod p$ does not exist for a prime p during the update process, then this prime p becomes *invalid* for the rest of the computation. The idea to circumvent this is simple: with each change, only a small number of primes become invalid. However, since the determinant can be computed in NC^2 (cf. [3]), using Theorem 4 we only need to be able to maintain a correct result for $\log^2 n$ many steps. Thus starting from sufficiently many primes will guarantee that enough primes are still valid after $\log^2 n$ steps.

We make these numbers more precise in the following.

Proof (of Theorem 6). By Theorem 4 and since values of the inverse of a matrix are almost domain-independent, it suffices to exhibit a dynamic program[4] that maintains non-zeroness of entries of A^{-1} for $\log^2 n$ changes of size $\frac{\log n}{\log\log n}$. The dynamic program maintains A^{-1}

[4] Actually we only describe a program that works correctly for sufficiently large n. However, small n can be easily dealt with separately.

(mod p) for each of the first $2n^3$ many primes p, which, by the Prime Number Theorem, can be found among the first n^4 numbers. Denote by P the set of the first $2n^3$ primes. The NC^2 initialization procedure computes $A^{-1} \pmod p$ for each prime in P. The update procedure for a change ΔA is simple:

(1) For each prime $p \in P$:
  (a) If $(A + \Delta A)^{-1} \pmod p$ is not invertible then remove p from P.
  (b) If $(A + \Delta A)^{-1} \pmod p$ is invertible then update $(A + \Delta A)^{-1} \pmod p$.

(2) Declare $[(A + \Delta A)^{-1}]_{st} \neq 0$ if there is a prime $p \in P$ with $[(A + \Delta A)^{-1}]_{st} \not\equiv 0 \pmod p$.

The Steps 1a and 1b can be performed in $\mathrm{FO}(+, \times)$ due to Proposition 9.

It remains to argue that the result from Step 2 is correct. Observe that the values of entries of A are at most n at all times, and therefore $\det(A) \leq n! n^n \leq 2^{n^2}$ for large enough n. Thus, since $\det(A) \neq 0$ over $\mathbb{Z}$ by assumption, there are at most n^2 primes p such that $\det(A) \equiv 0 \pmod p$, for all A reached after a sequence of changes.

In particular, $(A + \Delta A)^{-1} \pmod p$ is not invertible – equivalently, $(I + BVA^{-1}U)^{-1} \pmod p$ does not exist – for at most n^2 primes p. Hence, each time Step 1 is executed, at most n^2 primes are declared invalid and removed from P. All in all this step is executed at most $\log^2 n$ times, and therefore not more than n^3 primes are removed from P. Thus for the remaining n^3 valid primes, the inverses $(A + \Delta A)^{-1} \pmod p$ are computed correctly.

Each entry of $(A + \Delta A)^{-1}$ is, again, bounded by 2^{n^2}, so if $[(A + \Delta A)^{-1}]_{st} \neq 0$ there are at most n^2 primes $p \in P$ with $[(A + \Delta A)^{-1}]_{st} \equiv 0 \pmod p$. So, the result declared in Step 2 is correct. ◀

4.2 Defining the Determinant of Small Matrices

In this subsection we prove Theorem 8. The symbolic determinant of a $k \in \mathcal{O}(\frac{\log}{\log \log n})$ sized matrix is a sum of $k! \in n^{\mathcal{O}(1)}$ monomials and therefore cannot be naïvely defined in $\mathrm{FO}(+, \times)$. Here we use the fact that $\mathrm{FO}(+, \times)$ can easily convert $\log n$ bit numbers into their Chinese remainder presentation and back, and show how the determinant can be computed modulo $\log \log n$ bit primes.

It is easy to verify whether the value of a determinant modulo a $\mathcal{O}(\log \log n)$ bit prime is zero in $\mathrm{FO}(+, \times)$ by guessing a linear combination witnessing that the rank is less than full. We aim for a characterization that allows to reduce the verification of determinant values to such zeroness tests. To this end we use the self-reducibility and multilinearity of determinants. Assume $[A]_{11} \neq 0$ and that the determinant of A_{11} is also non-zero. Then the determinant can be written as $[A]_{11} \cdot d + r$ for some d and r. By finding an a such that the determinant is zero when $[A]_{11}$ is replaced by a in A we gain $r = -ad$. Repeating this step recursively for d – which is the determinant of a smaller matrix – one obtains a procedure for determining the value of the determinant that can be parallelized.

The following lemma is a preparation for deriving the characterization. We denote by A_i the matrix obtained from a matrix A by removing all rows and columns larger than i.

▶ **Lemma 10.** *Suppose $B = (\bar{b}_1, \ldots, \bar{b}_k) \in \mathbb{F}^{k \times k}$ is a non-singular matrix over a field $\mathbb{F}$. Then there is a permutation $\pi : [k] \to [k]$ such that for $A \stackrel{def}{=} (b_{\pi(1)}, \ldots, b_{\pi(k)})$:*

$$[A]_{ii} \neq 0 \text{ and } \det(A_i) \neq 0 \text{ for all } i \in [k]$$

The following proposition characterizes the determinant of a matrix. We will see that this characterization allows for parallel computation of the determinant of small matrices.

▶ **Proposition 11.** *Suppose* $A = (a_{ij})_{1 \leq i,j \leq k} \in \mathbb{F}^{k \times k}$ *is a matrix over a field* $\mathbb{F}$ *such that* $a_{ii} \neq 0$ *and* $\det(A_i) \neq 0$ *for all* $i \in [k]$*. Let* A_i^b *be the matrix obtained from* A_i *by replacing* a_{ii} *by* b *for some* $b \in \mathbb{F}$*. Then there are unique* $b_2, \ldots, b_k \in \mathbb{F}$ *and* $d_1, \ldots, d_k \in \mathbb{F}$ *such that*

1. $d_1 = a_{11}$,
2. $d_i = (a_{ii} - b_i)d_{i-1}$, *and*
3. $\det(A_i^b) = 0$

for $2 \leq i \leq k$*. Furthermore, it holds that* $d_i = \det(A_i)$.

Finally we show that the characterization from the previous proposition can be used to define the determinant of small matrices in $\mathrm{FO}(+, \times)$.

Proof (of Theorem 8). Suppose $A \in \mathbb{Z}_p^{k \times k}$ is a matrix with $p \in \mathcal{O}(n^c)$ and $k = \frac{\log n}{\log \log n}$. The idea is to define $\det(A) \pmod p$ in Chinese remainder representation for primes $q_1, \ldots, q_m$. A simple calculation shows that $m \in \mathcal{O}(\log n)$ primes each of $\mathcal{O}(\log \log n)$ bits suffice. The Chinese remainder representation can be defined from A and the value $\det(A) \pmod p$ can be recovered from the values $\det(A) \pmod{q_1}, \ldots, \det(A) \pmod{q_m}$ in $\mathrm{FO}(+, \times)$ due to Lemma 3. Thus let us show how to define $\det(A) \pmod q$ for a prime q of $\mathcal{O}(\log \log n)$ bits.

The idea is to first test whether the determinant is zero. If not, the fact that it is not zero is used to define the determinant using Proposition 11.

If $A \pmod q$ is singular then there exists a non-trivial linear combination of the columns that yields the all zero vector. Such a linear combination is determined by specifying one $\mathcal{O}(\log \log n)$ bit number for each of the k columns. It can thus be encoded in $\mathcal{O}(\log n)$ bits, and therefore existentially quantified by a first-order formula. Such a "guess" can be decoded (i.e., the k numbers of $\mathcal{O}(\log \log n)$ length can be extracted) in $\mathrm{FO}(+, \times)$, see Section 2. Checking if a guessed linear combination is zero requires to sum k small numbers and is hence in $\mathrm{FO}(+, \times)$ due to Lemma 3.

Now, for defining the determinant $\det(A) \pmod q$ when $A \pmod q$ is non-singular, a formula can guess a permutation π of $[k]$ and verify that it satisfies the conditions from Lemma 10. Note that such a permutation can be represented as a sequence of k pairs of numbers of $\log \log n$ bits each, and hence be stored in $\mathcal{O}(\log n)$ bits. The verification of the conditions from Lemma 10 requires the zero-test for determinants explained above. After fixing π, the values $b_2, \ldots, b_k$ as well as $d_1, \ldots, d_k$ from Proposition 11 can be guessed and verified. Again, these numbers can be stored in $\mathcal{O}(\log n)$ bits. For verifying the conditions from Proposition 11 on the determinants of A_i^b, the zero-test for determinants is used. ◀

5 Distances under Multiple Changes

In this section we extend the techniques from the previous section to show how distances can be maintained under changes that affect polylogarithmically many nodes with first-order updates that may use majority quantifiers. Afterwards we discuss how the techniques extend to other dynamic complexity classes.

▶ **Theorem 2.** *Reachability and Distance can be maintained in* DynFO+Maj$(+, \times)$ *under changes that affect* $\mathcal{O}(\log^c n)$ *nodes of a graph, where* $c \in \mathbb{N}$ *is fixed and* n *is the number of nodes of the graph.*

The idea is to use generating functions for counting the number of paths of each length, following Hesse [13]. Fix a graph G with adjacency matrix $A_G \in \mathbb{Z}^{n \times n}$ and a formal variable x. Then $D \stackrel{\text{def}}{=} \sum_{i=0}^{\infty} (xA_G)^i$ is a matrix of formal power series from $\mathbb{Z}[[x]]$ such that if $[D]_{st} = \sum_{i=0}^{\infty} c_i x^i$ then c_i is the number of paths from s to t of length i. In particular, the distance between s and t is the smallest i such that c_i is non-zero. Note that if such an i exists, then $i < n$.

Similarly to the corresponding matrix from the previous section, the matrix D is invertible over $\mathbb{Z}[[x]]$ and can be written as $(I - xA_G)^{-1}$ (cf. [10, Example 3.6.1]). The maintenance of distances thus reduces to maintaining for a matrix $A \in \mathbb{Z}[[x]]$, for each entry (s,t), the smallest $i < n$ such that the ith coefficient is non-zero.

▶ **Theorem 12.** *Suppose $A \in \mathbb{Z}[[x]]^{n\times n}$ stays invertible over $\mathbb{Z}[[x]]$. For all $s,t \in [n]$ one can maintain the smallest $i < n$ such that the ith coefficient of the st-entry of A^{-1} is non-zero in* DynFO+Maj$(+,\times)$ *under changes that affect $\mathcal{O}(\log^c n)$ nodes, for fixed $c \in \mathbb{N}$.*

The idea is the same as for Reachability. When updating A to $A + \Delta A$ then one can decompose the change matrix ΔA into UBV for suitable matrices U, B, and V, and apply the Sherman-Morrison-Woodbury identity ($\star$), this time over the field of fractions $\mathbb{Z}((x))$.

Of course computing with inherently infinite formal power series is not possible in DynFO+Maj$(+,\times)$. However, as stated in Theorem 12, in the end we are only interested in the first $i < n$ coefficients of power series. We therefore show that it suffices to truncate all occurring power series at the n-th term and use FO+Maj$(+,\times)$'s ability to define iterated sums and products of polynomials [14].

Formally, we have to show that no precision for the first $i < n$ coefficients is lost when computing with truncated power series. This motivates the following definition. A formal power series $g(x) = \sum_i c_i x^i \in \mathbb{Z}[[x]]$ is an *m-approximation* of a formal power series $h(x) = \sum_i d_i x^i \in \mathbb{Z}[[x]]$, denoted by $g(x) \approx_m h(x)$, if $c_i = d_i$ for all $i \leq m$. This notion naturally extends to matrices over $\mathbb{Z}[[x]]$: a matrix $A \in \mathbb{Z}[[x]]^{\ell\times k}$ is an m-approximation of a matrix $B \in \mathbb{Z}[[x]]^{\ell\times k}$ if each entry of A is an m-approximation of the corresponding entry of B. The notion of m-approximation is preserved under all arithmetic operations that will be relevant.

▶ **Lemma 13.** *Fix an $m \in \mathbb{N}$.*

1. *Suppose $g(x), g'(x), h(x), h'(x) \in \mathbb{Z}[[x]]$ with $g(x) \approx_m g'(x)$ and $h(x) \approx_m h'(x)$. Then*
   - **(i)** *$g(x) + h(x) \approx_m g'(x) + h'(x)$,*
   - **(ii)** *$g(x)h(x) \approx_m g'(x)h'(x)$, and*
   - **(iii)** *$\frac{1}{g(x)} \approx_m \frac{1}{g'(x)}$ whenever $g(x)$ and $g'(x)$ are normalized.*
2. *Suppose $A, A', B, B' \in \mathbb{Z}[[x]]^{n\times n}$ with $A \approx_m A'$ and $B \approx_m B'$. Then*
   - **(i)** *$A + B \approx_m A' + B'$,*
   - **(ii)** *$AB \approx_m A'B'$,*
   - **(iii)** *If A is invertible over $\mathbb{Z}[[x]]$ then so is A', and $A^{-1} \approx_m A'^{-1}$.*

Here, a formal power series $\sum_i c_i x^i \in \mathbb{Z}[[x]]$ is *normalized* if $c_0 = 1$.

An approximation of the inverse of a matrix $A \in \mathbb{Z}[[x]]^{n\times n}$ can be updated using the Sherman-Morrison-Woodbury identity.

▶ **Proposition 14.** *Suppose $A \in \mathbb{Z}[[x]]^{n\times n}$ is invertible over $\mathbb{Z}[[x]]$, and $C \in \mathbb{Z}[[x]]^{n\times n}$ is an m-approximation of A^{-1}. If $A + \Delta A$ is invertible over $\mathbb{Z}[[x]]$ and ΔA can be written as UBV with $U \in \mathbb{Z}[[x]]^{n\times k}, B \in \mathbb{Z}[[x]]^{k\times k}$, and $V \in \mathbb{Z}[[x]]^{k\times n}$, then*

$$(A + \Delta A)^{-1} \approx_m C - CU(I + BVCU)^{-1}BVC$$

Proof. This follows immediately from the Sherman-Morrison-Woodbury identity $(A + UBV)^{-1} = A^{-1} - A^{-1}U(I + BVA^{-1}U)^{-1}BVA^{-1}$ and Lemma 13. ◀

As already discussed in Section 4, the Sherman-Morrison-Woodbury identity involves inverting $k \times k$ matrices, which reduces to computing the determinant of such matrices. We show that this is possible in FO+Maj for $k \times k$ matrices of polynomials for $k \in \mathcal{O}(\log^c n)$.

▶ **Lemma 15.** *Fix a domain of size n and $c \in \mathbb{N}$. The determinant of a matrix $A \in \mathbb{Z}[x]^{k\times k}$, with entries of degree polynomial in n, can be defined in* FO+Maj$(+,\times)$ *for $k \in \mathcal{O}(\log^c n)$.*

Proof. We show that the value can be computed in uniform TC^0, which is as powerful as FO+Maj$(+,\times)$ [2].

Computing the determinant of an $k \times k$ matrix is equivalent to computing the iterated matrix product of k matrices of dimension at most $(k+1)\times(k+1)$ [3], and this reduction is a uniform TC^0-reduction as can be seen implicitly in [17, p. 482]. Thus the lemma statement follows from the fact that iterated products of matrices $A_1, \ldots, A_k \in \mathbb{Z}[x]^{k\times k}$ with $k \in \mathcal{O}(\log^c n)$ can be computed in uniform TC^0, which can be proven like in [1, p. 69]. ◀

Proof (of Theorem 12). The dynamic program maintains an n-approximation $C \in \mathbb{Z}[x]^{n\times n}$ of A^{-1} that truncates A^{-1} at degree n. When A is updated to $A + \Delta A$ then:

1. ΔA is decomposed into suitable $U \in \mathbb{Z}[x]^{n\times k}$, $B \in \mathbb{Z}[x]^{k\times k}$, and $V \in \mathbb{Z}[x]^{k\times n}$;
2. C is updated via $C' \stackrel{\text{def}}{=} C - CU(I + BVCU)^{-1}BVC$;
3. All entries of C' are truncated at degree n.

The steps can be defined in FO+Maj$(+,\times)$ due to Lemma 7, Lemma 15, and the fact that iterated addition and multiplication of polynomials can be defined in FO+Maj$(+,\times)$, see [14]. The maintained matrix C is indeed an n-approximation of A^{-1} due to Proposition 14. ◀

From the proof of Theorem 12 it is clear that the main obstacle towards maintaining distances for changes that affect a larger set of nodes is to compute determinants of larger matrices. Since distances can be computed in NL, only classes below NL are interesting from a dynamic perspective. As an example we state a result for the circuit class NC^1.

▶ **Corollary 16.** *Reachability and Distance can be maintained in* DynNC^1 *under changes that affect $\mathcal{O}(2^{\sqrt{\log n/\log^* n}})$ nodes.*

Here $\log^* n$ denotes the smallest number i such that i-fold application of log yields a number smaller than 1.

6 Conclusion

For us it came as a surprise that Reachability can be maintained under changes of non-constant size, without any structural restrictions. In contrast, the dynamic program for Reachability from [4] can only deal with changing $\log n$ many outgoing edges of single nodes (or, symmetrically, $\log n$ many incoming edges; a combination is not possible).

It would be interesting to improve our results for Dyn FO$(+,\times)$ to changes of size $\mathcal{O}(\log n)$. The obstacle is the computation of determinants of matrices of this size, which we can only do for $\mathcal{O}(\frac{\log n}{\log\log n})$ size matrices. Yet in principle our approach can deal with certain changes that affect more nodes: the matrices U and V in the Sherman-Morrison-Woodbury identity can be chosen differently, as long as all computations involve only adding $\mathcal{O}(\log n)$ numbers.

One of the big remaining open questions in dynamic complexity is whether distances are in Dyn FO. Our approach sheds some light. It can be adapted so as to maintain information within Dyn FO$(+,\times)$ from which shortest distances can be extracted in FO+Maj$(+,\times)$.

▶ **Theorem 17.** *Distances can be defined by a* FO+Maj$(+,\times)$ *query from auxiliary relations that can be maintained in* Dyn FO$(+,\times)$ *under changes that affect $\mathcal{O}(\frac{\log n}{\log\log n})$ nodes.*

Abstract

The containment problem for quantitative automata is the natural quantitative generalisation of the classical language inclusion problem for Boolean automata. We study it for probabilistic automata, where it is known to be undecidable in general. We restrict our study to the class of probabilistic automata with bounded ambiguity. There, we show decidability (subject to Schanuel's conjecture) when one of the automata is assumed to be unambiguous while the other one is allowed to be finitely ambiguous. Furthermore, we show that this is close to the most general decidable fragment of this problem by proving that it is already undecidable if one of the automata is allowed to be linearly ambiguous.

1 Introduction

Probabilistic automata (PA) are a quantitative extension of classical Boolean automata that were first introduced by Rabin [20]. Non-deterministic choices are replaced by probabilities: each transition carries a rational number which gives its probability to be chosen amongst all the other transitions going out of the same state and labelled by the same letter. Then, instead of simply accepting or rejecting a word, such an automaton measures the probability of it being accepted.

PA can be seen as (blind) partially observable Markov decision processes [19]. The latter have numerous applications in the field of artificial intelligence [22, 11]. Further applications for PA include, amongst others, verification of probabilistic systems [23, 14, 5], reasoning about inexact hardware [18], quantum complexity theory [25], uncertainty in runtime modelling [9], as well as text and speech processing [17]. PA are very expressive, as witnessed by the mentioned applications, most natural verification-related decision problems for them are consequently undecidable. However, equivalence and minimisation do admit efficient algorithms [13].

Due to the aforementioned negative results, many sub-classes of probabilistic automata have been studied. These include hierarchical [7] and leaktight [2] automata; and more recently, bounded-ambiguity automata [8] (see [6] for a survey).

In this paper, we continue the study of the class of PA with bounded ambiguity. We focus on the containment problem: *given two automata $\mathcal{A}$ and $\mathcal{B}$, determine whether for all words w, the probability of it being accepted by $\mathcal{A}$ is at most the probability of it being accepted by $\mathcal{B}$.* The problem is known to be undecidable even for the subclass of automata with polynomial ambiguity, more specifically, already for automata with quadratic ambiguity [8].

Contributions. In this paper, we refine the undecidability result by extending it to the class of linearly ambiguous automata.

▶ **Theorem 1.** *The containment problem is undecidable for the class of linearly ambiguous probabilistic automata.*

The proof we provide gives in fact two stronger results. Firstly, the containment problem for linearly ambiguous PA is already undecidable if one of the two input automata is unambiguous. Secondly, and perhaps more importantly, the better-known emptiness problem (*given a probabilistic automaton, does there exist a word accepted with probability at least* $1/2$*?*) is also undecidable for the class of linearly ambiguous PA. This strictly refines the previous best known result [8].

This negative result motivates us to turn our attention to the class of finitely ambiguous PA. For this class, we prove that the containment problem is decidable, provided that one of the two input automata is unambiguous (and conditional on Schanuel's conjecture).

▶ **Theorem 2.** *If Schanuel's conjecture holds then the containment problem is decidable for the class of finitely ambiguous probabilistic automata, provided that at least one of the input automata is unambiguous.*

The intermediate problem, i.e., when both input PA are finitely ambiguous, remains open.

Organisation of the paper. In Section 2, we give the formal definition of probabilistic automata, the notion of ambiguity, and the problems under consideration. We also recall classical results that will be useful in the paper. In Section 3, we explain how to translate the containment problem into a problem about the existence of integral exponents for certain exponential inequalities. Using this formalism, we prove that the containment problem for $\mathcal{A}$ and $\mathcal{B}$, as stated above, is decidable if $\mathcal{A}$ is finitely ambiguous and $\mathcal{B}$ is unambiguous. In Section 4, we tackle the more challenging direction and prove that the containment problem is also decidable if $\mathcal{A}$ is unambiguous and $\mathcal{B}$ is finitely ambiguous. Finally, in Section 5, we prove that the containment problem is undecidable provided that one of the automata is linearly ambiguous.

2 Preliminaries

In this section, we define probabilistic automata and recall some classical results.

Notation. We use boldface lower-case letters, e.g., $\boldsymbol{a}, \boldsymbol{b}, \ldots$, to denote vectors and upper-case letters, e.g., $M, N, \ldots$, for matrices. For a vector $\boldsymbol{a}$, we write a_i for its i-th component, and $\boldsymbol{a}^\top$ for its transpose.

2.1 Probabilistic automata and ambiguity

For a finite set S, we say that a function $f : S \to \mathbb{Q}_{\geq 0}$ is a *distribution over* S if $\sum_{s \in S} f(s) \leq 1$. We write $\mathcal{D}(S)$ for the set of all distributions over S. We also say that a vector $\boldsymbol{d} = (d_1, d_2, \ldots, d_n) \in \mathbb{Q}^n_{\geq 0}$ of non-negative rationals is a distribution if $\sum_{i=1}^n d_i \leq 1$.

A *probabilistic automaton (PA)* $\mathcal{A}$ is a tuple $(\Sigma, Q, \delta, \iota, F)$, where:

- Σ is the finite alphabet,
- Q is the finite set of states,
- $\delta : Q \times \Sigma \to \mathcal{D}(Q)$ is the (probabilistic) transition function,
- $\iota \in \mathcal{D}(Q)$ is the initial distribution, and
- $F \subseteq Q$ is the set of final states.

We write $\delta(q, a, p)$ instead of $\delta(q, a)(p)$ for the *probability of moving from q to p reading a*. Consider the word $w = a_1 \ldots a_n \in \Sigma^*$. A *run ρ of $\mathcal{A}$ over $w = a_1 \ldots a_n$* is a sequence of transitions $(q_0, a_1, q_1), (q_1, a_2, q_2), \ldots, (q_{n-1}, a_n, q_n)$ where $\delta(q_{i-1}, a_i, q_i) > 0$ for all $1 \leq i \leq n$. It is an *accepting run* if $\iota(q_0) > 0$ and $q_n \in F$. The *probability of the run ρ* is $\Pr_{\mathcal{A}}(\rho) \stackrel{\text{def}}{=} \iota(q_0) \cdot \prod_{i=1}^n \delta(q_{i-1}, a_i, q_i)$.

The automaton $\mathcal{A}$ realizes a function $[\![\mathcal{A}]\!]$ mapping words over the alphabet Σ to values in $[0, 1]$. Formally, for all $w \in \Sigma^*$, we set: $[\![\mathcal{A}]\!](w) \stackrel{\text{def}}{=} \sum_{\rho \in \mathrm{Acc}_{\mathcal{A}}(w)} \Pr_{\mathcal{A}}(\rho)$ where $\mathrm{Acc}_{\mathcal{A}}(w)$ is the set of all accepting runs of $\mathcal{A}$ over w.

Ambiguity. The notion of ambiguity depends only on the structure of the underlying automaton (i.e., whether a probability is null or not, but not on its actual value). An automaton $\mathcal{A}$ is said to be *unambiguous* (resp. *k-ambiguous*) if for all words w, there is at most one accepting run (resp. k accepting runs) over w in $\mathcal{A}$. If an automaton is k-ambiguous for some k, then it is said to be *finitely ambiguous*. If there exists a polynomial P, such that

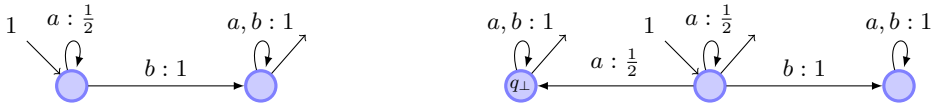

Figure 1 Two PA over the alphabet $\Sigma = \{a, b\}$ are depicted. On the left hand side, automaton $\mathcal{A}$ induces the function $a^n b\Sigma^* \mapsto \frac{1}{2^n}$ and $a^* \mapsto 0$. On the right hand side, the automaton $\overline{\mathcal{A}}$ induces the function $a^n b\Sigma^* \mapsto 1 - \frac{1}{2^n}$ and $a^* \mapsto 1$. Observe that $\mathcal{A}$ is unambiguous and $\overline{\mathcal{A}}$ is linearly ambiguous.

for every word w, the number of accepting runs of $\mathcal{A}$ on w is bounded by $P(|w|)$ (where $|w|$ is the length of w), then $\mathcal{A}$ is said to be *polynomially ambiguous*, and *linearly ambiguous* whenever the degree of P is at most 1.

It is well-known that if an automaton is not finitely ambiguous then it is at least linearly ambiguous (see, for example, the criterion in [24, Section 3]). The same paper shows that if an automaton is finitely ambiguous then it is k-ambiguous for k bounded exponentially in the number of states of that automaton.

We give two examples of PA and discuss their ambiguity in Figure 1. As usual, they are depicted as graphs. The initial distribution is denoted by ingoing arrows associated with their probability (when there is no such arrow, the initial probability is 0) and the final states are denoted by outgoing arrows.

2.2 Decision problems

In this work, we are interested in comparing the functions computed by PA. We write $[\![\mathcal{A}]\!] \leq [\![\mathcal{B}]\!]$ if "$\mathcal{A}$ is contained in $\mathcal{B}$", that is if $[\![\mathcal{A}]\!](w) \leq [\![\mathcal{B}]\!](w)$ for all $w \in \Sigma^*$; and we write $[\![\mathcal{A}]\!] < \frac{1}{2}$ if $[\![\mathcal{A}]\!](w) < \frac{1}{2}$ for all $w \in \Sigma^*$. We are interested in the following decision problems for PA.

- *Containment problem:* Given probabilistic automata $\mathcal{A}$ and $\mathcal{B}$, does $[\![\mathcal{A}]\!] \leq [\![\mathcal{B}]\!]$ hold?
- *Emptiness problem:* Given a probabilistic automaton $\mathcal{A}$, does $[\![\mathcal{A}]\!] < \frac{1}{2}$ hold?

We will argue that the containment and emptiness problems are both undecidable when considered for the class of linearly ambiguous automata (Section 5). The emptiness problem is known to be decidable for the class of finitely ambiguous automata [8]. We tackle here the more difficult containment problem (Sections 3 and 4).

2.3 Classical results

Weighted-sum automaton. For PA $\mathcal{A}_1, \mathcal{A}_2, \ldots, \mathcal{A}_n$ over the same alphabet, and for a discrete distribution $\boldsymbol{d} = (d_1, d_2, \ldots, d_n)$, the *weighted sum* (of $\mathcal{A}_1, \mathcal{A}_2, \ldots, \mathcal{A}_n$ with weights $\boldsymbol{d}$) is defined to be the disjoint union of the n automata with the initial distribution $\iota(q) \stackrel{\text{def}}{=} d_i \cdot \iota_i(q)$ if q is a state of $\mathcal{A}_i$, where ι_i is the initial distribution of $\mathcal{A}_i$. Note that if $\mathcal{B}$ is the weighted sum of $\mathcal{A}_1, \mathcal{A}_2, \ldots, \mathcal{A}_n$ with weights $\boldsymbol{d}$ then it is also a probabilistic automaton and $[\![\mathcal{B}]\!] = \sum_{i=1}^n d_i \cdot [\![\mathcal{A}_i]\!]$.

Complement automaton. For a PA $\mathcal{A}$, we define its *complement automaton* $\overline{\mathcal{A}}$ in the following way. First, define the PA $\mathcal{A}'$ by modifying $\mathcal{A}$ as follows:

- add a new sink state $q_\perp$;
- obtain the transition function δ' from δ by adding transitions:
  - $\delta'(q_\perp, a, q_\perp) = 1$ for all $a \in \Sigma$,
  - $\delta'(q, a, q_\perp) = 1 - \sum_{r \in Q} \delta(q, a, r)$ for all $(q, a) \in Q \times \Sigma$;
- obtain the initial distribution ι' from ι by adding $\iota'(q_\perp) = 1 - \sum_{q \in Q} \iota(q)$.

Observe that $[\![\mathcal{A}']\!] = [\![\mathcal{A}]\!]$, that $\sum_{r\in Q}\delta'(q,a,r) = 1$ for all $(q,a) \in Q \times \Sigma$, and that $\sum_{q\in Q}\iota'(q) = 1$. We obtain $\overline{\mathcal{A}}$ from $\mathcal{A}'$ by swapping its final and non-final states. As expected, it is the case that $[\![\overline{\mathcal{A}}]\!] = 1 - [\![\mathcal{A}]\!]$.

▶ Remark (Preserving ambiguity). The ambiguity of a weighted-sum automaton is the sum of the ambiguities of the individual automata, and the ambiguity of a complement automaton may be larger than the ambiguity of the original one (see Figure 1).

3 Decidability of the case finitely ambiguous vs. unambiguous

Our aim is to decide whether $[\![\mathcal{A}]\!] \leq [\![\mathcal{B}]\!]$. We first give a translation of the problem into a problem about the existence of integral exponents for certain exponential inequalities.

Notation. In the rest of the paper, we write $\exp(x)$ to denote the exponential function $x \mapsto e^x$, and $\log(y)$ for the natural logarithm function $y \mapsto \log_e(y)$. For a real number x and a positive real number y, we write y^x for $\exp(x\log(y))$.

3.1 Translating the containment problem into exponential inequalities

We are going to translate the negation of the containment problem: Given two finitely ambiguous PA $\mathcal{A}$ and $\mathcal{B}$, does there exist a word w, such that $[\![\mathcal{A}]\!](w) > [\![\mathcal{B}]\!](w)$? Consider two positive integers k and n, and vectors $\boldsymbol{p} \in \mathbb{Q}^k_{>0}$ and $\boldsymbol{q}_1, \ldots, \boldsymbol{q}_k \in \mathbb{Q}^n_{>0}$. We denote by $S(\boldsymbol{p}, \boldsymbol{q}_1, \ldots, \boldsymbol{q}_k) : \mathbb{N}^n \to \mathbb{R}$ the function associating a vector $\boldsymbol{x} \in \mathbb{N}^n$ to $\sum_{i=1}^k p_i q_{i,1}^{x_1} \cdots q_{i,n}^{x_n}$, where $q_{i,j}$ is the j-th component of vector $\boldsymbol{q}_i$.

▶ **Proposition 3.** *Given a k-ambiguous automaton $\mathcal{A}$ and an ℓ-ambiguous automaton $\mathcal{B}$, one can compute a positive integer n and a finite set Δ of tuples $(\boldsymbol{p}, \boldsymbol{q}_1, \ldots, \boldsymbol{q}_{k'}, \boldsymbol{r}, \boldsymbol{s}_1, \ldots, \boldsymbol{s}_{\ell'})$ of vectors $\boldsymbol{p} \in \mathbb{Q}^{k'}_{>0}, \boldsymbol{r} \in \mathbb{Q}^{\ell'}_{>0}$, for some $k' \leq k$ and $\ell' \leq \ell$; and $\boldsymbol{q}_i \in \mathbb{Q}^n_{>0}, \boldsymbol{s}_j \in \mathbb{Q}^n_{>0}$, for all i and j; such that the following two conditions are equivalent:*

- *there exists $w \in \Sigma^*$ such that $[\![\mathcal{A}]\!](w) > [\![\mathcal{B}]\!](w)$,*
- *there exist $(\boldsymbol{p}, \boldsymbol{q}_1, \ldots, \boldsymbol{q}_{k'}, \boldsymbol{r}, \boldsymbol{s}_1, \ldots, \boldsymbol{s}_{\ell'}) \in \Delta$ and $\boldsymbol{x} \in \mathbb{N}^n$ such that*

$$S(\boldsymbol{p}, \boldsymbol{q}_1, \ldots, \boldsymbol{q}_{k'})(\boldsymbol{x}) > S(\boldsymbol{r}, \boldsymbol{s}_1, \ldots, \boldsymbol{s}_{\ell'})(\boldsymbol{x}).$$

It thus follows that to prove Theorem 2, it suffices to show decidability of the second item of Proposition 3 for a given element of Δ in the cases where either k or ℓ are equal to 1. To prove Proposition 3, the idea is to decompose every run into a short path and simple cycles using the well-known simple-cycle decomposition (see, e.g., [21]). We do this simultaneously for all runs in $\mathcal{A}$ and $\mathcal{B}$. The vectors $\boldsymbol{p}$ and $\boldsymbol{r}$ then correspond to probabilities of simple paths in every run; $\boldsymbol{q}_i$ (resp. $\boldsymbol{s}_j$), to all simple cycles in the i-th run in $\mathcal{A}$ (resp. j-th run in $\mathcal{B}$). Finally, $\boldsymbol{x}$ specifies how many times each simple cycle occurs in the decomposition.

▶ **Example 4.** Consider the following instance of the problem, where $k = n = 2$, $\ell = 1$, and p is a fixed rational number $0 \leq p \leq 1$: Do there exist $x, y \in \mathbb{N}$ such that $p \cdot \left(\frac{1}{12}\right)^x \cdot \left(\frac{1}{2}\right)^y + (1-p) \cdot \left(\frac{1}{3}\right)^x \cdot \left(\frac{1}{18}\right)^y < \left(\frac{1}{6}\right)^x \cdot \left(\frac{1}{6}\right)^y$. This can be rewritten as

$$p \cdot \left(\frac{1}{2}\right)^x \cdot 3^y + (1-p) \cdot 2^x \cdot \left(\frac{1}{3}\right)^y < 1$$

or equivalently, using the exponential function, as follows

$$\exp(\log(p) - x\log(2) + y\log(3)) + \exp(\log(1-p) + x\log(2) - y\log(3)) < 1.$$

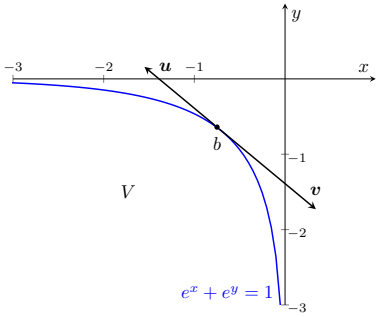

Figure 2 The set V is bounded by the plot $e^x + e^y = 1$ and the point b is on that plot.

Consider the set $V = \{(x, y) \in \mathbb{R}^2 \mid e^x + e^y < 1\}$ and denote by b the point $(\log(p), \log(1-p))$. Let $\boldsymbol{u} = (-\log(2), \log(2))$ and $\boldsymbol{v} = (\log(3), -\log(3))$ be two vectors. See Figure 2 for a geometric representation. The question is now: do there exist $x, y \in \mathbb{N}$ such that $b + x\boldsymbol{u} + y\boldsymbol{v} \in V$. We will show that the answer is yes if and only if $p \neq \frac{1}{2}$.

Let $C = \{(x, -x) \mid x \in \mathbb{R}\}$. For $p = \frac{1}{2}$, the affine line $C + p$ is tangent to the blue plot and so, whatever the values of x and y, $b + x\boldsymbol{u} + y\boldsymbol{v}$ cannot be in V. For $p \neq \frac{1}{2}$, there is a value δ such that the whole interval strictly between b and $b + (\delta, -\delta)$ is in V. Since $\log(2)$ and $\log(3)$ are rationally independent, the set $D = \{x\boldsymbol{u} + y\boldsymbol{v} \mid x, y \in \mathbb{N}\}$ is a dense subset of C, so in particular, there is a point of $D + b$ in the interval between b and $b + (\delta, -\delta)$ and thus there exist $x, y \in \mathbb{N}$ such that $b + x\boldsymbol{u} + y\boldsymbol{v} \in V$.

3.2 Decidability

We prove here the decidability of the containment problem when $\mathcal{A}$ is finitely ambiguous and $\mathcal{B}$ is unambiguous. The converse situation is tackled in Section 4.

▶ **Proposition 5.** *Determining whether $[\![\mathcal{A}]\!] \leq [\![\mathcal{B}]\!]$ is decidable when $\mathcal{A}$ is finitely ambiguous and $\mathcal{B}$ is unambiguous.*

Proof. Let $\mathcal{A}$ be k-ambiguous. Proposition 3 shows that it is sufficient to decide, given an integer n and positive rational numbers $p, q_j, r_i, s_{i,j}$ for $i \in \{1, \ldots, k\}$, $j \in \{1, \ldots, n\}$, whether there exists $x_1, \ldots, x_n \in \mathbb{N}$ such that

$$\sum_{i=1}^{k} p_i q_{i,1}^{x_1} \cdots q_{i,n}^{x_n} > r s_1^{x_1} \cdots s_n^{x_n}. \tag{1}$$

We consider two cases. First, assume that there exist i and j such that $q_{i,j} > s_j$. Then in that case, for a large enough $m \in \mathbb{N}$ condition (1) will be satisfied for $(x_1, \ldots, x_j, \ldots, x_n) = (0, \ldots, m, \ldots, 0)$. Otherwise, assume that $\max\{q_{i,j} \mid 1 \leq i \leq k\} \leq s_j$ for all $1 \leq j \leq n$. In this case, if there exists a valuation of the x_i satisfying (1) then $(x_1, \ldots, x_n) = (0, \ldots, 0)$ also satisfies it. It is then sufficient to test condition (1) for $x_1 = \cdots = x_n = 0$ to conclude. ◀

4 Decidability of the case unambiguous vs. finitely ambiguous

In this section we will show the more challenging part of Theorem 2, i.e., that the containment problem is decidable for $\mathcal{A}$ unambiguous and $\mathcal{B}$ finitely ambiguous. Our proof is conditional on the first-order theory of the reals with the exponential function being decidable. In [15], the authors show that this is the case if a conjecture due to Schanuel and regarding transcendental number theory is true.

▶ **Theorem 6.** *Determining whether* $[\![\mathcal{A}]\!] \leq [\![\mathcal{B}]\!]$ *is decidable when* $\mathcal{A}$ *is unambiguous and* $\mathcal{B}$ *is finitely ambiguous, assuming Schanuel's conjecture is true.*

4.1 Integer programming problem with exponentiation

Given two positive integers n and ℓ, we define $\mathcal{F}_{n,\ell}$ to be the set of all the functions $f : \mathbb{R}^n \to \mathbb{R}$ such that there exist $\boldsymbol{r} \in \mathbb{Q}^\ell_{>0}$ and $\boldsymbol{s}_1, \ldots, \boldsymbol{s}_\ell \in \mathbb{Q}^n_{>0}$ such that $f(\boldsymbol{x}) = \sum_{i=1}^{\ell} r_i s_{i,1}^{x_1} \ldots s_{i,n}^{x_n}$. Observe that this is just a lifting of the $S(\cdot)$ function, defined in the previous section, to real-valued parameters. Consider the following integer programming problem with exponentiation.

▶ **Problem 7** (IP+EXP).
Input: *Three positive integers n, ℓ and m, a function $f \in \mathcal{F}_{n,\ell}$, a matrix $M \in \mathbb{Z}^{m\times n}$, and a vector $\boldsymbol{c} \in \mathbb{Z}^m$.*
Question: *Does there exist $\boldsymbol{x} \in \mathbb{Z}^n$ such that $f(\boldsymbol{x}) < 1$ and $M\boldsymbol{x} < \boldsymbol{c}$?*

In the sequel, we will show that the above problem is decidable.

▶ **Theorem 8.** *The IP+EXP problem is decidable, assuming Schanuel's conjecture is true.*

Theorem 6 is a direct corollary of Theorem 8.

Proof of Theorem 6. Proposition 3 shows that, in order to prove Theorem 6, it is sufficient to decide, given an integer n and positive rational numbers $p, r_i, q_j, s_{i,j}$ for $i \in \{1, \ldots, \ell\}$, $j \in \{1, \ldots, n\}$, whether there exist $x_1, \ldots, x_n \in \mathbb{N}$ such that $pq_1^{x_1} \cdots q_n^{x_n} > \sum_{i=1}^{\ell} r_i s_{i,1}^{x_1} \cdots s_{i,n}^{x_n}$ or equivalently, whether there exist $x_1, \ldots, x_n \in \mathbb{N}$ such that:

$$\sum_{i=1}^{\ell} r_i p^{-1} (s_{i,1} q_1^{-1})^{x_1} \cdots (s_{i,n} q_n^{-1})^{x_n} < 1. \tag{2}$$

Define $f : \mathbb{R}^n \to \mathbb{R}$ such that $f(\boldsymbol{x}) = \sum_{i=1}^{\ell} r_i p^{-1} (s_{i,1} q_1^{-1})^{x_1} \cdots (s_{i,n} q_n^{-1})^{x_n}$. Then, inequality (2) becomes $f(\boldsymbol{x}) < 1$. We can now apply Theorem 8 with m set to be n; M, to be $-Id$, where Id is the identity matrix; and $\boldsymbol{c}$ to be the null vector. ◀

Since the IP+EXP problem is semi-decidable (indeed, we can enumerate the vectors $\boldsymbol{x}$ in $\mathbb{Z}^n$ to find one satisfying the conditions), it will suffice to give a semi-decision procedure to determine whether the inequalities $f(\boldsymbol{x}) < 1 \wedge M\boldsymbol{x} < \boldsymbol{c}$ have no integer solution. We give now such a procedure.

4.2 Semi-decision procedure for the complement of IP+EXP

Consider as input for the IP+EXP problem three positive integers n, ℓ, m, a function $f \in \mathcal{F}_{n,\ell}$, a matrix $M \in \mathbb{Z}^{m\times n}$, and a vector $\boldsymbol{c} \in \mathbb{Z}^m$. Denote by X the set of *real* solutions of the problem, i.e., the set of vectors $X = \{\boldsymbol{x} \in \mathbb{R}^n \mid f(\boldsymbol{x}) < 1 \wedge M\boldsymbol{x} < \boldsymbol{c}\}$.

Proc(n, ℓ, m, f, M, $\boldsymbol{c}$):

1. Search for a non-zero vector $\boldsymbol{d} \in \mathbb{Z}^n$ and $a, b \in \mathbb{Z}$ such that $\{\boldsymbol{d}^\top \boldsymbol{x} \mid \boldsymbol{x} \in X\} \subseteq [a, b]$. Set $i = a$.
2. If $i > b$, then stop and return `YES`. Otherwise, let Y_i be the set of vectors $\boldsymbol{x} \in \mathbb{Z}^n$ satisfying $d_1 x_1 + \cdots + d_n x_n = i$. If Y_i is empty, then increment i and start again from step 2. Otherwise:
   a. Compute $N \in \mathbb{Z}^{n\times(n-1)}$ and $\boldsymbol{h} \in \mathbb{Z}^n$ such that $Y_i = \{N\boldsymbol{y} + \boldsymbol{h} \mid \boldsymbol{y} \in \mathbb{Z}^{n-1}\}$.

b. If $n-1=0$ and $f(\boldsymbol{h}) < 1 \wedge M\boldsymbol{h} < \boldsymbol{c}$ then return `NO`, otherwise increment i and start again from step 2.

c. If $n-1>0$ then recursively call $\mathbf{Proc}(n-1,\ \ell,\ m,\ f',\ M',\ \boldsymbol{c}')$, where $f' \in \mathcal{F}_{n-1,\ell}$ is defined as $f'(\boldsymbol{y}) = f(N\boldsymbol{y}+\boldsymbol{h})$; $M' \in \mathbb{Z}^{m\times(n-1)}$, as $M' = MN$; and $\boldsymbol{c}' \in \mathbb{Z}^m$, as $\boldsymbol{c} - M\boldsymbol{h}$. If the procedure stops and returns `YES` then increment i and start again from step 2. If the procedure stops and returns `NO` then return `NO`.

▶ **Lemma 9.** *The above semi-decision procedure stops and outputs `YES` if and only if there is no integer valuation of $\boldsymbol{x}$ that satisfies the constraints, i.e. $X \cap \mathbb{Z}^n$ is empty.*

First, notice that the only step which might not terminate in a call to our procedure is step 1. Indeed, once $\boldsymbol{d}$, a, and b are fixed, there are only finitely many integers $i \in [a,b]$ that have to be considered in step 2. For each of them, one can compute in a standard way (see, e.g., [3]) the set of integer solutions of the equation $d_1x_1 + \cdots + d_nx_n = i$ and the corresponding N and $\boldsymbol{h}$ as in the procedure.

Moreover, for each integer vector $\boldsymbol{d} \in \mathbb{Z}^n$ and $a,b \in \mathbb{Z}$, the inclusion $\{\boldsymbol{d}^\top\boldsymbol{x} \mid \boldsymbol{x} \in X\} \subseteq [a,b]$ that needs to be checked in step 1 can be formulated as a decision problem in the first-order logic over the structure $(\mathbb{R}, +, \times, \exp)$. Since this structure has a decidable first-order theory subject to Schanuel's conjecture [15], the inclusion can be decided for each fixed $\boldsymbol{d}$, a, and b.

To prove Lemma 9 we use the two following lemmata. The first one is the most technical contribution of the paper and is proved in Section 4.3. It ensures termination of step 1 in the procedure when there is no integer solution.

▶ **Lemma 10.** *If the set X contains no integer point then there must exist a non-zero integer vector $\boldsymbol{d} \in \mathbb{Z}^n$ and $a,b \in \mathbb{Z}$ such that $\{\boldsymbol{d}^\top\boldsymbol{x} \mid \boldsymbol{x} \in X\} \subseteq [a,b]$.*

▶ **Lemma 11.** *Given a non-zero vector $\boldsymbol{d} \in \mathbb{Z}^n$ and an integer i, there exists $\boldsymbol{x} \in \mathbb{Z}^n$ such that $f(\boldsymbol{x}) < 1 \wedge M\boldsymbol{x} < \boldsymbol{c} \wedge \boldsymbol{d}^\top\boldsymbol{x} = i$ if and only if there exists $\boldsymbol{y} \in \mathbb{Z}^{n-1}$ such that $f'(\boldsymbol{y}) < 1 \wedge M'\boldsymbol{y} < \boldsymbol{c}'$ where f', M' and $\boldsymbol{c}'$ are as defined in the procedure.*

We can now prove Lemma 9.

First direction: when the procedure returns YES. Suppose first that the semi-decision procedure stops and outputs `YES`. Then there exist a non-zero vector $\boldsymbol{d} \in \mathbb{Z}^n$ and $a,b \in \mathbb{Z}$ such that $\{\boldsymbol{d}^\top\boldsymbol{x} \mid \boldsymbol{x} \in X\} \subseteq [a,b]$ as in step 1, and for all integers $i \in [a,b]$, one of the following situations occurs:

1. Y_i is empty,
2. $n-1=0$, $Y_i = \{\boldsymbol{h}\}$ as defined in step 2.a but $\boldsymbol{h}$ is not an integer solution of the problem,
3. $n-1>0$ and the recursive call stops and outputs `YES`.

By definition of $\boldsymbol{d}$, in order to prove that there is no integer solution of the problem, we need to show that in all those cases, and for all $i \in [a,b]$, $Y_i \cap X = \emptyset$. It is clear for items 1 and 2 and we use Lemma 11 and an induction for item 3.

Second direction: when $X \cap \mathbb{Z}^n = \emptyset$. If there is no integer solution then by Lemma 10, there must exist a non-zero vector $\boldsymbol{d} \in \mathbb{Z}^n$ and $a,b \in \mathbb{Z}$ such that $\{\boldsymbol{d}^\top\boldsymbol{x} \mid \boldsymbol{x} \in X\} \subseteq [a,b]$ as in step 1. Moreover, for any of those choices, if for an integer $i \in [a,b]$, the set Y_i of vectors $\boldsymbol{x} \in \mathbb{Z}^n$ satisfying $d_1x_1 + \cdots + d_nx_n = i$ is non-empty, then,

1. if $n=1$, then $\boldsymbol{h}$ as defined in step 2.a, is not a solution of the problem (by hypothesis) and thus the procedure stops and returns `YES`,
2. if $n>1$, we use Lemma 11 and, by induction, the recursive call must return `YES`.

4.3 Proof of Lemma 10

Fix three positive integers n, ℓ, m, a function $f \in \mathcal{F}_{n,\ell}$, a matrix $M \in \mathbb{Z}^{m\times n}$, and a vector $\boldsymbol{c} \in \mathbb{Z}^m$. Recall that we denote by X the set of vectors

$$X = \{\boldsymbol{x} \in \mathbb{R}^n \mid f(\boldsymbol{x}) < 1 \wedge M\boldsymbol{x} < \boldsymbol{c}\}.$$

We want to prove that if the set X contains no integer point then there must exist a non-zero integer vector $\boldsymbol{d} \in \mathbb{Z}^n$ and $a, b \in \mathbb{Z}$ such that $\{\boldsymbol{d}^\top \boldsymbol{x} \mid \boldsymbol{x} \in X\} \subseteq [a, b]$.

We will use the following corollary of Kronecker's theorem on simultaneous Diophantine approximation. It generalises the fact that any line in the plane with irrational slope passes arbitrarily close to integer points in the plane.

▶ **Proposition 12.** *[12, Corollary 2.8]. Let $\boldsymbol{u}, \boldsymbol{u}_1, \ldots, \boldsymbol{u}_s$ be vectors in $\mathbb{R}^n$. Suppose that for all $\boldsymbol{d} \in \mathbb{Z}^n$ we have $\boldsymbol{d}^\top \boldsymbol{u} = 0$ whenever $\boldsymbol{d}^\top \boldsymbol{u}_1 = \cdots = \boldsymbol{d}^\top \boldsymbol{u}_s = 0$. Then for all $\varepsilon > 0$ there exist real numbers $\lambda_1, \ldots, \lambda_s \geq 0$ and a vector $\boldsymbol{v} \in \mathbb{Z}^n$ such that $\|\boldsymbol{u} + \sum_{i=1}^s \lambda_i \boldsymbol{u}_i - \boldsymbol{v}\|_\infty \leq \varepsilon$.*

By definition, there exist vectors $\boldsymbol{r} \in \mathbb{Q}^\ell_{>0}$ and $\boldsymbol{s}_1, \ldots, \boldsymbol{s}_\ell \in \mathbb{Q}^n_{>0}$ such that $f(\boldsymbol{x}) = \sum_{i=1}^\ell r_i s_{i,1}^{x_1} \ldots s_{i,n}^{x_n}$. Let $\boldsymbol{a} \in \mathbb{R}^\ell$ and $\boldsymbol{b}_i \in \mathbb{R}^n$ be defined by $a_i = \log(r_i)$ and $\boldsymbol{b}_i = (\log(s_{i,1}), \ldots, \log(s_{i,n}))$. We can then rewrite $f(\boldsymbol{x})$ as follows

$$f(\boldsymbol{x}) = \exp(\boldsymbol{b}_1^\top \boldsymbol{x} + a_1) + \cdots + \exp(\boldsymbol{b}_\ell^\top \boldsymbol{x} + a_\ell).$$

Let us now consider the cone

$$C = \left\{\boldsymbol{x} \in \mathbb{R}^n \;\middle|\; \boldsymbol{b}_1^\top \boldsymbol{x} \leq 0 \wedge \cdots \wedge \boldsymbol{b}_\ell^\top \boldsymbol{x} \leq 0 \wedge M\boldsymbol{x} \leq 0\right\}. \tag{3}$$

It is easy to see that $X + C \subseteq X$.

▶ **Lemma 13.** *Suppose that X is non-empty and that no non-zero integer vector in $\mathbb{Z}^n$ is orthogonal to C. Then $X \cap \mathbb{Z}^n$ is non-empty.*

Proof. Let $\boldsymbol{u} \in X$. Since X is open, there exists $\varepsilon > 0$ such that the open ball $B_\varepsilon(\boldsymbol{u})$ is contained in X. We therefore have that $B_\varepsilon(\boldsymbol{u}) + C \subseteq X$.

We will apply Proposition 12 to show that $B_\varepsilon(\boldsymbol{u}) + C$ contains an integer point and hence that X contains an integer point. To this end, let vectors $\boldsymbol{u}_1, \ldots, \boldsymbol{u}_s \in C$ be such that $\operatorname{span}\{\boldsymbol{u}_1, \ldots, \boldsymbol{u}_s\} = \operatorname{span}(C)$. Then no non-zero vector in $\mathbb{Z}^n$ is orthogonal to $\boldsymbol{u}_1, \ldots, \boldsymbol{u}_s$. By Proposition 12, there exist real numbers $\lambda_1, \ldots, \lambda_s \geq 0$ and an integer vector $\boldsymbol{v} \in \mathbb{Z}^n$ such that $\|\boldsymbol{u} + \sum_{i=1}^s \lambda_i \boldsymbol{u}_i - \boldsymbol{v}\|_\infty \leq \varepsilon$. Thus, $\boldsymbol{v} \in B_\varepsilon(\boldsymbol{u}) + C \subseteq X$. ◀

The contrapositive of the above result states that if X contains no integer point, then there must exist an integer vector that is orthogonal to C. For the desired result, it remains for us to prove the boundedness claim.

▶ **Lemma 14.** *Suppose that $\boldsymbol{d} \in \mathbb{Z}^n$ is orthogonal to the cone C. Then $\{\boldsymbol{d}^\top \boldsymbol{u} \mid \boldsymbol{u} \in X\}$ is bounded.*

Proof. Define the "enveloping polygon" of X to be

$$\widehat{X} = \left\{\boldsymbol{x} \in \mathbb{R}^n \;\middle|\; \boldsymbol{b}_1^\top \boldsymbol{x} + \boldsymbol{a}_1 \leq 0 \wedge \cdots \wedge \boldsymbol{b}_\ell^\top \boldsymbol{x} + \boldsymbol{a}_\ell \leq 0 \wedge M\boldsymbol{x} \leq \boldsymbol{c}\right\}.$$

Clearly it holds that $X \subseteq \widehat{X}$. Moreover, by the Minkowski-Weyl decomposition theorem we can write $\widehat{X}$ as a sum $\widehat{X} = B + C$ for B a bounded polygon and C the cone defined in (3). Since $\boldsymbol{d}$ is orthogonal to C by assumption, it follows that $\{\boldsymbol{d}^\top \boldsymbol{u} \mid \boldsymbol{u} \in \widehat{X}\} = \{\boldsymbol{d}^\top \boldsymbol{u} \mid \boldsymbol{u} \in B\}$ is bounded and hence $\{\boldsymbol{d}^\top \boldsymbol{u} \mid \boldsymbol{u} \in X\}$ is bounded. The result immediately follows. ◀

We can now complete the proof of Lemma 10.

Proof of Lemma 10. By Lemma 13 there exists a non-zero integer vector $\boldsymbol{d} \in \mathbb{Z}^n$ such that $\boldsymbol{d}$ is orthogonal to the cone C defined in (3). Then by Lemma 14 we obtain that $\{\boldsymbol{d}^\top \boldsymbol{u} \mid \boldsymbol{u} \in X\}$ is contained in a bounded interval. ◀

5 Undecidability for linearly ambiguous automata

In this section we prove Theorem 1. That is, we argue that the containment problem is undecidable for the class of linearly ambiguous PA. For most of this section we deal with the following variant of the problem: does there exist a word w such that $[\![\mathcal{A}]\!](w) \leq [\![\mathcal{B}]\!](w)$. Towards the end, we shortly explain how our reduction proves undecidability for any variant of this problem (that is, with inequality $<$). Moreover, we derive from the proof that all variants of the emptiness problem are undecidable for a given linearly ambiguous automaton $\mathcal{A}$, i.e. whether there exists w such that $[\![\mathcal{A}]\!](w) \geq \frac{1}{2}$ (or resp. $>$, $\leq$, $<$).

The proof is done by a reduction from the halting problem for two-counter machines. The reduction resembles the one used to prove undecidability of the comparison problem for another quantitative extension of Boolean automata: max-plus automata [4, 1]. We give here an outline of the proof and the main ideas used in the reduction.

Two-counter machines. A *two-counter machine* (or a *Minsky machine*) is a deterministic finite-state machine, with an initial state, a final state, and two counters, each of which can be incremented or decremented (if its value is not 0). For each counter $i \in \{1, 2\}$, there are two types of transitions: $T_i^+ \subseteq Q^2$ such that a transition $(p, q) \in T_i^+$ moves from state p to state q and increments the i-th counter; and $T_i^- \subseteq Q^3$ such that a transition $(p, q, r) \in T_i^-$ moves from state p to state q if the i-th counter has value 0, and moves from state p to state r decrementing the i-th counter otherwise. The set of all transitions is denoted $T = T_1^+ \cup T_2^+ \cup T_1^- \cup T_2^-$.

The machine *halts* if there is a (unique) computation from the initial state to the final state. It is well-known that deciding whether a given machine halts is undecidable [16]. We use this fact to prove undecidability of the containment problem.

▶ **Proposition 15.** *Given a two-counter machine, one can construct two linearly ambiguous probabilistic automata $\mathcal{A}$ and $\mathcal{B}$, such that the machine halts if and only if there exists a word w such that $[\![\mathcal{A}]\!](w) \leq [\![\mathcal{B}]\!](w)$.*

Outline of the reduction. The general idea is to encode executions of the two-counter machine into words over the alphabet $\Sigma = \{a, b\} \cup T$. A block a^m (resp. b^m) encodes the fact that the value of the first (resp. second) counter is m. For example, given $t \in T_1^+$ and $t' \in T_2^-$, a word $a^n b^m t a^{n+1} b^m t' a^{n+1} b^{m'}$, encodes an execution starting with value n in the first counter and m in the second counter. Transition t then increases the value of the first counter to $n + 1$ without changing the value of the second one. The configuration is thus encoded by the infix $a^{n+1} b^m$. Next, transition t' is taken, and either $m' = m = 0$ or $m' = m - 1$. Moreover, if $t = (p, q)$ and $t' = (r, s, u)$ then $q = r$ (i.e., the states between transitions have to match).

Simulating executions faithfully. Our reduction has the following property: $[\![\mathcal{A}]\!](w) = [\![\mathcal{B}]\!](w)$ for the unique word w encoding the halting execution (if it exists), and $[\![\mathcal{A}]\!](w) > [\![\mathcal{B}]\!](w)$ for all other words. This suffices to prove Proposition 15.

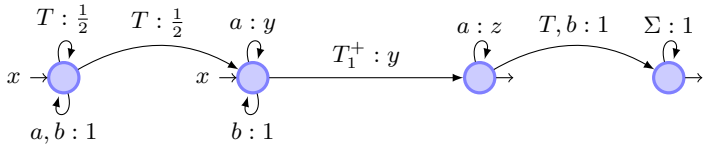

Figure 3 Gadget automaton $\mathcal{C}(x,y,z)$ used to check if the first counter is incremented properly.

There are several conditions that the constructed automata $\mathcal{A}$ and $\mathcal{B}$ need to check to ensure the correctness of the encoding: whether the states match; whether the counter values encoded by blocks of a and b are increased and decreased properly, etc. It is easy to define an automaton $\mathcal{A}_0$ that will allow us to focus only on *proper words* of the form

$$w = a^{n_1}b^{m_1}t_1a^{n_2}b^{m_2}t_2a^{n_3}b^{m_3}t_3\cdots a^{n_k}b^{m_k}t_k. \tag{4}$$

That is, $\mathcal{A}_0$ is such that $[\![\mathcal{A}_0]\!](w) = 0$ if the word w correctly alternates between blocks of a, b, and letters from T; it correctly implements the zero tests within decrement transitions; it observes the initial and final states and checks that the states of adjacent transitions match. Observe that the latter are all regular conditions. If w does not satisfy all these constraints, then $[\![\mathcal{A}_0]\!](w) = 1$.

For other (non-regular) conditions we construct pairs of automata $\mathcal{A}_i$ and $\mathcal{B}_i$, such that $[\![\mathcal{A}_i]\!](w) = [\![\mathcal{B}_i]\!](w)$ if a proper word w does not violate the condition and $[\![\mathcal{A}_i]\!](w) > [\![\mathcal{B}_i]\!](w)$ for all other proper words. In the end, the automata $\mathcal{A}$ and $\mathcal{B}$ are obtained as weighted sums of the automata $\mathcal{A}_i$ and $\mathcal{B}_i$.

Simulating increments. We present the construction for one of the components of $\mathcal{A}$ and $\mathcal{B}$. The remaining ones are obtained using similar gadgets. The automata $\mathcal{A}_1$ and $\mathcal{B}_1$ check that a proper word encodes an execution where the first counter is always correctly incremented after reading transitions from T_1^+. Consider the automaton $\mathcal{C}(x,y,z)$ in Figure 3. It is parameterised by three probability variables $x,y,z > 0$. The parameter x is the probability used by the initial distribution, and parameters y and z are used by some transitions.

Consider a word w as in (4). Notice that the only non-deterministic transitions in $\mathcal{C}(x,y,z)$ are the ones going out from the the leftmost state upon reading letters from T. It follows that $\mathcal{C}(x,y,z)$ is linearly ambiguous. In fact, for every position in w labelled by an element t from T_1^+ there is a unique accepting run that first reaches a final state upon reading t. By construction, we have

$$[\![\mathcal{C}(x,y,z)]\!](w) = \sum_{t_i \in T_1^+} x\left(\frac{1}{2}\right)^{i-1} y^{n_i+1}z^{n_{i+1}}. \tag{5}$$

Let $x = \frac{1}{2}$, $y = 1$ and $z = \frac{1}{4}$. We define $\mathcal{B}_1$ as $\mathcal{C}(x,x,x)$ and $\mathcal{A}_1$ as a weighted sum of $\mathcal{C}(x,y,z)$ and $\mathcal{C}(x,z,y)$ with weights $(\frac{1}{2},\frac{1}{2})$. Since $\mathcal{C}(\cdot,\cdot,\cdot)$ is linearly ambiguous the obtained automata are also linearly ambiguous. We prove that $[\![\mathcal{A}_1]\!](w) = [\![\mathcal{B}_1]\!](w)$ only if $n_i+1 = n_{i+1}$ for all i such that $t_i \in T_1^+$ and $[\![\mathcal{A}_1]\!](w) > [\![\mathcal{B}_1]\!](w)$ otherwise.

By (5) it suffices to show that for every i it holds that

$$\left(\frac{1}{2}\right)^{n_i+1+n_{i+1}} \leq \frac{1}{2}\left(\left(\frac{1}{4}\right)^{n_{i+1}} + \left(\frac{1}{4}\right)^{n_i+1}\right)$$

and that the equality holds only if $n_i + 1 = n_{i+1}$, which is the case.

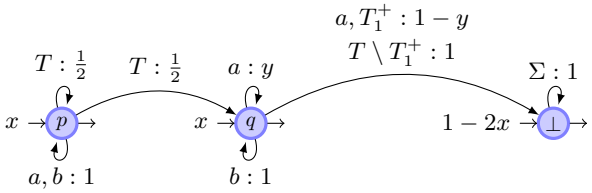

Figure 4 Complement automaton of $\mathcal{C}(x, y, z)$ after trimming.

Changes for version with strict inequalities. Observe that if PA $\mathcal{A}$ and $\mathcal{B}$ output different probabilities on a word w then the probabilities must differ by at least $x^{|w|+1}$ for some value x depending on the probabilities used in $\mathcal{A}$ and $\mathcal{B}$ (see, e.g., [10]). By a weighted sum construction, we can define a PA $\mathcal{B}'$ associating a word w to the value $[\![\mathcal{B}]\!](w) + x^{|w|+1}$. Then there is a word w such that $[\![\mathcal{A}]\!](w) \leq [\![\mathcal{B}]\!](w)$ if and only if there is a word w such that $[\![\mathcal{A}]\!](w) < [\![\mathcal{B}']\!](w)$.

Changes for the emptiness problem. Let us consider the containment problem $[\![\mathcal{A}]\!] \leq [\![\mathcal{B}]\!]$. For all words w, we have that $[\![\mathcal{A}]\!](w) \leq [\![\mathcal{B}]\!](w)$ holds if and only if $\frac{1}{2}[\![\mathcal{A}]\!](w) + \frac{1}{2}(1 - [\![\mathcal{B}]\!](w)) \leq \frac{1}{2}$. Thus, using the weighted sum and complement operations we can get a single probabilistic automaton that outputs $\frac{1}{2}[\![\mathcal{A}]\!](w) + \frac{1}{2}(1 - [\![\mathcal{B}]\!](w))$. Complementing an automaton may, in general, increase the ambiguity (see Figure 1). However, for the automata we have constructed, this is not the case. For example, it is easy to check that the complement automaton $\overline{\mathcal{C}(x, y, z)}$ depicted in Figure 4 is—just like $\mathcal{C}(x, y, z)$—also linearly ambiguous.

6 Conclusion

In this work we have shown that the containment problem for probabilistic automata is decidable if one of the automata is finitely ambiguous and the other one is unambiguous. Interestingly, for one of the two cases, our proposed algorithm uses a satisfiability oracle for a theory whose decidability is equivalent to a weak form of Schanuel's conjecture. We have complemented our decidability results with a proof of undecidability for the case when the given automata are linearly ambiguous.

Decidability of the containment problem when both automata are allowed to be finitely ambiguous remains open. One way to tackle it is to study generalizations of the IP+EXP problem introduced in Section 4. This problem asks whether there exists $\boldsymbol{x} \in \mathbb{N}^n$ such that $f(\boldsymbol{x}) < 1$ and $M\boldsymbol{x} < \boldsymbol{c}$ for a given function f defined using exponentiations, a given matrix M, and vector $\boldsymbol{c}$. A natural way to extend the latter would be to ask that $f(\boldsymbol{x}) < g(\boldsymbol{x})$, where g is obtained in a similar way as f. The main obstacle, when trying to generalize our decidability proof for that problem, is that we lack a replacement for the cone C needed in order to obtain a result similar to Lemma 14 using the Minkowski-Weyl decomposition.

On the Complexity of Infinite Advice Strings

Abstract

We investigate in this paper a notion of comparison between infinite strings. In a general way, if $\mathcal{M}$ is a computation model (e.g. Turing machines) and $\mathcal{C}$ a class of objects (e.g. languages), the complexity of an infinite word α can be measured with respect to the amount of objects from $\mathcal{C}$ that are presentable with machines from $\mathcal{M}$ using α as an oracle.

In our case, the model $\mathcal{M}$ is finite automata and the objects $\mathcal{C}$ are either recognized languages or presentable structures, known respectively as advice regular languages and advice automatic structures. This leads to several different classifications of infinite words that are studied in detail; we also derive logical and computational equivalent measures. Our main results explore the connections between classes of advice automatic structures, MSO-transductions and two-way transducers. They suggest a closer study of the resulting hierarchy over infinite words.

1 Introduction

Several measures have been defined to describe the (intuitive) complexity of infinite strings; among others we mention subword complexity, Kolmogorov complexity, and Turing degrees. Whereas the two first methods focus on the intrinsic information contained in a string, the other one studies the relation of computability from one word to another, defining a preorder whose properties are now quite well understood. Equivalently, this preorder compares the expressive power of Turing machines that use an infinite word as oracle.

This paper follows a similar idea: we consider finite automata that can access an infinite *advice* string while processing their input. Such automata define classes of *advice regular languages* [17], that generalize standard regularity. This notion enables us to introduce a way to compare infinite words: α is simpler (in the sense of languages) than β if every language recognized by an automaton with advice α can also be recognized with advice β. It corresponds to some intuition that α contains less information than β.

Before going further, we evoke the current motivations around advice regular languages. Standard regular languages can be used to encode finite-signature structures, known as *automatic structures*. This concept, derived from Büchi's early automata-logic connections, has been shown especially relevant since its formalization in the 1990's (see e.g. [8]). The model opened the door to a vast range of decision procedures via automata constructions, but it suffers from a lack of expressiveness, since e.g. $\langle \mathbb{Q}, + \rangle$ is not automatic [20]. However, $\langle \mathbb{Q}, + \rangle$ is an example of *advice automatic structure*: it can be encoded using advice regular

languages (instead of regular languages) [13]. Such structures share many properties with the former automatic structures, furthermore the use of advices builds a rich framework to discuss algorithmic meta-theorems [2]. We shall not follow a model-theoretic point of view on advice automatic structures, but we use them to define another notion of comparison over infinite words as follows: α is simpler (in the sense of structures) than β if every automatic structure with advice α is also automatic with advice β.

Objectives and outline. This paper is structured as a quest for a relevant way to compare infinite strings through the notion of advice. The informal criteria we use to define a "good" complexity measure are the following: it should have a simple definition, be robust enough, but not too coarse because we want to separate simple classes of sequences. Note that Turing degrees do not match this intuition since they make no distinction between all computable (thus useful in practise) sequences. Our results will establish an interesting correspondence between the expressive power of advices (compared more or less using *languages*) and certain forms of *transductions*, when considering the way they classify infinite strings. This is somehow surprising, since the theory of transformations between words tends to be more fruitful and more difficult than the study of languages, following an early remark of Dana Scott [18]: "the functions computed by the various machines are more important - or at least more basic - than the sets accepted by these devices". The concept of advice helps unifying these frameworks. Furthermore, we shall use this idea to provide slightly new perspectives on (advice) automatic presentations and logic over infinite words.

After recalling preliminary results on formal languages, structures and logic, we present formally in Section 3 the notion of regularity with advice, under several variants. We study the comparisons of words provided by the classes of advice languages, as evoked above. An easy correspondence is drawn with transductions, for instance we show that every regular language with advice α is also regular with β if and only if α is the image of β under a Mealy machine. Nevertheless, we conclude that comparisons via languages are far from being robust. The last part of this section introduces the classes of advice automatic structures and briefly describes some of their properties. We then show that some variants of advice regular languages have no influence on the classes of presentable structures. This first involved result is also a first step to obtain a new robust notion of comparison.

Section 4 intends to understand the comparison over infinite words defined with respect to advice automatic structures (see above); it develops our most interesting contributions. Similar investigations were built in [14] under the formalism of set-interpretations, a very close notion. We particularize their results to show that every automatic structure with advice α is also automatic with β if and only if α is the image of β under an MSO-transduction (some logical transformation between words). We then give a more handy equivalent statement: α is the image of β under a two-way transducer. This result is quite specific and original, since such transducers are however not powerful enough to realize all *functions* of infinite words defined by MSO-transductions [4]. In Section 5 we investigate the structural properties of this relation of comparison (defined in particular by two-way transductions). Even if no previous research was done on the subject, a similar study was carried out in [10] for comparison by one-way finite transducers. In the light of their results, we rough out the structure of a new hierarchy and explain why a more involved questioning may be fruitful.

2 Preliminaries

Greek capitals Σ, Γ and Δ are used to denote alphabets, i.e. finite sets of letters; $\Box$ is a padding letter that never belongs to these alphabets. If w is a (possibly infinite) word, let

$|w| \in \mathbb{N} \cup \{\omega\}$ be its length, and for $n \geq 0$ let $w[n]$ be its $(n+1)$-th letter (when defined). For $0 \leq m \leq n$, let $w[m:n] = w[m]w[m+1]\cdots w[n-1]$ (when defined, possibly ε). We write $w[:n]$ for the prefix $w[0:n]$, and $w[n:]$ for the (possibly infinite) suffix $w[n]w[n+1]\cdots$. Denote by Reg (resp. ωReg) the class of regular (resp. ω-regular) languages.

We shall deal with structures over a finite (relational) signature, denoted by fraktur letters $\mathfrak{A}$, $\mathfrak{B}$, etc. Equality implicitly belongs to every signature. If τ is a signature and $\mathcal{L}$ a logic, $\mathcal{L}[\tau]$-formulas are $\mathcal{L}$-formulas over the signature τ. Let $\alpha \in \Gamma^\omega$, its word structure $\mathfrak{W}^\alpha = \langle \mathbb{N}, <, (P_a)_{a\in\Gamma}\rangle$ is defined with $<$ the usual ordering, and $n \in P_a$ if $\alpha[n] = a$. For succinctness reasons, $\alpha \models \phi$ stands for $\mathfrak{W}^\alpha \models \phi$ and $\mathsf{MSO}[<,\Gamma]$ for $\mathsf{MSO}[<,(P_a)_{a\in\Gamma}]$. Recall that MSO-formulas can be interpreted using weak semantics (WMSO), where we allow set quantifications to range only over finite sets.

▶ **Definition 1** (convolution). If u and v are (possibly infinite) words, their *convolution* $u \otimes v$ is the word of length $\max(|u|,|v|)$ such that:
- $(u\otimes v)[n] = (u[n], v[n])$ if $n < \min(|u|,|v|)$;
- $(u\otimes v)[n] = (u[n], \square)$ if $|v| \leq n < |u|$;
- $(u\otimes v)[n] = (\square, v[n])$ if $|u| \leq n < |v|$.

▶ **Definition 2** (presentation). Let $\mathfrak{A} := \langle A, R_1 \dots R_n\rangle$ be a relational structure and $\mathcal{C}$ a class of languages (possibly over infinite words). A *$\mathcal{C}$-presentation* of $\mathfrak{A}$ is a tuple $(L, L_=, L_1 \dots L_n)$ of languages from $\mathcal{C}$ such that there exists a surjective function $\nu : L \to A$ with:
- $L_= = \{w \otimes w' \mid w, w' \in L \text{ and } \nu(w) = \nu(w')\}$;
- for R_i (arity r_i), $L_i = \{w_1 \otimes \cdots \otimes w_{r_i} \mid \forall 1 \leq j \leq r_i, w_j \in L \text{ and } (\nu(w_1), \dots, \nu(w_{r_i})) \in R_i\}$.

The function ν describes how A is encoded in L. Since we never consider the elements of A directly, it does not belong explicitly to the presentation and can be considered as a notation. The alphabet of L is called *encoding alphabet* and often denoted Σ. The presentation is said *injective* if $L_= = \{w \otimes w \mid w \in L\}$. Fairly recently, the class of (ω)Reg-presentable structures generated much attention, under the name of *(ω-)automatic structures* [8]. Such structures can be effectively represented using a tuple of automata recognizing the previous languages. We denote by (ω)AutStr the class of (ω-)automatic structures.

▶ **Example 3.** $\langle \mathbb{N}, +, 0, 1\rangle \in$ AutStr.

▶ **Proposition 4** (folklore, [8]). *Every (ω-)automatic structure has a decidable FO-theory.*

Automatic structures enjoy several other useful properties, but the presentation fails for simple structures with decidable theory, as shown in the next theorem.

▶ **Theorem 5** ([20]). *$\langle \mathbb{Q}, +\rangle$ is not an (ω-)automatic structure.*

A model-theoretic notion closely related to presentations is concept of *interpretation*, where we describe a structure in another (host) structure via a tuple of logical formulas.

▶ **Definition 6** (interpretation). Let $\mathfrak{A}$ be a structure over a signature τ, $\mathcal{L}$ be a logic and $\mathcal{I} := (\phi_\delta(\overline{x}), \phi_=(\overline{x},\overline{y}), \phi_1(\overline{x_1}\dots\overline{x_{r_1}})\dots\phi_p(\overline{x_1}\dots\overline{x_{r_p}}))$ a tuple of $\mathcal{L}[\tau]$-formulas where $\overline{x}, \overline{y}$ and the $\overline{x_i}$ are k-tuples of free variables. Let
- $A_\delta := \{\overline{a} = (a_1 \dots a_k) \mid \mathfrak{A} \models \phi_\delta(\overline{a})\}$;
- $\sim$ is a binary relation on A_δ with $\overline{a} \sim \overline{b}$ if $\mathfrak{A} \models \phi_=(\overline{a},\overline{b})$;
- for $1 \leq i \leq p$, R_i is a relation on A_δ defined as $(\overline{a_1}\dots\overline{a_{r_i}}) \in R_i$ if $\mathfrak{A} \models \phi_i(\overline{a_1}\dots\overline{a_{r_i}})$;

we say that $\mathcal{I}$ is a *k-dimensional $\mathcal{L}$-interpretation* of a structure $\mathfrak{B}$ in the structure $\mathfrak{A}$ if:
- $\sim$ defines an congruence relation on A_δ with respect to $R_1 \dots R_p$;
- $\langle A_\delta, R_1 \dots R_p\rangle / \sim$ is isomorphic to $\mathfrak{B}$.

The interpretation is said *injective* if $\sim$ is the equality relation of A_δ. In the literature, interpretations are often directly assumed to be *1-dimensional injective interpretations*. The choice of the logic $\mathcal{L}$ provides several kinds of interpretation, detailed in Definition 7.

▶ **Definition 7.**
1. An *FO-interpretation* is a tuple of FO-formulas. The elements of $\mathfrak{A}$ are encoded as tuples of elements in the host structure $\mathfrak{B}$.
2. An *MSO-interpretation* is a tuple of MSO-formulas with free first-order variables. If we use the weak semantics, we speak of WMSO-interpretation. Once more, the elements of $\mathfrak{A}$ are encoded as tuples of elements of $\mathfrak{B}$.
3. An *S-interpretation* (set) is a tuple of MSO-formulas with free set variables. If we use weak semantic, we speak of *FS-interpretation* (finite set). The elements of $\mathfrak{A}$ are encoded as tuples of (finite) sets of elements in the host structure.

▶ **Fact 8** (closure under composition)**.**
1. *If $\mathfrak{A}$ is k-dimensionally FO-interpretable in $\mathfrak{B}$ which is l-dimensionally FO-interpretable in $\mathfrak{C}$, then $\mathfrak{A}$ is directly kl-dimensionally FO-interpretable in $\mathfrak{C}$.*
2. *If $\mathfrak{A}$ is k-dimensionally MSO-interpretable in $\mathfrak{B}$ which is 1-dimensionally MSO-interpretable in $\mathfrak{C}$, then $\mathfrak{A}$ is directly k-dimensionally MSO-interpretable in $\mathfrak{C}$*

▶ Remark. The presence of sets and the use of several dimensions force to be careful in the statements of Fact 8. Indeed, there is no reason why the composition of two S-interpretations should be a S-interpretation, since we obtain sets of sets in the whole transformation. A similar argument works for MSO-interpretations without restrictions on the dimension.

▶ Remark. The above composition properties allow - in specific cases - to transfer the decidability of the logical theory from the host structure to the other one.

Interpretations are a key concept to extend standard automata-logic equivalences from regular languages to automatic structures.

▶ **Proposition 9** ([12])**.** *A structure $\mathfrak{A}$ is automatic (resp. ω-automatic) if and only if $\mathfrak{A}$ is FS-interpretable (resp. S-interpretable) in $(\mathbb{N}, <)$.*

3 From advice regular languages to advice automatic structures

We introduce in this section an extension of regular languages known as *regular languages with advice*. This concept enables us to study some preorders over infinite words; we discuss their relevance and establish a first link with transductions. In the last subsection, we describe the structures that can be presented with these classes of languages.

3.1 Terminating languages

The idea of advice regularity is to consider languages accepted by automata that read an infinite advice string while processing its input [5]. We provide an equivalent definition which does not directly deal with automata but only languages.

▶ **Definition 10.** $L \subseteq \Sigma^*$ is *terminating regular* with advice $\alpha \in \Gamma^\omega$ if there exists a regular language $L' \subseteq (\Sigma \times \Gamma)^*$ such that $L = \{w \mid w \otimes \alpha[: |w|] \in L'\}$.

▶ **Example 11.**
1. If $L \subseteq \Sigma^*$ is regular, so is $\{w \otimes w' \mid w \in L, w' \in \Gamma^*, |w| = |w'|\}$, and considering this language shows that L is regular with any advice of Γ^ω;
2. the set $\mathrm{Pref}(\alpha) := \{\alpha[: n] \mid n \geq 0\}$ is regular with advice α.

We denote by $\mathrm{Reg}[\alpha]$ the class of regular languages with advice α. As evoked in the introduction, our goal is to measure the complexity of infinite words, through the expressiveness of their advice classes. We write $\alpha \preccurlyeq_{\mathrm{Reg}} \beta$ whenever $\mathrm{Reg}[\alpha] \subseteq \mathrm{Reg}[\beta]$, this relation is clearly a preorder over infinite words. Let the $\preccurlyeq_{\mathrm{Reg}}$-*degrees* be the equivalence classes of the relation $\preccurlyeq_{\mathrm{Reg}} \cap \succcurlyeq_{\mathrm{Reg}}$, they describe the sets of equally complex advices. We remark that ultimately periodic words (i.e. infinite words of the form uv^ω) form the least $\preccurlyeq_{\mathrm{Reg}}$-degree; indeed the inclusion $\mathrm{Reg} \subseteq \mathrm{Reg}[\alpha]$ is strict if and only if α is not ultimately periodic [5, 16]. We now provide a first equivalence with transductions.

▶ **Definition 12.** A *Mealy machine* is a 6-tuple $(Q, q_0, \Delta, \Gamma, \delta, \theta)$ where Q is the finite set of states, $q_0 \in Q$ initial state, Δ is the input alphabet, Γ is the output alphabet, $\delta : Q \times \Delta \to Q$ is the (partial) transition function, and $\theta : Q \times \Delta \to \Gamma$ is the (partial) output function.

A run of a Mealy machine is a run of the underlying deterministic automaton. On input β, the machine outputs α the concatenation of the outputs along the run on β.

▶ **Proposition 13.** *The following conditions are equivalent:*
1. $\mathrm{Reg}[\alpha] \subseteq \mathrm{Reg}[\beta]$*;*
2. α *is the image of* β *under some Mealy machine.*

Comparison via $\preccurlyeq_{\mathrm{Reg}}$ thus corresponds to computability via Mealy machines. The properties of this preorder were studied under this form in [7]. However, tiny changes in the words completely modify their $\preccurlyeq_{\mathrm{Reg}}$-degree: those classes are far from being robust.

▶ **Fact 14** ([7])**.** *Whenever* α *is not ultimately periodic, we have a strictly increasing chain* $\alpha \prec_{\mathrm{Reg}} \alpha[1:] \prec_{\mathrm{Reg}} \cdots \prec_{\mathrm{Reg}} \alpha[n:] \prec_{\mathrm{Reg}} \cdots$*. A strictly decreasing chain can be obtained similarly with* $\alpha \succ_{\mathrm{Reg}} \Box\alpha \succ_{\mathrm{Reg}} \cdots \succ_{\mathrm{Reg}} \Box^n\alpha \succ_{\mathrm{Reg}} \cdots$*.*

An interesting point is the closure properties of these classes.

▶ **Proposition 15** ([5])**.** $\mathrm{Reg}[\alpha]$ *is closed under boolean operations.*

However, when α is not ultimately periodic, $\mathrm{Reg}[\alpha]$ is not closed under projection (with respect to $\otimes$) [16]. This is a serious issue if one intends to encode logical theories, what may explain why automata with advice have remained unused for many years. A possible solution, detailed in the next paragraph, is to use ω-regularity instead of finite regularity.

3.2 Non-terminating languages and ω-regularity

Once more, we shall provide a definition in terms of languages, but it could equivalently be stated with ω-automata that read an advice string.

▶ **Definition 16** ([13])**.** $L \subseteq \Sigma^\omega$ is ω*-regular* with advice $\alpha \in \Gamma^\omega$ if there is an ω-regular language $L' \subseteq (\Sigma \times \Gamma)^\omega$ such that $L = \{w \mid w \otimes \alpha \in L'\}$.

▶ **Example 17.**
1. Every ω-regular language is also ω-regular with any advice;
2. $\{\alpha\}$ is ω-regular with advice α.

We denote by $\omega\mathrm{Reg}[\alpha]$ the class of ω-regular languages with advice α. The next definition generalizes ω-regularity with advice to finite-words languages.

▶ **Definition 18** ([13])**.** A language $L \subseteq \Sigma^*$ is *non-terminating regular* with advice $\alpha \in \Gamma^\omega$ if there is an ω-regular language $L' \subseteq ((\Sigma \uplus \Box) \times \Gamma)^\omega$ such that $L = \{w \mid w \otimes \alpha \in L'\}$.

▶ **Example 19.** $\forall n \geq 0$, $\mathrm{Pref}(\alpha[n:])$ is non-terminating regular with advice α.

Let $\mathrm{Reg}^\infty[\alpha]$ be the class of non-terminating regular languages with advice α. It follows from the definitions that $L \in \mathrm{Reg}^\infty[\alpha]$ if and only if $\{w\Box^\omega \mid w \in L\} \in \omega\mathrm{Reg}[\alpha]$. These new definitions increase the expressiveness of advice languages, since $\mathrm{Reg}[\alpha] \subseteq \mathrm{Reg}^\infty[\alpha]$ and the inclusion is strict when α is not ultimately periodic [13]. Furthermore, they solves the lack of closure properties evoked in the end of Subsection 3.1.

▶ **Proposition 20** ([13]). $\mathrm{Reg}^\infty[\alpha]$ *and* $\omega\mathrm{Reg}[\alpha]$ *are closed under boolean operations, cylindrification, and projection (with respect to* $\otimes$*).*

Let us compare infinite words with respect to this ω-regular use of advice. We define the preorders $\preccurlyeq_{\mathrm{Reg}^\infty}$ (resp. $\preccurlyeq_{\omega\mathrm{Reg}}$) based on the inclusion of the Reg^∞ (resp. $\omega\mathrm{Reg}$) classes, and the corresponding notions of degrees. It is not hard to see that ultimately periodic words are again the least $\preccurlyeq_{\mathrm{Reg}^\infty}$- and $\preccurlyeq_{\omega\mathrm{Reg}}$-degree. We now make a non-trivial step towards a generic correspondence between advices, machine transductions, and logic.

▶ **Definition 21.** An ω-regular function f is a (partial) mapping $\Gamma^\omega \to \Delta^\omega$ whose graph $\{w \otimes f(w) \mid w \in \mathrm{dom}(f)\}$ is an ω-regular language.

▶ **Definition 22** (MSO-relabelling)**.** We say that $\alpha \in \Gamma^\omega$ is the image of $\beta \in \Delta^\omega$ under an *MSO-relabelling* if there is a tuple $\mathsf{MSO}[<, \Delta]$-formulas $(\phi_a(x))_{a\in\Gamma}$ such that $\forall n \geq 0$, $\alpha[n] = a$ if and only if $\beta \models \phi_a(n)$.

▶ **Proposition 23.** *The following conditions are equivalent:*
1. $\mathrm{Reg}^\infty[\alpha] \subseteq \mathrm{Reg}^\infty[\beta]$*;*
2. $\omega\mathrm{Reg}[\alpha] \subseteq \omega\mathrm{Reg}[\beta]$*;*
3. α *is the image of* β *under some* ω*-regular function;*
4. α *is the image of* β *under some MSO-relabelling.*

▶ Remark. A word α is the image of β under some Mealy machine if and only if α is the image of β under a *relativized MSO-relabelling*, defined as a relabelling where in the formulas $\phi_a(x)$ every quantification is relativized under x, i.e. of the form $Qy/Y \leq x$.

We obtain in particular $\preccurlyeq_{\omega\mathrm{Reg}} = \preccurlyeq_{\mathrm{Reg}^\infty}$ and $\preccurlyeq_{\mathrm{Reg}} \subsetneq \preccurlyeq_{\mathrm{Reg}^\infty}$ (see Fact 14 and Example 19). To understand its structure, we briefly give a simple necessary condition for $\alpha \preccurlyeq_{\mathrm{Reg}^\infty} \beta$.

▶ **Proposition 24.** *Let* p_γ *be the* subword complexity *function of* γ *[3]. If* $\alpha \in \Gamma^\omega$ *is the image of* $\beta \in \Delta^\omega$ *under some* ω*-regular function, then* $p_\alpha \leq K \times p_\beta$ *for some constant* K*.*

For all $n \geq 1$, there exists a (computable) string α_n such that $p_{\alpha_n} : k \mapsto n^k$. Necessarily $\mathrm{Reg}^\infty[\alpha_n]$ is not contained in any $\mathrm{Reg}^\infty[\beta]$ for $\beta \in \{1, \ldots, n-1\}^\omega$ because $p_\beta(k) \leq (n-1)^k$. This observation shows that the size of the alphabet is an unavoidable parameter for $\preccurlyeq_{\mathrm{Reg}^\infty}$, which is not good news when looking for a robust notion of complexity. The rest of this paper will no longer deal with the preorders defined by languages, but it move towards presentable structures in order to describe a more relevant notion of comparison.

3.3 Advice automatic structures

We now turn to classes of structures that are presentable by advice languages. Following Definition 2 and the notations of [2], we denote by $\mathrm{AutStr}[\alpha]$ the class of $\mathrm{Reg}[\alpha]$-presentable structures, $\mathrm{AutStr}^\infty[\alpha]$ for $\mathrm{Reg}^\infty[\alpha]$-presentable, and $\omega\mathrm{AutStr}[\alpha]$ for $\omega\mathrm{Reg}[\alpha]$-presentable. Such structures are said to be *(ω-)automatic with advice* α. Their study is located a level of abstraction higher than what was done above, since the languages have no longer importance in theirselves, but are only used to encode other objects.

An advice automatic structure can be described "effectively" via a tuple of automata (as for standard automatic structures), and a certain advice α. In fact, the decidability feature of automatic structures is preserved as soon as α is decidable enough.

▶ **Proposition 25** ([2]). *If $\mathfrak{W}^\alpha$ has a decidable MSO-theory, every structure in* $\omega\mathrm{AutStr}[\alpha]$, $\mathrm{AutStr}^\infty[\alpha]$ *or* $\mathrm{AutStr}[\alpha]$ *has a decidable FO-theory.*

Large classes of infinite words with decidable MSO-theory have been described, see e.g. [6] or [19]. We briefly show why the generalization from automatic structures to advice automatic structures can be fruitful (compare the next result to Theorem 5).

▶ **Fact 26** ([13]). $\langle \mathbb{Q}, + \rangle \in \mathrm{AutStr}[\alpha]$ *for some advice α with decidable MSO-theory.*

We now briefly describe basic properties of presentations with advice.

▶ **Fact 27.** *Inclusion of language classes give* $\mathrm{AutStr} \subseteq \mathrm{AutStr}[\alpha] \subseteq \mathrm{AutStr}^\infty[\alpha]$ *and* $\omega\mathrm{AutStr} \subseteq \omega\mathrm{AutStr}[\alpha]$. *Inclusions are equalities if α is ultimately periodic.*

▶ Remark. There is however no immediate argument to deduce $\mathrm{AutStr} \subsetneq \mathrm{AutStr}[\alpha]$ when α is not ultimately periodic. We shall see in Section 5 that this statement is true.

As an immediate consequence of the definitions, $\mathrm{AutStr}^\infty[\alpha] \subseteq \omega\mathrm{AutStr}[\alpha]$ and $\omega\mathrm{AutStr}[\alpha]$ contains uncountable structures, whereas $\mathrm{AutStr}^\infty[\alpha]$ does not. This idea can be refined.

▶ **Theorem 28** ([2]). $\mathrm{AutStr}^\infty[\alpha]$ *is exactly the subclass of countable structures of* $\omega\mathrm{AutStr}[\alpha]$.

The next result shows to what extent the advice contains the seeds of every presentation, and how we generalized the case of automatic structures.

▶ **Proposition 29** ([1]).
1. $\mathfrak{A} \in \omega\mathrm{AutStr}[\alpha]$ *if and only if $\mathfrak{A}$ is S-interpretable in $\mathfrak{W}^\alpha$;*
2. $\mathfrak{A} \in \mathrm{AutStr}^\infty[\alpha]$ *if and only if $\mathfrak{A}$ is FS-interpretable in $\mathfrak{W}^\alpha$.*

▶ Remark ([1]). If the presentation is injective and the encoding is alphabet binary, the resulting interpretation can be done 1-dimensional and injective.

Dealing directly with $\mathrm{Reg}[\alpha]$-presentations seems more difficult, since basic properties lack to this class of languages. We now show $\mathrm{AutStr}^\infty[\alpha] = \mathrm{AutStr}[\alpha]$, hence the expression "advice automatic structure" is not ambiguous. To give an intuition of the proof, we note that an ω-automaton performs an infinite run on $w \otimes \alpha$ (for w finite) in two steps: first, it follows a finite run on $w \otimes \alpha[: |w|]$, then it checks some ω-regularity on $\square^\omega \otimes \alpha[|w| :] \simeq \alpha[|w| :]$. Basically, the ω-regularity feature is only used on suffixes of the advice. On the other hand, a automaton for $\mathrm{Reg}[\alpha]$ is blind to the ω-future. We show that it can nevertheless look at some "finite amount of future" and deduce corresponding ω-regularity on the suffixes. A key idea is that since the advice is *fixed*, so are several properties of its suffixes.

▶ **Theorem 30.** *Let L be an ω-regular language and $\alpha \in \Gamma^\omega$ a fixed word. There is a (finite words) regular language L' and $N \geq 0$ such that for all $n \geq N$, $\alpha[n :] \in L$ if and only if $\alpha[n :]$ has a finite prefix in L'. Furthermore, if L can be described by an $\mathsf{FO}[<, \Gamma]$-sentence, L' can be described by an $\mathsf{FO}[<, \Gamma]$-sentence as well.*

Proof sketch. The case of FO is treated via equivalence with LTL, known [15] as Kamp's Theorem. For MSO in general, we deduce the result from the work of A.L. Semenov [19]. ◀

Corollary 31 will formalize our intuition that terminating automata can check ω-regular properties on suffixes. It thus enables us to explicit the relationships between $\mathrm{Reg}[\alpha]$ and $\mathrm{Reg}^\infty[\alpha]$, and between $\mathrm{AutStr}[\alpha]$ and $\mathrm{AutStr}^\infty[\alpha]$.

▶ **Corollary 31.** *Let $L \subseteq \Gamma^\omega$ be an ω-regular language and $\alpha \in \Gamma^\omega$. There is a function $f : \mathbb{N} \to \mathbb{N}$ such that $\{0^n\Box^{f(n)} \mid \alpha[n:] \in L\} \in \mathrm{Reg}[\alpha]$.*

▶ **Corollary 32.** *Let $\alpha \in \Gamma^\omega$. For every language $L \in \mathrm{Reg}^\infty[\alpha]$, there is a function $f : \mathbb{N} \to \mathbb{N}$ such that $\{w\Box^{f(|w|)} \mid w \in L\} \in \mathrm{Reg}[\alpha]$.*

▶ **Corollary 33.** *For every advice α,* $\mathrm{AutStr}[\alpha] = \mathrm{AutStr}^\infty[\alpha]$.

▶ Remark. Thanks to these results, we also managed to build a normal form for MSO-formulas (with free variables) when interpreted in a fixed word model, see [9].

4 Complexity of advices when describing structures

After the first results of the previous section on advice automatic structures, we are now able to understand which preorder they describe over infinite words. Corollary 33 implies in particular that $\mathrm{AutStr}[\alpha] \subseteq \mathrm{AutStr}[\beta]$ if and only if $\mathrm{AutStr}^\infty[\alpha] \subseteq \mathrm{AutStr}^\infty[\beta]$. The objective of this section is to show equivalence with $\omega\mathrm{AutStr}[\alpha] \subseteq \omega\mathrm{AutStr}[\beta]$ and give several other characterizations. The climax lies in Theorem 39 and Theorem 45, where we relate our notions to well-known logical transformations and finite transducers.

▶ **Definition 34.** A (k-copying) *MSO-transduction (MSOT)* from Δ^ω to Γ^ω is a tuple of $\mathsf{MSO}[<, \Delta]$-formulas with free first-order variables.

$$(\phi_1^a(x))_{a\in\Gamma} \dots (\phi_k^a(x))_{a\in\Gamma}, (\phi_{i,j}^<(x,y))_{1\le i,j\le k})$$

The semantics of an MSOT τ is defined as that of an MSO-interpretation in k disjoint copies of a host word structure. More precisely, the structure $I_\tau(\mathfrak{W}^\beta)$ (not necessarily a word) has signature $\{<, (P_a)_{a\in\Gamma}\}$ and is defined as follows:

- $\mathrm{dom}(I_\tau(\mathfrak{W}^\beta)) = \bigcup_{1\le i\le k}\{(n,i) \mid$ there is $a \in A$ such that $\beta \models \phi_i^a(n)\}$;
- if $(n,i) \in \mathrm{dom}(I_\tau(\mathfrak{W}^\beta))$, then $(n,i) \in P_a$ if and only if $\beta \models \phi_i^a(n)$;
- if $(m,j) \in \mathrm{dom}(I_\tau(\mathfrak{W}^\beta))$, then $(n,i) < (m,j)$ if and only if $\mathcal{U} \models \phi_{i,j}^<(n,m)$.

Since we are interested in transformations between words, we only consider the case when $I_\tau(\mathfrak{W}^\beta)$ is a word structure (what is syntactically definable by adding an $\mathsf{MSO}[<,\Delta]$-sentence for the domain). Each MSO-transduction τ then realizes a (partial) function $\tau : \Delta^\omega \to \Gamma^\omega$ whose domain is $\{\beta \in \Delta^\omega \mid I_\tau(\mathfrak{W}^\beta)$ is (isomorphic to) a word structure$\}$, the image $\tau(\beta)$ of β being the unique α such that $I_\tau(\mathfrak{W}^\beta) \simeq \mathfrak{W}^\alpha$.

The reader is asked to keep in mind that MSOT define a certain class of functions on infinite strings, even if our main concern is only the existence of a transduction between two fixed words. We write $\alpha \preccurlyeq_{\mathsf{MSOT}} \beta$ if there is a MSO-transduction τ such that $\tau(\beta) = \alpha$.

▶ Remark. MSO-relabelings (see Definition 22), relativized MSO-relabelings, and 1- dimensional MSO-interpretations can all seen as syntactical fragments of 1-copying MSOT.

▶ Remark. Even if MSO-interpretations in general are not closed under composition, it is the case of MSOT [4]. Thus $\preccurlyeq_{\mathsf{MSOT}}$ is transitive, and is even a preorder over infinite words.

▶ **Example 35.**

1. If $\alpha \preccurlyeq_{\mathrm{Reg}^\infty} \beta$ then $\alpha \preccurlyeq_{\mathsf{MSOT}} \beta$ (thus $\preccurlyeq_{\mathsf{MSOT}}$ is a more generic notion of comparison than the preorders of Section 3, we shall see that the increase of power is strict);
2. modifying a finite part of α does not change its MSOT-degree;
3. if w is a finite word, we denote by $\widetilde{w}$ its mirror image; if $\alpha := w_1\#w_2\#\dots \in (\Gamma^*\#)^\omega$, let $\widetilde{\alpha} := \widetilde{w_1}\#\widetilde{w_2}\#\dots$; then $\widetilde{\alpha} \preccurlyeq_{\mathsf{MSOT}} \alpha$.

4.1 From automatic structures to MSO-transductions

When searching a complete structure of an advice, a naive idea is that $\mathfrak{W}^\alpha \in \mathrm{AutStr}^\infty[\beta]$ if and only if $\mathrm{AutStr}^\infty[\alpha] \subseteq \mathrm{AutStr}^\infty[\beta]$. However, this statement will turn out to be false. We need a stronger object that is presented in Definition 36.

▶ **Definition 36** ([14]). Let $\mathfrak{A} = \langle A, R_1 \dots R_n \rangle$ be a structure, we define its *weak powerset structure* $\mathcal{P}^f(\mathfrak{A})$ as the structure $\langle \mathcal{P}^f(A), R'_1 \dots R'_n, \subseteq \rangle$ where:

- $\mathcal{P}^f(A)$ is the weak powerset (set of finite subsets) of A;
- $\subseteq$ is the inclusion relation on $\mathcal{P}^f(A)$;
- $R'_i(A_1, \dots, A_{r_i})$ holds in $\mathcal{P}^f(\mathfrak{A})$ if and only if $A_1, \dots A_{r_i}$ are singletons $\{a_1\}, \dots, \{a_{r_i}\}$ and $R_i(a_1, \dots a_{r_i})$ holds in $\mathfrak{A}$.

▶ Remark. $\mathfrak{A}$ is FS-interpretable in $\mathfrak{B}$ if and only if $\mathfrak{A}$ is FO-interpretable in $\mathcal{P}^f(\mathfrak{B})$.

▶ **Fact 37.** $\mathrm{AutStr}^\infty[\alpha]$ *is the class of structures FO-interpretable in* $\mathcal{P}^f(\mathfrak{W}^\alpha)$ *(see Proposition 29). We have* $\mathrm{AutStr}^\infty[\alpha] \subseteq \mathrm{AutStr}^\infty[\beta]$ *if and only if* $\mathcal{P}^f(\mathfrak{W}^\alpha) \in \mathrm{AutStr}^\infty[\beta]$.

This result provides a characterization which is abstract and, in some respects, trivial. Nevertheless, we get the intuition that powerset structures are a key notion to understand advice automaticity. In the sequel, a (Δ-labelled) tree structure has the form $\langle A, <, (P_a)_{a \in \Delta} \rangle$ where the domain A is a prefix-closed subset of $\{0,1\}^*$, $w < w'$ holds whenever w is a prefix of w' and the P_a label the nodes of A with $a \in \Delta$. Word structures are particular trees.

▶ **Theorem 38** ([14], Corollary 4.4). *Let* $\mathfrak{A}$ *a structure and* $\mathfrak{T}$ *a tree structure. If* $\mathcal{P}^f(\mathfrak{A})$ *is* 1*-dimensionally injectively FS-interpretable in* $\mathfrak{T}$*, then* $\mathfrak{A}$ *is* 1*-dimensionally injectively WMSO-interpretable in* $\mathfrak{T}$.

In the case of advice automatic structures, Theorem 38 is at the same time too generic and too restrictive. On the one hand, we only use interpretations in word structures $\mathfrak{W}^\alpha$. On the other hand, we need arbitrarily dimensional FS-interpretations, and they are not supposed to be injective. We will manage to meet this conditions, up to a slight modification of the advice, and the WMSO-interpretation will be transformed into a more generic MSOT.

▶ **Theorem 39.** *The following conditions are equivalent:*

1. $\omega\mathrm{AutStr}[\alpha] \subseteq \omega\mathrm{AutStr}[\beta]$*;*
2. $\mathrm{AutStr}^\infty[\alpha] \subseteq \mathrm{AutStr}^\infty[\beta]$*;*
3. $\alpha \preccurlyeq_{MSOT} \beta$.

Proof sktech. We use Proposition 29 several times. The way from 1. to 2. is a consequence of Theorem 28. If 2. holds, we show that $\mathcal{P}^f(\mathfrak{W}^\alpha)$ has an injective binary $\mathrm{Reg}^\infty[\beta']$-presentation for some infinite word β' so that $\beta' \preccurlyeq_{\mathsf{MSOT}} \beta$. As remarked above, $\mathcal{P}^f(\mathfrak{W}^\alpha)$ is thus 1-dimensionally injectively FS-interpretable in the tree $\mathfrak{W}^{\beta'}$, hence Theorem 38 provides a 1-dimensionally WMSO-interpretation of $\mathfrak{W}^\alpha$ in $\mathfrak{W}^{\beta'}$, what implies $\alpha \preccurlyeq_{\mathsf{MSOT}} \beta'$. Composing MSOT concludes that $\alpha \preccurlyeq_{\mathsf{MSOT}} \beta$. If 3. is true and $\mathfrak{A}$ is S-interpretable in $\mathfrak{W}^\alpha$, then $\mathfrak{A}$ is S-interpretable in $\mathfrak{W}^\beta$ by some composition argument. ◀

As a consequence, all the preorders defined by advice-presentable structures converge towards the same comparison via MSO-transductions. This point gives a deep theoretical meaning to their study. Another virtue of Theorem 39 is the ability to translate immediately the results of Example 35 in terms of advice automatic structures.

▶ **Example 40.**

1. If $\alpha \preccurlyeq_{\mathrm{Reg}^\infty} \beta$ then $\mathrm{AutStr}[\alpha] \subseteq \mathrm{AutStr}[\beta]$;
2. modifying a finite part of α does not modify $\mathrm{AutStr}[\alpha]$;
3. if $\alpha \in (\Gamma^*\#)^\omega$, then $\mathrm{AutStr}[\alpha] = \mathrm{AutStr}[\widetilde{\alpha}]$.

4.2 An equivalent computational model: two-way transducers

We will complete our parallel with transductions via an equivalent simple machine model. Furthermore, it will be very useful to describe the structural properties of the preorder.

▶ **Definition 41.** A *two-way finite transducer* (2WFT) is a 6-tuple $(Q, q_0, \Delta \uplus \{\vdash\}, \Gamma, \delta, \theta)$ where Q is the finite set of states, $q_0 \in Q$ is initial, Δ is the input alphabet, Γ is the output alphabet, $\delta : Q \times (\Delta \uplus \{\vdash\}) \to Q \times \{\triangleleft, \triangleright\}$ is the (partial) transition function, and $\theta : Q \times (\Delta \uplus \{\vdash\}) \to \Gamma^*$ is the (partial) output function.

A 2WFT has a two-way read-only input tape and a one-way output mechanism. The component $\{\triangleleft, \triangleright\}$ determines the left or right move of the head on the input tape. When the 2WFT is given $\beta \in \Delta^\omega$ as an input word, this tape contains $\vdash \beta$ (adding a symbol $\vdash$ helps the transducer to notice the beginning of its input when going left). The definition of the (partial) function $\Delta^\omega \to \Gamma^\omega$ realized the 2WFT follows like for Mealy machines.

▶ Remark. The transducer is said to be *one-way* (1WFT, or just finite transducer) if all its transitions are of the form $(q, \triangleright)$. Mealy machines are a particular case of 1WFT.

▶ **Example 42.** There is a three-state 2WFT outputting $\widetilde{\alpha}$ on every $\alpha \in (\Gamma\#)^\omega$. Its behavior is the following: scan a maximal #-free block, read it in a reversed way while outputting, then output # and move to the next block.

When considering definable *functions* between *finite* strings, a well-known equivalence holds between MSOT and 2WFT (Theorem 43). The definitions of MSOT and 2WFT have to be slightly sharpened to get the exact correspondence, see details in [11].

▶ **Theorem 43** ([11])**.** *(Partial) functions over finite words $\Delta^* \to \Gamma^*$ definable by MSOT are the (partial) functions realized by 2WFT.*

Fairly recently, this result was extended to functions between infinite strings, but some complications quickly appear: deciding the validity of MSO-sentences is not always possible without reading the (variable) input entirely. Thus 2WFT alone are not powerful enough and they need extra features like ω-regular lookahead, i.e. ability to check instantly ω-regular properties of the suffixes of the input starting in the position of the reading head.

▶ **Theorem 44** ([4])**.** *(Partial) functions over infinite words $\Delta^\omega \to \Gamma^\omega$ definable by MSOT are the (partial) functions realized by 2WFT with ω-regular lookahead whose runs always visit the whole input string.*

When looking closely at Theorem 43 and Theorem 44 in the light of our previous results, a question arises naturally: it is possible to get rid of the lookaheads when fixing the input infinite word? Indeed, we have always considered transformations from a *fixed* word and we noticed in Subsection 3.3 that this restriction simplified certain notions. Theorem 45 gives a positive answer. This involved result is not a direct consequence of Theorem 44, since we are not aware of a simple manner to remove the ω-lookaheads when fixing the input.

▶ **Theorem 45.** *$\alpha \preccurlyeq_{MSOT} \beta$ if and only if $\alpha \preccurlyeq_{2WFT} \beta$.*

Proof sketch. If $\alpha \preccurlyeq_{\mathsf{2WFT}} \beta$, the result follows from Theorem 44. Indeed the transformation can be computed by some 2WFT (with a trivial ω-lookahead) whose run visits the whole input. Assume now that $\alpha \preccurlyeq_{\mathsf{MSOT}} \beta$. It follows from [4] that α can be computed from β by an *ω-streaming string transducer (SST)*. We provide a rather long argument to show that an SST can be transformed into a 2WFT with a *lookbehind* feature, when the input word is fixed. Lastly, the lookbehind can be removed by some standard techniques (a lookbehind only deals with a *finite* part of the input, which is not the case of an ω-lookahead). ◀

5 The two-way transductions hierarchy

We initiate in this section a study of the previous two-way transductions between infinite words. It can equivalently be seen as the preorder defined by MSOT, or classes AutStr[α], AutStr$^\infty$[α] and ωAutStr[α]; but the 2WFT formulation is - as predicted above - the easiest way to deduce interesting statements. We shall use the term *2WFT hierarchy* to describe the ordered set of 2WFT-degrees (i.e. equivalence classes of $\preccurlyeq_{\mathsf{2WFT}} \cap \succcurlyeq_{\mathsf{2WFT}}$).

A more or less similar work has been done in [10], with the relation $\preccurlyeq_{\mathsf{1WFT}}$ defined by computability via 1WFT. This definition clearly describes a preorder. Even if no previous research exists on the 2WFT hierarchy, we shall see that several results on the 1WFT can be adapted in our context, after a variable amount of work. Note that $\preccurlyeq_{\mathsf{1WFT}} \subseteq \preccurlyeq_{\mathsf{2WFT}}$.

▶ **Proposition 46.**
1. *There are uncountably many distinct 2WFT-degrees;*
2. *a set of 2WFT-degree has an upper bound if and only if it is countable;*
3. *the 2WFT hierarchy has no greatest degree;*
4. *every 2WFT-degree contains a binary string.*

▶ Remark. Considering binary strings is thus sufficient to describe all the degrees. Comparing this result with Proposition 24 shows that the preorder $\preccurlyeq_{\mathrm{Reg}^\infty}$ defined by MSO-relabelings is strictly weaker than $\preccurlyeq_{\mathsf{2WFT}} = \preccurlyeq_{\mathsf{MSOT}}$.

As a consequence of Proposition 46, the 2WFT hierarchy is not trivial. We now show that it is fine-grained enough to distinguish ultimately periodic words.

▶ **Proposition 47.** *Ultimately periodic words are the least 2WFT-degree.*

This result shows, through the equivalences of Section 4, that non-trivial advices *strictly* increase the class of presentable structures (what had no reason to be obvious).

▶ **Corollary 48.** *$\mathcal{P}^f(\mathfrak{W}^\alpha)$ is automatic if and only if α is ultimately periodic.*

▶ Remark. There are non-ultimately periodic sequences α such that $\mathfrak{W}^\alpha$ is automatic [6]. However, no sufficient and necessary condition is known to describe such sequences.

We now turn to a more involved statement. A sequence β is said to be *prime* if it is a minimal but non-trivial word. Formally, β non-ultimately periodic is prime in the 2WFT hierarchy if for all $\alpha \preccurlyeq_{\mathsf{2WFT}} \beta$, either $\beta \preccurlyeq_{\mathsf{2WFT}} \alpha$ or α is ultimately periodic. The existence of prime sequences shows in particular that the 2WFT hierarchy is not dense.

▶ **Theorem 49.** *The sequence $\pi := \prod_{n=0}^{\infty} 0^n 1$ is prime in the 2WFT hierarchy.*

Proof sketch. Our work is to show that if $\alpha \preccurlyeq_{\mathsf{2WFT}} \pi$, then $\alpha \preccurlyeq_{\mathsf{1WFT}} \pi$. Now, since π is prime in the 1WFT-hierarchy [10], either $\pi \preccurlyeq_{\mathsf{1WFT}} \alpha$ or α is in the least 1WFT-degree, which is also the set of ultimately periodic words. ◀

Classifying all infinite strings may neither be relevant nor useful in practice. We now look at two particular classes of infinite words closed under 2WFT transformations.

▶ **Proposition 50** (subhierarchies)**.**
1. *If $\alpha \preccurlyeq_{\mathsf{2WFT}} \beta$ and if β is computable, then α is computable;*
2. *if $\alpha \preccurlyeq_{\mathsf{2WFT}} \beta$ and if $\mathfrak{W}^\beta$ has a decidable MSO-theory, so has $\mathfrak{W}^\alpha$.*

▶ **Fact 51.** *The string π has a decidable MSO-theory (see e.g. [6]).*

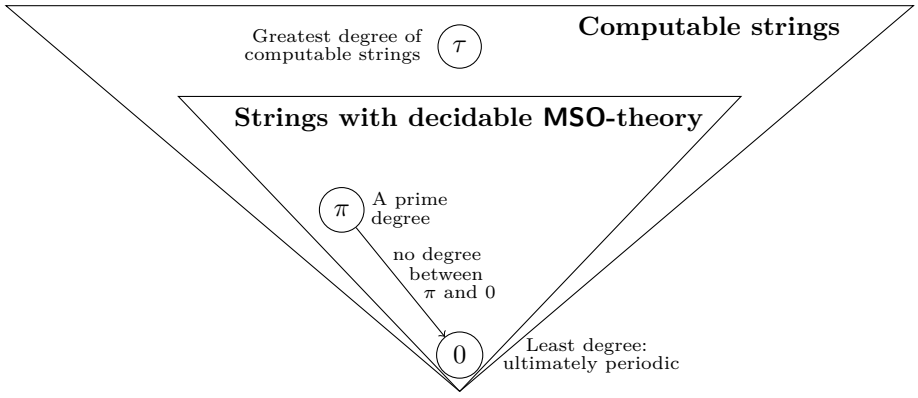

Figure 1 An partial look on the 2WFT hierarchy

Table 1 Equivalent definitions for preorders over ω-words

Advice	Reg	Reg^∞ ωReg	AutStr AutStr^∞ ωAutStr
Logic	rel. MSO-relabelings	MSO-relabelings	MSOT
Machine	Mealy machines	ω-regular functions	2WFT

▶ **Proposition 52** (adapted from [10] for 1WFT). *There exists a greatest degree τ of computable strings in the 2WFT hierarchy.*

▶ **Fact 53.** *The MSO theory of τ is not decidable.*

Figure 1 summarizes the previous results. Note that the 2WFT-degree of ultimately periodic sequences, the 2WFT-degree of π and the 2WFT-degree of τ have to be distinct. Several challenging issues naturally arise about the structure of the 2WFT hierarchy and its subhierarchies. Among others, an interesting question is to describe the degrees of well-known sequences with decidable MSO-theory, for instance morphic words [6].

6 Conclusion and outlook

Preorders of advices, logic and transducers. Our first concern in this paper was the study of various preorders over infinite words, related to the notion of advice strings. The results draw a generic correspondance between definability with advice, logical transductions and machine transductions. Table 1 summarizes this philosophy in an elegant way, note that the notion of (relativized) MSO-relabelings is less standard than MSOT. The gap between MSO-relabelings and MSOT shows that having basic knowledge on the languages is far from being sufficient to understand the richness of presentable structures.

A meaningful hierarchy of infinite words. Two-way transductions appear here to be more basic than relations defined by one-way machines, since they are clearly motivated by logical issues. Furthermore, it fits our informal conditions to be a "good" complexity measure over infinite words. A more involved study of the 2WFT hierarchy may help classifying certain hierarchies of structures, or even understand standard automatic presentations. We recall that such transductions over infinite words are (rather) unexplored.

Resynchronizing Classes of Word Relations

Abstract

A natural approach to define binary word relations over a finite alphabet $\mathbb{A}$ is through two-tape finite state automata that recognize regular languages over $\{1,2\} \times \mathbb{A}$, where (i,a) is interpreted as reading letter a from tape i. Accordingly, a word $w \in L$ denotes the pair $(u_1, u_2) \in \mathbb{A}^* \times \mathbb{A}^*$ in which u_i is the projection of w onto i-labelled letters. While this formalism defines the well-studied class of Rational relations (*a.k.a.* non-deterministic finite state transducers), enforcing restrictions on the reading regime from the tapes, which we call *synchronization*, yields various sub-classes of relations. Such synchronization restrictions are imposed through regular properties on the projection of the language onto $\{1,2\}$. In this way, for each regular language $C \subseteq \{1,2\}^*$, one obtains a class $\textsc{Rel}(C)$ of relations. Regular, Recognizable, and length-preserving rational relations are all examples of classes that can be defined in this way.

We study the problem of containment for synchronized classes of relations: given $C, D \subseteq \{1,2\}^*$, is $\textsc{Rel}(C) \subseteq \textsc{Rel}(D)$? We show a characterization in terms of C and D which gives a decidability procedure to test for class inclusion. This also yields a procedure to re-synchronize languages from $\{1,2\} \times \mathbb{A}$ preserving the denoted relation whenever the inclusion holds.

1 Introduction

We study are relations of finite words, that is, binary relations $R \subseteq \mathbb{A}^* \times \mathbb{A}^*$ for a finite alphabet $\mathbb{A}$. The study of these relations dates back to the works of Büchi, Elgot, Mezei, and Nivat in the 1960s [4, 8, 13], with much subsequent work done later (*e.g.*, [2, 6]). Most of the investigations focused on extending the standard notion of regularity from languages to relations. This effort has followed the long-standing tradition of using equational, operational, and descriptive formalisms – that is, finite monoids, automata, and regular expressions – for describing relations, and gave rise to three different classes of relations: the *Recognizable*, the *Automatic* (*a.k.a. Regular* [2] or *Synchronous* [6]), and the *Rational* relations.

The above classes of relations can be seen as three particular examples of a much larger (in fact infinite) range of possibilities, where relations are described by special languages over extended alphabets, called *synchronizing languages* [10]. Intuitively, the idea is to describe a binary relation by means of a two-tape automaton with two heads, one for each tape, which can move independently one of the other. In the basic framework of synchronized relations, one lets each head of the automaton to either move right or stay in the same

position. In addition, one can constrain the possible sequences of head motions by a suitable regular language $C \subseteq \{1,2\}^*$. In this way, each regular language $C \subseteq \{1,2\}^*$ induces a class of binary relations, denoted $\textsc{Rel}(C)$, which is contained in the class of Rational relations (due to Nivat's Theorem [13]). For example, the class of Recognizable, Automatic, and Rational relations are captured, respectively, by the languages $C_{\text{Rec}} = \{1\}^* \cdot \{2\}^*$, $C_{\text{Aut}} = \{12\}^* \cdot \{1\}^* \cup \{12\}^* \cdot \{2\}^*$, and $C_{\text{Rat}} = \{1,2\}^*$. However, it should be noted that other well-known subclasses of rational relations, such as deterministic or functional relations, are not captured by notion of synchronization. In general, the correspondence between a language $C \subseteq \{1,2\}^*$ and the induced class $\textsc{Rel}(C)$ of synchronized relations is not one-to-one: it may happen that different languages C, D induce the same class of synchronized relations. There are thus fundamental questions that arise naturally in this framework: *When do two classes of synchronized relations coincide, and when is one contained in the other?* Our contribution is a precise algorithmic answer to this type of questions.

More concretely, given a binary alphabet $\mathbb{2} = \{1,2\}$ and another finite alphabet $\mathbb{A}$, a word $w \in (\mathbb{2} \times \mathbb{A})^*$ is said to *synchronize* the pair $(w_1, w_2) \in \mathbb{A}^* \times \mathbb{A}^*$ if, for both $i = 1, 2$, w_i is the projection of w on $\mathbb{A}$ restricted to the positions marked with i. For short, we denote this by $[\![w]\!] = (w_1, w_2)$ – *e.g.*, $[\![(1,a)(1,b)(2,b)(1,a)(2,c)]\!] = (aba, bc)$. According to this definition, every word over $\mathbb{2} \times \mathbb{A}$ synchronizes a pair of words over $\mathbb{A}$, and every pair of words over $\mathbb{A}$ is synchronized by (perhaps many) words over of $\mathbb{2} \times \mathbb{A}$. This notion is readily lifted to languages: a language $L \subseteq (\mathbb{2} \times \mathbb{A})^*$ synchronizes the relation $[\![L]\!] = \{[\![w]\!] \mid w \in L\} \subseteq \mathbb{A}^* \times \mathbb{A}^*$. For example, $[\![((1,a)(2,a) \cup (1,b)(2,b))^*]\!]$ denotes the equality relation over $\mathbb{A} = \{a,b\}$.

In this setup, one can define classes of relations by restricting the set of admitted synchronizations. The natural way of doing so is to fix a language $C \subseteq \mathbb{2}^*$, called *control language*, and let L vary over all regular languages over the alphabet $\mathbb{2} \times \mathbb{A}$ whose projections onto $\mathbb{2}$ are in C. Thus, for every regular $C \subseteq \mathbb{2}^*$, there is an associated class $\textsc{Rel}(C)$ of C-controlled relations, namely, relations synchronized by regular languages $L \subseteq (\mathbb{2} \times \mathbb{A})^*$ whose projection onto $\mathbb{2}$ are in C. Clearly, $C \subseteq D \subseteq \mathbb{2}^*$, implies $\textsc{Rel}(C) \subseteq \textsc{Rel}(D)$, but the converse does not hold: while $\textsc{Rel}(C_{\text{Rec}}) = \textit{Recognizable} \subseteq \textit{Automatic} = \textsc{Rel}(C_{\text{Aut}})$, we have $C_{\text{Rec}} \not\subseteq C_{\text{Aut}}$. Moreover, as we have mentioned earlier, different control languages may induce the same class of synchronized relations. For example, once again, the class of Recognizable relations is induced by the control language $C_{\text{Rec}} = \{1\}^*\{2\}^*$, but also by $C'_{\text{Rec}} = \{1\}^*\{2\}^*\{1\}^*$, and the class of Automatic relations is induced by $C_{\text{Aut}} = \{12\}^* \cdot \{1\}^* \cup \{12\}^* \cdot \{2\}^*$, or equally by $C'_{\text{Aut}} = \{21\}^* \cdot \{1\}^* \cdot \{2\}^*$. This 'mismatch' between control languages and induced classes of relations gives rise to the following algorithmic problem.

Class Containment Problem	
Input:	Two regular languages $C, D \subseteq \mathbb{2}^*$
Question:	Is $\textsc{Rel}(C) \subseteq \textsc{Rel}(D)$?

Note that the above problem is different from the (C, D)-membership problem on synchronized relations, which consists in deciding whether $R \in \textsc{Rel}(D)$ for a given $R \in \textsc{Rel}(C)$, and which can be decidable or undecidable depending on C, D [5]. The Class Containment Problem can be seen as the problem of whether *every* C-controlled regular language L has a D-controlled regular language L' so that $[\![L]\!] = [\![L']\!]$. It was proved in [10] that this problem is decidable for some particular instances of D, namely, for $D =$ *Recognizable*, *Automatic*, *Length-preserving* or *Rational*. More specifically, given a regular language C over the binary alphabet $\mathbb{2}$, it is decidable whether $\textsc{Rel}(C)$ is contained or not in *Recognizable* (respectively, *Automatic*, *Length-preserving* and *Rational*). Our main contribution is a procedure for deciding the Class Containment Problem in full generality, i.e. for arbitrary C and D.

▶ **Main Theorem.** *The Class Containment Problem is decidable.*

In addition, our results show that, for positive instances (C, D), one can effectively transform any regular C-controlled language L into a regular D-controlled language L' so that $[\![L]\!] = [\![L']\!]$. By 'effectively transform' we mean that one can receive as input an automaton (or a regular expression) for L and produce an automaton (or a regular expression) for L'. In particular, we show a normal form of control languages, implying that every synchronized class can be expressed through a control language of star-height at most 1.

Related work. The formalization of a framework in which one can describe classes of word relations by means of synchronization languages is quite recent [10]. As already mentioned, the class containment problem was only addressed for the classes of Recognizable, Automatic and Rational relations, for which several characterizations have been proposed [10]. The formalism of synchronizations has been extended beyond rational relations by means of semi-linear constraints [9] in the context of path querying languages for graph databases.

The paper [3] studies relations with origin information, as induced by non-deterministic (one-way) finite state transducers. Origin information can be seen as a way to describe a synchronization between input and output words – somehow in the same spirit of our synchronization languages – and was exploited to recover decidability of the equivalence problem for transducers. The paper [11] pursues further this principle by studying "distortions" of the origin information, called resynchronizations. Despite the similar terminology and the connection between origins and synchronizing languages, the problems studied in [3, 11] are of rather different nature than our Class Containment Problem.

Organization. After the preliminaries on subclasses of regular languages, we define in Section 3 the framework of synchronized relations. Section 4 provides a roadmap with the three key ingredients of our characterization. Sections 5, 6 and 7 contain the technical details for these main ingredients. In Section 8 we discuss the computability of the characterization.

2 Preliminaries

We denote by $\mathbb{N}, \mathbb{Q}$ the sets of non-negative integers and rationals. We use standard interval notation as in, for example, $(a, b]_{\mathbb{Q}} = \{c \in \mathbb{Q} \mid a < c \leq b\}$. $\mathbb{A}, \mathbb{B}$ denote arbitrary finite alphabets, and $\mathbb{2}$ the special binary alphabet $\{1, 2\}$.

Words and shuffles. For a word $w \in \mathbb{A}^*$, $|w|$ is its length, and $|w|_a$ is the number of occurrences of symbol a in w. We denote by $w[i, j]$ the factor of w between positions i and j (included), for $1 \leq i \leq j \leq |w|$, and we write $w[i]$ for $w[i, i]$. We will also make use of the **shuffle** operation, which maps a finite set of words $w_1, \ldots, w_n$ to the language $\mathrm{shuffle}\{w_1, \ldots, w_n\}$ of all words w for which there is a partition $I_1, \ldots, I_n$ of $[1, |w|]$ so that each w_i is the projection of w onto I_i. For example, $\mathrm{shuffle}\{ab, cd\} = \{abcd, cdab, acbd, acdb, \ldots\}$.

Parikh image. The **Parikh image** of a word w over $\mathbb{A}$ is the tuple $\pi(w)$ associating each symbol $a \in \mathbb{A}$ to its number of occurrences $|w|_a$ in w. We will mostly use Parikh images for words over $\mathbb{2}^*$, which are thus pairs $\pi(w) = (|w|_1, |w|_2)$. We naturally extend this to languages by letting $\pi(L) \stackrel{\text{def}}{=} \{\pi(w) \mid w \in L\}$ $(\subseteq \mathbb{N}^2)$. For $\bar{x}, \bar{x}_1, \ldots, \bar{x}_n \in \mathbb{N}^2$, we denote by $\langle \bar{x}, P \rangle$ the 2-dimensional linear set $\{\bar{x} + \alpha_1 \bar{x}_1 + \cdots + \alpha_n \bar{x}_n \mid \alpha_1, \ldots, \alpha_n \in \mathbb{N}\}$, and call $\bar{x} \in \mathbb{N}^2$ its **basis** and $\bar{x}_1, \ldots, \bar{x}_n$ its **periods**. A **semi-linear** set is a finite union of linear sets.

Regular languages. We use standard notation for regular expressions without complement, namely, for expressions build up from the empty set, the empty word ε and the symbols $a \in \mathbb{A}$, using the operations $\cdot$, $\cup$, and $(\,)^*$. For economy of space and clarity we also use the abbreviated notation $(\,)^k$, $(\,)^{k*}$ – which is a shorthand for $((\,)^k)^*$ – , $(\,)^{\geq k}$, $(\,)^{<k}$, and we identify regular expressions with the defined languages. For example, we may write $abbc \in a \cdot b^{\geq 2} \cdot (c \cup d)^*$, $b(ab)^* = (ba)^*b$ and $\{a, b\}^* \cdot c = (a \cup b)^* \cdot c$. Given $u = a_1 \cdots a_n \in \mathbb{A}^*$ and $v = b_1 \cdots b_n \in \mathbb{B}^*$, we write $u \otimes v$ for the word $(a_1, b_1) \cdots (a_n, b_n) \in (\mathbb{A} \times \mathbb{B})^*$. Similarly, given $U \subseteq \mathbb{A}^*$, $V \subseteq \mathbb{B}^*$, we write $U \otimes V \subseteq (\mathbb{A} \times \mathbb{B})^*$ for the set $\{u \otimes v \mid u \in U, v \in V, |u| = |v|\}$.

The **star-height** of a regular expression is the maximum number of nestings of Kleene stars $(\,)^*$. By abuse of terminology, when referring to the star-height of a language, we mean the star-height of some regular expression that represents it (in particular, we do not need to work with the minimum star-height over all expressions). Besides regular expressions, we also work with automata, and use classical techniques on them (notably, pumping arguments). Given an accepting run γ of an automaton $\mathcal{A}$, we often identify **cycles** in it, that is, factors that start and end in the same state, and that can thus be pumped. Such cycles are called **simple** if they do not contain proper factors that are also cycles. Moreover, to avoid mentioning explicitly an automaton for a language L and a run of it, we call **cycle of** L (resp. **simple cycle of** L) the word spelled out by any cycle (resp. simple cycle) of any accepting run of the minimal deterministic automaton recognizing L, and denote the set of all cycles (resp. simple cycles) of L by *cycles*(L) (resp. *simple-cycles*(L)). We remark that, however, that the use of the minimal automaton as a presentation of a regular language L is only to avoid ambiguity when referring to the cycles of L – in fact, our results do not depend on determinism or minimality, and can thus be applied to arbitrary non-deterministic automata, without any difference in the characterizations we present.

A regular language C is **concat-star** (*a.k.a. unit-form* [1]), if it is of the form

$$C = C_1^* u_1 C_2^* u_2 \cdots C_n^* u_n, \tag{$\star$}$$

for $n \in \mathbb{N}$, words $u_1, \ldots, u_n$, and regular languages $C_1, \ldots, C_n$. Without loss of generality, we can always assume that the empty word does not belong to any of the languages C_i. The following trivial decomposition lemma will be used throughout.

▶ **Lemma 1.** *Every regular language is a finite union of concat-star languages.*

The C_i^*'s from $(\star)$ are called **components** of the concat-star language C. Note that (an expression of) a concat-star language as in $(\star)$ has star-height 1 if and only if every C_i is finite. A component C_i^* is **homogeneous** if $C_i^* \subseteq 1^*$ or $C_i^* \subseteq 2^*$. A component which is not homogeneous is called **heterogeneous** (e.g. $C_i^* = \{1, 2\}^*$). It will also be convenient to distinguish a few types of concat-star languages. We say that C is

- **heterogeneous** if it contains at least one heterogeneous component, otherwise it is **homogeneous**;
- **smooth** if every homogeneous component is a language of the form 1^{k*} or 2^{k*}, for some $k > 0$, and there are no consecutive homogeneous components;
- **simple** if it has star-height 1 and it is either homogeneous or smooth heterogeneous.

Hereafter, by "simple language" we mean simple concat-star language. The picture below summarizes the different types of control languages, together with some separating examples.

	homogeneous	smooth heterogeneous	non-smooth heterogeneous	non concat-star
s.-h. > 1	$(1^*1)^*2^*$	$1^*(1^*2)^*2^*$	$1^*2^*(1^*2)^*$	$(1^*2)^* \cup (12)^*$
s.-h. $= 1$	$1^*(11)^*2^*$	$1^*(12)^*2^*$	$1^*2^*(12)^*$	$(12)^*1^* \cup (12)^*2^*$
	simple			

In Section 5 we will see that the Class Containment Problem is reduced to the case of finite unions of simple languages. The latter languages thus form the basis of our characterization.

3 Synchronized relations

A **synchronization** of a pair (w_1, w_2) of words over $\mathbb{A}$ is a word over $\mathbb{2} \times \mathbb{A}$ so that the projection on $\mathbb{A}$ of positions labeled i is exactly w_i, for $i = 1, 2$ – in other words, $\text{shuffle}\{1^{|w_1|} \otimes w_1, 2^{|w_2|} \otimes w_2\}$ is the set of all synchronizations of (w_1, w_2). For example, the words $(1, a)(1, b)(2, a)$ and $(1, a)(2, a)(1, b)$ are two possible synchronizations of the same pair (ab, a). Every word $w \in (\mathbb{2} \times \mathbb{A})^*$ is a synchronization of a unique pair (w_1, w_2), where w_i is the sequence of $\mathbb{A}$-letters corresponding to the symbol i in the first position of $\mathbb{2} \times \mathbb{A}$. We denote such pair (w_1, w_2) by $[\![w]\!]$ and extend the notation to languages $L \subseteq (\mathbb{2} \times \mathbb{A})^*$ by $[\![L]\!] \stackrel{\text{def}}{=} \{[\![w]\!] \mid w \in L\}$.

Given a regular language $C \subseteq \mathbb{2}^*$, we define the class of ***C*-controlled relations** as

$$\textsc{Rel}(C) \stackrel{\text{def}}{=} \big\{[\![L]\!] \;\mid\; L \subseteq C \otimes \mathbb{A}^* \text{ is regular}, \mathbb{A} \text{ is some finite alphabet}\big\}.$$

A slightly different definition is possible, which restricts the class of C-controlled relations to be over a fixed alphabet $\mathbb{A}$, that is, one can define $\textsc{Rel}_{\mathbb{A}}(C) = \{[\![L]\!] \mid L \subseteq C \otimes \mathbb{A}^* \text{ regular}\}$. As far as we are concerned with comparing classes of relations controlled by different languages, the two definitions are somehow interchangeable, in the sense that containment between classes is not sensible to whether we fix or not the alphabet. For example, we will see that, for any alphabet $\mathbb{A}$ with at least two symbols, $\textsc{Rel}_{\mathbb{A}}(C) \subseteq \textsc{Rel}_{\mathbb{A}}(D)$ iff $\textsc{Rel}(C) \subseteq \textsc{Rel}(D)$.

For economy of space, we use $C \subseteq_{\textsc{Rel}} D$ and $C =_{\textsc{Rel}} D$ as shorthands for $\textsc{Rel}(C) \subseteq \textsc{Rel}(D)$ and $\textsc{Rel}(C) = \textsc{Rel}(D)$, respectively. The following properties are easy to verify.

▶ **Lemma 2.** *For every regular $C, D, C', D' \subseteq \mathbb{2}^*$,*

P1. *if $C \subseteq D$, then $C \subseteq_{\textsc{Rel}} D$;*
P2. *if $C \subseteq_{\textsc{Rel}} D$ and $C' \subseteq_{\textsc{Rel}} D'$, then $C \cdot C' \subseteq_{\textsc{Rel}} D \cdot D'$ and $C \cup C' \subseteq_{\textsc{Rel}} D \cup D'$;*
P3. *if $C \subseteq_{\textsc{Rel}} D$, then $C^* \subseteq_{\textsc{Rel}} D^*$;*
P4. *if $C \subseteq 1^*$ and $D \subseteq 2^*$, then $C \cdot D =_{\textsc{Rel}} D \cdot C$;*
P5. *if C is finite, then $C \cdot D =_{\textsc{Rel}} D \cdot C$;*
P6. *if $C \subseteq_{\textsc{Rel}} D$ then $\pi(C) \subseteq \pi(D)$; moreover, if C is finite, the converse also holds;*
P7. *if C is homogeneous concat-star, then $C =_{\textsc{Rel}} \bigcup_{i \in I} 1^{\ell_i *} 1^{k_i} 2^{\hat{\ell}_i *} 2^{\hat{k}_i}$ for a finite I;*
P8. *if C is homogeneous concat-star, $C \subseteq_{\textsc{Rel}} D$ if and only if $\pi(C) \subseteq \pi(D)$.*

Proof idea. P1 is immediate from definitions; henceforth we use it without referencing it. P2 and P3 follow readily from the following decomposition properties.

(a) For every $R \in \textsc{Rel}(C \cdot C')$, there are $R_1, \ldots, R_n \in \textsc{Rel}(C)$, $R'_1, \ldots, R'_n \in \textsc{Rel}(C')$ so that $R = \bigcup_i R_i \cdot R'_i$.
(b) For every $R \in \textsc{Rel}(C \cup C')$, there are $R_1 \in \textsc{Rel}(C)$, $R_2 \in \textsc{Rel}(C')$ so that $R = R_1 \cup R_2$.

(c) For every $R \in \text{REL}(C^*)$, there are $R_1, \ldots, R_n \in \text{REL}(C)$ and $I \subseteq \{1, \ldots, n\}^*$ regular so that $R = \bigcup_{w \in I} R_{w[1]} \cdots R_{w[|w|]}$.

P4 can be verified by first decomposing any relation $R \in \text{REL}(C \cdot D)$ into $\bigcup_i R_i \cdot R'_i$ as in (a), and then observing that in this case $[\![\bigcup_i R_i \cdot R'_i]\!] = [\![\bigcup_i R'_i \cdot R_i]\!]$. For P5, it is easy to see that $1 \cdot D =_{\text{REL}} D \cdot 1$ and $2 \cdot D =_{\text{REL}} D \cdot 2$ for any D, and thus by P2 this extends to commuting with arbitrary finite languages. For P6, observe that if $C \subseteq_{\text{REL}} D$ then $[\![C \otimes a^*]\!] \in \text{REL}(D)$ for $a \in \mathbb{A}$, which means that $\pi(C) \subseteq \pi(D)$. P7 is a consequence of P4 and the so-called Chrobak normal form for regular languages over unary alphabets [7]. Finally, the proof of P8 is a variant of the proof that the operation of shuffle preserves regularity of languages. ◀

4 Characterization of the Class Containment Problem

We give an overview of the main ingredients of our decision procedure for class containment.

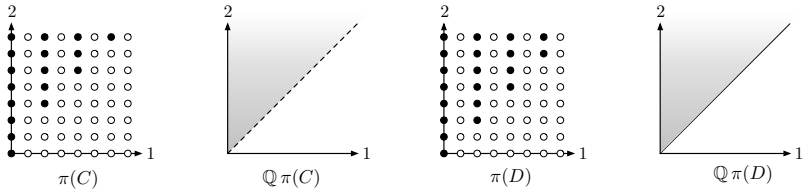
Decomposition. A first ingredient is a decomposition result for regular control languages into $=_{\text{REL}}$-equivalent finite unions of simple languages. Here we only state the result with a short proof sketch; the complete proof will be given in Section 5.

▶ **Proposition 3.** *Every regular language $C \subseteq 2^*$ is effectively $=_{\text{REL}}$-equivalent to a finite union of simple languages.*

Proof idea. One first applies Lemma 1, so as to decompose the regular language C into a finite union of concat-star languages. Then, the concat-star languages are further decomposed into unions of concat-star languages of star-height 1. For example, $(112(12)^* \cup 122)^* =_{\text{REL}} (122)^* \cup (112 \cup 122)^*112 \cup (112 \cup 122)^*11122 \cup (112 \cup 122)^*1111222$. This latter step is more difficult and exploits the increased flexibility of the relation $=_{\text{REL}}$ compared to equality. It also exploits in a crucial way properties of linear sets, and more specifically those that result from taking the Parikh images of concat-star languages. Finally, to get the desired decomposition, one needs to decompose further the concat-star languages of star-height 1 into finite unions of simple languages as in, for example, $(12)^*1^*2^* =_{\text{REL}} (12)^*1^* \cup (12)^*2^*$. This last decomposition makes use of some basic properties from Lemma 2. ◀

Parikh ratios. The **Parikh ratio** of a pair $\bar{x} = (n_1, n_2) \in \mathbb{N}^2 \setminus \{(0,0)\}$ is $\rho(\bar{x}) = \frac{n_1}{n_1+n_2}$. We naturally extend this to non-empty words $w \in 2^*$ by letting $\rho(w) = \rho(\pi(w))$ (this describes the proportion of 1's in w). We further extend the notation to languages: $\rho(C) = \{\rho(w) \mid w \in C \setminus \{\varepsilon\}\}$. Note that $\rho(C) \subseteq [0,1]_{\mathbb{Q}}$. It is sometimes useful to think of $\rho(C)$ as the cone $\mathbb{Q}\,\pi(C) = \{q \cdot \pi(w) \mid q \in \mathbb{Q}, w \in C\}$ inside the rational plane $\mathbb{Q} \times \mathbb{Q}$.

▶ **Example 4.** The Parikh images of the languages $C = (2(2112)^*)^*$ and $D = (2 \cup 2112)^*$ are depicted below. Note that $\rho(C) = \left[0, \frac{1}{2}\right)_{\mathbb{Q}}$, while $\rho(D) = \left[0, \frac{1}{2}\right]_{\mathbb{Q}}$.



The following lemma summarizes the main properties of Parikh ratios that we will need.

▶ **Lemma 5.** *The Parikh ratio of a concat-star language C verifies the following properties:*

1. *If $C = C_1^* u_1 \cdots C_n^* u_n$, then $\rho(\text{cycles}(C)) \subseteq [\min_i \inf \rho(C_i^*), \max_i \sup \rho(C_i^*)]_{\mathbb{Q}}$;*
2. *Moreover, if $C = D^*$ for a finite D, then $\rho(C) = \rho(\text{cycles}(C)) = [\min \rho(D), \max \rho(D)]_{\mathbb{Q}}$.*

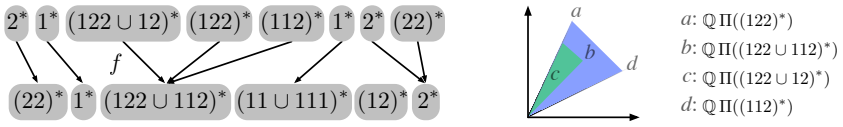
Synchronizing morphisms. Another fundamental ingredient is the notion of *synchronizing morphism*, which intuitively relates the components of a concat-star language C to the components of a concat-star language D by comparing the Parikh ratios.

Let $C = C_1^* u_1 \cdots C_n^* u_n$ be a heterogeneous concat-star language and $D = D_1^* v_1 \cdots D_m^* v_m$ any concat-star language. We say that a function $f : [1, n] \to [1, m]$ is a **synchronizing morphism** (abbreviated *s.m.*) from C to D if

- it is monotonic: $f(i) \leq f(j)$ whenever $i \leq j$; and
- it preserves Parikh-ratio: for every $i \in [1, n]$, $\rho(C_i^*) \subseteq \rho(D_{f(i)}^*)$.

We write $C \xrightarrow{s.m.} D$ to denote the existence of such synchronizing morphism. By convention, if C is homogeneous, then we say that there is always a synchronizing morphism from C to D. In particular, $u \xrightarrow{s.m.} v$ for every $u, v \in \mathbb{2}^*$. The sole purpose of this trivial definition on homogeneous concat-star languages is to make the characterization statements simpler.

▶ **Example 6.** The following function f is a synchronizing morphism:



Observe that synchronizing morphisms are closed under composition and hence $\xrightarrow{s.m.}$ defines a pre-order on concat-star languages.

Class Containment Problem for simple languages. The existence of synchronizing morphism is the key property that characterizes $\subseteq_{\text{Rel}}$ on simple languages. A complete proof of the following proposition will be the theme of Section 6.

▶ **Proposition 7.** *For all simple $C, D \subseteq \mathbb{2}^*$, $C \subseteq_{\text{Rel}} D$ iff $\pi(C) \subseteq \pi(D)$ and $C \xrightarrow{s.m.} D$.*

Note that the case of C homogeneous follows from P8. Intuitively, for any C smooth heterogeneous concat-star language of star-height 1, the characterization says that, $C \subseteq_{\text{Rel}} D$ iff $\pi(C) \subseteq \pi(D)$ and for every component of C, there is a component of D that contains its Parikh ratio. Further, the matching between components is monotonic. For example, we have $(12)^*(112)^* \subseteq_{\text{Rel}} (12 \cup 11122)^*(121)^*1^*2^*$, because the Parikh ratios of $(12)^*$ and $(112)^*$ are included in those of $(12 \cup 11122)^*$ and $(121)^*$, respectively. On the other hand, we have $(112)^*(12)^* \not\subseteq_{\text{Rel}} (12 \cup 11122)^*(121)^*1^*2^*$ because in this case there is no motononic matching between components.

Generalization to unions of simple languages. Section 7 concerns the generalization of the characterization to finite unions of simple languages, which cover arbitrary regular languages up to $=_{\text{Rel}}$-equivalence. The previous characterization for simple languages thus constitutes the base case of our characterization. The lemma below allows a first generalization when C is a union of simple languages and D is a simple language.

▶ **Lemma 8.** *$C_1 \cup C_2 \subseteq_{\text{Rel}} D$ iff $C_1 \subseteq_{\text{Rel}} D$ and $C_2 \subseteq_{\text{Rel}} D$.*

The analogous of Lemma 8 for unions on the right hand-side does not hold in general, as shown by the following example.

▶ **Example 9.** Let $C = (12)^*$, $D_1 = (112 \cup 1122)^*$, and $D_2 = (122 \cup 1122)^*12$. We have $C \subseteq_{\text{Rel}} D_1 \cup D_2$, although $C \not\subseteq_{\text{Rel}} D_1$ and $C \not\subseteq_{\text{Rel}} D_2$.

Neither it holds that Parikh image containment together with the existence of s.m. to one of the disjuncts suffices. For instance, for $C' = (12)^*$, $D'_1 = (1212)^*$, $D'_2 = 1^*2^*$, we have $C' \not\subseteq_{\text{Rel}} D'_1 \cup D'_2$ although $\pi(C') \subseteq \pi(D'_1 \cup D'_2)$ and $C' \xrightarrow{s.m.} D'_1$.

The characterization we provide is inductive on the number of languages that are unioned on the right hand-side. Concretely, for a union of two languages, we will show that $C \subseteq_{\text{Rel}} D_1 \cup D_2$ iff $C \xrightarrow{s.m.} D_i$ for some i and $C \setminus [D_i]_\pi \subseteq_{\text{Rel}} D_{3-i}$, where $[D_i]_\pi$ is the closure of D_i under permutations, that is, $[D_i]_\pi \stackrel{\text{def}}{=} \{w \in \mathbb{2}^* \mid \pi(w) \in \pi(D_i)\}$. The idea that underlies the proof of the necessity of our characterization is that C can be split into a disjoint union of $C \cap [D_i]_\pi$ and $C \setminus [D_i]_\pi$, in such a way that $C \cap [D_i]_\pi \subseteq_{\text{Rel}} D_i$ and $C \setminus [D_i]_\pi \subseteq_{\text{Rel}} D_{3-i}$.

For finite unions of simple languages, we have the following characterization. A complete proof of this theorem will be the theme of Section 7.

▶ **Theorem 10.** *For finite unions $C = \bigcup_i C_i$ and $D = \bigcup_j D_j$ of simple languages, the following are equivalent:*

- $C \subseteq_{\text{Rel}} D$,
- *For all i $\pi(C_i) \subseteq \pi(D)$ and there is j with $C_i \xrightarrow{s.m.} D_j$. In addition, if C_i is heterogeneous, then $C_i \setminus [D_j]_\pi$ is regular and $C_i \setminus [D_j]_\pi \subseteq_{\text{Rel}} \bigcup_{j' \neq j} D_{j'}$.*

Coming back to Example 9, note that $\rho(C) = \{\frac{1}{2}\}$, $\rho(D_1) = [\frac{1}{2}, \frac{2}{3}]_{\mathbb{Q}}$ and $\rho((122 \cup 1122)^*) = [\frac{1}{3}, \frac{1}{2}]_{\mathbb{Q}}$. Therefore, one can explain $C \subseteq_{\text{Rel}} D_1 \cup D_2$ by the fact of having $C \xrightarrow{s.m.} D_1$ and $C \setminus [D_1]_\pi = (1212)^*12 \subseteq_{\text{Rel}} D_2$, where the latter containment holds by the fact that $(1212)^*12 \xrightarrow{s.m.} D_2$ and $\pi((1212)^*12) \subseteq \pi(D_2)$.

Note that there's a caveat in the statement of Theorem 10: $C_i \setminus [D_j]_\pi$ needs to be *regular*. And in fact this is not the case in general: if $C_i = 1^*2^*$ and $D_j = (12)^*$, we get a non-regular language $C_i \setminus [D_j]_\pi = \{1^n 2^m \mid n \neq m\}$. However, provided $C_i \xrightarrow{s.m.} D_j$ for C_i heterogeneous, we show that $C_i \setminus [D_j]_\pi$ is effectively regular (in the sense that an automaton recognizing it can be computed from automata recognizing C_i and D_j). This is a non-trivial fact, and will be proved in Section 5 (Proposition 12).

The second key ingredient is that if $C_i \subseteq_{\text{Rel}} D_1 \cup \cdots \cup D_n$, then there must be some j so that $C_i \xrightarrow{s.m.} D_j$. This will be proved in Section 6 (Lemma 15).

5 Decomposition into simple languages

As already mentioned, we start by reducing the Class Containment Problem for arbitrary regular languages to the case of finite unions of simple languages (Proposition 3 below). We do this in two steps. First, we decompose regular languages into finite unions of concat-star languages of star-height 1 (Lemma 13 below). Then, we further decompose the latter languages into finite unions of simple languages (Lemma 14 below).

Unions of star-height 1 languages. Lemma 13 relies on two key results, which are also of independent interest. The first result is a normal form representation of the Parikh image $\pi(C)$ of a concat-star language C. Formally, we say that a linear set $\langle \bar{x}, P \rangle$ is in **normal form** if the elements of P are linearly independent. We extend this notion to semi-linear sets by saying that $\langle \bar{x}_1, P_1 \rangle \cup \cdots \cup \langle \bar{x}_n, P_n \rangle$ is in normal form if the vectors in $\bigcup_i P_i$ are linearly independent. In particular, in dimension 2, this means that there are at most two vectors in P. Note that if the representation of a semi-linear set is in normal form then all its linear sets are in normal form, but the converse does not hold – for example, consider $\langle \bar{0}, \{(2,0)\} \rangle \cup \langle \bar{0}, \{(3,0)\} \rangle$. The following lemma shows that Parikh images of concat-star languages enjoy normal forms.

▶ **Lemma 11.** *For every concat-star language $C = C_1^* u_1 \cdots C_n^* u_n$, there exists a normal form representation of its Parikh image $\pi(C)$. Moreover, if C is infinite, the union of the period sets is $\{\bar{x}_-, \bar{x}_+\}$, where $\rho(\bar{x}_-) = \min_j(\inf \rho(C_j^*))$ and $\rho(\bar{x}_+) = \max_j(\sup \rho(C_j^*))$.*

Proof idea. Using some basic properties of Parikh images, we reduce to the case where C is a concatenation of expressions of the form u^* (for u a non-empty word) or $(u_1^* \cdots u_n^* u)^*$ (for $u_1, \ldots, u_n, u$ non-empty words). For any C in this form, the Parikh image of words in C can be expressed in terms of some words w_-, w_+ such that $\pi(w_-) = \bar{x}_-$ and $\pi(w_+) = \bar{x}_+$. Then, any word of C can be represented as a constrained iteration of these two words. ◀

It is worth pointing out the difference with the normal form from [12]. While the normal form of [12] holds for arbitrary regular languages, our normal form holds only for *concat-star* languages over *binary* alphabets (*e.g.*, it fails for $(12)^* \cup 1^* \cup 2^*$). Conversely, the normal form from [12] does not guarantee the linear independence of the vectors in the union of the periods, as we do here instead. Proposition 12 below relies on such an additional property. (Also, [1] gives a procedure to compute Parikh images, though no normal form is implied.)

The second result shows that, under certain conditions, one can intersect a regular language C by a language of the form $[D]_\pi = \pi^{-1}(\pi(D))$, with D concat-star, and obtain a language that is again regular. This result not only enables the decomposition into star-height 1 languages, but will be used also later to formalize a recursive characterization of $\subseteq_{\text{REL}}$ for unions of simple languages (cf. Section 7).

▶ **Proposition 12.** *Given C regular and D concat-star so that $\rho(\mathit{cycles}(C)) \subseteq \rho(\mathit{cycles}(D))$, the languages $C \cap [D]_\pi$ and $C \setminus [D]_\pi$ are effectively regular. If in addition D is of the form $D_1^* u$, then $C \cap [D]_\pi \subseteq_{\text{REL}} D$.*

Proof idea. We exploit the fact that words in $\mathbb{2}^*$ are in bijection with paths inside $\mathbb{N}^2$ that originate in $\bar{0} = (0, 0)$ and, furthermore, that words with the same Parikh image correspond to paths with the same endpoints. The claim boils down to considering some word $w \in \mathbb{2}^*$ and proving that, under suitable hypotheses, the path induced by w can be approximated by a path inside $\pi(D)$ that stays sufficiently close to the former path. The use of Lemma 11 will be crucial here, since it gives a normal form $\bigcup_i \langle \bar{x}_i, P_i \rangle$ for the latter set $\pi(D)$. Intuitively, it implies that the words from $[D]_\pi$ are represented by paths that never get too far from the linear set $\langle \bar{0}, \bigcup_i P_i \rangle$. For example, by pairing this property with the assumption that $\rho(\mathit{cycles}(C)) \subseteq \rho(\mathit{cycles}(D))$, one can show that the path induced by a word $w \in C$ stays close to $\langle \bar{0}, \bigcup_i P_i \rangle$, and hence also to $\pi(D)$. Stronger variants of this property are shown, that take into account the exact displacement of points along the path induced by w from the points in $\pi(D)$. These latter properties are used by suitable automata that recognize the languages $C \cap [D]_\pi$ and $C \setminus [D]_\pi$. ◀

As we explained in the proof sketch, the above proposition relies on the normal form for the semi-linear set $\pi(D)$, which in turns relies on the fact that D is concat-star. The proposition does not hold if we replace D with an arbitrary regular language. For instance, consider $C = 1(11)^*2(22)^*$ and $D = (12)^* \cup (11)^*(22)^*$, and observe that $\rho(\mathit{cycles}(C)) = [0, 1]_{\mathbb{Q}} = \rho(\mathit{cycles}(D))$, but $C \cap [D]_\pi = \{1(11)^n 2(22)^n \mid n \in \mathbb{N}\}$ is clearly not regular.

Although Proposition 12 is stated in full generality, that is, for every regular language C so that $\rho(\mathit{cycles}(C)) \subseteq \rho(\mathit{cycles}(D))$, in the proof of the decomposition result below we will use it only for a smooth heterogeneous concat-star language C so that $C \xrightarrow{s.m.} D$ (this is sufficient but not necessary for verifying the hypothesis $\rho(\mathit{cycles}(C)) \subseteq \rho(\mathit{cycles}(D))$).

▶ **Lemma 13.** *Every regular $C \subseteq \mathbb{2}^*$ is $=_{\text{REL}}$-equivalent to a finite union $\bigcup_i D_i$ of concat-star languages of star-height* 1.

Towards the proof of this lemma, note that, by Lemma 1, C is a finite union of concat-star languages $C_1^* u_1 \cdots C_n^* u_n$. The lemma then follows from applying Claim 1 below to each component of the concat-star languages, and then using P2.

▶ **Claim 1.** *Every regular D^* is $=_{\text{REL}}$-equivalent to a finite union $\bigcup_i D_i^* u_i$, with finite D_i's.*

Proof idea of Claim 1. Since $\pi(D^*)$ is a finite union of linear sets, from the latter we can extract languages of the form $D_i^* u_i$. Then we can decompose D^* as the union of $D^* \cap [D_i^* u_i]_\pi$. From there, the result follows easily from Proposition 12 and P2. ◀

Unions of simple languages. We finally show how to decompose into simple languages.

▶ **Lemma 14.** *Every concat-star $C \subseteq \mathbb{2}^*$ of star-height 1 is $=_{\text{REL}}$-equivalent to a finite union $\bigcup_i C_i$ of simple languages.*

Proof idea. By using the basic properties given in Lemma 2, we can reduce the problem to the case where C is of the form $1^{k*}\hat{2}^{\hat{k}*}w^*$ for some heterogeneous word w and some natural numbers $k, \hat{k}$. This case is easy to prove by using again those basic properties. ◀

As a corollary of Lemmas 13 and 14, we have our desired result.

▶ **Proposition 3.** Every regular language $C \subseteq \mathbb{2}^*$ is effectively $=_{\text{REL}}$-equivalent to a finite union of simple languages.

6 Simple languages

We prove the characterization result for simple languages, which we recall here.

▶ **Proposition 7.** For all simple $C, D \subseteq \mathbb{2}^*$, $C \subseteq_{\text{REL}} D$ iff $\pi(C) \subseteq \pi(D)$ and $C \xrightarrow{s.m.} D$.

For the left-to-right direction, by P6, $C \subseteq_{\text{REL}} D$ implies $\pi(C) \subseteq \pi(D)$. The proof that $C \subseteq_{\text{REL}} D$ implies $C \xrightarrow{s.m.} D$ is given in a more general setup where D is a finite union of simple languages. This statement will be used in the characterization of the next section.

▶ **Lemma 15.** *For C a simple language and $D = \bigcup_i D_i$ finite union of simple languages, if $C \subseteq_{\text{REL}} D$, then $C \xrightarrow{s.m.} D_i$ for some i. In particular, for C, D simple languages, if $C \subseteq_{\text{REL}} D$, then $C \xrightarrow{s.m.} D$. Further, the statement holds even if we consider $\text{REL}_{\mathbb{A}}$-containment for any $\mathbb{A}$ with at least two letters.*

Proof idea. The idea is to construct a relation $R \in \text{REL}(C)$ so that from $R \in \text{REL}(D)$, using suitable pumping arguments, one can extract a synchronizing morphism from C to some D_i. The relation R must depend on both languages C, D, but the underlying alphabet can be fixed and taken binary, say $\mathbb{A} = \{a, b\}$. For example, if C is of the form C_1^* and contains two words u^- and u^+ with minimum and maximum Parikh ratios, and if the automaton for D has a single strongly connected component, then one can define the relation $R = [\![(u^- \otimes a^{|u^-|})^* \cdot (u^+ \otimes b^{|u^+|})^*]\!]$. In this case, $R \in \text{REL}(D)$ would imply $\rho(u^-), \rho(u^+) \in \rho(D)$, and hence $C \xrightarrow{s.m.} D$. This construction can be modified for more general languages C, D, by using words with different Parikh ratios from each component of C and by increasing the number of alternations between these ratios on the basis of the number of components of D. While the construction is more involved in the general case, and in particular needs to include iterations of words which are not necessarily of minimum or maximum Parikh ratios for a component, the intuition remains the same. ◀

▶ **Observation 16.** *The previous Lemma 15 does not hold for arbitrary concat-star languages C. For example, consider $(12)^*1^*2^* =_{\text{Rel}} (12)^*1^* \cup (12)^*2^*$, where there is no s.m. from $(12)^*1^*2^*$ to $(12)^*1^*$, nor from $(12)^*1^*2^*$ to $(12)^*2^*$.*

Conversely, to show that the conditions $\pi(C) \subseteq \pi(D)$ and $C \xrightarrow{s.m.} D$ are sufficient to have $C \subseteq_{\text{Rel}} D$, where C, D are simple, it is useful to introduce a normal form for languages of the form C^*, with C finite.

▶ **Lemma 17.** *For every $p, q > 0$, finite $C \subseteq \mathbb{2}^*$, and $u_-, u_+ \in C$ so that $\rho(u_-) = \min \rho(C)$ and $\rho(u_+) = \max \rho(C)$, there exists a finite $C' \subseteq C^*$ so that $C^* =_{\text{Rel}} (u_-^p \cup u_+^q)^* \cdot C'$.*

In particular, the lemma implies that $C^* =_{\text{Rel}} (u_- \cup u_+)^* \cdot C'$ for some finite $C' \subseteq C^*$ and u_-, u_+ words of C of minimum and maximum ratio. In other words, it just suffices to iterate two words from C and then append tails of bounded length to obtain the class $\text{Rel}(C^*)$. With this in mind, we can easily prove our characterization for simple languages.

Proof idea of Proposition 7. The left-to-right direction follows from P6 and Lemma 15. For the opposite direction, the case where C is homogeneous is straightforward by P8. For C heterogeneous, we use P5 to we assume wlog that $C = C_1^* \cdots C_n^* u$ and $D = D_1^* \cdots D_m^* v$. Since every C_i is finite (recall that simple languages have star-height 1), we can consider words $w_{i,-}, w_{i,+}$ of minimum and maximum Parikh ratio. Using the normal form of Lemma 17 plus the existence of s.m., we obtain $C_i^* \subseteq_{\text{Rel}} D_{f(i)}^* C_i'$ for a finite $C_i' \subseteq C_i^*$. Thus, $C_1^* \cdots C_n^* u \subseteq_{\text{Rel}} D_{j_1}^* C_1' \cdots D_{j_n}^* C_n' u =_{\text{Rel}} D_{j_1}^* \cdots D_{j_n}^* C_1' \cdots C_n' u \subseteq_{\text{Rel}} D_1^* \cdots D_m^* v$. ◀

7 Regular languages

We now prove the characterization theorem for unions of simple languages. Thanks to this theorem and to Proposition 3, we will obtain an effective characterization for arbitrary regular languages, and thus solve the Class Containment Problem in its full generality.

▶ **Theorem 10.** For finite unions $C = \bigcup_i C_i$ and $D = \bigcup_j D_j$ of simple languages, we have $C \subseteq_{\text{Rel}} D$ if and only if for all i $\pi(C_i) \subseteq \pi(D)$, there is j with $C_i \xrightarrow{s.m.} D_j$ and if C_i is heterogeneous, then $C_i \setminus [D_j]_\pi$ is regular and $C_i \setminus [D_j]_\pi \subseteq_{\text{Rel}} \bigcup_{j' \neq j} D_{j'}$.

Note in particular that the conditions in the characterization of Theorem 10 require that $C_i \setminus [D_j]_\pi$ is regular. Despite that, this property is always verified when $C_i \xrightarrow{s.m.} D_j$ and C_i is heterogeneous by Proposition 12 from Section 5. Indeed, $C_i \xrightarrow{s.m.} D_j$ for C_i heterogeneous implies that all components of C_i are mapped to components of D_j. In view of Lemma 5 and the fact that C_i and D_j have star-height 1, this implies that $\rho(\mathit{cycles}(C_i)) \subseteq \rho(\mathit{cycles}(D_j))$, and hence, by Proposition 12, $C_i \setminus [D_j]_\pi$ is regular. We are now ready to prove the theorem.

Proof of Theorem 10. For the left-to-right implication, by Lemma 8, we have that $C_i \subseteq_{\text{Rel}} D$ for every i. Containment of Parikh images follows then from P6. For any fixed i, if C_i is homogeneous we have $C_i \xrightarrow{s.m.} D_j$ for every j, and if it is smooth heterogeneous, then Lemma 15 yields the existence of some j so that $C_i \xrightarrow{s.m.} D_j$. By Proposition 12, $C_i \setminus [D_j]_\pi$ is regular, and we now prove that $C_i \setminus [D_j]_\pi \subseteq_{\text{Rel}} \bigcup_{j' \neq j} D_{j'}$. Take $R \in \text{Rel}(C_i \setminus [D_j]_\pi)$ and a regular $L \subseteq (C_i \setminus [D_j]_\pi) \otimes \mathbb{A}^*$ so that $[\![L]\!] = R$. Since $C_i \setminus [D_j]_\pi \subseteq C_i$, we have $R \in \text{Rel}(C_i) \subseteq \text{Rel}(D)$, by P1 and hypothesis. Let $L' \subseteq D \otimes \mathbb{A}^*$ be a regular language so that $[\![L']\!] = [\![L]\!] = R$. Since the projection onto $\mathbb{2}$ of L and L' have necessarily the same Parikh image, it follows that $L' \cap (D_j \otimes \mathbb{A}^*) = \emptyset$, and thus that $L' \subseteq (\bigcup_{j' \neq j} D_{j'}) \otimes \mathbb{A}^*$ or, in other words, that $R \in \text{Rel}(\bigcup_{j' \neq j} D_{j'})$.

For the right-to-left implication, for C_i homogeneous, $\pi(C_i) \subseteq \pi(D)$ implies $C_i \subseteq_{\text{REL}} D$ by P8. For C_i heterogeneous, we have $C_i = (C_i \setminus [D_j]_\pi) \cup (C_i \cap [D_j]_\pi)$. By hypothesis plus property P1, $C_i \setminus [D_j]_\pi \subseteq_{\text{REL}} D$. Then, by Lemma 8, it only remains to check that $C_i \cap [D_j]_\pi \subseteq_{\text{REL}} D$. Now, by Proposition 12 and Proposition 3, $C_i \cap [D_j]_\pi$ is $=_{\text{REL}}$-equivalent to a finite union of simple languages $(C'_k)_{k\in K}$. Note that $C'_k \subseteq_{\text{REL}} C_i$ for all $k \in K$. Then, by the left-to-right direction of Proposition 7, we have $C'_k \xrightarrow{s.m.} C_i$ for all k. By composition of synchronizing morphisms, we obtain $C'_k \xrightarrow{s.m.} D_j$ for all $k \in K$. Since we also have that $\pi(C'_k) \subseteq \pi(D_j)$, by the right-to-left direction of Proposition 7, we have that $C'_k \subseteq_{\text{REL}} D_j$ for all $k \in K$. Then, from Lemma 8 it follows that $C_i \subseteq_{\text{REL}} D_j \subseteq D$. Since this happens for every C_i, again by Lemma 8 the statement follows. ◀

8 Decidability and complexity

We have given a characterization of the pairs C, D of regular languages that satisfy $C \subseteq_{\text{REL}} D$. We argue that this characterization is effective.

As explained in Section 7, there are three main steps that one need to take for deciding whether $C \subseteq_{\text{REL}} D$, for two given regular languages C, D: First, one needs to decompose C and D as finite unions $\bigcup_i C_i$ and $\bigcup_j D_j$ of simple languages. This preprocessing relies on two constructions: the computation of the normal form for semi-linear sets and the construction of an automaton for $C \cap [D]_\pi$, proving that is regular. A close inspection of these proofs in Section 5 shows that both procedures are effective, and thus so is the decomposition.

Then, based on the characterization of Theorem 10, one has to identify suitable synchronizing morphisms from each C_i to some D_j. This step boils down to checking whether two components $C^*_{i,i'}$ and $D^*_{j,j'}$ of concat-star languages satisfy $\rho(C^*_{i,i'}) \subseteq \rho(D^*_{j,j'})$. Thanks to the insight of Lemma 5, the containment of Parikh ratios and thus the existence of such synchronizing morphism is decidable.

Finally, the third step uses Theorem 10, reducing the problem $\bigcup_i C_i \subseteq_{\text{REL}} \bigcup_j D_j$ to sub-problems of the form $C_i \setminus [D_{j_i}]_\pi \subseteq_{\text{REL}} \bigcup_{j' \neq j_i} D_{j'}$, which has a smaller union in the right hand-side and thus can be solved recursively (but in principle non-elementary).

The above arguments show that the Class Containment Problem is decidable. Once we know that $C \subseteq_{\text{REL}} D$ for two given regular languages C, D, it is reasonable to ask whether it is possible to resynchronize any relation from C to D, namely, whether there is an algorithm that transforms any automaton $\mathcal{A}$ recognizing $L \subseteq C \otimes \mathbb{A}^*$ into an automaton $\mathcal{A}'$ recognizing $L' \subseteq D \otimes \mathbb{A}^*$ so that $[\![L']\!] = [\![L]\!]$. A close inspection to our decision procedure for $C \subseteq_{\text{REL}} D$ gives a positive answer to the question. Indeed, all our proofs are constructive.

We can summarize the above arguments with the following corollary.

▶ **Corollary 18.** *There is a non-elementary algorithm that, given two regular languages $C, D \subseteq \mathbb{2}^*$, decides whether $C \subseteq_{\text{REL}} D$.*
There is also a non-elementary algorithm that, given an automaton for $L \subseteq C \otimes \mathbb{A}^*$, constructs an automaton for some $L' \subseteq D \otimes \mathbb{A}^*$ so that $[\![L']\!] = [\![L]\!]$, provided $C \subseteq_{\text{REL}} D$.

9 Discussion

The overall picture we obtain from our results is that $\text{REL}(C) \subseteq \text{REL}(D)$ depends on comparing the ratio growth of the two coordinates on the cycles of the transition graph of the automata $\mathcal{A}_C$, $\mathcal{A}_D$ recognizing C, D. Concretely, our reduction into synchronizing morphisms for simple languages can be thought of restricting our attention to cycles $c_1, \ldots, c_n$ of $\mathcal{A}_C$ so that: c_{i+1} is reachable from c_i, and c_i or c_{i+1} is heterogeneous (recall that in a

simple concat-star language, there are no consecutive homogeneous components). Intuitively, $\textsc{Rel}(C) \subseteq \textsc{Rel}(D)$ whenever $\pi(C) \subseteq \pi(D)$ and for every sequence of cycles $c_1, \ldots, c_n$ as before, there exists a corresponding sequence of cycles $c'_1, \ldots, c'_n$ in $\mathcal{A}_D$ with the same properties so that c_i and c'_i have the same Parikh ratio for every i.

We also recall (cf. proof of Lemma 15) that our characterization holds for the containment problem $\textsc{Rel}(C) \subseteq \textsc{Rel}(D)$, but also for any variant with a fixed alphabet of cardinality at least 2. For the variant with a unary alphabet $\mathbb{A}$, it is easy to see that $\textsc{Rel}_{\mathbb{A}}(C) \subseteq \textsc{Rel}_{\mathbb{A}}(D)$ is equivalent to $\pi(C) \subseteq \pi(D)$. As concerns relations of higher arity defined by control languages $C \subseteq \mathbb{k}^* = [1, k]^*$, it is not clear if a similar characterization may hold. For example, the normal form of Lemma 11 does not generalize to control alphabets of more than two letters. Finally, we leave for future work the issue of determining the precise complexity of the Class Containment Problem.

Abstract

In this paper, we study the problem of deciding the winner of reachability switching games. We study zero-, one-, and two-player variants of these games. We show that the zero-player case is NL-hard, the one-player case is NP-complete, and that the two-player case is PSPACE-hard and in EXPTIME. For the zero-player case, we also show P-hardness for a succinctly-represented model that maintains the upper bound of NP ∩ coNP. For the one- and two-player cases, our results hold in both the natural, explicit model and succinctly-represented model. We also study the structure of winning strategies in these games, and in particular we show that exponential memory is required in both the one- and two-player settings.

1 Introduction

A *switching system* (also known as a Propp machine) attempts to replicate the properties of a random system in a deterministic way [14]. It does so by replacing the nodes of a Markov chain with *switching nodes*. Each switching node maintains a queue over its outgoing edges. When the system arrives at the node, it is sent along the first edge in this queue, and that edge is then sent to the back of the queue. In this way, the switching node ensures that, after a large number of visits, each outgoing edge is used a roughly equal number of times.

The Propp machine literature has focussed on *many-token* switching systems and has addressed questions such as how well these systems emulate Markov chains. Recently, Dohrau

et. al. [7] initiated the study of *single-token* switching systems and found that the reachability problem raised interesting complexity-theoretic questions. Inspired by that work, we study the question *how hard is it to model check single-token switching systems?* A switching node is a simple example of a fair scheduler, and thus it is natural to consider model checking of switching systems. We already have a good knowledge about the complexity of model checking Markovian systems, but how does this change when we instead use switching nodes?

Our contribution. In this paper, we initiate the study of model checking in switching systems. We focus on *reachability* problems, one of the simplest model checking tasks. This corresponds to determining the winner of a *two-player reachability switching game*. We study zero-, one-, and two-player variants of these games, which correspond to switching versions of Markov chains, Markov decision processes [20], and simple stochastic games [2], respectively.

The main message of the paper is that deciding reachability in one- and two-player switching games is harder than deciding reachability in Markovian systems. Specifically, we show that deciding the winner of a one-player game is NP-complete, and that the problem of deciding the winner of a two-player game is PSPACE-hard and in EXPTIME.

We also study the complexity of zero-player games, where we show hardness results that complement the upper bounds shown in previous work [7]. For the standard model of switching systems, which we call *explicit games*, we are able to show a lower bound of NL-hardness, which is still quite far from the known upper bound of $\mathtt{UP} \cap \mathtt{coUP}$. We also show that if one extends the model by allowing the switching order to be represented in a concise way, then a stronger lower bound of P-hardness can be shown, while still maintaining an $\mathtt{NP} \cap \mathtt{coNP}$ upper bound. We call these concisely represented games *succinct games*, and we also observe that all of our other results, both upper and lower bounds, still apply to succinct games. Our results are summarised in the following table.

	Markovian	Switching (explicit)	Switching (succinct)
0-player	PL-complete[2]	NL-hard; in CLS, in $\mathtt{UP} \cap \mathtt{coUP}$	P-hard; in $\mathtt{NP} \cap \mathtt{coNP}$
1-player	P-complete	NP-complete	NP-complete
2-player	$\mathtt{NP} \cap \mathtt{coNP}$	PSPACE-hard; in EXPTIME	PSPACE-hard; in EXPTIME

For the explicit zero-player case the first bound was an $\mathtt{NP} \cap \mathtt{coNP}$ upper bound given by Dohrau et al. [7], and a PLS upper bound was then given by Karthik [15]. The CLS and $\mathtt{UP} \cap \mathtt{coUP}$ upper bounds, which subsume the two earlier bounds, were given by Gärtner et al. [10], who also produced a $O(1.4143^n)$ algorithm for solving explicit zero-player games. All the other upper and lower bounds in the table are proved in this paper.

Finally, we address the memory requirements of winning strategies in reachability switching games. It is easy to see that winning strategies exist that use exponential memory. These strategies simply remember the current switch configuration of the switching nodes, and their existence can be proved by blowing up a switching game into an exponentially sized reachability game, and then following the positional winning strategies from that reachability game. This raises the question of whether there are winning strategies that use less than

[2] PL, or probabilistic L, is the class of languages recognizable by a polynomial time logarithmic space randomized machine with probability $> 1/2$.

exponential memory. We answer this negatively, by showing that the reachability player may need $\Omega(2^{n/2})$ memory states to win a one-player reachability switching game, and that both players may need to use $\Omega(2^n)$ memory states to win a two-player game.

Related work. Switching games are part of a research thread at the intersection of computer science and physics. This thread has studied zero-player switching systems, also known as *deterministic random walks*, *rotor-router walks*, the *Eulerian walkers model* [19] and *Propp machines* [3–6, 13, 14]. Propp machines have been studied in the context of derandomizing algorithms and pseudorandom simulation, and in particular have received a lot of attention in the context of load balancing [1, 9]. However, most work on Propp machines has focused on how well multi-token switching systems simulate Markov chains. The idea of studying *single-token* reachability should be credited to Dohrau at al. [7].

Katz et al. [16], Groote and Ploeger [12], and others [12, 18, 21], considered *switching graphs*; these are graphs in which certain vertices (switches) have exactly one of their two outgoing edges activated. However, the activation of the alternate edge does not occur when a vertex is traversed by a run; this is the key difference to switching games in this paper.

Markov decision processes [20] and simple stochastic games [2] are important objects of study in *probabilistic model checking*, which is an central topic in the field of formal verification. Probabilistic model checking is now a mature topic, with tools like PRISM [17] providing an accessible interface to the research that has taken place.

2 Preliminaries

A reachability switching game (RSG) is defined by a tuple $(V, E, V_{\mathrm{R}}, V_{\mathrm{S}}, V_{\mathrm{Swi}}, \mathrm{Ord}, s, t)$, where (V, E) is a finite directed graph, and V_{R}, V_{S}, V_{Swi} partition V into *reachability vertices*, *safety vertices*, and *switching vertices*, respectively. The reachability vertices V_{R} are controlled by the *reachability player*, the safety vertices V_{S} are controlled by the *safety player*, and the switching vertices V_{Swi} are not controlled by either player, but instead follow a predefined "switching order". The function Ord defines this *switching order*: for each switching vertex $v \in V_{\mathrm{Swi}}$, we have that $\mathrm{Ord}(v) = \langle u_1, u_2, \ldots, u_k \rangle$ where we have that $(v, u_i) \in E$ for all u_i in the sequence. Note that a particular vertex u may appear more than once in the sequence. The vertices $s, t \in V$ specify *source* and *target* vertices for the game.

A *state* of the game is defined by a tuple (v, C), where v is a vertex in V, and $C : V_{\mathrm{Swi}} \to \mathbb{N}$ is a function that assigns a number to each switching vertex, which represents how far that vertex has progressed through its switching order. Hence, it is required that $C(u) \leq |\mathrm{Ord}(v)| - 1$, since the counts specify an index to the sequence $\mathrm{Ord}(v)$.

When the game is at a state (v, C) with $v \in V_{\mathrm{R}}$ or $v \in V_{\mathrm{S}}$, then the respective player chooses an outgoing edge at v, and the count function does not change. For states (v, C) with $v \in V_{\mathrm{Swi}}$, the successor state is determined by the count function. More specifically, we define $\mathrm{Upd}(v, C) : V_{\mathrm{Swi}} \to \mathbb{N}$ so that for each $u \in V_{\mathrm{Swi}}$ we have $\mathrm{Upd}(v, C)(u) = C(u)$ if $v \neq u$, and $\mathrm{Upd}(v, C)(u) = (C(u) + 1) \bmod |\mathrm{Ord}(u)|$ otherwise. This function increases the count at v by 1, and wraps around to 0 if the number is larger than the length of the switching order at v. Then, the successor state of (v, C), denoted as $\mathrm{Succ}(v, C)$ is $(u, \mathrm{Upd}(v, C))$, where u is the element at position $C(v)$ in $\mathrm{Ord}(v)$.

A *play* of the game is a (potentially infinite) sequence of states $(v_1, C_1), (v_2, C_2), \ldots$ with the following properties:

1. $v_1 = s$ and $C_1(v) = 0$ for all $v \in V_{\mathrm{Swi}}$;
2. If $v_i \in V_{\mathrm{R}}$ or $v_i \in V_{\mathrm{S}}$ then $(v_i, v_{i+1}) \in E$ and $C_i = C_{i+1}$;

3. If $v_i \in V_{\text{Swi}}$ then $(v_{i+1}, C_{i+1}) = \text{Succ}(v_i, C_i)$;
4. If the play is finite, then the final state (v_n, C_n) must either satisfy $v_n = t$, or v_n must have no outgoing edges.

A play is *winning for the reachability player* if it is finite and the final state is the target vertex. A (deterministic, history dependent) *strategy for the reachability player* is a function that maps each play prefix $(v_1, C_1), (v_2, C_2), \ldots, (v_k, C_1)$, with $v_k \in V_{\text{R}}$, to an outgoing edge of v_k. A play $(v_1, C_1), (v_2, C_2), \ldots$ is *consistent* with a strategy if, whenever $v_i \in V_{\text{R}}$, we have that (v_i, v_{i+1}) is the edge chosen by the strategy. Strategies for the safety player are defined analogously. A strategy is *winning* if all plays consistent with it are winning.

The representation of the switching order. Recall that $\text{Ord}(v) = \langle u_1, u_2, \ldots, u_k \rangle$ gives a sequence of outgoing edges for every switching vertex. We consider two possible ways of representing $\text{Ord}(v)$ in this paper. In *explicit* RSGs, $\text{Ord}(v)$ is represented by simply writing down the sequence $\langle u_1, u_2, \ldots, u_k \rangle$.

We also consider games in which $\text{Ord}(v)$ is written down in a more concise way, which we call *succinct* RSGs. In these games, for each switching vertex v, we have a sequence of pairs $\langle (u_1, t_1), (u_2, t_2), \ldots, (u_k, t_k) \rangle$, where each u_i is a vertex with $(v, u_i) \in E$, and each t_i is a natural number. The idea is that $\text{Ord}(v)$ should contain t_1 copies of u_1, followed by t_2 copies of u_2, and so on. So, if $\text{Rep}(u, t)$ gives the sequence containing t copies of u, and if $\cdot$ represents sequence concatenation, then $\text{Ord}(v) = \text{Rep}(u_1, t_1) \cdot \text{Rep}(u_2, t_2) \cdot \ \ldots \ \cdot \text{Rep}(u_k, t_k)$. Any explicit game can be written down in the succinct encoding by setting all $t_i = 1$. Note, however, that in a succinct game $\text{Ord}(v)$ may have exponentially many elements, even if the input size is polynomial, since each t_i is represented in binary.

3 One-player reachability switching games

In this section we consider one-player RSGs, i.e., where $V_{\text{S}} = \emptyset$.

3.1 Containment in NP

We show that deciding whether the reachability player wins a one-player RSG is in NP. Our proof holds for both explicit and succinct games. The proof uses *controlled switching flows*. These extend the idea of switching flows, which were used by Dohrau et al. [7] to show containment of the zero-player reachability problem in $\text{NP} \cap \text{coNP}$.

Controlled switching flow. A *flow* is a function $F : E \to \mathbb{N}$ that assigns a natural number to each edge in the game. For each vertex v, we define $\text{Bal}(F, v) = \sum_{(v,u) \in E} F(v, u) - \sum_{(w,v) \in E} F(w, v)$, which is the difference between the outgoing and incoming flow at v. For each switching node $v \in V_{\text{Swi}}$, let $\text{Succ}(v)$ denote the set of vertices that appear in $\text{Ord}(v)$, and for each index $i \leq |\text{Ord}(v)|$ and each vertex $u \in \text{Succ}(v)$, let $\text{Out}(v, i, u)$ be the number of times that u appears in the first i entries of $\text{Ord}(v)$. In other words, $\text{Out}(v, i, u)$ gives the amount of flow that should be sent to u if we send exactly i units of flow into v.

A flow F is a *controlled switching flow* if it satisfies the following constraints:

- The source vertex s satisfies $\text{Bal}(F, s) = 1$, and the target vertex t satisfies $\text{Bal}(F, t) = -1$.
- Every vertex v other than s or t satisfies $\text{Bal}(F, v) = 0$.
- Let $v \in V_{\text{Swi}}$ be a switching node, $k = |\text{Ord}(v)|$, and let $I = \sum_{(u,v) \in E} F(u, v)$ be the total amount of flow incoming to v. Define p to be the largest integer such that $p \cdot k \leq I$ (which may be 0), and $q = I \bmod k$. For every vertex $w \in \text{Succ}(v)$ we have that $F(v, w) = p \cdot \text{Out}(v, k, w) + \text{Out}(v, q, w)$.

The first two constraints ensure that F is a flow from s to t, while the final constraint ensures that the flow respects the switching order at each switching node. Note that there are no constraints on how the flow is split at the nodes in V_{R}. For each flow F, we define the size of F to be $\sum_{e \in E} F(e)$. A flow of size k can be written down using at most $|E| \cdot \log k$ bits.

Marginal strategies. A *marginal* strategy for the reachability player is defined by a function $M : E \to \mathbb{N}$, which assigns a target number to each outgoing edge of the vertices in V_{R}. The strategy ensures that each edge e is used no more than $M(e)$ times. That is, when the play arrives at a vertex $v \in V_{\mathrm{R}}$, the strategy checks how many times each outgoing edge of v has been used so far, and selects an arbitrary outgoing edge e that has been used strictly less than $M(e)$ times. If there is no such edge, then the strategy is undefined.

Observe that a controlled switching flow defines a marginal strategy for the reachability player. We prove that this strategy always reaches the target.

▶ **Lemma 1.** *If a one-player RSG has a controlled switching flow F, then any corresponding marginal strategy is winning for the reachability player.*

In the other direction, if the reachability player has a winning strategy, then there exists a controlled switching flow, and we can give an upper bound on its size.

▶ **Lemma 2.** *If the reachability player has a winning strategy for a one-player RSG , then that game has a controlled switching flow F, and the size of F is at most $n \cdot l^n$, where n is the number of nodes in the game and $l = \max_{v \in V_{Swi}} |\operatorname{Ord}(v)|$.*

▶ **Corollary 3.** *If the reachability player has a winning strategy for a one-player RSG, then he also has a marginal winning strategy.*

Finally, we can show that solving a one-player RSG is in NP.

▶ **Theorem 4.** *Deciding the winner of an explicit or succinct one-player RSG is in* NP.

3.2 NP-hardness

In this section we show that deciding the winner of a one-player RSG is NP-hard. Our construction will produce an explicit RSG, so we obtain NP-hardness for both explicit and succinct games. We reduce from 3SAT. Throughout this section, we will refer to a 3SAT instance with variables $x_1, x_2, \ldots, x_n$, and clauses $C_1, C_2, \ldots, C_m$. It is well-known [22, Thm. 2.1] that 3SAT remains NP-hard even if all variables appear in at most three clauses. We make this assumption during our reduction.

Overview. The idea behind the construction is that the player will be asked to assign values to each variable. Each variable x_i has a corresponding vertex that will be visited 3 times during the game. Each time this vertex is visited, the player will be asked to assign a value to x_i in a particular clause C_j. If the player chooses an assignment that *does not* satisfy C_j, then the game records this by incrementing a counter. If the counter corresponding to any clause C_j is incremented to three (or two if the clause only has two variables), then the reachability player immediately loses, since the chosen assignment fails to satisfy C_j.

The problem with the idea presented so far is that there is no mechanism to ensure that the reachability player chooses a consistent assignment to the same variable. Since each variable x_i is visited three times, there is nothing to stop the reachability player from choosing contradictory assignments to x_i on each visit. To address this, the game also counts

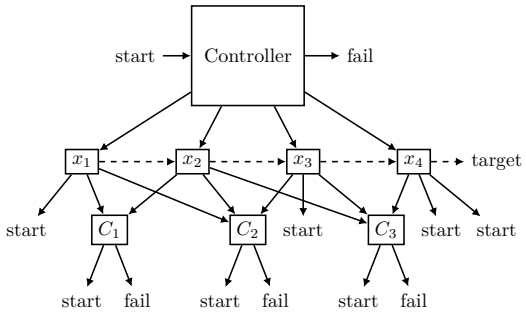

Figure 1 Overview of our construction for one player for the example formula $C_1 \wedge C_2 \wedge C_3 = (x_1 \vee \neg x_2) \wedge (\neg x_1 \vee \neg x_2 \vee x_3) \wedge (x_2 \vee x_3 \vee x_4)$. Note that the negations of variables in the formula are not relevant for this high-level view; they will feature in the clause gadgets as explained below. The edges for the variable phase are solid, and the edges for the verification phase are dashed.

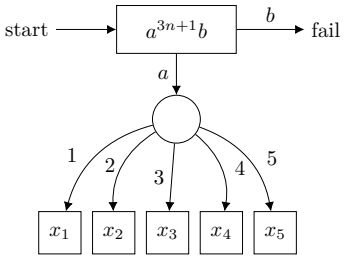

Figure 2 The control gadget.

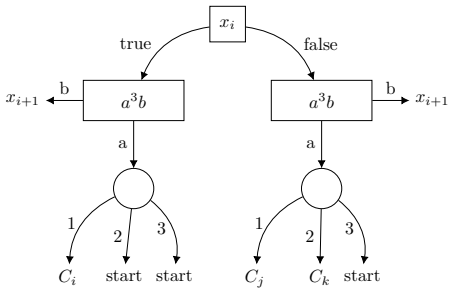

Figure 3 A variable gadget.

how many times each assignment is chosen for x_i. At the end of the game, if the reachability player has not already lost by failing to satisfy the formula, the game is configured so that the target is only reachable if the reachability player chose a consistent assignment. A high-level overview of the construction for an example formula is given in Fig. 1.

The control gadget. The sequencing in the construction is determined by the control gadget, which is shown in Fig. 2. In our diagramming notation, square vertices belong to the reachability player. Circle vertices are switching nodes, and the switching order of each switching vertex is labelled on its outgoing edges. Our diagrams also include *counting gadgets*, which are represented as non-square rectangles that have labelled output edges. The counting gadget is labelled by a sequence over these outputs, with the idea being that if the play repeatedly reaches the gadget, then the corresponding output sequence will be produced. In Fig. 2 the gadget is labelled by $a^{3n+1}b$, which means the first $3n+1$ times the gadget is used the token will be moved along the a edge, and the $3n+2$nd time the gadget is used the token will be moved along the b edge. This gadget can be easily implemented by a switching node that has $3n+2$ outgoing edges, the first $3n+1$ of which go to a, while the $3n+2$nd edge goes to b. We use gadgets in place of this because it simplifies our diagrams.

The control gadget has two phases. In the *variable phase*, each variable gadget, represented by the vertices x_1 through x_n is used exactly 3 times, and thus overall the gadget will be used $3n$ times. This is accomplished by a switching node that ensures that each variable is used 3 times. After each variable gadget has been visited 3 times, the control gadget then sends the token to the x_1 variable gadget for the *verification phase* of the game. In this phase, the reachability player must prove that he gave consistent assignments to all variables.

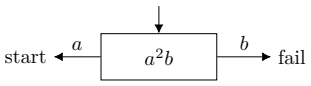

Figure 4 A gadget for a clause with three variables.

If the control gadget is visited $3n + 2$ times, then the token will be moved to the *fail* vertex. This vertex has no outgoing edges, and thus is losing for the reachability player.

The variable gadgets. Each variable x_i is represented by a variable gadget, which is shown in Fig. 3. This gadget will be visited 3 times in total during the variable phase, and each time the reachability player must choose either the true or false edges at the vertex x_i. In either case, the token will then pass through a counting gadget, and then move to a switching vertex which either moves the token to a clause gadget, or back to the start vertex.

It can be seen that the gadget is divided into two almost identical branches. One corresponds to a true assignment to x_i, and the other to a false assignment to x_i. The clause gadgets are divided between the two branches of the gadget. In particular, a clause appears on a branch if and only if the variable appears in that clause and the choice made by the reachability player *fails* to satisfy the clause. So, the clauses in which x_i appears positively appear on the false branch of the gadget, while the clauses in which x_i appears negatively appear on the true branch.

The switching vertices each have exactly three outgoing edges. These edges use an arbitrary order over the clauses assigned to the branch. If there are fewer than 3 clauses on a particular branch, the remaining edges of the switching node go back to the start vertex. Note that this means that a variable can be involved with fewer than three clauses.

The counting gadgets will be used during the verification phase of the game, in which the variable player must prove that he has chosen consistent assignments to each of the variables. Once each variable gadget has been used 3 times, the token will be moved to x_1 by the control gadget. If the reachability player has used the same branch three times, then he can choose that branch, and move to x_2, which again has the same property. So, if the reachability player gives a consistent assignment to all variables, he can eventually move to x_n, and then on to x_{n+1}, which is the target vertex of the game. Since, as we will show, there is no other way of reaching x_{n+1}, this ensures that the reachability player must give consistent assignments to the variables in order to win the game.

The clause gadgets. Each clause C_j is represented by a clause gadget, an example of which is shown in Fig. 4. The gadget counts how many variables have failed to satisfy the corresponding clause. If the number of times the gadget is visited is equal to the number of variables involved with the clause, then the game moves to the fail vertex, and the reachability player immediately loses. In all other cases, the token moves back to the start vertex.

Correctness. The following lemma shows that the reachability player wins the one-player RSG if and only if the 3SAT instance is satisfiable.

▶ **Lemma 5.** *The reachability player wins the one-player RSG if and only if the 3SAT instance is satisfiable.*

Note that our game can be written down as an explicit game, so our lower bound applies to both explicit and succinct games. Hence, we have the following theorem.

▶ **Theorem 6.** *Deciding the winner of an explicit or succinct one-player RSG is* NP*-hard.*

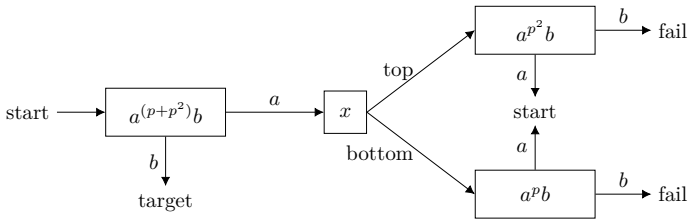

Figure 5 One-player memory lower bound construction.

3.3 Memory requirements of winning strategies in one-player games

Consider the game shown in Fig. 5, which takes as input a parameter p that we will fix later. The only control state for the player is x. By construction, x will be visited $p + p^2$ times. Each time, the player must choose either the top or bottom edge. If the player uses the top edge strictly more than p^2 times, or the bottom edge strictly more than p times, then he will immediately lose the game. If the player does not lose the game in this way, then after $p^2 + p$ rounds the target will be reached, and the player will win the game.

The player has an obvious winning strategy: use the top edge p^2 times and the bottom edge p times. Intuitively, there are two ways that the player could implement the strategy. (1) Use the bottom edge p times, and then use the top edge p^2 times. This approach uses p memory states to count the number of times the bottom edge has been used. (2) Use the bottom edge once, use the top edge p times, and then repeat. This approach uses p memory states to count the number of times the top state has been used after each use of the bottom edge. We can prove that one cannot do significantly better.

▶ **Lemma 7.** *The reachability player must use at least $p - 1$ memory states to win the game shown in Fig. 5.*

Setting $p = 2^{n/2}$ gives us our lower bound. Even though p is exponential, it is possible to create an explicit switching gadget that produces the sequence $a^{2^n}b$ with n switching nodes.

▶ **Lemma 8.** *For all $x \in \mathbb{N}$ there is an explicit switching gadget of size $\log_2(x)$ with output $a^x b$.*

▶ **Theorem 9.** *The number of memory states needed in an explicit one-player RSG is $\Omega(2^{\frac{n}{2}})$.*

4 Two-player reachability switching games

4.1 Containment in EXPTIME

We first observe that solving a two-player RSG lies in `EXPTIME`. This can be proved easily, either by blowing the game up into an exponentially sized reachability game, or equivalently, by simulating the game on an alternating polynomial-space Turing machine.

▶ **Theorem 10.** *Deciding the winner of an RSG is in* `EXPTIME`.

4.2 PSPACE-hardness

We show that deciding the winner of an explicit two-player RSG is `PSPACE`-hard, by reducing *true quantified boolean formula* (TQBF), the canonical `PSPACE`-complete problem, to our problem. Throughout this section we will refer to a TQBF instance $\exists x_1 \forall x_2 \ldots \exists x_{n-1} \forall x_n \cdot \phi(x_1, x_2, \ldots, x_n)$, where ϕ denotes a boolean formula given in negation normal form, which requires that negations are only applied to variables, and not sub-formulas. The problem is to decide whether this formula is true.

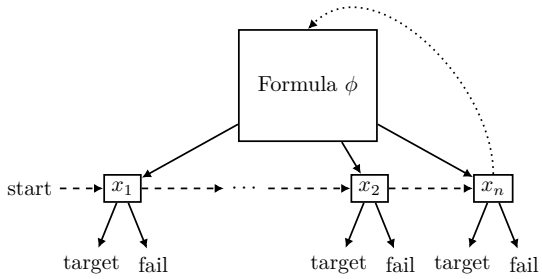

Figure 6 High-level overview of our construction for two players. The dashed lines between variables are part of the first, quantifier phase; the dotted line from variable x_n to the Formula is the transition between phases, and the solid edges are part of the second, formula phase.

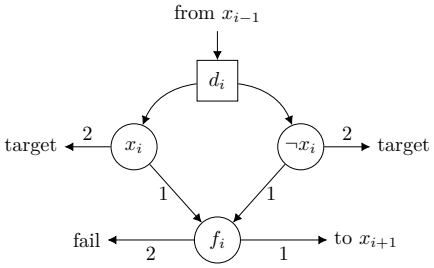

Figure 7 The initialization gadget for an existentially quantified variable x_i.

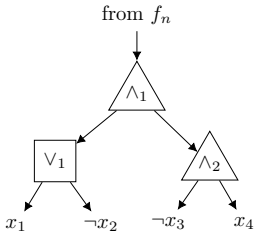

Figure 8 The formula phase game for the formula $(x_1 \vee \neg x_2) \wedge \neg x_3 \wedge x_4$.

Overview. We will implement the TQBF formula as a game between the reachability player and the safety player. This game will have two phases. In the *quantifier phase*, the two players assign values to their variables in the order specified by the quantifiers. In the *formula phase*, the two players determine whether ϕ is satisfied by these assignments by playing the standard model-checking game for propositional logic. The target state of the game is reached if and only if the model checking game determines that the formula is satisfied. This high-level view of our construction is depicted in Fig. 6.

The quantifier phase. Each variable in the TQBF formula will be represented by an *initialization gadget*. The initialization gadget for an existentially quantified variable is shown in Fig. 7. The gadget for a universally quantified variable is almost identical, but the state d_i is instead controlled by the safety player.

During the quantifier phase, the game will start at d_1, and then pass through the gadgets for each of the variables in sequence. In each gadget, the controller of d_i must move to either x_i or $\neg x_i$. In either case, the corresponding switching node moves the token to f_i, which then subsequently moves the token on to the gadget for x_{i+1}.

The important property to note here is that once the player has made a choice, any subsequent visit to x_i or $\neg x_i$ will end the game. Suppose that the controller of d_i chooses to move to x_i. If the token ever arrives at x_i a second time, then the switching node will move to the target vertex and the reachability player will immediately win the game. If the token ever arrives at $\neg x_i$ the token will move to f_i and then on to the fail vertex, and the Safety player will immediately win the game. The same property holds symmetrically if the controller of d_i chooses $\neg x_i$ instead. In this way, the controller of d_i selects an assignment to x_i. Hence, the reachability player assigns values to the existentially quantified variables, and the safety player assigns values to the universally quantified variables.

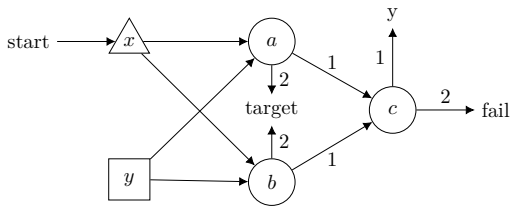

Figure 9 An RSG in which the reachability player needs to use memory.

The formula phase. Once the quantifier phase has ended, the game moves into the formula phase. In this phase the two players play a game to determine whether ϕ is satisfied by the assignments to the variables. This is the standard model checking game for first order logic. The players play a game on the parse tree of the formula, starting from the root. The reachability player controls the $\vee$ nodes, while the safety player controls the $\wedge$ nodes (recall that the game is in negation normal form, so there are no internal $\neg$ nodes.) Each leaf is either a variable or its negation, which in our game are represented by the x_i and $\neg x_i$ nodes in the initialization gadgets. An example of this game is shown in Fig. 8. In our diagramming notation, nodes controlled by the safety player are represented by triangles.

Intuitively, if ϕ is satisfied by the assignment to $x_1, \ldots, x_n$, then no matter what the safety player does, the reachability player is able to reach a leaf node corresponding to a true assignment, and as mentioned earlier, he will then immediately win the game. Conversely, if ϕ is not satisfied, then no matter what the reachability player does, the safety player can reach a leaf corresponding to a false assignment, and then immediately win the game.

▶ **Lemma 11.** *The reachability player wins if and only if the QBF formula is true.*

Since we have shown the lower bound for explicit games, we also get the same lower bound for succinct games as well. We have shown the following theorem.

▶ **Theorem 12.** *Deciding the winner of an explicit or succinct RSG is* PSPACE*-hard.*

Note that all runs of the game have polynomial length, a property that is not shared by all RSGs. This gives us the following corollary.

▶ **Corollary 13.** *Deciding the winner of a polynomial-length RSG is* PSPACE*-complete.*

4.3 Memory requirements for two player games

We can show even stronger memory lower bounds in two-player games compared to one-player games. Fig. 9 shows a simple gadget that forces the reachability player to use memory. The game starts by allowing the safety player to move the token from x to either a or b. Whatever the choice, the token then moves to c and then on to y. At this point, if the reachability player moves the token to the node chosen by the safety player, then the token will arrive at the target node and the reachability player will win. If the reachability player moves to the other node, the token will move to c for a second time, and then on to the fail vertex, which is losing for the reachability player. Thus, every winning strategy of the reachability player must remember the choice made by the safety player.

We can create a similar gadget that forces the safety player to use memory by swapping the players. In the modified gadget, the safety player has to choose the vertex *not chosen* by the reachability player. Thus, in an RSG, winning strategies for both players need to use memory. By using n copies of the memory gadget, we can show the following lower bound.

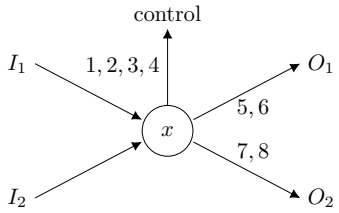

Figure 10 An AND-gate of depth 2.

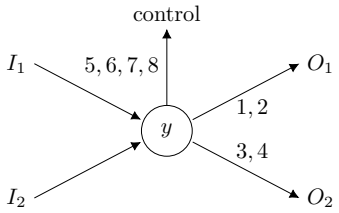

Figure 11 An OR-gate of depth 2.

▶ **Lemma 14.** *In an explicit or succinct RSG, winning strategies for both players may need to use 2^n memory states, where n is the number of switching nodes.*

5 Zero-player reachability switching games

5.1 Explicit zero-player games

We show that deciding the winner of an explicit zero-player game is NL-hard. To do this, we reduce from the problem of deciding s-t connectivity in a directed graph. The idea is to make every node in the graph a switching node. We then begin a walk from s. If, after $|V|$ steps we have not arrived at t, we go back to s and start again. So, if there is a path from s to t, then the switching nodes must eventually send the token along that path.

Formally, given a graph (V, E), we produce a zero-player RSG played on $V \times V \cup \{\mathsf{fin}\}$, where the second component of each state is a counter that counts up to $|V|$. Every vertex is a switching node, the start vertex is $(s, 1)$, and the target vertex is fin. Each vertex (v, k) with $v \neq t$ and $k < |V|$ has outgoing edges to $(u, k + 1)$ for each outgoing edge $(v, u) \in E$. Each vertex $(v, |V|)$ with $v \neq t$ has a single outgoing edge to $(s, 1)$. Every vertex (t, k) with $1 \leq k \leq |V|$ has a single outgoing edge to fin. This game can be constructed in logarithmic space by looping over each element in $V \times V$ and producing the correct outgoing edges.

▶ **Theorem 15.** *Deciding the winner of an explicit zero-player RSG is* NL*-hard under logspace reductions.*

5.2 Succinct games

Deciding reachability for succinct zero-player games still lies in NP ∩ coNP. This can be shown using essentially the same arguments that were used to show NP ∩ coNP containment for explicit games [7]. The fact that the problem lies in NP follows from Theorem 4, since every succinct zero-player game is also a succinct one-player game, and so a switching flow can be used to witness reachability. To put the problem in coNP, one can follow the original proof given by Dohrau et al. [7, Theorem 3] for explicit games. This proof condenses all losing and infinite plays into a single failure state, and then uses a switching flow to witness reachability for that failure state. Their transformation uses only the graph structure of the game, and not the switching order, and so it can equally well be applied to succinct games.

In contrast to explicit games, we can show a stronger lower bound of P-hardness for succinct games. We will reduce from the problem of evaluating a boolean circuit (the *circuit value problem*), which is one of the canonical P-complete problems. We will assume that the circuit has fan-in and fan-out 2, that all gates are either AND-gates or OR-gates, and that the circuit is *synchronous*, meaning that the outputs of the circuit have depth 1, and all gates at depth i get their inputs from gates of depth exactly $i + 1$. This is Problem A.1.6

"Fanin 2, Fanout 2 Synchronous Alternating Monotone CVP" of Greenlaw et al. [11]. We will reduce from the following decision problem: for a given input bit-string $B \in \{0,1\}^n$, and a given output gate g, is g evaluated to true when the circuit is evaluated on B?

Boolean gates. We will simulate the gates of the circuit using switching nodes. A gate at depth $i > 1$ is connected to exactly two gates of depth $i+1$ from which it gets its inputs, and exactly two gates at depth $i-1$ to which it sends its output. If a gate evaluates to true, then it will send a *signal* to the output-gates, by sending the token to that gate's gadget. More precisely, for a gate of depth $i > 1$, the following signals are sent. If the gate evaluates to true, then the gate will send the token exactly 2^{i-1} times to each output gate. If the gate evaluates to false, then the gate will send the token exactly 0 times to each output gate. So the number of signals sent by a gate grows exponentially with the depth of that gate.

Fig. 10 shows our construction for an AND-gate of depth 2. It consists of a single switching node (with a succinct order). I_1 and I_2 are two input edges that come from the two inputs to this gate, and O_1 and O_2 are two output edges that go to the outputs of this gate. The control state is a special state that drives the construction, which will be described later. The switching order was generated by the following rules. For a gate at depth i, the switching order of an AND-gate is defined so that the first 2^i positions in the switching order go to control, the next 2^{i-1} positions in the switching order go to O_1, and the final 2^{i-1} positions in the switching order go to O_2. Observe that this switching order captures the behavior of an AND-gate. If the gadget receives 2^i signals from both inputs, then it sends 2^{i-1} signals to both outputs. On the other hand, if at least one of the two inputs sends no signals, then the gadget sends no signals to the outputs.

The same idea is used to implement OR-gates. Fig. 11 shows the construction for an OR-gate of depth 2. For an OR-gate of depth i we have that the first 2^{i-1} positions in the switching order go to O_1, the next 2^{i-1} positions in the switching order go to O_2, and the final 2^i positions in the switching order go to control. These conditions simulate an OR-gate. If either of the inputs produces 2^i input signals, then 2^{i-1} signals are sent to both outputs. If both inputs produce no signals, then no signals are sent to either output.

The control state and the depth 1 gates. Suppose that the inputs to the circuit are at depth d. The control state is a single switching node that has the following switching order. Each input edge to a gate at depth d refers to some bit contained in the bit-string B. The control state sends 2^d inputs using that edge if that bit is true, and 0 inputs using that edge if that bit is false. Once those signals have been sent, the control state moves the token to an absorbing failure state. The token begins at the control state.

Each gate at depth 1 is represented by a single state, and has the same structure and switch configuration as the gates at depth $i > 1$. The only difference is the destination of the edges O_1 and O_2. The gate g (which we must evaluate) sends all outputs to an absorbing target state. All other gates send all outputs back to the control state.

▶ **Lemma 16.** *The token reaches the target state if and only if the gate g evaluates to true when the circuit is evaluated on the bit-string B.*

Since these gadgets use exponential switching orders, this construction would have exponential size if written down in the explicit format. Note, however, that all of the switching orders can be written down in the succinct format in polynomially many bits. Moreover, the construction has exactly one switching state for each gate in the circuit, and three extra states for the control, target, and failure nodes. Every state in the construction

can be created using only the inputs and outputs of the relevant gate in the circuit, which means that the reduction can be carried out in logarithmic space. Thus, we have the following.

▶ **Theorem 17.** *Deciding the winner of a succinct zero-player RSG is* P*-hard under logspace reductions.*

Abstract

We consider Pareto analysis of reachable states of multi-priced timed automata (MPTA): timed automata equipped with multiple observers that keep track of costs (to be minimised) and rewards (to be maximised) along a computation. Each observer has a constant non-negative derivative which may depend on the location of the MPTA.

We study the Pareto Domination Problem, which asks whether it is possible to reach a target location via a run in which the accumulated costs and rewards Pareto dominate a given objective vector. We show that this problem is undecidable in general, but decidable for MPTA with at most three observers. For MPTA whose observers are all costs or all rewards, we show that the Pareto Domination Problem is PSPACE-complete. We also consider an ε-approximate Pareto Domination Problem that is decidable without restricting the number and types of observers.

We develop connections between MPTA and Diophantine equations. Undecidability of the Pareto Domination Problem is shown by reduction from Hilbert's 10^{th} Problem, while decidability for three observers is shown by a translation to a fragment of arithmetic involving quadratic forms.

1 Introduction

Multi Priced Timed Automata (MPTA) [5, 7, 8, 11, 17, 18, 19] extend priced timed automata [2, 3, 4, 6, 16] with *multiple observers* that capture the accumulation of costs and rewards along a computation. This extension allows to model multi-objective optimization problems beyond the scope of timed automata [1]. MPTA lie at the frontier between timed automata (for which reachability is decidable [1]) and linear hybrid automata (for which reachability is undecidable [14]). The observers exhibit richer dynamics than the clocks of timed automata

by not being confined to unit slope in locations, but may neither be queried nor reset while taking edges. This *observability restriction* has been exploited in [17] (under a cost-divergence assumption) for carrying out a *Pareto analysis* of reachable values of the observers.

In this paper we distinguish between observers that represent *costs* (to be minimised) and those that represent *rewards* (to be maximised). Formally, we partition the set $\mathcal{Y}$ of observers into cost and reward variables and say that $\gamma \in \mathbb{R}^{\mathcal{Y}}_{\geq 0}$ *Pareto dominates* $\gamma' \in \mathbb{R}^{\mathcal{Y}}_{\geq 0}$ if $\gamma(y) \leq \gamma'(y)$ for each cost variable y and $\gamma(y) \geq \gamma'(y)$ for each reward variable y. Then the *Pareto curve* corresponding to an MPTA consists of all undominated vectors γ that are reachable in an accepting location. While cost and reward variables are syntactically identical in the underlying automaton model, distinguishing between them changes the notion of Pareto domination and the associated decision problems.

We introduce in Section 3 a decision version of the problem of computing Pareto curves for MPTA, called the *Pareto Domination Problem*. Here, given a target vector $\gamma \in \mathbb{R}^{\mathcal{Y}}_{\geq 0}$, one asks to reach an accepting location with a valuation $\gamma' \in \mathbb{R}^{\mathcal{Y}}_{\geq 0}$ that Pareto dominates γ. This has not been addressed in prior work on Pareto analysis of MPTA [17], which considers only costs or only rewards. Other works on MPTA either do not address Pareto analysis [5, 8, 11, 18, 19], or have only discrete costs updated on edges [22], or are confined to a single clock [7].

Our first main result is that the Pareto Domination Problem is undecidable in general. The undecidability proof in Section 4 is by reduction from Hilbert's 10^{th} problem. Owing to the existence of so-called "universal Diophantine equations" (of degree 4 with 58 variables [15]), our proof shows undecidabililty of the Pareto Domination Problem for some fixed but large number of observers. Undecidability of the Pareto Domination Problem entails that one cannot compute an exact Pareto curve for an arbitrary MPTA.

We consider three different approaches to recover decidability of the Pareto Domination Problem, which all have a common foundation, namely a *monotone* VASS described in Sections 2 and 5, which simulates integer runs of a given MPTA. By analysing the semi-linear reachability set of this VASS we can reduce the Pareto Domination Problem to satisfiability of a class of bilinear mixed integer-real constraints. We then consider restrictions on MPTA and variants of the Pareto Domination Problem that allow us to solve this class of constraints.

We first show in Section 6 that restricting to MPTA with only costs or only rewards yields PSPACE-completeness of the Pareto Domination Problem. Here we are able to eliminate integer variables from our bilinear constraints, resulting in a formula of linear real arithmetic. This strengthens [17, Theorem 1 and Corollary 1], whose decision procedures (that exploit well-quasi-orders for termination) do not yield complexity bounds.

Next we confine the MPTA in Section 7 to at most three observers, but allow a mix of costs and rewards. Decidability is now achieved by eliminating real variables from the bilinear constraint system, thus reducing the Pareto Domination Problem to deciding the existence of positive integer zeros of a quadratic form, which is known to be decidable from [12].

We consider in Section 8 another method to restore decidability for general MPTA with arbitrarily many costs and rewards, by studying an approximate version of the Pareto Domination Problem, called the *Gap Domination Problem*. Similar to the setting of [9], the Gap Domination Problem represents the decision version of the problem of computing ε-Pareto curves. This problem, whose input includes a tolerance $\varepsilon > 0$ and a vector $\gamma \in \mathbb{R}^{\mathcal{Y}}_{\geq 0}$, places no requirement on the answer if γ is dominated and all solutions dominating γ do so with slack at most ε. We solve the Gap Domination Problem by relaxation and rounding applied to our bilinear system of constraints.

In this paper we consider only MPTA with non-negative rates. Our approach can be generalised to obtain decidability results also in the case of negative rates by extending our foundation in Sections 2 and 5 from monotone VASS to $\mathbb{Z}$-VASS [13].

2 Background

Quadratic Diophantine Equations. For later use we recall a decidable class of non-linear Diophantine problems. Consider the quadratic equation

$$\sum_{i,j=1}^{n} a_{ij} X_i X_j + \sum_{j=1}^{n} b_j X_j + c = 0 \tag{1}$$

whose coefficients a_{ij}, b_j, and c are rational numbers. Consider also the family of constraints

$$f_1(X_1, \ldots, X_n) \sim c_1 \wedge \ldots \wedge f_k(X_1, \ldots, X_n) \sim c_k\,, \tag{2}$$

where $f_1, \ldots, f_k$ are linear forms with rational coefficients, $c_1, \ldots, c_k \in \mathbb{Q}$, and $\sim \in \{<, \leq\}$.

▶ **Theorem 1** ([12]). *There is an algorithm that decides whether a given quadratic equation (1) and a family of linear inequalities (2) have a solution in $\mathbb{Z}^n$.*

Let us emphasize that in Theorem 1 at most one quadratic constraint is permitted. It is clear (e.g., by introducing a slack variable) that the theorem remains true if the equality symbol in (1) is replaced by any comparison operator in $\{<, \leq, >, \geq\}$.

Monotone VASS. A *monotone vector addition system with states* (monotone VASS) is a tuple $\mathcal{Z} = \langle n, Q, q_0, Q_f, \Sigma, \Delta \rangle$, where $n \in \mathbb{N}$ is the *dimension*, Q is a set of *states*, $q_0 \in Q$ is the *initial state*, $Q_f \subseteq Q$ is a set of *final states*, Σ is the set of *labels*, and $\Delta \subseteq Q \times \mathbb{N}^n \times \Sigma \times Q$ is the set of *transitions*.

Given such a monotone VASS $\mathcal{Z}$ as above, the family of sets $\mathrm{Reach}_{\mathcal{Z},q} \subseteq \mathbb{N}^n$, for $q \in Q$, is the minimal family (w.r.t. to set inclusion) of integer vectors such that $\mathbf{0} \in \mathrm{Reach}_{\mathcal{Z},q_0}$ and for all $q \in Q$, if $\boldsymbol{u} \in \mathrm{Reach}_{\mathcal{Z},q}$ and $(q, \boldsymbol{v}, \ell, p) \in \Delta$ for some $\ell \in L$, then $\boldsymbol{u} + \boldsymbol{v} \in \mathrm{Reach}_{\mathcal{Z},p}$. Finally we define the *reachability set* of $\mathcal{Z}$ to be $\mathrm{Reach}_{\mathcal{Z}} := \bigcup_{q \in Q_f} \mathrm{Reach}_{\mathcal{Z},q}$.

For every vector $\boldsymbol{v} \in \mathbb{N}^n$ and every finite set $P = \{\boldsymbol{u}_1, \ldots, \boldsymbol{u}_m\}$ of vectors in $\mathbb{N}^n$, we define the $\mathbb{N}$-*linear set* $S(\boldsymbol{v}, P) := \{\boldsymbol{v} + \sum_{i=1}^{m} a_i \boldsymbol{u}_i : a_1, \ldots, a_m \in \mathbb{N}\}$. We call $\boldsymbol{v}$ the *base vector* and $\boldsymbol{u}_1, \ldots, \boldsymbol{u}_m \in P$ the *period vectors* of the set.

The following proposition follows from [20, Proposition 4.3] (see [10, Appendix B.1]).

▶ **Proposition 2.** *Let $\mathcal{Z} = \langle n, Q, q_0, Q_f, \Sigma, \Delta \rangle$ be a monotone VASS. Then the set* $\mathrm{Reach}_{\mathcal{Z}}$ *can be written as a finite union of $\mathbb{N}$-linear sets $S(\boldsymbol{v}_1, P_1), \ldots, S(\boldsymbol{v}_k, P_k)$, where for $i = 1, \ldots, k$ the components of $\boldsymbol{v}_i$ and of each vector in P_i are bounded by $\mathrm{poly}(n, |Q|, M)^n$ in absolute value, where M is maximum absolute value of the entries of vectors in $\mathbb{N}^n$ occurring in Δ.*

3 Multi-Priced Timed Automata and Pareto Domination

Let $\mathbb{R}_{\geq 0}$ denote the set of non-negative real numbers. Given a set $\mathcal{X} = \{x_1, \ldots, x_n\}$ of *clocks*, the set $\Phi(\mathcal{X})$ of *clock constraints* is generated by the grammar $\varphi ::= \texttt{true} \mid x \leq k \mid x \geq k \mid \varphi \wedge \varphi$, where $k \in \mathbb{N}$ is a natural number and $x \in \mathcal{X}$. A *clock valuation* is a mapping $\nu : \mathcal{X} \to \mathbb{R}_{\geq 0}$ that assigns to each clock a non-negative real number. We denote by $\mathbf{0}$ the valuation such that $\mathbf{0}(x) = 0$ for all clocks $x \in \mathcal{X}$. We write $\nu \models \varphi$ to denote that ν satisfies the constraint φ. Given $t \in \mathbb{R}_{\geq 0}$, we let $\nu + t$ be the clock valuation such that $(\nu + t)(x) = \nu(x) + t$ for all clocks $x \in \mathcal{X}$. Given $\lambda \subseteq \mathcal{X}$, let $\nu[\lambda \leftarrow 0]$ be the clock valuation such that $\nu[\lambda \leftarrow 0](x) = 0$ if $x \in \lambda$, and $\nu[\lambda \leftarrow 0](x) = \nu(x)$ otherwise.

A *multi-priced timed automaton* (MPTA) is a tuple $\mathcal{A} = \langle L, \ell_0, L_f, \mathcal{X}, \mathcal{Y}, E, R \rangle$, where L is a finite set of *locations*, $\ell_0 \in L$ is an *initial location*, $L_f \subseteq L$ is a set of *accepting locations*,

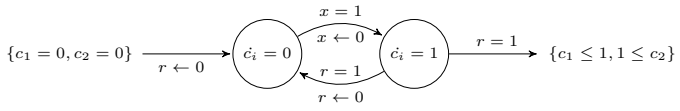

Figure 1 Predicates in curly brackets denote observer values enforced by initialisation, $c_i = 0$ with $i \in \{1, 2\}$, and by the Pareto constraint upon exit $\{c_1 \leq 1, 1 \leq c_2\}$. Denoting the initial value of clock x by x^*, the value of both c_1 and c_2 after n full traversals of the central cycle is nx^*. Meeting the final Pareto constraint from initial values thus requires that x^* be $\frac{1}{n}$ for some positive integer n.

$\mathcal{X}$ is a finite set of *clock variables*, $\mathcal{Y}$ is a finite set of *observers*, $E \subseteq L \times \Phi(\mathcal{X}) \times 2^{\mathcal{X}} \times L$ is the set of *edges*, $R : L \to \mathbb{N}^{\mathcal{Y}}$ is a *rate function*. Intuitively $R(\ell)$ is a vector that gives the rates of each observer in location ℓ.

A *state* of $\mathcal{A}$ is a triple (ℓ, ν, t) where ℓ is a location, ν a clock valuation, and $t \in \mathbb{R}_{\geq 0}$ is a *time stamp*. A *run* of $\mathcal{A}$ is an alternating sequence of states and edges $\rho = (\ell_0, \nu_0, t_0) \xrightarrow{e_1} (\ell_1, \nu_1, t_1) \xrightarrow{e_2} \ldots \xrightarrow{e_m} (\ell_m, \nu_m, t_m)$, where $t_0 = 0$, $\nu_0 = \mathbf{0}$, $t_{i-1} \leq t_i$ for all $i \in \{1, \ldots, m\}$, and $e_i = \langle \ell_{i-1}, \varphi, \lambda, \ell_i \rangle \in E$ is such that $\nu_{i-1} + (t_i - t_{i-1}) \models \varphi$ and $\nu_i = (\nu_{i-1} + (t_i - t_{i-1}))[\lambda \leftarrow 0]$ for $i = 1, \ldots, m$. The run is *accepting* if $\ell_m \in L_f$ and said to have *granularity* $\frac{1}{g}$ for a fixed $g \in \mathbb{N}$ if all $t_i \in \mathbb{Q}$ are positive integer multiples of $\frac{1}{g}$. The *cost* of such a run is a vector $\mathrm{cost}(\rho) \in \mathbb{R}^{\mathcal{Y}}$, defined by $\mathrm{cost}(\rho) = \sum_{j=0}^{m-1} (t_{i+1} - t_i) R(\ell_i)$.

Henceforth we will assume that the set $\mathcal{Y}$ of observers of a given MPTA is partitioned into a set $\mathcal{Y}_c$ of *cost variables* and a set $\mathcal{Y}_r$ of *reward variables*. With respect to this partition we define a *domination ordering* $\preccurlyeq$ on the set of valuations $\mathbb{R}^{\mathcal{Y}}$, where $\gamma \preccurlyeq \gamma'$ if $\gamma(y) \leq \gamma'(y)$ for all $y \in \mathcal{Y}_r$ and $\gamma'(y) \leq \gamma(y)$ for all $y \in \mathcal{Y}_c$. Intuitively $\gamma \preccurlyeq \gamma'$ (read γ' dominates γ) if γ' is at least as good as γ in all respects.

Given $\varepsilon > 0$ we define an *ε-domination ordering* $\preccurlyeq_\varepsilon$, where $\gamma \preccurlyeq_\varepsilon \gamma'$ (read γ' ε-dominates γ) if $\gamma(y) + \varepsilon \leq \gamma'(y)$ for all $y \in \mathcal{Y}_r$ and $\gamma'(y) + \varepsilon \leq \gamma(y)$ for all $y \in \mathcal{Y}_c$. We can think of $\gamma \preccurlyeq_\varepsilon \gamma'$ as denoting that γ' is better than γ by an additive factor of ε in all dimensions. In particular we clearly have that $\gamma \preccurlyeq_\varepsilon \gamma'$ implies $\gamma \preccurlyeq \gamma'$.

The *Pareto Domination Problem* is as follows. Given an MPTA $\mathcal{A}$ with a set $\mathcal{Y}$ of observers and a partition of $\mathcal{Y}$ into sets $\mathcal{Y}_c$ and $\mathcal{Y}_r$ of cost and reward variables, with a target $\gamma \in \mathbb{R}^{\mathcal{Y}}$, decide whether there is an accepting run ρ of $\mathcal{A}$ such that $\gamma \preccurlyeq \mathrm{cost}(\rho)$.

The *Gap Domination Problem* is a variant of the above problem in which the input additionally includes an accuracy parameter $\varepsilon > 0$. If there is some run ρ such that $\gamma \preccurlyeq_\varepsilon \mathrm{cost}(\rho)$ then the output should be "dominated" and if there is no run ρ such that $\gamma \preccurlyeq \mathrm{cost}(\rho)$ then the output should be "not dominated". In case neither of these alternatives hold (i.e., γ is dominated but not ε-dominated) then there is no requirement on the output.

In the (Pareto) Domination Problem the objective is to *reach* an accepting location while satisfying a family of upper-bound constraints on cost variables and lower-bound constraints on reward variables. We say that an instance of the problem is *pure* if all observers are cost variables or all are reward variables (and hence all constraints are upper bounds or all are lower bounds); otherwise we call the instance *mixed*. Our problem formulation involves only simple constraints on observers, i.e., those of the form $y \leq c$ or $y \geq c$ for $y \in \mathcal{Y}$. However such constraints can be used to encode more general linear constraints of the form $a_1 y_1 + \cdots + a_k y_k \sim c$, where $y_1, \ldots, y_k \in \mathcal{Y}$, $a_1, \ldots, a_k, c \in \mathbb{N}$ and $\sim \in \{\leq, \geq, =\}$. To do this one introduces a fresh observer to denote each linear term $a_1 y_1 + \cdots + a_k y_k$ (two fresh observers are needed for an equality constraint).

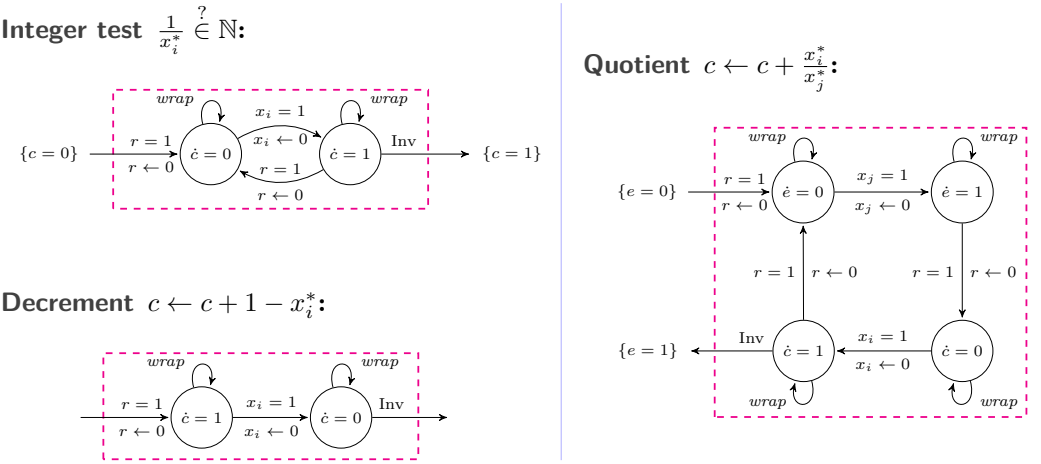

Figure 2 The *wrap* self-loop denotes a family of m wrapping edges, as in [14, Fig. 14], where the j-th edge has guard $x_j = 1$ and resets x_j. In the quotient gadget, e is a fresh observer, as is c in the integer test. The integer test and quotient gadgets are annotated with predicates in curly brackets indicating the initial values of observers on entering and their target values on exiting the gadget. Enforcing these target values through a corresponding Pareto constraint guarantees the desired behaviour of the gadget.

Note that we consider timed automata without *difference constraints* on clocks, i.e., without clock guards of the form $x_i - x_j \sim k$, for $k \in \mathbb{N}$. As discussed in [10, Appendix A] all our decidability and complexity results hold also in case of such constraints.

4 Undecidability of the Pareto Domination Problem

In this section we prove undecidability of the Pareto Domination Problem. To give some insight we first give in Figure 1 an MPTA, in which the Pareto constraint $c_1 \leq 1, c_2 \geq 1$ is used to enforce that when control enters the MPTA the value of clock x is $\frac{1}{n}$ for some positive integer n.

We prove undecidability of the Pareto Domination Problem by reduction from the satisfiability problem for a fragment of arithmetic given by a language $\mathcal{L}$ that is defined as follows. There is an infinite family of variables $X_1, X_2, X_3, \ldots$ and formulas are given by the grammar $\varphi ::= X = Y + Z \mid X = YZ \mid \varphi \wedge \varphi$, where X, Y, Z range over the set of variables. The satisfiability problem for $\mathcal{L}$ asks, given a formula φ, whether there is an assignment of positive integers to the variables that satisfies φ. In [10, Appendix B.2] we show that the satisfiability problem for $\mathcal{L}$ is undecidable by reduction from Hilbert's Tenth Problem.

▶ **Theorem 3.** *The Pareto Domination Problem is undecidable.*

Proof. Consider the following problem of reaching a single valuation in $\mathbb{R}^{\mathcal{Y}}_{\geq 0}$: given an MPTA $\mathcal{A} = \langle L, \ell_0, L_f, \mathcal{X}, \mathcal{Y}, E, R \rangle$, and target valuation $\gamma \in \mathbb{R}^{\mathcal{Y}}_{\geq 0}$, decide whether there is an accepting run ρ of $\mathcal{A}$ such that $\text{cost}(\rho) = \gamma$.

One can reduce the problem of reaching a given valuation to the Pareto Domination Problem as follows. Transform the MPTA $\mathcal{A}$ to an MPTA $\mathcal{A}'$ that has the same locations and edges as $\mathcal{A}$ but with two copies of each observer $y \in \mathcal{Y}$, with each copy having the same rate as y in each location. Formally $\mathcal{A}'$ has set of observers $\mathcal{Y}' = \{y_1, y_2 : y \in \mathcal{Y}\}$, where y_1 is a cost variable and y_2 is a reward variable. Then, defining $\gamma' \in \mathbb{R}^{\mathcal{Y}'}_{\geq 0}$ by $\gamma'(y_1) = \gamma'(y_2) = \gamma(y)$,

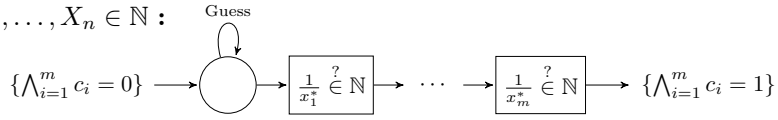
we have that $\mathcal{A}'$ has an accepting run ρ' such that $\mathrm{cost}(\rho')$ dominates γ' just in case A has an accepting run ρ such that $\mathrm{cost}(\rho) = \gamma$.

Now we give a reduction from the satisfiability problem for $\mathcal{L}$ to the problem of reaching a single valuation. Consider an $\mathcal{L}$-formula φ over variables $X_1, \ldots, X_m$. We define an MPTA $\mathcal{A}$ over the set of clocks $\mathcal{X} = \{x_1, \cdots, x_m, r\}$. Clock x_i corresponds to the variable X_i, for $i = 1, \ldots, m$, while r is a *reference clock*. The reference clock is reset whenever it reaches 1 and is not otherwise reset—thus it keeps track of global time modulo one. After an initialisation phase the remaining clocks $x_1, \ldots, x_m$ are likewise reset in a cyclic fashion, whenever they reach 1 and not otherwise. We denote by x_i^* the value of clock x_i whenever r is 1. During the initialisation phase the values x_i^* are established non-deterministically such that $0 < x_i^* \leq 1$. The idea is that $\frac{1}{x_i^*}$ represents the value of variable X_i in φ; in particular, x_i^* is the reciprocal of a positive integer. For each atomic sub-formula in φ the automaton $\mathcal{A}$ contains a gadget that checks that the guessed valuation satisfies the sub-formula.

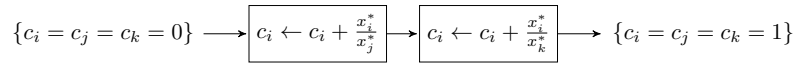
To present the reduction we first define three primitive gadgets. The first "integer test" gadget checks that the initial value x_i^* of clock x_i is a reciprocal of a positive integer, by adding wrapping edges on all clocks x_j other than x_i to the MPTA from Figure 1. The construction of each gadget is such that the precondition $r = 0$ holds when control enters the gadget and the postcondition $r = 1 \wedge \bigwedge_{j=1}^{m} x_j \leq 1$ holds on exiting the gadget. This last postcondition is abbreviated to Inv in the figures. For an observer c and $1 \leq i, j \leq m$, we define these three gadgets as in Figure 2.

In the following we show how to compose the three primitive operations in an MPTA to enforce the atomic constraints in the language $\mathcal{L}$. The initialisation automaton below is such that for $i = 1, \ldots, m$ the value x_i^* of clock x_i is such that $\frac{1}{x_i^*} \in \mathbb{N}$. Herein the Guess self-loop denotes a family of m edges, where the j-th edge non-deterministically resets clock x_j. Note that the incoming edge of the integer test gadget enforces $r = 1$ such that the initial guesses for the clocks x_i satisfy $x_i^* \in [0, 1]$. Of these, only reciprocals $\frac{1}{x_i^*} \in \mathbb{N}$ pass the subsequent series of integer tests.

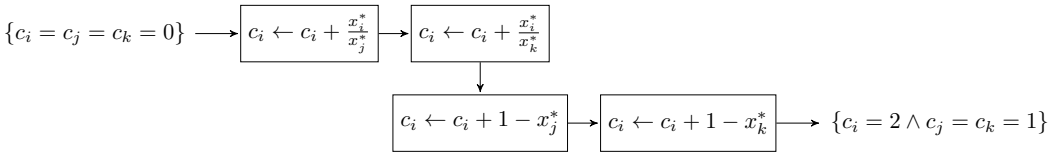
Initialisation $X_1, \ldots, X_n \in \mathbb{N}$ **:**



Sum $X_i = X_j + X_k$**:** According to the encoding of integer value X_n as clock value $x_n = \frac{1}{X_n}$, we have to enforce $\frac{1}{x_i^*} = \frac{1}{x_j^*} + \frac{1}{x_k^*}$, which is achieved by the following sequential combination of two quotient gadgets.



Product $X_i = X_j X_k$**:** The following gadget enforces $\frac{1}{x_i^*} = \frac{1}{x_j^*} \cdot \frac{1}{x_k^*}$:



The satisfiability problem for a given $\mathcal{L}$ formula φ can now directly be reduced to the problem of reaching a single valuation $\gamma \in \mathbb{R}_{\geq 0}^{\mathcal{Y}}$ by translating each of the conjuncts of φ into the corresponding above MPTA gadget. The valuation γ encodes the target costs of the respective gadgets. ◀

Let us remark that the proof of Theorem 3 shows that undecidability of the Pareto Domination Problem already holds in case all observers have rates in $\{0,1\}$. Separately we observe that undecidability also holds in the special case that exactly one observer is a cost variable and the others are reward variables, and likewise when exactly one observer is a reward variable and the others are cost variables, when allowing rates beyond $\{0,1\}$. The idea is to reduce the problem of reaching a particular valuation $\gamma \in \mathbb{R}^{\mathcal{Y}}_{\geq 0}$ in an MPTA $\mathcal{A}$ to that of dominating a valuation $\gamma' \in \mathbb{R}^{\mathcal{Y}'}_{\geq 0}$ in a derived MPTA $\mathcal{A}'$ with set of observers $\mathcal{Y}' = \mathcal{Y} \cup \{y_{\text{sum}}\}$, where y_{sum} is a fresh variable. In $\mathcal{A}'$ we designate all $y \in \mathcal{Y}$ as cost variables and y_{sum} as a reward variable, or vice versa. Valuation γ' is specified by $\gamma'(y) = \gamma(y)$ for all $y \in \mathcal{Y}$ and $\gamma'(y_{\text{sum}}) = \sum_{y \in \mathcal{Y}} \gamma(y)$. Automaton $\mathcal{A}'$ has the same locations, edges, and rate function as those of $\mathcal{A}$ except that $R'(y_{\text{sum}}) = \sum_{y \in \mathcal{Y}} R(y)$.

5 The Simplex Automaton

This section introduces the basic construction from which we derive our positive decidability results and complexity upper bounds.

Let $\mathcal{A} = \langle L, \ell_0, L_f, \mathcal{X}, \mathcal{Y}, E, R \rangle$ be an MPTA. For a sequence of edges $e_1, \ldots, e_m \in E$, define $\mathit{Runs}(e_1, \ldots, e_m) \subseteq \mathbb{R}^m_{\geq 0}$ to be the collection of sequences of timestamps $(t_1, \ldots, t_m) \in \mathbb{R}^m_{\geq 0}$ such that $\mathcal{A}$ has a run $\rho = (\ell_0, \nu_0, t_0) \xrightarrow{e_1} (\ell_1, \nu_1, t_1) \xrightarrow{e_2} \ldots \xrightarrow{e_m} (\ell_m, \nu_m, t_m)$. Recalling that by convention $t_0 = 0$ and $\nu_0 = \mathbf{0}$, once the edges $e_1, \ldots, e_m$ have been fixed then the run ρ is determined solely by the timestamps $t_1, \ldots, t_m$. When the sequence of edges $e_1, \ldots, e_m$ is understood, we call such a sequence of timestamps a run.

▶ **Proposition 4.** *$\mathit{Runs}(e_1, \ldots, e_m) \subseteq \mathbb{R}^m_{\geq 0}$ is defined by a conjunction of difference constraints.*

The proof of Proposition 4 is in [10, Appendix B.3].

▶ **Proposition 5.** *$\mathit{Runs}(e_1, \ldots, e_m)$ is equal to the convex hull of the set of its integer points.*

Proof. Fix a positive integer M. From Proposition 4 it immediately follows that the set $\mathit{Runs}(e_1, \ldots, e_m) \cap [0, M]^m$ can be written as a conjunction of closed difference constraints $A\boldsymbol{t} \leq \boldsymbol{b}$, where A is an integer matrix, $\boldsymbol{t}$ the vector of time-stamps $t_1 \ldots t_m$, and $\boldsymbol{b}$ an integer vector. Given this, it follows that $\mathit{Runs}(e_1, \ldots, e_m) \cap [0, M]^m$, being a closed and bounded polygon, is the convex hull of its vertices. Moreover each vertex is an integer point since the matrix A here, being by Proposition 4 the incidence matrix of a balanced signed graph with half edges, is totally unimodular [21, Proposition 8A.5]. ◀

Proposition 6 shows that for Pareto reachability on an MPTA $\mathcal{A}$ with $|\mathcal{Y}| = d$ observers, it suffices to look at $d+1$-simplices of integer runs.

▶ **Proposition 6.** *For any run ρ of $\mathcal{A}$ there exists a set of at most $d+1$ integer-time runs S, all over the same sequence of edges as ρ, such that $\mathrm{cost}(\rho)$ lies in the convex hull of $\mathrm{cost}(S)$.*

Proof. Let ρ be a run of $\mathcal{A}$ over an edge-sequence $e_1, \ldots, e_m$ with time stamps $t_0, \ldots, t_m$, given by $\rho = (\ell_0, \nu_0, t_0) \xrightarrow{e_1} (\ell_1, \nu_1, t_1) \xrightarrow{e_2} \ldots \xrightarrow{e_m} (\ell_m, \nu_m, t_m)$. By Proposition 5, $(t_1, \ldots, t_m)$ lies in the convex hull of the set I of integer points in $\mathit{Runs}(e_1, \ldots, e_m)$.

Since the map $\mathit{cost} : \mathit{Runs}(e_1, \ldots, e_m) \to \mathbb{R}^d$ is linear we have that $\mathrm{cost}(\rho)$ lies in the convex hull of $\mathrm{cost}(I)$. Moreover by Carathéodory's Theorem there exists a subset $S \subseteq I$ of cardinality at most $d+1$ such that $\mathrm{cost}(\rho)$ lies in the convex hull of $\mathrm{cost}(S)$. ◀

We now exploit Proposition 6 by introducing the so-called *simplex automaton* $\mathcal{S}(\mathcal{A})$, which is a monotone VASS obtained from a given MPTA $\mathcal{A}$. The automaton $\mathcal{S}(\mathcal{A})$ generates $(d+1)$-tuples of integer-time runs of $\mathcal{A}$, such that each run in the tuple executes the same sequence of edges in $\mathcal{A}$ and the runs differ only in the times at which the edges are taken. The basic component underlying the definition of the simplex automaton is the *integer-time automaton* $\mathcal{Z}(\mathcal{A})$. This automaton is a monotone VASS that generates the integer-time runs of $\mathcal{A}$, using its counters to keep track of the running cost for each observer.

The definition of $\mathcal{Z}(\mathcal{A})$ is as follows. Let $\mathcal{A} = \langle L, \ell_0, L_f, \mathcal{X}, \mathcal{Y}, E, R\rangle$ be an MPTA. Let also $M_{\mathcal{X}} \in \mathbb{N}$ be a positive constant greater than the maximum clock constant in $\mathcal{A}$. We define a monotone VASS $\mathcal{Z}(\mathcal{A}) = \langle d, Q, q_0, Q_f, E, \Delta\rangle$, in which the dimension $d = |\mathcal{Y}|$, the set of states is $Q = L \times \{0, 1, \ldots, M_{\mathcal{X}}\}^{\mathcal{X}}$, the initial state is $q_0 = (\ell_0, \mathbf{0})$, the set of accepting states is $Q_f = L_f \times \{0, 1, \ldots, M_{\mathcal{X}}\}^{\mathcal{X}}$, the set of labels is E (i.e., the set of edges of the MPTA), and the transition relation $\Delta \subseteq Q \times \mathbb{N}^d \times E \times Q$ includes a transition $((\ell, \nu), t \cdot R(\ell), e, (\ell', \nu'))$ for every $t \in \{0, 1, \ldots, M_{\mathcal{X}}\}$ and edge $e = (\ell, \varphi, \lambda, \ell')$ in $\mathcal{A}$ s.t. $\nu \oplus t \models \varphi$ and $\nu' = (\nu \oplus t)[\lambda \leftarrow 0]$. Here $(\nu \oplus t)(x) = \min(\nu(x) + t, M_{\mathcal{X}})$ for all $x \in \mathcal{X}$. We then have:

▶ **Proposition 7.** *Given a valuation $\gamma \in \mathbb{R}^{\mathcal{Y}}_{\geq 0}$, there exists an integer-time accepting run ρ of $\mathcal{A}$ with $\mathrm{cost}(\rho) = \gamma$ if and only if $\gamma \in \mathrm{Reach}_{\mathcal{Z}(\mathcal{A})}$.*

The simplex automaton $\mathcal{S}(\mathcal{A})$ is built by taking $d+1$ copies of $\mathcal{Z}(\mathcal{A}) = \langle d, Q, q_0, Q_f, E, \Delta\rangle$ that synchronize on transition labels. Formally, $\mathcal{S}(\mathcal{A}) = \langle d(d+1), Q^{d+1}, \boldsymbol{q}_0, Q_f^{d(d+1)}, E, \boldsymbol{\Delta}\rangle$, where $\boldsymbol{q}_0 = (q_0, \ldots, q_0)$ and $\boldsymbol{\Delta} \subseteq Q^{d+1} \times \mathbb{Z}^{d(d+1)} \times E \times Q^{d+1}$ comprises those tuples $((q_1, \ldots, q_{d+1}), (\boldsymbol{v}_1, \ldots, \boldsymbol{v}_{d+1}), e, (q'_1, \ldots, q'_{d+1}))$ s.t. $(q_i, \boldsymbol{v}_i, e, q'_i) \in \Delta$ for all $i \in \{1, \ldots, d+1\}$.

From Propositions 6 and 7 we have:

▶ **Proposition 8.** *Given $\gamma \in \mathbb{R}^{\mathcal{Y}}_{\geq 0}$, there exists an accepting run ρ of $\mathcal{A}$ with $\mathrm{cost}(\rho) = \gamma$ if and only if there exists $(\gamma_1, \ldots, \gamma_{d+1}) \in \mathrm{Reach}_{\mathcal{S}(\mathcal{A})}$ with γ in the convex hull of $\{\gamma_1, \ldots, \gamma_{d+1}\}$.*

We now introduce the following "master system" of bilinear inequalities that expresses whether $\gamma \preccurlyeq \mathrm{cost}(\rho)$ for some accepting run ρ of $\mathcal{A}$.

$$\begin{array}{lll} \gamma & \preccurlyeq & \lambda_1\gamma_1 + \cdots + \lambda_{d+1}\gamma_{d+1} \\ (\gamma_1, \ldots, \gamma_{d+1}) & \in & \mathrm{Reach}_{\mathcal{S}(\mathcal{A})} \end{array} \qquad \begin{array}{lll} 1 & = & \lambda_1 + \cdots + \lambda_{d+1} \\ 0 & \leq & \lambda_1, \ldots, \lambda_{d+1} \end{array} \tag{3}$$

The system has real variables $\lambda_1, \ldots, \lambda_{d+1} \in \mathbb{R}^{\mathcal{Y}}_{\geq 0}$ and integer variables $\gamma_1, \ldots, \gamma_{d+1} \in \mathbb{N}^{\mathcal{Y}}$. The key property of the master system is stated in the following Proposition 9, which follows immediately from Proposition 8.

▶ **Proposition 9.** *Given a valuation $\gamma \in \mathbb{R}^{\mathcal{Y}}_{\geq 0}$ there is an accepting run ρ of $\mathcal{A}$ such that $\gamma \preccurlyeq \mathrm{cost}(\rho)$ if and only if the system of inequalities (3) has a solution.*

Given Proposition 9, the results of Section 4 imply that satisfiability of the master system (3) is not decidable in general. In the rest of the paper we pursue different approaches to showing decidability of restrictions and variants of the Pareto Domination Problem by solving appropriately restricted versions of (3).

6 Pareto Domination Problem with Pure Constraints

In this section we show that the Pareto Domination Problem is decidable in polynomial space for the class of MPTA in which the observers are all costs. We prove this complexity

upper bound by exhibiting for such an MPTA $\mathcal{A}$ and target $\gamma \in \mathbb{R}^{\mathcal{Y}}_{\geq 0}$ a positive integer M, whose bit-length is polynomial in the size of $\mathcal{A}$ and γ, such that there exists a run ρ of $\mathcal{A}$ reaching the target location with $\gamma \preccurlyeq \text{cost}(\rho)$ iff there exists such a run of granularity $\frac{1}{M_1}$ for some $M_1 \leq M$. To show this we rewrite the bilinear system of inequalities (3) into an equisatisfiable disjunction of linear systems of inequalities. We thus obtain a bound on the bit-length of any satisfying assignment of (3) from which we obtain the above granularity bound. A similar bound in case of all reward variables is obtained in [10, Appendix C].

Consider an MPTA $\mathcal{A} = \langle L, \ell_0, L_f, \mathcal{X}, \mathcal{Y}, E, R\rangle$. Recall that the reachability set $\text{Reach}_{\mathcal{S}(\mathcal{A})}$ can be written as a union of linear sets $S(\boldsymbol{v}_i, P_i)$, $i \in I$. More precisely, let $M_{\mathcal{Y}}$ be the maximum rate occurring in the rate function R of the given MPTA $\mathcal{A}$. We then have the following, see [10, Appendix B.4] for the proof.

▶ **Proposition 10.** *The set* $\text{Reach}_{\mathcal{S}(\mathcal{A})}$ *can be written as a finite union of linear sets* $\bigcup_{i\in I} S(\boldsymbol{v}_i, P_i)$ *such that for each* $i \in I$ *the base vectors* $\boldsymbol{v}_i$ *and period vectors in* P_i *have entries of magnitude bounded by* $\text{poly}(d, |L|, M_{\mathcal{Y}}, M_{\mathcal{X}})^{d(d+1)|\mathcal{X}|}$.

Suppose that the set of observers $\mathcal{Y}$ with $|\mathcal{Y}| = d$ is comprised exclusively of cost variables. We will apply Proposition 10 to analyse the Pareto Domination Problem. The key observation is that in this case we can equivalently rewrite the bilinear system (3) as a disjunction of linear systems of inequalities.

As a first step we can rewrite the constraint $(\gamma_1, \ldots, \gamma_{d+1}) \in \text{Reach}_{\mathcal{S}(\mathcal{A})}$ in (3) as a disjunction of constraints $(\gamma_1, \ldots, \gamma_{d+1}) \in S(\boldsymbol{v}_i, P_i)$, for $i \in I$. But since the period vectors in P_i are non-negative we can further observe that in order to satisfy the upper bound constraints on cost variables, the optimal choice of $(\gamma_1, \ldots, \gamma_{d+1}) \in S(\boldsymbol{v}_i, P_i)$ is the base vector $\boldsymbol{v}_i$. Thus we can treat $\gamma_1, \ldots, \gamma_{d+1}$ as a constant in (3).

Thus we rewrite (3) as a finite disjunction of systems of linear inequalities—one such system for each $i \in I$. For a given $i \in I$ let $\boldsymbol{v}_i = (\gamma_1^{(i)}, \ldots, \gamma_{d+1}^{(i)})$ be the base vector of the linear set $S(\boldsymbol{v}_i, P_i)$. The corresponding system of inequalities specialising (3) is

$$\gamma \preccurlyeq \lambda_1\gamma_1^{(i)} + \ldots + \lambda_{d+1}\gamma_{d+1}^{(i)},\ 1 = \lambda_1 + \cdots + \lambda_{d+1},\ 0 \leq \lambda_1, \ldots, \lambda_{d+1} \tag{4}$$

Recall that if a set of linear inequalities $A\boldsymbol{x} \geq \boldsymbol{a}$, $B\boldsymbol{x} > \boldsymbol{b}$ is feasible then it is satisfied by some $\boldsymbol{x} \in \mathbb{Q}^n$ of bit-length $\text{poly}(n, b)$, where b is the total bit-length of the entries of A, B, $\boldsymbol{a}$, and $\boldsymbol{b}$. Applying this bound and Proposition 10 we see that a solution of (4) can be written in the form $\lambda_1 = \frac{p_1}{g}, \ldots, \lambda_{d+1} = \frac{p_{d+1}}{g}$ for integers $p_1, \ldots, p_{d+1}, g$ of bit-length at most $\text{poly}(d, |\mathcal{X}|, |L|, \log(M_{\mathcal{Y}}), \log(M_{\mathcal{X}}))$. This entails that the cost vector $\lambda_1\gamma_1^{(i)} + \ldots + \lambda_{d+1}\gamma_{d+1}^{(i)}$ arises from a run of $\mathcal{A}$ with granularity $\frac{1}{g}$, thus indirectly addressing the open problem stated in [17, Section 8] on the granularity of optimal runs in MPTA.

Together with Proposition 10, this yields PSPACE-membership for the Pareto Domination Problem. As reachability in timed automata is already PSPACE-hard [1] we have:

▶ **Theorem 11.** *The Pareto Domination Problem with pure constraints is PSPACE-complete.*

7 Pareto Domination Problem with Three Mixed Observers

In this section we consider the Pareto Domination Problem for MPTA with three observers. In the case of three cost variables or three reward variables the results of Section 6 apply. Below we show decidability for two cost variables and one reward variable. The similar case of two reward variables and one cost variable is handled in [10, Appendix E].

Consider an instance of the Pareto Domination Problem given by an MPTA $\mathcal{A}$ with $|\mathcal{Y}| = 3$ observers, and a target vector $\gamma \in \mathbb{R}^{\mathcal{Y}}_{\geq 0}$. Our starting point is again Proposition 9. To apply

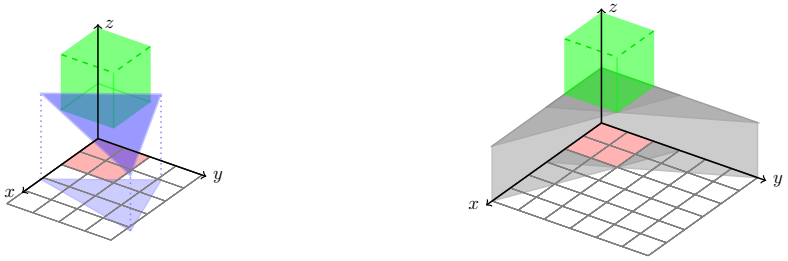


Figure 3 The target T is the green rectangular region and the blue region is S. The pink region is $\pi(T)$ and the light blue region $\pi(S)$. The grey region F is described in equation (5).

this proposition the idea is to eliminate the quantifiers over the real variables (the λ_i) in the system of equations (3) and thereby obtain a formula that lies in a decidable fragment of arithmetic (namely disjunctions of constraints of the form considered in Theorem 1).

To explain this quantifier-elimination step in more detail, let us identify $\mathbb{R}^{\mathcal{Y}}_{\geq 0}$ with $\mathbb{R}^3_{\geq 0}$. Denote by $T \subseteq \mathbb{R}^3_{\geq 0}$ the set of valuations that dominate a given fixed valuation $\gamma \in \mathbb{R}^3_{\geq 0}$. We can write $T = \{(x, y, z) \in \mathbb{R}^3_{\geq 0} : x \leq a \wedge y \leq b \wedge z \geq c\}$, where a, b, c are non-negative integer constants (see the left-hand side of Figure 3). We seek a quantifier-free formula of arithmetic that expresses that T meets a 4-simplex $S \subseteq \mathbb{R}^3_{\geq 0}$ given by the convex hull of $\{\gamma_1, \ldots, \gamma_4\}$, where $(\gamma_1, \ldots, \gamma_4) \in \mathrm{Reach}_{S(\mathcal{A})}$. However, since T is unbounded, it is clear that T meets a given 4-simplex S just in case it meets a face of S (which is a 3-simplex). Thus it will suffice to write a quantifier-free formula of arithmetic φ_T expressing that a 3-simplex in $\mathbb{R}^3_{\geq 0}$ meets T. Such a formula has nine free variables—one for each of the coordinates of the three vertices of S. We describe φ_T in the remainder of this section.

It is geometrically clear that S intersects T iff either S lies inside T, the boundary of S meets T, or the boundary of T meets S. More specifically we have the following proposition, whose proof is given in [10, Appendix B.5].

▶ **Proposition 12.** *Let $S \subseteq \mathbb{R}^3_{\geq 0}$ be a 3-simplex. Then $T \cap S$ is nonempty if and only if at least one of the following holds: (a) Some vertex of S lies in T; (b) Some bounding edge of S intersects either the face of T supported by the plane $x = a$ or the face of T supported by the plane $y = b$; (c) The bounding edge of T supported by the line $x = a \cap y = b$ intersects S.*

The following definition and proposition are key to expressing intersections of the form identified in Case (c) of Proposition 12 in terms of quadratic constraints. The idea is to identify a bounded region $F \subseteq \mathbb{R}^3_{\geq 0}$ such that in Case (c) one of the vertices of S lies in F. The proof of Proposition 13 can be found in [10, Appendix B.6].

Define a region $F \subseteq \mathbb{R}^3_{\geq 0}$ (depicted as the grey-shaded region on the right of Figure 3) by:

$$F = \{(x, y, z) \in \mathbb{R}^3_{\geq 0} \mid z < c \wedge (x + ay \leq a(b+1) \vee y + bx \leq b(a+1))\}. \tag{5}$$

Then we have:

▶ **Proposition 13.** *Let $S \subseteq \mathbb{R}^3_{\geq 0}$ be a 3-simplex such that $S \cap T$ is non-empty but none of the bounding edges of S meets T. Then some vertex of S lies in F.*

Denote by $\pi : \mathbb{R}^3 \to \mathbb{R}^2$ the projection of $\mathbb{R}^3$ onto the xy-plane, where $\pi(x, y, z) = (x, y)$ for all $x, y, z \in \mathbb{R}$. Write $\pi(T)$ and $\pi(S)$ for the respective images of T and S under π.

We write separate formulas $\varphi_T^{(1)}, \varphi_T^{(2)}, \varphi_T^{(3)}$, respectively expressing the three necessary and sufficient conditions for $T \cap S$ to be nonempty, as identified in Proposition 12. These are formulas of arithmetic whose free variables denote the coordinates of the three vertices of S.

Figure 4 Two cases for expressing that $\boldsymbol{c} \in \pi(S)$. The grey region is $\pi(F)$.

Some vertex of S lies in T. Denote the vertices of S by $\boldsymbol{p}, \boldsymbol{q}, \boldsymbol{r}$. Formula $\varphi_T^{(1)}$ expresses that $\boldsymbol{p} \in T$ or $\boldsymbol{q} \in T$ or $\boldsymbol{r} \in T$. This is clearly a formula of linear arithmetic.

Some bounding edge of S meets a face of T. It is straightforward to obtain $\varphi_T^{(2)}$ given a formula ψ expressing that an arbitrary line segment $\boldsymbol{xy}$ in $\mathbb{R}^3_{\geq 0}$ meets a given fixed face of T. We outline such a formula in the rest of this sub-section. For concreteness we consider the face of T supported by the plane $x = a$, which maps under π to the line segment $L = \{(a, y) : 0 \leq y \leq b\}$. Formula ψ has six free variables, respectively denoting the coordinates of $\boldsymbol{x} = (x_1, x_2, x_3)$ and $\boldsymbol{y} = (y_1, y_2, y_3)$.

Formula ψ is a conjunction of two parts. The first part expresses that $\pi(\boldsymbol{x})\pi(\boldsymbol{y})$ meets L. Since the complement of $\pi(F)$ is a convex region in $\mathbb{R}^2_{\geq 0}$ that excludes $\pi(T)$ we have that either $\pi(\boldsymbol{x}) \in \pi(F)$ or $\pi(\boldsymbol{y}) \in \pi(F)$. Moreover since $\pi(F)$ contains finitely many integer points, we can write separate sub-formulas expressing that $\pi(\boldsymbol{x})\pi(\boldsymbol{y})$ meets L for each fixed value of $\pi(\boldsymbol{x}) \in \pi(F)$ and each fixed value of $\pi(\boldsymbol{y}) \in \pi(F)$. Each of these sub-formulas can then be written in linear arithmetic [10, Appendix D].

Suppose now that $\pi(\boldsymbol{x})\pi(\boldsymbol{y})$ meets L. Then the line $\boldsymbol{xy}$ meets the face of T supported by the plane $x = a$ iff the line in xz-plane connecting (x_1, x_3) and (y_1, y_3) passes above (a, c). This requirement is expressed by the quadratic constraint (8) in [10, Appendix D].

A bounding edge of T meets S. We proceed to describe the formula $\varphi_T^{(3)}$ expressing that the bounding edge E of T, supported by the line $x = a \cap y = b$, meets S. Note that image of E under the projection π is the single point $\boldsymbol{c} = (a, b)$. Thus E meets S just in case $\boldsymbol{c} \in \pi(S)$ and the point (a, b, c) lies below the plane affinely spanned by S. We describe two formulas that respectively express these requirements.

Denote the vertices of S by $\boldsymbol{p}$, $\boldsymbol{q}$, and $\boldsymbol{r}$. We first give a formula of linear arithmetic expressing that $\boldsymbol{c} \in \pi(S)$. Notice that if $\boldsymbol{c} \in \pi(S)$ then at least one vertex of $\pi(S)$ must lie in $\pi(F)$. We now consider two cases. The first case is that exactly one vertex of $\pi(S)$ (say $\pi(\boldsymbol{p})$) lies in $\pi(F)$. The second case is that at least two vertices of of $\pi(S)$ (say $\pi(\boldsymbol{p})$ and $\pi(\boldsymbol{q})$) lie in $\pi(F)$. The two cases are respectively denoted in Figure 4, that we refer to in the following.

In the first case we can express that $\boldsymbol{c} \in \pi(S)$ by requiring that the line segment $\pi(\boldsymbol{p})\pi(\boldsymbol{q})$ crosses the edge $\boldsymbol{f}_2\boldsymbol{c}$ and $\pi(\boldsymbol{p})\pi(\boldsymbol{r})$ crosses the edge $\boldsymbol{f}_1\boldsymbol{c}$. By writing a separate constraint for each fixed value of $\pi(\boldsymbol{p}) \in \pi(F)$ the above requirements can be expressed in linear arithmetic.

In the second case we can express that $\boldsymbol{c} \in \pi(S)$ by requiring that $\boldsymbol{c}$ lies on the left of each of the directed line segments $\pi(\boldsymbol{p})\pi(\boldsymbol{q})$, $\pi(\boldsymbol{q})\pi(\boldsymbol{r})$, and $\pi(\boldsymbol{r})\pi(\boldsymbol{p})$. By writing such a constraint for each fixed value of $\pi(\boldsymbol{p})$ and $\pi(\boldsymbol{q})$ in $\pi(F)$ we obtain, again, a formula of linear arithmetic [10, Appendix D].

It remains to give a formula expressing that (a, b, c) lies below the plane affinely spanned by $\boldsymbol{p}$, $\boldsymbol{q}$, and $\boldsymbol{r}$ under the assumption that $\boldsymbol{c} \in \pi(S)$. Note here that the above-described

formula expressing that $\pi(\boldsymbol{c}) \in \pi(S)$ specifies *inter alia* that $\pi(\boldsymbol{p})$, $\pi(\boldsymbol{q})$, and $\pi(\boldsymbol{r})$ are oriented counter-clockwise. Thus (a, b, c) lies below the plane affinely spanned by $\boldsymbol{p}$, $\boldsymbol{q}$, and $\boldsymbol{r}$ iff

$$\begin{vmatrix} q_1 - p_1 & r_1 - p_1 & a - p_1 \\ q_2 - p_2 & r_2 - p_2 & b - p_2 \\ q_3 - p_3 & r_3 - p_3 & c - p_3 \end{vmatrix} < 0$$

The above expression is cubic, but by Proposition 13 we may assume that $\boldsymbol{p}$ lies in the set F, which has finitely many integer points. Thus by a case analysis we may regard $\boldsymbol{p}$ as being fixed and so write the desired formula as a disjunction of atoms, each with a single quadratic term, whose satisfiability is known to be decidable from Theorem 1. This leads us to:

▶ **Theorem 14.** *The Pareto Domination Problem is decidable for at most three observers.*

Theorem 14 was proven by reduction to satisfiability of a system of arithmetic constraints with a *single* quadratic term. For the case of four observers this technique does not appear to yield arithmetic constraints in a known decidable class. Note that satisfiability of systems of constraints featuring two distinct quadratic terms is not known to be decidable in general.

In [10, Appendix F] we consider (a generalisation of) the Pareto Domination Problem for MPTA with at most two observers. In contrast to the case of three observers, we are able to show decidability for two observers by reduction to satisfiability in linear arithmetic.

8 Gap Domination Problem

In this section we give a decision procedure for the Gap Domination Problem. Given an MPTA $\mathcal{A}$, valuation $\gamma \in \mathbb{R}^{\mathcal{Y}}_{\geq 0}$, and a rational tolerance $\varepsilon > 0$, our procedure is such that

- if there is an accepting run ρ of $\mathcal{A}$ such that $\gamma \preccurlyeq_\varepsilon \mathrm{cost}(\rho)$ then we output "dominated";
- if there is no accepting run ρ of A such that $\gamma \preccurlyeq \mathrm{cost}(\rho)$ then we output "not dominated".

To do this, our approach is to find approximate solutions of the bilinear system (3) by relaxation and rounding.

Recall from Proposition 9 that (3) is satisfiable iff $\mathcal{A}$ has an accepting run ρ such that $\gamma \preccurlyeq \mathrm{cost}(\rho)$. Now we use the semi-linear decomposition of $\mathrm{Reach}_{\mathcal{S}(\mathcal{A})}$ to eliminate the constraints on integer variables from (3). In more detail, fix a decomposition of $\mathrm{Reach}_{\mathcal{S}(\mathcal{A})}$ as a union of linear sets and let $S := S(\boldsymbol{v}, P)$ be one such linear set, where $P = \{\boldsymbol{u}_1, \ldots, \boldsymbol{u}_k\}$. Then we replace the constraint $(\gamma_1, \ldots, \gamma_{d+1}) \in \mathrm{Reach}_{\mathcal{S}(\mathcal{A})}$ in (3) with

$$(\gamma_1, \ldots, \gamma_{d+1}) = \boldsymbol{v} + n_1\boldsymbol{u}_1 + \cdots + n_k\boldsymbol{u}_k\,,$$

where $n_1, \ldots, n_k$ are variables ranging over $\mathbb{N}$. We thus obtain for each choice of S a bilinear system of inequalities φ_S of the form (6), where I and J are finite sets and for each $i \in I$ and $j \in J$, it holds that f_i, g_j are linear forms (i.e., polynomials of degree one with no constant terms) with non-negative integer coefficients and c_i and d_j are rational constants.

$$\begin{array}{rcll} f_i(n_1\lambda_1, n_1\lambda_2, \ldots, n_k\lambda_{d+1}) & \leq & c_i & (i \in I) \\ g_j(n_1\lambda_1, n_1\lambda_2, \ldots, n_k\lambda_{d+1}) & \geq & d_j & (j \in J) \\ n_1, \ldots, n_k \in \mathbb{N} & & & \end{array} \qquad \begin{array}{rcl} \lambda_1, \ldots, \lambda_{d+1} & \geq & 0 \\ \lambda_1 + \cdots + \lambda_{d+1} & = & 1 \end{array} \tag{6}$$

Fix a particular system φ_S, as depicted in (6). Let μ be the maximum coefficient of the f_i, $i \in I$. Given $T \subseteq \{1, \ldots, d+1\}$, we define the following constraint ψ_T on $\lambda_1, \ldots, \lambda_{d+1}$:

$$\psi_T := \bigwedge_{i \in T} \lambda_i \leq \tfrac{\varepsilon}{(d+1)k\mu} \wedge \bigwedge_{i \notin T} \lambda_i \geq \tfrac{\varepsilon}{(d+1)k\mu}\,.$$

Intuitively, ψ_T expresses that λ_i is "small" for $i \in T$ and "large" for $i \notin T$. Given any satisfying assignment of φ_S it is clear that $\lambda_1, \ldots, \lambda_{d+1}$ must satisfy φ_T for some $T \subseteq \{1, \ldots, d+1\}$.

Now fix a set $T \subseteq \{1, \ldots, d+1\}$ and consider the satisfiability of $\varphi_S \wedge \psi_T$. If $i \notin T$ then for any term $\lambda_i n_j$ that appears in an upper-bound constraint with right-hand side c in φ_S, we must have $n_j \leq \lceil \frac{c(d+1)\mu}{\varepsilon} \rceil$ in order for the constraint to be satisfied. Thus by enumerating all values of n_j we can eliminate this variable. By doing this we may assume that in $\varphi_S \wedge \psi_T$, for any term $\lambda_i n_j$ that appears on the left-hand side of an upper-bound constraint we have $i \in T$ and hence that λ_i must be "small" in any satisfying assignment.

The next step is relaxation—try to solve $\varphi_S \wedge \psi_T$ (after the above described elimination step), letting the variables $n_1, \ldots, n_k$ range over the non-negative reals. Recall here that the existential theory of real closed fields is decidable in polynomial space. If there is no real solution of $\varphi_S \wedge \psi_T$ for any S and T then there is certainly no solution over the naturals. and we can output "not dominated". On the other hand, if there is a run ρ with $\gamma \preccurlyeq_\varepsilon \mathrm{cost}(\rho)$ then for some S and T, the system $\varphi_S \wedge \psi_T$ will have a real solution in which moreover the inequalities $f_i(n_1\lambda_1, \ldots, n_k\lambda_{d+1}) \leq c_i$ for $i \in I$ all hold with slack at least ε. Given such a solution, replace n_j with $\lceil n_j \rceil$ for $j = 1, \ldots, k$. Consider the left-hand side $f_i(n_1\lambda_1, \ldots, n_k\lambda_{d+1})$ of an upper bound constraint in φ_S. Since the variables λ_i mentioned in such a linear form are small, the effect of rounding is to increase this term by at most ε. Hence the rounded valuation still satisfies φ_S thanks to the slack in the original solution. This then leads to Theorem 15 below:

▶ **Theorem 15.** *The Gap Domination Problem is decidable.*

Abstract

The notion of bounded expansion captures uniform sparsity of graph classes and renders various algorithmic problems that are hard in general tractable. In particular, the model-checking problem for first-order logic is fixed-parameter tractable over such graph classes. With the aim of generalizing such results to dense graphs, we introduce classes of graphs with *structurally bounded expansion*, defined as first-order interpretations of classes of bounded expansion. As a first step towards their algorithmic treatment, we provide their characterization analogous to the characterization of classes of bounded expansion via low treedepth decompositions, replacing treedepth by its dense analogue called shrubdepth.

1 Introduction

The interplay of methods from logic and graph theory has led to many important results in theoretical computer science, notably in algorithmics and complexity theory. The combination of logic and algorithmic graph theory is particularly fruitful in the area of *algorithmic meta-theorems*. Algorithmic meta-theorems are results of the form: *every computational problem definable in a logic $\mathcal{L}$ can be solved efficiently on any class of structures satisfying a property $\mathcal{P}$*. In other words, these theorems show that the *model-checking problem* for the logic $\mathcal{L}$ on any class $\mathcal{C}$ satisfying $\mathcal{P}$ can be solved efficiently, where *efficiency* usually means *fixed-parameter tractability*.

The archetypal example of an algorithmic meta-theorem is Courcelle's theorem [1, 2], which states that model-checking a formula φ of *monadic second-order logic* can be solved in time $f(\varphi) \cdot n$ on any graph with n vertices which comes from a fixed class of graphs of *bounded treewidth*, for some computable function f. Seese [27] proved an analogue of Courcelle's result for the model-checking problem of first-order logic on any class of graphs of bounded degree. Following this result, the complexity of first-order model-checking on specific classes of graphs has been studied extensively in the literature. See e.g. [17, 7, 19, 21, 4, 9, 10, 27, 8, 22, 28, 16, 5, 6, 13, 20]. One of the main goals of this line of research is to find a structural property $\mathcal{P}$ which precisely defines those graph classes $\mathcal{C}$ for which model checking of first-order logic is tractable.

So far, research on algorithmic meta-theorems has focused predominantly on *sparse* classes of graphs, such as classes of bounded *treewidth*, *excluding a minor* or which have *bounded expansion* or are *nowhere dense*. The concepts of *bounded expansion* and *nowhere denseness* were introduced by Nešetřil and Ossona de Mendez with the goal of capturing the intuitive notion of *sparseness*. See [25] for an extensive cover of these notions. The large number of equivalent ways in which they can be defined using either notions from combinatorics, theoretical computer science or logic, indicate that these two concepts capture some very natural limits of "well-behavedness" and algorithmic tractability. For instance, Grohe et al. [19] proved that if $\mathcal{C}$ is a class of graphs closed under taking subgraphs then model checking first-order logic on $\mathcal{C}$ is tractable if, and only if, $\mathcal{C}$ is nowhere dense (the lower bound was proved in [7]). As far as algorithmic meta-theorems for fixed-parameter tractability of first-order model-checking are concerned, this result completely solves the case for graph classes which are *closed under taking subgraphs*, which is a reasonable requirement for sparse but not for dense graph classes.

Consequently, research in this area has shifted towards studying the dense case, which is much less understood. While there are several examples of algorithmic meta-theorems on dense classes, such as for monadic second-order logic on classes of bounded *cliquewidth* [3] or for first-order logic on *interval graphs*, *partial orders*, classes of bounded *shrubdepth* and other classes, see e.g. [13, 11, 14, 12], a general theory of meta-theorems for dense classes is still missing. Moreover, unlike the sparse case, there is no canonical hierarchy of dense graph classes similar to the sparse case which could guide research on algorithmic meta-theorems in the dense world.

Hence, the main research challenge for dense model-checking is not only to prove tractability results and to develop the necessary logical and algorithmic tools. It is at least as important to define and analyze promising candidates for "structurally simple" classes of graph classes which are not necessarily sparse. This is the main motivation for the research in this paper. Since bounded expansion and nowhere denseness form the limits for tractability of certain problems in the sparse case, any extension of the theory should provide notions

which collapse to bounded expansion or nowhere denseness, under the additional assumption that the classes are closed under taking subgraphs. Therefore, a natural way of seeking such notions is to base them on the existing notions of bounded expansion or nowhere denseness.

In this paper, we take bounded expansion classes as a starting point and study two different ways of generalizing them towards dense graph classes preserving their good properties. In particular, we define and analyze classes of graphs obtained from bounded expansion classes by means of first-order interpretations and classes of graphs obtained by generalizing another, more combinatorial characterization of bounded expansion in terms of low treedepth colorings into the dense world. Our main structural result shows that these two very different ways of generalizing bounded expansion into the dense setting lead to the same classes of graphs. This is explained in greater detail below.

Interpretations and transductions. One possible way of constructing "well-behaved" and "structurally simple" classes of graphs is to use logical *interpretations*, or the related concept of *transductions* studied in formal language and automata theory. For our purpose, transductions are more convenient and we will use them in this paper. Intuitively, a *transduction* is a logically defined operation I which takes a structure as input and nondeterministically produces as output a target structure. In this paper we use *first-order* transductions, which involve first-order formulas (see Section 2 for details). Two examples of such transductions are graph complementation, and the squaring operation which, given a graph G, adds an edge between every pair of vertices at distance 2 from each other.

We postulate that if we start with a "structurally simple" class $\mathcal{C}$ of graphs, e.g. a class of bounded expansion or a nowhere dense class, and then study the graph classes $\mathcal{D}$ which can be obtained from $\mathcal{C}$ by first-order transductions, then the resulting classes should still have a simple structure and thus be well-behaved algorithmically as well as in terms of logic. In other words, the resulting classes are interesting graph classes with good algorithmic and logical properties, and which are certainly not sparse in general. For instance, a useful feature of transductions is that they provide a canonical way of reducing model-checking problems from the generated classes $\mathcal{D}$ to the original class $\mathcal{C}$, provided that given a graph $H \in \mathcal{D}$, we can effectively compute some graph $G \in \mathcal{C}$ that is mapped to H by the transduction. In general, this is a hard problem, requiring a *combinatorial* understanding of the structure of the resulting classes $\mathcal{D}$.

The above principle has so far been successfully applied in the setting of graph classes of bounded treewidth and monadic second-order transductions: it was shown by Courcelle, Makowsky and Rotics [3] that transductions of classes of bounded treewidth can be combinatorially characterized as classes of bounded cliquewidth. This, combined with Oum's result [26] gives a fixed-parameter algorithm for model-checking monadic second-order logic on classes of bounded cliquewidth. More recently, the same principle, but for first-order logic, has been applied to graphs of bounded degree [12], leading to a combinatorial characterization of first-order transductions of such classes, and to a model-checking algorithm.

Applying our postulate to bounded expansion classes yields the central notion of this paper: a class of graphs has *structurally bounded expansion* if it is the image of a class of bounded expansion under some fixed first-order transduction. This paper is a step towards a combinatorial, algorithmic, and logical understanding of such graph classes.

Low Shrubdepth Covers. The method of transductions is one way of constructing complex graphs out of simple graphs. A more combinatorial approach is the method of *decompositions* (or *colorings*) [25], which we reformulate below in terms of *covers*. This method can be used

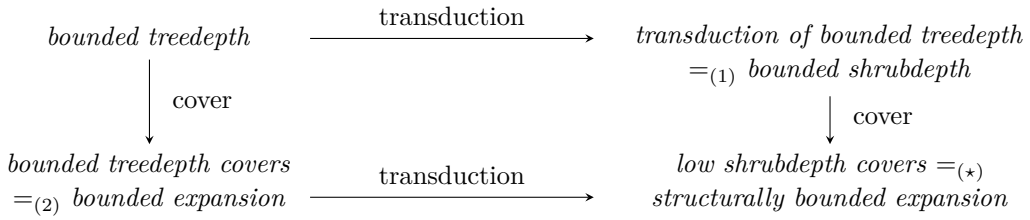

Figure 1 The nodes in the diagram depict properties of graph classes, and the arrows depict operations on properties of graph classes. Equality (1) is by [14]. Equality (2) is by [24]. Equality ($\star$) is the main result of this paper, Theorem 5.1.

to provide a characterization of bounded expansion classes in terms of very simple graph classes, namely classes of *bounded treedepth*. A class of graphs has bounded treedepth if there is a bound on the length of simple paths in the graphs in the class (see Section 2 for a different but equivalent definition). A class $\mathcal{C}$ has *low treedepth covers* if for every number $p \in \mathbb{N}$ there is a number N and a class of bounded treedepth $\mathcal{T}$ such that for every $G \in \mathcal{C}$, the vertex set $V(G)$ can be covered by N sets $U_1, \ldots, U_N$ so that every set $X \subseteq V(G)$ of at most p vertices is contained in some U_i, and for each $i = 1, \ldots, N$, the subgraph of G induced by U_i belongs to $\mathcal{T}$. A consequence of a result by Nešetřil and Ossona de Mendez [24] on a related notion of *low treedepth colorings* is that a graph class has bounded expansion if, and only if, it has low treedepth covers.

The decomposition method allows to lift algorithmic, logical, and structural properties from classes of bounded treedepth to classes of bounded expansion. For instance, this was used to show tractability of first-order model-checking on bounded expansion classes [7, 18].

An analogue of treedepth in the dense world is the concept of *shrubdepth*, introduced in [14]. Shrubdepth shares many of the good algorithmic and logical properties of treedepth. This notion is defined combinatorially, in the spirit of the definition of cliquewidth, but can be also characterized by logical means, as first-order transductions of classes of bounded treedepth. Applying the method of decompositions to the notion of shrubdepth leads to the following definition. A class $\mathcal{C}$ of graphs has *low shrubdepth covers* if for every number $p \in \mathbb{N}$ there is a number N and a class $\mathcal{B}$ of bounded shrubdepth such that for every $G \in \mathcal{C}$, there is a *p-cover* of G consisting of N sets $U_1, \ldots, U_N \subseteq V(G)$, so that every set $X \subseteq V(G)$ of at most p vertices is contained in some U_i and for each $i = 1, \ldots, N$, the subgraph of G induced by U_i belongs to $\mathcal{B}$. Shrubdepth properly generalizes treedepth and consequently classes admitting low shrubdepth covers properly extend bounded expansion classes.

It was observed earlier [23] that for every fixed $r \in \mathbb{N}$ and every class $\mathcal{C}$ of bounded expansion, the class of rth power graphs G^r of graphs from $\mathcal{C}$ (the rth power of a graph is a simple first-order transduction) admits low shrubdepth colorings.

Our contributions. Our main result, Theorem 5.1, states that the two notions introduced above are the same: a class of graphs $\mathcal{C}$ has structurally bounded expansion if, and only if, it has bounded shrubdepth covers. That is, transductions of classes of bounded expansion are the same as classes with low shrubdepth covers (cf. Figure 1). This gives a combinatorial characterization of structurally bounded expansion classes, which is an important step towards their algorithmic treatment.

One of the key ingredients of our proof is a quantifier-elimination result (Lemma 5.5) for transductions on classes of structurally bounded expansion. This result strengthens

in several ways similar results for bounded expansion classes due to Dvořák, Kráľ, and Thomas [7] and Grohe and Kreutzer [18]. Our assumption is more general, as they assume that $\mathcal{C}$ has bounded expansion, and here $\mathcal{C}$ is only required to have low shrubdepth covers. Also, our conclusion is stronger, as their results provide quantifier-free formulas involving some unary functions and unary predicates which are computable algorithmically, whereas our result shows that these functions can be defined using very restricted transductions. Quantifier-elimination results of this type proved to be useful for the model-checking problem on bounded expansion classes [7, 18], and this is also the case here.

As explained earlier, the transduction method allows to reduce the model-checking problem to the problem of finding inverse images under transductions, which is a hard problem in general and depends very much on the specific transduction. On the other hand, as we show, the cover method allows to reduce the model-checking problem for classes with low shrubdepth covers to the problem of computing a bounded shrubdepth cover of a given graph. In fact, as a consequence of our proof, in Theorem 6.1 we show that it is enough to compute a 2-cover of a given graph G from a structurally bounded expansion class, in order to obtain an algorithm for the model-checking problem for such classes. We strongly conjecture that such an algorithm exists and that therefore first-order model-checking is fixed-parameter tractable on any class of graphs of structurally bounded expansion. We leave this problem for future work.

2 Transductions

In this section, apart from recalling some background notions from logic and graph theory, we introduce the notion of transductions which we use in this paper.

Structures. We use standard logical notation and terminology with the following exceptions. A *signature* Σ is a finite set of relation and function symbols. We allow relations of any finite arity but only unary functions. We use boldface letters $\mathbf{A}$ for logical structures and denote their domains by $V(\mathbf{A})$. A structure $\mathbf{A}$ over Σ is defined as usual with the exception that each function symbol $f \in \Sigma$ is interpreted as a *partial* function $f^{\mathbf{A}} \colon V(\mathbf{A}) \rightharpoonup V(\mathbf{A})$. If $\mathbf{A}$ is a structure and $X \subseteq V(\mathbf{A})$ then we define the *substructure* of $\mathbf{A}$ induced by X in the usual way except that a unary function $f(x)$ in $\mathbf{A}$ becomes undefined on all $x \in X$ for which $f(x) \notin X$. The semantics of first-order logic is defined as usual, with the proviso that an atomic formula evaluates to false if any of the terms involved in it is undefined.

Graphs and colored graphs. We consider finite, simple and undirected graphs. These can be viewed as finite structures over the signature consisting of a binary relation symbol E, interpreted as the edge relation, in the usual way. For a finite label set Λ, by a Λ-*colored* graph we mean a graph enriched by a unary predicate U_λ for every $\lambda \in \Lambda$. We will follow the convention that if $\mathcal{C}$ is a class of colored graphs, then we implicitly assume that all graphs in $\mathcal{C}$ are over the same fixed finite signature. A rooted forest is an acyclic graph F together with a unary predicate $R \subseteq V(F)$ selecting one root in each connected component of F.

Transductions. We now define the notion of transduction used in the sequel. A *transduction* is a special type of first-order interpretation with set parameters, which we see here (from a computational point of view) as a nondeterministic operation that maps input structures to output structures. Transductions are defined as compositions of *atomic operations* listed below.

An **extension** operation is parameterized by a first-order formula $\varphi(x_1, \ldots, x_k)$ and a relation symbol R. Given an input structure $\mathbf{A}$, it outputs the structure $\mathbf{A}$ extended by the relation R interpreted as the set of k-tuples of elements satisfying φ in $\mathbf{A}$. A **restriction** operation is parameterized by a unary formula $\psi(x)$. Applied to a structure $\mathbf{A}$ it outputs the substructure of $\mathbf{A}$ induced by all elements satisfying ψ. A **reduct** operation is parameterized by a relation symbol R, and results in removing the relation R from the input structure. **Copying** is an operation which, given a structure $\mathbf{A}$ outputs a disjoint union of two copies of $\mathbf{A}$ extended with a new unary function which maps both copies of a vertex v back to v. A **function extension** operation is parameterized by a binary formula $\varphi(x, y)$ and a function symbol f, and extends a given input structure by a partial function f defined as follows: $f(x) = y$ if y is the unique vertex such that $\varphi(x, y)$ holds. Note that if there is no such y or more than one such y, then $f(x)$ is undefined. Finally, suppose σ is function that maps each structure $\mathbf{A}$ to a nonempty family $\sigma(\mathbf{A})$ of subsets of its universe. A **unary lift** operation, parametrized by σ, takes as input a structure $\mathbf{A}$ and outputs the structure $\mathbf{A}$ enriched by a unary predicate X interpreted by a nondeterministically chosen set $U \in \sigma(\mathbf{A})$.

We remark that a function extension operations can be simulated by extension operations, defining the graphs of the functions in the obvious way. They are, however, useful as a means of extending the expressive power of transductions in which only quantifier-free formulas are allowed, as defined below.

▶ **Definition 2.1.** *Transductions* are defined inductively: every atomic transduction is a transduction, and the composition of two transductions I and J is the transduction $\mathsf{I};\mathsf{J}$ that, given a structure $\mathbf{A}$, first applies J to $\mathbf{A}$ and then I to the output $\mathsf{J}(\mathbf{A})$. A transduction is *deterministic* if it does not use unary lifts. In this case, for every input structure there is exactly one output structure. A transduction is *almost quantifier-free* if all formulas that parameterize atomic operations comprising it are quantifier-free (observe that such transductions still can access elements that are not among its free variables via functions, hence, to avoid confusion we do not speak of quantifier-free transductions), and is *deterministic almost quantifier-free* if it additionally does not use unary lifts.

If $\mathcal{C}$ is a class of structures, we write $\mathsf{I}(\mathcal{C})$ for the class which contains all possible outputs $\mathsf{I}(\mathbf{A})$ for $\mathbf{A} \in \mathcal{C}$. We say that two transductions I and J are *equivalent* on a class $\mathcal{C}$ of structures if every possible output of $\mathsf{I}(\mathbf{A})$ is also a possible output of $\mathsf{J}(\mathbf{A})$, and vice versa, for every $\mathbf{A} \in \mathcal{C}$.

▶ **Example 2.2.** Let $\mathcal{C}$ be the class of rooted forests of depth at most d, for some fixed $d \in \mathbb{N}$. We describe an almost quantifier-free transduction which defines the *parent function* in $\mathcal{C}$. First, using unary lifts introduce $d+1$ unary predicates $D_0, ..., D_d$, where D_i marks the vertices of the input tree which are at distance i from a root. Next, using a function extension, define a function f which maps a vertex v in the input tree to its parent, or is undefined in case of a root. This can be done by a quantifier-free formula, which selects those pairs x, y such that x and y are adjacent and $D_i(x)$ implies $D_{i-1}(y)$.

It will sometimes be convenient to work with the encoding of bounded-depth trees and forests as node sets endowed with the parent function, rather than graphs with prescribed roots. As seen in Example 2.2, these two encodings can be translated to each other by means of almost quantifier-free transductions, which render them essentially equivalent.

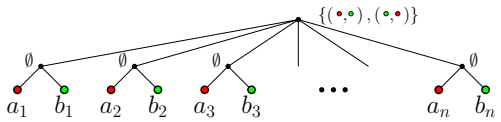
3 Treedepth, shrubdepth and bounded expansion

Treedepth. The *depth* of a node x in a rooted forest F is the number of edges on the root-to-x path in F. The *depth* of F is the maximal depth of any of its nodes. The *treedepth* of a graph G is the minimal depth of a rooted forest F with the same vertex set as G, such that for every edge vw of G, v is an ancestor of w, or w is an ancestor of v in F. A class $\mathcal{C}$ of graphs has *bounded treedepth* if there is a bound $d \in \mathbb{N}$ such that every graph in $\mathcal{C}$ has treedepth at most d. Equivalently, there is some number k such that no graph in $\mathcal{C}$ has a simple path of length k [25].

Shrubdepth. The following notion of *shrubdepth* has been proposed in [14] as a dense analogue of treedepth. Originally, shrubdepth was defined using the notion of *tree-models*. We present an equivalent definition based on the notion of *connection models*, introduced in [14] under the name of *m-partite cographs* of bounded depth.

▶ **Definition 3.1.** A *connection model* with labels from Λ is a rooted labeled tree T in which every leaf x is assigned a label $\lambda(x) \in \Lambda$, and every non-leaf node v is labeled by a (symmetric) binary relation $C(v) \subseteq \Lambda \times \Lambda$. Such a model defines a graph G on the leaves of T, in which two distinct leaves x and y are connected by an edge if and only if $(\lambda(x), \lambda(y)) \in C(v)$, where v is the common ancestor of x and y of largest depth. We say that T is a *connection model* of the resulting graph G.

▶ **Example 3.2.** Fix $n \in \mathbb{N}$, and let G_n be the bi-complement of a matching of order n, i.e., the bipartite graph with nodes $a_1, \ldots, a_n$ and $b_1, \ldots, b_n$, such that a_i is adjacent to b_j if, and only if, $i \neq j$. A connection model for G_n is shown below:



▶ **Definition 3.3.** A class $\mathcal{C}$ of graphs has *bounded shrubdepth* if there is an $h \in \mathbb{N}$ and a finite set Λ such that every $G \in \mathcal{C}$ has a connection model of depth at most h using labels from Λ. A class of colored graphs has bounded shrubdepth if the class of underlying graphs has bounded shrubdepth.

Note that contrary to other graph parameters, it is meaningless to speak about the shrubdepth of a single graph. Rather, shrubdepth measures directly the complexity of a class.

Shrubdepth can be equivalently defined in terms of another graph parameter, as follows.

▶ **Definition 3.4.** Given a graph G and a set of vertices $W \subseteq V(G)$, the graph obtained by *flipping the adjacency within* W is the graph G' with vertices $V(G)$ and edge set which is the symmetric difference of the edge set of G and the edge set of the clique on W. The *subset-complementation depth*, or *SC-depth*, of a graph is defined inductively as follows: (1) a graph with one vertex has SC-depth 0, and (2) for $d \geqslant 1$ a graph G has SC-depth at most d if there is a set $W \subseteq V(G)$ of vertices such that in the graph obtained from G by flipping the adjacency within W all connected components have SC-depth at most $d-1$.

The notion of SC-depth leads to a natural notion of decompositions. An *SC-decomposition* of a graph G of SC-depth at most d is a rooted tree T of depth d with leaf set $V(G)$, equipped with unary predicates $W_0, \ldots, W_d$ on the leaves. Each child s of the root in T corresponds to a connected component C_s of the graph G' obtained from G by flipping the adjacency within W_0, such that the subtree of T rooted at s, together with the unary predicates $W_1, \ldots, W_d$ restricted to $V(C_s)$, form an SC-decomposition of C_s.

We will make use of the following properties, where the first one follows from the definition of shrubdepth, and the remaining ones follow from [14].

▶ **Proposition 3.5.** *Let $\mathcal{C}$ be a class of graphs. Then:*

1. *If $\mathcal{C}$ has bounded shrubdepth, then the class of all induced subgraphs of graphs from $\mathcal{C}$ also has bounded shrubdepth.*
2. *$\mathcal{C}$ has bounded shrubdepth if and only if for some $d \in \mathbb{N}$ all graphs in $\mathcal{C}$ have SC-depth at most d.*
3. *If $\mathcal{C}$ has bounded treedepth, then $\mathcal{C}$ has bounded shrubdepth.*
4. *If $\mathcal{C}$ has bounded shrubdepth and I is a transduction that outputs colored graphs, then $\mathsf{I}(\mathcal{C})$ has bounded shrubdepth.*

Bounded expansion. A graph H is a *depth-r minor* of a graph G if H can be obtained from a subgraph of G by contracting mutually disjoint connected subgraphs of radius at most r. A class $\mathcal{C}$ of graphs has *bounded expansion* if there is a function $f : \mathbb{N} \to \mathbb{N}$ such that $\frac{|E(H)|}{|V(H)|} \leqslant f(r)$ for every $r \in \mathbb{N}$ and every depth-r minor H of a graph from $\mathcal{C}$. Examples include the class of planar graphs, or any class of graphs with bounded maximum degree.

The connection between treedepth and graph classes of bounded expansion can be established via *treedepth-p colorings*. For an integer p, a function $c : V(G) \to C$ is a treedepth-p coloring if, for every $i \leqslant p$ and set $X \subseteq V(G)$ with $|c(X)| = i$, the induced graph $G[X]$ has treedepth at most i. A graph class $\mathcal{C}$ has *low treedepth colorings* if for every $p \in \mathbb{N}$ there is a number N_p such that for every $G \in \mathcal{C}$ there exists a treedepth-p coloring $c\colon V(G) \to C$ with $|C| \leqslant N_p$.

▶ **Theorem 3.6** ([24])**.** *A class $\mathcal{C}$ of graphs has bounded expansion if, and only if, it has low treedepth colorings.*

4 Structurally bounded expansion and low shrubdepth covers

In this section we introduce two notions which generalize the concept of bounded expansion. First, we introduce classes of *structurally bounded expansion*. This notion arises from closing bounded expansion graph classes under transductions.

▶ **Definition 4.1.** A class $\mathcal{C}$ of graphs has *structurally bounded expansion* if there exists a class of graphs $\mathcal{D}$ of bounded expansion and a transduction I such that $\mathcal{C} \subseteq \mathsf{I}(\mathcal{D})$.

The second notion, *low shrubdepth covers*, arises from the low treedepth coloring characterization of bounded expansion (see Theorem 3.6) by replacing treedepth by its dense counterpart, shrubdepth. For convenience, we formally define this in terms of *covers*.

▶ **Definition 4.2.** A *cover* of a graph G is a family $\mathcal{U}_G$ of subsets of $V(G)$ such that $\bigcup \mathcal{U}_G = V(G)$. A cover $\mathcal{U}_G$ is a *p-cover*, where $p \in \mathbb{N}$, if every set of at most p vertices is contained in some $U \in \mathcal{U}_G$. If $\mathcal{C}$ is a class of graphs, then a (p-)cover of $\mathcal{C}$ is a family $\mathcal{U} = (\mathcal{U}_G)_{G \in \mathcal{C}}$, where $\mathcal{U}_G$ is a (p-)cover of G. The cover $\mathcal{U}$ is *finite* if $\sup\{|\mathcal{U}_G| \colon G \in \mathcal{C}\}$ is finite. Let $\mathcal{C}[\mathcal{U}]$ denote the class of graphs $\{G[U] \colon G \in \mathcal{C}, U \in \mathcal{U}_G\}$. We say that the cover $\mathcal{U}$ has *bounded treedepth* (respectively, bounded shrubdepth) if the class $\mathcal{C}[\mathcal{U}]$ has bounded treedepth (respectively, shrubdepth).

▶ **Example 4.3.** Let $\mathcal{T}$ be the class of trees and $p \in \mathbb{N}$ be a number. We construct a finite p-cover $\mathcal{U}$ of $\mathcal{T}$ which has bounded treedepth. Given a rooted tree T, let $\mathcal{U}_T = \{U_0, \ldots, U_p\}$, where U_i is the set of vertices of T whose depth is not congruent to i modulo $p+1$. Note that $T[U_i]$ is a forest of height p, and that $\mathcal{U}_T$ is a p-cover of T. Hence $\mathcal{U} = (\mathcal{U}_T)_{T \in \mathcal{T}}$ is a finite p-cover of $\mathcal{T}$ of bounded treedepth.

In analogy to low treedepth colorings, we can now characterize graph classes of bounded expansion using covers. We say that a class $\mathcal{C}$ of graphs has *low treedepth covers* if for every $p \in \mathbb{N}$ there is a finite p-cover $\mathcal{U}$ of $\mathcal{C}$ with bounded treedepth. The following lemma follows easily from Theorem 3.6.

▶ **Lemma 4.4.** *A class of graphs has bounded expansion if, and only if, it has low treedepth covers.*

We now define the second notion generalizing the concept of bounded expansion. The idea is to use low shrubdepth covers instead of low treedepth covers.

▶ **Definition 4.5.** A class $\mathcal{C}$ of structures has *low shrubdepth covers* if, and only if, for every $p \in \mathbb{N}$ there is a finite p-cover $\mathcal{U}$ of $\mathcal{C}$ with bounded shrubdepth.

It is easily seen that Lemma 4.4 together with Proposition 3.5 (3) imply that every class of bounded expansion has low shrubdepth covers.

5 Main Result

The main result of our paper is the followiong.

▶ **Theorem 5.1.** *A class of graphs has structurally bounded expansion if, and only if, it has low shrubdepth covers.*

We prove the left-to-right direction of Theorem 5.1 in Section 5.1 and the right-to-left direction in Section 5.2. But before we need some lemmas on classes of bounded shrubdepth.

The first lemma is an analogue of a known fact that every class of bounded cliquewidth which excludes a fixed bi-clique as a subgraph has bounded treewidth. The lemma is proved by an easy induction on the depth of the connection models.

▶ **Lemma 5.2.** *A class $\mathcal{C}$ of graphs has bounded treedepth if, and only if, $\mathcal{C}$ has bounded shrubdepth and all $G \in \mathcal{C}$ exclude some fixed bi-clique as a subgraph.*

The second lemma, Lemma 5.3 below, is substantially more involved, and is the combinatorial cornerstone of our approach. Essentially, it says that if $\mathcal{C}$ is a class of bounded shrubdepth, then a bounded-depth SC-decomposition of a graph $G \in \mathcal{C}$ can be computed using an *almost quantifier-free* transduction B. In other words, an SC-decomposition of a graph $G \in \mathcal{C}$ can be encoded in G using a finite number of unary predicates and reconstructed using function extension operations involving deterministic almost quantifier-free formulas.

▶ **Lemma 5.3.** *Let $\mathcal{B}$ be a class of graphs of bounded shrubdepth. Then there is a class $\mathcal{T}$ of colored trees of bounded height and a pair of transductions T and B such that T is almost quantifier-free, B is deterministic almost quantifier-free, $\mathsf{T}(\mathcal{B}) \subseteq \mathcal{T}$, $\mathsf{B}(\mathcal{T}) \subseteq \mathcal{B}$, and*

$$\mathsf{B}(\mathsf{T}(G)) = \{G\} \quad \text{for all} \quad G \in \mathcal{B} \quad \text{and} \quad \mathsf{T}(\mathsf{B}(t)) \ni t \quad \text{for all} \quad t \in \mathcal{T}.$$

Moreover, for any $G \in \mathcal{B}$, every $t \in \mathsf{T}(G)$ is an SC-decomposition of G.

The key ingredient in the proof of Lemma 5.3 is that we can provide an almost quantifier-free transduction that defines connected components in graphs of bounded shrubdepth, as formulated in the following lemma.

▶ **Lemma 5.4.** *Let $\mathcal{C}$ be a class of graphs of bounded shrubdepth. There is an almost quantifier-free transduction F such that for a given $G \in \mathcal{C}$, every output of F on G is equal to G enriched by a function $g\colon V(G) \to V(G)$ such that $g(v) = g(w)$ if, and only if, v and w are in the same connected component of G.*

In the proof of Lemma 5.4 we use the fact that bounded shrubdepth implies bounded diameter [14], and the connection between bounded shrubdepth and (bi-)cographs [15].

5.1 Structurally bounded expansion implies low shrubdepth covers

The left-to-right implication of Theorem 5.1 – that every graph class with structurally bounded expansion has low shrub-depth covers – follows from the two lemmas below, whose proofs are outlined later in this section.

▶ **Lemma 5.5.** *Let $\mathcal{C}$ be a class of colored graphs which has low shrubdepth covers. Then every transduction I is equivalent on $\mathcal{C}$ to an almost quantifier-free transduction J.*

▶ **Lemma 5.6.** *If a class of graphs $\mathcal{C}$ has low shrubdepth covers and J is an almost quantifier-free transduction which outputs graphs, then $\mathsf{J}(\mathcal{C})$ also has low shrubdepth covers.*

We first show how to conclude the left-to-right implication of Theorem 5.1 from Lemma 5.5 and Lemma 5.6. Let $\mathcal{C}$ be a class of bounded expansion and I be a transduction which outputs graphs. By Lemma 4.4, $\mathcal{C}$ has low treedepth covers and hence, by Lemma 3.5, also has low shrubdepth covers. Applying Lemma 5.5, we obtain an almost quantifier-free transduction J such that $\mathsf{I}(\mathcal{C}) = \mathsf{J}(\mathcal{C})$. By Lemma 5.6, we deduce that $\mathsf{J}(\mathcal{C}) = \mathsf{I}(\mathcal{C})$ has low shrubdepth covers, proving the left-to-right implication of Theorem 5.1.

In the remainder of this section we sketch the proofs of Lemma 5.5 and Lemma 5.6.

Proof outline for Lemma 5.5. Our proof of Lemma 5.5 is a quantifier elimination procedure similar to that of Dvořák et al. [7] and Grohe and Kreutzer [18]. First, we prove the statement for classes of colored trees of bounded depth, just as in [7, 18]. Lemma 5.3 allows us to immediately lift the statement to classes of bounded shrubdepth. Finally, this is lifted to classes with low shrubdepth covers. ◀

Proof outline for Lemma 5.6. To prove the lemma, we first observe that every almost quantifier-free transduction is equivalent to a transduction which consists of a sequence of unary lifts followed by a deterministic almost quantifier-free transduction. Since, by Proposition 3.5, adding colors (the result of applying unary lifts) to a graph class of bounded shrubdepth will again result in a graph class of bounded shrubdepth, it suffices to prove the lemma for a deterministic almost quantifier-free transduction and a class of colored graphs $\mathcal{C}$.

Consider a p-cover $\mathcal{U}$ of $\mathcal{C}$ of bounded shrubdepth. As a very special case, suppose that I is a single quantifier-free extension operation that does not use any functions in the formula governing it. Then $\mathsf{I}(G[W]) = \mathsf{I}(G)[W]$ for $G \in \mathcal{C}$ and any $W \subseteq V(G)$. As a consequence, $\mathcal{U}_G$ is a p-cover of $\mathsf{I}(G)$ and hence $\mathsf{I}(\mathcal{C}[\mathcal{U}]) = \mathsf{I}(\mathcal{C})[\mathcal{U}]$ is a p-cover of $\mathsf{I}(\mathcal{C})$. Moreover, by Proposition 3.5, $\mathsf{I}(\mathcal{C})[\mathcal{U}]$ has bounded shrubdepth, so $\mathcal{U}$ is a finite cover of $\mathcal{C}$ of bounded shrubdepth. As p is arbitrary, this proves that $\mathsf{I}(\mathcal{C})$ has bounded shrubdepth covers.

For a general deterministic almost quantifier-free transduction I, the equality $\mathsf{I}(G[W]) = \mathsf{I}(G)[W]$ may fail, due to the fact that I may involve functions which reach outside of W. However, the value of any term involved in I depends only on a bounded number of vertices of G. This leads to the following lemma.

▶ **Lemma 5.7.** *For every deterministic almost quantifier-free transduction I there is a number c such that the following holds. For every graph G and vertex v of $\mathsf{I}(G)$ there is a set $S_v \subseteq V(G)$ of size at most c such that for any sets U, W with $W \subseteq V(\mathsf{I}(G))$ and $U \subseteq V(G)$, if $U \supseteq \bigcup_{v \in W} S_v$, then*

$$\mathsf{I}(G)[W] = \mathsf{I}(G[U])[W].$$

We now proceed to the general case. Choose any $p \in \mathbb{N}$. Let c be as in Lemma 5.7. Let $\mathcal{U}$ be a finite $(p \cdot c)$-cover of $\mathcal{U}$ of bounded shrubdepth. For a graph $G \in \mathcal{C}$ and a set $U \in \mathcal{U}_G$, define $W_U \subseteq \mathsf{I}(G)$ as the set of all vertices $v \in \mathsf{I}(G)$ such that $S_v \subseteq U$, where S_v is as in Lemma 5.7. From the lemma and the fact that classes of bounded shrubdepth are closed under transductions and induced subgraphs it follows easily that letting $\mathcal{W}_{\mathsf{I}(G)} = \{W_U : U \in \mathcal{U}_G\}$ yields a p-cover of $\mathsf{I}(G)$, which collectively, for all $G \in \mathcal{C}$, form a p-cover of $\mathsf{I}(\mathcal{C})$ which has bounded shrubdepth. Since p is arbitrary, this proves the lemma. ◀

5.2 Low shrubdepth covers imply structurally bounded expansion

For the right-to-left implication of Theorem 5.1, we prove the following statement.

▶ **Lemma 5.8.** *Let $\mathcal{C}$ be a class of graphs with low shrubdepth covers. There is a pair of transductions S and I, where S is almost quantifier-free and I is deterministic almost quantifier-free, such that $\mathsf{S}(\mathcal{C})$ is a class of colored graphs of bounded expansion and $\mathsf{I}(\mathsf{S}(G)) = \{G\}$ for each $G \in \mathcal{C}$.*

Clearly, the lemma implies that $\mathcal{C}$ has structurally bounded expansion, since it can be obtained as a result of a transduction I to a class $\mathsf{S}(\mathcal{C})$ of bounded expansion. Thus, the right-to-left implication of Theorem 5.1 is a consequence of the lemma.

Proof outline. Let $\mathcal{U}$ be a finite 2-cover of $\mathcal{C}$, and let $N = \sup\{|\mathcal{U}_G| : G \in \mathcal{C}\}$. We define a transduction S as follows. For a given $G \in \mathcal{C}$, let $\{U_1, \ldots, U_N\} = \mathcal{U}_G$. Given G, the transduction S introduces unary predicates $U_1, \ldots, U_N$, and then, using the transduction T from Lemma 5.3, computes the union $\bigcup_{i=1}^{N} \mathsf{T}(G[U_i])$, which is a union of N trees glued along the leaves. It is easy to see that the resulting graph excludes the bi-clique $K_{N+1,N+1}$ as a subgraph. By Lemma 5.6, the class $\mathsf{S}(\mathcal{C})$ has low shrubdepth covers. Any p-cover of $\mathsf{S}(\mathcal{C})$ of bounded shrubdepth has bounded treedepth by Lemma 5.2. Therefore, $\mathsf{S}(\mathcal{C})$ has low treedepth covers, so has bounded expansion.

The transduction I is easily constructed from the transduction B from Lemma 5.3, allowing to reconstruct the graph G from the colored union of the trees produced by S. ◀

6 Algorithmic aspects

In this section we give a partial result about efficient computability of transductions on classes with structurally bounded expansion. When we refer to the size of a structure in the algorithmic context, we refer to its total size, i.e., the sum of its universe size and the total sum of sizes of tuples in its relations.

Call a class $\mathcal{C}$ of graphs of structurally bounded expansion *efficiently decomposable* if there is a finite 2-cover $\mathcal{U}$ of $\mathcal{C}$ and an algorithm that, given a graph $G \in \mathcal{C}$, in linear time computes the cover $\mathcal{U}_G$ and for each $U \in \mathcal{U}_G$, an SC-decomposition S_U of depth at most d of the graph $G[U]$, for some constant d depending only on $\mathcal{C}$. Our result is as follows.

▶ **Theorem 6.1.** *Suppose J is a deterministic transduction and $\mathcal{C}$ is a class of graphs that has structurally bounded expansion and is efficiently decomposable. Then given a graph $G \in \mathcal{C}$, one may compute $\mathsf{J}(G)$ in time linear in the size of the input plus the size of the output.*

We remark that instead of efficient decomposability we could assume that the 2-cover $\mathcal{U}_G$ of a graph G and corresponding SC-decompositions for all $U \in \mathcal{U}_G$ is given together with G as input. If only the cover is given but not the SC-decompositions, we would obtain cubic running time because bounded shrubdepth implies bounded cliquewidth and we can compute

an approximate clique decomposition in cubic time [26]. Then, SC-decompositions of small height are definable in monadic second-order logic, and hence they can be computed in linear time using the result of Courcelle, Makowski and Rotics [3].

Observe that the theorem implies that we can efficiently evaluate a first-order sentence and enumerate all tuples satisfying a formula $\varphi(x_1, \ldots, x_k)$ on the given input graph, since this amounts to applying the theorem to a transduction consisting of a single extension operation. This strengthens the analogous result of Kazana and Segoufin [21] for classes of bounded expansion.

Proof outline. We will make use of transductions S and I constructed in the proof of Lemma 5.8. Recall that $\mathsf{S}(\mathcal{C})$ is a class of colored graphs of bounded expansion, I is deterministic, and $\mathsf{I}(\mathsf{S}(G)) = \{G\}$ for each $G \in \mathcal{C}$. Observe that J is equivalent to $\mathsf{S}; \mathsf{I}; \mathsf{J}$ on $\mathcal{C}$. Defining K as $\mathsf{I}; \mathsf{J}$, we get that $\mathsf{J}(G) = \mathsf{K}(\mathsf{S}(G))$ for $G \in \mathcal{C}$. Moreover, since I is deterministic, it follows that K is deterministic.

Let $G \in \mathcal{C}$ be an input graph. By efficient decomposability of $\mathcal{C}$, in linear time we can compute a cover $\mathcal{U}_G$ of G together with an SC-decomposition S_U of depth at most d of $G[U]$, for $U \in \mathcal{U}_G$. Each S_U is a colored tree, and by the construction described in the proof of Lemma 5.8, the trees S_U for $U \in \mathcal{U}_G$, glued along the leaves form a structure belonging to $\mathsf{S}(G)$. As $\mathsf{J}(G) = \mathsf{K}(\mathsf{S}(G))$, it suffices to apply the enumeration result of Kazana and Segoufin for classes of bounded expansion [21] to the colored graph $\mathsf{S}(G)$ and to all formulas occurring in the transduction K. ◀

7 Conclusion

In this paper we have provided a natural combinatorial characterization of graph classes that are first-order transductions of bounded expansion classes of graphs. Our characterization parallels the known characterization of bounded expansion classes by the existence of low treedepth decompositions, by replacing the notion of treedepth by shrubdepth. We believe that we have thereby taken a big step towards solving the model-checking problem for first-order logic on classes of structurally bounded expansion.

On the structural side we remark that transductions of bounded expansion graph classes are just the same as transductions of classes of structures of bounded expansion (i.e., classes whose Gaifman graphs or whose incidence encodings have bounded expansion). On the other hand, it remains an open question to characterize classes of relational structures, rather than just graphs, which are transductions of bounded expansion classes. We are lacking the analogue of Lemma 5.3; the problem is that within the proof we crucially use the characterization of shrubdepth via SC-depth, which works well for graphs but is unclear for structures of higher arity.

Finally, observe that classes of bounded expansion can be characterized among classes with structurally bounded expansion as those which are bi-clique free. It follows, that every monotone (i.e., subgraph closed) class of structurally bounded expansion has bounded expansion. Exactly the same statement holds characterizing bounded treedepth among bounded shrubdepth, and the second item holds for treewidth vs cliquewidth. In particular, for monotone graph classes all pairs of notions collapse.

We do not know how to extend our results to nowhere dense classes of graphs, mainly due to the fact that we do not know whether there exists a robust quantifier-elimination procedure for these graph classes. Obtaining such a procedure remains an open problem of prime importance in this field of research.

Abstract

A sliding window algorithm receives a stream of symbols and has to output at each time instant a certain value which only depends on the last n symbols. If the algorithm is randomized, then at each time instant it produces an incorrect output with probability at most ϵ, which is a constant error bound. This work proposes a more relaxed definition of correctness which is parameterized by the error bound ϵ and the failure ratio ϕ: a randomized sliding window algorithm is required to err with probability at most ϵ at a portion of $1 - \phi$ of all time instants of an input stream. This work continues the investigation of sliding window algorithms for regular languages. In previous works a trichotomy theorem was shown for deterministic algorithms: the optimal space complexity is either constant, logarithmic or linear in the window size. The main results of this paper concerns three natural settings (randomized algorithms with failure ratio zero and randomized/deterministic algorithms with bounded failure ratio) and provide natural language theoretic characterizations of the space complexity classes.

1 Introduction

Sliding window algorithms process an input sequence $a_1 a_2 \cdots a_m$ from left to right and have at time t only direct access to the current symbol a_t. Moreover, at each time instant t the algorithm is required to compute a value that depends on the last n symbols. The value n is called the *window size* and the last n symbols form the *active window* at time t. In many streaming applications, data items are outdated after a certain time and the sliding window model is a simple way to model this. A general goal in the area of sliding window algorithms is to avoid the explicit storage of the window content (which requires $\Omega(n)$ bits), and, instead, to work in considerably smaller space, e.g. polylogarithmic space with respect to the window size n. A detailed introduction into the sliding window model can be found in [1, Chapter 8].

Regular languages over sliding windows. In our recent papers [7, 8] we initiated the study of sliding window algorithms for regular languages. In general, a sliding window algorithm for a language $L \subseteq \Sigma^*$ decides at every time instant whether the active window belongs to L. In [8] we proved that for every regular language L the optimal space bound for a sliding window algorithm for L is either constant, logarithmic or linear in the window size. This trichotomy result resembles the well-known fact that every regular (even context-free) language has either polynomial or exponential growth. In [7] we also gave several characterizations for these space classes: A regular language has a sliding window algorithm with space $\mathcal{O}(\log n)$ if and only if it belongs to $\langle \mathbf{LI}, \mathbf{Len} \rangle$, which denotes the Boolean closure of the class **LI** of regular left ideals and the class **Len** of regular length languages. Moreover, a regular language has a sliding window algorithm that uses space $\mathcal{O}(1)$ if and only if it belongs to $\langle \mathbf{ST}, \mathbf{Len} \rangle$, where **ST** is the class of suffix-testable languages. The formal definitions of these and other language classes can be found in Section 2. The goal of this work is to extend the results from [7, 8] to randomized algorithms.

Main results. Consider a Monte-Carlo sliding window algorithm which can produce incorrect outputs. Abstracting away from the actual computation, we will view such a randomized sliding window algorithm (SWA for short) as a family $\mathcal{R} = (R_n)_{n \geq 0}$ of probabilistic automata, where R_n is the algorithm for window size n. We denote by $f(\mathcal{R}, n)$ the number of bits stored by R_n, which is the logarithm of the number of states. There are different ways to define correctness of $\mathcal{R}$ for a certain language L. The maybe most natural choice is to require that after reading an arbitrary input word $a_1 a_2 \cdots a_m$, the algorithm R_n correctly decides whether $a_{m-n+1} \cdots a_m \in L$ with probability at least $2/3$. This ensures that for every input stream and every time instant, one can be sure to get a correct answer with probability at least $2/3$. By a standard probability amplification argument, $2/3$ can be replaced by any probability strictly between $1/2$ and 1. With this definition (formal details can be found in Section 3) our first main result is the following, where **SF** denotes the class of all regular suffix-free languages (point (1) and (5) are from [8]).

▶ **Theorem 1.1.** *Let $L \subseteq \Sigma^*$ be a regular language.*

1. *If $L \in \langle \mathbf{ST}, \mathbf{Len} \rangle$, then L has a deterministic SWA $\mathcal{R}$ with $f(\mathcal{R}, n) = \mathcal{O}(1)$.*
2. *If $L \notin \langle \mathbf{ST}, \mathbf{Len} \rangle$, then $f(\mathcal{R}, n) \notin o(\log \log n)$ for every randomized SWA $\mathcal{R}$ for L.*
3. *If $L \in \langle \mathbf{ST}, \mathbf{SF}, \mathbf{Len} \rangle$, then L has a randomized SWA $\mathcal{R}$ with $f(\mathcal{R}, n) = \mathcal{O}(\log \log n)$.*
4. *If $L \notin \langle \mathbf{ST}, \mathbf{SF}, \mathbf{Len} \rangle$, then $f(\mathcal{R}, n) \notin o(\log n)$ for every randomized SWA $\mathcal{R}$ for L.*
5. *If $L \in \langle \mathbf{LI}, \mathbf{Len} \rangle$, then L has a deterministic SWA $\mathcal{R}$ with $f(\mathcal{R}, n) = \mathcal{O}(\log n)$.*
6. *If $L \notin \langle \mathbf{LI}, \mathbf{Len} \rangle$, then $f(\mathcal{R}, n) \notin o(n)$ for every randomized SWA $\mathcal{R}$ for L.*

One may argue that an algorithm which occasionally produces a wrong answer with probability $> 1/3$ is acceptable as well. This motivates the following definition: We say that a randomized algorithm for a certain language L and a window size n has *failure ratio* ϕ if for every input stream, the portion of all time instants where the algorithm gives a wrong answer with probability $> 1/3$ is bounded by ϕ. The second main result concerns algorithms with a bounded failure ratio. If we ask for an arbitrarily small non-zero failure ratio we get the following space dichotomy, where **PF** denotes the class of regular prefix-free languages:

▶ **Theorem 1.2.** *Let $L \subseteq \Sigma^*$ be a regular language.*

1. *If $L \in \langle \mathbf{LI}, \mathbf{PF}, \mathbf{Len} \rangle$ and $0 < \phi \leq 1$, then L has a randomized SWA with $f(\mathcal{R}, n) = \mathcal{O}(1)$ and failure ratio ϕ.*
2. *If $L \notin \langle \mathbf{LI}, \mathbf{PF}, \mathbf{Len} \rangle$, then there exists a failure ratio $0 < \phi \leq 1$ such that $f(\mathcal{R}, n) \notin o(n)$ for every randomized SWA $\mathcal{R}$ for L with failure ratio ϕ.*

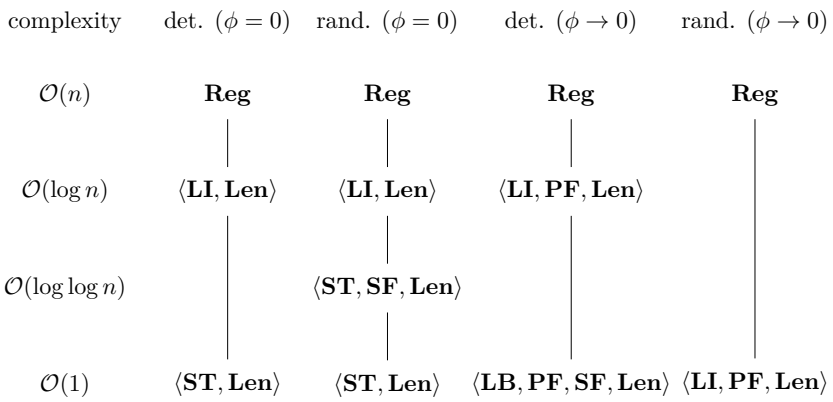

Figure 1 All language classes are defined in Section 2.

The notion of failure ratio makes sense for deterministic sliding window algorithms as well. Our third main result is a space trichotomy for deterministic sliding window algorithms having a bounded failure ratio. Let **LB** denote the class of left ideals generated by bifix-free (i.e., prefix- and suffix-free) regular languages. We then show:

▶ **Theorem 1.3.** *Let $L \subseteq \Sigma^*$ be a regular language.*

1. *If $L \in \langle \mathbf{LB}, \mathbf{PF}, \mathbf{SF}, \mathbf{Len} \rangle$ and $0 < \phi \leq 1$, then L has a deterministic SWA with $f(\mathcal{R}, n) = \mathcal{O}(1)$ and failure ratio ϕ.*
2. *If $L \notin \langle \mathbf{LB}, \mathbf{PF}, \mathbf{SF}, \mathbf{Len} \rangle$, then there exists a failure ratio $0 < \phi \leq 1$ such that $f(\mathcal{R}, n) \notin o(\log n)$ for every deterministic SWA $\mathcal{R}$ for L with failure ratio ϕ.*
3. *If $L \in \langle \mathbf{LI}, \mathbf{PF}, \mathbf{Len} \rangle$ and $0 < \phi \leq 1$, then L has a deterministic SWA with $f(\mathcal{R}, n) = \mathcal{O}(\log n)$ and failure ratio ϕ.*
4. *If $L \notin \langle \mathbf{LI}, \mathbf{PF}, \mathbf{Len} \rangle$, then there exists a failure ratio $0 < \phi \leq 1$ such that $f(\mathcal{R}, n) \notin o(n)$ for every deterministic SWA $\mathcal{R}$ for L with failure ratio ϕ.*

Note that Theorem 1.3(4) is an immediate corollary of Theorem 1.2(2), and that Theorem 1.3(3) follows from Theorem 1.3(1) and Theorem 1.1(5). Figure 1 summarizes the resulting space classes for each setting; the left column shows the three classes for the deterministic setting [7, 8]. Figure 2 shows an inclusion diagram for the language classes in Figure 1. One can show that the example languages in Figure 2 witness the strictness of the inclusions.

Technical contributions. Our randomized algorithms are based on a simulation of a counter by a Bernoulli random variable. Albeit simple, this *Bernoulli algorithm* can be utilized for sliding window algorithms with a bounded failure ratio. We present automata-theoretic descriptions of several Boolean closed language classes, to derive certain witness words for proving the lower bounds. Concerning lower bounds for sliding window algorithms with a bounded failure ratio, we consider a promise variant of the communication problem IDX_n, which has randomized one-way communication complexity $\Omega(n)$. Also we prove that a DFA which can count up to n, allowing a bounded failure ratio, needs $\Omega(n)$ states.

Related work. Let us emphasize related results which prove bounds on randomized sliding window algorithms. In the seminal paper of Datar et al. [6], where the sliding window model was introduced, the authors prove that the number of 1's in a 0/1-sliding window of

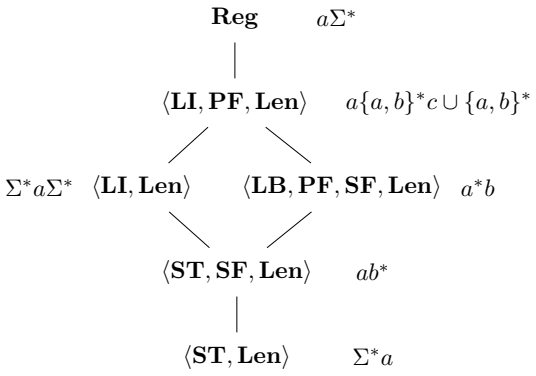

Figure 2 Examples for all occurring language classes where $\Sigma = \{a, b, c\}$.

size n can be maintained in space $\mathcal{O}(\frac{1}{\epsilon} \cdot \log^2 n)$ if one allows a multiplicative error of $1 \pm \epsilon$. Furthermore, they proved a matching lower bound for both deterministic and randomized algorithms. Ben-Basat et al. [3] present a sliding window algorithm for the related problem of approximating counts with an additive error, and present a deterministic and randomized lower space bound. We remark that both papers [3, 6] use a stronger notion of correctness: A randomized sliding window algorithm must have the property that for every input w, the probability that the algorithm produces some incorrect output while reading w is bounded by $1/3$. The authors utilize Yao's minimax principle to lift the deterministic lower bound to a randomized lower bound [13, Chapter 2]. Arasu et al. [2] study the problem of maintaining approximate frequency counts and quantiles over sliding windows. They present a deterministic algorithm and a randomized algorithm with improved space complexity using a simple sampling technique. Chan et al. [5] present a randomized sliding window algorithm for a certain measure of monotonicity. Furthermore, they present randomized lower bounds using communication complexity. The randomized algorithm analyzed in both papers comply with our standard definition of correctness with failure ratio 0. Further references can be found in [1, 4].

Finally let us mention the study of the communication complexity of regular languages by Tesson and Thérien [17], where a trichotomy (resp., quatrochotomy) for the deterministic (resp., randomized) communication complexity was shown. These results resemble our results, but the language classes that appear in [17] are different from the classes in our results.

2 Preliminaries

For integers $i, j \in \mathbb{N}$ let $[i, j] = \{k \in \mathbb{N} \colon i \leq k \leq j\}$. The set of all words over a finite alphabet Σ is denoted by Σ^*. The empty word is denoted by ε whereas error probabilities are denoted by the lunate epsilon ϵ. The sets of words over Σ of length exactly, at most and at least n are denoted by Σ^n, $\Sigma^{\leq n}$ and $\Sigma^{\geq n}$, respectively. Consider a word $w = a_1 a_2 \cdots a_m$. The *reversal* of w is defined as $w^{\mathsf{R}} = a_m \cdots a_2 a_1$, and for a language L we set $L^{\mathsf{R}} = \{w^{\mathsf{R}} \colon w \in L\}$. For a non-empty interval $[i, j] \subseteq [1, m]$ we define $w[i, j] = a_i a_{i+1} \cdots a_j$. If $i > j$ we set $w[i, j] = \varepsilon$. A *prefix* of w is a word of the form $w[1, i]$ for some $0 \leq i \leq m$; a *suffix* of w is a word of the form $w[i, m]$ for some $1 \leq i \leq m + 1$. A language $L \subseteq \Sigma^*$ is *prefix-free* (resp., *suffix-free*) if there are no two words $x, y \in L$ with $x \neq y$ and x is a prefix (resp., suffix) of y. A language is *bifix-free* if it is both prefix- and suffix-free.

Automata and regular languages. For general background in automata theory see [10]. A *deterministic finite automaton* (DFA) $A = (Q, \Sigma, q_0, \delta, F)$ consists of a finite set of states Q, a finite alphabet Σ, an initial state $q_0 \in Q$, a transition function $\delta\colon Q \times \Sigma \to Q$ and a set of final states $F \subseteq Q$. We inductively extend δ to a function $\delta\colon Q \times \Sigma^* \to Q$ as usual. If $P \subseteq Q$ is a set of states, then $L(A, P) = \{w \in \Sigma^*\colon \delta(q_0, w) \in P\}$. The language accepted by A is $L(A) = L(A, F)$. A language is *regular* if it is accepted by a DFA. Classes of languages are denoted by boldfaced letters. In this paper we will deal with the following language classes:

- **Reg**: the class of all *regular languages*.
- **Len**: the class of *regular length languages*, i.e., regular languages L such that for all $n \in \mathbb{N}$ we have $\Sigma^n \subseteq L$ or $\Sigma^n \cap L = \emptyset$.
- **LI** (resp., **RI**): the class of *regular left (resp., right) ideals*, i.e., languages of the form $\Sigma^* L$ (resp., $L\Sigma^*$) where L is regular.
- **ST** (resp., **PT**): the class of *suffix testable (resp., prefix testable) languages*, i.e., finite Boolean combinations of languages $\Sigma^* w$ (resp., $w\Sigma^*$) where $w \in \Sigma^*$.
- **SF** (resp., **PF**): the class of *regular suffix-free (resp., prefix-free) languages*
- **LB** (resp., **RB**): the class of *left ideals (resp., right ideals) generated by regular bifix-free languages*, i.e., languages of the form $\Sigma^* L$ (resp., $L\Sigma^*$) where $L \in \mathbf{PF} \cap \mathbf{SF}$.[1]

It is easy to see that every finite language is prefix and suffix testable. Moreover, prefix testable and suffix testable languages are regular. If $\mathbf{A}_1, \ldots, \mathbf{A}_n$ are language classes, then $\langle \mathbf{A}_1, \ldots, \mathbf{A}_n \rangle$ denotes the smallest boolean-closed class which contains $\bigcup_{i=1}^n \mathbf{A}_i$.

Probabilistic automata. In the following we introduce probabilistic automata [14, 15] as a model for randomized streaming algorithms. A *probabilistic automaton* $R = (Q, \Sigma, \iota, \rho, F)$ consists of a (possibly infinite) set of states Q, an alphabet Σ, an initial state distribution $\iota\colon Q \to \{r \in \mathbb{R}\colon 0 \leq r \leq 1\}$, a transition probability function $\rho\colon Q \times \Sigma \times Q \to \{r \in \mathbb{R}\colon 0 \leq r \leq 1\}$ and set of final states $F \subseteq Q$ such that $\sum_{q \in Q} \iota(q) = 1$ and $\sum_{q \in Q} \rho(p, a, q) = 1$ for all $p \in Q$, $a \in \Sigma$. If ι and ρ map into $\{0, 1\}$, then R is a *deterministic automaton*. A *run* on a word $a_1 \cdots a_m \in \Sigma^*$ in R is a sequence $\pi = (q_0, a_1, q_1, a_2, \ldots, a_m, q_m)$ where $q_0, \ldots, q_m \in Q$ and $\rho(q_{i-1}, a_i, q_i) > 0$ for all $1 \leq i \leq m$. Given such a run π in R we define $\rho_\iota(\pi) = \iota(q_0) \cdot \prod_{i=1}^n \rho(q_{i-1}, a_i, q_i)$. For each $w \in \Sigma^*$ the function ρ_ι is a probability distribution on the set $\mathrm{Runs}(w)$ of all runs of $\mathcal{R}$ on w.

3 Randomized streaming and sliding window algorithms

A *randomized streaming algorithm* (R, enc) consists of a probabilistic automaton $R = (Q, \Sigma, \iota, \rho, F)$ as above and an injective function $\mathrm{enc}\colon Q \to \{0, 1\}^*$. Usually, we will only refer to the underlying automaton R. If R is deterministic, we speak of a *deterministic streaming algorithm*. The maximum number of bits stored during a run $\pi = (q_0, a_1, \ldots, a_m, q_m)$ is denoted by $\mathrm{space}(R, \pi)$, i.e., $\mathrm{space}(R, \pi) = \max\{|\mathrm{enc}(q_i)| : 0 \leq i \leq m\}$. The worst case space complexity of R on w is $\mathrm{space}(R, w) = \max\{\mathrm{space}(R, \pi) : \pi \in \mathrm{Runs}(w), \rho_\iota(\pi) > 0\}$. A run $\pi = (q_0, a_1, \ldots, a_m, q_m)$ is *correct* with respect to a language $K \subseteq \Sigma^*$ if $q_m \in F \Leftrightarrow a_1 \cdots a_m \in K$ holds. The *error probability* of R on w for K is

$$\epsilon(R, w, K) = \sum \{\rho_\iota(\pi) : \pi \in \mathrm{Runs}(w) \text{ is not correct with respect to } K\}.$$

[1] or equivalently, the class of all left ideals generated by regular prefix-free languages. Since our proofs related to **LB** yield decompositions of the form $\Sigma^* L$ with L bifix-free, we decided to define **LB** as above.

Given an error bound $0 \leq \epsilon \leq 1$, the *failure ratio* of R on w is defined as

$$\phi(R, w, K, \epsilon) = \frac{1}{m+1} |\{t \in [0, m] : \epsilon(R, a_1 a_2 \cdots a_t, K) > \epsilon\}|.$$

For a window length $n \geq 0$ and a stream $x \in \Sigma^*$ we define $\text{last}_n(x)$ to be the suffix of $\square^n x$ of length n where $\square \in \Sigma$ is a fixed alphabet symbol. The word $\text{last}_n(\varepsilon) = \square^n$ is the initial window content. Given a language $L \subseteq \Sigma^*$ and a window size $n \geq 0$ we define the language

$$L_n = \{x \in \Sigma^* \colon \text{last}_n(x) \in L\}. \tag{1}$$

A *randomized sliding window algorithm* (*randomized SWA* for short) is a sequence $\mathcal{R} = (R_n)_{n \geq 0}$ of randomized streaming algorithms R_n over the same alphabet Σ. If every R_n is deterministic, we speak of a *deterministic SWA*. The *space complexity* of the randomized SWA $\mathcal{R} = (R_n)_{n \geq 0}$ is the function $f(\mathcal{R}, n) = \sup\{\text{space}(R_n, w) : w \in \Sigma^*\} \in \mathbb{N} \cup \{\infty\}$. Clearly, if R_n is finite, then one can always find a state encoding such that $f(\mathcal{R}, n) = \lfloor \log_2 |R_n| \rfloor$.

▶ **Definition 3.1.** Let $0 \leq \epsilon \leq 1$ and $0 \leq \phi \leq 1$. A randomized SWA $\mathcal{R} = (R_n)_{n \geq 0}$ is (ϵ, ϕ)-*correct* for a language $L \subseteq \Sigma^*$ if $\phi(R_n, w, L_n, \epsilon) \leq \phi$ for all $n \geq 0$ and $w \in \Sigma^{\geq n}$. The number ϵ is the *error probability* and ϕ is the *failure ratio* of $\mathcal{R}$ (with respect to ϵ).

Definition 3.1 also makes sense in the special case that $\mathcal{R}$ is deterministic and $\epsilon = 0$. A $(0, \phi)$-correct deterministic SWA $\mathcal{R} = (R_n)_{n \geq 0}$ for L has the property that R_n produces at most $\phi \cdot (m+1)$ many incorrect answers when running on any input word of length $m \geq n$.

We will set the error probability to $\epsilon = 1/3$, which is justified by the following lemma (that follows from a standard Chernoff bound).

▶ **Lemma 3.2.** *Let $L \subseteq \Sigma^*$, $0 < \epsilon' < \epsilon < \frac{1}{2}$ and $0 \leq \phi \leq 1$. Given a randomized SWA $\mathcal{R}$ which is (ϵ, ϕ)-correct for L, one can construct a randomized SWA $\mathcal{R}'$ which is (ϵ', ϕ)-correct for L such that $f(\mathcal{R}', n) \leq \ln(\frac{1}{\epsilon'}) \cdot \frac{1}{\text{poly}(\epsilon)} \cdot f(\mathcal{R}, n)$.*

▶ **Definition 3.3.** Let $L \subseteq \Sigma^*$ be a language and $0 \leq \phi \leq 1$.

- A *randomized SWA for L* with failure ratio ϕ is a randomized SWA which is $(1/3, \phi)$-correct for L. If moreover $\phi = 0$, then we speak of a *randomized SWA for L*.
- A *deterministic SWA for L* with failure ratio ϕ is a deterministic SWA which is $(0, \phi)$-correct for L. If moreover $\phi = 0$, then we speak of a *deterministic SWA for L*.

We only consider randomized SWAs $\mathcal{R} = (R_n)_{n \geq 0}$ where every R_n has a finite state set Q_n. This is justified by the fact that for every language L and every n the language L_n from (1) is regular and hence can be accepted by a DFA. The space-optimal deterministic SWA for a language L therefore consists of the minimal DFA for L_n for every $n \geq 0$. For a fixed error probability $\epsilon < 1/2$ a space-optimal randomized SWA for L consists of a minimal probabilistic finite automaton for L_n which accepts a word w with probability at least $1 - \epsilon$ if $w \in L_n$ and accepts w with probability at most ϵ if $w \notin L_n$. By a result of Rabin [15] such a probabilistic finite automaton can be transformed into an equivalent DFA with an exponential blow-up. Hence, we get:

▶ **Lemma 3.4.** *Let $\mathcal{R}$ be a randomized SWA for the language L. Then, there exists a deterministic SWA $\mathcal{D}$ for L such that $f(\mathcal{D}, n) \in \mathcal{O}(2^{f(\mathcal{R}, n)})$.*

4 Upper bounds

In this section we prove the upper bounds in Theorem 1.1, 1.2 and 1.3. We use the simple fact that space complexity classes in the sliding window model are Boolean-closed:

▶ **Lemma 4.1.** *Let L be a Boolean combination of languages $L_1, \dots, L_k$. For each $i \in [1,k]$ let $\mathcal{R}_i$ be a randomized SWA for L_i with failure ratio ϕ_i. Then L has a SWA $\mathcal{R}$ with failure ratio $\sum_{i=1}^k \phi_i$ and $f(\mathcal{R},n) = \mathcal{O}(\sum_{i=1}^k f(\mathcal{R}_i,n))$.*

4.1 The Bernoulli algorithm

In this section, we introduce a randomized SWA that will be used for the proof of the upper bounds (3) from Theorem 1.1 and (1) from Theorem 1.2. The idea is based on the algorithm from [7], which stores *path summaries* in the reversal DFA. Consider a regular language $L \subseteq \Sigma^*$ and let $A = (Q, \Sigma, q_0, \delta, F)$ be a DFA for L^{R}. Observe that if L is a left-ideal then any run in A switches from $Q \setminus F$ to F at most once; if L is suffix-free then any run in A visits F at most once. For a stream $w \in \Sigma^*$ define the function $\ell_w \colon Q \to \mathbb{N} \cup \{\infty\}$ by

$$\ell_w(q) = \inf\{k \in \mathbb{N} : \delta(q, \mathrm{last}_k(w)^{\mathsf{R}}) \in F\}, \tag{2}$$

where we set $\inf(\emptyset) = \infty$. By the observations above we know:

- If L is a left ideal, then $\mathrm{last}_n(w) \in L$ if and only if $\ell_w(q_0) \leq n$.
- If L is suffix-free, then $\mathrm{last}_n(w) \in L$ if and only if $\ell_w(q_0) = n$.

One can define a deterministic SWA which stores the function ℓ_w on input stream w. If a symbol $a \in \Sigma$ is read, we can determine ℓ_{wa} from ℓ_w: If $q \in F$, then $\ell_{wa}(q) = 0$. Otherwise $\ell_{wa}(q) = 1 + \ell_w(\delta(q,a))$ where $1 + \infty = \infty$.

Using a Bernoulli random variable, we define a randomized approximation of the above deterministic SWA to reduce the space complexity to $\mathcal{O}(1)$. Let $\beta \colon \mathbb{N} \to \mathbb{R}$ be a function such that for some n_0, $0 \leq \beta(n) \leq 1$ for all $n \geq n_0$, which controls the Bernoulli random variable and will later be instantiated by concrete functions. We define the following constant-space randomized SWA $\mathcal{B} = (B_n)_{n \geq 0}$ (which depends on the language L, the DFA A and the function β), which we call the Bernoulli algorithm. If $n < n_0$ let B_n be the trivial deterministic streaming algorithm for L_n. For $n \geq n_0$ the algorithm B_n stores a Boolean flag for each state in form of a function $b \colon Q \to \{0,1\}$. All flags $b(q)$ for $q \in F$ are fixed to 1 forever. For all other states $q \in Q \setminus F$ we define the initial value of the flag $b(q)$ as follows, where $\ell = \ell_\varepsilon(q) \in \mathbb{N} \cup \{\infty\}$:

$$b(q) := \begin{cases} 0 \text{ with probability } 1 - (1-\beta(n))^{\ell} \\ 1 \text{ with probability } (1-\beta(n))^{\ell}. \end{cases} \tag{3}$$

Here we set $x^\infty = 0$ for $0 \leq x < 1$. For all states $q \in Q \setminus F$ we do the following upon arrival of a symbol $a \in \Sigma$:

$$b(q) := \begin{cases} 0 & \text{with probability } \beta(n) \\ b(\delta(q,a)) & \text{with probability } 1 - \beta(n) \end{cases} \tag{4}$$

The algorithm accepts if and only if $b(q_0) = 1$. An induction on $|w|$ shows:

▶ **Lemma 4.2.** *For all $n \geq n_0$ and $w \in \Sigma^*$ we have $\Pr[B_n \text{ accepts } w] = (1-\beta(n))^{\ell_w(q_0)}$.*

4.2 Randomized SWAs with failure ratio zero

In this section we present a $\mathcal{O}(\log\log n)$ space algorithm for suffix-free regular languages L. Since languages in **ST** and **Len** have constant space deterministic SWAs (Theorem 1.1(1)) and the space complexity classes are closed under Boolean combinations by Lemma 4.1, this implies Theorem 1.1(3).

Let $L \in \mathbf{SF}$ and $A = (Q, \Sigma, q_0, \delta, F)$ be a DFA for $L^{\mathsf{R}} \in \mathbf{PF}$. Since the case $L = \emptyset$ is trivial, we can assume that A contains at least one final state which is reachable from q_0. Furthermore, since L^{R} is prefix-free, any run in A from q_0 contains at most one final state. Therefore, we can assume that F contains exactly one final state q_F, and all outgoing transitions from q_F lead to a sink state.

Recall the function $\ell_w \colon Q \to \mathbb{N} \cup \{\infty\}$ defined in (2). Notice that $\mathrm{last}_n(w) \in L$ if and only if $\ell_w(q_0) = n$ for all $w \in \Sigma^*$. Our randomized SWA $\mathcal{R} = (R_n)_{n \geq 0}$ consists of two parts: Firstly, we take the Bernoulli algorithm $\mathcal{B} = (B_n)_{n \geq 0}$ from Section 4.1 for the function $\beta(n) = 1/(2n)$ and $n_0 = 1$. From Lemma 4.2 we know that B_n accepts a word $w \in \Sigma^*$ with probability $(1 - 1/(2n))^{\ell_w(q_0)}$. Secondly, we simultaneously run a modulo-counting algorithm M_n. Let p_i be the i-th prime number and let $s(m)$ be the product of all prime numbers $\leq m$. It is known that $\ln(s(m)) > m \cdot (1 - 1/\ln m)$ for $m \geq 41$ [16, 3.16] and $p_i < i \cdot (\ln i + \ln \ln i)$ for $i \geq 6$ [16, 3.13]. Let k be the first natural number such that $\prod_{i=1}^{k} p_i \geq n$. By the above bounds we get $k \in \mathcal{O}(\log n)$ and $p_{3k} \in \mathcal{O}(\log n \cdot \log \log n)$. The algorithm M_n initially picks a random prime $p \in \{p_1, \ldots, p_{3k}\}$, which is stored throughout the run using $\mathcal{O}(\log \log n)$ bits. Then, after reading $w \in \Sigma^*$, M_n stores for every $q \in Q$ a bit telling whether $\ell_w(q) < \infty$ and, if the latter holds, the values $\ell_w(q) \bmod p$ using $\mathcal{O}(|Q| \cdot \log \log n)$ bits. The algorithm accepts if and only if $\ell_w(q_0) \equiv n \bmod p$.

The combined algorithm R_n accepts if and only if both B_n and T_n accept. Let us bound the error probability on an input stream $w \in \Sigma^*$ with $\ell = \ell_w(q_0)$.

Case 1. $\ell = n$, i.e., $\mathrm{last}_n(w) \in L$. Then M_n accepts w with probability 1. Moreover, B_n accepts w with probability $(1 - 1/(2n))^n \geq 0.6$ for $n \geq 12$ (note that $(1 - 1/(2n))^n$ converges to $1/\sqrt{e} \approx 0.60653$ from below). Hence, R_n accepts with probability at least 0.6.

Case 2. $\ell \geq 2n$ and hence $\mathrm{last}_n(w) \notin L$. Then B_n rejects with probability $1 - (1 - 1/(2n))^{\ell} \geq 1 - (1 - (1/2n))^{2n} \geq 1 - 1/e \geq 0.6$. Here, we use the well-known inequality $(1 - 1/y)^y \leq e^{-1}$ for all $y \geq 1$. Hence, R_n also rejects with probability at least 0.6.

Case 3. $\ell < 2n$ and $\ell \neq n$, and thus $\mathrm{last}_n(w) \notin L$. Since $\ell - n \in [-n, n]$ and any product of at least $k + 1$ pairwise distinct primes exceeds n, the number $\ell - n \neq 0$ has at most k prime factors. Therefore, M_n (and thus R_n) rejects with probability at least $2/3$.

4.3 SWAs with arbitrarily small non-zero failure ratio

In this section we sketch the proofs of Theorem 1.2(1) and Theorem 1.3(1). We focus on the main base case $L \in \mathbf{LI}$ from Theorem 1.2(1).

Let $L \subseteq \Sigma^*$ be a regular left ideal. Let $A = (Q, \Sigma, q_0, \delta, F)$ be the minimal DFA for L^{R}. Since the case $L = \emptyset$ is trivial, we can assume that $L \neq \emptyset$. It is easy to see that F contains a single state q_F from which all outgoing transitions lead back to q_F. Recall the function $\ell_w \colon Q \to \mathbb{N} \cup \{\infty\}$ defined in (2). Since L is a left ideal, we have: $\mathrm{last}_n(w) \in L$ if and only if $\ell_w(q_0) \leq n$: The following lemma says that the portion of prefixes of an input stream, where $\ell_w(q_0)$ is close to n, is small:

▶ **Lemma 4.3.** *Let $0 < \xi < 1$. Let $n \geq 0$ be a window size and $w \in \Sigma^{\geq n}$ be an input stream. Then the number of prefixes v of w such that $\lceil \xi n \rceil \leq \ell_v(q_0) \leq n$ is at most*

$$\frac{(1 - \xi + \frac{1}{n}) \cdot |Q|}{\xi} \cdot (|w| + 1 + \xi n). \tag{5}$$

Proof. Let us say that a prefix v of w is a *hit*, if $\lceil \xi n \rceil \leq \ell_v(q_0) \leq n$. Consider an interval $I = [i, i']$ with $0 \leq i \leq i' \leq |w|$ and $i' - i \leq \lceil \xi n \rceil$. With each position $j \in I$ we associate the prefix $w[1, j]$. We claim that $V := \{w[1, j] \colon j \in I\}$ contains at most $|Q| \cdot (n - \lceil \xi n \rceil + 1)$ hits. Let us assume the contrary. Since $\lceil \xi n \rceil \leq \ell_v(q_0) \leq n$ for every hit v, and the interval $[\lceil \xi n \rceil, n]$ contains $n - \lceil \xi n \rceil + 1$ many different values, there is a subset $U \subseteq V$ and some $\ell \in [\lceil \xi n \rceil, n]$ such that (i) $|U| > |Q|$ and (ii) $\ell_v(q_0) = \ell$ for all $v \in U$. Let $U = \{w[1, j_1], w[1, j_2], \ldots, w[1, j_k]\}$, where $k > |Q|$. Consider the words $u_1 = \mathrm{last}_\ell(w[1, j_1]), u_2 = \mathrm{last}_\ell(w[1, j_2]), \ldots, u_k = \mathrm{last}_\ell(w[1, j_k])$. Since $j_k - j_1 \leq \lceil \xi n \rceil$ and $\ell \geq \lceil \xi n \rceil$, we have $\ell - j_k + j_1 \geq 0$. Hence, we can consider the words $v_1 = \mathrm{last}_{\ell - j_k + j_1}(w[1, j_1]), v_2 = \mathrm{last}_{\ell - j_k + j_2}(w[1, j_2]), \ldots, v_k = \mathrm{last}_\ell(w[1, j_k])$. Clearly, v_j is a suffix of u_j. Moreover, the words v_j all start in the same position of $\square^n w$, i.e., every v_j is a prefix of $v_{j'}$ for $j \leq j'$. Consider now the state $q_j = \xi(q_0, v_j^{\mathsf{R}})$ for $1 \leq j \leq k$. Since $k > |Q|$ there exist $j < j'$ such that $q_j = q_{j'}$. But this would imply that $\ell_{v_j}(q_0) < \ell_{v_{j'}}(q_0)$, which contradicts $\ell_{v_j}(q_0) = \ell = \ell_{v_{j'}}(q_0)$. This shows the above claim.

Now we can finish the proof of the lemma: We divide the interval $[0, |w|]$ into intervals of size $\lceil \xi n \rceil + 1$ and one last interval of possibly shorter length. This yields $\lceil (|w|+1)/(\lceil \xi n \rceil + 1) \rceil$ many intervals. In each of these intervals we find at most $|Q| \cdot (n - \lceil \xi n \rceil + 1)$ many hits by the above claim. Hence, the total number of hits is bounded by

$$\begin{aligned} \left\lceil \frac{|w|+1}{\lceil \xi n \rceil + 1} \right\rceil \cdot |Q| \cdot (n - \lceil \xi n \rceil + 1) &\leq \left(\frac{|w|+1}{\xi n} + 1 \right) \cdot |Q| \cdot (n - \xi n + 1) \\ &= (|w| + 1 + \xi n) \cdot |Q| \cdot \frac{1 - \xi + \frac{1}{n}}{\xi}. \end{aligned}$$

This concludes the proof of the lemma. ◀

We now consider the Bernoulli algorithm $\mathcal{B}^\epsilon = (B_n^\epsilon)_{n \geq 0}$ for $\beta_\epsilon \colon \mathbb{N} \to \mathbb{R}$ with $\beta_\epsilon(n) = \ln(1/\epsilon)/n$. Note that $0 < \beta_\epsilon(n) \leq 1$ for $n \geq \ln(1/\epsilon)$. With Lemma 4.2 one can show:

▶ **Lemma 4.4.** *For every $0 < \xi < 1$ there exists $0 < \epsilon < 1/2$ and $n_0 \geq 1$ such that for all $n \geq n_0$ the following holds: If $w \in \Sigma^*$ and $\ell_w(q_0) \notin [\lceil \xi n \rceil, n]$, then $\epsilon(B_n^\epsilon, w, L_n) \leq \epsilon$.*

▶ **Theorem 4.5.** *Let L be a regular left ideal and $0 < \phi < 1$. Then L has a randomized SWA $\mathcal{R}$ with $f(\mathcal{R}, n) = \mathcal{O}(1)$ and failure ratio ϕ.*

Proof. Let us fix a failure ratio $0 < \phi < 1$ and let $0 < \xi < 1$, which will be defined later (depending on ϕ). Let ϵ and n_0 be the numbers from Lemma 4.4. Let $\mathcal{B}^\epsilon = (B_n^\epsilon)_{n \geq 0}$ be the randomized SWA described above. Let $n \geq n_0$ be a window size and $w \in \Sigma^{\geq n}$ be an input stream. Consider the set $P(w)$ of all prefixes v of w such that $\ell_v(q_0) \in [\lceil \xi n \rceil, n]$. By Lemma 4.4 the algorithm B_n^ϵ errs on each prefix $v \notin P(w)$ with probability at most ϵ, i.e.,

$$\begin{aligned} \phi(B_n^\epsilon, w, L_n, \epsilon) &\leq \frac{|P(w)|}{|w|+1} \overset{\text{Lemma 4.3}}{\leq} \frac{(1 - \xi + \frac{1}{n}) \cdot |Q|}{\xi} \cdot \left(1 + \frac{\xi n}{|w|+1} \right) \\ &\leq \left(1 - \xi + \frac{1}{n} \right) \cdot |Q| \cdot \left(1 + \frac{1}{\xi} \right). \end{aligned} \tag{6}$$

Note that if ξ converges to 1, then the probability (6) tends towards $2|Q|/n$. Hence we can choose numbers $n_1 \geq n_0$ and $0 < \xi < 1$ such that for all $n \geq n_1$ the probability (6) is smaller than our fixed failure ratio ϕ.

Finally for window sizes $n < n_1$ we can use the optimal deterministic sliding-window algorithms for L and window size n. The space complexity of the resulting algorithm is a constant that depends only on ϕ. ◀

The base case $L \in \mathbf{Len}$ in Theorem 1.2(1) is trivial (there is a constant-space deterministic SWA). Finally, for the case $L \in \mathbf{PF}$, one can show that the constant-space deterministic SWA that always rejects has a failure ratio of $\mathcal{O}(1/n)$ for window length n. This fact also covers the base case $L \in \mathbf{PF}$ from Theorem 1.3(1), and a similar argument covers the case $L \in \mathbf{SF}$. For the remaining base case $L \in \mathbf{LB}$ in Theorem 1.3(1), one can basically use a DFA for L itself as a sliding window algorithm. One can prove that this algorithm gives only $\mathcal{O}(1)$ incorrect answers in n consecutive windows.

5 Lower bounds

To prove the claimed lower bounds, we apply the same proof strategy in all cases (with one exception). We first show that if a regular language does not belong to the language class under consideration then there exist certain witness words. These words can then be used to apply known lower bounds from randomized one-way communication complexity [11, 12] by deriving a randomized communication protocol from a randomized SWA. This is a standard technique for showing lower bounds for streaming algorithms.

The setting in (one-way) communication complexity is as follows: Alice holds an element $x \in X$ and Bob holds an element $y \in Y$ and they aim to compute $f(x, y)$ according to a randomized one-way protocol P. Alice computes from her input $x \in X$ and from a random string a message and sends it to Bob. Using this message, his input $y \in Y$ and a random string, Bob computes an output bit. The cost of the protocol P is the maximal number of bits sent from Alice to Bob. We say that P computes f if the protocol computes $f(x, y)$ with probability at least $2/3$ for all inputs (x, y). The minimal cost of a protocol which computes f is denoted by $C(f)$.

Due to space constraints we only prove Theorem 1.1(4) in detail and discuss the proofs of the remaining lower bounds only briefly in Section 5.2.

5.1 Proof of point 4 from Theorem 1.1

Let $A = (Q, \Sigma, q_0, \delta, F)$ be a DFA. A state q is *trivial* if $\delta(q, x) \neq q$ for all $x \in \Sigma^+$, otherwise it is *non-trivial*. A pair $(p, q) \in Q \times Q$ of states is called *synchronized* if there exist words $x, y, z \in \Sigma^*$ with $|x| = |y| = |z| \geq 1$ such that $\delta(p, x) = p$, $\delta(p, y) = q$ and $\delta(q, z) = q$. A pair (p, q) is called *reachable* from a state r if p is reachable from r. A state pair (p, q) is called *F-consistent* if either $\{p, q\} \cap F = \emptyset$ or $\{p, q\} \subseteq F$. We remark that synchronized state pairs have no connection to the notion of synchronizing words. A simple pumping argument shows:

▶ **Lemma 5.1.** *A state pair (p, q) is synchronized if and only if p and q are non-trivial and there exists $y \in \Sigma^+$ such that $|Q|!$ divides $|y|$ and $\delta(p, y) = q$.*

Let $Q = T \cup N$ be the partition of the state set into the set T of trivial states and the set N of non-trivial states. A function $\beta\colon \mathbb{N} \to \{0, 1\}$ is *k-periodic* if $\beta(i) = \beta(i + k)$ for all $i \in \mathbb{N}$.

▶ **Lemma 5.2.** *Assume that every synchronized pair in A which is reachable from q_0 is F-consistent. Then for every word $v \in \Sigma^*$ of length at least $|Q|! \cdot (|T| + 1)$ there exists a $|Q|!$-periodic function $\beta_v\colon \mathbb{N} \to \{0, 1\}$ such that the following holds: If $w \in v\Sigma^*$ and $\delta(q_0, w) \in N$, then we have $w \in L$ iff $\beta(|w|) = 1$.*

Proof. Let $v = a_1 a_2 \cdots a_k$ with $k \geq |Q|! \cdot (|T| + 1)$, and consider the run $q_0 \xrightarrow{a_1} \cdots \xrightarrow{a_k} q_k$ of A on v. Clearly, each trivial state can occur at most once in the run. First notice that for each $0 \leq i \leq |Q|! - 1$ at least one of the states in $Q_i = \{q_{i+j|Q|!} : 0 \leq j \leq |T|\}$ is non-trivial because otherwise the set would contain $|T| + 1$ pairwise distinct trivial states.

Furthermore, we claim that the non-trivial states in Q_i are either all final or all non-final: Take two non-trivial states $q_{i+j_1|Q|!}$ and $q_{i+j_2|Q|!}$ with $j_1 < j_2$. Since we have a run of length $(j_2 - j_1)|Q|!$ from $q_{i+j_1|Q|!}$ to $q_{i+j_2|Q|!}$, the states form a synchronized pair by Lemma 5.1. Hence, by assumption the two states are F-consistent. Now define $\beta_v \colon \mathbb{N} \to \{0,1\}$ by

$$\beta_v(m) = \begin{cases} 1 & \text{if the states in } Q_{m \bmod |Q|!} \cap N \text{ are final,} \\ 0 & \text{if the states in } Q_{m \bmod |Q|!} \cap N \text{ are non-final,} \end{cases}$$

which is well-defined by the remarks above. Clearly β_v is $|Q|!$-periodic.

Let $w = a_1 \cdots a_m \in v\Sigma^*$ be a word of length $m \geq k$. The run of A on w prolongs the run on v, say $q_0 \xrightarrow{a_1} \cdots \xrightarrow{a_k} q_k \xrightarrow{a_{k+1}} \cdots \xrightarrow{a_m} q_m$. Assume that $q_m \in N$. As argued above, there is a position $0 \leq i \leq k$ such that $i \equiv m \pmod{|Q|!}$ and $q_i \in N$. Hence (q_i, q_m) is a synchronized pair by Lemma 5.1 which is F-consistent by assumption. Therefore $w \in L$ iff $q_m \in F$ iff $q_i \in F$ iff $\beta_v(|w|) = 1$. ◀

▶ **Lemma 5.3.** *Assume that every synchronized pair in A which is reachable from q_0 is F-consistent. Then $L(A)$ belongs to $\langle \mathbf{PT}, \mathbf{PF}, \mathbf{Len} \rangle$.*

Proof. Let $F_N = N \cap F$ and $F_T = T \cap F$. We decompose L into

$$L = L(A, F_N) \cup \bigcup_{q \in F_T} L(A, \{q\}).$$

First observe that $L(A, \{q\}) \in \mathbf{PF}$ for all $q \in F_T$ because a trivial state q can occur at most once in a run of A. It remains to show that $L(A, F_N)$ belongs to $\langle \mathbf{PT}, \mathbf{PF}, \mathbf{Len} \rangle$. Using the threshold $k = |Q|! \cdot (|T| + 1)$, we distinguish between words of length at most $k-1$ and words of length at least k, and group the latter set by their prefix of length k, i.e.,

$$L(A, F_N) = (L(A, F_N) \cap \Sigma^{\leq k-1}) \cup \bigcup_{v \in \Sigma^k} (L(A, F_N) \cap v\Sigma^*).$$

The first part $L(A, F_N) \cap \Sigma^{\leq k-1}$ is finite and thus prefix testable. To finish the proof, we will show that $L(A, F_N) \cap v\Sigma^* \in \langle \mathbf{PT}, \mathbf{PF}, \mathbf{Len} \rangle$ for each $v \in \Sigma^k$. Let $v \in \Sigma^k$ and let $\beta_v \colon \mathbb{N} \to \{0,1\}$ be the $|Q|!$-periodic function from Lemma 5.2. We know

$$L(A, F_N) \cap v\Sigma^* = (v\Sigma^* \cap \{w \in \Sigma^* : \beta(|w|) = 1\}) \setminus L(A, T).$$

Note that $\{w \in \Sigma^* : \beta(|w|) = 1\} \in \mathbf{Len}$, $v\Sigma^* \in \mathbf{PT}$ and $L(A, T) \in \langle \mathbf{PF} \rangle$. ◀

By applying Lemma 5.3 to the language L^{R}, we obtain:

▶ **Lemma 5.4.** *If $L \in \mathbf{Reg} \setminus \langle \mathbf{ST}, \mathbf{SF}, \mathbf{Len} \rangle$, then there exist $u, x, y, z \in \Sigma^*$ with $|x| = |y| = |z| \geq 1$ such that one of the following cases holds:*

- $x^*u \subseteq L$ *and* $z^*yx^*u \cap L = \emptyset$
- $x^*u \cap L = \emptyset$ *and* $z^*yx^*u \subseteq L$.

We can now conclude the proof of Theorem 1.1(4). Let $L \in \mathbf{Reg} \setminus \langle \mathbf{ST}, \mathbf{SF}, \mathbf{Len} \rangle$. We reduce from the communication problem $\mathrm{GT}_m \colon [1,m]^2 \to \{0,1\}$ where $\mathrm{GT}_m(i,j) = 1$ iff $i > j$. It is known that $C(\mathrm{GT}_m) \in \Theta(\log m)$ [11, Theorem 3.8].

Consider the words $u, x, y, z \in \Sigma^*$ described in Lemma 5.4. Let $\mathcal{R} = (R_n)_{n \geq 0}$ be a randomized SWA for L. Let $m \geq 0$. We describe a randomized one-way protocol P_m for GT_m: Let $i \in [1,m]$ be the input of Alice and $j \in [1,m]$ be the input of Bob. Let $n = |x| \cdot m + |u| \in \Theta(m)$. Alice starts by running the probabilistic automaton R_n on

$z^m y x^{m-i}$ using her random bits in order to simulate the random choices of R_n. Afterwards, she sends the encoding of the reached state to Bob. Bob then continues the run of R_n from the transmitted state with the word $x^j u$. Hence, R_n is simulated on the word $w := z^m y x^{m-i} x^j u = z^m y x^{m-i+j} u$. We have

$$\text{last}_n(w) = \begin{cases} z^{i-1-j} y x^{m-i+j} u, & \text{if } i > j, \\ x^m u, & \text{if } i \leq j. \end{cases}$$

By Lemma 5.4, $\text{last}_n(w)$ belongs to L in exactly one of the two cases $i > j$ and $i \leq j$. Hence Bob can distinguish these two cases with probability at least $2/3$. It follows that the protocol computes GT_m and its cost is bounded by $f(\mathcal{R}, n)$. We have $f(\mathcal{R}, |x| \cdot m + |u|) = f(\mathcal{R}, n) \geq \text{cost}(P_m) \in \Omega(\log m)$ and therefore $f(\mathcal{R}, n) \notin o(\log n)$.

5.2 Remaining lower bounds

The remaining lower bounds in Theorem 1.1–1.3 are shown by reductions from communication problems as well, with one exception:

- For Theorem 1.1(2) we reduce from the communication problem EQ_m, where Alice holds a number $i \in [1, m]$, Bob holds a number $j \in [1, m]$ and Bob has to verify whether $i = j$. It is known that $C(\text{EQ}_m) \in \Theta(\log \log m)$ [12].
- For Theorem 1.1(6) we reduce from the communication problem IDX_m, where Alice holds a bitstring $a_1 \cdots a_m$, Bob holds an index $i \in [1, m]$ and Bob has to output the bit a_i. By [11, Theorem 3.7] we know that $C(\text{IDX}_m) \in \Theta(m)$.
- For Theorem 1.2(2) we reduce from a promise variant of IDX_m. Let $D \subseteq \{0,1\}^m \times [1, m]$ such that for each $x \in \{0,1\}^m$ there exist at least $7/8 \cdot m$ pairs $(x, i) \in D$. We prove that IDX_m still has communication complexity $\Omega(m)$ if the inputs for Alice and Bob are restricted to D. This extends [11, Theorem 3.7] and allows us to incorporate the notion of failure ratio into a communication protocol.
- Theorem 1.3(2) is not shown via a reduction to a communication problem. Instead, we utilize a combinatorial result on the ability of DFAs to count up to a threshold n, modulo a failure ratio ϕ.

6 Further results

The technical report [9] contains several further results that we briefly want to discuss.

In this paper, we only considered randomized SWAs with a two sided error (analogously to the complexity class BPP). Randomized SWAs with a one-sided error (analogously to the class RP) can be motivated by applications, where all "yes" outputs have to be correct, but a small probability for a false negative answer is acceptable. We prove that for every regular language the optimal space bound with respect to randomized SWAs with one-sided error coincides (up to constant factors) with the optimal space bound in the deterministic setting [7, 8] (which was discussed in the introduction).

In the introduction (related work) we remarked that some authors use a stronger correctness notion for randomized SWAs, where for every input w, the probability that the algorithm produces some incorrect output while reading w is bounded by $1/3$. We show that for every approximation problem (where approximation problems are defined by specifying for every input string a set of possible output values) every randomized SWA that fulfills this stronger notion of correctness can be completely derandomized without a space increase.

Abstract

We consider the structure of aperiodic points in $\mathbb{Z}^2$-subshifts, and in particular the positions at which they fail to be periodic. We prove that if a $\mathbb{Z}^2$-subshift contains points whose smallest period is arbitrarily large, then it contains an aperiodic point. This lets us characterise the computational difficulty of deciding if an $\mathbb{Z}^2$-subshift of finite type contains an aperiodic point. Another consequence is that $\mathbb{Z}^2$-subshifts with no aperiodic point have a very strong dynamical structure and are almost topologically conjugate to some $\mathbb{Z}$-subshift. Finally, we use this result to characterize sets of possible slopes of periodicity for $\mathbb{Z}^3$-subshifts of finite type.

A subshift on $\mathbb{Z}^d$ is a set of colorings of $\mathbb{Z}^d$ by a finite set of colors avoiding some family of forbidden patterns. When this family is finite, the subshift is called a *subshift of finite type* (SFT). In dimension 2, SFTs are equivalent to sets of tilings by Wang tiles: Wang tiles are unit squares with colored borders that cannot be rotated and may be placed next to each other only if the borders match.

Wang tiles were introduced by Wang in order to study the decidability of some fragments of logic [18, 19]. He thus introduced the Domino Problem: given a set of Wang tiles, do they tile the plane? (in other words, is the corresponding subshift nonempty?) Wang first conjectured that whenever a tileset tiles the plane, it can do so in a periodic manner, which would have implied the decidability of the Domino Problem.

In dimension 1 the problem is decidable. A $\mathbb{Z}$-SFT corresponds to the set of biinfinite walks on some automaton and it tiles the line if and only if the automaton contains a cycle. Such a cycle provides a periodic point of the SFT, so non-empty $\mathbb{Z}$-SFTs always contain a periodic point. The situation is dramatically different in higher dimension. Berger [3] proved that there exists tilesets in dimension 2 that tile the plane only aperiodically, and that the Domino Problem was therefore undecidable.

Thus, from the start, periodicity and aperiodicity have been at the heart of the study of Wang tiles and SFTs, and the main tool in understanding their structural properties and the answer to various decision problems. To give a few examples:

- The presence of a dense set of periodic points is related to the decidability of the problem of deciding whether a given pattern appears in some point of an SFT [12].
- The finite subshifts on $\mathbb{Z}^d$ are exactly the subshifts containing only periodic configurations with d non-colinear vectors of periodicity [1, Theorem 3.8]. These configurations can be seen as finite configurations. This result has recently been extended to subshifts on groups [15].
- Countable SFTs always contain a finite configuration and if they are not finite, then they contain a configuration with exactly one vector of periodicity [1, Theorem 3.11].
- A subshift always contains a quasiperiodic configuration [4, 6], a configuration in which every finite pattern appears in any window of sufficiently large size depending only on the size of the pattern.

In this article we study the structure of aperiodic points in $\mathbb{Z}^2$-SFTs, and in particular the repartition of the coordinates where it avoids to be periodic. Our main result is:

▶ **Theorem 1.** *There exists a computable function f that satisfies the following. Assume X is a $\mathbb{Z}^2$-subshift such that for any finite set of periods P, X contains a configuration that avoids all periods of P. Then X contains an aperiodic point that avoids every period p at distance at most $f(\|p\|)$ from 0.*

This means that aperiodicity can be "organised" in concentric balls around a common center, in such a way that a proof of aperiodicity for any vector may be found near this center. As a consequence, when a subshift does not contain any aperiodic point, it must have a finite number of directions of periodicity:

▶ **Corollary 2.** *For any subshift X with no aperiodic point, there is a finite set of periods P such that any configuration of X is periodic for some period $p \in P$.*

This will lead to a further characterization of subshifts containing no aperiodic points in Section 3.2.

These results have a variety of consequences. Gurevich and Koryakov [8] proved that for $d \geq 2$ it is undecidable to know whether an SFT contains a periodic, resp. aperiodic configuration. While it is easy to see that checking whether an SFT contains a periodic configuration is a recursively enumerable problem (Σ_1^0 in the arithmetical hierarchy), it remained an open problem whether deciding if an SFT contains an aperiodic configuration was even in the arithmetical hierarchy. One of the consequences of Theorem 1 is that it is Π_1^0.

Periodicity is also a central topic of symbolic dynamics since sets of periods and directions of periodicity constitute conjugacy invariants. For example, we prove that a $\mathbb{Z}^2$-subshift with no aperiodic point has a very strong dynamical structure and is essentially equivalent (almost topologically conjugate) to some $\mathbb{Z}$-subshift, and this is true for SFTs as well. In particular, various classical decision problems are decidable for this class, its topological entropy is 0 and

its entropy dimension is at most 1. Sets of periods have also been studied and characterized through computability and complexity theory [9]. [16] recently proved that any Σ_2^0 set of $(\mathbb{Q} \cup \{\infty\})^2$ can be realized as a set of slopes of a $\mathbb{Z}^3$-SFT. Another consequence of Theorem 1 is that this becomes a characterization.

The article is organized as follows: Section 1 recalls some definitions and notations, Section 2 is devoted to the proof of Theorem 1, Section 3 is devoted to its consequences and Section 4 shows a counter example for $\mathbb{Z}^d$ subshifts when $d \geq 3$.

1 Definitions

Throughout the paper, we consider the distance on $\mathbb{Z}^d$ defined by the uniform norm $d(i,j) = ||i-j||_\infty$.

1.1 Subshifts

We provide here standard definitions about subshifts, which may be found in greater detail in [13].

The d-dimensional full shift is the set $\Sigma^{\mathbb{Z}^d}$ where Σ is a finite alphabet whose elements are called *letters* or *symbols*. Each element of $\Sigma^{\mathbb{Z}^d}$ is called a *configuration* or *point*. A configuration may be seen as a coloring of $\mathbb{Z}^d$ with the letters of Σ. For $v \in \mathbb{Z}^d$, the *shift function* $\sigma_v : \Sigma^{\mathbb{Z}^d} \to \Sigma^{\mathbb{Z}^d}$ is defined by $\sigma_v(x)_z = x_{z+v}$. The *full shift* equipped with the distance $d(x,y) = 2^{-\min\{\|v\| \mid v \in \mathbb{Z}^d, x_v \neq y_v\}}$ forms a compact metric space on which the shift functions act as homeomorphisms. A closed shift invariant subset X of $\Sigma^{\mathbb{Z}^d}$ is called a *subshift* or *shift*.

A *pattern* of shape Γ, where Γ is a finite subset of $\mathbb{Z}^d$, is an element of Σ^Γ or alternatively a function $p : \Gamma \to \Sigma$. A configuration x *avoids a pattern* γ of shape Γ if $\forall z \in \mathbb{Z}^d$, $\sigma_v(x)_{|\Gamma} \neq \gamma$ and *contains* γ if it does not avoid it.

For a family of forbidden patterns $\mathcal{F}$, denote $X_\mathcal{F}$ the set of configurations that avoid $\mathcal{F}$. Then $X_\mathcal{F}$ is a subshift, and every subshift can be defined in this way. When a subshift can be defined this way by a finite family, it is called a *subshift of finite type*. When a subshift can be defined by a recursively enumerable family of forbidden patterns, it is called an *effectively closed subshift*.

If X is a subshift, we denote by $\mathcal{L}(X)$ its *language*, *i.e.* the set of patterns that appear somewhere in one of its points.

▶ **Definition 3** (Periodicity). A configuration x is *periodic* of period v if there exists $v \in \mathbb{Z}^d \setminus \{(0,0)\}$ such that $\forall z \in \mathbb{Z}^d, x_z = x_{z+v}$. More precisely, a configuration is *k-periodic* if it has exactly k linearly independent periods. If a configuration has no period, then it is said to be *aperiodic*. A subshift is *aperiodic* if all its points are aperiodic.

Denote by $B(z,n)$ the ball of radius n centered in $z \in \mathbb{Z}^d$.

Let $x \in \Sigma^{\mathbb{Z}^d}$ and $p \in \mathbb{Z}^2$. If there exists $z \in \mathbb{Z}^2$ such that $x_z \neq x_{z+p}$, we say that x *avoids* period p. The pair $(z, z+p)$ is called an *avoidance* of period p in configuration x. We say that a configuration *avoids a set of periods* P if it avoids every period in P.

Let P be a set of periods. We denote P' the set obtained from P by replacing each period p by the least commun multiple of all periods of P that are colinear to p. More formally : $P' = \{\text{lcm}(q \mid q \in P \text{ and } q \text{ and } p \text{ are colinear}) \mid p \in P\}$. Observe that P' is a set of pairwise non-colinear periods.

Except in the last section, the subshifts we will be considering will implicitely be $\mathbb{Z}^2$-subshifts.

1.2 Arithmetical hierarchy

We give some basic definitions used in computability theory and in particular about the arithmetical hierarchy. More details may be found in [17].

Usually the arithmetical hierarchy is seen as a classification of sets according to their logical characterization. For our purpose we use an equivalent definition in terms of computability classes and Turing machines with oracles:

- $\Delta_0^0 = \Sigma_0^0 = \Pi_0^0$ is the class of recursive (or computable) problems.
- Σ_n^0 is the class of recursively enumerable (RE) problems with an oracle Π_{n-1}^0.
- Π_n^0 the complementary of Σ_n^0, or the class of co-recursively enumerable (coRE) problems with an oracle Σ_{n-1}^0.
- $\Delta_n^0 = \Sigma_n^0 \cap \Pi_n^0$ is the class of recursive (R) problems with an oracle Π_{n-1}^0.

In particular, Σ_1^0 is the class of recursively enumerable problems and Π_1^0 is the class of co-recursively enumerable problems.

2 Main result

This whole section is dedicated to the proof of the Theorem 1 and Corollary 2. Given a subshift that contains an aperiodic point, we prove that it contains some aperiodic point where all period avoidances are organised in concentric balls around a common center, in such a way that each period p is in a ball whose radius only depends on $\|p\|$. This result is used in a compactness argument to prove that, if a subshift contains configurations whose smallest period is arbitrarily large, then it contains an aperiodic point.

Actually, our algorithm can only gather avoidances in a small ball if all the periods are non-colinear. Fortunately we can easily build a set P'.

▶ **Lemma 4.** *Let P be a set of periods. Any configuration avoiding P' also avoids P.*

Proof. Each period p in P has an integer multiple $p' \in P'$. Each avoidance of p' induces an avoidance of p. ◀

▶ **Lemma 5.** *Let P be a set of pairwise non-colinear periods. Let x be a configuration avoiding P. Then x avoids every period of P in some ball of radius $\sum_{p\in P} \|p\|$.*

Proof. We prove the result by induction on the number of periods in P. When P is a singleton the case is trivial. Now suppose P is not a singleton. Denote $p_0, p_1, \dots, p_n$ the periods in P. By induction hypothesis, we can find a ball B_{n-1} of radius $\sum_{i<n} \|p_i\|$ centered in b_{n-1} containing avoidances for every period in P except p_n. Similarly, we find a ball B'_{n-1} of radius $\sum_{i>0} \|p_i\|$, centered in b'_{n-1} that contains avoidances of every period in P except p_0. We now show that either an avoidance of p_0 exists near a copy of B'_{n-1} or an avoidance of p_n exists near a copy of B_{n-1}.

Consider the ball $B(b_{n-1} + p_n, \sum_{i<n} \|p_i\|)$, the translated image of B_{n-1} by the vector p_n. Either $x_z = x_{z+p_n}$ for all $z \in B_{n-1}$, *i.e.* the two balls are filled the same way, or we found an avoidance $(z, z + p_n)$ with $z \in B_{n-1}$. In the latter case, the result is proved.

As depicted in Figure 1, this process can be iterated for both B'_{n-1} and B_{n-1} until either we find the necessary avoidance or the centers of the balls are close to each other: Since p_0 and p_n are not colinear, and assuming $\|p_n\| \geq \|p_0\|$, there exists $i, j \in \mathbb{Z}$ such that $\left\|b_{n-1} + ip_n - b'_{n-1} + jp_0\right\| \leq \left\|\frac{p_n}{2}\right\| + \left\|\frac{p_0}{2}\right\| < \|p_n\|$. We thus found a ball centered in $b'_{n-1} + jp_0$ and of radius $\sum_i \|p_i\|$ containing the two balls we translated, and therefore an avoidance of each period in P. Denote B_n this new ball and b_n its center. ◀

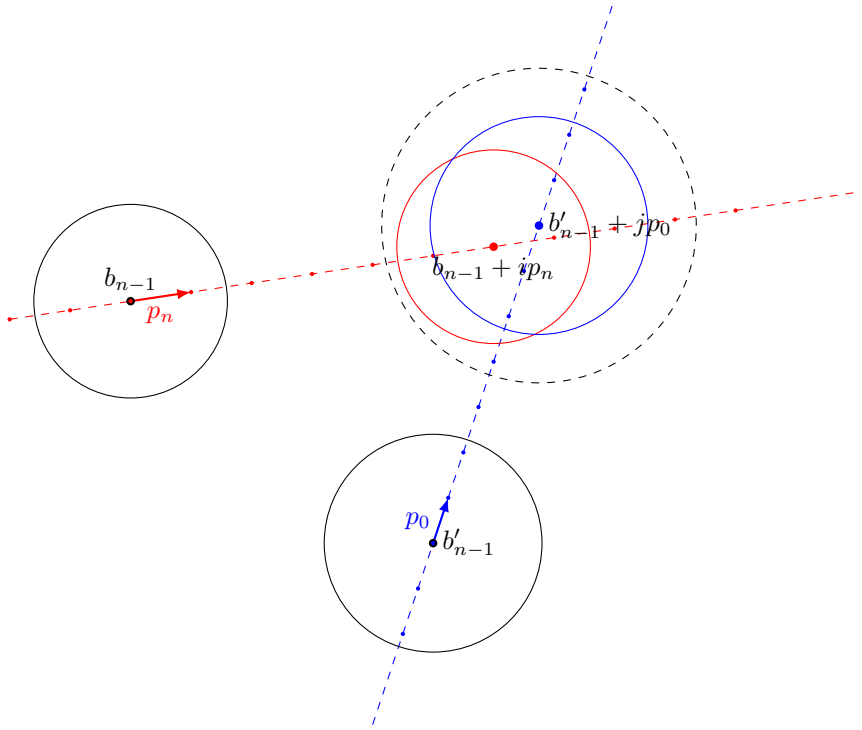

Figure 1 The process of translating B_{n-1} and B'_{n-1} close to each other: each translation may uncover the desired avoidance and if not, the two balls next to each other necessarily do so.

In the previous proof, the distance between b_{n-1} and b_n only depends on p_0, p_n and the distance between b_{n-1} and b'_{n-1}.

Therefore there is a computable function $f(p_0, p_n, r)$ such that, if b_{n-1} and b'_{n-1} belong to a common ball $B(z, r)$, then $\|b_n - z\| \leq f(p_0, p_n, r)$.

▶ **Lemma 6.** *Let $P = \{p_0, \dots, p_n\}$ be a set of non-colinear periods. Define $f'(P, r)$ recursively as:*

- *if $n = 0$, $f'(P, r) = r$;*
- *if $n > 1$, $f'(P, r) = f\big(p_0, p_n, \max\big[f'(P\backslash\{p_0\}, r), f'(P\backslash\{p_n\}, r)\big]\big)$*

Take $x \in X$, and assume that x avoids every period $p \in P$ in some ball $B(z, r)$. Then x avoids every period $p \in P$ in some ball $B(z', \sum_P \|p\|)$, with $\|z' - z\| \leq f'(P, r)$.

Proof. We prove the lemma by induction. If $n = 0$, the result is obvious.

Now assume $n > 1$. By applying the induction hypothesis twice on $p_0, \dots, p_{n-1}$ and $p_1, \dots, p_n$, we find two balls $B_{n-1} = B(b_{n-1}, \sum_{i<n} \|p_i\|)$ and $B'_{n-1} = B(b'_{n-1}, \sum_{i>0} \|p_i\|)$ such that $\|b_n - z\| \leq f'(P\backslash\{p_n\}, r)$ and $\|b'_n - z\| \leq f'(P\backslash\{p_0\}, r)$. Applying Lemma 5 on these balls, we obtain the desired ball with $\|b_n - z\| \leq f'(P, r)$. ◀

The next lemma states that in a configuration avoiding periods $p_1, \dots, p_n$, we can organise the avoidances in concentric balls around a common center, so that the distance of the avoidance of any given period from the center does not depend on n but only on the period itself.

▶ **Lemma 7.** *Let $P_n = \{p_0, \dots, p_n\}$ be a set of periods. Denote $P_i = \{p_0, \dots, p_i\}$ for $i \leq n$. Define recursively a function g such that*

$$g(\{p\}) = \|p\| \quad \text{and} \quad g(P_n) = g(P_{n-1}) + f'\left({P_{n-1}}', \sum_{{P_n}'} \|p\|\right) + \sum_{{P_n}'} \|p\|$$

Take x a point that avoids ${P_n}'$ in a ball $B(z, \sum_{{P_n}'} \|p\|)$. There exist $z' \in \mathbb{Z}^2$ such that:

- $\|z' - z\| \leq g(P_n)$
- *x avoids P_i in the ball $B(z', g(P_i))$ for any $i \leq n$.*

Proof. We proceed by induction on n.

If $n = 0$, then since $B(z, \|p_0\|)$ contains an avoidance of $P_0 = \{p_0\}$, taking z' to be this avoidance satisfies the requisite.

Assume $n > 0$. Since $B(z, \sum_{{P_n}'} \|p\|)$ contains avoidances of every period in ${P_n}'$, it contains avoidances of every period in ${P_{n-1}}'$. Indeed, if some period q is in ${P_{n-1}}'$ but not in ${P_n}'$, then by construction a multiple of q, say Mq, is in ${P_n}'$. Now if $(z_q, z_q + Mq)$ is an avoidance of Mq, at least one of $(z_q + mq, z_q + (m+1)q)$ for $m < M$ is an avoidance of q and is contained in the same ball.

Applying Lemma 6 on ${P_{n-1}}'$, we find a ball $B(z_0, \sum_{{P_{n-1}}'} \|p\|)$ that contains avoidances for all periods in ${P_{n-1}}'$ and such that $\|z_0 - z\| \leq f'({P_{n-1}}', \sum_{{P_n}'} \|p\|)$.

Now apply the induction hypothesis on this ball, obtaining z' such that $\|z' - z_0\| \leq g(P_{n-1})$ and for any $i \leq n-1$, the ball $B(z', g(P_i))$ contains avoidances of every period in P_i. This inductive process is depicted in Figure 2.

By the triangular inequality, $\|z' - z\| \leq g(P_{n-1}) + f'({P_n}', \sum_{{P_{n-1}}'} \|p\|)$. Since $g(P_n) \geq \|z - z'\| + \sum_{{P_n}'} \|p\|$, $B(z', g(P_n))$ contains entirely the ball $B(z, \sum_{{P_n}'} \|p\|)$. Therefore $B(z', g(P_n))$ avoids P_n and $\|z' - z\| \leq g(P_n)$, proving the lemma. ◀

▶ **Theorem 1.** *Let X be a $\mathbb{Z}^2$-subshift. Assume that for every finite set of periods P, X contains a configuration that avoids all periods of P.*

Then X contains an aperiodic configuration that has an avoidance of every period p at distance at most $g'(\|p\|) = g(B(0, \|p\|)')$ from 0, where g is the function defined in Lemma 7.

▶ Remark. g' is not polynomial because $B(0,n)'$ contains exponentially large vectors. Since our bounds are likely very far from sharp, we leave the exact computation to the reader.

Proof. Take $B(0,n)$ the set of periods of norm n or less and $x_1, \dots, x_n, \dots$ a sequence of configurations such that x_n avoids $B(0,n)'$.

By applying Lemma 5 on $B(0,n)'$, we obtain for each x_n a ball of radius $\sum_{B(0,n)'} \|p\|$ that avoids $B(0,n)'$. Applying Lemma 7 on $B(0,n)$, we get that x_n avoids all periods in $B(0,i)'$ in some ball $B(z_n, g(B(0,i))'))$ for all $i \leq n$. Since X is compact, any limit point of the sequence $(\sigma_{z_n}(x_n))_{n \in \mathbb{N}}$ is in X, and it avoids all periods in $B(0,i)$ in the ball $B(0, g(B(0,i)'))$ for all $i \in \mathbb{N}$. It is in particular aperiodic. ◀

▶ **Corollary 2.** *For any subshift X with no aperiodic point, there is a finite set of periods P such that any configuration of X is periodic for some period $p \in P$.*

Proof. This is a simple reciprocal to Theorem 1. ◀

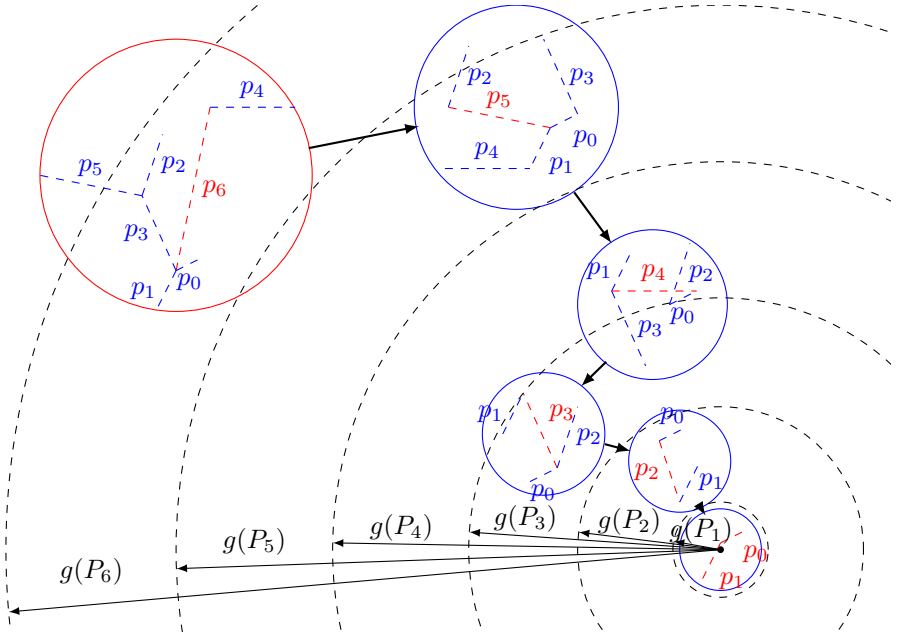

Figure 2 The red ball contains avoidance for $P_n{}'$. Each dashed line represents an avoidance. We then consider the set of blue lines, $P_{n-1}{}'$. We gather these avoidances in a close smaller ball with Lemma 6. We repeat this process until there are only two avoidances in the ball. The red avoidances are disposed in the way we wanted, around the center of the smallest blue ball.

3 Consequences

3.1 Existence of an aperiodic configuration is Π_1^0

▶ **Corollary 8.** *The following problem is Π_1^0-computable:*
Input *A finite set of forbidden patterns $\mathcal{F}$.*
Output *Does the $\mathbb{Z}^2$-SFT $X_\mathcal{F}$ contain an aperiodic configuration?*

Proof. Let $(p_i)_{i\in\mathbb{N}}$ be an enumeration of all possible periods and $P_n = \{p_0, \dots, p_n\}$. Theorem 1 gives us a bound on the size of the patterns in which to look for avoidances of each period. For each $n \in \mathbb{N}$ in order, the algorithm enumerates all patterns on a ball of radius $g(P_n)$ that do not contain a forbidden pattern, and check if one of them contains avoidances for every period of P_k ($k \leq n$) in the ball of radius $g(P_k)$ in its center. If such a pattern does not exist for some n, it means that either the SFT is empty or that all its points are periodic for some period p with $\|p\| \leq n$.

Assume the algorithm runs infinitely. For every k, there exists some $n \geq k$ such that if a pattern on the ball of radius $g(P_n)$ does not contain a forbidden pattern, then the subpattern on the ball of radius $g(P_k)$ is in the language of X. Therefore, for each P_k we find a pattern in $Ł(X)$ that avoids all periods of P_k, and we conclude by Theorem 1. ◀

3.2 Structure of subshifts without aperiodic points

In this subsection, we consider notions from dynamical system theory. A dynamical system is given by a pair (C, Φ) where C is a compact set and $\Phi : C \to C$ is a continuous function.

▶ **Definition 9** (Topological conjugacy). Let (C_1, Φ_1) and (C_2, Φ_2) be dynamical systems.

(C_1, Φ_1) and (C_2, Φ_2) are *topologically conjugate* if there exists a continuous bijection $\pi : C_1 \to C_2$ such that $\pi \circ \Phi_1 = \Phi_2 \circ \pi$.

(C_1, Φ_1) and (C_2, Φ_2) are *almost topologically conjugate* if there exists (C_3, Φ_3) and continuous surjections $\pi_i : C_3 \to C_i$ that are bijective almost everywhere[3] such that $\pi_i \circ \Phi_3 = \Phi_i \circ \pi_i$ for $i = 1, 2$.

See [13] or [11] for more information on topological conjugacy and almost conjugacy in the context of symbolic dynamics. We need slightly more general definitions since we consider subshifts of different dimensions.

Notice that we can have $(C_2, \Phi_2) = (C_3, \Phi_3)$ (and $\pi_2 = id$) in the last definition; this is the case in the next proof.

▶ **Theorem 10.** *Let X be a two-dimensional subshift with no aperiodic point. There exists a vector v and a one-dimensional subshift Y such that (X, σ_v) is almost topologically conjugate to (Y, σ).*

If X is of finite type, then Y can be chosen of finite type as well.

Proof. Let X be a two-dimensional subshift of finite type with no aperiodic point. By Corollary 2, there is a finite set of periods P such that any configuration of X is periodic of some period $p \in P$. We assume that P does not contain two colinear periods, by taking their least common integer multiple if necessary.

For the clarity of the argument, we assume in the following that P does not contain any period colinear to $(0, 1)$. Since P is finite, the proof can be adapted for a different vector.

Take $p = (p^0, p^1) \in P$, assuming $p^0 > 0$, and denote $X_p = \{x \in X : x \text{ admits } p \text{ as a period.}\}$. X_p is a closed set and it is a classical argument (see for instance [9, §2.1.2] or [2, Lemma 5.2]) that $(X_p, \sigma_{(0,1)})$ is topologically conjugate to a one-dimensional SFT, which we repeat here for completeness. Define:

$$\pi_p = \left\{ \begin{array}{ccc} \Sigma^{\mathbb{Z}^2} & \to & (\Sigma^{p^0-1})^{\mathbb{Z}} \\ x & \mapsto & ((x_{i,j})_{0 \le i < p^0})_{j \in \mathbb{Z}} \end{array} \right.$$

Denote $Y_p = \pi_p(X_p)$. It is not hard to see that π_p is a one-to-one continuous function between X_p and Y_p and that Y_p is a subshift of finite type if X_p is, since it can be defined by a finite recoding of the forbidden patterns of X_p. Furthermore, $\pi_p \circ \sigma_{(0,1)} = \sigma \circ \pi_p$, so it is a topological conjugacy between $(X_p, \sigma_{(0,1)})$ and (Y_p, σ).

For any $p_1 \neq p_2 \in P$, $X_{p_1} \cap X_{p_2}$ is a set of 2-periodic configurations that admit non-colinear periods p_1 and p_2; there are a finite number of such configurations, so $|X_{p_1} \cap X_{p_2}| < +\infty$. In other words, $X = \bigcup_{p \in P} X_p$ and the union is disjoint except for a finite set of configurations.

Denote $Y = \sqcup_{p \in P} Y_p$ (disjoint union). Y is a subshift on the alphabet $\sqcup_{p \in P} \Sigma_p$, where Σ_p is the alphabet of Y_p. Furthermore, Y is of finite type if every Y_p is of finite type.

Define $\varphi : Y \to X$ by $\varphi|_{Y_p} = \pi_p^{-1}$. We can check that φ is surjective and almost everywhere bijective, and that $\varphi \circ \sigma_1 = \sigma_{(0,1)} \circ \varphi$. We have proved that (Y, σ_1) is almost topologically conjugate to $(X, \sigma_{(0,1)})$. ◀

3.3 Various properties of subshifts with no aperiodic points

Theorem 10 implies that the property of having no aperiodic point gives a very strong structure to a subshift. This is particularly the case for subshifts of finite type, where many

[3] Except for a finite set of points.

problems that are indecidable in dimension 2 are completely solved in dimension 1, and these solutions carry through almost topological conjugacy.

In this section, we make use of notations that were defined in the proof of Theorem 10: X_p, Y_p, π_p and φ.

3.3.1 Decision problems

Decision problems have been a staple of the theory of multidimensional subshifts of finite type: the seminal paper of Wang proved that the emptiness problem (given a list of forbidden patterns $\mathcal{F}$, is $X_\mathcal{F} = \emptyset$?) is decidable for two-dimensional non-aperiodic subshifts of finite type, but Berger later proved that the problem was undecidable without this assumption [3]. We consider other classical decision problems: the extension problem, which is undecidable for multidimensional subshifts of finite type (as a consequence of the above), and the injectivity and surjectivity problems, which are undecidable even on the two-dimensional full shift [10].

A $\mathbb{Z}^d$-*cellular automaton* is a continuous function $F : \Sigma^{\mathbb{Z}^d} \to \Sigma^{\mathbb{Z}^d}$ that commutes with every shift function. It can be defined equivalently by a local rule $f : \Sigma^\Gamma \to \Sigma$ for a finite shape Γ by $F(x)_v = f(\sigma_v(x)_\Gamma)$ for all $v \in \mathbb{Z}^d$.

▶ **Corollary 11.** *The following problems are decidable for two-dimensional subshifts of finite type with no aperiodic point:*

Extension problem *given a list of forbidden patterns $\mathcal{F}$ and a pattern w, do we have $w \in \mathcal{L}(X_\mathcal{F})$?*

Injectivity / surjectivity problem *given a list of forbidden patterns $\mathcal{F}$ and a cellular automaton $\Phi : \Sigma^{\mathbb{Z}^2} \to \Sigma^{\mathbb{Z}^2}$, is $\Phi|_{X_\mathcal{F}}$ injective? surjective on $X_\mathcal{F}$?*

Links between periodic points and the above problems have already been considered in [12, 7].

Proof sketches.

Extension problem. Assume w has shape $[-n, n]^2$. By Theorem 10 we have $X = \varphi(Y)$ where φ is continuous on a compact space, hence uniformly continuous. In other words, for every n, there exists r such that the value of $\varphi(y)_{[-n,n]^2}$ only depends on $y_{[-r,r]}$. Since the extension problem is decidable on one-dimensional subshifts of finite type, enumerate all words $v \in \mathcal{L}(Y)$ and check whether $w = \varphi(v)$ for some v.

Injectivity problem. By Corollary 2, there is a finite set of periods P such that $X_\mathcal{F} = \bigcup_{p \in P} X_p$.

A cellular automaton is injective if and only if it is reversible. Since the image of a configuration of period p by a cellular automaton also has period p, we have $\Phi|_{X_\mathcal{F}}(X_p) \subset X_p$ and (in the injective case) $\Phi|^{-1}_{X_\mathcal{F}}(X_p) \subset X_p$. It follows that $\Phi|_{X_\mathcal{F}}$ is injective if, and only if, $\Phi|_{X_p}$ is injective for every period $p \in P$.

Let $\pi_p : X_p \to Y_p$ be the continuous bijection defined in the proof of Theorem 10. $\pi_p \circ \Phi|_{X_p} \circ \pi_p^{-1}$ is a CA on Y_p and it shares injectivity with $\Phi|_{X_\mathcal{F}}$. Injectivity of CA is decidable for one-dimensional subshifts of finite type [7].

Surjectivity problem. Surjectivity is more delicate as a point in $X_p \cap X_q$ can be the image of a point from X_p or X_q. However, $\Phi|_{X_\mathcal{F}}$ is surjective if and only if:

1. $\forall p \in P,\ \forall x \in X_p \setminus \bigcup_{p' \neq p} X_{p'},\ x \in \Phi|_{X_\mathcal{F}}(X_p)$;
2. $\forall p \neq p' \in P,\ \forall x \in X_p \cap X_{p'},\ \exists p'' \in P,\ x \in \Phi|_{X_\mathcal{F}}(X_{p''})$,

Denote $X^\cap$ the finite set of configurations in case 2 (notice that we do not necessarily have $p'' = p$ or $p'' = p'$ if x admits other periods as well).
As in the previous case, we translate these properties on Y_p and $\Phi_p = \pi_p \circ \Phi|_{X_p} \circ \pi_p^{-1}$ to work on $\mathbb{Z}$-SFT. Following [7], we can describe $\Phi_p(Y_p)$ by a finite automaton.
For case 1, add to the finite automaton describing $\Phi_p(Y_p)$ an independent cycle for each element of $X^\cap$ and determine whether the resulting automaton describe the same SFT as the automaton describing Y_p. This algorithm is explained in [13], Section 3.4.
For case 2, since $x \in X^\cap$ is 2-periodic, $\pi_p(x)$ is periodic, and it is easy to check by hand whether some $\Phi_p(Y_p)$ accepts x. Do this for all $x \in X^\cap$. ◀

▶ Remark. If we did not know that X admits a finite set of periods, the first proof would still show that the extension problem is in Σ_1^0 (RE). Since it is easy to show that it is in Π_1^0 (co-RE), our main result is technically unnecessary here.

3.3.2 Topological entropy

Topological entropy is a widely-used parameter in information theory (channel capacity) and dynamical systems theory (conjugacy invariant). Entropy dimension is a more refined notion for systems of entropy zero, introduced in [5] and mainly used for multidimensional subshifts [14].

▶ **Corollary 12.** *Any two-dimensional subshift X with no aperiodic point has zero topological entropy. Its entropy dimension is at most one.*

Proof sketch. By Corollary 2, there is a finite set of periods P such that $\mathcal{L}(X) = \bigcup_{p \in P} \mathcal{L}(X_p)$. Consider a pattern w of shape $[0, n-1]^2$ in $\mathcal{L}(X_p)$, assuming for clarity that $p = (p^0, p^1)$ with $p^0 \geq 0$ and $p^1 \geq 0$. Since w cannot contain an avoidance for p, it is entirely determined by its p^0 bottommost rows and p^1 leftmost columns. Therefore there are at most $(p^0 + p^1)n$ such patterns. A similar argument applies when $p^0 < 0$ or $p^1 < 0$.

It follows that there are at most $\sum_p (|p^0| + |p^1|)n$ patterns of shape $[0, n-1]^2$ in $\mathcal{L}(X)$, proving the statement. ◀

3.3.3 Density of periodic points

Density of periodic points is a typical question in dynamical systems, for example when studying chaos in the sense of Devaney. See [7] for more details, including a proof that two-dimensional subshifts of finite type do not have dense 2-periodic points in general, even under an additional irreducibility hypothesis.

X is *irreducible* (or *transitive*) if for any two patterns $\gamma_1,\ \gamma_2 \in \mathcal{L}(X)$ of shapes Γ_1 and Γ_2 respectively, there exists $x \in X$ and two coordinates v_1, v_2 such that $\sigma_{v_1}(x)_{\Gamma_1} = \gamma_1$ and $\sigma_{v_2}(x)_{\Gamma_2} = \gamma_2$.

▶ **Corollary 13.** *Any irreducible two-dimensional subshift of finite type X with no aperiodic point has dense 2-periodic points.*

Proof sketch. By Corollary 2, consider P a finite and minimal set of periods such that any configuration of X is periodic for some period $p \in P$. If P is not a singleton, take $p_1 \neq p_2 \in P$. There exists two finite patterns γ_1 and γ_2 that contain an avoidance of p_1 and p_2, respectively (otherwise, P would not be minimal). By irreducibility, there exists $x \in X$ where γ_1 and γ_2 both appear, and therefore x avoids every $p \in P$, a contradiction. Therefore P is a singleton $\{p\}$ and $X = X_p$ is conjugated to Y_p. One-dimensional irreducible subshifts of finite type, such as Y_p, have dense periodic points ([7], Proposition 9.1). The image by π_p^{-1} of a periodic point in Y_p is a 2-periodic point in X, from which the statement follows. ◀

3.4 The full caracterization of slopes of $\mathbb{Z}^3$-SFTs

Intuitively, slopes of a subshift are the directions that some configuration admits as a unique direction of periodicity. More formally:

▶ **Definition 14.** Let X be a $\mathbb{Z}^d$-subshift. $\theta \in (\mathbb{Q} \cup \infty)^{d-1}$ is a *slope of periodicity* of X if there exists a configuration $x \in X$ and a vector $v \in \mathbb{Z}^d$ such that:
- $v\mathbb{Z} = \{v' \mid \sigma_{v'}(x) = x\}$
- and $\theta_i = v_1/v_{i+1}$, for all $i \in \{0, \dots, d-1\}$.

The set of slopes of periodicity of a subshift is a conjugacy invariant. A consequence of Corollary 8 is that the sets of slopes of periodicity of $\mathbb{Z}^3$-SFTs is a Σ^0_2-computable set, and together with [16] this implies the following caracterization:

▶ **Theorem 15.** *Σ^0_2-computable subsets of $S \subseteq (\mathbb{Q} \cup \{\infty\})^2$ are exactly the sets realizable as sets of slopes of $\mathbb{Z}^3$-subshifts of finite type.*

Proof. We know from [16] that one can realize any such Σ^0_2 set S as a set of slopes of a $\mathbb{Z}^3$-subshift. Let us now show the remaining direction.

Given a slope θ and a set of forbidden patterns $\mathcal{F}$ as an input, we want to check whether there exists a configuration in $X_\mathcal{F}$ whose vectors of periodicity all have direction θ.

Using the notations of the proof of Theorem 10, for any $p \in \mathbb{Z}^2$, the set X_p of configurations of period p (for some $k > 0$) can be seen as a $\mathbb{Z}^2$-SFT Y computable from $\mathcal{F}$ and p.

There is a smallest vector p_θ such that all vectors of direction θ are integer multiples of it. Remark that θ is a slope of periodicity of $X_\mathcal{F}$ is and only if X_{kp_θ} contains an aperiodic configuration for some $k > 0$. By Corollary 8, checking whether X_{kp_θ} contains an aperiodic configuration for a given k is Π^0_1-computable. Therefore checking whether there is a $k > 0$ for which this holds is Σ^0_2-computable. ◀

4 Counterexample for dimensions $d > 2$

We build a counterexample to Theorem 1 in higher dimension. Take $\Sigma = \{0, 1\}$ and define X as follows:
- All symbols 1 must form lines of direction vector $(1, 0, 0)$ (horizontal) or $(0, 0, 1)$ (vertical);
- There is at most one vertical line;
- All horizontal lines are repeated periodically with period $(0, 0, n)$, where n is the distance of the vertical line to any horizontal line.

In particular, if there is no vertical line, then there is at most one horizontal line. To sum up, a subshift configuration can be :
1. all zeroes,
2. one horizontal line,
3. one vertical line, or
4. the situation depicted in Figure 3.

The configuration described in Figure 3 admits $(0, 0, n)$ as period, and no shorter period. In particular, for every finite set of periods P, X contains a configuration that avoids P (by taking n large enough). However, Σ admits no aperiodic point[4]. This example can easily be

[4] Notice that there cannot be a configuration with a single horizontal line and a single vertical line, which would be aperiodic.

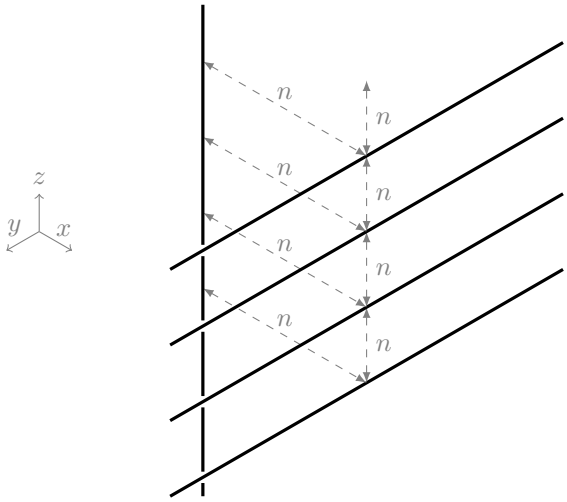

Figure 3 A typical configuration of X: a line of ones along z at distance n of an (xy) plane of lines along x. The only other types of configurations of X are the configurations containing either a single vertical line, a single horizontal line, or no line at all.

generalised to any $d > 3$ by considering a $\mathbb{Z}^d$-subshift X' that contains a copy of X in at most one coordinate, and 0 everywhere else: that is,

$$x \in X' \Leftrightarrow \forall j \in \mathbb{Z}^{d-3}, (x_{i,j})_{i\in\mathbb{Z}^3} \in X \text{ and } (\forall j_1 \neq j_2, (x_{i,j_1})_{i\in\mathbb{Z}^3} = 0 \text{ or } (x_{i,j_2})_{i\in\mathbb{Z}^3} = 0).$$

This proves that Theorem 1 does not hold in any dimension $d > 2$.

5 Open problems

We have made clear that our main result does not hold for subshifts of dimension $d \geq 3$. We do not know, however, whether Theorem 10 or Corollary 12 holds in higher dimension, since the counterexample introduced in Section 4 does not contradict these results.

This counterexample is a subshift containing points with arbitrarily large periods but no aperiodic point. We do not know whether such a counterexample with infinitely many directions of periodicity exist. Moreover, the structure of d-dimensional subshifts of finite type for $d \geq 3$ remains open; the existence of this counterexample suggests that a making use of the finite type hypothesis is necessary in higher dimension.
