To match our upper bound (1), we need two lower bounds. The lower bound of $\Omega(\frac{1}{\varepsilon^2}\log(1/\delta))$ is straightforward from the same lower bound as for distinguishing a fair coin from an ε-biased coin, while the $\sqrt{n\log(1/\delta)}/\varepsilon^2$ bound is more challenging.

For intuition, we start with a $\sqrt{n\log(1/\delta)}$ lower bound for constant ε. When $p = U_n$, the chance that all m samples are distinct is at least $(1-m/n)^m \approx e^{-m^2/n}$. Hence, if $m \ll \sqrt{n\log(1/\delta)}$, this would happen with probability significantly larger than 2δ. On the other hand, if p is uniform over a random subset of $n/2$ coordinates, the m samples will also all be distinct with probability $(1-2m/n)^m > 2\delta$. The two situations thus look the same with 2δ probability, so no tester could have accuracy $1-\delta$.

This intuition can easily be extended to include a $1/\varepsilon$ dependence, but getting the desired $1/\varepsilon^2$ dependence requires more work. First, we Poissonize the number of samples, so we independently see $\mathrm{Poi}(mp_i)$ samples of each coordinate i; with exponentially high probability, this Poissonization only affects the sample complexity by constant factors. Then, in the alternative hypothesis, we set each p_i independently at random to be $\frac{1\pm\varepsilon}{n}$. This has the unfortunate property that p no longer sums to 1, so it is a "pseudo-distribution" rather than an actual distribution. Still, it is exponentially likely to sum to $\Theta(1)$, and using techniques from [24, 10] this is sufficient for our purposes.

At this point, we are considering a situation where the number of times we see each coordinate is either $\mathrm{Poi}(m/n)$ or $\frac{1}{2}(\mathrm{Poi}((1-\varepsilon)\frac{m}{n}) + \mathrm{Poi}((1+\varepsilon)\frac{m}{n}))$, and every coordinate is independent of the others. These two distributions have Hellinger distance at least $\varepsilon^2 m/n$ in each coordinate. Then the composition property for Hellinger distance over n independent coordinates implies $m \geq \sqrt{n\log(1/\delta)}/\varepsilon^2$ is necessary for success probability $1-\delta$.

1.5 Notation

We write $[n]$ to denote the set $\{1,\ldots,n\}$. We consider discrete distributions over $[n]$, which are functions $p : [n] \to [0,1]$ such that $\sum_{i=1}^n p_i = 1$. We use the notation p_i to denote the probability of element i in distribution p. For $S \subseteq [n]$, we will denote $p(S) = \sum_{i\in S} p_i$. We will also sometimes think of p as an n-dimensional vector. We will denote by U_n the uniform distribution over $[n]$.

For $r \geq 1$, the ℓ_r-norm of a distribution is identified with the ℓ_r-norm of the corresponding vector, i.e., $\|p\|_r = (\sum_{i=1}^n |p_i|^r)^{1/r}$. The ℓ_r-distance between distributions p and q is defined as the the ℓ_r-norm of the vector of their difference. The total variation distance between distributions p and q is defined as $d_{\mathrm{TV}}(p,q) \stackrel{\mathrm{def}}{=} \max_{S\subseteq[n]} |p(S)-q(S)| = (1/2)\cdot\|p-q\|_1$. The Hellinger distance between p and q is $H(p,q) \stackrel{\mathrm{def}}{=} (1/\sqrt{2})\cdot\|\sqrt{p}-\sqrt{q}\|_2 = (1/\sqrt{2})\cdot\sqrt{\sum_{i=1}^n(\sqrt{p_i}-\sqrt{q_i})^2}$. We denote by $\mathrm{Poi}(\lambda)$ the Poisson distribution with parameter λ.

2 Sample-Optimal Uniformity Testing

In this section, we describe and analyze our optimal uniformity tester. Given samples from an unknown distribution p over $[n]$, our tester returns "YES" with probability $1-\delta$ if $p = U_n$, and "NO" with probability $1-\delta$ if $d_{\mathrm{TV}}(p,U_n) \geq \varepsilon$.

2.1 Our Test Statistic

We define a very natural statistic that yields a uniformity tester with optimal dependence on the domain size n, the proximity parameter ε, and the error probability δ. Our statistic is a thresholded version of the empirical total variation distance between the unknown distribution p and the uniform distribution. Our tester Test-Uniformity is described in the following pseudocode:

Algorithm Test-Uniformity$(p, n, \varepsilon, \delta)$
Input: sample access to a distribution p over $[n]$, $\varepsilon > 0$, and $\delta > 0$.
Output: "YES" if $p = U_n$; "NO" if $d_{\mathrm{TV}}(p, U_n) \geq \varepsilon$.

1. Draw $m = \Theta\left((1/\varepsilon^2) \cdot \left(\sqrt{n \log(1/\delta)} + \log(1/\delta)\right)\right)$ i.i.d. samples from p.
2. Let $X = (X_1, X_2, \ldots, X_n) \in \mathbb{Z}^n_{>0}$ be the histogram of the samples. That is, X_i is the number of times domain element i appears in the (multi-)set of samples.
3. Define the random variable $S = \frac{1}{2} \sum_{i=1}^{n} \left| \frac{X_i}{m} - \frac{1}{n} \right|$ and set the threshold

$$t = \mu(U_n) + C \cdot \begin{cases} \varepsilon^2 \cdot \frac{m^2}{n^2} & \text{for } m \leq n \\ \varepsilon^2 \cdot \sqrt{\frac{m}{n}} & \text{for } n < m \leq \frac{n}{\varepsilon^2} \\ \varepsilon & \text{for } \frac{n}{\varepsilon^2} \leq m \end{cases},$$

   where C is a universal constant (derived from the analysis of the algorithm), and $\mu(U_n)$ is the expected value of the statistic in the completeness case. (We can compute $\mu(U_n)$ in $O(m)$ time using the procedure in Appendix A of the full version.)
4. If $S \geq t$ return "NO"; otherwise, return "YES".

The main part of this section is devoted to the analysis of Test-Uniformity, establishing the following theorem:

▶ **Theorem 3.** *There exists a universal constant $C > 0$ such that the following holds: Given*

$$m \geq C \cdot (1/\varepsilon^2) \left(\sqrt{n \log(1/\delta)} + \log(1/\delta)\right)$$

samples from an unknown distribution p, Algorithm Test-Uniformity *is an (ε, δ)-tester for uniformity of distribution p.*

As we point out in Appendix A of the full version, the value $\mu(U_n)$ can be computed efficiently, hence our overall tester is computationally efficient. To prove correctness of the above tester, we need to show that the expected value of the statistic in the completeness case is sufficiently separated from the expected value in the soundness case, and also that the value of the statistic is highly concentrated around its expectation in both cases. In Section 2.2, we bound from below the difference in the expectation of our statistic in the completeness and soundness cases. The proof the desired concentration, which completes the proof of Theorem 3, is deferred to the full version.

2.2 Bounding the Expectation Gap

The expectation of the statistic in algorithm Test-Uniformity can be viewed as a function of the n variables $p_1, \ldots, p_n$. We denote this expectation by $\mu(p) \stackrel{\text{def}}{=} \mathbb{E}[S(X_1, \ldots, X_n)]$ when the samples are drawn from distribution p.

Our analysis has a number of complications for the following reason: the function $\mu(p) - \mu(U_n)$ is a linear combination of sums that have no indefinite closed form, even if the distribution p assigns only two possible probabilities to the elements of the domain. This statement is made precise in Appendix B of the full version. As such, we should only hope to obtain an approximation of this quantity.

A natural approach to try and obtain such an approximation would be to produce separate closed form approximations for $\mu(p)$ and $\mu(U_n)$, and combine these quantities to obtain an approximation for their difference. However, one should not expect such an approach to work in our context. The reason is that the difference $\mu(p) - \mu(U_n)$ can be much smaller than $\mu(p)$ and $\mu(U_n)$; it can even be arbitrarily small. As such, obtaining separate approximations of $\mu(p)$ and $\mu(U_n)$ to any fixed accuracy would contribute too much error to their difference.

To overcome these difficulties, we introduce the following technique, which is novel in this context. We directly bound from below the difference $\mu(p) - \mu(U_n)$ using *strong convexity*. Specifically, we show that the function μ is strongly convex with appropriate parameters and use this fact to bound the desired expectation gap. The main result of this section is the following lemma:

▶ **Lemma 4.** *Let p be a distribution over $[n]$ and $\varepsilon = d_{\mathrm{TV}}(p, U_n)$. For all $m \geq 6$ and $n \geq 2$, we have that:*

$$\mu(p) - \mu(U_n) \geq \Theta(1) \cdot \begin{cases} \varepsilon^2 \cdot \frac{m^2}{n^2} & \text{for } m \leq n \\ \varepsilon^2 \cdot \sqrt{\frac{m}{n}} & \text{for } n < m \leq \frac{n}{\varepsilon^2} \\ \varepsilon & \text{for } \frac{n}{\varepsilon^2} \leq m \end{cases} .$$

We note that the bounds in the right hand side above are tight, up to constant factors. Any asymptotic improvement would yield a uniformity tester with sample complexity that violates our tight information-theoretic lower bounds.

The proof of Lemma 4 (which will be deferred to the full version) requires a couple of important intermediate lemmas. Our starting point is as follows: By the intermediate value theorem, we have the quadratic expansion

$$\mu(p) = \mu(U_n) + \nabla\mu(U_n)^\intercal (p - U_n) + \frac{1}{2}(p - U_n)^\intercal H_{p'} (p - U_n) \,,$$

where $H_{p'}$ is the Hessian matrix of the function μ at some point p' which lies on the line segment between U_n and p. This expression can be simplified as follows: First, we show that our μ is minimized over all probability distributions on input U_n (see the full version of the paper for details). Thus, the gradient $\nabla\mu(U_n)$ must be orthogonal to being a direction in the space of probability distributions. In other words, $\nabla\mu(U_n)$ must be proportional to the all-ones vector. More formally, since μ is symmetric its gradient is a symmetric function, which implies it will be symmetric when given symmetric input. Moreover, $(p - U_n)$ is a direction within the space of probability distributions, and therefore sums to 0, making it orthogonal to the all-ones vector. Thus, we have that $\nabla\mu(U_n)^\intercal (p - U_n) = 0$, and we obtain

$$\mu(p) - \mu(U_n) = \frac{1}{2}(p - U_n)^\intercal H_{p'} (p - U_n) \geq \frac{1}{2}\|p - U_n\|_2^2 \cdot \sigma \geq \frac{1}{2}\|p - U_n\|_1^2 / n \cdot \sigma \,, \tag{2}$$

where σ is the minimum eigenvalue of the Hessian of μ on the line segment between U_n and p.

The majority of this section is devoted to proving a lower bound for σ. Before doing so, however, we must first address a technical consideration. Because we are considering a function over the space of probability distributions – which is not full-dimensional – the

Hessian and gradient of μ with respect to $\mathbb{R}^n$ depend not only on the definition of our statistic S, but also its parameterization. For the purposes of this subsection, we parameterize S as $S(x) = \sum_{i=1}^{n} \max\left\{\frac{x_i}{m} - \frac{1}{n}, 0\right\} = \frac{1}{m}\sum_{i=1}^{n} \max\left\{x_i - \frac{m}{n}, 0\right\}$.

In the analysis we are about to perform, it will be helpful to replace $\frac{m}{n}$ with a free parameter t which we will eventually set back to roughly m/n. Thus, we define

$$S_t(x) \triangleq \frac{1}{m}\sum_{i=1}^{n} \max\{x_i - t, 0\}$$

and

$$\mu_t(p) \triangleq \mathbb{E}_{x\sim\text{Multinomial}(m,p)}[S_t(x)] = \frac{1}{m}\sum_{i=1}^{n}\sum_{k=\lceil t\rceil}^{m}\binom{m}{k}p_i^k(1-p_i)^{m-k}(k-t)\ . \tag{3}$$

Note that when $t = m/n$ we have $S_t = S$ and $\mu_t = \mu$. Also note that when we compute the Hessian of $\mu_t(p)$, we are treating $\mu_t(p)$ as a function of p and not of t. In the following lemma, we derive an exact expression for the entries of the Hessian. This result is perhaps surprising in light of the likely nonexistence of a closed form expression for $\mu(p)$. That is, while the expectation $\mu(p)$ may have no closed form, we prove that the Hessian of $\mu(p)$ does in fact have a closed form.

▶ **Lemma 5.** *The Hessian of $\mu_t(p)$ viewed as a function of p is a diagonal matrix whose ith diagonal entry is given by*

$$h_{ii} = s_{t,i}\ ,$$

where we define $s_{t,i}$ as follows: Let Δt be the distance of t from the next largest integer, i.e., $\Delta t \triangleq \lceil t\rceil - t$. Then, we have that

$$s_{t,i} = \begin{cases} 0 & \text{for } t = 0 \\ (m-1)\binom{m-2}{t-1}p_i^{t-1}(1-p_i)^{m-t-1} & \text{for } t \in \mathbb{Z}_{>0} \\ \Delta t\cdot s_{\lfloor t\rfloor,i} + (1-\Delta t)\cdot s_{\lceil t\rceil,i} & \text{for } t \geq 0 \text{ and } t \notin \mathbb{Z} \end{cases}.$$

In other words, we will derive the formula for integral $t \geq 1$ and then prove that the value for nonintegral $t \geq 0$ can be found by linearly interpolating between the closest integral values of t.

Proof. Note that because $S_t(x)$ is a separable function of x, $\mu_t(p)$ is a separable function of p, and hence the Hessian of $\mu_t(p)$ is a diagonal matrix. By Equation 3, the i-th diagonal entry of this Hessian can be written explicitly as the following expression:

$$s_{t,i} = \frac{\partial^2}{\partial p_i^2}\mu_t(p) = \frac{d^2}{dp_i^2}\frac{1}{m}\sum_{k=\lceil t\rceil}^{m}\binom{m}{k}p_i^k(1-p_i)^{m-k}(k-t)\ .$$

Notice that if we sum starting from $k = 0$ instead of $k = \lceil t\rceil$, then the sum equals the expectation of $\text{Bin}(m, p_i)$ minus t. That is, notice that:

$$\frac{\mathrm{d}^2}{\mathrm{d}p_i^2}\frac{1}{m}\sum_{k=0}^{m}\binom{m}{k}p_i^k(1-p_i)^{m-k}(k-t) = \frac{\mathrm{d}^2}{\mathrm{d}p_i^2}\frac{1}{m}(p_i m - t) = 0\ .$$

By this observation and the fact that the summand is 0 for integer t when $k = t$, we can switch which values of k we are summing over to k from 0 through $\lfloor t \rfloor$ if we negate the expression:

$$s_{t,i} = \frac{\partial^2}{\partial^2 p_i}\mu_t(p) = \frac{1}{m}\frac{\mathrm{d}^2}{\mathrm{d}p_i^2}\sum_{k=0}^{\lfloor t \rfloor}\binom{m}{k}p_i^k(1-p_i)^{m-k}(t-k) \; .$$

We first prove the case when $t \in \mathbb{Z}_+$. In this case, we view $s_{t,i}$ as a sequence with respect to t (where i is fixed), which we denote s_t. We now derive a generating function for this sequence.[5] Observe that derivatives that are not with respect to the formal variable commute with taking generating functions. Then, the generating function for the sequence $\{s_t\}$ is

$$\frac{\mathrm{d}^2}{\mathrm{d}p_i^2}\frac{1}{m}\left(x\frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{(p_i x + 1 - p_i)^m}{1-x}\right) - \frac{x\frac{\mathrm{d}}{\mathrm{d}x}(p_i x + 1 - p_i)^m}{1-x}\right) = (m-1)(p_i x + 1 - p_i)^{m-2}x \; .$$

Note that the coefficient on x^0 is 0, so $s_{0,i} = 0$ as claimed. For $t \in \mathbb{Z}_{>0}$, the right hand side is the generating function of

$$(m-1)\binom{m-2}{t-1}p^{t-1}(1-p)^{m-t-1} \; .$$

Thus, this expression gives the i-th entry Hessian in the $t \in \mathbb{Z}_{\geq 0}$, as claimed.

Now consider the case when t is not an integer. In this case, we have:

$$\begin{aligned}
s_{t,i} &\triangleq \frac{\mathrm{d}^2}{\mathrm{d}p_i^2}\frac{1}{m}\sum_{k=\lceil t \rceil}^{m}\binom{m}{k}p_i^k(1-p_i)^{m-k}(k-t) \\
&= \frac{\mathrm{d}^2}{\mathrm{d}p_i^2}\frac{1}{m}\sum_{k=\lceil t \rceil}^{m}\binom{m}{k}p_i^k(1-p_i)^{m-k}(k-\lceil t \rceil + \Delta t) \\
&= s_{\lceil t \rceil,i} + \Delta t\frac{\mathrm{d}^2}{\mathrm{d}p_i^2}\frac{1}{m}\sum_{k=\lceil t \rceil}^{m}\binom{m}{k}p_i^k(1-p_i)^{m-k}. \\
&= s_{\lceil t \rceil,i} - \Delta t\frac{\mathrm{d}^2}{\mathrm{d}p_i^2}\frac{1}{m}\sum_{k=0}^{\lceil t \rceil - 1}\binom{m}{k}p_i^k(1-p_i)^{m-k} \; .
\end{aligned}$$

The last equality is because if we change bounds on the sum so they are from 0 through m, we get 1 which has partial derivative 0. Thus, we can flip which terms we are summing over if we negate the expression.

Note that this expression we are subtracting above can be alternatively written as:

$$\Delta t\frac{\mathrm{d}^2}{\mathrm{d}p_i^2}\frac{1}{m}\sum_{k=0}^{\lceil t \rceil - 1}\binom{m}{k}p_i^k(1-p_i)^{m-k} = \Delta t \cdot (s_{\lceil t \rceil,i} - s_{\lfloor t \rfloor,i}) \; .$$

Thus, we have

$$s_{t,i} = s_{\lceil t \rceil,i} - \Delta t \cdot (s_{\lceil t \rceil,i} - s_{\lfloor t \rfloor,i}) = \Delta t \cdot s_{\lfloor t \rfloor,i} + (1 - \Delta t) \cdot s_{\lceil t \rceil,i} \; ,$$

as desired. This completes the proof of Lemma 5. ◀

[5] To avoid potential convergence issues, we view generating functions as formal polynomials from the ring of infinite formal polynomials. Under this formalism, there is no need to deal with convergence at all.

It will be convenient to simplify the exact expressions of Lemma 5 into something more manageable. This is done in the following lemma:

▶ **Lemma 6.** *Fix any constant $c > 0$. The Hessian of $\mu(p)$, viewed as a function of p, is a diagonal matrix whose i-th diagonal entry is given by*

$$h_{ii} = s_{t:=m/n,i} \geq \Theta(1) \cdot \begin{cases} \frac{m^2}{n} & \text{for } m \leq n \\ \sqrt{mn} & \text{for } n < m \leq c \cdot \frac{n}{\varepsilon^2} \end{cases},$$

assuming $p_i = \frac{1 \pm \varepsilon}{n}$, $m \geq 6$, $n \geq 2$, and $\varepsilon \leq 1/2$.

Similarly, these bounds are tight up to constant factors, as further improvements would violate our sample complexity lower bounds.

Proof. By Lemma 5, we have an exact expression $s_{t,i}$ for the ith entry of the Hessian of $\mu_t(p)$.

First, consider the case where $m \leq n$. Then we have

$$s_{t,i} = (1 - \Delta t) \cdot s_{\lceil t \rceil, i} \, .$$

Substituting $t = m/n$, $\lceil t \rceil = 1$, and $\Delta t = \lceil t \rceil - t = 1 - m/n$ gives

$$s_{t,i} = \frac{m}{n} \cdot (m-1)(1-p_i)^{m-2} = \Theta(1) \cdot \frac{m^2}{n} \, .$$

Now consider the case where $n < m \leq \Theta(1) \cdot \frac{n}{\varepsilon^2}$. Note that the case where $n < m < 2n$ follows from (i) the fact that $s_{t,i}$ for fractional t linearly interpolates between the value of $s_{t',i}$ the nearest two integral values of t' and (ii) the analyses of the cases where $m \leq n$ and $2n \leq m \leq \Theta(1)\frac{n}{\varepsilon^2}$. Thus, all we have left to do is prove the case where $2n \leq m \leq \Theta(1) \cdot \frac{n}{\varepsilon^2}$.

Since $s_{t,i}$ is a convex combination of $s_{\lceil t \rceil, i}$ and $s_{\lfloor t \rfloor, i}$, it suffices to bound from below these quantities for $t = m/n$. Both of these tasks can be accomplished simultaneously by bounding from below the quantity $s_{t=m/n+\gamma,i}$ for arbitrary $\gamma \in [-1, 1]$.

We do this as follows: Let $t = m/n + \gamma$. Using Stirling's approximation, we can show that for any $\gamma \in [-1, 1]$, we get:

$$s_{t,i} \geq \Theta(1) \cdot \sqrt{mn}$$

The calculations are deferred to the full version. ◀

3 Conclusions and Future Work

In this paper, we gave the first uniformity tester that is sample-optimal, up to constant factors, as a function of the confidence parameter. Our tester is remarkably simple and our novel analysis may be useful in other related settings. By using a known reduction of identity to uniformity, we also obtain the first sample-optimal identity tester in the same setting.

Our result is a step towards understanding the behavior of distribution testing problems in the high-confidence setting. We view this direction as one of fundamental theoretical and important practical interest. A number of interesting open problems remain. Perhaps the most appealing one is to design a *general technique* (see, e.g., [10]) that yields sample-optimal testers in the high confidence regime for a wide range of properties. From the practical standpoint, it would be interesting to perform a detailed experimental evaluation of the various algorithms (see, e.g., [16, 2]).

Approximating All-Pair Bounded-Leg Shortest Path and APSP-AF in Truly-Subcubic Time

Abstract

In the bounded-leg shortest path (BLSP) problem, we are given a weighted graph G with nonnegative edge lengths, and we want to answer queries of the form "what's the shortest path from u to v, where only edges of length $\leq L$ are considered?". A more general problem is the APSP-AF (all-pair shortest path for all flows) problem, in which each edge has two weights – a length d and a capacity f, and a query asks about the shortest path from u to v where only edges of capacity $\geq f$ are considered.

In this article we give an $\tilde{O}(n^{(\omega+3)/2}\epsilon^{-3/2}\log W)$ time algorithm to compute a data structure that answers APSP-AF queries in $O(\log(\epsilon^{-1}\log(nW)))$ time and achieves $(1+\epsilon)$-approximation, where $\omega < 2.373$ is the exponent of time complexity of matrix multiplication, W is the upper bound of integer edge lengths, and n is the number of vertices. This is the first truly-subcubic time algorithm for these problems on dense graphs. Our algorithm utilizes the $O(n^{(\omega+3)/2})$ time max-min product algorithm [Duan and Pettie 2009]. Since the all-pair bottleneck path (APBP) problem, which is equivalent to max-min product, can be seen as all-pair reachability for all flow, our approach indeed shows that these problems are almost equivalent in the approximation sense.

1 Introduction

The shortest path problem is one of the most fundamental problems in algorithmic graph theory. In this paper we study one of its variants, the apBLSP(all-pair *bounded-leg* shortest path), and a more general problem, the APSP-AF(all-pair shortest path for all flows) problem.

In apBLSP, we are given a weighted graph G, and we want to find the shortest path from u to v when only using edges with length no more than L. Answering one such query is easy: just discard edges with length $> L$ and run a shortest-path algorithm. So we consider that there are many queries (u, v, L), and we need to preprocess the graph G to answer these queries efficiently.

The apBLSP problem is a special case of the APSP-AF problem. In the APSP-AF problem, we're given a directed graph G, and each edge has a *length* d and a *capacity* f. Let W and K be the maximum length and maximum capacity, respectively. We assume that all lengths are nonnegative integers. The length of a path is the sum of lengths of all its edges, while the capacity of a path is the minimum capacity over its edges. The goal

is to compute from G a data structure that handles such queries: given $u, v \in V(G)$ and $1 \leq f \leq K$, determine the shortest path (in terms of length) from u to v with capacity at least f. We call the length of this shortest path "distance from i to j under flow constraint f". Given an instance of the apBLSP problem, we can give the capacity of edges in the order reversely as the order of their lengths, then the apBLSP is easily reducible to APSP-AF.

We consider data structures whose query algorithm uses *no* arithmetic operations. In other words, such a data structure would precompute the answers for all possible queries and store them up. As observed in [7], any such data structure requires $\Omega(n^4)$ space to report the exact answer. It's easy to come up with an $O(n^4)$ exact algorithm: let $\delta(i, j, f)$ be the distance from i to j under flow constraint f, we add edges in descending order of their capacities, and when we add an edge e from i to j with length d and capacity f, we set

$$\delta(i', j', f) \leftarrow \min\{\delta(i', j', f_0), \delta(i', i, f_0) + d + \delta(j, j', f_0)\}, \forall i', j' \in V,$$

where f_0 is the capacity of the last edge we added before e. In this sense, the exact version of APSP-AF is not very interesting. In the approximation setting, what we would like to compute is actually a *df*-matrix[2] A, which is a matrix whose entries are sets of pairs (d, f). The answer to the query (i, j, f) is simply $\min\{d : (d, f') \in A_{ij}, f' \geq f\}$, and can be computed in $O(\log |A_{ij}|)$ time by binary search. The data structure achieves a stretch of $(1 + \epsilon)$ if for any possible query (i, j, f), the returned value is in $[D, (1 + \epsilon)D]$ where D is the actual APSP-AF distance.

Related work. The bounded-leg shortest path problem was firstly considered by Bose *et al.* [4], where they showed that a data structure of size $O(\epsilon^{-1}n^2 \log n)$ can be constructed in $O(n^5)$ time to $(1 + \epsilon)$-approximate the bounded-leg length in Euclidean graphs; if explicit paths are required, their data structure needs $O(\epsilon^{-1}n^3 \log n)$ size. They also gave a data structure of size $O(n^{5/2})$ computable in $O(n^{5/2})$ time to support exact apBLSP queries in planar graphs. Roditty and Segal [11] showed a $(1 + \epsilon)$-approximate data structure for general graphs, which has size $\tilde{O}(n^{2.5})$ and can be computed in $\tilde{O}(n^4)$ time.[3] They also obtained a $(1 + \epsilon)$-approximate data structure for apBLSP in any l_p-metric, which has size $O(n^2 \log n)$ and is computable in $O(n^3(\log^3 n + \log^2 n \cdot \epsilon^{-d}))$ time. In [7], Duan and Pettie improved the time complexity for general graphs to $O(n^3 \log^3 n)$ and the space complexity to $O(\epsilon^{-1}n^2 \log n)$. For planar directed graphs, they also gave a data structure with size $O(kn^{1+1/k})$ that answers bounded-leg reachability queries in $\tilde{O}(n^{\frac{k-1}{2k}})$ time, for any integer $k \geq 2$.

The APSP-AF problem was introduced by Shinn and Takaoka [12, 13, 14, 15]. In graphs with unit edge lengths, they showed an $O(\sqrt{K}n^{(\omega+9)/4})$ exact algorithm. In general graphs, they showed exact algorithms of running time $O(Kn^3)$, $\tilde{O}(\sqrt{K}W^{(\omega+5)/4}n^{(\omega+9)/4})$ and $O(m^2n + \min(nW, mn^2 \log \frac{W}{mn}))$ respectively.

We can also view APSP-AF as an *offline* version of partially dynamic shortest path problem: edge insertions and distance queries appear by descending order of f, and we know the whole sequence of insertions and queries at the beginning of algorithm. Most works on dynamic shortest path problem are *online*: the sequence of operations and queries must be processed in order. In *incremental* setting, Ausiello *et al.* [1] showed an algorithm to handle all pair distance queries and edge insertions in a digraph in $O(Wn^3 \log(nW))$ time. In *decremental* setting, Bernstein [3] showed a $(1+\epsilon)$-approximate algorithm with a total running

[2] See section 2.2.
[3] $\tilde{O}$ hides poly$(\log n)$ factor.

time of $\tilde{O}(mn\epsilon^{-1}\log R)$ in weighted digraphs, where R is the ratio of the largest weight that was ever seen in the graph to the smallest such weight. For unweighted digraphs, Baswana, Hariharan and Sen [2] showed a randomized algorithm with $O(\min(n^{3/2}m\sqrt{\log n}, n^3\log^2 n))$ total update time which returns exact answers w.h.p, and a $(1+\epsilon)$-approximate algorithm with $O(nm\epsilon^{-2}\log n + n^2\epsilon^{-1}\sqrt{m\log n})$ total update time. More results can be found in surveys [6, 10]. However, the online setting has its disadvantages: in both incremental and decremental settings, even a reachability oracle in a truly-subcubic total time would refute the OMV conjecture [9].

Our algorithm relies on fast algorithms for max-min product. The first truly-subcubic time algorithm for max-min product was discovered by Vassilevska, Williams and Yuster [16], which has running time $O(n^{2+\omega/3})$. Subsequently, Duan and Pettie [8] improved this algorithm to $O(n^{(\omega+3)/2})$ time.

Our contribution. We show that a data structure for APSP-AF within stretch $(1+\epsilon)$ can be computed in $\tilde{O}(n^{(\omega+3)/2}\epsilon^{-3/2}\log W)$ time for any n-vertex graph and any $\epsilon > 0$, where $\omega < 2.373$ is the exponent of time complexity of matrix multiplication [5]. This is the first truly-subcubic time (*i.e.* $O(n^{3-\delta}\mathrm{poly}(\epsilon^{-1}, \log W))$ for some $\delta > 0$) algorithm to approximate apBLSP or APSP-AF problem in general graphs when $m = \Theta(n^2)$ and $W = \Omega(n)$. Our data structure uses $O(n^2\epsilon^{-1}\log n \log(nW))$ space.

We also establish the equivalence between approximating APSP-AF and computing max-min product. In particular, it's shown in Section 3 that if the max-min product of two matrices can be computed in $T(n)$ time, then a $(1+\epsilon)$-approximate data structure for APSP-AF can be computed in $\tilde{O}(T(n)\epsilon^{-2}\log W)$ time. This is optimal up to $\mathrm{poly}(\epsilon^{-1}, \log n, \log W)$ factors in the sense that APSP-AF approximation is at least as hard as max-min product. In fact, max-min product is reducible to the special case of *bounded-leg reachability problem* where the goal is only to query if u can reach v via edges of capacity $\geq f$. [4] Consider computing the max-min product of two $n \times n$ matrices A, B. We construct a directed graph $G = (V, E)$ with $3n$ vertices $V = \{u_1, u_2, \ldots, u_n, v_1, v_2, \ldots, v_n, w_1, w_2, \ldots, w_n\}$. For every i, j, link an edge from u_i to v_j with capacity A_{ij} and link an edge from v_i to w_j with capacity B_{ij}. Let C be the max-min product of A and B, then $C_{ij} \geq f$ iff w_j is reachable from u_i by edges of capacity $\geq f$.

2 Preliminaries

We denote $[n] = \{1, \ldots, n\}$, $[n]_0 = [n] \cup \{0\}$, $\min(\varnothing) = +\infty, \max(\varnothing) = -\infty$. Rows and columns of matrices are numbered from 1 to n. Let $\omega < 2.373$ be the exponent of time complexity of matrix multiplication. For a set of $m \times n$ matrices $\{A_i\}$, $\min\{A_i\}$ is the entry-wise minimum of them. Let W, K be the upper bound of lengths and capacities of edges, respectively; *i.e.* for any edge, its length is in $[W]_0$ and its capacity is in $[K]$.

2.1 Matrix products

We introduce the *distance product* and *max-min product* for two matrices, denoted as $\star$ and $\circledvee$ respectively.

[4] It should be "edges of length $\leq L$" for bounded-leg reachability problem; However this constraint is equivalent.

▶ **Definition 2.1.** For two matrices A, B of size $n \times n$, we define:

$$(A \star B)_{ij} = \min_{k\in[n]}\{A_{ik} + B_{kj}\};$$
$$(A \circledcirc B)_{ij} = \max_{k\in[n]}\{\min\{A_{ik}, B_{kj}\}\}.$$

A simpler version of our algorithm in Section 3, which runs in $\tilde{O}(n^{(\omega+3)/2}\epsilon^{-2}\log W)$, makes use of max-min product algorithm [8] for two matrices.

▶ **Lemma 2.2** ([8]). *There is an algorithm that, given two $n \times n$ matrices A and B, compute $A \circledcirc B$ in $O(n^{(\omega+3)/2})$ time.*

We also need the following lemma, stating that the distance product of matrices with large entries can be approximated by several distance products of matrices with small entries:

▶ **Lemma 2.3** (Lemma 5.1 of [17]). *Suppose A, B are two matrices whose entries are in $[M]_0 \cup \{+\infty\}$, $C = A \star B$. Let R be a power of 2, and* Scale(A, M, R) *be a matrix A' such that*

$$A'_{ij} = \begin{cases} \lceil RA_{ij}/M \rceil & \text{if } 0 \le A_{ij} \le M \\ +\infty & \text{otherwise} \end{cases}.$$

Define C' as:

$$C' = \min_{\lfloor \log_2 R\rfloor \le r \le \lceil \log_2 M\rceil} \{(2^r/R)\cdot(\textsc{Scale}(A, 2^r, R) \star \textsc{Scale}(B, 2^r, R))\}$$

Then for any i, j, $C_{ij} \le C'_{ij} \le (1 + \frac{4}{R})C_{ij}$.

2.2 The distance/flow pairs and their operations

We introduce the notion of *df-pairs* in [12]. Our algorithm is based on manipulations of *df*-pairs and *df*-matrices.

▶ **Definition 2.4.** A *df-pair* is a pair (d, f) where d represents distance and f represents capacity or flow. We may assume $f \in [K]$.

A *df-set* is a set of *df*-pairs.

A *df-matrix* is a matrix whose entries are *df*-sets. If for every *df*-pair $(d, f) \in A_{ij}$, $d \in [R]_0$, then we say A is *within distance R*.

▶ **Definition 2.5** ([12]). The *merit* order $<_m$ is defined as $(d_1, f_1) >_m (d_2, f_2)$ iff $d_1 < d_2 \wedge f_1 \ge f_2$. For a *df*-set S, define $\mathcal{C}(S) = \{(d, f) : \nexists (d', f') \in S, (d', f') >_m (d, f)\}$.

▶ Remark. Given a *df*-set S sorted by distances, $\mathcal{C}(S)$ can be computed in $O(|S|)$ time.

We can see if $(d_1, f_1) >_m (d_2, f_2)$, then (d_2, f_2) is not useful since its distance is larger but flow is no larger. The operator $\mathcal{C}$ can be used to delete redundant elements of a *df*-set.

▶ **Definition 2.6** ([12]). For two *df*-sets, define their addition and multiplication as

$$S_1 + S_2 = \mathcal{C}(S_1 \cup S_2)$$
$$S_1 \cdot S_2 = \mathcal{C}(\{(d_1 + d_2, \min(f_1, f_2)) : (d_1, f_1) \in S_1, (d_2, f_2) \in S_2\}).$$

The multiplication of two *df*-sets S_1, S_2 can be understood as we try to link the paths pair-wisely in them, so the distance is the sum of their distances, and the flow is the minimum of their flows.

▶ **Definition 2.7.** For a *df*-set S, define $S(f) = \min\{d : (d, f') \in S, f' \geq f\}$. Similarly, for a *df*-matrix A, define $A(f)$ be the matrix whose entries are in $\mathbb{R} \cup \{+\infty\}$ such that $(A(f))_{ij} = A_{ij}(f)$.

For two *df*-sets S, S', we say $S = S'$ if $\forall f \in [K]$, $S(f) = S'(f)$. The relation $=$ is an equivalence relation. We say S' is a $(1+\epsilon)$-approximation of S, denoted as $S' \approx_\epsilon S$, if $S(f) \leq S'(f) \leq (1+\epsilon)S(f)$ for any $f \in [K]$. Similarly, for two *df*-matrices A, A' of size $n \times n$, say $A = A'$ if $A_{ij} = A'_{ij}$ for all $i, j \in [n]$, and say A' is a $(1+\epsilon)$-approximation of A, denoted as $A' \approx_\epsilon A$, if A'_{ij} is a $(1+\epsilon)$-approximation of A_{ij} for all $i, j \in [n]$.

▶ **Definition 2.8.** The *product* of two *df*-matrices A, B, denoted as $A \star B$, is defined as $(A \star B)_{ij} = \sum_{k\in[n]} A_{ik} \cdot B_{kj}$. We define $A^1 = A$ and $A^p = A^{p-1} \star A$ for integer $p > 1$.

Intuitively, this product can be understood in the following way: suppose we have a 3-layer graph $G = (V, E)$ where $V = \{u_1, u_2, \ldots, u_n, v_1, v_2, \ldots, v_n, w_1, w_2, \ldots, w_n\}$. Let A be the *df*-matrix representing edges among $\{u_i\}$ and $\{v_k\}$: for all $(d, f) \in A_{ik}$, there is an edge with length d and capacity f from u_i and v_k. Similarly let B be the *df*-matrix representing edges among $\{v_k\}$ to $\{w_j\}$. Let $C = A \star B$, then each element $(d, f) \in C_{ij}$ corresponds to a path from u_i to w_j with total length d and capacity f.

We have the following facts:

▶ **Fact 2.9.** *Let S_1, S_2 be two df-sets and $f \in [K]$. Then $(\mathcal{C}(S))(f) = S(f)$, $(S_1 + S_2)(f) = \min\{S_1(f), S_2(f)\}$ and $(S_1 \cdot S_2)(f) = S_1(f) + S_2(f)$.*

Proof. These are immediate from definition. ◀

▶ **Fact 2.10.** *For three df-matrices A, B, C and $\epsilon \geq 0$, $C \approx_\epsilon A \star B$ if and only if $C(f) \approx_\epsilon A(f) \star B(f)$ for any $f \in [K]$. In particular when $\epsilon = 0$, $C = A \star B$ iff $C(f) = A(f) \star B(f)$ for all $f \in [K]$.*

Proof. For all i, j, f, from Fact 2.9,

$$(A \star B)_{ij}(f) = (\sum_{k\in[n]} A_{ik} \cdot B_{kj})(f) = \min_{k\in[n]}\{A_{ik}(f) + B_{kj}(f)\} = (A(f) \star B(f))_{ij},$$

and

$$\begin{aligned}
&C \approx_\epsilon (A \star B)\\
\iff &\forall i, j, f,\ C_{ij}(f)/(A \star B)_{ij}(f) \in [1, 1+\epsilon]\\
\iff &\forall i, j, f,\ C_{ij}(f)/(A(f) \star B(f))_{ij} \in [1, 1+\epsilon]\\
\iff &\forall f,\ C(f) \approx_\epsilon A(f) \star B(f).
\end{aligned}$$

◀

▶ **Fact 2.11.** *Let A, B, C be df-matrices. If B is a $(1+\epsilon_1)$-approximation of A and C is a $(1+\epsilon_2)$-approximation of B, then C is a $(1+\epsilon_1)(1+\epsilon_2)$-approximation of A.*

Proof. For any i, j, f, $A_{ij}(f) \leq B_{ij}(f) \leq C_{ij}(f) \leq (1+\epsilon_2)B_{ij}(f) \leq (1+\epsilon_1)(1+\epsilon_2)A_{ij}(f)$. ◀

▶ **Fact 2.12.** *Let A, B be df-matrices and $\epsilon > 0$. If $B \approx_\epsilon A$, then $B \star B \approx_\epsilon A \star A$.*

Proof. For any i, j, f, from Fact 2.10, $(A \star A)(f) = A(f) \star A(f)$, and:

$$\begin{aligned}
(A \star A)(f)_{ij} =& \min_{k\in[n]}\{A(f)_{ik} + A(f)_{kj}\}\\
\leq& \min_{k\in[n]}\{B(f)_{ik} + B(f)_{kj}\} = (B \star B)(f)_{ij}\\
\leq& (1+\epsilon) \min_{k\in[n]}\{A(f)_{ik} + A(f)_{kj}\}\\
=& (1+\epsilon)(A \star A)(f)_{ij}.
\end{aligned}$$

◀

3 Main Algorithm

In this section we introduce an $\tilde{O}(n^{(\omega+3)/2}\epsilon^{-2}\log W)$ algorithm for approximating APSP-AF problem within a stretch of $(1+\epsilon)$. The idea is not hard. Suppose M is the *df*-matrix corresponding to G, and $D = M^n$, then D is the exact *df*-matrix representing all-pair distances for all flows. To approximate D, we only need an algorithm that approximates the product of *df*-matrices by a stretch of $(1+\Theta(\epsilon/\log n))$. By Lemma 2.3, this can be done by exact *df*-matrix product algorithms that only handles distances no more than $R = O(\epsilon^{-1}\log n)$, which turns out to be expressible as $O(R^2)$ max-min products.

3.1 Exact product for small distances

The following algorithm shows that the product of two *df*-matrices A and B can be reduced to $O(R^2)$ max-min products if the distances are integers between 0 and R.

Algorithm 1 Exact product for two *df*-matrices.

function EXACT-PROD(A, B, R)
  $C_{ij} \leftarrow \varnothing$
  for d_0 in $[R]_0$ **do**
    $A_{ij}^{(d_0)} \leftarrow \max\{f : (d,f) \in A_{ij}, d \le d_0\}$
    $B_{ij}^{(d_0)} \leftarrow \max\{f : (d,f) \in B_{ij}, d \le d_0\}$
  for d_1, d_2 in $[R]_0^2$ **do**
    $C' \leftarrow A^{(d_1)} \mathbin{\textcircled{\vee}} B^{(d_2)}$
    $C_{ij} \leftarrow C_{ij} \cup \{(d_1+d_2, C'_{ij})\}$
  $C_{ij} \leftarrow \{\mathcal{C}(C_{ij})\}$; **return** C

▶ **Lemma 3.1.** EXACT-PROD *correctly returns the product $A \star B$ of two df-matrices A, B which are both within distance R.*

Proof. Let $C = \text{EXACT-PROD}(A, B, R)$. For any $i, j \in [n]$ and $f \in [K]$,

$$\begin{aligned}
&(A(f) \star B(f))_{ij} \\
=& \min_{k\in[n]}\{A(f)_{ik} + B(f)_{kj}\} \\
=& \min_{k\in[n]}\{\min\{d_1 : (d_1,f_1) \in A_{ik}, f_1 \ge f\} + \min\{d_2 : (d_2,f_2) \in B_{kj}, f_2 \ge f\}\} \\
=& \min_{d_1,d_2}\{d_1+d_2 : \exists k \in [n], A_{ik}^{(d_1)} \ge f, B_{kj}^{(d_2)} \ge f\} \\
=& \min_{d_1,d_2}\{d_1+d_2 : \left(A^{(d_1)} \mathbin{\textcircled{\vee}} B^{(d_2)}\right)_{ij} \ge f\} \\
=& \min\{d' : (d',f') \in C_{ij}, f' \ge f\} = (C(f))_{ij},
\end{aligned}$$

thus $C = A \star B$ by Fact 2.10. ◀

3.2 Approximate product for arbitrary distances

For two *df*-matrices A, B within distance M, we can compute an approximation of $A \star B$ by applying Lemma 2.3. Given a parameter R which is a power of 2, the following algorithm computes a $(1+\frac{4}{R})$-approximation of $A \star B$.

Algorithm 2 Approximate product of two *df*-matrices.

function SCALE(a, M, R)
  $a' = \begin{cases} \lceil R \cdot a/M \rceil & 0 \le a \le M \\ +\infty & \text{otherwise} \end{cases}$
  return a'
function APPROX-PROD(A, B, M, R)
  $C_{ij} \leftarrow \varnothing$
  for $r \leftarrow \lfloor \log_2 R \rfloor$ to $\lceil \log_2 M \rceil$ **do**
    $A^{(r)}_{ij} \leftarrow \mathcal{C}(\{(\text{SCALE}(d, 2^r, R), f) : (d, f) \in A_{ij}\})$
    $B^{(r)}_{ij} \leftarrow \mathcal{C}(\{(\text{SCALE}(d, 2^r, R), f) : (d, f) \in B_{ij}\})$
    $C^{(r)} = \text{EXACT-PROD}(A^{(r)}, B^{(r)}, R)$
    $C_{ij} \leftarrow C_{ij} \cup \{((2^r/R) \cdot d, f) : (d, f) \in C^{(r)}_{ij}\}$
  $C_{ij} \leftarrow \{\mathcal{C}(C_{ij})\}$; **return** C

▶ **Lemma 3.2.** *Let A, B be two df-matrices within distance M, and R a power of 2, $C =$ APPROX-PROD(A, B, M, R), then $C \approx_{\frac{4}{R}} A \star B$. Moreover, for each i, j, $|C_{ij}| = O(R \log M)$.*

Proof. Fix $f \in [K]$. Then $A^{(r)}(f) = \text{SCALE}(A(f), 2^r, R)$, $B^{(r)}(f) = \text{SCALE}(B(f), 2^r, R)$. By Lemma 3.1,

$$C(f) = \min_{\lfloor \log_2 R \rfloor \le r \le \lceil \log_2 M \rceil} \{(2^r/R) \cdot (A^{(r)}(f) \star B^{(r)}(f))\}.$$

From Lemma 2.3, $C(f) \approx_{\frac{4}{R}} A(f) \star B(f)$ for all f. The lemma is immediate from Fact 2.10. The "moreover" part holds since $|C_{ij}| \le \sum_{r=\lfloor \log_2 R \rfloor}^{\lceil \log_2 M \rceil} |C^{(r)}_{ij}| \le 2R\lceil \log_2 M \rceil$ for any i, j. ◀

3.3 Main procedure

Consider an instance G of APSP-AF problem, we represent G as a *df*-matrix A: A_{ij} is the set of all (d, f) such that there is an edge from i to j with length d and capacity f. Given $\epsilon > 0$, the following algorithm computes a *df*-matrix that approximates answers of APSP-AF problem within a stretch of $1 + \epsilon$.

Algorithm 3 the main procedure

function APSP-AF-APPROX(A, W, ϵ)
  $M \leftarrow nW$
  $R \leftarrow 4\lceil \log_2 n \rceil / \ln(1 + \epsilon)$
  $R \leftarrow 2^{\lceil \log_2 R \rceil}$
  $\tilde{D}^{(0)}_{ij} \leftarrow A_{ij}$
  $\tilde{D}^{(0)}_{ii} \leftarrow \{(0, K)\}$
  for $t = 1$ to $\lceil \log_2 n \rceil$ **do**
    $\tilde{D}^{(t)} \leftarrow \text{APPROX-PROD}(\tilde{D}^{(t-1)}, \tilde{D}^{(t-1)}, M, R)$
  return $\tilde{D}^{(\lceil \log_2 n \rceil)}$

▶ **Theorem 3.3.** *For a graph G, let A be the df-matrix representing G as above, D be the df-matrix such that $D(f)_{ij}$ is the shortest distance from i to j under flow constraint f in G, and $\tilde{D} =$ APSP-AF-APPROX(A, W, ϵ). Then $\tilde{D} \approx_\epsilon D$. Moreover,* APSP-AF-APPROX *runs in $\tilde{O}(n^{(\omega+3)/2}\epsilon^{-2} \log W)$ time, and $\tilde{D}$ occupies $O(n^2\epsilon^{-1} \log n \log(nW))$ space.*

Proof. The time bottleneck of APSP-AF-Approx is $O(\log(nW))$ invocations of Exact-Prod, which runs in $\tilde{O}(n^{(\omega+3)/2}R^2)$ time. From Lemma 3.2, for each i, j, we have $|\tilde{D}_{ij}| = O(R\log(nW))$. Since $R = O(\epsilon^{-1}\log n)$, the "moreover" part is proved.

Let $D^{(t)}_{ij}(f)$ be the shortest distance from i to j under flow constraint f, where only paths of $\le 2^t$ edges are considered. Then $D^{(t)} = D^{(t-1)} \star D^{(t-1)}$, $\tilde{D}^{(t)} \approx_{\frac{4}{R}} \tilde{D}^{(t-1)} \star \tilde{D}^{(t-1)}$ (by Lemma 3.2), and $D^{(0)} = \tilde{D}^{(0)}$. We can prove by induction that $\tilde{D}^{(t)}$ is a $(1+\frac{4}{R})^t$-approximation of $D^{(t)}$. Base case ($t = 0$) is obvious; suppose this is true for t_0, let $\hat{D}^{(t_0+1)} = \tilde{D}^{(t_0)} \star \tilde{D}^{(t_0)}$, then $\hat{D}^{(t_0+1)}$ is a $(1+\frac{4}{R})^{t_0}$-approximation of $D^{(t_0+1)}$ by induction hypothesis and Fact 2.12. Since $\tilde{D}^{(t_0+1)} \approx_{\frac{4}{R}} \hat{D}^{(t_0+1)}$, $\tilde{D}^{(t_0+1)}$ is a $(1+\frac{4}{R})^{(t_0+1)}$-approximation of $D^{(t_0+1)}$ by Fact 2.11.

Since

$$\left(1+\frac{4}{R}\right)^{\lceil\log_2 n\rceil} \le \left(1+\frac{\ln(1+\epsilon)}{\lceil\log_2 n\rceil}\right)^{\lceil\log_2 n\rceil} \le 1+\epsilon,$$

$\tilde{D} = \tilde{D}^{(\lceil\log_2 n\rceil)}$ is a $(1+\epsilon)$-approximation of D. ◀

3.4 Computing witnesses

Our algorithm can be adapted to answer path queries in addition to distance queries: given $i, j \in [n]$ and $f \in [K]$, we not only find the approximated distance from i to j under flow constraint f, but also find an actual path with that distance. Suppose the path contains ℓ vertices, then a query takes $O(\ell \log\log_{1+\epsilon}(nW))$ time to report the whole path.

First we notice that the max-min product algorithm in [8] can be modified to return *witnesses* of max-min product:

▶ **Lemma 3.4** ([8]). *For two $n \times n$ matrices A, B, a pair of matrices (C, W) can be computed in $O(n^{(\omega+3)/2})$ time, where $C = A \otimes B$ and for any $i, j \in [n]$, suppose $k = W_{ij}$, then $C_{ij} = \min\{A_{ik}, B_{kj}\}$. We call W a* witness *of $A \otimes B$.*

We attach a node in the graph as additional information to every *df*-pair we encounter. For a *df*-pair representing a path p from i to j, suppose node x is attached to it, then x is on p. Moreover, if $x = i$ or $x = j$, then p contains at most one edge. More precisely:

- In Algorithm 1, we compute a witness matrix W besides computing $C' = A^{(d_1)} \otimes B^{(d_2)}$. Each *df*-pair $(d_1 + d_2, C'_{ij})$ in line 8 is attached with W_{ij};
- In Algorithm 2, line 10, the node attached with $((2^r/R)\cdot d, f)$ is the same as the node attached with (d, f);
- In Algorithm 3, line 6, the node attached with $(0, K) \in \tilde{D}^{(0)}_{ii}$ is i.

It is easy to see from above modifications that, suppose node x is attached with $(d, f) \in \tilde{D}_{ij}$, then there is a path from i to j with distance $\le d$, flow $\ge f$ which passes through node x.

We give a simple recursive algorithm that, based on nodes attached to *df*-pairs in the data structure, find the whole path for a query (u, v, f).

Algorithm 4 Path querying

```
1: function QUERY(u, v, f)
2:     (d', f') ← arg min{d' : (d', f') ∈ D̃_uv, f' ≥ f}
3:     x ← the node attached with (d', f')
4:     if x = u or x = v then
5:         return edge u → v
6:     else
7:         return QUERY(u, x, f)+QUERY(x, v, f)
```

4 Faster Implementation of Exact Product

In this section we show how to multiply two *df*-matrices within distance R in $\tilde{O}(n^{(\omega+3)/2}R^{3/2})$ time. This implies an $\tilde{O}(n^{(\omega+3)/2}\epsilon^{-3/2}\log W)$ time algorithm for the original APSP-AF approximation problem.

The idea is to look into details of the max-min product algorithm in [8]. The task of computing max-min product of two matrices can be composed into $O(t)$ Boolean matrix multiplications and $O(n^3/t)$ extra work, so in our case we have $O(tR^2)$ matrix multiplications and $O(R^2n^3/t)$ extra work. However, these $O(tR^2)$ matrix multiplications can be expressed as $O(t)$ distance products of matrices whose elements are in $[R]$, thus can be accelerated by Zwick's algorithm for distance product [17] to run in $\tilde{O}(tRn^\omega)$ time.

▶ **Lemma 4.1** ([17]). *The distance product of two $n \times n$ matrices whose entries are in $[M]$ can be computed in $\tilde{O}(Mn^\omega)$ time.*

4.1 Row-balancing and column-balancing

The max-min product algorithm in [8] uses the concept of row-balancing and column-balancing. The function of row (column)-balancing is to rearrange the entries of a sparse matrix such that every row (column) has a moderate number of entries. We adapt this technique to *df*-matrices here.

▶ **Definition 4.2.** Let A be an $n \times n$ *df*-matrix where $m = \sum_{i,j\in[n]} |A_{ij}|$. We define the *row-balancing* of A, denoted by $\mathbf{rb}(A)$, as a pair of $n \times n$ *df*-matrices (A', A''), where each row of A' or A'' contains at most $k = \lceil m/n \rceil$ *df*-pairs in total. More precisely, we first sort all *df*-pairs in the i-th row of A by ascending order of f values, and partition them into blocks of size $\le k$: $T_i^1, T_i^2, \ldots, T_i^{a_i}$. The last block $T_i^{a_i}$ has *at most* k *df*-pairs, and other blocks have *exactly* k *df*-pairs. We define A' to contain all entries in the last block: $A'_{ij} = A_{ij} \cap T_i^{a_i}$. Since $\sum_{i\in[n]}(a_i - 1) \le m/k \le n$, we can rearrange all $T_i^j (1 \le j < a_i)$ into n distinct rows, by selecting an injection $\rho : \{(i, j) : i \in [n], j \in [a_i - 1]\} \to [n]$. Then we define $A''_{ij} = A_{i'j} \cap T_{i'}^q$ where $(i', q) = \rho^{-1}(i)$.

The *column-balancing* of A, denoted by $\mathbf{cb}(A)$, is a pair of $n \times n$ *df*-matrices (A', A'') such that $(A'^\top, A''^\top) = \mathbf{rb}(A^\top)$.

4.2 Dominance product

▶ **Definition 4.3.** The *dominance product* of two *df*-matrices A, B, denoted as $A \circledcirc B$, is defined as $(A \circledcirc B)_{ij} = \min\{d_1 + d_2 : (d_1, f_1) \in A_{ik}, (d_2, f_2) \in B_{kj}, f_1 \le f_2\}$.

There is also a "3-layer graph interpretation" of the dominance product of two *df*-matrices: consider a graph $G = (V, E)$ where $V = \{u_1, u_2, \ldots, u_n, v_1, v_2, \ldots, v_n, w_1, w_2, \ldots, w_n\}$. Let

A be the *df*-matrix representing edges among $\{u_i\}$ and $\{v_k\}$: for all $(d, f) \in A_{ik}$, there is an edge with length d and capacity f from u_i and v_k. Similarly let B be the *df*-matrix representing edges among $\{v_k\}$ to $\{w_j\}$. Let $C = A \circledcirc B$, then C_{ij} is the minimum distance of a path from u_i to w_j, where it's required that the capacity of the first edge is no more than the capacity of the second edge.

▶ **Lemma 4.4.** *Given two df-matrices A, B within distance R, let $m_1 = \sum_{i,j\in[n]} |A_{ij}|$, $m_2 = \sum_{i,j\in[n]} |B_{ij}|$. The dominance product $A \circledcirc B$ can be computed in $\tilde{O}(m_1 m_2/n + Rn^\omega)$ time.*

Proof. Let $(A', A'') = \mathbf{cb}(A)$, the column-balancing of A. Define two (scalar) matrices $\tilde{A}$ and $\tilde{B}$:

$$\tilde{A}_{ik} = \min\{d : (d, f) \in A''_{ik}\}, \tilde{B}_{kj} = \min\{d : (d, f) \in B_{k'j}, f \geq \text{max flow of } T^{q'}_{k'}\},$$

where $(k', q') = \rho^{-1}(k)$. Note that $(\tilde{A} \star \tilde{B})_{ij}$ is the smallest $d_1 + d_2$ such that:

- $(d_1, f_1) \in A_{ik'}$, $(d_2, f_2) \in B_{k'j}$;
- $(d_1, f_1) \in T^{q'}_{k'}$, $q' < a_{k'}$, and f_2 dominates all flows in $T^{q'}_{k'}$.

What we haven't considered are pairs $(d_1, f_1) \in A_{ik'}$ and $(d_2, f_2) \in B_{k'j}$ such that (d_1, f_1) is contained in the largest part of column k', or f_2 is smaller than the largest flow in $T^{q'}_{k'}$, that is, f_1 and f_2 locate in the same "block". In either cases, for any (d_2, f_2) there are only $O(m_1/n)$ entries in A' or A'' to compare. The time complexity for distance product is $\tilde{O}(Rn^\omega)$, and the time complexity for the rest pairs are $O(m_1 m_2/n)$. ◀

4.3 Faster exact product

▶ **Theorem 4.5.** *Given two df-matrices A, B within distance R, their product $A \star B$ can be computed in $\tilde{O}(n^{(\omega+3)/2} R^{3/2})$ time.*

Proof. Let $D^{(d)}_{ij} = \max\{f_1 : d_1 + d_2 = d, f_1 \leq f_2, (d_1, f_1) \in A_{ik}, (d_2, f_2) \in B_{kj}\}$ and $D'^{(d)}_{ij} = \max\{f_2 : d_1 + d_2 = d, f_1 \geq f_2, (d_1, f_1) \in A_{ik}, (d_2, f_2) \in B_{kj}\}$, then $(A \star B)_{ij} = \mathcal{C}\left(\bigcup_d \left\{(d, \max\{D^{(d)}_{ij}, D'^{(d)}_{ij}\})\right\}\right)$. We show $D^{(d)}$ for all $0 \leq d \leq 2R$ can be computed in $\tilde{O}(n^{(\omega+3)/2} R^{3/2})$ total time; $D'^{(d)}$ is similar.

Sort all *df*-pairs of A and B by their f values in increasing order, and then partition this sorted list into t parts $L_1, L_2, \ldots, L_t$, where each part has $O(n^2 R/t)$ elements. Let $A^{(r)}_{ij} = A_{ij} \cap L_r$, $B^{(r)}_{ij} = B_{ij} \cap L_r$ for $1 \leq r \leq t$. For each r we let $(A'^{(r)}, A''^{(r)}) = \mathbf{rb}(A^{(r)})$, and compute $A^{(r)} \circledcirc B$, $A'^{(r)} \circledcirc B$, $A''^{(r)} \circledcirc B$. For each d, i, j, we can compute $D^{(d)}_{ij}$ as follows:

1. We first determine which part $D^{(d)}_{ij}$ lies in, *i.e.* find the largest r such that $(A^{(r)} \circledcirc B)_{ij} \leq d$;
2. If $(A'^{(r)} \circledcirc B)_{ij} \leq d$, then we only need to consider k where $A'^{(r)}_{ik} \neq \varnothing$ to determine $D^{(d)}_{ij}$;
3. Otherwise, we find the largest q such that $(A''^{(r)} \circledcirc B)_{\rho(i,q),j} \leq d$, and determine $D^{(d)}_{ij}$ by looking through the q-th part of i-th row of $A^{(r)}$.

The above procedure takes $O(nR/t)$ time for each d, i, j. We compute $A^{(r)} \circledcirc B$ in $\tilde{O}(n^3 R^2/t^2 + Rn^\omega)$ time as follows. Let $f' = \min\{f : (d, f) \in L_{r+1}\}$, then $A^{(r)} \circledcirc B = \min\{A^{(r)} \circledcirc B^{(r)}, A^{(r)}(0) \star B(f')\}$. The $A^{(r)} \circledcirc B^{(r)}$ part considers comparisons inside L_r, which we compute in $\tilde{O}((n^2 R/t)^2/n + Rn^\omega)$ time by Lemma 4.4; the $A^{(r)}(0) \star B(f')$ part represents comparisons between L_r and $\bigcup_{r<r'\leq t} L_{r'}$, and is simply a distance product computable in $\tilde{O}(Rn^\omega)$ time. We can compute $A'^{(r)} \circledcirc B$ and $A''^{(r)} \circledcirc B$ similarly as we did in $A^{(r)} \circledcirc B$. Therefore, we spend $\tilde{O}(n^3 R^2/t + tRn^\omega)$ time in total for all $1 \leq r \leq t$. The theorem follows by setting $t = n^{(3-\omega)/2} R^{1/2}$. ◀

4.4 Computing witnesses

We modify this algorithm to support path queries as in Section 3.4. We call $k \in [n]$ is a witness of $D^{(d)}_{ij}$ if there is $(d_1, f_1) \in A_{ik}$, $(d_2, f_2) \in B_{kj}$ such that $d_1 + d_2 = d$, $f_1 \le f_2$ and $D^{(d)}_{ij} = f_1$. For any d, i, j, a witness of $D^{(d)}_{ij}$ can be found by step 2,3 when computing $D^{(d)}_{ij}$. Similarly we can find witnesses of $D'^{(d)}_{ij}$. For each d, i, j, if $D^{(d)}_{ij} \ge D'^{(d)}_{ij}$, attach the witness of $D^{(d)}_{ij}$ to the df-pair $(d, D^{(d)}_{ij})$; otherwise attach the witness of $D'^{(d)}_{ij}$ to the df-pair $(d, D'^{(d)}_{ij})$. The time complexity remains the same.

5 Conclusions

Our work shows that the apBLSP and APSP-AF problem can be approximated within a stretch of $(1+\epsilon)$ in $\tilde{O}(n^{(\omega+3)/2}\epsilon^{-3/2}\log W)$ time. Also, a faster algorithm for max-min product would imply a faster algorithm for approximating APSP-AF problem. In this sense, since approximating APSP-AF is at least as hard as max-min product, our algorithm is optimal up to $\tilde{O}(\mathrm{poly}(\epsilon^{-1})\log W)$ factors.

We think the main open problem left by our work is to further improve the dependence on ϵ. Can the APSP-AF problem be approximated in, say, $\tilde{O}(n^{(\omega+3)/2}\epsilon^{-1}\log W)$ time? There is an $\epsilon^{-1/2}$ gap here, and we might need a more refined approach to fill this gap.

Abstract

In a directed graph $G = (V, E)$ with a capacity on every edge, a *bottleneck path* (or *widest path*) between two vertices is a path maximizing the minimum capacity of edges in the path. For the single-source all-destination version of this problem in directed graphs, the previous best algorithm runs in $O(m + n \log n)$ ($m = |E|$ and $n = |V|$) time, by Dijkstra search with Fibonacci heap [Fredman and Tarjan 1987]. We improve this time bound to $O(m\sqrt{\log n} + \sqrt{mn \log n \log\log n})$, which is $O(n\sqrt{\log n \log\log n})$ when $m = O(n)$, thus it is the first algorithm which breaks the time bound of classic Fibonacci heap when $m = o(n\sqrt{\log n})$. It is a Las-Vegas randomized approach. By contrast, the s-t bottleneck path has algorithm with running time $O(m\beta(m, n))$ [Chechik et al. 2016], where $\beta(m, n) = \min\{k \geq 1 : \log^{(k)} n \leq \frac{m}{n}\}$.

1 Introduction

The *bottleneck path* problem is a graph optimization problem finding a path between two vertices with the maximum flow, in which the flow of a path is defined as the minimum capacity of edges on that path. The bottleneck problem can be seen as a mathematical formulation of many network routing problems, e.g. finding the route with the maximum transmission speed between two nodes in a network, and it has many other applications such as digital compositing [11]. It is also the important building block of other algorithms, such as the improved Ford-Fulkerson algorithm [10, 12], and k-splittable flow algorithm [1]. The minimax path problem which finds the path that minimizes the maximum weight on it is symmetric to the bottleneck path problem, thus has the same time complexity.

1.1 Our Results

In a directed graph $G = (V, E)$ ($n = |V|, m = |E|$), we consider the single-source bottleneck path (SSBP) problem, which finds the bottleneck paths from a given source node s to all other vertices. In the comparison-based model, the previous best time bound for SSBP is the traditional Dijkstra's algorithm [8] with Fibonacci heap [14], which runs in $O(m + n \log n)$ time. Some progress has been made for slight variants of the SSBP problem: When the graph is undirected, SSBP is reducible to minimum spanning tree [16], thus can be solved in randomized linear time [18]; for the single-source single-destination bottleneck path (s-t BP) problem in directed graphs, Gabow and Tarjan [15] showed that it can be solved in $O(m \log^* n)$ time, and this bound was subsequently improved by Chechik et al [5] to $O(m\beta(m, n))$. However, until now no algorithm is known to be better than Dijkstra's algorithm for SSBP in directed graphs. And as noted in [14], Dijkstra's algorithm can be used to sort n numbers, so a "sorting barrier", $O(m + n \log n)$, prevents us from finding a more efficient implementation of Dijkstra's algorithm.

In this paper, we present a breakthrough algorithm for SSBP that overcomes the sorting barrier. Our main result is shown in the following theorem:

▶ **Theorem 1.** *Let $G = (V, E)$ be directed graph with edge weights $w : E \to \mathbb{R}$. In comparison-based model, SSBP can be solved in expected $O\left(\sqrt{nm \log n \log\log n} + m\sqrt{\log n}\right)$ time.*

An alternative way to state our result is: for $m \leq n \log\log n$, SSBP can be solved in $O(\sqrt{nm \log n \log\log n})$ time; for $m > n \log\log n$, SSBP can be solved in $O(m\sqrt{\log n})$ time. In particular, when $m = O(n)$ the time bound is $O(n\sqrt{\log n \log\log n})$. Our algorithm is inspired by previous works on the s-t BP problem: the $O(m \log^* n)$-time algorithm by Gabow and Tarjan [15] and the $O(m\beta(m, n))$-time algorithm by Chechik et al [5]. See Section 3 for our intuitions.

1.2 Related Works

A "sorting barrier" seemed to exist for the the Minimum Spanning Tree problem (MST) for many years [3, 17, 19], but it was eventually broken by [25, 6]. Fredman and Tarjan [14] gave an $O(m\beta(m, n))$-time algorithm by introducing Fibonacci heap. The current best time bounds for MST include randomized linear time algorithm by Karger et al [18], Chazelle's $O(m\alpha(m, n))$-time deterministic algorithm [4] and Pettie and Ramachandran's optimal approach [20].

The single-source single-destination version of the bottleneck path (s-t BP) problem is proved to be equivalent to the Bottleneck Spanning Tree (BST) problem (see [5]). In the bottleneck spanning tree problem, we want to find a spanning tree rooted at source node s minimizing the maximum edge weight in it. For undirected graph, the s-t BP can be reduced to the MST problem. For directed graph, Dijkstra's algorithm [8] gave an $O(n \log n + m)$-time solution using Fibonacci heap [14]. Then Gabow and Tarjan [15] gave an $O(m \log^* n)$-time algorithm based on recursively splitting edges into levels. Recently, Chechik et al. [5] improved the time complexity of BST and BP to randomized $O(m\beta(m, n))$ time, where $\beta(m, n) = \min\{k \geq 1 : \log^{(k)} n \leq \frac{m}{n}\}$. All these algorithms are under comparison-based model. For word RAM model, an $O(m)$-time algorithm has been found by Chechik et al. [5].

For the all-pairs version of the bottleneck path (APBP) problem, we can sort all the edges and use Dijkstra search to obtain an $O(mn)$ time bound. For dense graphs, it has been shown that APBP can be solved in truly subcubic time. Shapira et al. [21] gave an $O(n^{2.575})$-time APBP algorithm on vertex-weighted graphs. Then Vassilevska et al. [23]

showed that APBP for edge-weighted graphs can be solved in $O(n^{2+\omega/3}) = O(n^{2.791})$ time based on computing $(\max, \min)$-product of real matrices, which was then improved by Duan and Pettie [9] to $O(n^{(3+\omega)/2}) = O(n^{2.686})$. Here $\omega < 2.373$ is the exponent of time bound for fast matrix multiplication [7, 24].

2 Preliminaries

For a directed graph G, we denote $w(u, v)$ to be the edge weight of $(u, v) \in E$. Without additional explanation, we use the symbol n to denote the number of nodes and m to denote the number of edges in G.

2.1 Bottleneck Path Problems

The *capacity* of a path is defined to be the minimum weight among traversed edges, i.e., if a path traverses $e_1, \ldots, e_l \in E$, then the capacity of the path is $\min_{i=1}^{l} w(e_i)$. For any $u, v \in V$, a path from u to v with maximum capacity is called a *bottleneck path from u to v*, and we denote this maximum capacity by $b(u, v)$.

▶ **Definition 2.** The *Single-Source Bottleneck Path* (SSBP) problem is: Given a directed graph $G = (V, E)$ with weight function $w : E \to \mathbb{R}$ and a source $s \in V$, output $b(s, t)$ for every $t \in V$, which is the maximum path capacity among all the paths from s to t.

We use the triple (G, w, s) to denote a SSBP instance with graph G, weight function $w(\cdot)$ and source node s.

It is more convenient to present our algorithm on a slight variant of the SSBP problem. We shall call it *Arbitrary-Source Bottleneck Path with Initial Capacity* (ASBPIC) problem. We assume that the edge weight $w(e)$ of an edge $e \in E$ is either a real number or infinitely large $(+\infty)$. We say an edge e is *unrestricted* if $w(e) = +\infty$; otherwise we say the edge e is *restricted*. In the ASBPIC problem, an *initial capacity* $h(v)$ is given for every node $v \in V$, and the *capacity* of a path is redefined to be the minimum between the initial capacity of the starting node and the minimum edge weights in the path, i.e., if the path starts with the node $v \in V$ and traverses $e_1, \ldots, e_l$, then its capacity is $\min\left(\{h(v)\} \cup \{w(e_i)\}_{i=1}^{l}\right)$. For any $v \in V$, a path ended with v with maximum capacity is called a *bottleneck path ended with v*, and we denote this maximum capacity as $d(v)$.

▶ **Definition 3.** The *Arbitrary-Source Bottleneck Path with Initial Capacity* (ASBPIC) problem is: Given a directed graph $G = (V, E)$ with weight function $w : E \to \mathbb{R} \cup \{+\infty\}$ and initial capacity function $h : V \to \mathbb{R} \cup \{\pm\infty\}$, output $d(v)$ for every $v \in V$, which is the maximum path capacity among all the paths ended with v.

We use the triple (G, w, h) to denote an ASBPIC instance with graph G, weight function $w(\cdot)$, and inital capacity function $h(\cdot)$.

Note that ASBPIC and SSBP are equivalent under linear-time reductions. Given an ASBPIC instance, we construct a new graph G' from G by adding a new node v_0 which has outgoing edges with weight $h(v)$ to all the nodes $v \in V$ having $h(v) > -\infty$, then it suffices to find bottleneck paths from v_0 to all other nodes in G'. On the other hand, a SSBP instance (G, w, s) can be easily reduced to the ASBPIC instance (G, w, h), where $h(s) = \max_{e \in E}\{w(e)\}$ and $h(v) = -\infty$ for all $v \neq s$.

2.2 Dijkstra's Algorithm for SSBP and ASBPIC

SSBP can be easily solved using a variant of Dijkstra's algorithm [8]. In this algorithm, each node is in one of the three status: *unsearched*, *active*, or *scanned*. We associate each node $v \in V$ with a *label* $d'(v)$, which is the maximum path capacity among all the paths from s to v that only traverse scanned nodes or v.

Initially, all the nodes are unsearched except s is active, and we set $d'(s) = +\infty$ and $d'(v) = -\infty$ for all $v \neq s$. We repeat the following step, which we call the *Dijkstra step*, until none of nodes is active:

- Select an active node u with maximum label and mark u as scanned. For every outgoing edge (u, v) of u, update the label of v by

$$d'(v) \leftarrow \max\{d'(v), \min\{d'(u), w(u, v)\}\}, \tag{1}$$

  and mark v as active if v is unsearched.

We use priority queue to maintain the order of labels for active nodes. This algorithm runs in $O(m + n \log n)$ time when Fibonacci heap [14] is used.

The algorithm we introduced above can also be adapted for solving ASBPIC. The only thing we need to change is that in the initial stage all nodes are active and $d'(v) = h(v)$ for every $v \in V$. The resulting algorithm again runs in $O(m + n \log n)$ time. We shall call these two algorithms as *Dijkstra's algorithm for SSBP* and *Dijkstra's algorithm for ASBPIC*, or simply call any of them *Dijkstra's algorithm* when no confusion can arise.

2.3 Weak and Strong Connectivity in Directed Graph

We also need some definitions about connectivity in graph theory in this paper. A directed graph is said to be *weakly-connected* if it turns to be a connected undirected graph when changing all of its directed edges to undirected edges. A directed graph is said to be *strongly-connected* if every pair of nodes can be reached from each other. A *weakly-* (or *strongly-*) *connected components* is defined to be a maximal weakly- (or strongly-) connected subgraph.

3 Intuitions for SSBP

If all the edge weights are integers and are restricted in $\{1, \ldots, c\}$, then SSBP can be solved in $O(m + c)$ time using Dijkstra's algorithm with bucket queue. If the edge weights are not necessarily small integers but all the edges given to us are already sorted by weights, then we can replace the edge weights by their ranks and use Dijkstra's algorithm with bucket queue to solve the problem in $O(m)$ time. However, edges are not sorted in general. If we sort the edges directly, then a cost of $\Omega(m \log m)$ time is unavoidable in a comparison-based model, which is more expensive than the $O(m + n \log n)$ running time of Dijkstra's algorithm.

Our algorithm is inspired by previous works on the single-source single-destination bottleneck path problem (s-t BP): the $O(m \log^* n)$-time algorithm by Gabow and Tarjan [15] and the $O(m\beta(m, n))$-time algorithm by Chechik et al [5]. Gabow and Tarjan's algorithm for s-t BP consists of several stages. Let $b(s, t)$ be the capacity of a bottleneck path from s to t. Initially, we know that $b(s, t)$ is in the interval $(-\infty, +\infty)$. In each stage, we narrow the interval of possible values of $b(s, t)$. Assume that $b(s, t)$ is known to be in the range (l, r). Let $m_{(l,r)}$ be the the number of edges with weights in the range (l, r) and k be a parameter. By applying the median-finding algorithm [2] repeatedly, we choose k thresholds $\lambda_1, \cdots, \lambda_k$ to split (l, r) into $k + 1$ subintervals $(l, \lambda_1), [\lambda_1, \lambda_2), [\lambda_2, \lambda_3), \ldots, [\lambda_{k-1}, \lambda_k), [\lambda_k, r)$ such that for each subinterval, there are $O(m_{(l,r)}/k)$ edges of weight in it. Gabow and Tarjan then show

that *locating* which subinterval contains $b(s,t)$ can be done in $O(m_{(l,r)})$ time by incremental search. Finally, the $O(m \log^* n)$ running time bound is achieved by setting k appropriately at each stage.

The algorithm by Chechik et al. is based on the framework of Gabow and Tarjan's algorithm, but instead of selecting the thresholds $\lambda_1, \ldots, \lambda_k$ by median-finding repeatedly in $O(m_{(l,r)} \log k)$ time, in this algorithm we select the k thresholds by randomly sampling in edge weights, and sort them in $O(k \log k)$ time. These thresholds partition the edges evenly with high probability, but it requires $\Omega(m \log k)$ time to compute the partition explicitly. Then they show that actually we can locate which subinterval contains $b(s,t)$ in $O(m_{(l,r)}+nk)$ (or $O(m_{(l,r)} + n \log k)$) time, without computing the explicit partition. The time bound for the overall algorithm is again obtained by setting k appropriately at each stage.

We adapt Chechik et al.'s framework for the s-t BP problem to the SSBP problem. Our SSBP algorithm actually works on an equvialent problem called ASBPIC. In ASBPIC, there is no fixed source but every node has an initial capacity, and for all destination $t \in V$ we need to compute the capacity $d(t)$ of a bottleneck path ended with t (See Section 2.1 for details). Instead of locating the subinterval for a single destination t, our algorithm locates the subintervals for all destinations $t \in V$. Thus we adopt a divide-and-conquer methodology. At each recursion, we follow the idea from Chechik et al. [5] to randomly sample k thresholds. Then we *split* the nodes into $k+1$ levels $V_0, \ldots, V_k$, where the i-th level contains the nodes t that have $d(t)$ in the i-th subinterval ($0 \le i \le k$). For each level V_i of nodes, we compute $d(t)$ for every $t \in V_i$ by reducing to solve the SSBP on a subgraph consisting of all the nodes in V_i and some of the edges connecting them. We set k to be fixed in all recursive calls, and the maximum recursion depth is $O(\log n / \log k)$ with high probability.

The split algorithm becomes the key part of our algorithm. Note that at each recursion, we should reduce or avoid the use of operations that cost time $O(\log k)$ per node or per edge (e.g., binary searching for the subinterval containing a particular edge weight). This is because that, for example, if we execute an $O(\log k)$-time operation for each edge at each recursion, then the overall time cost is $O(m \log k) \cdot O(\log n / \log k) = O(m \log n)$, which means no improvement comparing with the previous $O(m+n \log n)$-time Dijkstra's algorithm. Surprisingly, we can design an algorithm such that whenever we execute an $O(\log k)$-time operation, we can always find one edge that does not appear in any subsequent recursive calls. Thus total time complexity for such operations is $O(m \log k)$, which gives us some room to obtain a better time complexity by adjusting the parameter k.

4 Our Algorithm

Our algorithm for SSBP is as follows: Given a SSBP instance (G, w, s), we first reduce the SSBP problem to an ASBPIC instance (G, w, h), and then use a recursive algorithm (Figure 1) to solve the ASBPIC problem. The reduction is done by setting $h(s) = \max_{e \in E}\{w(e)\}$ and $h(v) = -\infty$ for all $v \neq s$ as described in the preliminaries.

For convenience, we assume that in the original graph, all edge weights are distinct. This assumption can be easily removed.

A high-level description of our recursive algorithm for ASBPIC is shown in Figure 1. For two set A and B, $A \uplus B$ stands for the union of A and B with the assumption that $A \cap B = \varnothing$. We use $E^{(r)}$ to denote the set of restricted edges in G, and similarly we use $E_i^{(r)}$ to denote the set of restricted edges in G_i for each ASBPIC instance (G_i, w_i, h_i). When the thresholds $\lambda_0, \ldots, \lambda_{k+1}$ are presence, we define the *index* of x for every $x \in \mathbb{R}$ to be the unique index i such that $\lambda_i \le x < \lambda_{i+1}$, and we denote it as $I(x)$. For $x = \pm\infty$, we define

Algorithm 1 Main Algorithm.

Input: Directed graph $G = (V, E)$, weight function $w(\cdot)$, initial capacity function $h(\cdot)$; Parameter $k \geq 1$.

Output: For each $v \in V$, output $d(v)$, the capacity of a bottleneck path ended with v.

1: **if** G is not weakly-connected **then**
2: Compute $\{d(v)\}_{v \in V}$ in each weakly-connected component recursively.
3: Let $E^{(r)} = \{e \in E \mid w(e) < +\infty\}$ be the set of restricted edges.
4: **if** $|E^{(r)}| \leq 1$ **then**
5: Compute $\{d(v)\}_{v \in V}$ in linear time and exit. ▷ Section 4.2
6: Sample $l = \min\{k, |E^{(r)}|\}$ distinct edges from $E^{(r)}$ uniformly randomly.
7: Sort the sampled edges by weights, and let $\lambda_1 < \cdots < \lambda_l$ be their weights.
8: Let $\lambda_0 = -\infty, \lambda_{l+1} = +\infty$.
9: Split V into $l + 1$ levels: $V_0 \uplus V_1 \uplus \cdots \uplus V_l$, where $V_i = \{v \in V \mid \lambda_i \leq d(v) < \lambda_{i+1}\}$. ▷ Section 4.3
10: For every level V_i, reduce the computation of $\{d(v)\}_{v \in V_i}$ to a new ASBPIC instance (G_i, w_i, h_i), where $G_i = (V_i, E_i)$ is a subgraph of G consisting of all the nodes in V_i and some of edges that connect them. Solve each (G_i, w_i, h_i) instance recursively.

$I(-\infty) = 0, I(+\infty) = l$. Note that all the subgraphs G_i at Line 10 are disjoint. We denote $r = |E| - \sum_{i=0}^{l} |E_i|$ to be the total number of edges in E that do not appear in any recursive calls of (G_i, w_i, h_i). For an edge $(u, v) \in E$, if u and v belong to different levels, then we say that (u, v) is *cross-level*. If u and v belong to the same level V_i and $w(u, v) < \lambda_i$, then we say that (u, v) is *below-level*; conversely, if $w(u, v) \geq \lambda_{i+1}$ then we say that (u, v) is *above-level*.

Besides the problem instance (G, w, h) of ASBPIC, our algorithm requires an additional integral parameter k. At the top level of recursion, we set the parameter $k = 2^{\Theta\left(\sqrt{n \log n \log\log n / m}\right)}$ if $m \leq n \log\log n$, or $k = 2^{\Theta\left(\sqrt{\log n}\right)}$ if $m > n \log\log n$. We fix this value k all through our algorithm. The value of the parameter k does not affect the correctness of our algorithm, but it controls the number of recursive calls at each recursion.

At each recursion, our algorithm first checks if G contains only one weakly-connected component. If not, then our algorithm calls itself to compute d in each weakly-connected component recursively. Now we can assume that G is weakly-connected (so $n \leq m$).

If the number of restricted edges is no more than 1, we claim that we can compute $d(v)$ for all v in linear time. The specific algorithm will be introduced in Section 4.2.

▶ **Lemma 4.** *ASBPIC can be solved in $O(m)$ time if there is at most one restricted edge.*

If the number of restricted edges is more than 1, then our algorithm first sample $l = \min\{k, |E^{(r)}|\}$ distinct edges from $E^{(r)}$ uniformly randomly and sort them by weights, that is, if the number of restricted edges is more than k, then we sample k distinct restricted edges and sort them; otherwise we just sort all the restricted edges. Let λ_i be the weight of the edge with rank i $(1 \leq i \leq l)$ and $\lambda_0 = -\infty$, $\lambda_{l+1} = +\infty$.

Next, we split V into $l + 1$ levels of nodes $V = V_0 \uplus V_1 \uplus \cdots V_l$, where the i-th level of nodes is $V_i = \{v \in V \mid I(d(v)) = i\} = \{v \in V \mid \lambda_i \leq d(v) < \lambda_{i+1}\}$. The basic idea of the split algorithm is: we run Dijkstra's algorithm for ASBPIC on the graph produced by mapping every edge weight $w(e)$ and initial capacity $h(v)$ in G to their indices $I(w(e))$ and $I(h(v))$, and we obtain the final label value $d'(v)$ for each node $v \in V$ (Remember that $d'(v)$ is the label of v in Dijkstra's algorithm). It is easy to show that the final label value $d'(v)$ equals $I(d(v))$, so the nodes can be easily split into levels according to their final labels. The specific

split algorithm will be introduced in Section 4.3. The time complexity for a single splitting is given below. In Theorem 9 we show that this implies that the total time cost for splitting is $O(m \log n / \log k + n \log n \log\log k / \log k + m \log k)$.

▶ **Lemma 5.** *Splitting V into levels at Line 9 can be done in $O(m + n \log\log k + r \log k)$.*

Finally, for every level V_i, we compute $d(\cdot)$ for nodes in this level by reducing to a new ASBPIC instance (G_i, w_i, h_i), where G_i is a subgraph of G consisting of all the nodes in V_i and some of edges that connect them. We solve each new instance by a recursive call. The construction of (G_i, w_i, h_i) is as follows:

- $G_i = (V_i, E_i)$, where V_i is the nodes at level i in G, and E_i is the set of edges which connect two nodes at level i and are not below-level, i.e., $E_i = \{(u, v) \in E \mid u, v \in V_i, w(u, v) \geq \lambda_i\}$;
- For any $e \in E_i$, $w_i(e) = +\infty$ if e is above-level; otherwise $w_i(e) = w(e)$;
- For any $v \in V_i$, $h_i(v) = \max(\{h(v)\} \cup \{w(u, v) \in E \mid u \in V_{i+1} \uplus \cdots \uplus V_l\})$.

▶ **Lemma 6.** *We can construct all the new ASBPIC instances $(G_0, w_0, h_0), \ldots, (G_l, w_l, h_l)$ in $O(m)$ time. For $v \in V_i$, the value of $d(v)$ in the instance (G_i, w_i, h_i) exactly equals to the value of $d(v)$ in the instance (G, w, h).*

Proof. We can construct all these instances (G_i, w_i, h_i) for all $0 \leq i \leq l$ by linearly scanning all the nodes and edges, which runs in $O(m)$ time. We prove the correctness by transforming (G, w, h) to (G_i, w_i, h_i) step by step, while preserving the values of $d(v)$ for all $v \in V_i$.

By definition, $\lambda_i \leq d(v) < \lambda_{i+1}$ for all $v \in V_i$. We can delete all the nodes at level less than i and delete all the edges with weight less than λ_i, since no bottleneck path ended with a node in V_i can traverse them. Also, for every edge e with weight $w(e) \geq \lambda_{i+1}$, we can replace the edge weight with $+\infty$ since $w(e)$ is certainly not the minimum in any path ended with a node in V_i.

For every edge $e = (u, v)$ where $u \in V_{i+1} \uplus \cdots \uplus V_l$ and $v \in V_i$, the edge weight $w(e)$ must be less than λ_{i+1}, otherwise $d(v) \geq \min\{d(u), w(u, v)\} \geq \lambda_{i+1}$ leads to a contradiction. Thus contracting all the nodes in $V_{i+1} \uplus \cdots \uplus V_l$ to a single node v_0 with infinite initial capacity is a transformation preserving the values of $d(v)$ for all $v \in V_i$. Finally, our construction follows by taking $h_i(v)$ to be the maximum between the weight of incoming edges from v_0 and the initial capacity $h(v)$ for every $v \in V_i$. ◀

▶ Remark. In any subsequent recursive calls of (G_i, w_i, h_i), neither cross-level nor below-level edges will appear, and all the above-level edges will become unrestricted. Also, it is easy to see that r is just the total number of cross-level and below-level edges (Recall that r is the number of edges that do not appear in any recursive calls).

4.1 Running Time

First we analyze the maximum recursion depth. The following lemma shows that randomly sampled thresholds evenly partition the restricted edges with high probability.

▶ **Lemma 7.** *Let $E^{(r)} = \{e_1, \ldots, e_q\}$ be q restricted edges sorted by their weights in E. Let $f_1, \ldots, f_k$ be $k \geq 2$ random edges sampled from $E^{(r)}$ such that $w(f_1) < w(f_2) < \cdots < w(f_k)$. Let $\lambda_i = w(f_i)$ for $i = 1, \ldots, k$, and $\lambda_0 = -\infty$, $\lambda_{k+1} = +\infty$. Let $F_i = \{e \in E \mid \lambda_i \leq w(e) < \lambda_{i+1}\}$. Then for every $t > 0$, $\max_{0 \leq i \leq k}\{|F_i|\} < tq \log k / k$ holds with probability $1 - k^{-\Omega(t)}$.*

Proof. Let $M = tq \log k / k$. If $\max_{0 \leq i \leq k}\{|F_i|\} \geq M$, then there exists an edge e_p such that e_p is chosen but for any $p + 1 \leq j < p + M$, e_j is not chosen. Note that when p is given, this

event happens with probability $\leq k \cdot (1/q) \cdot \prod_{i=1}^{k-1}((q-M-i)/(q-i)) \leq (k/q) \cdot (1-M/q)^{k-1}$. By the union bound for all possible p, we have

$$\Pr\left[\max_{0\leq i\leq k}\{|F_i|\} \geq tq\log k/k\right] \leq k(1-t\log k/k)^{k-1} \leq k^{-\Omega(t)},$$

which completes the proof. ◀

For our purposes it is enough to analyze the case that $k = 2^{\Omega\left(\sqrt{\log n}\right)}$. The following lemma gives a bound for the maximum recursion depth using Lemma 7.

▶ **Lemma 8.** *For $k = 2^{\Omega\left(\sqrt{\log n}\right)}$ where n is the number of nodes at the top level of recursion, the maximum recursion depth is $O(\log n/\log k)$ with probability $1 - n^{-\omega(1)}$.*

Proof. It is not hard to see that the total number of recursive calls of our main algorithm is $O(m)$. Applying Lemma 7 with $t = \Theta(\log n)$ and the union bound for all recursive calls, we know that with probability at least $1 - k^{-\Omega(t)} \cdot O(m) = 1 - n^{-\Omega(\log n)^{3/2}}$, after every split with $|E^{(r)}| > k$, the number of restricted edges in G_i is less than $(t\log k/k) \cdot |E^{(r)}|$ for every (G_i, w_i, h_i). Thus after $O(\log m/\log(k/(t\log k))) = O(\log n/\log k)$ levels of recursion, every ASBPIC instance (G, w, h) has $|E^{(r)}| \leq k$, and this means that in any recursive call of (G_i, w_i, h_i), the graph G_i has at most one restricted edge, which will be directly solved at Line 5. ◀

The overall time complexity of our algorithm is given by the following theorem:

▶ **Theorem 9.** *For $k = 2^{\Omega\left(\sqrt{\log n}\right)}$, with probability $1 - n^{-\omega(1)}$, our main algorithm shown in Figure 1 runs in $O(n\log n\log\log k/\log k + m\log n/\log k + m\log k)$ time.*

Proof. Let $r = |E| - \sum_{i=0}^{l}|E_i|$, $r' = |E^{(r)}| - \sum_{i=0}^{l}|E_i^{(r)}|$. First we show that the running time in each recursive call is $O(m + n\log\log k + (r+r')\log k)$.

In each recursive call of our algorithm, the time cost for sorting at Line 7 is $O(l\log l)$. For the sample edge e_i with rank i, either V_i is not empty, or this edge is cross-level, below-level, or above-level. Let l_1 be the number of edges in the former case, and l_2 be the number of edges in the latter case. For the former case, note that we only run the split algorithm for weakly-connected graphs, so there are at least $l_1 - 1$ cross-level edges, which implies $l_1 \leq r + 1$. For the latter case, e_i becomes unrestricted or does not appear for every G_i, so $l_2 \leq r'$. Thus $l = l_1 + l_2 \leq r + r' + 1$ and the time cost for sorting is $O((r+r')\log k)$.

By Lemma 5, the split algorithm runs in $O(m + n\log\log k + r\log k)$ time in each recursive call. All other parts of our algorithm run in linear time. Thus the running time for each recursion is $O(m + n\log\log k + (r+r')\log k)$. Note that the recursion depth is $O(\log n/\log k)$ with probability $1 - n^{\omega(1)}$. We can complete the proof by adding the time cost for all the $O(m)$ recursive calls together. ◀

Finally, we can get our main result by setting $k = 2^{\Theta\left(\sqrt{n\log n\log\log n/m}\right)}$ for $m \leq n\log\log n$ and setting $k = 2^{\Theta\left(\sqrt{\log n}\right)}$ for $m > n\log\log n$.

▶ **Theorem 10.** *For $m \leq n\log\log n$, SSBP can be solved in $O(\sqrt{nm\log n\log\log n})$ time with high probability; For $m > n\log\log n$, SSBP can be solved in $O(m\sqrt{\log n})$ time with high probability.*

▶ Remark. The above time bounds are also true for expected running time. It can be easily derived from the fact that the worst-case running time is at most $n^{O(1)}$.

In the rest of this section, we introduce the algorithm for ASBPIC with at most one restricted edge and the split algorithm.

4.2 Algorithm for the Graph with at Most One Restricted Edge

We introduce our algorithm for the graph with at most one restricted edge in the following two lemmas.

▶ **Lemma 11.** *For a given ASBPIC instance (G, w, h), if there is no restricted edge in G, then the values of $d(v)$ for all $v \in V$ can be computed in linear time.*

Proof. G contains only unrestricted edges, so for every $v \in V$, $d(v)$ is just equal to the maximum value of $h(u)$ among all the nodes u that can reach v. If v_1 and v_2 are in the same strongly-connected component, then $d(v_1) = d(v_2)$. Thus we can use Tarjan's algorithm [22] to contract every strongly-connected component to a node. The initial capacity of a node is the maximum $h(u)$ for all u in the component, and the capacity of an edge between nodes is the maximum among edges connecting components. Then Dijkstra approach on DAG takes linear time. ◀

▶ **Lemma 12.** *For a given ASBPIC instance (G, w, h), if there is exactly one restricted edge in G, then the values of $d(v)$ for all $v \in V$ can be computed in linear time.*

Proof. Let $e_0 = (u_0, v_0)$ be the only restricted edge in G. There are two kinds of paths in G:

1. Paths that do not traverse e. We remove e from G and use the algorithm in Lemma 11 to get $d(v)$ for every node $v \in V$.
2. Paths that traverse e. Note that $d(u_0)$ got in the previous step is the maximum capacity to u_0 through only restricted edges. Then we update $d(v)$ by $\max\{d(v), \min\{d(u_0), w(u_0, v_0)\}\}$ for every node v that can be reached from v_0.

We output the values of $d(\cdot)$ after these two kinds of updates, then all the paths should have been taken into account. ◀

4.3 Split

Now we introduce the split algorithm at Line 9 in our main algorithm. As before, we use the notation $I(x)$ for the index of a value x and $d'(v)$ is the label of v in Dijkstra's algorithm. The goal of this procedure is to split V into $l + 1$ levels, $V = V_0 \uplus V_1 \uplus \cdots \uplus V_l$, where $V_i = \{v \in V \mid I(d(v)) = i\}$. We need to show that this can be done in $O(m + n \log\log k + r \log k)$ time, where $r = |E| - \sum_{i=0}^{l} |E_i|$ is the total number of edges in E that do not appear in any (G_i, w_i, h_i).

A straightforward approach to achieve this goal is to use Dijkstra's algorithm as described in Section 2.2. We map all the edge weights and initial capacities to their indices using binary searches, and run Dijkstra's algorithm for ASBPIC. The output should be exactly $d'(v) = I(d(v))$ for every v. However, this approach is rather inefficient. Evaluating the index $I(x)$ for a given x requires $\Omega(\log l)$ time in a comparison-based model, thus in total, this algorithm needs $\Omega(n \log l)$ time to compute indices, and this does not meet our requirement for the running time.

The major bottleneck of the above algorithm is the inefficient index evaluations. Our algorithm overcomes this bottleneck by reducing the number of index evaluations for both edge weights and initial capacities to be at most $O(r + n/\log l)$.

4.3.1 Index Evaluation for Edge Weights

First we introduce our idea to reduce the number of index evaluations for edge weights. Recall that in Dijkstra's algorithm for ASBPIC we maintain a label $d'(v)$ for every $v \in V$.

In every Dijkstra step, we extract an active node u with the maximum label, and for all edges $(u, v) \in E$ we compute $\min\{d'(u), I(w(u, v))\}$ to update $d'(v)$. In the straightforward approach we evaluate every $I(w(u, v))$ using binary search, but actually this is a big waste:

1. If $w(u, v) \geq \lambda_{d'(u)}$, then $\min\{d'(u), I(w(u, v))\} = d'(u)$, so there is no need to evaluate $I(w(u, v))$.
2. If $w(u, v) < \lambda_{d'(u)}$, then $\min\{d'(u), I(w(u, v))\} = I(w(u, v))$, so we do need to evaluate $I(w(u, v))$. However, it can be shown that (u, v) is either a cross-level edge or a below-level edge, so (u, v) will not appear in any subsequent recursive calls of (G_i, w_i, h_i).

Using the method discussed above, we can reduce the number of index evaluations for edge weights to be at most $r = |E| - \sum_{i=0}^{l} |E_i|$ in Dijkstra's algorithm. Lemma 14 gives a formal proof for this.

4.3.2 Index Evaluation for Initial Capacities

Now we introduce our idea to reduce the number of index evaluations for initial capacities. Recall that in Dijkstra's algorithm, we need to initialize the label $d'(v)$ to be $I(h(v))$ for each $v \in V$, and maintain a priority queue for the labels of all active nodes. If we evaluate every $I(h(v))$ directly, we have to pay a time cost $\Omega(n \log l)$.

In our split algorithm, we first find a spanning tree T of G after replacing all the edges with undirected edges. Then we partition the tree T into $b = O(n/s)$ edge-disjoint (but not necessarily node-disjoint) subtrees, $T_1, \ldots, T_b$, each of size $O(s)$. This partition can be found in $O(n)$ time using a slight variant of the topological partition algorithm in Frederickson's paper [13].

▶ **Theorem 13.** *(see [13]) Given a tree $T = (V, E)$ with n nodes and given an integer $1 \leq s \leq n$, there exists a linear time algorithm that can partition T into edge-disjoint subtrees, $T_1, \ldots, T_b$, such that the number of nodes in each subtree is in the range $[s, 3s)$.*

We form b groups of nodes, $U_1, \ldots, U_b$, where U_i is the group of nodes that are in the i-th subtree T_i. In the running of Dijkstra's algorithm, we divide the active nodes in V into two kinds:

1. **Updated node**. This is the kind of node v that has $d'(v)$ already been updated by Dijkstra's update rule (1), which means $d'(v) = \min\{d'(u), I(w(u, v))\} \geq I(h(v))$ for some u after a previous update. The value of $\min\{d'(u), I(w(u, v))\}$ is evaluated according to Section 4.3.1, so the value of $d'(v)$ can be easily known. We can store such nodes in buckets to maintain the order of their labels.
2. **Initializing node**. This is the kind of node v whose $d'(v)$ has not been updated by Dijkstra's update rule (1), so $d'(v) = I(h(v))$. However, we do not store the value of $I(h(v))$ explicitly. For each group U_i, we put the initializing nodes in U_i into a priority queue in descending order by their initial capacities $h(\cdot)$. We only compute the value of $I(h(v))$ when v is the maximum in its group, and use buckets to maintain the maximum values from all groups.

At each iteration in Dijkstra's algorithm, we extract the active node with the maximum label among the updated nodes and initializing nodes and mark it as scanned. For the case that the maximum node $v \in U_j$ is an initializing node, we remove v from the priority queue of U_j, and compute $d'(u) = I(h(u))$ for the new maximum node u. However, if we compute this value directly using an index evaluation for $h(u)$, then we will suffer a total cost $\Omega(n \log l)$, which is rather inefficient.

Algorithm 2 Split Algorithm.

Input: Directed graph $G = (V, E)$, weight function $w(\cdot)$, initial capacity function $h(\cdot)$, $l + 2$ thresholds $-\infty = \lambda_0 < \lambda_1 < \cdots < \lambda_l < \lambda_{l+1} = +\infty$

Output: Split V into $V_0 \uplus V_1 \uplus \cdots \uplus V_l$ where $V_i = \{v \in V \mid \lambda_i \le d(v) < \lambda_{i+1}\}$.

1: Let $s = \min\{\lceil \log l \rceil, n\}$. Find a spanning tree T of G after replacing all the edges with undirected edges and partition T into $b = O(n/s)$ edge-disjoint subtrees $T_1, \ldots, T_b$, each of size $O(s)$. Form b groups of nodes, $U_1, \ldots, U_b$, where U_i is the group of nodes that are in the i-th subtree T_i.
2: For nodes in each group, we maintain a priority queue implemented by binary heap by the order of $h(\cdot)$.
3: Evaluate $I(h(v))$ only for the maximum node in each group, and initialize $l + 1$ buckets $B_0, \ldots, B_l$ which store the groups according to the index of $h(\cdot)$ of their maximum nodes.
4: Initialize $l + 1$ buckets $C_0, \ldots, C_l \leftarrow \varnothing$ which store the active nodes according to $d'(\cdot)$.
5: **for** $i \leftarrow l, l-1, \ldots, 1, 0$ **do**
6: **for all** $U \in B_i$ **do**
7: **while** $U \neq \varnothing$ **and** the maximum node u in U has $I(h(u)) = i$ **do**
8: Extract u from U and put u into C_i
9: $d'(u) \leftarrow i$
10: **while** $C_i \neq \varnothing$ **do**
11: Extract a node u from C_i
12: **for all** $(u, v) \in E$ **do**
13: $\bar{w} \leftarrow \min\{d'(u), I(w(u, v))\}$. (Evaluate $I(w(u, v))$ only if $w(u, v) < \lambda_{d'(u)}$)
14: **if** $\lambda_{\bar{w}} > h(v)$ **then**
15: **if** $d'(v)$ does not exist **or** $\bar{w} > d'(v)$ **then**
16: Delete v from $C_{d'(v)}$
17: Delete v from the group U containing it (if any) and put v into $C_{\bar{w}}$
18: $d'(v) \leftarrow \bar{w}$
19: **while** B_i contains at least one non-empty group **do**
20: Extract a non-empty group U from B_i
21: Evaluate $I(h(u))$ for the maximum node u in U and put U into $B_{I(h(u))}$
22: Split V according to d' and return

The idea to speed up is to check whether $d'(u) = d'(v)$ before performing an index evaluation. This can be done in $O(1)$ time since we can know the corresponding interval of $h(u)$ from the value of $d'(v)$ if $I(h(u)) = d'(v)$. We only actually evaluate $I(h(u))$ if $d'(u) \neq d'(v)$ after the Dijkstra step scans all nodes with level $d'(v)$. In this way, we can always ensure that the number of index evaluations in a group never exceeds the number of different final label values $d'(\cdot)$ in this group. Indeed, it can be shown that if there are c different final label values $d'(\cdot)$ in a group U_i, then there must be at least $c - 1$ cross-level edges in T_i, which implies that the number of index evaluations for initial capacities should be no greater than $r + b$. (Remember b is the number of groups in the partition.) Lemma 15 gives a formal proof for this.

4.3.3 The $O(m + n \log\log k + r \log k)$-time Split Algorithm

Now we are ready to introduce our split algorithm in full details. A pseudocode is shown in Figure 2. During the search at Line 5 - 21, B_i may contain groups with maximum nodes not at the i-th level, e.g., when the maximum node in a group U is deleted at Line 17 and

$I(h(u))$ of the new maximum node u in U has not been evaluated yet. We have the following observations:

- For all $v \in V$, $d'(v)$ is non-decreasing, and at the end we have $d'(v) = I(d(v))$.
- All the binary heaps of U_i are deletion only (so the priority queue can also be implemented by a sorted linked list).
- Only at Line 3, 13 and 21 we need to evaluate the index of $h(\cdot)$ of a node. Each index evaluation costs $O(\log l)$ time.
- The numbers of executions of the while loops at Line 7 - 9, Line 10 - 18, Line 19 - 21 are all bounded by $O(n)$.

Our algorithm is an implementation of Dijkstra's algorithm, so the correctness is obvious. The running time analysis is based on the following lemmas:

▶ **Lemma 14.** *If we evaluate $I(w(u,v))$ at Line 13, then the edge (u,v) will not be in any recursive calls of (G_i, w_i, h_i).*

Proof. We evaluate $I(w(u,v))$ only if $w(u,v) < \lambda_{d'(u)}$, so $\bar{w} = I(w(u,v))$ right after Line 13. Since u has already been scanned, $d'(u)$ here is just its final value $I(d(u))$. Note that $I(d(v)) \geq \min\{I(d(u)), I(w(u,v))\} = I(w(u,v))$. If $I(d(v)) > I(w(u,v))$, then $I(w(u,v))$ is smaller than both $I(d(u))$ and $I(d(v))$, thus (u,v) is a below-level edge or cross-level edge. If $I(d(v)) = I(w(u,v))$, then $I(d(v)) < I(d(u))$ and (u,v) is a cross-level edge. ◀

▶ **Lemma 15.** *At Line 3 and 21, if we evaluate $I(h(u))$ for c nodes u in some group U_i, then the number of different final label values $d'(\cdot)$ in U_i is at least c. Thus, the number of edges in the subtree T_i corresponding to U_i that do not appear in any recursive calls of (G_i, w_i, h_i) is at least $c-1$.*

Proof. At line 21, $I(d(u))$ must be less than i; otherwise, u should have been extracted at Line 11 before extracting u at Line 20, which is impossible. Also note that $d(u) \geq h(u)$, so $I(h(u)) \leq I(d(u))$ for all $u \in V$. Thus, if $u_1 \in U_i$ is evaluated at Line 3 and there are $c-1$ nodes $u_2, \ldots, u_c$ extracted from U_i at Line 21, then $I(d(u_1)), I(d(u_2)), \ldots, I(d(u_c))$ should be in c distinct ranges: $[I(h(u_1)), +\infty), [I(h(u_2)), I(h(u_1))), \ldots, [I(h(u_c)), I(h(u_{c-1})))$, which implies that the number of different final values of $d'(u)$ in U_i is at least c.

Suppose we remove all the cross-level edges in T_i, i.e., remove all the edges (u,v) in T_i whose final values of $d'(u)$ and $d'(v)$ differ. Then the tree should be decomposed into at least c components since there are at least c different final values of $d'(u)$ in U_i. Thus there are at least $c-1$ cross-level edges in T_i. ◀

Finally, we can derive the $O(m + n \log\log k + r \log k)$ time bound for our split algorithm.

Proof for Lemma 5. By Lemma 14, the number of index evaluations at Line 13 is at most r. Let c_i be the number of index evaluations at Line 3 and 21 for nodes in the group U_i. Then by Lemma 15, $\sum_{i=1}^{b} c_i \leq r + b$. Thus the total number of index evaluations in our split algorithm can be bounded by $2r + b \leq O(r + n/\log l)$, which costs $O(r \log l + n)$ time.

The extraction operations of the maximum element at Line 8 and 21 and the deletion operation at Line 17 runs in $O(\log s) \leq O(\log\log l)$ time per operation. Note that there are $O(n)$ such operations, thus all these operations cost $O(n \log\log l)$ time in total.

It can be easily seen that all other parts of our split algorithm runs in linear time, so the overall time complexity is $O(m + n\log\log l + r\log l) \leq O(m + n\log\log k + r\log k)$. ◀

5 Discussion

We give an improved algorithm for solving SSBP in $O(m\sqrt{\log n} + \sqrt{mn \log n \log\log n})$ faster than sorting for sparse graphs. This algorithm is a breakthrough compared to traditional Dijkstra's algorithm using Fibonacci heap. There are some open questions remained to be solved. Can our algorithm for SSBP be further improved to $O(m\beta(m, n))$, which is the time complexity for the currently best algorithm for s-t BP? Can we use our idea to obtain an algorithm for SSBP that runs faster than Dijkstra in word RAM model?

Abstract

We present improved algorithms for solving the All Pairs Non-decreasing Paths (APNP) problem on weighted digraphs. Currently, the best upper bound on APNP is $\tilde{O}(n^{(9+\omega)/4}) = O(n^{2.844})$, obtained by Vassilevska Williams [TALG 2010 and SODA'08], where $\omega < 2.373$ is the usual exponent of matrix multiplication. Our first algorithm improves the time bound to $\tilde{O}(n^{2+\omega/3}) = O(n^{2.791})$. The algorithm determines, for every pair of vertices s, t, the minimum last edge weight on a non-decreasing path from s to t, where a non-decreasing path is a path on which the edge weights form a non-decreasing sequence. The algorithm proposed uses the combinatorial properties of non-decreasing paths. Also a slightly improved algorithm with running time $O(n^{2.78})$ is presented.

1 Introduction

Given a digraph with arbitrary real weights, a non-decreasing path is a path on which the edge weights form a non-decreasing sequence. Two of the problems studied on non-decreasing paths are the *Single Source Non-decreasing Paths* (SSNP) problem and the *All Pairs Non-decreasing Paths* (APNP) problem. The problem of SSNP was first studied by Minty [13]. The motivation is a train scheduling problem, as reviewed in [22]. Every train stop is mapped to a vertex. A train from stop v_1 with departure time t_1 to stop v_2 with arrival time t_2 is mapped to a vertex v with two edges (v_1, v), (v, v_2), of which the weights are t_1, t_2 resp. Now a trip from s to t is possible only when there exists a non-decreasing path from s to t in the

constructed digraph. As said in [22], for SSNP a folklore modification of Dijkstra's algorithm [5], implemented using Fibonacci heaps [8], gives the running time of $O(m + n \log n)$, where m, n are the number of edges and vertices resp. In the word RAM model the first linear-time algorithm was given by Vassilevska Williams [22]. With a slight modification, the algorithm also runs in $O(m \log \log n)$ time in the standard addition-comparison model.

A restriction of APNP in vertex-weighted digraphs is computationally equivalent to the problem of *Maximum Witness for Boolean Matrix Multiplication* (MWBMM) [22]. (Note that the complexity of computing MWBMM is at least $\Omega(n^\omega)$ [17].) An algorithm of $O(n^{2+\mu})$ time for the latter problem was given by Czumaj et al. [3], where μ satisfies the equation $\omega(1, \mu, 1) = 1 + 2\mu$ and $\omega(1, \mu, 1)$ is the exponent of the multiplication of an $n \times n^\mu$ matrix by an $n^\mu \times n$ matrix. Currently, the best available bounds on $\omega(1, \mu, 1)$ by Le Gall and Urrutia [11] imply that $\mu < 0.5286$. The first truly sub-cubic algorithm for edge-weighted APNP was also presented in [22]. The algorithm originally runs in $\tilde{O}(n^{(15+\omega)/6}) = O(n^{2.896})$ time[2] based on an $O(n^{2+\omega/3})$-time $(\min, \leq)$-product ($\min_k\{B[k, j] \mid A[i, k] \leq B[k, j]\}$ for $(\min, \leq)(A, B)$) algorithm from [21], where ω is the exponent of square matrix multiplication. The best upper bound on ω is currently $\omega < 2.373$ [12, 23]. By using a faster $O(n^{(3+\omega)/2})$-time algorithm from [6] for $(\min, \leq)$-product, the result can be improved to $\tilde{O}(n^{(9+\omega)/4})$ as indicated in the abstract. These two algorithms for $(\min, \leq)$-product are from [21] and [6] resp. The faster algorithm of [6] utilizes a simple technique called *row-balancing*, which we introduce in details in Section 2.

A closely related problem of APNP is the *All Pairs Bottleneck Paths* (APBP) problem, where the bottleneck weight of a path is the smallest weight of an edge on the path. Intuitively for a digraph with non-negative edge weights, APBP determines, for every pair of vertices s, t, the maximum amount of flow that can be routed from s to t along any single path. As indicated in [22], APNP is at least as hard as APBP. We briefly explain it here. Consider an $O(n^{3-\delta})$-time algorithm for APNP with $0 < \delta \leq 1$. Now to compute the $(\min, \leq)$-product of two $n \times n$ matrices A, B, a tripartite digraph $G' = (V_1 \cup V_2 \cup V_3, E')$ can be constructed as follows. The edge from $i \in V_1$ to $k \in V_2$ is represented by $A[i, k]$; the edge from $k \in V_2$ to $j \in V_3$ is similarly represented by $B[k, j]$. Hence the $(\min, \leq)$-product is solved in $O(n^{3-\delta})$ time. The $(\max, \min)$-product ($\max_k \min\{A[i, k], B[k, j]\}$ for $(\max, \min)(A, B)$) is a combination of two variants of $(\min, \leq)$-product. Therefore it can also be computed in $O(n^{3-\delta})$ time. If $(\max, \min)$-product is computable in $O(n^{3-\delta})$ time, then APBP is computable in $O(n^{3-\delta})$ time, as $(\mathbb{R}, \min, \max, \infty, -\infty)$ is a closed semiring [21]. There are several results on the APBP problem. On vertex-weighted digraphs, Shapira et al. [17] showed that APBP can be solved in $O(n^{2+\mu})$ time. They also demonstrated the computational equivalence (up to constant factors) among vertex-weighted APBP and several other problems. The forementioned problem of MWBMM is one of them. The first truly sub-cubic algorithm for edge-weighted APBP was given by Vassilevska et al. [21], with the running time of $O(n^{2+\omega/3})$. Later an improved algorithm was proposed in [6], which runs in $O(n^{(3+\omega)/2})$ time. There are several variants of APBP. One is the *All Pairs Bottleneck Shortest Paths* (APBSP) problem, which for every pair of vertices u, v, determines a path with the maximum bottleneck weight among all the shortest paths from u to v. The shortest paths here are measured w.r.t. the unweighted distances. On edge-capacitated digraphs, Vassilevska et al. [21] gave an algorithm for APBSP with the running time $\tilde{O}(n^{(15+\omega)/6})$, which was improved to $\tilde{O}(n^{(3+\omega)/2})$ in [6]. On vertex-capacitated digraphs, Shapira et al. [17] presented an $\tilde{O}(n^{(8+\mu)/3})$-time algorithm. Also the result was later improved by [6].

[2] Here $\tilde{O}(\cdot)$, as usual, hides poly-logarithmic factors.

Fast matrix multiplication algorithms have numerous applications in other graph problems as well. We list here only a subset of them, which includes finding a maximum triangle in vertex-weighted graphs [19, 20, 4], to obtain the All Pairs Shortest Paths [9, 10, 16, 18, 1, 25, 7], finding minimum weight cycles in directed or undirected graphs with integral edge weights [14, 24, 2, 15].

Our Results: We give faster algorithms for solving APNP on digraphs. The results are listed in Theorem 1, which follows directly from Theorem 18 and Theorem 21.

▶ **Theorem 1.** *Let $G = (V, E, w)$ be a real edge-weighted digraph. There exists a* deterministic *algorithm which solves the problem of APNP in $\tilde{O}(n^{2+\omega/3}) = O(n^{2.791})$ time. There also exists another slightly faster* deterministic *algorithm which runs in $O(n^{2.78})$ time using rectangular matrix multiplications.*

A High-level Overview: The problem of APNP can be solved by running (essentially) $(n-1)$ steps of the $(\min, \leq)$-product of the adjacency matrix of the input digraph. We utilize the fact that the adjacency matrix in the computation is always *fixed*, and therefore when the rows of it all have a bounded number of $(< \infty)$ entries, we find a simple (and faster) alternative to the repeated applications of the $(\min, \leq)$-product. To make use of this simple alternative, we partition the input digraph into many sparse subgraphs, and compute APNP by considering the edges one subgraph by one subgraph. However, even in a sparse subgraph the number of $(< \infty)$ entries in a row might be still as large as $\Omega(n)$. Thus we further classify a row as type *low* or *high*, where a high row corresponds to a high out-degree vertex in the subgraph. The simple alternative is used to replace the $(\min, \leq)$-product for the submatrix consisting of low rows. Also it computes the portion of a non-decreasing path until the *first* vertex of high out-degree. The remaining portion from this high out-degree vertex to the destination can be constructed by the relevant queries on a slightly modified data structure from [22]. However, to get an efficient algorithm we should first make sure of the queries worthy of asking, which is actually a weaker problem of the existence of non-decreasing paths.

The paper is organized as follows. We introduce the preliminaries required in the next section. Then in Section 3 we propose an algorithm for a simple case, which is also a sub-routine of the improved algorithms presented in Section 4.

2 Preliminaries

Given a real edge-weighted digraph $G = (V, E, w)$, where $w : E \to \mathbb{R}$ is a weight function defined on its edges, the All-Pairs Non-decreasing Paths (APNP) problem asks to determine, for every pair of vertices u, v, the minimum last edge weight on a non-decreasing path from u to v (∞ if such a path does not exist). Typically the output is in tabular form, i.e. a matrix R with $R[i, j]$ corresponding to the minimum last edge weight of a non-decreasing path from u_i to u_j. Also conventionally the entries $R[i, i]$'s are set as $-\infty$ [22]. The matrix R is called the "APNP matrix" of G. Given a matrix A, the i-th row, the j-th column of A are denoted as $A[i, \cdot]$, $A[\cdot, j]$ resp. Also for two matrices A, B of the same size, the entry-wise minimum of them is denoted as $\min(A, B)$. Given a path p in G, if vertex k_1 appears earlier on p than k_2, then the portion of p from k_1 to k_2 is denoted as $p[k_1, k_2]$. Notations $p(k_1, k_2]$, $p[k_1, k_2)$, $p(k_1, k_2)$ represent $p[k_1, k_2]$ excluding k_1, k_2, both k_1 and k_2 resp. The following special matrix products are used in later algorithms.

▶ **Definition 2** (Various Products). Given two $n \times n$ matrices A and B over a totally ordered set, the dominance product $A \circledS B$ is defined as

$$(A \circledS B)[i,j] = |\{k \mid A[i,k] \leq B[k,j]\}|.$$

The $(\min, \leq)$-product $A \circledcirc B$ is defined as

$$(A \circledcirc B)[i,j] = \begin{cases} \min_k\{B[k,j] \mid A[i,k] \leq B[k,j]\} & \text{if } \exists k, A[i,k] \leq B[k,j], \\ \infty & \text{otherwise.} \end{cases}$$

Next we review a simple technique called *row-balancing* [6]. Basically by row-balancing, a matrix is decomposed into a sparse matrix and a dense one, where the finite entries of the dense matrix are uniformly re-distributed across the rows.

▶ **Definition 3** ([6] Row-Balancing). Let A be an $n \times p$ matrix with m finite elements. Depending on context, the other elements will either all be ∞ or all be $-\infty$. We assume the former below. The row-balancing of A, or $\mathbf{rb}(A)$, is a pair (A', A'') of $n \times p$ matrices, each with at most $k = \lceil m/n \rceil$ elements in each row. The row-balancing is obtained by the following procedure: First, sort all the finite elements in the i-th row of A in non-increasing or non-decreasing order depending on context , and divide this list into several parts $T_i^1, T_i^2, \ldots, T_i^{a_i}$ such that all parts except the last one contain k elements and the last part $(T_i^{a_i})$ contains at most k elements. Let A' be the submatrix of A containing the last parts:

$$A'[i,j] = \begin{cases} A[i,j] & \text{if } A[i,j] \in T_i^{a_i}, \\ \infty & \text{otherwise.} \end{cases}$$

Since the remaining parts have exact k elements, there can be at most $m/k \leq n$ of them. We assign each part to a distinct row in A'', i.e., we choose an arbitrary mapping $\rho : [n] \times [p/k] \to [n]$ such that $\rho(i,q) = i'$ if T_i^q is assigned row i'; it is undefined if T_i^q doesn't exist. Let A'' be defined as:

$$A''[i',j] = \begin{cases} A[i,j] & \text{if } \rho^{-1}(i') = (i,q) \text{ and } (i,j) \in T_i^q, \\ \infty & \text{otherwise.} \end{cases}$$

Thus, every finite $A[i,j]$ in A has a corresponding element in either A' or A'', which is also in the j-th column. The column-balancing of A, or $\mathbf{cb}(A)$, is similarly defined as (A'^T, A''^T), where $(A', A'') = \mathbf{rb}(A^T)$.

This simple technique is very useful for computing $A \circledS B$, $A \circledcirc B$, $(\max, \min)(A, B)$, and several new hybrid products defined in [6]. Below is a theorem from [6], which shows how to compute $A \circledS B$ using $\mathbf{cb}(A)$.

▶ **Theorem 4** ([6] Sparse Dominance Product). *Let A and B be two $n \times n$ matrices where the number of non-(∞) values in A is m_1 and the number of non-$(-\infty)$ values in B is m_2. Then $A \circledS B$ can be computed in time $O(m_1 m_2/n + n^\omega)$.*

There is a symmetric problem of computing non-decreasing paths with maximum first edge weights. Note that the maximum first edge weight on a non-decreasing path from i to i is defined as ∞, and for $i \neq j$, if no non-decreasing path exists, the maximum first edge weight is defined as $-\infty$. The time complexity of the single source version is given below.

▶ **Theorem 5** ([22] Maximum First Edge Weight). *Given a digraph G with n vertices, m edges, and a vertex s, there exists an algorithm which in $O(m \log n)$ time outputs the maximum first edge weight on a non-decreasing path from s to v for every $v \in V$.*

We need a slightly modified auxiliary data structure from [22] to efficiently compute a non-decreasing path with the minimum last edge weight starting from a subset of the out-edges of the source vertex. A paraphrased proof is given below.

▶ **Theorem 6.** *Given a digraph $G = (V, E, w)$ with n vertices, m edges, and a vertex s, there exists an algorithm which in $O(m \log n)$ time constructs a balanced binary search tree $T(t)$ for every $t \in V$. With $T(t)$, given a weight value w', the algorithm can determine in $O(\log n)$ time the minimum last edge weight of a non-decreasing path from s to t, starting from any out-edge e of s with $w(e) \geq w'$.*

Proof. For every vertex v, add an attribute $d[v]$ and a list $L(v)$, where $d[s] = -\infty$, $d[v] = \infty$ if $v \neq s$, and $L(v) = \varnothing$ initially. Next start a search resembling DFS from s, where differently the edges of s are explored in *reverse* sorted order, and the search only follows non-decreasing paths. Also for every edge (u, v), once explored, we first run $d[v] \leftarrow \min\{d[v], w(u, v)\}$ and then remove (u, v) from G. Lastly, vertices can be repeatedly visited. Consider the time when this recursive search backtracks to the initial search at s. The algorithm will explore the next *unexplored* out-edge of s in the reverse sorted order. We can thus partition the search into different phases, each of which corresponds to the search starting from an unexplored out-edge of s until the algorithm backtracks to s. Consider the end of a specific phase corresponding to an out-edge e of s. For every v of which $d[v]$ becomes *strictly* smaller in this phase, append $(w(e), d[v])$ to $L(v)$. At the end of the whole search, for every v, scan $L(v)$, where for consecutive elements of equal $w(e)$, only the last one is retained. Next transform $L(v)$ into a balanced binary search tree $T(v)$ keyed by $w(e)$.

Given a weight value w', the value required is the $d[v]$ attribute of the predecessor found. ◀

We last review a standard technique called *bridging set*, which is repeatedly used in the literature [6, 22, 25, 17]. The following lemma is one from [22]. The set of size $\frac{n \log n}{L}$ constructed is an L-bridging set.

▶ **Lemma 7** ([22, 25])**.** *Given a collection of N subsets of $\{1, \ldots, n\}$, each of size L, one can find in deterministic $O(NL)$ time a set of $\frac{n \log n}{L}$ elements of $\{1, \ldots, n\}$ hitting every one of the subsets.*

Model of Computation: We use the standard addition-comparison computational model. The only operations performed on real numbers are comparisons in this paper.

3 Warm Up: A Simple Case

As a warm up for our main algorithms, we consider a simple algorithm, which is efficient if the out-edges are uniformly distributed across the vertices. The main purpose is to give an idea of how the combinatorial properties of non-decreasing paths are utilized, and the difficulty of extending the algorithm to the general case.

Given a digraph $G = (V, E, w)$, let $L(E)$ be a sorted list of the edges in E. We evenly divide $L(E)$ into t parts such that each part has at most $\lceil n^2/t \rceil$ edges. Each part corresponds to a subgraph of G. Therefore there are t subgraphs. Denote them as G_r for $1 \leq r \leq t$. The edge weights in G_{r-1} is no greater than those in G_r.

Consider the adjacency matrix A_j of G_j. By saying a *simple* case, we mean the number of $(< \infty)$ elements of any row in any A_j is bounded by d, which has $n/t \leq d \leq n$. This assumption is *only* used in Theorem 15 later. We use the notation $G_{\leq r}$ to represent the

subgraph induced by the ($< \infty$) entries of A_j for $1 \leq j \leq r$. The notation $G_{<r}$ can be inferred similarly. The proposed algorithm consists of t iterations. In the r-th iteration, the APNP matrix of $G_{<r}$ is extended to the APNP matrix of $G_{\leq r}$. Consider the APNP matrix R of $G_{<r}$. Except a technical issue of edges of equal weights straddling across different A_r's (which is handled later in this section), one can verify that by running $R \leftarrow \min(R, R \otimes A_r)$ for $(n-1)$ steps, the matrix R will be the APNP matrix of $G_{\leq r}$. Intuitively by n' steps of $R \leftarrow \min(R, R \otimes A_r)$, the algorithm considers all the non-decreasing paths containing at most n' edges of G_r. The combinatorial properties of non-decreasing paths bring the following observations in the extension from $G_{<r}$ to $G_{\leq r}$.

The APNP matrices of $G_{<r}$, $G_{\leq r}$ are denoted as R, R' resp. If $R[i,j] < \infty$, then the non-decreasing path in G from i to j with the minimum last edge weight is already computed, for existing non-decreasing paths with minimum last edge weights cannot be improved by introducing edges of no smaller weights.

▶ **Observation 8** (An Entry Only Computed Once)**.** If $R[i,j] < \infty$, then $R'[i,j] = R[i,j]$.

The above observation indicates that the exact value of an entry of the APNP matrix is computed in at most one extension among all the extensions.

By allowing non-decreasing paths with more edges of G_r, minimum last edge weights of non-decreasing paths never become larger. Therefore we have the following observation.

▶ **Observation 9** (Non-increasing of Entries)**.** In the process of the $(n-1)$ steps of $R \leftarrow \min(R, R \otimes A_r)$, the entry $R[i,j]$ is non-increasing.

Generally, given a non-decreasing path p from s to t with the minimum last edge weight, we can only claim subpaths starting from s (*prefixes*) can be replaced with non-decreasing paths with minimum last edge weights. However, as shown below, except the technicality on equal weights handled later, the claim also holds for certain other subpaths.

▶ **Observation 10** (Two Parts of A Path)**.** Consider a non-decreasing path p in $G_{\leq r}$ with the minimum last edge weight. W.l.o.g. the path p can be split into two portions p_1, p_2 lying within $G_{<r}$, G_r resp. Any prefix of p_2 can be replaced with a non-decreasing path in G_r with the minimum last edge weight.

We use the following definition to capture the entries of interest in R'.

▶ **Definition 11.** An entry $R'[i,j]$ is *new* w.r.t. R if $R'[i,j] < \infty$ but $R[i,j] = \infty$. Otherwise, it is *old*.

Use n_r to denote the number of new entries of the APNP matrix of $G_{\leq r}$ w.r.t. the APNP matrix of $G_{<r}$. The following observation is then obvious.

▶ **Observation 12** (Bounded Number of New Entries)**.** $\sum_{1 \leq r \leq t} n_r \leq n^2$.

We also need a different view of computing $C = \min(A, A \otimes B)$, where A, B are $n \times n$ matrices. The matrix C is the entry-wise minimum of A and the n matrices $A[\cdot, k] \otimes B[k, \cdot]$ for $1 \leq k \leq n$. An algorithm for computing C using this view is given in Table 1. Now we present the intuition of the algorithm for the simple case.

The Intuition: The matrices R, R' are defined as before. Among all the non-decreasing paths from i to j in $G_{\leq r}$ with the minimum last edge weight, consider one path p with the least number of edges in G_r. As in Observation 10 (Two Parts of A Path), w.l.o.g. p is a concatenation of subpaths $p[i,k_1]$, $p[k_1,j]$. Subpaths $p[i,k_1]$, $p[k_1,j]$ are within $G_{<r}$, G_r resp. The entry $R'[i,k_1]$ is old, whereas the entries $R'[i,k']$'s are new for $k' \in p(k_1,j)$

Algorithm 1 An algorithm for computing $C = \min(A, A \otimes B)$.

(S1) Initialize C as A. Construct a sorted list $L(B[k,\cdot])$ of the $(< \infty)$ elements of $B[k,\cdot]$ in non-increasing order, for every k.
(S2) For every $A[\cdot,k]$, and for every $A[i,k]$ within:
  (S21) Scan $L(B[k,\cdot])$ from head to tail until the first element of $L(B[k,\cdot])$ which is less than $A[i,k]$.
  (S22) $C[i,j] \leftarrow \min\{C[i,j], B[k,j]\}$ for every $B[k,j]$ scanned, excluding the first element of $L(B[k,\cdot])$ which is less than $A[i,k]$.

due to p having the least number of edges in G_r. Therefore during the $(n-1)$ steps of $R \leftarrow \min(R, R \otimes A_r)$, the old entries effectively change R *only* in the first step. The changes of R in the later $(n-2)$ steps are contributed only by the *new* entries. In the view of the algorithm in Table 1, the entry (i,k') of R is only compared with the k'-th row of A_r. As the number of $(<\infty)$ elements of the k'-th row of A_r is assumed to be bounded, the cost brought by all the new entries is bounded due to Observation 9 (Non-increasing of Entries) and Observation 12 (Bounded Number of New Entries).

Besides the algorithm in Table 1, we also need an "ordinary" way to compute $R \otimes A_r$ as shown below.

▶ **Lemma 13** (The First Edge). *Given the APNP matrix R of $G_{<r}$, the product $R \otimes A_r$ can be computed in $\tilde{O}(n^\omega + n_r \cdot \frac{n}{t})$ time.*

Proof. According to Observation 8 (An Entry Computed Only Once), only the new entries of $R \otimes A_r$ w.r.t. R are of concern. To get these, we first determine the set S of (i,j)'s with $(R \otimes A_r)[i,j] < \infty$ but $R[i,j] = \infty$. Again to determine whether $(R \otimes A_r)[i,j] < \infty$, we only need to compute $R \circledcirc A_r$, where a slight difference is that here only the $(<\infty)$ entries of A_r are considered. As the $(<\infty)$ entries of R are no greater than those of A_r, the product $R \circledcirc A_r$ is a matrix product of two Boolean matrices corresponding to the $(<\infty)$ entries of R, A_r resp., which is computable in $O(n^\omega)$ time.

To determine the exact value of $(R \otimes A_r)[i,j] < \infty$, we use an idea similar to one in [6]. Let $(A'_r, A''_r) = \mathbf{cb}(A_r)$. Compute $R \circledcirc A'_r$ and $R \circledcirc A''_r$ in $O(n^\omega)$ time. The value of $(R \otimes A_r)[i,j]$ is $R[i,\cdot] \otimes A_r[\cdot,j]$. In $\mathbf{cb}(A_r)$, the column $A_r[\cdot,j]$ is divided into a_j parts $T_j^1, \ldots, T_j^{a_j}$. To determine the right q' where $(R \otimes A_r)[i,j] \in T_j^{q'}$, check $(R \circledcirc A'_r)[i,j] > 0$, and if it does not hold, search for the largest q with $(R \circledcirc A''_r)[i, \rho(j,q)] > 0$. Note that T_j^q's with $q < a_j$ are assigned to columns $\rho(j,q)$'s in matrix A''_r. Once q' is known, the exact value of $(R \otimes A_r)[i,j]$ is returned by an exhaustive enumeration within $T_j^{q'}$. The total time for the new entries of $R \otimes A_r$ is $\tilde{O}(n^\omega + n_r \cdot \frac{n}{t})$, as each entry of $R \circledcirc A''_r$ is checked no more than once, and $T_j^{q'}$'s are of size $O(n/t)$. ◀

A Technicality on Equal Weights: To let the edges of a non-decreasing path first come from $G_{<r}$, then from G_r, we need to handle the case in which the edges of equal weight straddle across different A_r's. We split out these special edges and merge them into single matrices. Consider one such a matrix A'. The APNP matrix R' of the corresponding subgraph of A' can be computed by a transitive closure algorithm in $O(n^\omega)$ time. Suppose the APNP matrix before processing A' is R. Next we run $R \leftarrow \min(R, R \otimes R')$, which is similar to Lemma 13 (The First Edge), but now the finite entries of R' are all equal to the single value. Therefore the cost is $O(n^\omega)$. As there are only $O(t)$ such A''s, the total cost for the technicality is only $O(t \cdot n^\omega)$.

Algorithm 2 The algorithm for the simple case.

(S1) An APNP matrix R is initialized as $R[i,i] = -\infty$, and $R[i,j] = \infty$ for $i \neq j$.

(S2) $\forall r, 1 \leq r \leq t$, the APNP matrix R of $G_{<r}$ is extended to the APNP matrix of $G_{\leq r}$. Construct a sorted list $L(A_r[k,\cdot])$ of the $(< \infty)$ elements of $A_r[k,\cdot]$ in non-increasing order, for $1 \leq k \leq n$.

(S21) Run $R \leftarrow \min(R, R \circledcirc A_r)$ as in Lemma 13 (The First Edge). Let S be the set of the entries of R which get *strictly* smaller. Any entry *first* added to S, say $R[i,k]$, is associated with a pointer pointing to the head of $L(A_r[k,\cdot])$.

(S22) Run the following for $(n-2)$ steps or until $S = \varnothing$.

i. For every $R[i,k] \in S$:

A. Starting from the position of $L(A_r[k,\cdot])$ pointed to by the pointer associated with $R[i,k]$, move the pointer element by element until the first element of $L(A_r[k,\cdot])$ which is less than $R[i,k]$.

B. $R[i,j] \leftarrow \min\{R[i,j], A_r[k,j]\}$, for every element $A_r[k,j]$ of $L(A_r[k,\cdot])$ scanned, excluding the first element of $L(A_r[k,\cdot])$ which is less than $R[i,k]$.

ii. Re-initialize S as the set of the entries of R which get *strictly* smaller in this step.

iii. Any entry *first* added to S, say $R[i,k]$, is associated with a pointer pointing to the head of $L(A_r[k,\cdot])$.

The formal algorithm for the simple case is given in Table 2. The analysis for it is given in Theorem 15. Also by Observation 8 (An Entry Only Computed Once), the set S in Table 2 has the following property which is useful in the proof.

▶ **Observation 14.** The set S in Table 2 contains only the new entries of the APNP matrix of $G_{\leq r}$ w.r.t. the APNP matrix of $G_{<r}$.

▶ **Theorem 15.** *If the number of $(< \infty)$ elements in any row of A_r is bounded by d, then the steps S21 and S22 in Table 2 can find the APNP matrix of $G_{\leq r}$ in $\tilde{O}(n^\omega + n_r \cdot (d + \frac{n}{t}))$ time in every iteration. So the total time is $\tilde{O}(t \cdot n^\omega + n^2 \cdot (d + \frac{n}{t}))$.*

Proof. To show the correctness, we only need to prove that the step S22 in Table 2 is equivalent to $(n-2)$ steps of the algorithm in Table 1. This is almost obvious, as the entries not getting *strictly* smaller during the previous step of $R \leftarrow \min(R, R \circledcirc A_r)$ do not contribute anything in the current step of $R \leftarrow \min(R, R \circledcirc A_r)$. Also if S in the step S22 of Table 2 is empty, we can stop earlier than $(n-2)$ steps, as later steps of $R \leftarrow \min(R, R \circledcirc A_r)$ give the same R.

Note that the cost of the step S22 in Table 2 is charged to the scanning induced by the entries in S. By Observation 9 (Non-increasing of Entries) and Observation 14, the time of the step S22 of Table 2 in r-th iteration is $\tilde{O}(n_r \cdot d)$. Also by Lemma 13 (The First Edge), the step S21 of Table 2 takes $\tilde{O}(n^\omega + n_r \cdot \frac{n}{t})$ time, thus prove the theorem. ◀

So if the out-edges are uniformly distributed across all vertices, i.e., the number of $(< \infty)$ elements of any row in any A_r is always bounded by $O(n/t)$ for any t, then we can get a $\tilde{O}(n^{(3+\omega)/2})$ time APNP algorithm by setting $t = n^{(3-\omega)/2}$.

Generally a row of an A_r could have as many as $\Omega(n)$ $(< \infty)$ elements. Rows with a large number of $(< \infty)$ elements correspond to vertices of high out-degree. A new approach for them is given in the next section.

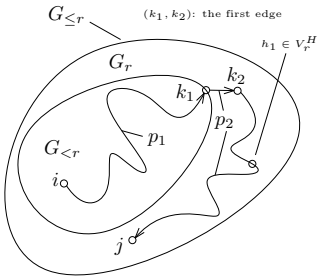

Figure 1 An illustration of the extension of the APNP matrix from $G_{<r}$ to $G_{\le r}$ in the general case.

4 Improved Algorithms for APNP

We move to the general case, in which the number of $(< \infty)$ elements in a row might not be bounded by $O(n/t)$. For ease of analysis, the edge set is divided into n^t subsets, each with at most $\lceil n^2/n^t \rceil = \lceil n^{2-t} \rceil$ edges. The vertices of G_r are classified as *high* out-degree with out-degree $> n^{1-t+s}$, or *low* out-degree otherwise, where $s > 0$ is a parameter to be chosen. Denote the sets of high out-degree, low out-degree vertices of G_r as V_r^H, V_r^L resp. Note that $|V_r^H| = O(n^{1-s})$.

The Intuition: As illustrated in Figure 1, among all the non-decreasing paths in $G_{\le r}$ from i to j with the minimum last edge weight, consider one path p with the least number of edges in G_r. By running the step S21 of Table 2, we construct the first edge (k_1, k_2). Thanks to p having the least number of edges in G_r, entries (i, k') of the APNP matrix of $G_{\le r}$ for $k' \in p[k_2, j)$ are new w.r.t. the APNP matrix of $G_{<r}$. The hard case is when there exists a vertex from V_r^H on $p[k_2, j)$. Consider the first such vertex h_1 from V_r^H. The important observation is that the edges on $p[k_2, h_1]$ are the out-edges of *low* out-degree vertices. Therefore, if we run the step S22 of Table 2, but differently only on the *low* out-degree vertices, then the portion $p[i, h_1]$ is successfully constructed. The last portion $p[h_1, j]$ can be constructed by Theorem 6, as $p[h_1, j]$ represents a non-decreasing path starting with an edge of weight no smaller than the last edge weight of $p[i, h_1]$. However, to get an efficient algorithm, we could not afford to construct $p[h_1, j]$ if it did not exist. To determine the existence of $p[h_1, j]$, we replace $p[h_1, j]$ with a non-decreasing path in G_r from h_1 to j with the *maximum* first edge weight. Then the existence of $p[h_1, j]$ is reduced to whether $p[i, h_1]$ can be concatenated with this replacement of $p[h_1, j]$.

The algorithm for the general case is described in Table 3. For the matrix H_1^N in Table 3, we have the following properties which are crucial for the correctness and an efficient algorithm.

▶ **Observation 16.** Consider one path p with the least number of edges in G_r among all the non-decreasing paths in $G_{\le r}$ from i to j with the minimum last edge weight. Let $p[k_1, j]$ be the portion of p in G_r. If $p[k_1, j] \neq \varnothing$, and there exists a vertex from V_r^H on $p(k_1, j)$, then the last edge weight of $p[i, h_1]$ is stored in $H_1^N[i, h_1]$, where h_1 is the first vertex in V_r^H on $p(k_1, j)$. For the matrix H_1^N, the number of $(< \infty)$ entries of H_1^N is no greater than n_r.

For the matrix X, the number of $X[i, j] = 1$ with $R[i, j] = \infty$ is no more than n_r. Such (i, j)'s of X are associated with non-decreasing paths never appearing in $G_{<r}$. Hence these (i, j)'s in the APNP matrix of $G_{\le r}$ are new w.r.t. R. By Theorem 6, the running time of the step S24 therefore is as follows.

Algorithm 3 The algorithm for the general case.

(S1) An APNP matrix R is initialized as $R[i,i] = -\infty$, and $R[i,j] = \infty$ for $i \neq j$.

(S2) $\forall r, 1 \leq r \leq n^t$, the APNP matrix R of $G_{<r}$ is extended to the APNP matrix of $G_{\leq r}$.

- **(S21)** Split out a sub-matrix A_r^L of A_r, which contains only the rows with the number of ($< \infty$) elements no greater than n^{1-t+s}. Initialize a matrix R' as R.
  - **i.** Run the steps S21, S22 in Table 2 with inputs R', A_r and A_r^L. The step S22 of Table 2 only works on A_r^L instead of A_r.
- **(S22)** With Theorem 5 (Maximum First Edge Weight), compute an $n^{1-s} \times n$ matrix H_2 with $H_2[i,j]$ representing the maximum first edge weight on a non-decreasing path in G_r from $i \in V_r^H$ to j.
- **(S23)** Group the entries of R' from V to V_r^H that are *new* w.r.t. R as an $n \times n^{1-s}$ matrix H_1^N. Construct a Boolean matrix X with $X[i,j] = 1$ if $(H_1^N \circledS H_2)[i,j] > 0$.
- **(S24)** Initialize a matrix R'' as R. For every $h_1 \in V_r^H$, use Theorem 6 to build the auxiliary data structure for h_1 in G_r, i.e., a set of $T(h_1, j)$'s for all $j \in V$.
  For every $X[i,j] = 1$ with $R[i,j] = \infty$:
  - **i.** For every $h_1 \in V_r^H$:
    - **A.** Query $T(h_1, j)$ with $w' = H_1^N[i, h_1]$. Get the minimum last edge weight w'' of a non-decreasing path from h_1 to j in G_r, starting from any out-edge e of h_1 with $w(e) \geq w'$.
    - **B.** $R''[i,j] \leftarrow \min(R''[i,j], w'')$.
- **(S25)** $R \leftarrow \min(R', R'')$.

▶ **Observation 17.** The step S24 of Table 3 has the running time of $\tilde{O}(n_r \cdot n^{1-s} + n^{1-s} \cdot n^{2-t})$.

▶ **Theorem 18.** *Given a real edge-weighted digraph on n vertices, the APNP matrix can be computed in $\tilde{O}(n^{2+\omega/3}) = O(n^{2.791})$ time.*

Proof. We show the APNP matrix R is correctly extended from $G_{<r}$ to $G_{\leq r}$. Among all the non-decreasing paths in $G_{\leq r}$ from i to j with the minimum last edge weight, consider one path p with the least number of edges in G_r. We show p can be constructed by the algorithm. As in Observation 10 (Two Parts of A Path), the path p consists of two subpaths $p[i, k_1]$, $p[k_1, j]$, lying within $G_{<r}$, G_r resp. An illustration is given in Figure 1. If $p[k_1, j] = \varnothing$, then $R[i,j]$ is an old entry. Therefore p is already constructed. Consider the case in which $p[k_1, j] \neq \varnothing$. Let (k_1, k_2) be the first edge on $p[k_1, j]$. If there is no vertex in V_r^H on $p[k_2, j)$, the circumstance is similar to the simple case of Section 3. The step S21 successfully constructs p under this circumstance. The only case left is when there exists a vertex in V_r^H on $p[k_2, j)$. Consider the first such vertex h_1. Due to Observation 16, the subpath $p[i, h_1]$ is successfully constructed by the step S21. The last portion $p[h_1, j]$ is constructed by the step S24, as $X[i,j] = 1$ and $R[i,j] = \infty$ in this case.

Next we proceed to the analysis of the time complexity. The step S1 costs $O(n^2)$. According to Theorem 15, the step S21 needs the running time of $\tilde{O}(n^\omega + n_r \cdot n^{1-t+s})$ to compute R'. By Theorem 5 (Maximum First Edge Weight), the step S22 takes $\tilde{O}(n^{1-s} \cdot n^{2-t})$ time, as $|V_r^H| = O(n^{1-s})$ and G_r has $O(n^{2-t})$ edges. The step S23 involves the computation of $H_1^N \circledS H_2$, for which Theorem 4 (Sparse Dominance Product) is used. Due to Observation 16, the cost for it is $\tilde{O}(n^\omega + n_r \cdot n^{1-s})$. Note that the number of ($> -\infty$) entries of H_2 is no greater than n^{2-s}. Also H_1^N, H_2 are *expanded* to $n \times n$ matrices in Theorem 4. For easy understanding, one can do $\mathbf{rb}(H_2)$ rather than $\mathbf{cb}(H_1^N)$ in the proof of Theorem 4, which can be found in [6]. The step S24 takes $\tilde{O}(n_r \cdot n^{1-s} + n^{1-s} \cdot n^{2-t})$ time according to

Observation 17. The step S25 costs $O(n^2)$. Summing up all these costs, we have the total running time within $\tilde{O}(\cdot)$ as follows.

$$\begin{aligned}&\sum_{1\le r\le n^t}(n^\omega + n_r\cdot n^{1-t+s}) + n^{3-s}\\ &+\sum_{1\le r\le n^t}(n^\omega + n_r\cdot n^{1-s})\\ &+\sum_{1\le r\le n^t}(n_r\cdot n^{1-s} + n^{1-s}\cdot n^{2-t})\\ =&n^{t+\omega} + n^{3-t+s} + n^{3-s},\end{aligned}$$

where by choosing $t = 2s$, and $s = 1 - \frac{\omega}{3}$, we have the final result $n^{2+\omega/3}$. ◀

4.1 A Slight Improvement via Rectangular Matrix Multiplication

The algorithm in Table 3 builds auxiliary data structures of Theorem 6 for all vertices in V_r^H. We can lessen this cost a little bit at the price of considering more vertices like h_1 in Figure 1.

The Intuition: As illustrated in Figure 1, formerly we consider the first vertex h_1 in V_r^H on $p[k_2, j)$. Now we look at more vertices from V_r^H on $p[k_2, j)$. Consider the second such vertex h_2. Similarly the edges on $p(h_1, h_2]$ are the out-edges of *low* out-degree vertices. Also thanks to p having the least number of edges in G_r, entries (i, k') of the APNP matrix of $G_{\le r}$ for $k' \in p(h_1, h_2)$ are new w.r.t. the APNP matrix of $G_{<r}$. Therefore, if we had constructed the first edge of $p[h_1, h_2]$, the cost for constructing later edges on $p[h_1, h_2]$ could be charged to the step S22 in Table 2. The idea for the improvement is to look at the first n^q vertices from V_r^H on $p[k_2, j)$. Name them as $h_1, \ldots, h_{n^q}$. If $p[k_2, j)$ contains no more than n^q vertices from V_r^H, the path p is then fully constructed. If $p[k_2, j)$ contains more than n^q vertices from V_r^H, we could sample only $O(n^{1-s-q}\log n)$ vertices from V_r^H, such that w.h.p. at least one vertex in $\{h_1, \ldots, h_{n^q}\}$ is hit. Say one such vertex is h. Note that $p[i, h]$ is already constructed. We then use the same auxiliary data structures as in Table 3 to construct $p[h, j]$. Also we use the same algorithm as in Table 3 to first determine the existence of $p[h, j]$. The difference is that the construction of $p[h, j]$ only involves the computation on $O(n^{1-s-q}\log n)$ vertices, instead of $O(n^{1-s})$ vertices as before. The improvement comes from this difference.

The algorithm is given in Table 4, which needs to compute $H_1^N \circledcirc A_r^H$ for matrices H_1^N, A_r^H defined within. The time complexity of the computation is given as follows, for which the idea is similar to one in [6]. Note that Theorem 4 (Sparse Dominance Product) can be extended to handling two matrices of sizes $n \times n^{1-s}$ and $n^{1-s} \times n$. The time complexity similar to the one in Theorem 4 is $O(m_1 m_2/n^{1-s} + n^{\omega(1,1-s,1)})$.

▶ **Lemma 19.** *The computation for $H_1^N \circledcirc A_r^H$ takes $\tilde{O}(n^{\omega(1,1-s,1)+q} + n_r\cdot n^{1-t-q+s})$ time.*

Proof. Let $L(A_r^H)$ be the sorted list of $(<\infty)$ entries of A_r^H. We divide $L(A_r^H)$ into n^q parts, so each part contains at most $\lceil n^{2-t}/n^q\rceil$ entries. We have n^q matrices $A_{r,1}^H, \ldots, A_{r,n^q}^H$ corresponding to each part. The entries of H_1^N with values no greater than $\max\{e \mid e \in A_{r,n^q}^H\}$ are partitioned into (n^q+1) matrices $H_{1,0}^N, H_{1,1}^N, \ldots, H_{1,n^q}^N$. The matrix $H_{1,p}^N$ with $1 \le p \le n^q$ consists of the entries $H_1^N[i, j]$'s satisfying $\min\{e \mid e \in A_{r,p}^H\} < H_1^N[i, j] \le \max\{e \mid e \in A_{r,p}^H\}$. The matrix $H_{1,0}^N$ consists of the entries $H_1^N[i, j]$'s satisfying $H_1^N[i, j] \le \min\{e \mid e \in A_{r,1}^H\}$.

We compute $H_1^N \circledcirc A_{r,p}^H$ for $1 \le p \le n^q$. Note that the following holds.

$$H_1^N \circledcirc A_{r,p}^H = (H_{1,0}^N + \cdots + H_{1,p}^N) \circledcirc A_{r,p}^H,$$

Algorithm 4 A slightly faster algorithm via rectangular matrix multiplication.

(S1) An APNP matrix R is initialized as $R[i,i] = -\infty$, and $R[i,j] = \infty$ for $i \neq j$.

(S2) $\forall r, 1 \leq r \leq n^t$, the APNP matrix R of $G_{<r}$ is extended to the APNP matrix of $G_{\leq r}$. Split A_r into two sub-matrices A_r^H, A_r^L, representing out-edges of high, low out-degree vertices resp.

- **(S21)** Initialize a matrix R' as R.
  - **i.** Run the steps S21, S22 in Table 2 with inputs R', A_r and A_r^L. The step S22 of Table 2 only works on A_r^L instead of A_r.
- **(S22)** Run the following for n^q steps:
  - **i.** Group the entries of R' from V to V_r^H that are *new* w.r.t. R as an $n \times n^{1-s}$ matrix H_1^N.
  - **ii.** $R' \leftarrow \min(R', H_1^N \circledcirc A_r^H)$. Determine the set S of the entries of R' which get *strictly* smaller in this step.
  - **iii.** Run the step S22 of Table 2 with inputs R', S and A_r^L.
- **(S23)** Sample uniformly at random $O(n^{1-s-q} \cdot \log n)$ vertices from V_r^H. Run the steps S22–S25 in Table 3, but only on the sampled vertices, rather than V_r^H.

where $(H_{1,0}^N + \cdots + H_{1,p-1}^N) \circledcirc A_{r,p}^H$ is computable in $O(n^{\omega(1,1-s,1)})$ time, as the entries in $(H_{1,0}^N + \cdots + H_{1,p-1}^N)$ are no greater than $\min\{e \mid e \in A_{r,p}^H\}$. Use $|H_{1,p}^N|$ to represent the number of $(< \infty)$ entries in $H_{1,p}^N$. We use Theorem 4 (Sparse Dominance Product) to compute $H_{1,p}^N \circledcirc A_{r,p}^H$ in $\tilde{O}(n^{\omega(1,1-s,1)} + |H_{1,p}^N| \cdot n^{2-t-q}/n^{1-s})$ time, as $A_{r,p}^H$ only has n^{1-s} rows. The total time for computing $H_1^N \circledcirc A_{r,p}^H$ for $1 \leq p \leq n^q$ is $\tilde{O}(n^{\omega(1,1-s,1)} \cdot n^q + n_r \cdot n^{2-t-q}/n^{1-s})$, as $\sum_{1 \leq p \leq n^q} |H_{1,p}^N| \leq n_r$.

Let $((A_{1,p}^H)', (A_{1,p}^H)'') = \mathbf{cb}(A_{1,p}^H)$. The computation of $H_1^N \circledcirc (A_{r,p}^H)'$, $H_1^N \circledcirc (A_{r,p}^H)''$ for $1 \leq p \leq n^q$ also takes $\tilde{O}(n^{\omega(1,1-s,1)} \cdot n^q + n_r \cdot n^{2-t-q}/n^{1-s})$ time.

For an entry $(H_1^N \circledcirc A_r^H)[i,j]$ to be determined, we find the smallest p with $(H_1^N \circledcirc A_{r,p}^H)[i,j] > 0$. Then $(H_1^N \circledcirc A_r^H)[i,j] \in A_{r,p}^H$. The remaining steps are similar to Lemma 13 (The First Edge). The total time is $\tilde{O}(n^{\omega(1,1-s,1)} \cdot n^q + n_r \cdot n^{2-t-q}/n^{1-s} + n_r \cdot n^{2-t-q}/n)$, as $A_{r,p}^H$ has n columns and only the new entries of $H_1^N \circledcirc A_r^H$ are of interest, of which the number is at most n_r. ◀

The step S23 in Table 4 constructs an L-bridging set with $L = n^q$. We use Lemma 7 to compute it *deterministically* as follows. Consider p as in the intuition of Section 4.1. The N subsets in Lemma 7 are p's with exactly n^q vertices from V_r^H on $p[k_2, j)$'s, where $j \in V_r^H$. To get the subset related to p, we need to extract the vertices in V_r^H on $p[k_2, j)$. This is solvable in $O(n^q)$ time if we know the predecessors in V_r^H of the vertices on $p(k_2, j]$.

We notice that for a specific i, just before the Step 23 of Table 4, for the j's of which $R'[i,j]$'s are new w.r.t. R, the edges corresponding to these $R'[i,j]$ form a forest, i.e., we know the predecessors in V (rather than in V_r^H) of these j's. Given such a forest, a DFS will give us the required predecessors in V_r^H of these j's. The cost of DFS for different i's is $O(n_r)$, as there are no more than n_r new $R'[i,j]$'s w.r.t. R. Thus the following holds.

▶ **Observation 20.** An L-bridging set with $L = n^q$ in the step S23 of Table 4 can be constructed *deterministically* in $\tilde{O}(n^{1-s} \cdot n^q)$ time.

▶ **Theorem 21.** *The APNP matrix of a real edge-weighted digraph with n vertices is computable in deterministic $O(n^{2.78})$ time.*

Proof. The correctness proof is almost similar to the one in Theorem 18. There we consider the first vertex h_1 in V_r^H, whereas here we consider the vertex h in V_r^H hit by the bridging

set. According to Observation 20, the total time for the construction of the bridging sets is $\tilde{O}(n^{t+1-s+q}) = \tilde{O}(n^{2+t-2s})$ (as $q \leq 1-s$), which is absorbed by the other terms.

Now we turn to the analysis of time complexity. The step S21 is the same as before, taking $\tilde{O}(n^{\omega} + n_r \cdot n^{1-t+s})$ time. The second step of S22 takes $\tilde{O}(n^{\omega(1,1-s,1)+q} + n_r \cdot n^{1-t-q+s})$ time, as shown in Lemma 19. The third step of S22 in one iteration of the step S2 is charged to the step S21, resulting in $\tilde{O}(n_r \cdot n^{1-t+s})$ time. The other steps are similar to Theorem 18, for which the time is $\tilde{O}(n^{\omega} + n_r \cdot n^{1-s-q} + n^{1-s-q} \cdot n^{2-t})$. Summing up all of them, we have the total running time within $\tilde{O}(\cdot)$ as follows.

$$n^{t+\omega} + n^{3-t+s} + n^{3-s-q} + n^{t+\omega(1,1-s,1)+2q},$$

where $\omega(1, 1-s, 1) \leq 2 + (1-s)(\omega - 2)$ if rectangular matrix multiplications are reduced to square matrix multiplications. By setting $s = \frac{3-\omega}{\omega+1}$, $t = \frac{1}{2}(3 + s - \omega)$, and $q = t - 2s$, we have the final result $n^{\frac{1}{2}(3+\frac{3-\omega}{\omega+1}+\omega)} = O(n^{2.78})$. ◀

Abstract

Edit distance between trees is a natural generalization of the classical edit distance between strings, in which the allowed elementary operations are contraction, uncontraction and relabeling of an edge. Demaine et al. [ACM Trans. on Algorithms, 6(1), 2009] showed how to compute the edit distance between rooted trees on n nodes in $O(n^3)$ time. However, generalizing their method to unrooted trees seems quite problematic, and the most efficient known solution remains to be the previous $O(n^3 \log n)$ time algorithm by Klein [ESA 1998]. Given the lack of progress on improving this complexity, it might appear that unrooted trees are simply more difficult than rooted trees. We show that this is, in fact, not the case, and edit distance between unrooted trees on n nodes can be computed in $O(n^3)$ time. A significantly faster solution is unlikely to exist, as Bringmann et al. [SODA 2018] proved that the complexity of computing the edit distance between rooted trees cannot be decreased to $O(n^{3-\varepsilon})$ unless some popular conjecture fails, and the lower bound easily extends to unrooted trees. We also show that for two unrooted trees of size m and n, where $m \leq n$, our algorithm can be modified to run in $O(nm^2(1 + \log \frac{n}{m}))$. This, again, matches the complexity achieved by Demaine et al. for rooted trees, who also showed that this is optimal if we restrict ourselves to the so-called decomposition algorithms.

1 Introduction

Computing the edit distance between two strings [30] is the most well-known example of dynamic programming. Thanks to the new fine-grained complexity paradigm, we know that this simple approach is essentially the best possible [1, 5], so the problem appears to be solved from the theoretical perspective. However, in many real-life applications we would like to operate on more complicated structures than strings. As a prime example, while primary structure of RNA can be seen as a string, computational biology is often interested in comparing also secondary structures. Second structure of RNA can be modeled as an ordered tree [17, 26], so we would like to generalize computing the edit distance between strings to computing the edit distance between ordered trees.

Tai [29] defined the edit distance between two ordered trees as the minimum total cost of a sequence of elementary operations that transform one tree into the other. For unrooted

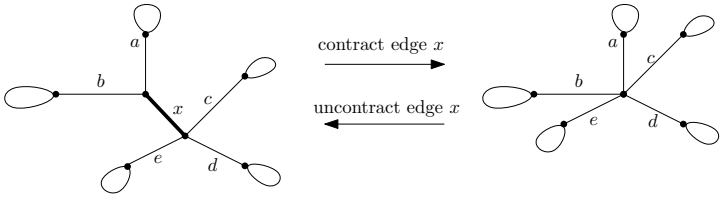

Figure 1 Contraction and uncontraction of the edge with label x costs $c_{del}(x) = c_{ins}(x)$.

trees, which are the focus of this paper, the trees are edge-labeled, and we have three elementary operations: contraction, uncontraction and relabeling of an edge. We think that the trees are embedded in the plane, i.e., there is a cyclic order on the neighbors of every node that is preserved by the contraction/uncontraction. See Figure 1. The cost of an operation depends on the label(s) of the edge(s): $c_{del}(\tau)$, $c_{ins}(\tau)$, $c_{match}(\tau_1, \tau_2)$, respectively. We assume that every operation has the same cost as its reverse counterpart: $c_{del}(\tau) = c_{ins}(\tau)$, $c_{match}(\tau_1, \tau_2) = c_{match}(\tau_2, \tau_1)$, and each edge participates in at most one elementary operation.

Computing the edit distance between trees is used as a measure of similarity in multiple contexts. The most obvious, given that some biological structures resemble trees, is computational biology [26]. Others include comparing XML data [10, 11, 16], programming languages [18]. Others, less obvious, include computer vision [6, 20, 22, 25], character recognition [24], automatic grading [3], and answer extraction [31]. See also the survey by Bille [7].

Tai [29] introduced the edit distance between rooted node-labeled trees on n nodes and designed an $O(n^6)$ algorithm. Zhang and Shasha [27] improved the time complexity to $O(n^4)$ by designing a recursive formula, which reduces computing the edit distance between two trees to computing the edit distance between two smaller trees. Then, Klein [21] considered the more general problem of computing the edit distance between unrooted edge-labeled trees and further improved the complexity to $O(n^3 \log n)$ using essentially the same formula, but applying it more carefully to restrict the number of different trees that appear in the whole process. This high-level idea of using the recursive formula can be formalized using the notion of decomposition strategy algorithms as done by Dulucq and Touzet [15]. Finally, Demaine et al. [13] further improved the complexity for rooted node-labeled trees to $O(n^3)$. For trees of different sizes m and n, where $m \leq n$, their algorithm runs in $O(nm^2(1 + \log \frac{n}{m}))$ time. At a very high level, the gist of their improvement was to apply the heavy path decomposition to both trees, while in Klein's algorithm only one tree is decomposed. This requires some care, as switching from being guided by the heavy path decomposition of the first tree to the second tree cannot be done too often.

Although Demaine et al. [13] showed that their algorithm is optimal among all decomposition strategies, it is not clear that any algorithm must be based on such a strategy. Nevertheless, there has been no progress on beating the best known $O(n^3)$ time worst-case bound for exact tree edit distance. Pawlik and Augsten [23] presented an experimental comparison of the known algorithms. Aratsu et al. [4], Akutsu et al. [2], and Ivkin [19] designed approximation algorithms. Only very recently a convincing explanation for the lack of progress on improving this worst-case complexity has been found by Bringmann et al. [9], who showed that a significant improvement on the cubic time complexity for rooted node-labeled trees is rather unlikely: an $O(n^{3-\varepsilon}$ algorithm for computing the edit distance between rooted trees on n nodes implies an $O(n^{3-\varepsilon})$ algorithm for APSP (assuming alphabet of size $\Theta(n)$) and an $O(n^{k(1-\varepsilon)})$ algorithm for Max-Weight k-Clique (assuming alphabet of sufficiently large but constant size).

Thus, the complexity of computing the edit distance between rooted trees seems well-understood by now. However, in multiple important applications, the trees are, in fact, unrooted. For example, Sebastian et al. [25] use unrooted trees to recognize shapes (in a paper with over 700 citations). Unfortunately, while the almost 20 years old algorithm presented by Klein works for unrooted trees in $O(n^3 \log n)$ time, it is not clear how to translate Demaine et al.'s improvement to the unrooted case. In fact, even if one of the trees is a rooted full binary tree and the other is a simple caterpillar, their approach appears to use $O(n^4)$ time, and it is not clear how to modify it. Given the lack of further progress, it might seem that unrooted trees are simply more difficult than rooted trees.

Our contribution. We present a new algorithm for computing the edit distance between unrooted trees which runs in $O(n^3)$ time and $O(n^2)$ space. For the case of trees of possibly different sizes n and m where $m \leq n$, it runs in $O(nm^2(1 + \log \frac{n}{m}))$ time and $O(nm)$ space. This matches the complexity of Demaine et al.'s algorithm for the rooted case and improves Klein's algorithm for the unrooted case. By a simple reduction, unrooted trees are as difficult as rooted trees, so our algorithm is optimal among all decomposition algorithms [13], and significantly faster approach is unlikely to exist unless some popular conjecture fails [9].

Our starting point is dynamic programming using the recursive formula of Zhang and Shasha, similarly as done by Klein and Demaine et al., but instead of presenting the computation in a top-down order, we prefer to work bottom-up. This gives us more control and allows us to be more precise about the details of the implementation. In the simpler $O(n^3 \log \log n)$ version of the algorithm, we apply the heavy path decomposition to both trees. As long as the first tree is sufficiently big, we proceed similarly as Klein, that is, look at its heavy path decomposition. However, if the first tree is small (roughly speaking) we consider the heavy path decomposition of the second tree and design a new divide and conquer strategy that is applied on every heavy path separately.

In the full version of the paper [14] we further improve the complexity to $O(n^3)$. Instead of a global parameter we modify the divide and conquer strategy so that the larger the first tree is the sooner the strategy terminates and switches to another approach. A careful analysis of such a modification leads to $O(nm^2(1 + \log^2 \frac{n}{m})) = O(n^3)$ running time. Then, we shave one $\log \frac{n}{m}$ by making the divide and conquer sensitive to the sizes of the subtrees attached to the heavy path instead of its length, that is, making some nodes more important than the other, reminiscing the so-called telescoping trick [8, 12]. All the improvements applied together decrease the overall complexity to $O(nm^2(1 + \log \frac{n}{m}))$, thus matching the running time of the algorithm by Demaine et al. for rooted trees [13].

▶ **Theorem 1.** *Edit distance between unrooted trees of size n and m, where $m \leq n$, can be computed in $O(nm^2(1 + \log \frac{n}{m})) = O(n^3)$ time and $O(nm)$ space.*

A straightforward reduction shows that computing edit distance between unrooted trees is at least as difficult as computing edit distance between rooted trees. Thus, invoking the lowerbound of Demaine et al. [13] we obtain that our algorithm is optimal if we restrict ourselves to the so-called decomposition algorithms, and by the result of Bringmann et al. [9] a significantly faster $O(n^{3-\varepsilon})$ algorithm is not possible assuming some popular conjecture.

Roadmap. In Section 2 we introduce the notation and the recursive formula that are then used to present Klein's algorithm adapted for the rooted case. Next, in Section 3 we return to the unrooted case, introduce new notation and transform both input trees by adding some auxiliary edges. Then, in Section 4 we present our new $O(n^3 \log \log n)$ algorithm for the

unrooted case which already improves the state-of-the-art Klein's algorithm and is essential for understanding our main $O(n^3)$ algorithm described in the full version of the paper. Both algorithms are described in a bottom-up fashion. In the simpler $O(n^3 \log\log n)$ version we first assume that one of the trees is a caterpillar and then generalize to arbitrary trees. In the more complicated $O(n^3)$ algorithm we start with an even more restricted case of one tree being a caterpillar and the other a rooted full binary tree. When analyzing both algorithms we only bound the total number of considered subproblems. As explained in the full version, this can be translated into an implementation with the same running time.

2 Preliminaries

We are given two unrooted trees T_1, T_2 with every edge labeled by an element of Σ and a cyclic order on the neighbors of every node. For every label $\alpha \in \Sigma$, we know the cost $c_{del}(\alpha) = c_{ins}(\alpha)$ of contracting or uncontracting of an edge with label α. For every $\alpha, \beta \in \Sigma$, $c_{match}(\alpha, \beta) = c_{match}(\beta, \alpha)$ is the cost of changing the label of an edge from α to β. All costs are non-negative and each edge can participate in at most one operation. Edit distance between T_1 and T_2 is defined as the minimum total cost of a sequence of the above operations transforming T_1 to T_2. Equivalently, it is the minimum cost of transforming both the trees to a common tree using only contracting and relabeling operations, as each operation has the same cost as its undo-counterpart. Note that for unrooted trees, edit distance is the minimum edit distance over all possible rootings of T_1 and T_2, where a rooting is uniquely determined by choice of the root and the leftmost edge from the root.

We first assume, that both trees are of equal size $n = |T_1| = |T_2|$, but later we will also address the case when one of them is significantly larger than the other. We start with the case when both trees are rooted, which is essential for the understanding of the unrooted case. Then, every node has its children ordered left-to-right. We also assume that both (rooted) trees are binary, as we can add $O(n)$ edges with a fresh label that costs 0 to contract and ∞ to relabel.

Naming convention. We use a similar naming convention as in [13]. We call main left and right edges of a (rooted) tree respectively the leftmost and rightmost edge from the root. For a given rooted tree T with at least 2 nodes, let r_T denote the right main edge of T and R_T denote the rooted subtree of T that is under (not including) r_T. By $T - r_T$ we denote a tree obtained from T by contracting edge r_T and by $T - R_T$ a tree obtained from T by contracting edge r_T and all edges from its subtree R_T. Thus the tree T consists of R_T, the edge r_T and edges $(T - R_T)$. l_T and L_T are defined analogously and T^v denotes subtree of T rooted at v. See Figure 2(a) and (b).

We define a pruned subtree of a tree T to be the tree obtained from T by a sequence of contractions of the left or right main edge. Note that every pruned subtree is uniquely represented by the pair of its left and right main edges. It also corresponds to an interval on the Euler tour of the tree started in the root when we remove from the interval each edge that occurs once. Thus we can completely represent a pruned subtree in $O(1)$ space by storing two edges. We can preprocess all the $O(n^2)$ pruned subtrees T' of a tree T to be able to obtain trees $R_{T'}, L_{T'}, T' - l_{T'}, T' - r_{T'}$ and edges $r_{T'}, l_{T'}$ in $O(1)$ time.

Dynamic programming. Zhang and Shasha [27] introduced the following recursive formula for computing the edit distance between two rooted trees:

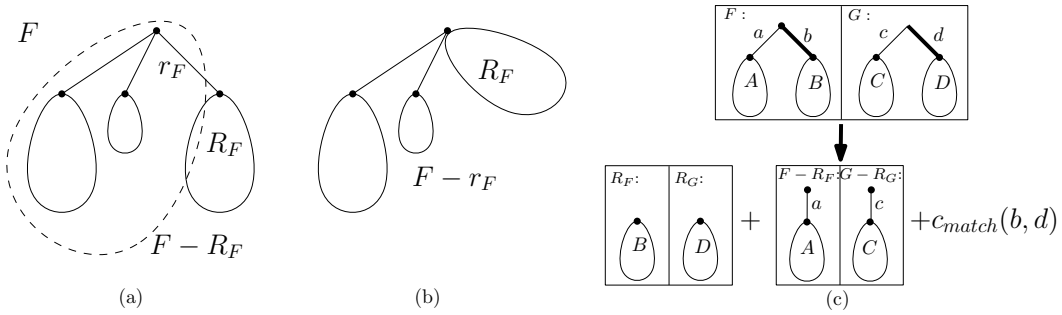

Figure 2 (a) Tree F with both r_F and R_G contracted. (b) F with its right main edge contracted. (c) When both right main edges are not contracted we obtain two independent problems.

▶ **Lemma 2.** *Let $\delta(F, G)$ be the edit distance between two pruned subtrees F and G of respectively T_1 and T_2. Then:*

- $\delta(\emptyset, \emptyset) = 0$
- $$\delta(F, G) = \min \begin{cases} \delta(F - r_F, G) + c_{del}(r_F) & \text{if } F \neq \emptyset \\ \delta(F, G - r_G) + c_{del}(r_G) & \text{if } G \neq \emptyset \\ \delta(R_F, R_G) + \delta(F - R_F, G - R_G) + c_{match}(r_F, r_G) & \text{if } F, G \neq \emptyset \end{cases}$$

The above recurrence also holds if we contract or match the left main edge.

It contracts the right main edge in one of the two trees or matches the right main edges of the two trees. In the latter case, we get two independent subproblems (R_F, R_G) and $(F - R_F, G - R_G)$ that must be transformed to equal trees. See Figure 2(c) for an illustration of this case.

To estimate time complexity of the algorithm, we only count different pairs (F, G) for which $\delta(F, G)$ is computed. Each such value is computed at most once and stored. Note that F is always a pruned subtree of T_1, while G is a pruned subtree of T_2, thus there are $O(n^4)$ possible pairs (F, G). In the worst case, all such pairs might be considered. The formula from Lemma 2 can be evaluated in constant time, and any previously computed value can be retrieved in constant time from a four-dimensional table.

The above algorithm always contracts or relabels the right main edge. A more deliberate choice of direction (whether to choose the left or right main edge) will lead to a different behavior of the algorithm which in turn might result in a smaller total number of considered pairs (F, G). Such a family of algorithms is called decomposition algorithms. When analyzing the time complexity of such an algorithm, we assume that any already computed $\delta(F, G)$ can be retrieved in constant time. If our goal is to compute significantly fewer than $O(n^4)$ subproblems, we cannot afford to allocate the four-dimensional table anymore. An obvious solution is to store the already computed values in a hash table, but this requires randomization. In the full version [14] we explain how to carefully arrange the order of the computation and store the partial results as to obtain deterministic algorithms with the same running time.

While the formula from Lemma 2 suggests a top-down strategy, we phrase the algorithms in a bottom-up perspective, which allows us to present the details of the computation more precisely. The aim of all the algorithms is to compute $\delta(T_1, T_2)$ knowing only $\delta(\emptyset, \cdot)$ and $\delta(\cdot, \emptyset)$, as the costs of contraction of an arbitrary pruned subtree are precomputed.

Algorithm 1 Klein's algorithm.

```
1: for each heavy path H in T_1 in the bottom-up order do
2:     let v_1, v_2, ..., v_{|H|} = H
3:     for i = |H| - 1, ..., 0 do
           ▷ avoiding the heavy child:
4:         ComputeFrom(δ(T_1^{v_i}, ·), δ(T_1^{v_{i+1}}, ·))
```

Klein's $O(n^3 \log n)$ algorithm. Klein's algorithm [21] uses heavy path decomposition [28] of T_1. The root is called light and every node calls its child with the largest subtree (and the leftmost in case of ties) heavy and all other children light. An edge is heavy if it leads to the heavy child.

While applying the dynamic formula from Lemma 2, Klein's algorithm uses a strategy that we call "avoiding the heavy child" in T_1. It chooses the direction (either left or right) in such a way that the edge leading to the heavy child of the root is contracted or relabeled as late as possible. Observe that contracting the main edge not leading to the heavy child of the root of a pruned subtree T, does not change the heavy child of the root of T, as its subtree is still the largest. Note that Klein's strategy does not depend on the considered pruned subtree of T_2.

Even though Klein uses top-down view to describe his algorithm, we find it more convenient to implement the computations in bottom-up order. Therefore the algorithm processes heavy paths of T_1 in the bottom-up order as shown in Algorithm 1. Consider a heavy path H with nodes $v_1, v_2, \ldots, v_{|H|}$ where v_1 is the closest node to the root and $v_{|H|}$ is a leaf. By $\delta(T_1^v, \cdot)$ we denote a table of $O(n^2)$ distances between tree T_1^v and all pruned subtrees of T_2. The algorithm considers all nodes on H also bottom-up. It starts from $\delta(T_1^{v_{|H|}}, \cdot) = \delta(\emptyset, \cdot)$, which is precomputed, and then iteratively computes $\delta(T_1^{v_i}, \cdot)$ from $\delta(T_1^{v_{i+1}}, \cdot)$ for decreasing values of i. We denote such a step by ComputeFrom subroutine. Note that in every step the strategy avoiding the heavy child always chooses the same direction (recall that the tree is binary) and visits altogether at most $O(n)$ pruned subtrees of T_1. Also when actually implementing the ComputeFrom step we proceed bottom-up. That is, suppose we have already computed $\delta(T_1^{v_{i+1}}, \cdot)$ and that v_{i+1} is the left child of v_i. Then the strategy avoiding the heavy child says R that is chooses first the right main edge to consider. We compute $\delta(T_1^{v_i}, \cdot)$ as follows. First we consider the tree $T_1^{v_{i+1}} \cup \{\{v_i, v_{i+1}\}\}$ (we call this uncontracting the heavy edge), next $T_1^{v_{i+1}} \cup \{\{v_i, v_{i+1}\}, \{v_i, w\}\}$ if exists a light child w of v_i and then uncontract the subsequent edges of T_1^w. This guarantees that while computing $\delta(F, G)$ the subtrees $F - r_F$ and $F - R_F$ have been already processed. Pruned subtrees of T_2 are also considered in the order of increasing sizes. Clearly, as argued for Zhang and Shasha's algorithm, the algorithm visits $O(n^2)$ pruned subtrees of T_2, so we need to bound the number of pruned subtrees of T_1.

▶ **Observation 3.** Consider an arbitrary tree T. Suppose that strategy avoiding the heavy child in T says R for a pruned subtree F. Then $F - R_F$ is also obtained by a sequence of contractions of the main edge according to the strategy.

The observation implies that in order to count the relevant intervals of T_1 we can only consider the trees obtained by contraction of the main edge according to the strategy, and trees of the form L_F and R_F. Note that the only trees of the form L_F or R_F that are not obtained in this way are rooted at a light node so will be counted separately for another heavy path.

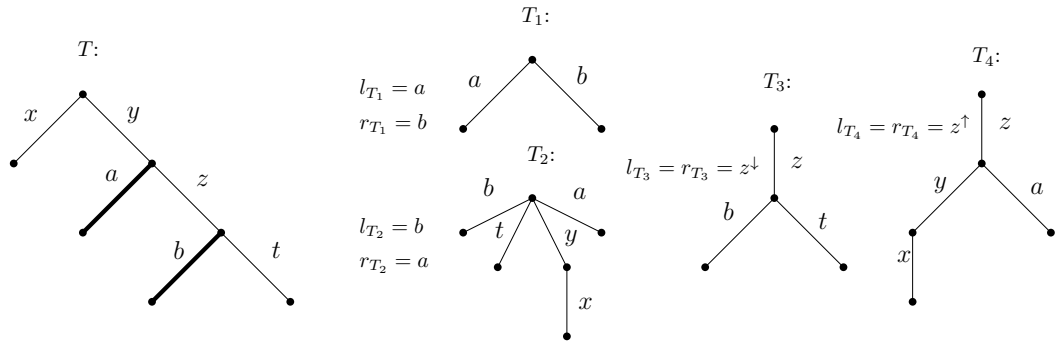

Figure 3 Every pruned subtree is uniquely represented by its left and right main edges or a dart.

We denote $\mathsf{apex}(F)$ to be the top node of the heavy path containing the lowest common ancestor of all endpoints of edges of F. In other words, $\mathsf{apex}(F)$ is the lowest light ancestor of all edges of F. Now grouping all the visited pruned subtrees by their apex-es we bound their total number:

▶ **Observation 4.** For an arbitrary tree T, there is $\sum_{v\text{: light node in } T} |T^v|$ pruned subtrees of T visited while applying strategy avoiding the heavy child of T.

Let the light-depth $\mathsf{ldepth}(u)$ of a node u be the number of light nodes that are ancestors of u (node is also an ancestor of itself). Because $\mathsf{ldepth}(u) \leq \log(n) + 1$, we obtain:

$$\sum_{v\text{: light node in } T_1} |T_1^v| = \sum_{v\text{: node in } T_1} \mathsf{ldepth}(v) \in O(n \log n) \tag{1}$$

Recalling that there are $O(n^2)$ relevant intervals of T_2 we conclude that Klein's algorithm visits $O(n^3 \log n)$ subproblems. As we assume the constant time memoization, it runs in $O(n^3 \log n)$ time.

3 Back to Unrooted Case

Recall that edit distance between two unrooted trees T_1 and T_2 is the minimum edit distance between T_1 and T_2 over all possible rootings of them, where rooting is determined by the root of the tree and its the left main edge. As Klein [21] mentioned, it is enough to choose an arbitrary rooting in one of the trees and try all possible rootings of the other to find an optimal setting. Observe, that we can treat the Euler tour of T_2 as a cyclic string and represent every pruned subtree of T_2 as an interval of it, for all possible rootings of T_2. Thus Klein's algorithm works in $O(n^3 \log n)$ time also for the edit distance between unrooted trees. Before we present our faster algorithm for this case, we need to introduce some new definitions. Recall, that even in the unrooted case, we first arbitrarily root both trees and the initial rooting remains unchanged throughout the algorithm.

Darts. We replace every edge e with two darts corresponding to two ways of traversing the edge, either down $e^{\downarrow}$ or up the tree $e^{\uparrow}$ (with respect to the fixed rooting). Subtree of a dart $\mathsf{subtree}((u, v))$ is defined as the subtree rooted at node v, when u is its parent. Note that $e^{\uparrow}$ and $e^{\downarrow}$ belong neither to $\mathsf{subtree}(e^{\uparrow})$ nor to $\mathsf{subtree}(e^{\downarrow})$. Every pruned subtree of (unrooted) tree is uniquely represented by its left and right main edges or a dart (if there is one edge from the root). See Figure 3.

Auxiliary edges for rootings. We observed that every rooting of T_2 corresponds to a subrange of a cyclic Euler tour E_{T_2}, but later it will be convenient to represent every rooting as a subtree of a dart. For this purpose, we add new edges labeled with a fresh label $\# \notin \Sigma$ which will be used only to denote a rooting. Setting $c_{del}(\#) = 0$ and $c_{match}(\#, \cdot) = \infty$ we force that these edges are only contracted. For every node v we add new edges alternating with the original ones. Thus in total, there are $2(n-1)$ edges added. Using these new edges we can compute edit distance between the unrooted trees from the values of $\delta(T_1, \mathsf{subtree}(d))$ for all darts d in T_2. Thus, our aim is to fill the table Δ where $\Delta[u, d] := \delta(T_1^u, \mathsf{subtree}(d))$.

Auxiliary edges to bound the degrees. As the last step, again we add $O(n)$ edges with appropriate costs as to ensure that the degree of every node is at most 3. Observe that the cost of the optimal solution for the modified trees is the same as for the initial ones and having a sequence of operations for the modified trees, we can easily obtain an optimal sequence for the original instance of the problem.

4 $O(n^3 \log\log n)$ Algorithm for Unrooted Case

After initial modifications both trees are binary and the algorithm needs to fill the table Δ where $\Delta[u, d] := \delta(T_1^u, \mathsf{subtree}(d))$ for all nodes $u \in T_1$ and darts $d \in T_2$. We first run Demaine et al.'s algorithm operating on labels on edges instead of nodes which computes $\delta(T_1^u, T_2^v)$ for all nodes $u \in T_1$ and $v \in T_2$ in $O(n^3)$ time and stores them in $\Delta[u, e_v^{\downarrow}]$ where $e_v^{\downarrow}$ is the dart to v from its parent. Now we need to fill the remaining fields $\Delta[u, e^{\uparrow}]$ for all darts $e^{\uparrow}$ up the tree T_2.

This is the main difficulty in the unrooted case, in which we need to handle many big subtrees which are significantly different from each other. Our approach is to successively reduce different subproblems to smaller ones, in a way that there are fewer subproblems to consider in the next step. We use divide and conquer paradigm, in which there is more and more sharing after every step.

In the beginning, we call each node of T_1 and T_2 light or heavy as in the Klein's algorithm and all the time the notion is with respect to the initial rootings. Similarly, the notion of traversing an edge up or down the tree is always with respect to the rooting. Recall that we denote $\mathsf{apex}(T)$ as the top node on the heavy path containing the lowest common ancestor of all edges of T. We first fix a global value b, which will be determined exactly later. On a high level, from the top-down perspective, the algorithm uses the following strategy to compute $\delta(F, G)$: if $|T_1^{\mathsf{apex}(F)}| > n/b$, then avoid the heavy child in F, and otherwise apply a new strategy based only on G and T_2.

Considering it bottom-up, the algorithm first fills values of $\Delta[u, e^{\uparrow}]$ for all nodes u such that $|T_1^{\mathsf{apex}(u)}| \leq n/b$ and all darts up T_2. For the remaining fields of Δ, it uses strategy avoiding the heavy child in T_1. As in the Klein's algorithm, in this phase, the algorithm needs to process heavy paths of T_1 in the bottom-up order. Note that for each light node v such that $|T_1^v| > n/b$ holds $\mathsf{ldepth}(v) < \log b + 1$. Thus there are $O(n^3 \log b)$ subproblems visited in total in this phase.

For the other phase note that there are $O(n^2/b)$ relevant subtrees in T_1, and now we need to carefully design and analyze the new strategy for T_2. It will be easier to think, that in this phase the algorithm needs to compute $\Delta[u, e^{\uparrow}]$ for all darts $e^{\uparrow}$ up T_2 and all nodes $u \in T_1$ such that $|T_1^u| \leq n/b$, call them interesting. Clearly, all subproblems in which there is a switch to the strategy based on T_2 are of this form.

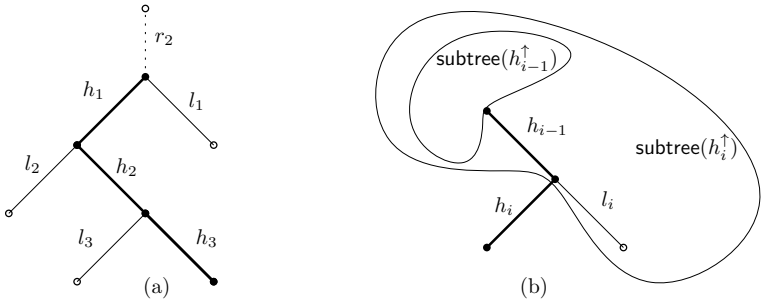

Figure 4 (a) A heavy path H with edge r_2 (dotted) denoting the rooting of T_2. (b) To compute $\delta(*, \mathsf{subtree}(h_i^{\uparrow}))$ we use $\delta(*, \mathsf{subtree}(h_{i-1}^{\uparrow}))$, first uncontract the edge h_{i-1} and then l_i (if exists).

As now the strategy will be more complex than before, we first describe it for the case when T_2 is a caterpillar: a heavy path with possibly single nodes connected to it. This example is already difficult in the unrooted case and will require divide and conquer approach to handle all the possible rootings of T_2 at once. Next, we will slightly modify the approach to handle arbitrary trees T_2.

4.1 Caterpillar T_2

Now we consider the case when T_2 is a heavy path H with possibly single nodes connected to it. Let h_i denote (heavy) edges on H, $r_2 = h_0$ be the edge denoting the initial rooting of T_2 and (if exists) l_i be the light edge connected to the i-th node on H. See Figure 4(a) for an example.

In the first step we compute values of $\delta(*, \mathsf{subtree}(h_i^{\uparrow}))$ for all heavy edges h_i, where $*$ denotes all pruned subtrees of T_1 of size at most n/b. The strategy is to avoid the parent, that is to contract the edge leading to the parent as late as possible. See Figure 4(b).

More precisely, in the beginning, we already know $\delta(*, \mathsf{subtree}(h_0^{\uparrow}))$, because it is the cost of contraction of the whole pruned subtree of T_1 (which is precomputed), as $h_0 = r_2$ and $\mathsf{subtree}(h_0^{\uparrow}) = \emptyset$. Then, having values of $\delta(*, \mathsf{subtree}(h_{i-1}^{\uparrow}))$ we compute $\delta(*, \mathsf{subtree}(h_i^{\uparrow}))$ by uncontracting first h_{i-1} and then l_i if it exists. It is an extension of the ComputeFrom subroutine, but now we do not have subtrees T^x and T^y, where x is the parent of y, but two edges h_i and h_{i-1} with a common endpoint. Note that in this step all uncontractions are from the same direction.

There are $O(n)$ pruned subtrees of T_2 obtained by uncontractions of a main edge according to the strategy, starting from the empty subtree. Now we need to show that the algorithm did not consider any other pruned subtree of T_2. Suppose it uncontracted the left main edge. Then $G - L_G \in \{\emptyset, G - l_G\}$, depending on whether l_G was the heavy edge leading to the parent or not. Also $L_G \in \{\emptyset, G - l_G\}$, so in both cases, all the obtained pruned subtrees are among the $O(n)$ described above. Finally, as there are $O(n^2/b)$ pruned subtrees of T_1, in total we computed and stored the edit distance of $O(n^3/b)$ subproblems. Now, using the computed values we fill $\Delta[u, h_i^{\uparrow}]$ for all interesting nodes $u \in T_1$ and heavy edges $h_i \in T_2$. Thus, later on, we do not have to consider the pruned subtrees of the form $\delta(L_F, L_G)$ or $\delta(R_F, R_G)$ as their values are already stored in Δ, because either one of them is empty or they are of the form $\delta(T_1^v, \mathsf{subtree}(dh))$ for an interesting node $u \in T_1$ and a dart dh from a heavy edge in T_2. We only have not computed values $\Delta[u, l^{\uparrow}]$ for darts from light edges up the tree, but in this phase of the algorithm, they never appear in $\delta(L_F, L_G)$ or $\delta(R_F, R_G)$ subproblem. However, we need to compute these values because they correspond to some rootings of T_2, so we will consider them in the following paragraph.

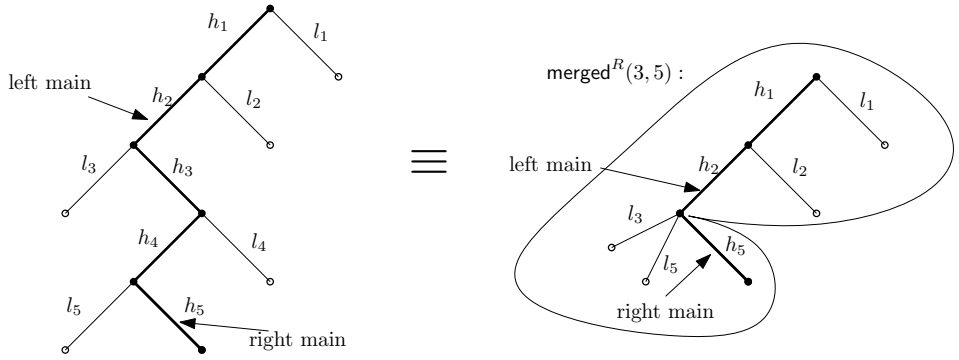

Figure 5 Pruned subtree $\mathsf{merged}^R(3,5)$ has the left main edge h_2 and right h_5.

Algorithm 2 Computes input tables needed for processing a heavy path H

1: **function** ProcessHeavyPath($\delta(*, \mathsf{subtree}(h_0^\uparrow))$)
2: **for** $i = 1..|H|$ **do**
▷ avoiding the parent:
3: ComputeFrom($\delta(*, \mathsf{subtree}(h_i^\uparrow)), \delta(*, \mathsf{subtree}(h_{i-1}^\uparrow))$)
4: fill $\Delta[u, h_i^\uparrow]$ for all interesting nodes u

▷ repeatedly uncontracting the left main edge:
5: ComputeFrom($\delta(*, \mathsf{merged}^R(1, |H|)), \delta(*, \mathsf{subtree}(h_0^\uparrow))$)
▷ repeatedly uncontracting the right main edge:
6: ComputeFrom($\delta(*, \mathsf{merged}^L(1, |H|)), \delta(*, \mathsf{subtree}(h_0^\uparrow))$)

7: Group($1, |H|, \mathsf{Data}(1, |H|)$)

Darts from light nodes up the tree. From now on, our algorithm processes heavy paths of T_2 one-by-one. In particular, in this subsection, we process the only heavy path H of T_2. Thus, unless explicitly stated otherwise all the notion is relative to the current heavy path H. First, we define $\mathsf{merged}^R(A, B)$ as the pruned subtree obtained by contraction of edges between the A-th and B-th node on H or to the right of H:

▶ **Definition 5.** Let H be a heavy path and A and B ($A \leq B$) denote indices of two nodes on H. Then $\mathsf{merged}^R(A, B)$ is a tree with the left main edge h_{A-1} and the right main edge h_B. $\mathsf{merged}^L(A, B)$ is a tree with the left main edge h_B and the right main edge h_{A-1}.

See Figure 5. Note that $\mathsf{subtree}(l_A^\uparrow)$ is either $\mathsf{merged}^R(A, A)$ or $\mathsf{merged}^L(A, A)$, depending on which side of H is l_A.

As explained earlier, in the beginning the algorithm computes $\delta(*, \mathsf{subtree}(h_i^\uparrow))$ for all heavy edges on H. Additionally, it calculates $\delta(*, \mathsf{merged}^L(1, |H|))$ and $\delta(*, \mathsf{merged}^R(1, |H|))$ from $\delta(*, \mathsf{subtree}(h_0^\uparrow))$ by repeatedly uncontracting respectively the right and left main edge. See Algorithm 2 for the summary of the whole preprocessing. Then it calls a recursive procedure Group($1, |H|, \mathsf{Data}(1, |H|)$). The final goal of this call is to fill $\Delta[u, l_i^\uparrow]$ for all light edges l_i connected to the heavy path H.

Group($A, B, \mathsf{Data}(A, B)$) is a procedure which considers an interval $[A, B]$ of indices on H given tables of values $\delta(*, \mathsf{subtree}(h_{A-1}^\uparrow)), \delta(*, \mathsf{subtree}(h_B^\downarrow)), \delta(*, \mathsf{merged}^L(A, B))$ and $\delta(*, \mathsf{merged}^R(A, B))$, which we denote as $\mathsf{Data}(A, B)$. Intuitively, $\mathsf{Data}(A, B)$ contains in-

Algorithm 3 Fills $\Delta[u, l_i^{\uparrow}]$ for light edges l_i connected to the heavy path H with $i \in [A, B]$.

```
1:  function GROUP(A, B, Data(A, B))
2:      if A = B then
3:          if there is a light edge l_A connected to H then
4:              fill Δ[u, l_A^↑] for interesting nodes u ∈ T_1
5:          return
6:      M := ⌊(A + B)/2⌋
7:      for i = (B − 1)..M do
            ▷ avoiding the heavy child:
8:          COMPUTEFROM(δ(∗, subtree(h_i^↓)), δ(∗, subtree(h_{i+1}^↓)))
        ▷ repeatedly uncontracting the right main edge:
9:      COMPUTEFROM(δ(∗, merged^R(A, M)), {δ(∗, merged^R(A, B)); δ(∗, subtree(h_{A−1}^↑))})
        ▷ repeatedly uncontracting the left main edge:
10:     COMPUTEFROM(δ(∗, merged^L(A, M)), {δ(∗, merged^L(A, B)); δ(∗, subtree(h_{A−1}^↑))})

11:     GROUP(A, M, Data(A, M))
12:     symmetric computations for interval [M + 1, B]
13:     GROUP(M + 1, B, Data(M + 1, B))
```

formation about subtrees "outside" the considered interval $[A, B]$ which are relevant during intermediate computations. Then, the procedure calls itself recursively for shorter intervals until it holds that $A = B$ when $\delta(*, \mathsf{merged}^L(A, A))$ or $\delta(*, \mathsf{merged}^R(A, A))$ contains the fields of $\Delta[u, l_A^{\uparrow}]$ for all interesting nodes u and then the recurrence stops.

In more detail, for an interval $[A, B]$, the procedure computes $\mathsf{Data}(A, M)$ and $\mathsf{Data}(M + 1, B)$ for $M = \lfloor \frac{A+B}{2} \rfloor$ and calls itself recursively for the smaller intervals. Note that for $\mathsf{Data}(A, M)$ it needs to compute tables $\delta(*, G)$ for trees $G = \mathsf{merged}^R(A, M), \mathsf{merged}^L(A, M)$ or $\mathsf{subtree}(h_M^{\downarrow})$ and can reuse table $\delta(*, \mathsf{subtree}(h_{A-1}^{\uparrow}))$ which is a part of $\mathsf{Data}(A, B)$. Similarly for interval $[M + 1, B]$. See Algorithm 3.

To analyze the complexity of the GROUP procedure, first note that in every step of the loop in line 7, it considers a constant number of pruned subtrees from T_2, so in total there are $O(B - M)$ of them. After this loop, we have $\delta(*, \mathsf{subtree}(h_M^{\downarrow}))$ computed.

The call of COMPUTEFROM in line 9 needs more input than the call in line 8, even though the strategy is always uncontracting the right main edge. Note that if the dynamic program only tried contracting the right main edge, it would be possible to compute $\delta(*, \mathsf{merged}^R(A, M))$ only from $\delta(*, \mathsf{merged}^R(A, B))$. However, it is not the case when the algorithm also matches edges. The first case when r_G is a light edge ($r_G = l_X$ for some value of X) is not problematic, because then $R_G = \emptyset$ and $G - R_G = G - r_G$, so this pruned subtree is already visited. Although, if r_G is a heavy edge then $R_G = \mathsf{subtree}(r_G^{\downarrow})$ and $G - R_G$ is a pruned subtree, which has not been considered yet. Observe that in this situation the pruned subtree can be obtained from $\mathsf{subtree}(h_{A-1}^{\uparrow})$ by a sequence of $O(B - A)$ contractions of the right main edge, so we need it as a separate input to the COMPUTEFROM subroutine. A similar reasoning applies to the edges to the left of H in line 10 and to the computations for interval $[M + 1, B]$.

To sum up, one call of GROUP(A, B) (not including recursive calls) visits $O(B - A)$ pruned subtrees of T_2. As we start from an interval of length $|H|$ and in every recursive call its length is roughly halved, the procedure considers in total $O(|H| \log |H|) = O(n \log n)$ pruned subtrees of T_2.

4.2 Arbitrary Tree T_2

Now we describe, how to modify the above algorithm to process not only a caterpillar, but an arbitrary tree T_2. In this case, there can be non-empty subtrees connected to the main heavy path.

Note that for an arbitrary heavy path H inside T_2, the ProcessHeavyPath procedure only needs to know $\delta(*, \mathsf{subtree}(h_0^{\uparrow}))$ to be able to compute all the remaining input parameters in $\mathsf{Data}(1, |H|)$, because $\delta(*, \mathsf{subtree}(h_{|H|}^{\downarrow})) = \delta(*, \emptyset)$ is precomputed. In the beginning, the algorithm calls $\textsc{ProcessHeavyPath}_{H^0}(\delta(*, \emptyset))$, where H^0 is the heavy path of T_2 containing the root of T_2. The only place we need to change inside the Group procedure to handle arbitrary trees T_2 is to not only fill $\Delta[u, l_A^{\uparrow}]$ in line 4 of Algorithm 3, but also recursively call $\textsc{ProcessHeavyPath}_{H'}(\delta(*, \mathsf{subtree}(l_A^{\uparrow})))$ where H' is the heavy path connected to the A-th node of the considered heavy path. As we pointed earlier, $\mathsf{subtree}(l_A^{\uparrow})$ is either $\mathsf{merged}^R(A, A)$ or $\mathsf{merged}^L(A, A)$, depending on which side of H is l_A. Now observe, that each subsequent pruned subtree that appears in the recursive formula is already visited and processed:

▶ **Observation 6.** In the modified Group procedure, during the call of ComputeFrom subroutine in line 9 of Algorithm 3, all the intermediate pruned subtrees of T_2 are obtained by a sequence of uncontractions of the right main edge from the root either from $\mathsf{merged}^R(A, B)$ or $\mathsf{subtree}(h_{A-1}^{\uparrow})$. A similar property holds for the other three calls of ComputeFrom in lines 10 and 12.

What changes in the analysis of the procedure is that now there are not $O(|H| \log |H|)$ pruned subtrees of T_2 but $O(|T_2^v| \log |H|) = O(|T_2^v| \log n)$, where v is the top node of H. In other words, the heavy path H itself might be short, but there might be big subtrees connected to it. However, every subtree connected to H is completely contracted (edge-by-edge) a constant number of times on every level of recursion of Group procedure and thus the bound.

Recall that top node of every heavy path is light, so using equation (1) we bound the overall number of subtrees of T_2 considered during this part of the algorithm:

$$\sum_{v\text{: top node of a heavy path in } T_2} |T_2^v| \cdot \log n = \sum_{v\text{: light node in } T_2} |T_2^v| \cdot \log n \in O(n \log^2 n)$$

4.3 Final Analysis

To conclude, the above algorithm computes $\Delta[u, e^{\uparrow}]$ for all nodes $u \in T_1$ such that $|T_1^u| \leq n/b$ and all darts up the tree T_2 by considering $O(n \log^2 n)$ pruned subtrees of T_2 and $O(n^2/b)$ of T_1. At the beginning of Section 4 we described the second phase of the algorithm, which avoids the heavy child in T_1 and fills the remaining fields of Δ considering $O(n \log b)$ pruned subtrees of T_1 and $O(n^2)$ of T_2. Thus, during the two phases, the whole algorithm visits $O(n^3 \frac{\log^2 n}{b} + n^3 \log b)$ subproblems. Setting $b = \log^2 n$ we obtain the overall complexity $O(n^3 \log \log n)$.

Abstract

For a hypergraph H, let $q(H)$ denote the expected number of monochromatic edges when the color of each vertex in H is sampled uniformly at random from the set of size 2. Let $s_{\min}(H)$ denote the minimum size of an edge in H. Erdős asked in 1963 whether there exists an unbounded function $g(k)$ such that any hypergraph H with $s_{\min}(H) \geqslant k$ and $q(H) \leqslant g(k)$ is two colorable. Beck in 1978 answered this question in the affirmative for a function $g(k) = \Theta(\log^* k)$. We improve this result by showing that, for an absolute constant $\delta > 0$, a version of random greedy coloring procedure is likely to find a proper two coloring for any hypergraph H with $s_{\min}(H) \geqslant k$ and $q(H) \leqslant \delta \cdot \log k$.

1 Introduction

A *hypergraph* $H = (V, E)$ is a finite set of vertices V and a set of edges E where each edge is a set of at least two vertices. A *two coloring* of H is an assignment of color blue or red to each vertex in H. A coloring is *proper* if each edge in H contains both a vertex colored blue and a vertex colored red. We say that H is *two colorable* if it admits a proper two coloring. Hypergraph H is *k-uniform* if every edge in H has size exactly k – we also say that H is a *k-graph*. For every $n \in \mathbb{N}$, the set $\{1, \ldots, n\}$ is denoted by $[n]$. We use standard O-notation to describe asymptotic properties of various functions.

One of the most classical problems in the extremal combinatorics is to find the minimum number of edges $m(k)$ in a k-uniform hypergraph that is not two colorable. The research on this problem has been started in the 60s by Erdős and Hajnal [5], who used the term *Property B* for two colorability. Today, by the result of Radhakrishnan and Srinivasan [10], we know that $m(k) = \Omega((k/\log k)^{1/2}) \cdot 2^k$. The best known upper bound, proved by Erdős [4] in 1964, is $m(k) = O(k^2) \cdot 2^k$. This upper bound follows from the fact that a random k-graph with k^2 vertices and $O(k^2) \cdot 2^k$ edges is very unlikely to be two colorable. Interestingly, known deterministic constructions require much larger structures – the best one is by Gebauer [7] and gives a not two colorable k-graph with roughly $2^{k+k^{2/3}}$ edges.

Lovász [8] proved that for $k \geqslant 3$, the problem of deciding if a given k-graph is two colorable is NP-complete. For k-graphs with the number of edges smaller than $m(k)$ the decision problem is trivial – by the definition they are all two colorable. Nevertheless, constructing a two coloring of such k-graphs is not necessarily an easy task. Luckily, the known lower bounds for $m(k)$ are constructive. In fact, the bound of [10] is proved by showing that some randomized coloring procedure succeeds with high probability for the considered hypergraphs. Cherkashin and Kozik [2] showed that the same bound is obtained by the analysis of a random greedy algorithm (i.e., a procedure that colors the vertices of a hypergraph in a random order and assigns color blue to each vertex unless it is the last vertex of a monochromatic blue edge – only then color red is assigned).

For a hypergraph $H = (V, E)$, let $q(H)$ denote the expected number of monochromatic edges when the color of each vertex is sampled uniformly at random. Clearly, for a k-graph H, we have $q(H) = |E| \cdot 2^{-k+1}$, and determining the value of $m(k)$ is equivalent to finding a not two colorable k-graph H with the minimal possible value of $q(H)$. This formulation allows for a neat generalization of the question to hypergraphs with edges of arbitrary sizes (i.e., nonuniform hypergraphs). For a hypergraph $H = (V, E)$, let $s_{\min}(H) = \min_{e \in E} |e|$ and observe that $q(H) = \sum_{e \in E} 2^{-|e|+1}$. Erdős [3, 6] asked whether there exists an unbounded function g such that any hypergraph H with $s_{\min}(H) \geqslant k$ and $q(H) \leqslant g(k)$ is two colorable. A positive answer has been given in 1978 by Beck [1] who proved the result for $g(k) = \Theta(\log^*(k))$. This has not been improved since then. (In 2008 Lu [9] announced a proof of a bound $\Omega(\log(k)/\log\log(k))$, but it turned out to work only for some specific class of hypergraphs[1]. The class contains all simple hypergraphs, but for these Shabanov in [11] improved the bound to $\Omega(\sqrt{k})$.) In this paper we prove the same result for $g(k) = \Theta(\log(k))$. The random construction of a not two colorable k-graph by Erdős [4] shows that the best possible g is $O(k^2)$, even when restricted to uniform hypergraphs. Interestingly, there are no better nonuniform constructions known. Our main result is the following.

▶ **Theorem 1.** *There exists a constant $\delta > 0$ such that for all sufficiently large k, any hypergraph $H = (V, E)$ with $s_{\min}(H) \geqslant k$ and $q(H) \leqslant \delta \cdot \log k$ is two colorable.*

Moreover, we prove the theorem by showing that a version of a random greedy coloring procedure succeeds with positive probability for these hypergraphs.

[1] The proof in the preprint available on the authors web page is very close to the developments of Section 3.3 "Simple bound". In our opinion it is incorrect, since it does not take into account that a vertex of some edge f can be recolored because of some other edge e with $|e \cap f| > 1$ (despite irreducibility). We avoid this problem by considering the vertices in a random order and allowing only the last vertex of an initially monochromatic edge to be recolored, provided that the edge is not already repaired.

2 Basic notions and the coloring procedure

2.1 Tools

We start with a simple lemma on convex functions of random variables.

▶ **Lemma 2.** *Let X be a nonnegative random variable such that $0 \leqslant X \leqslant M$ and $\mathbb{E}[X] \leqslant \lambda M$ for some $M \geqslant 0$, and $0 \leqslant \lambda \leqslant 1$. Then, for any convex function $f : [0, M] \to [0, \infty)$ with $f(M) \geqslant f(0)$, the following inequality holds*

$$\mathbb{E}[f(X)] \leqslant \lambda f(M) + (1 - \lambda) f(0).$$

Proof. Consider another random variable $Y := \frac{X}{M} f(M) + (1 - \frac{X}{M}) f(0)$. From the convexity of f we have $f(X) \leqslant Y$. Therefore

$$\begin{aligned}\mathbb{E}[f(X)] &\leqslant \frac{\mathbb{E}[X]}{M} \cdot f(M) + f(0) - \frac{\mathbb{E}[X]}{M} \cdot f(0) \leqslant f(0) + (f(M) - f(0)) \cdot \frac{\mathbb{E}[X]}{M} \\ &\leqslant \lambda f(M) + (1 - \lambda) f(0),\end{aligned}$$

as desired. ◀

2.2 Preliminaries

Let $H = (V, E)$ be a hypergraph and let k denote the minimum size of an edge in H. For any $j \geqslant k$ we define

$$q_j := \sum_{e \in E, |e| = j} 2^{-j+1},$$

which is the expected number of monochromatic edges of size j when the color of each vertex is sampled uniformly at random. Let $q := q(H)$ and observe that $q = \sum_{j \geqslant k} q_j$.

We aim to prove that if $q = O(\log k)$ then the hypergraph is two colorable. In order to do that, we describe a random coloring procedure and with a careful analysis we bound the probability that a fixed edge is monochromatic after the procedure finishes. The obtained bound allows us to conclude that the expected number of monochromatic edges after the procedure finishes is smaller than one. Thus, the hypergraph is two colorable.

2.3 The coloring procedure

Our algorithm is based on the *random greedy coloring* and it works in two phases. In the first one, for every vertex v we sample uniformly and independently an *initial color* $ic(v)$ and a *weight* $w(v) \in (0, 1)$. Then, an edge in which all vertices get the same initial color is called *initially monochromatic*. For an edge e, the *heaviest* vertex in e is the one with maximum weight among vertices in e (we assume that no two vertices have the same weight). We define the weight $w(e)$ of e to be the weight of the heaviest vertex in e (i.e. $w(e) = \max_{v \in e} w(v)$). The procedure is defined as follows:

- **Phase 1: Initial coloring**
  For every vertex v sample independently the following two values:
  - $ic(v)$ – the *initial color* of v: blue or red, each with probability $\frac{1}{2}$,
  - $w(v)$ – the *weight* of v, sampled uniformly at random from the real interval $(0, 1)$.
- **Phase 2: Recoloring**
  Arrange the vertices in the order of increasing weights. Iterating over vertices in that order, for every vertex v, we assign $c(v)$ – the *color* of v according to the following rules:

- if v is the heaviest vertex of some initially monochromatic edge e, and for all other vertices w of e we have $c(w) = ic(w)$, we set $c(v)$ to be the color that is different than $ic(v)$,
- otherwise we put $c(v) = ic(v)$.

Observe that once the color $c(v)$ is assigned, it is never changed. We say that a vertex v is *recolored* if $c(v)$ is different than $ic(v)$. Note also that if v is the heaviest vertex in some initially monochromatic edge e, then, at the moment when we assign color $c(v)$ to v, the color of every other vertex in e is already defined. At that point, if none of the other vertices in e is recolored, we define $c(v)$ to be the color other than $ic(v)$ (i.e. we recolor v), and we say that e is a *reason* to recolor v. Note that there may be more than one reason to recolor v. On the other hand, if there is no reason to recolor v we simply assign $c(v) = ic(v)$. Observe that eventually every initially monochromatic edge gets one of the vertices recolored.

2.4 Main result

For a better exposition of the argument, we first prove a statement slightly weaker than Theorem 1. In Section 3.3 we give a proof of the following result about the coloring procedure.

▶ **Proposition 3.** *If $q = O(\frac{\log k}{\log\log k})$ then, for any edge e, the probability that all vertices in e are colored red does not exceed $\frac{1}{3q2^{|e|-1}}$.*

This immediately implies that the expected number of monochromatic edges is at most $2 \cdot \sum_{e\in E} \frac{1}{3\cdot q\cdot 2^{|e|-1}} = \frac{2}{3}$ and thus, not only H is two colorable but also that our coloring procedure succeeds with probability at least $\frac{1}{3}$. In Section 3.4 we introduce more technical details to the argument and improve the bound.

▶ **Proposition 4.** *If $q = O(\log k)$ then, for any edge e, the probability that all vertices in e are colored red does not exceed $\frac{1}{3q2^{|e|-1}}$.*

This immediately implies Theorem 1.

3 Analysis

3.1 Bad events

The proof focuses on bounding the probability that one, fixed edge becomes monochromatic red. Nevertheless, we want to first exclude some problematic but unlikely events from happening. The simplest example is that we don't want two different vertices to receive the same weight. The probability of this event is zero and we want to simply assume that it doesn't happen. To be more precise, we allow our coloring procedure to fail during the initial phase of coloring. We give a few different reasons to fail and we argue that the probability that any of those bad events happens is small. Then, for the rest of the proof, we assume that none of the bad events happens.

3.1.1 Event $\mathcal{A}$ – too many initially monochromatic edges

The expected number of initially monochromatic edges is q. For a constant $\alpha_{\mathcal{A}}$ (to be fixed later) let $\mathcal{A}$ denote the event that there are more than $\alpha_{\mathcal{A}} \cdot q$ initially monochromatic edges. Markov's inequality gives that $\Pr[\mathcal{A}] < 1/\alpha_{\mathcal{A}}$.

3.1.2 Event $\mathcal{B}$ – a light monochromatic edge

For a constant $\alpha_{\mathcal{B}}$ (to be fixed later) and every j we define

$$p_j := \frac{\ln(\alpha_{\mathcal{B}} q)}{j}.$$

An edge f of size j is *light* if it is initially monochromatic and the weight of every vertex in f is smaller than $1 - p_j$. The expected number of light monochromatic edges of size j is

$$q_j 2^{j-1} \cdot (1-p_j)^j \cdot 2^{-j+1} < q_j \cdot \exp(-p_j \cdot j) = \frac{q_j}{\alpha_{\mathcal{B}} q}.$$

Therefore, the expected total number of light edges (of any size) is at most $1/\alpha_{\mathcal{B}}$. Let $\mathcal{B}$ denote the event that there is a light monochromatic edge. Clearly $\Pr[\mathcal{B}] < 1/\alpha_{\mathcal{B}}$.

3.1.3 Event $\mathcal{C}$ – too many almost monochromatic edges

An edge f is *almost monochromatic* if there is a vertex $v \in f$ such that all vertices in $f - v$ have the same initial color (in particular, an initially monochromatic edge is also an almost monochromatic edge). With every almost monochromatic edge f we can injectively associate a *certifying pair* $(f, v) \in E \times V$ for which $v \in f$ and $f - v$ is initially monochromatic.

Let Q_j be a random variable that denotes the number of almost monochromatic edges of size j. Since the number of such edges cannot exceed the number of certifying pairs associated with edges of size j, we get $\mathbb{E}[Q_j] \leqslant q_j 2^{j-1} \cdot j \cdot 2^{-j+2} = 2j \cdot q_j$. We define random variable

$$Y := \sum_j \frac{Q_j}{j},$$

and get that $\mathbb{E}[Y] \leqslant 2q$. Let $\mathcal{C}$ denote the event that $Y > \alpha_{\mathcal{C}} q$. Markov's inequality gives $\Pr[\mathcal{C}] < 2/\alpha_{\mathcal{C}}$.

For any fixed $\varepsilon > 0$ we can choose constants $\alpha_{\mathcal{A}}, \alpha_{\mathcal{B}}, \alpha_{\mathcal{C}}$ so that $1/\alpha_{\mathcal{A}} + 1/\alpha_{\mathcal{B}} + 2/\alpha_{\mathcal{C}} < \varepsilon$. Denote by $\mathcal{G}$ the intersection $\overline{\mathcal{A}} \cap \overline{\mathcal{B}} \cap \overline{\mathcal{C}}$ and observe that $\Pr[\mathcal{G}] > 1 - \varepsilon$. That is, with arbitrarily high probability none of the bad events happens. For any event $\mathcal{V}$, we denote $\Pr[\mathcal{V} \cap \mathcal{G}]$ by $\Pr_{\mathcal{G}}[\mathcal{V}]$ and similarly by $\Pr_{\mathcal{G}}[\mathcal{V}|\mathcal{C}]$ we mean $\Pr[\mathcal{V} \cap \mathcal{G}|\mathcal{C}]$.

3.2 e-focused coloring

For the rest of this section and the next section we fix an arbitrary edge e in E. Let s denote the size of e. The event "e *becomes red*" denotes the situation that all vertices in e are colored red by the coloring procedure. First observation is that if e is initially monochromatic red, then at least one vertex in e gets recolored and e can't become red in the end. Thus, if e becomes red then e contains some initially blue vertices and each of them gets recolored. In particular, every initially blue vertex in e is the heaviest vertex in some initially monochromatic blue edge. Additionally, it needs to happen that none of the initially red vertices in e gets recolored, but this condition seems impossible to use.

Taking into account the bad events we aim to prove that for a proper q we have:

$$\Pr_{\mathcal{G}}[e \text{ becomes red}] < \frac{1}{3} \cdot \frac{1}{q 2^{s-1}}.$$

3.2.1 The threat hypergraph

In what follows we try to understand better which initially blue vertices in e are recolored to red. The important observation is that if edges f and e have more than one vertex in common and f is a reason to recolor any of the common vertices, then e does not become red. To see that, let v be the heaviest vertex in f, and let w be any vertex in $f \cap e$ other than v. If f is a reason to recolor v then f is initially monochromatic blue and w is not recolored. Thus, w retains the initial blue color, and edge e does not become red.

This motivates the following construction of the *threat hypergraph* H_e. We define the vertex set of H_e to be $V \setminus e$. For each edge f in E that has exactly one common vertex with e (i.e., $|f \cap e| = 1$), let $f_e = f \setminus e$. We define the edge set of H_e to be $\{f_e : f \in E, |f \cap e| = 1\}$. Observe that for different edges $f \neq f'$ in E it might happen that $f_e = f'_e$. Thus, H_e is a multihypergraph. For each edge f_e of H_e we call f to be the *extension edge* of f_e and we call the only vertex in $f \cap e$ to be the *extension vertex* of f_e.

For the sake of our analysis, we reveal the outcomes of the random experiments used in the coloring procedure in four steps. In the first step we reveal the initial colors of the vertices in H_e. In the second step, we reveal the initial colors of the vertices in e. Then, we reveal the weights of vertices in H_e. Finally, we reveal the weights of the vertices in e. It is crucial to understand that this does not influence the coloring procedure in any way.

After the first step, some edges in H_e are monochromatic blue. For every such edge f_e, let v be the extension vertex of f_e, and we say that v is *endangered* by f_e. Observe that if e is to become red, then among vertices in e, only the endangered ones can be recolored from blue to red. For every endangered vertex v in e we define the *severity* of v to be the minimum size $|f|$ of an edge such that v is endangered by f_e. We define $\mathcal{R}^e_j$ to be the set of all vertices in e that are endangered and with severity j. Let $R^e_j := |\mathcal{R}^e_j|$. Note that both R^e_j and $\mathcal{R}^e_j$ are random variables which are determined after the first step (i.e., by the initial colors of the vertices in H_e).

Thus, a necessary condition for e to become red is that in the second step only the endangered vertices get initial color blue. Consider an endangered vertex with severity j which is initially blue and which is to become red. There is an edge f_e that endangers v, and v becomes the heaviest vertex in the extension of f_e. In particular, since the size of f is at least j, the weight of v (revealed in the fourth step) has to be at least $1 - p_j$. Otherwise, the edge f is a light monochromatic edge and bad event $\mathcal{B}$ happens.

Observe that there are no more vertices recolored than there are initially monochromatic edges. As we assume that bad event $\mathcal{A}$ does not happen, there are at most $\alpha_{\mathcal{A}} q$ vertices recolored in total. Let us sum up the observed necessary conditions for the edge e to become red:

1. at least one and at most $\alpha_{\mathcal{A}} q$ vertices in e are initially blue,
2. every initially blue vertex v in e is endangered. If severity of v is j then $w(v) \geqslant 1 - p_j$.

We use these conditions to obtain an upper bound on the probability of e becoming red.

3.3 Simple bound

We define, mainly for technical convenience, a random variable

$$X := \sum_j R^e_j \cdot p_j.$$

Observe that X is determined after the first step and that X takes only a finite number of possible values. For the rest of this section whenever we condition on event $X = x$ we always assume that the value x is such that $\Pr[X = x] > 0$. Recall that s is the size of e. The bound will follow from the following result:

▶ **Proposition 5.**

$$\Pr_{\mathcal{G}}[e \text{ becomes red } | X = x] < \frac{\exp(x) - 1}{2^s}.$$

Proof. Assume that we are after the first step and the values of variables $\mathcal{R}^e_j$, R^e_j, and X are determined. For each $j \geqslant k$, let $r_j := R^e_j$. With this assumption, we compute the probability of e becoming red. We claim that

$$\Pr_{\mathcal{G}}[e \text{ becomes red } | \text{the first step}] \leqslant \frac{1}{2^{s-\sum_j r_j}} \sum_{1 \leqslant c_k + c_{k+1} + \ldots \leqslant \alpha_{\mathcal{A}} q} \prod_j \binom{r_j}{c_j} \left(\frac{p_j}{2}\right)^{c_j} \left(\frac{1}{2}\right)^{r_j - c_j}.$$

The first factor corresponds to the not endangered vertices in e – each of them needs to be initially colored red. The sum spans over the values $c_k, c_{k+1}, \ldots$, where c_j corresponds to the number of initially blue vertices in R^e_j. There are exactly $\sum_j c_j$ initially blue elements and we know that this number is at least 1 and at most $\alpha_{\mathcal{A}} q$.

Once the number of initially blue elements in each $\mathcal{R}^e_j$ is fixed, there are $\binom{r_j}{c_j}$ possibilities to choose these elements from $\mathcal{R}^e_j$. Finally, all the chosen elements have to be initially colored blue and their weight has to be at least $1 - p_j$. The remaining elements of $\mathcal{R}^e_j$ have to be initially colored red.

Observe that the expression depends not on a particular result of the first phase, but rather only on the values of R^e_j. We use the fact that $\binom{r_j}{c_j} \leqslant \frac{r_j^{c_j}}{c_j!}$, rearrange the terms, and obtain:

$$\begin{aligned}\Pr_{\mathcal{G}}[e \text{ becomes red } | (R^e_j = r_j)_{j \geqslant k}] &\leqslant \frac{1}{2^s} \sum_{c=1}^{\alpha_{\mathcal{A}} q} \sum_{c_k + c_{k+1} + \ldots = c} \prod_j \binom{r_j}{c_j} p_j^{c_j} \\ &\leqslant \frac{1}{2^s} \sum_{c=1}^{\alpha_{\mathcal{A}} q} \frac{1}{c!} \left(\sum_j r_j \cdot p_j \right)^c.\end{aligned}$$

Let $x := \sum_j r_j \cdot p_j$, recall that $X = \sum_j R^e_j \cdot p_j$, and observe that the last expression depends not on the particular values of R^e_j, but rather only on the value of X.

$$\Pr_{\mathcal{G}}[e \text{ becomes red } | X = x] \leqslant \frac{1}{2^s} \sum_{c=1}^{\alpha_{\mathcal{A}} q} \frac{x^c}{c!} \tag{1}$$

$$< \frac{\exp(x) - 1}{2^s}. \tag{2}$$

◀

Proof of Proposition 3. Recall that the random variable Q_j denotes the number of almost monochromatic edges of size j, while R^e_j is the number of endangered vertices in e with severity j. For every such vertex v we have an initially blue edge f in H_e for which v is the extension vertex. Since the extension edge of f is almost blue we obtain that $R^e_j \leqslant Q_j$. This implies:

$$X = \sum_j R^e_j \cdot p_j = \ln(\alpha_{\mathcal{B}} q) \cdot \sum_j \frac{R^e_j}{j} \leqslant \ln(\alpha_{\mathcal{B}} q) \cdot \sum_j \frac{Q_j}{j} = \ln(\alpha_{\mathcal{B}} q) \cdot Y. \tag{3}$$

Therefore $X \leqslant \ln(\alpha_{\mathcal{B}} q) \cdot \alpha_{\mathcal{C}} q$ unless bad event $\mathcal{C}$ happens. We now have:

$$\begin{aligned}\Pr_{\mathcal{G}}[e \text{ becomes red}] &= \sum_{x \leqslant \ln(\alpha_{\mathcal{B}} q) \cdot \alpha_{\mathcal{C}} q} \Pr[X = x] \cdot \Pr_{\mathcal{G}}[e \text{ becomes red } | X = x] \\ &< \sum_{x \leqslant \ln(\alpha_{\mathcal{B}} q) \cdot \alpha_{\mathcal{C}} q} \Pr[X = x] \cdot \frac{\exp(x) - 1}{2^s} \\ &\leqslant \frac{1}{2^s} \cdot \mathbb{E}\left[\exp(X) - 1 \middle| X \leqslant \ln(\alpha_{\mathcal{B}} q) \cdot \alpha_{\mathcal{C}} q\right].\end{aligned}$$

Inequality (3) also yields

$$\mathbb{E}[X] \leqslant \sum_j q_j \cdot p_j \leqslant \frac{q \ln(\alpha_{\mathcal{B}} q)}{k}.$$

We apply Lemma 2 for $f(x) = \exp(x) - 1$, $M = \alpha_{\mathcal{C}} q \ln(\alpha_{\mathcal{B}} q)$ and $\lambda = \frac{1}{\alpha_{\mathcal{C}} k}$, and obtain:

$$\mathbb{E}[\exp(X) - 1] \leqslant \frac{\exp(\ln(\alpha_{\mathcal{B}} q) \cdot \alpha_{\mathcal{C}} q)}{\alpha_{\mathcal{C}} k}.$$

Hence

$$\Pr_{\mathcal{G}}[e \text{ becomes red}] < \frac{1}{2^s} \cdot \frac{\exp(\ln(\alpha_{\mathcal{B}} q) \cdot \alpha_{\mathcal{C}} q)}{\alpha_{\mathcal{C}} k}.$$

Let $\alpha > \max\{\alpha_{\mathcal{B}}, \alpha_{\mathcal{C}}\}$. Now, suppose that:

$$q \leqslant \frac{1}{\alpha} \cdot \frac{\ln k}{\ln \ln k}.$$

For k large enough, $\ln(\alpha_{\mathcal{B}} q) \leqslant \ln \ln(k)$ which yields:

$$\frac{\exp(\ln(\alpha_{\mathcal{B}} q) \cdot \alpha_{\mathcal{C}} q)}{\alpha_{\mathcal{C}} k} \leqslant \frac{1}{\alpha_{\mathcal{C}} k} \cdot \exp\left(\frac{\alpha_{\mathcal{C}} \ln k}{\alpha \ln \ln k} \cdot \ln \ln k\right) \leqslant \frac{k^{(\alpha_{\mathcal{C}}/\alpha)-1}}{\alpha_{\mathcal{C}}}.$$

For k large enough, the last term is less than $\frac{1}{6q}$, which implies:

$$\Pr_{\mathcal{G}}[e \text{ becomes red}] < \frac{1}{3q \cdot 2^{s-1}}$$

and completes the proof. ◀

An astute reader may have realised that we did not use bad event $\mathcal{A}$ in any essential way. Currently, the only reason to introduce $\mathcal{A}$ is that it makes the proof slightly easier. We could, however, use $\mathcal{A}$ to improve bound (2) for the values of x greater than q, leading to a slightly better condition $q = O(\frac{\log k}{\log \log \log k})$. We do not elaborate on that since the argument in Section 3.4 already gives an even better result.

3.4 Improved bound

In order to obtain an improved bound we introduce one more bad event.

3.4.1 Event $\mathcal{D}$ – large second weight deficit

For every edge f in E which is initially monochromatic, we define its *second weight deficit* as $d_2(f) := (|f|+1)\cdot(1-w_2(f))$, where $w_2(f)$ is the weight of the second heaviest vertex in f. For an edge f that is not initially monochromatic, $d_2(f)$ is defined to be 0.

Note that, conditioned on f being initially monochromatic, the variable $1-w_2(f)$ has mean $\frac{2}{|f|+1}$. In particular $\mathbb{E}[d_2(f)|\ f \text{ is monochromatic}] = 2$ and hence $\mathbb{E}[d_2(f)] = \frac{2}{2^{|f|-1}}$. Let $D_2 := \sum_{f\in E} d_2(f)$ and observe that we have

$$\mathbb{E}[D_2] = \sum_j 2q_j = 2q.$$

Event $\mathcal{D}$ is defined as $D_2 > \alpha_{\mathcal{D}} q$. By Markov's inequality, we get $\Pr[\mathcal{D}] < 2/\alpha_{\mathcal{D}}$ and we can chose $\alpha_{\mathcal{D}}$ so that this probability is arbitrarily small.

3.4.2 Analysis

In the first step of e-focused coloring we reveal the initial colors of all the vertices from $V\setminus e$. This step determines the endangered vertices in e – we denote their set by $\mathcal{R}$. For every value of $c = 1, 2, \dots \alpha_{\mathcal{A}} q$ and every c-subset $S = \{v_1, \dots, v_c\}$ of $\mathcal{R}$ we consider an event that S contains exactly the vertices in e which become recolored. Thus, these are the only initially blue vertices in e. Once we fix the subset S, the probability that S is the set of initially blue vertices in e is precisely 2^{-s}. This event is determined after the second step of e-focused coloring – when the initial colors of vertices in e are revealed. In order to be recolored, every vertex v_j must receive a weight that makes it heavier than some edge that endangers it. Let us reveal the weights of the vertices in $V\setminus e$ (third step of e-focused coloring). The vertex v_j is endangered by some edges $f^1_{v_j}, \dots, f^t_{v_j}$ of H_e, and let f_{v_j} be the lightest of these edges (i.e. the edge whose heaviest vertex is the lightest among the heaviest vertices of $f^1_{v_j}, \dots, f^t_{v_j}$). Clearly in order for vertex v_j to be recolored, it has to get a weight greater than $w(f_{v_j})$ – this happens with probability $1-w(f_{v_j})$. We choose a parametrization that takes into account the size of f_{v_j} and denote the value $1-w(f_{v_j})$ by $\frac{\delta_j}{|f_{v_j}|+2}$. Now, conditioned on the result of the first three steps, the probability that all vertices $\{v_1, \dots, v_c\}$ are heavy enough is

$$\prod_{j=1}^{c} \frac{\delta_j}{|f_{v_j}|+2} < \prod_{j=1}^{c} \frac{\delta_j}{|f_{v_j}|+1}. \tag{4}$$

The edge f_{v_j} together with v_j forms an edge of H, which we denote by h_{v_j}. Although the value of $d_2(h_{v_j})$ is not determined until we reveal the weight of v_j (in the fourth step), we already know at this point that $\delta_j \leqslant d_2(h_{v_j})$ (it becomes an equality when v_j becomes the heaviest vertex in h_{v_j}). Assuming the bad event $\mathcal{D}$ does not happen, we have $\sum_{j=1}^{c} \delta_j \leqslant \alpha_{\mathcal{D}} q$. Using the AM-GM inequality we deduce that $\prod_{j=1}^{c} \delta_j \leqslant \left(\frac{\alpha_{\mathcal{D}} q}{c}\right)^c$, which bounds the value of (4):

$$\prod_{j=1}^{c} \frac{\delta_j}{|f_{v_j}|+1} \leqslant \left(\frac{\alpha_{\mathcal{D}} q}{c}\right)^c \prod_{j=1}^{c} \frac{1}{|f_{v_j}|+1}.$$

Summing over all c-subsets of $\mathcal{R}$ we get that the probability that some c-subset contains all initially blue vertices in e and they are all recolored does not exceed

$$\sum_{S\in\binom{\mathcal{R}}{c}} \frac{1}{2^s}\left(\frac{\alpha_{\mathcal{D}} q}{c}\right)^c \prod_{v\in S} \frac{1}{|f_v|+1} \leqslant \frac{1}{2^s}\left(\frac{\alpha_{\mathcal{D}} q}{c}\right)^c \frac{1}{c!}\left(\sum_{v\in\mathcal{R}} \frac{1}{|f_v|+1}\right)^c.$$

Define random variable

$$Y_e := \sum_{f_e \text{ in } H_e,\ f_e \text{ is blue}} \frac{1}{|f_e|+1},$$

which gets determined after the first step of e-focused coloring. For each endangered vertex v in e, all the edges, including the lightest one, that endanger v are blue and thus are taken into the sum defining Y_e. Therefore, $Y_e \geqslant \sum_{v\in\mathcal{R}} \frac{1}{|f_v|+1}$. On the other hand, the extension edge of every blue edge in H_e is an almost monochromatic edge in H. As Y counts the number of almost monochromatic edges in H, we get $Y_e \leqslant Y \leqslant \alpha_{\mathcal{C}} q$ unless bad event $\mathcal{C}$ happens. We can also bound the expected value of Y_e:

$$\mathbb{E}[Y_e] = \sum_{f\in H_e} \frac{2^{-|f|}}{|f|+1} < \frac{1}{k} \sum_{f'\in H} 2^{-|f'|+1} = \frac{q}{k}.$$

Note that Y_e takes only a finite number of possible values. For any value y such that $\Pr[Y_e = y] > 0$, we get the following bound:

$$\begin{aligned}
\Pr_{\mathcal{G}}[e \text{ becomes red } | Y_e = y] &\leqslant \frac{1}{2^s} \sum_{c=1}^{\alpha_{\mathcal{A}} q} \left(\frac{\alpha_{\mathcal{D}} q}{c}\right)^c \frac{y^c}{c!} \\
&\leqslant \frac{1}{2^s} \sum_{c=1}^{\alpha_{\mathcal{A}} q} \frac{(\alpha_{\mathcal{D}} q y)^c}{c! \cdot c^c} \\
&\leqslant \frac{1}{2^s} \sum_{c=1}^{\alpha_{\mathcal{A}} q} \frac{(2\alpha_{\mathcal{D}} q y)^c}{(2c)!}
\end{aligned}$$

as $\frac{(2c)!}{2^c} \leqslant \frac{c!\cdot(2c)^c}{2^c} = c! \cdot c^c$. For any x, we have $\sum_{c=0}^{\infty} \frac{x^{2c}}{(2c)!} = \frac{\exp(x)+\exp(-x)}{2} = \cosh(x)$. Therefore

$$\Pr_{\mathcal{G}}[e \text{ becomes red } | Y_e = y] \leqslant \frac{1}{2^s}(\cosh\left(\sqrt{2\alpha_{\mathcal{D}} q y}\right) - 1),$$

and

$$\Pr_{\mathcal{G}}[e \text{ becomes red}] \leqslant \mathbb{E}\left[\frac{1}{2^s}(\cosh\left(\sqrt{2\alpha_{\mathcal{D}} q Y_e}\right) - 1)\middle| Y_e \leqslant \alpha_{\mathcal{C}} q\right].$$

Observe that for any $a > 0$, the function $\cosh(a\sqrt{x})$ is convex and increasing in $[0, \infty)$. Therefore, we apply Lemma 2 for $f(x) = \cosh(\sqrt{2\alpha_{\mathcal{D}} q x}) - 1$, $M = \alpha_{\mathcal{C}} q$ and $\lambda = \frac{1}{\alpha_{\mathcal{C}} k}$, and obtain:

$$\Pr_{\mathcal{G}}[e \text{ becomes red}] \leqslant \frac{1}{2^s}\frac{1}{\alpha_{\mathcal{C}} k}(\cosh\left(\sqrt{2\alpha_{\mathcal{D}}\alpha_{\mathcal{C}} q q}\right) - 1) \leqslant \frac{1}{\alpha_{\mathcal{C}} k 2^s} \exp\left(\sqrt{2\alpha_{\mathcal{D}}\alpha_{\mathcal{C}}} \cdot q\right).$$

The obtained value is smaller than $\frac{1}{3q2^{s-1}}$ whenever

$$\frac{3q \exp\left(\sqrt{2\alpha_{\mathcal{D}}\alpha_{\mathcal{C}}} \cdot q\right)}{2\alpha_{\mathcal{C}} k} \leqslant 1.$$

The last inequality is easily seen to hold for $q \leqslant \frac{0.9}{\sqrt{2\alpha_{\mathcal{D}}\alpha_{\mathcal{C}}}} \ln k$ and all large enough k.

4 Remarks

4.1 Bounded maximal size

We can derive better bounds when the size of the maximum edge is not much larger than k. Suppose that $\max_{e\in E}|e| \leqslant K$. We apply the proof strategy from [2] and analyze the random greedy coloring procedure (i.e. we arrange the vertices in random order and color consecutive vertices blue if this does not create a monochromatic edge, otherwise we color it red). As a technical convenience, instead of sampling a random ordering of the vertices, for every vertex we choose uniformly a weight from the real interval $(0,1)$. We color vertices greedily in the order of increasing weights. We choose (with foresight) parameter $p := \ln(4q)/k$. An edge is called *light* if the weight of its heaviest vertex is at most $(1-p)/2$. Similarly an edge f is *heavy* if every verex in f has weight at least $(1+p)/2$. The probability that there exists a light edge is bounded by the expected number of such:

$$\sum_{f\in E}\left(\frac{1-p}{2}\right)^{|f|} \leqslant (1-p)^k \cdot q.$$

The same bound holds for *heavy* edges. It is easy to see that in order for the procedure to fail there must exist a pair of edges f_1, f_2 such that the heaviest vertex of f_1 is the lightest vertex of f_2. Such a pair is called *conflicting*. Therefore for the procedure to fail it is necessary that either there exists a conflicting pair f_1, f_2 for which the weight of the unique common vertex belongs to $((1-p)/2, (1+p)/2)$ or there exists a light or heavy edge. The expected number of such conflicting pairs is at most

$$\begin{aligned}
&\sum_{f_1,f_2\in E}\int_{-p/2}^{p/2}\left(\frac{1}{2}+x\right)^{|f_1|-1}\left(\frac{1}{2}-x\right)^{|f_2|-1}dx\\
&\leqslant \sum_{f_1,f_2\in E} 2^{-|f_1|-|f_2|+2}\cdot p\cdot \max_{x\in(-p/2,p/2)}(1+2x)^{|f_1|-1}(1-2x)^{|f_2|-1}\\
&\leqslant p\cdot\sum_{f_1,f_2\in E} 2^{-|f_1|-|f_2|+2}\cdot \max_{x\in(-p/2,p/2)}(1+2x)^{|f_1|-|f_2|}\\
&= p\cdot\sum_{f_1,f_2\in E} 2^{-|f_1|-|f_2|+2}\cdot (1+p)^{|f_1|-|f_2|}\\
&\leqslant p\cdot(1+p)^{K-k}\sum_{f_1,f_2\in E} 2^{-|f_1|-|f_2|+2} = p(1+p)^{K-k}q^2.
\end{aligned}$$

Altogether the probability of failure is at most

$$p(1+p)^{K-k}q^2 + 2(1-p)^k q \sim pq^2\exp(p(K-k)) + 2q\exp(-pk).$$

Plugging in the value of p we get

$$\frac{\ln(4q)q^2(4q)^{K/k-1}}{k} + 1/2 \leqslant \frac{\ln(k)(4q)^{K/k+1}}{k} + 1/2$$

where we additionally assumed that $q \leqslant k$. As long as this value is below 1 we can be sure that random greedy coloring strategy succeeds with positive probability. For $k = K$ we recover the result of [2]. When K is bounded by a linear function of k, e.g. $K \leqslant \alpha k$ it is sufficient that q does not exceed

$$\frac{1}{5}\left(\frac{k}{\ln(k)}\right)^{\frac{1}{\alpha+1}}$$

The resulting bound for q starts to be worse than the one from Theorem 1 when K is roughly of the order $k\log(k)$.

4.2 Uniform case

It is instructive to observe how our analysis works for uniform hypergraphs. We focus on modifications in the proof of our simple bound, since the ideas used for the improved bound do not help in the uniform case. Using an obvious bound $R_k^e \leqslant k$, we improve inequality (3) to $X \leqslant \ln(\alpha_{\mathcal{B}} q)$. Then we apply Lemma 2 with $M = \ln(\alpha_{\mathcal{B}} q)$ and $\lambda = \frac{q}{k}$ obtaining

$$\Pr_{\mathcal{G}}[e \text{ becomes red}] < 2^{-k}\frac{q}{k}\exp(\ln(\alpha_{\mathcal{B}} q)) = 2^{-k}\frac{q^{1+\alpha_{\mathcal{B}}}}{k}.$$

Since in this case the only bad event that we use is $\mathcal{B}$, we can afford to set $\alpha_{\mathcal{B}} = 1+\varepsilon$, for any small $\varepsilon > 0$. We get that $\mathcal{B}$ does not happen with probability at least $\frac{\varepsilon}{1+\varepsilon}$. Then

$$\Pr_{\mathcal{G}}[e \text{ becomes red}] < 2^{-k}\frac{q^{2+\varepsilon}}{k}$$

and in order for this value to be at most $\frac{1}{2^k q}\cdot\frac{\varepsilon}{1+\varepsilon}$ it suffices that

$$q \leqslant k^{\frac{1}{3+\varepsilon}}\cdot\left(\frac{\varepsilon}{1+\varepsilon}\right)^{\frac{1}{3+\varepsilon}}.$$

This way we obtain a result analogous to that of Beck from [1] (i.e. $m(k) \geqslant k^{1/3-o(1)}2^k$). Incorporating the ideas from [10] or [2] that allowed to derive a bound $m(k) = \Omega(\sqrt{k/\log(k)})\cdot 2^k$ does not bring any significant improvement of our main result.

4.3 Hypergraphs with random-like characteristics

The weakest points of our analysis are the places where we apply Lemma 2. The lemma works for any bounded non-negative random variable X. It is clear from the bound that the worst case distribution of X is the one that assumes only values 0 and M. The variables for which we apply the lemma are related to the numbers of initially monochromatic edges in hypergraphs H_e. If these variables exhibit sufficiently strong concentration around their mean (like in the case of random hypergraphs) we may get a much stronger bound than the one of Lemma 2 and obtain results that are much closer to the case of uniform hypergaphs.

Abstract

Robin Thomas asked whether for every proper minor-closed class $\mathcal{G}$, there exists a polynomial-time algorithm approximating the chromatic number of graphs from $\mathcal{G}$ up to a constant additive error independent on the class $\mathcal{G}$. We show this is not the case: unless P = NP, for every integer $k \geq 1$, there is no polynomial-time algorithm to color a K_{4k+1}-minor-free graph G using at most $\chi(G)+k-1$ colors. More generally, for every $k \geq 1$ and $1 \leq \beta \leq 4/3$, there is no polynomial-time algorithm to color a K_{4k+1}-minor-free graph G using less than $\beta\chi(G) + (4 - 3\beta)k$ colors. As far as we know, this is the first non-trivial non-approximability result regarding the chromatic number in proper minor-closed classes.

We also give somewhat weaker non-approximability bound for K_{4k+1}-minor-free graphs with no cliques of size 4. On the positive side, we present an additive approximation algorithm whose error depends on the apex number of the forbidden minor, and an algorithm with additive error 6 under the additional assumption that the graph has no 4-cycles.

1 Introduction

The problem of determining the chromatic number of a graph, or even of just deciding whether a graph is colorable using a fixed number $c \geq 3$ of colors, is NP-complete [7], and thus it cannot be solved in polynomial time unless P = NP. Even the approximation version of the problem is hard: for every $\varepsilon > 0$, Zuckerman [16] proved that unless P = NP, there exists no polynomial-time algorithm approximating the chromatic number of an n-vertex graph within multiplicative factor $n^{1-\varepsilon}$.

There are more restricted settings in which the graph coloring problem becomes more tractable. For example, the well-known Four Color Theorem implies that deciding c-colorability of a planar graph is trivial for any $c \geq 4$; still, 3-colorability of planar graphs is NP-complete [7]. From the approximation perspective, this implies that chromatic number of planar graphs can be approximated in polynomial time up to multiplicative factor of 4/3 (but not better), and additively up to 1.

Let Σ be a fixed surface, and consider a graph G embedded in Σ. If G is large enough, Euler's formula implies that its average degree is less than 7, and thus G contains a vertex v of degree at most 6. Removing v and repeating this observation, we conclude that the vertex set of G can be partitioned in parts A and B such that A has bounded size (depending only on Σ) and $G[B]$ is 6-degenerate. We can now by brute force find an optimal coloring of $G[A]$ and color $G[B]$ greedily using at most 7 additional colors, thus obtaining a proper coloring of G using at most $\chi(G[A]) + 7 \leq \chi(G) + 7$ colors. That is, for any fixed surface Σ, there exists a linear-time algorithm to approximate chromatic number of graphs embedded in Σ with additive error at most 7, independent of the surface (this additive error can be improved to 2 using the fact that c-colorability of embedded graphs can be decided in polynomial-time for $c \geq 5$ based on a deep result of Thomassen [14]).

If a graph can be drawn in a given surface, all its minors can be drawn there as well. Hence, it is natural to also consider the coloring problem in the more general setting of proper minor-closed classes. Motivated by the simple algorithm for embedded graphs from the previous paragraph (and the minor structure theorem [12], which relates proper minor-closed classes to embedded graphs), Robin Thomas [13] conjectured that such an additive approximation algorithm exists for graphs from any proper minor-closed class.

▶ **Conjecture 1.** *For some fixed constant $\alpha \geq 0$, the following holds: for every proper minor-closed class $\mathcal{G}$, there exists a polynomial-time algorithm taking as an input a graph $G \in \mathcal{G}$ and returning an integer c such that $\chi(G) \leq c \leq \chi(G) + \alpha$.*

The fact that we do not allow α depend on the class $\mathcal{G}$ is important: any K_k-minor-free graph is $O(k\sqrt{\log k})$-colorable [10], and thus its chromatic number can be trivially approximated with additive error $O(k\sqrt{\log k})$.

Since it is easy to decide whether $\chi(G) < 3$, Conjecture 1 would imply that chromatic number in proper minor-closed classes can be approximated up to a fixed multiplicative factor (at most $1 + \alpha/3$). And indeed, this weaker statement holds: As shown by DeVos et al. [4] and algorithmically by Demaine et al. [2], for every proper minor-closed class $\mathcal{G}$, there exists a constant $\gamma_{\mathcal{G}}$ such that the vertex set of any graph $G \in \mathcal{G}$ can be partitioned in polynomial time into two parts A and B with both $G[A]$ and $G[B]$ having tree-width at most $\gamma_{\mathcal{G}}$. Consequently, $\chi(G[A])$ and $\chi(G[B])$ can be determined exactly in linear time [1], and we can color $G[A]$ and $G[B]$ using disjoint sets of colors, obtaining a coloring of G using at most $\chi(G[A]) + \chi(G[B]) \leq 2\chi(G)$ colors.

In the light of this evidence, Conjecture 1 seems quite plausible. Kawarabayashi et al. [9] conjectured that it actually holds even in a stronger form, in the list coloring setting. As our main result, we show that Conjecture 1 is actually false, even if we allow further multiplicative error by a factor smaller than 4/3. A graph F is *t-apex* if there exists a set X of at most t vertices of F such that $F - X$ is planar.

▶ **Theorem 2.** *Let k_0 be a positive integer, let F be a $(4k_0 - 3)$-connected graph that is not $(4k_0 - 4)$-apex, and let $1 \leq \beta \leq 4/3$ be a real number. Unless $P = NP$, there is no polynomial-time algorithm taking as an input an F-minor-free graph G and returning an integer c such that $\chi(G) \leq c < \beta\chi(G) + (4 - 3\beta)k_0$.*

In particular, in the special case of $\beta = 1$ and F being a clique, we obtain the following.

▶ **Corollary 3.** *Let k_0 be a positive integer. Unless $P = NP$, there is no polynomial-time algorithm taking as an input a K_{4k_0+1}-minor-free graph G and returning an integer c such that $\chi(G) \leq c \leq \chi(G) + k_0 - 1$.*

On the positive side, Kawarabayashi et al. [9] showed it is possible to approximate the chromatic number of K_k-minor free graphs in polynomial time additively up to $k-2$. We leave open the question whether a better additive approximation (of course above the bound $\approx k/4$ given by Corollary 3) is possible. Another positive result was given by Demaine et al. [3], who proved that if H is a 1-apex graph, then the chromatic number of H-minor-free graphs can be approximated additively up to 2. Let us also remark that if H is 0-apex (i.e., planar), then H-minor-free graphs have bounded tree-width [11], and thus their chromatic number can be determined exactly in linear time [1].

The *apex number* of a graph F is the minimum t such that F is t-apex. Theorem 2 shows that the additive error of any approximation algorithm for chromatic number of F-minor-free graphs must depend on the apex number of F. On the positive side, we show that such algorithm exists, generalizing the results from the previous paragraph.

▶ **Theorem 4.** *Let t be a positive integer and let H be a t-apex graph. There exists a polynomial-time algorithm taking as an input an H-minor-free graph G and returning an integer c such that $\chi(G) \leq c \leq \chi(G) + t + 3$.*

The construction we use to establish Theorem 2 results in graphs with large clique number (on the order of k_0). On the other hand, forbidding triangles makes the coloring problem for embedded graphs more tractable—all triangle-free planar graphs are 3-colorable [8] and there exists a linear-time algorithm to decide 3-colorability of a triangle-free graph embedded in any fixed surface [6]. It is natural to ask whether Conjecture 1 could not hold for triangle-free graphs, and this question is still open. On the negative side, we show that forbidding cliques of size 4 is not sufficient.

▶ **Theorem 5.** *Let β and d be real numbers such that $1 \leq \beta < 4/3$ and $d \geq 0$. Let $m = \lceil d/(4-3\beta) \rceil$. There exists a positive integer $k_0 = O\big(m^4 \log^2 m\big)$ such that the following holds. Let F be a $(4k_0-1)$-connected graph with at least $4k_0+8$ vertices that is not $(4k_0-4)$-apex. Unless $P = NP$, there is no polynomial-time algorithm taking as an input an F-minor-free graph G with $\omega(G) \leq 3$ and returning an integer c such that $\chi(G) \leq c < \beta\chi(G) + d$.*

In particular, in the special case of $\beta = 1$ and F being a complete graph, we get the following.

▶ **Corollary 6.** *For every positive integer k_0, there exists an integer $d = \Omega(k_0^{1/4}/\log^{1/2} k_0)$ as follows. Unless $P = NP$, there is no polynomial-time algorithm taking as an input a K_{4k_0+8}-minor-free graph G with $\omega(G) \leq 3$ and returning an integer c such that $\chi(G) \leq c \leq \chi(G) + d$.*

On the positive side, we offer the following small improvement to the additive error of Theorem 4.

▶ **Theorem 7.** *Let t be a positive integer and let H be a t-apex graph. There exists a polynomial-time algorithm taking as an input an H-minor-free graph G with no triangles and returning an integer c such that $\chi(G) \leq c \leq \chi(G) + \lceil (13t+172)/14 \rceil$.*

What about graphs of larger girth? It turns out that Conjecture 1 holds for graphs of girth at least 5, with $\alpha = 6$. Somewhat surprisingly, it is not even necessary to forbid triangles to obtain this result, just forbidden 4-cycles are sufficient. Indeed, we can show the following stronger result.

▶ **Theorem 8.** *Let $a \leq b$ be positive integers and let $\mathcal{G}$ be a proper minor-closed class of graphs. There exists a polynomial-time algorithm taking as an input a graph $G \in \mathcal{G}$ not containing $K_{a,b}$ as a subgraph and returning an integer c such that $\chi(G) \leq c \leq \chi(G) + a + 4$.*

Let us remark that the multiplicative 2-approximation algorithm of Demaine et al. [2] can be combined with the algorithms of Theorems 4, 7, and 8 by returning the minimum of their results. E.g., if H is a t-apex graph, then there is a polynomial-time algorithm coloring an H-minor-free graph G using at most $\min(2\chi(G), \chi(G)+t+3) \leq \beta\chi(G)+(2-\beta)(t+3)$ colors, for any β such that $1 \leq \beta \leq 2$; the combined multiplicative-additive non-approximability bounds of Theorems 2 and 5 are also of interest in this context.

The rest of the paper is organized as follows. In Section 2, we present a graph construction which we exploit to obtain the non-approximability results in Section 3. The approximation algorithms are presented in Section 4.

2 Tree-like product of graphs

Let G and H be graphs, and let $|V(G)| = n$ and $V(H) = \{u_1, \ldots, u_k\}$. Let $T_{n,k}$ denote the rooted tree of depth $k+1$ such that each vertex at depth at most k has precisely n children (the *depth* of the tree is the number of vertices of a longest path starting with its root, and the depth of a vertex x is the number of vertices of the path from the root to x; i.e., the root has depth 1). For each non-leaf vertex $x \in V(T_{n,k})$, let G_x be a distinct copy of the graph G and let θ_x be a bijection from $V(G_x)$ to the children of x in $T_{n,k}$. If $v \in V(G_x)$, y is a non-leaf vertex of the subtree of $T_{n,k}$ rooted in $\theta_x(v)$, and $z \in V(G_y)$, then we say that v is a *progenitor* of z. The *level* of v is defined to be the depth of x in $T_{n,k}$. Note that a vertex at level j has exactly one progenitor at level i for all positive $i < j$. The graph $T(G,H)$ is obtained from the disjoint union of the graphs G_x for non-leaf vertices $x \in V(T_{n,k})$ by, for each edge $u_iu_j \in E(H)$ with $i < j$, adding all edges from vertices of $T(G,H)$ at level j to their progenitors at level i. Note that the graph $T(G,H)$ depends on the ordering of the vertices of H, which we consider to be fixed arbitrarily.

Let Q_1 and Q_2 be graphs, containing cliques K_1 and K_2 of the same size k. A graph Q is a *clique-sum* of graphs Q_1 and Q_2 on cliques K_1 and K_2 if Q is obtained from Q_1 and Q_2 by identifying the two cliques and possibly removing some edges of the resulting clique. We use the following well-known observation: If F is a $(k+1)$-connected graph and F is a minor of Q, then F is also a minor of Q_1 or Q_2.

▶ **Lemma 9.** *Let G and H be graphs with $|V(G)| = n \geq 2$ and $V(H) = \{u_1, \ldots, u_k\}$. Let $q \leq k$ be the maximum integer such that $\{u_{k-q+1}, \ldots, u_k\}$ is an independent set in H. The graph $T(G,H)$ has $O(n^k)$ vertices and $\omega(T(G,H)) = \omega(G) + \omega(H) - 1$. Furthermore, if F is a minor of $T(G,H)$ and F is $(k-q+1)$-connected, then there exists a set $X \subseteq V(F)$ of size at most $k-q$ such that $F - X$ is a minor of G.*

Proof. The tree $T_{n,k}$ has $1 + n + n^2 + \ldots + n^{k-1} \leq 2n^{k-1}$ non-leaf vertices, and thus $|V(T(G,H))| \leq 2n^k$.

Consider a clique K in $T(G,H)$, and let v be a vertex of K of largest level. Let x be the vertex of $T_{n,k}$ such that $v \in V(G_x)$. Note that all vertices of $K \setminus V(G_x)$ are progenitors of v, and the vertices of H corresponding to their levels are pairwise adjacent. Consequently, $|K \setminus V(G_x)| \leq \omega(H) - 1$ and $|K \cap V(G_x)| \leq \omega(G)$. Therefore, each clique in $T(G,H)$ has size at most $\omega(G) + \omega(H) - 1$. A converse argument shows that cliques K_G in G and K_H in H give rise to a clique in $T(G,H)$ of size $|K_G| + |K_H| - 1$, implying that $\omega(T(G,H)) = \omega(G) + \omega(H) - 1$.

For $i = 0, \ldots, k-q$, let G_i denote the graph obtained from G by adding i universal vertices. Observe that $T(G,H)$ is obtained from copies of $G_0, \ldots, G_{k-q}$ by clique-sums on cliques of size at most $k-q$ (corresponding to the progenitors whose level is most $k-q$). Hence, each $(k-q+1)$-connected minor F of $T(G,H)$ is a minor of one of $G_0, \ldots, G_{k-q}$, and thus a minor of G can be obtained from F by removing at most $k-q$ vertices. ◀

For an integer $p \geq 1$, the *p-blowup* of a graph H_0 is the graph H obtained from H_0 by replacing every vertex u by an independent set S_u of p vertices, and by adding all edges zz' such that $z \in S_u$ and $z' \in S_{u'}$ for some $uu' \in E(H_0)$. For the purposes of constructing the graph $T(G, H)$, we order the vertices of H so that for each $u \in V(H_0)$, the vertices of S_u are consecutive in the ordering. Note that $\chi(H) \leq \chi(H_0)$, since we can assign all the vertices of S_u the color of u.

The *strong p-blowup* of H_0 is obtained from the p-blowup by making the sets S_u into cliques for each $u \in V(H_0)$. For integers $a \geq b \geq 1$, an $(a : b)$-*coloring* of H_0 is a function φ that to each vertex of H_0 assigns a subset of $\{1, \ldots, a\}$ of size b such that $\varphi(u) \cap \varphi(v) = \emptyset$ for each edge uv of H_0. The *fractional chromatic number* $\chi_f(H_0)$ is the infimum of $\{a/b : H_0 \text{ has an } (a : b)\text{-coloring}\}$. Note that if H is the strong p-blowup of a graph H_0, then a c-coloring of H gives a $(c : p)$-coloring of H_0. Consequently, we have the following.

▶ **Observation 10.** *If H is the strong p-blowup of a graph H_0, then $\chi(H) \geq p\chi_f(H_0)$.*

We now state a key result concerning the chromatic number of the graph $T(G, H)$.

▶ **Lemma 11.** *Let $p, c \geq 1$ be integers and let G be a graph. Let H_0 be a graph such that $\chi(H_0) = \chi_f(H_0) = c$, and let H be the p-blowup of H_0. Then*

$$\chi(T(G, H)) \leq c\chi(G)$$

and if $\chi(G) \geq p$, then

$$\chi(T(G, H)) \geq cp.$$

Proof. Let $V(H) = \{u_1, \ldots, u_k\}$, where $k = p|V(H_0)|$. Note that $\chi(H) \leq \chi(H_0) = c$. Let φ_H be a proper coloring of H using c colors. Let $C_1, \ldots, C_c$ be pairwise disjoint sets of $\chi(G)$ colors. For each non-leaf vertex x of $T_{n,k}$ of depth i, color G_x properly using the colors in $C_{\varphi_H(u_i)}$. Observe that this gives a proper coloring of $T(G, H)$ using at most $c\chi(G)$ colors, and thus $\chi(T(G, H)) \leq c\chi(G)$.

Suppose now that $\chi(G) \geq p$ and consider a proper coloring φ of $T(G, H)$. We construct a path $P = x_1 x_2 \ldots x_{k+1}$ in the tree $T_{n,k}$ from its root x_1 to one of the leaves and a coloring ψ of H, as follows. Suppose that we already selected $x_1, \ldots, x_i$ for some $i \leq k$. Let Z_i denote the set of progenitors of level at least $i - p + 1$ of the vertices of G_{x_i}. Since $|Z_i| \leq p - 1$ and φ uses at least $\chi(G) \geq p$ distinct colors on G_{x_i}, there exists $v \in V(G_{x_i})$ such that $\varphi(v)$ is different from the colors of all vertices of Z_i. We define $x_{i+1} = \theta_{x_i}(v)$ be the child of x_i in $T_{n,k}$ corresponding to v, and set $\psi(u_i) = \varphi(v)$.

Note that ψ is a proper coloring of H such that for each $u \in V(H_0)$, ψ assigns vertices in S_u pairwise distinct colors. Consequently, ψ is a proper coloring of the strong p-blowup of H_0, and thus ψ (and φ) uses at least $p\chi_f(H_0) = cp$ distinct colors by Observation 10. We conclude that $\chi(T(G, H)) \geq cp$. ◀

For positive integers p and k, let $K_{k\times p}$ denote the p-blowup of K_k, i.e., the complete k-partite graph with parts of size p. Let us summarize the results of this section in the special case of the graph $T(G_0, K_{k\times 4})$ with G_0 planar.

▶ **Corollary 12.** *Let G_0 be a planar graph with n vertices and let k_0 be a positive integer. Let $G = T(G_0, K_{k_0\times 4})$. The graph G has $O(n^{4k_0})$ vertices. If G_0 is 3-colorable, then $\chi(G) \leq 3k_0$, and otherwise $\chi(G) \geq 4k_0$. Furthermore, every $(4k_0 - 3)$-connected graph appearing as a minor in G is $(4k_0 - 4)$-apex.*

Proof. Note that $\chi(K_{k_0}) = \chi_f(K_{k_0}) = k_0$, $|V(K_{k_0\times 4})| = 4k_0$ and the last 4 vertices of $K_{k_0\times 4}$ form an independent set. The claims follow from Lemma 9 (with $H = K_{k_0\times 4}$, $k = 4k_0$ and $q = 4$, using the fact that every minor of a planar graph is planar) and Lemma 11 (with $H_0 = K_{k_0}$, $p = 4$ and $c = k_0$). ◀

3 Non-approximability

The main non-approximability result is a simple consequence of Corollary 12 and NP-hardness of testing 3-colorability of planar graphs.

Proof of Theorem 2. Suppose for a contradiction that there exists such a polynomial-time algorithm $\mathcal{A}$, taking as an input an F-minor-free graph G and returning an integer c such that $\chi(G) \leq c < \beta\chi(G) + (4 - 3\beta)k_0$.

Let G_0 be a planar graph, and let $G = T(G_0, K_{k_0\times 4})$. By Corollary 12, the size of G is polynomial in the size of G_0 and G is F-minor-free. Furthermore, if G_0 is 3-colorable, then $\chi(G) \leq 3k_0$, and otherwise $\chi(G) \geq 4k_0$. Hence, if G_0 is 3-colorable, then the value returned by the algorithm $\mathcal{A}$ applied to G is less than $\beta\chi(G) + (4 - 3\beta)k_0 \leq 4k_0$, and if G_0 is not 3-colorable, then the value returned is at least $\chi(G) \geq 4k_0$. This gives a polynomial-time algorithm to decide whether G_0 is 3-colorable.

However, it is NP-hard to decide whether a planar graph is 3-colorable [7], which gives a contradiction unless P = NP. ◀

Note that the graphs $T(G_0, K_{k_0\times 4})$ used in the proof of Theorem 2 have large cliques (of size greater than k_0). This turns out not to be essential—we can prove somewhat weaker non-approximability result even for graphs with clique number 3. To do so, we need to apply the construction with both G and H_0 being triangle-free. A minor issue is that testing 3-colorability of triangle-free planar graphs is trivial by Grötzsch' theorem [8]. However, this can be worked around easily.

▶ **Lemma 13.** *Let $\mathcal{G}$ denote the class of graphs such that all their 3-connected minors with at least 12 vertices are planar. The problem of deciding whether a triangle-free graph $G \in \mathcal{G}$ is 3-colorable is NP-hard.*

Proof. Let R_0 be the Grötzsch graph (R_0 is a triangle-free graph with 11 vertices and chromatic number 4, and all its proper subgraphs are 3-colorable). Let R be a graph obtained from R_0 by removing any edge uv. Note that R is 3-colorable and the vertices u and v have the same color in every 3-coloring.

Let G_1 be a planar graph. Let G_2 be obtained from G_1 by replacing each edge xy of G_1 by a copy of R whose vertex u is identified with x and an edge is added between v and y (i.e., G_2 is obtained from G_1 by a sequence of Hajós sums with copies of R_0). Clearly, G_2 is triangle-free, it is 3-colorable if and only if G_1 is 3-colorable, and $|V(G_2)| = |V(G_1)| + 10|E(G_1)|$. Furthermore, G_2 is obtained from a planar graph by clique-sums with R_0 on cliques of size two, and thus every 3-connected minor of G_2 is either planar or a minor of R_0 (and thus has at most 11 vertices). Hence, G_2 belongs to $\mathcal{G}$.

Since testing 3-colorability of planar graphs is NP-hard, it follows that testing 3-colorability of triangle-free graphs from $\mathcal{G}$ is NP-hard. ◀

We also need a graph H_0 which is triangle-free and its fractional chromatic number is large and equal to its ordinary chromatic number. Such a graph can be obtained by a standard probabilistic argument (omitted).

▶ **Lemma 14.** *For every positive integer m, there exists a triangle-free graph H_m with $O(m^4 \log^2 m)$ vertices such that $\chi(H_m) = \chi_f(H_m) = m$.*

Theorem 5 now follows in the same way as Theorem 2, using the graphs from Lemma 14 instead of cliques.

Proof of Theorem 5. Suppose for a contradiction that there exists such a polynomial-time algorithm $\mathcal{A}$, taking as an input an F-minor-free graph G with $\omega(G) \leq 3$ and returning an integer c such that $\chi(G) \leq c < \beta\chi(G) + d$. Recall that $m = \lceil d/(4-3\beta) \rceil$. Let H_m be the graph from Lemma 14. Let $k_0 = |V(H_m)|$ and let H be the 4-blowup of H_m. Let $\mathcal{G}$ be the class of graphs such that all their 3-connected minors with at least 12 vertices are planar.

Consider a triangle-free graph $G_0 \in \mathcal{G}$, and let $G = T(G_0, H)$. By Lemma 9, the size of G is polynomial in the size of G_0. Consider any $(4k_0 - 1)$-connected minor F' of G. By Lemma 9, there exists a set X of size at most $4k_0 - 4$ such that $F' - X$ is a minor of G_0. Since $F' - X$ is 3-connected and $G_0 \in \mathcal{G}$, we conclude that either $|V(F')| \leq |X| + 11 \leq 4k_0 + 7$ or $F' - X$ is planar. Consequently, $F' \neq F$, and thus G does not contain F as a minor. Furthermore, $\omega(G) \leq \omega(G_0) + \omega(H) - 1 \leq 3$.

Recall that $\chi(H_m) = \chi_f(H_m) = m$. By Lemma 11, if G_0 is 3-colorable, then $\chi(G) \leq 3m$, and otherwise $\chi(G) \geq 4m$. Hence, if G_0 is 3-colorable, then the value returned by the algorithm $\mathcal{A}$ applied to G is less than $\beta\chi(G) + d \leq 3\beta m + d \leq 4m$, and if G_0 is not 3-colorable, then the value returned is at least $\chi(G) \geq 4m$. This gives a polynomial-time algorithm to decide whether G_0 is 3-colorable, in contradiction to Lemma 13 unless P = NP. ◀

4 Approximation algorithms

Let us now turn our attention to the additive approximation algorithms. The algorithms we present use ideas similar to the ones of the 2-approximation algorithm of Demaine et al. [2] and of the additive approximation algorithms of Kawarabayashi et al. [9] and Demaine et al. [3]. We find a partition of the vertex set of the input graph G into parts L and C such that $G[L]$ has bounded tree-width (and thus its chromatic number can be determined exactly) and $G[C]$ has bounded chromatic number, and color the parts using disjoint sets of colors. The existence of such a decomposition is proved using the minor structure theorem [12], in the variant limiting the way apex vertices attach to the surface part of the decomposition. The proof of this stronger version can be found in [5]. Let us now introduce definitions necessary to state this variant of the structure theorem.

A *tree decomposition* of a graph G is a pair (T, β), where T is a tree and β is a function assigning to each vertex of T a subset of $V(G)$, such that for each $uv \in E(G)$ there exists $z \in V(T)$ with $\{u, v\} \subseteq \beta(z)$, and such that for each $v \in V(G)$, the set $\{z \in V(T) : v \in \beta(z)\}$ induces a non-empty connected subtree of T. The *width* of the tree decomposition is $\max\{|\beta(z)| : z \in V(T)\} - 1$, and the *tree-width* of a graph is the minimum of the widths of its tree decompositions.

The decomposition is *rooted* if T is rooted. For a rooted tree decomposition (T, β) and a vertex z of T distinct from the root, if w is the parent of z in T, we write $\beta \uparrow z := \beta(z) \cap \beta(w)$ and $\beta \downarrow z := \beta(z) \setminus \beta(w)$. If z is the root of T, then $\beta \uparrow z := \emptyset$ and $\beta \downarrow z := \beta(z)$. The *torso expansion* of a graph G with respect to its rooted tree decomposition (T, β) is the graph obtained from G by adding a clique on $\beta \uparrow z$ for all $z \in V(T)$.

A *path decomposition* is a tree decomposition (T, β) where T is a path. A *vortex with boundary sequence $v_1, \ldots, v_s$ and depth d* is a graph with a path decomposition $(p_1 p_2 \ldots p_s, \beta)$ such that $|\beta(p_i)| \leq d + 1$ and $v_i \in \beta(p_i)$ for $i = 1, \ldots, s$. An embedding of a graph in a surface is *2-cell* if each face of the embedding is homeomorphic to an open disk.

▶ **Theorem 15** (Dvořák and Thomas [5]). *For every non-negative integer t and a t-apex graph H, there exists a constant a_H such that the following holds. For every H-minor-free graph G, there exists a rooted tree decomposition (T, β) of G with the following properties. Let G' denote the torso expansion of G with respect to (T, β). For every $v \in V(T)$, there exists a set $A_v \subseteq \beta(v)$ of size at most a_H with $\beta \uparrow v \subseteq A_v$, a set $A'_v \subseteq A_v$ of size at most $t-1$, and subgraphs G_v, $G_{v,1}$, ..., $G_{v,m}$ of $G'[\beta(v) \setminus A_v]$ for some $m \leq a_H$ such that*

- **(a)** *$G'[\beta(v) \setminus A_v] = G_v \cup G_{v,1} \cup \ldots \cup G_{v,m}$, and for $1 \leq i < j \leq m$, the graphs $G_{v,i}$ and $G_{v,j}$ are vertex-disjoint and G' contains no edges between $V(G_{v,i})$ and $V(G_{v,j})$,*
- **(b)** *the graph G_v is 2-cell embedded in a surface Σ_v in which H cannot be drawn,*
- **(c)** *for $1 \leq i \leq m$, $G_{v,i}$ is a vortex of depth a_H intersecting G_v only in its boundary sequence, and this sequence appears in order in the boundary of a face $f_{v,i}$ of G_v, and $f_{v,i} \neq f_{v,j}$ for $1 \leq i < j \leq m$,*
- **(d)** *vertices of G_v have no neighbors in $A_v \setminus A'_v$, and*
- **(e)** *if w is a child of v in T and $\beta(w) \cap V(G_v) \neq \emptyset$, then $\beta \uparrow w \subseteq V(G_v) \cup A'_v$.*

Furthermore, the tree decomposition and the sets and subgraphs as described can be found in polynomial time.

Informally, the graph G is a clique-sum of the graphs $G'[\beta(v)]$ for $v \in V(T)$, and $\beta(v)$ contains a bounded-size set A_v of apex vertices such that $G'[\beta(v)] - A_v$ can be embedded in Σ_v up to a bounded number of vortices of bounded depth. Furthermore, at most $t-1$ of the apex vertices (forming the set A'_v) can have neighbors in the part G_v of $G'[\beta(v)] - A_v$ drawn in Σ_v, or in the other bags of the decomposition that intersect G_v. Note that it is also possible that Σ_v is the null surface, and consequently $A_v = \beta(v)$.

We need the following observation on graphs embedded up to vortices.

▶ **Lemma 16.** *Let Σ be a surface of Euler genus g and let a be a non-negative integer. Let G be a graph and let G_0, G_1, ..., G_m be its subgraphs such that $G = G_0 \cup G_1 \cup \ldots \cup G_m$, the subgraphs G_1, ..., G_m are pairwise vertex-disjoint and G contains no edges between them, G_0 is 2-cell embedded in Σ, and there exist pairwise distinct faces f_1, ..., f_m of this embedding such that for $1 \leq i \leq m$, G_i intersects G_0 only in a set of vertices contained in the boundary of f_i. If the graphs G_1, ..., G_m have tree-width at most a, then there exists a subset L_0 of vertices of G_0 such that $G_0 - L_0$ is planar and the graph $G_0[L_0] \cup G_1 \cup \ldots \cup G_m$ has tree-width at most $26g + 9m + a$.*

Proof. If Σ is the sphere, then we can set $L_0 = \emptyset$; hence, we can assume that $g \geq 1$. Let G'_0 be the graph obtained from G_0 by, for $1 \leq i \leq m$, adding a new vertex r_i drawn inside f_i and joined by edges to all vertices of $V(G_0) \cap V(G_i)$. Note that G'_0 has a 2-cell embedding in Σ extending the embedding of G. Let F be a subgraph of G'_0 such that the embedding of F in Σ inherited from the embedding of G'_0 is 2-cell and $|V(F)| + |E(F)|$ is minimum. Then F has only one face, since otherwise it is possible to remove an edge separating distinct faces of F, and F has minimum degree at least two, since otherwise we can remove a vertex of degree at most 1 from F. By generalized Euler's formula, we have $|E(F)| = |V(F)| + g - 1$, and thus F contains at most $2(g-1)$ vertices of degree greater than two. By considering the graph obtained from F by suppressing vertices of degree two, we see that F is either a cycle (if $g = 1$) or a subdivision of a graph with at most $3(g-1)$ edges.

Let M_0 be the set of vertices of F of degree at least three and their neighbors. We claim that each vertex of $V(F) \setminus M_0$ is adjacent in G'_0 to only two vertices of $V(F)$. Indeed, suppose that a vertex $x \in V(F) \setminus M_0$ has at least three neighbors in G'_0 belonging to $V(F)$. Let w and y be the neighbors of x in F, and let z be a vertex distinct from w and y adjacent to x in G'_0. The graph $F + xz$ has two faces, and by symmetry, we can assume that the edge xy separates them. Since $x \notin M_0$, the vertex y has degree two in F, and thus the embedding of $F + xz - y$ is 2-cell, contradicting the minimality of F.

Let M_1 be the set of vertices of F at distance at most 4 from a vertex of degree greater than two. Note that $|M_1| \leq 26g$. For $1 \leq i \leq m$, let N_i denote the set of vertices of $F - M_1$ that are in G_0' adjacent to a vertex of $V(G_i) \cap V(G_0) \setminus V(F)$. We claim that $|N_i| \leq 9$. Indeed, suppose for a contradiction that $|N_i| \geq 10$ and consider a path $w_4w_3w_2w_1xy_1y_2y_3y_4$ in F such that x belongs to N_i (vertices x, w_1, …, w_4, y_1, …, y_4 have degree two in F, since $x \notin M_1$). If $r_i \in V(F)$, then let Q be a path in G_0' of length two between x and r_i through a vertex of $V(G_i) \cap V(G_0) \setminus V(F)$; note that $r_i \notin \{w_1, w_2, y_1, y_2\}$, since r_i has at least 10 neighbors in $V(F)$ and belongs to M_0 by the previous paragraph and $x \notin M_1$. If $r_i \notin V(F)$, then there exists a vertex $z \in N_i \setminus \{x, w_1, \ldots, w_4, y_1, \ldots, y_4\}$; we let Q be a path of length at most four between x and z passing only through their neighbors in $V(G_i) \cap V(G_0) \setminus V(F)$ and possibly through r_i. By symmetry, we can assume that the edge xy_1 separates the two faces of $F + Q$, and the graph $F + Q - \{y_1, y_2\}$ if $r_i \in V(F)$ or $F + Q - \{y_1, y_2, y_3, y_4\}$ if $r_i \notin V(F)$ contradicts the minimality of F.

Let $M = (M_1 \cup \bigcup_{i=1}^{m} N_i) \cap V(G_0)$; we have $|M| \leq 26g + 9m$. Let $L_0 = V(F) \cap V(G_0)$. Clearly, $G_0 - L_0 \subseteq G_0' - V(F)$ is planar. Let G' be the graph obtained from $G_1 \cup \ldots \cup G_m$ by adding vertices of M as universal ones, adjacent to all other vertices of G'. The tree-width of G' is at most $a + |M| \leq 26g + 9m + a$. Note that each vertex of $L_0 \setminus V(G')$ has degree two in $G_0[L_0] \cup G_1 \cup \ldots \cup G_m$, and thus $G_0[L_0] \cup G_1 \cup \ldots \cup G_m$ is a subgraph of a subdivision of G'. We conclude that the tree-width of $G_0[L_0] \cup G_1 \cup \ldots \cup G_m$ is also at most $26g + 9m + a$. ◀

Note that the set L_0 can be found in polynomial time. For the clarity of presentation of the proof we selected F with $|V(F)| + |E(F)|$ minimum; however, it is sufficient to start with an arbitrary inclusionwise-minimal subgraph with exactly one 2-cell face (obtained by repeatedly removing edges that separate distinct faces and vertices of degree at most 1) and repeatedly perform the reductions described in the proof until each vertex of $V(F) \setminus M_0$ is adjacent in G_0' to only two vertices of $V(F)$ and until $|N_i| \leq 9$ for $1 \leq i \leq m$.

For positive integers t and a, we say that a rooted tree decomposition (T, β) of a graph G is (t, a)-*restricted* if for each vertex v of T, the subgraph of the torso expansion of G induced by $\beta \downarrow v$ is planar, $|\beta \uparrow v| \leq t - 1$, and each vertex of $\beta \downarrow v$ has at most $a - 1$ neighbors in G that belong to $\beta \uparrow v$. Using the decomposition from Theorem 15, we now partition the considered graph into a part of bounded tree-width and a (t, t)-restricted part.

▶ **Theorem 17.** *For every positive integer t and a t-apex graph H, there exists a constant c_H with the following property. The vertex set of any H-minor-free graph G can be partitioned in polynomial time into two parts L and C such that $G[L]$ has tree-width at most c_H and $G[C]$ has a (t, t)-restricted rooted tree decomposition. Additionally, for any such graph H and positive integers $a \leq b$, there exists a constant $c_{H,a,b}$ such that if G is H-minor-free and does not contain $K_{a,b}$ as a subgraph, then L and C can be chosen so that $G[L]$ has tree-width at most $c_{H,a,b}$ and $G[C]$ has a (t, a)-restricted rooted tree decomposition.*

Proof. Let a_H be the constant from Theorem 15 for H, and let g be the maximum Euler genus of a surface in which H cannot be embedded. Let $c_H = 26g + 11a_H$ and $c_{H,a,b} = c_H + \binom{t-1}{a}(b-1)$.

Since G is H-minor-free, we can in polynomial time find its rooted tree decomposition (T, β), its torso expansion G', and for each $v \in V(T)$, find A_v, A_v', G_v, $G_{v,1}$, …, $G_{v,m}$, and Σ_v as described in Theorem 15. Let L_v' be the set of vertices obtained by applying Lemma 16 to G_v, $G_{v,1}$, …, $G_{v,m}$; i.e., $G_v - L_v'$ is planar and the graph $G_v[L_v'] \cup G_{v,1} \cup \ldots \cup G_{v,m}$ has tree-width at most $26g + 10a_H$. When considering the case that G does not contain $K_{a,b}$ as a subgraph, let S_v be the set of vertices of G_v that have at least a neighbors in G belonging to A_v (and thus to A_v'); otherwise, let $S_v = \emptyset$. Since there are at most $\binom{t-1}{a}$ ways how to choose a set of a neighbors in A_v' and no b vertices can have the same set of a neighbors in A_v', we have $|S_v| \leq \binom{t-1}{a}(b-1)$. Let $L_v = (A_v \setminus \beta \uparrow v) \cup V(G_{v,1} \cup \ldots \cup G_{v,m}) \cup L_v' \cup S_v$.

We define $L = \bigcup_{v \in V(T)} L_v$. Note that $L \cap \beta(v) \subseteq L_v \cup (\beta \uparrow v) \subseteq L_v \cup A_v$. Consequently, $G'[L \cap \beta(v)]$ is obtained from $G_v[L'_v] \cup G_{v,1} \cup \ldots \cup G_{v,m}$ by adding S_v and some of the vertices of A_v, and consequently $G'[L \cap \beta(v)]$ has tree-width at most $c_{H,a,b}$ when considering the case that G does not contain $K_{a,b}$ as a subgraph and at most c_H otherwise. The graph $G[L]$ is a clique-sum of the graphs $G'[L \cap \beta(v)]$ for $v \in V(T)$, and thus the tree-width of $G[L]$ is also at most $c_{H,a,b}$ or c_H.

Let $C = V(G) \setminus L$, and consider the graph $G[C]$. For $v \in V(T)$, let $\beta'(v) = \beta(v) \cap C$. Then (T, β') is a rooted tree decomposition of $G[C]$ such that for every $v \in V(T)$, the graph $G'[\beta' \downarrow v] \subseteq G_v - L'_v$ is planar, all vertices of $\beta' \uparrow v$ adjacent in G to a vertex of $\beta' \downarrow v$ belong to A'_v (and thus there are at most $t-1$ such vertices), and when considering the case that G does not contain $K_{a,b}$ as a subgraph, each vertex of $\beta' \downarrow v$ has at most $a-1$ neighbors in G belonging to $\beta' \uparrow v$.

Note that $\beta' \uparrow v$ can contain vertices not belonging to A'_v, and thus $\beta' \uparrow v$ can have size larger than $t-1$, and the tree decomposition (T, β') is not necessarily (t,t)-restricted. However, by the condition (e) from the statement of Theorem 15, the vertices of $(\beta' \uparrow v) \setminus A'_v$ can only be contained in the bags of descendants of v which are disjoint from $V(G_v)$, and thus we can fix up this issue as follows.

If w is a child of v and $\beta'(w) \cap V(G_v) = \emptyset$, we say that the edge vw is *skippable*; note that in that case $\beta' \uparrow w \subseteq \beta' \uparrow v$. For each vertex w of T, let $f(w)$ be the nearest ancestor of w such that the first edge on the path from $f(w)$ to w in T is not skippable. Let T' be the rooted tree with vertex set $V(T)$ where the parent of each vertex w is $f(w)$. Observe that (T', β') is a tree decomposition of $G[C]$. Furthermore, denoting by z the child of $f(w)$ on the path from $f(w)$ to w in T, note that if a vertex $x \in \beta' \uparrow f(w)$ is contained in $\beta'(w)$, then $x \in \beta(z)$, and since the edge $f(w)z$ is not skippable, the condition (e) from the statement of Theorem 15 implies that $x \in A'_{f(w)}$.

Hence, letting $\beta''(v) = (\beta' \downarrow v) \cup (A'_v \cap C)$ for each vertex v of T', we conclude that (T', β'') is a rooted tree decomposition of $G[C]$ which is (t,t)-restricted, and when considering the case that G does not contain $K_{a,b}$ as a subgraph, the decomposition is (t,a)-restricted. ◀

Let us now consider the chromatic number of graphs with a (t,a)-restricted tree decomposition.

▶ **Lemma 18.** *Let a and t be positive integers. Let G be a graph with a (t,a)-restricted rooted tree decomposition (T, β). The chromatic number of G is at most $\min(t+3, a+4)$. Additionally, if G is triangle-free, then the chromatic number of G is at most $\lceil (13t+172)/14 \rceil$.*

Proof. We can color G using $t+3$ colors, starting from the root of the tree decomposition, as follows. Suppose that we are considering a vertex $v \in V(T)$ such that $\beta \uparrow v$ is already colored. Since $|\beta \uparrow v| \leq t-1$, this leaves at least 4 other colors to be used on $G[\beta \downarrow v]$. Hence, we can extend the coloring to $G[\beta \downarrow v]$ by the Four Color Theorem.

We can also color G using $a+4$ colors, starting from the root of the tree decomposition, as follows. For each vertex x of $\beta \downarrow v$, at most $a-1$ colors are used on its neighbors in $\beta \uparrow v$, leaving x with at least 5 available colors not appearing on its neighbors. Since $G[\beta \downarrow v]$ is planar, we can color it from these lists of size at least 5 using the result of Thomassen [15], again extending the coloring to $G[\beta \downarrow v]$.

Finally, suppose that G is triangle-free. Let G' be the torso expansion of G with respect to (T, β), and let $c = \lceil (13t+172)/14 \rceil$. We again color G starting from the root of the tree decomposition using at most c colors. Additionally, we choose the coloring so that the following invariant is satisfied: ($\star$) for each vertex w of T and for each independent set I in $G[\beta(w)]$ such that $I \cap \beta \downarrow w$ induces a clique in G', at most $c-6$ distinct colors are used on I.

Let v be a vertex of T. Suppose we have already colored $\beta \uparrow v$, and we want to extend the coloring to $\beta \downarrow v$. Note that the choice of this coloring may only affect the validity of the invariant $(\star)$ at v and at descendants of v in T. Consider any descendant w of T. Coloring $\beta \downarrow v$ can only assign color to vertices of $\beta \uparrow w$, and since G' is the torso expansion of G, the set $\beta \uparrow w \cap \beta \downarrow v$ induces a clique in G'. Consequently, the validity of $(\star)$ at v implies the validity at w (until more vertices of G are assigned colors), and thus when choosing the coloring of $\beta \downarrow v$, we only need to ensure that $(\star)$ holds at v.

The graph $G'[\beta \downarrow v]$ is planar, and thus it is 5-degenerate; i.e., there exists an ordering of its vertices such that each vertex is preceded by at most 5 of its neighbors. Let us color the vertices of $\beta \downarrow v$ according to this ordering, always preserving the validity of $(\star)$ at v. Suppose that we are choosing a color for a vertex $x \in V(\beta \downarrow v)$. Let P_x consist of the neighbors of x in G' belonging to $\beta \downarrow v$ that precede it in the ordering; we have $|P_x| \leq 5$. Note that all cliques in $G'[\beta \downarrow v]$ containing x and with all other vertices already colored are subsets of $P_x \cup \{x\}$. Let $Q_x = P_x \cup \beta \uparrow v$; we have $|Q_x| \leq t + 4$.

Let N_x consist of vertices of Q_x that are adjacent to x in G. We say that a color a is forbidden at x if there exists an independent set $A_a \subseteq Q_x \setminus N_x$ of G such that $A_a \cap P_x$ is a clique in G' and $c - 6$ colors distinct from a appear on A_a. Observe that assigning x a color which neither appears on N_x nor is forbidden results in a proper coloring that preserves the invariant $(\star)$ at v.

Suppose first that no color is forbidden at x. Since G is triangle-free, $N_x \setminus P_x$ is an independent set in $G[\beta \uparrow v]$, and by $(\star)$, at most $c - 6$ colors appear on $N_x \setminus P_x$. Since $|P_x| \leq 5$, it follows that some color does not appear on N_x, as required.

Hence, we can assume that some color is forbidden at x, and thus there exists an independent set $Z_1 \subseteq Q_x \setminus N_x$ of size at least $c - 6$ such that vertices of Z_1 are assigned pairwise distinct colors. Since $|Q_x| \leq t + 4$, at most $t + 4 - (c - 6) = t + 10 - c$ of these colors appear at least twice on Q_x, and thus there exists a set $Z_2 \subseteq Z_1$ of size at least $c - 6 - (t + 10 - c) = 2c - t - 16$ such that the color of each vertex of Z_2 appears exactly once on Q_x (and thus does not appear on N_x). Let $Z = Z_2 \setminus P_x$; we have $|Z| \geq 2c - t - 21$. We claim that not all colors appearing on Z are forbidden; since such colors do not appear on N_x, we can use them to color x.

For contradiction, assume that colors of all vertices of Z are forbidden at x. Let $Z = \{z_1, \ldots, z_m\}$ for some $m \geq 2c - t - 21$, and for $a = 1, \ldots, m$, let a be the color of z_a. Since a is forbidden at x, there exists an independent set $A_a \subseteq Q_x \setminus N_x$ such that $A_a \cap P_x$ is a clique in G' and $c - 6$ colors distinct from a appear on A_a. Note that $A_a \cup \{z_a\}$ is not an independent set, as otherwise this set contradicts the invariant $(\star)$ at v. Hence, we can choose a neighbor $f(a)$ of z_a in A_a. Since Z is an independent set, we have $f(a) \notin Z$. Furthermore, we claim that the preimage in f of each vertex has size at most 6: if say $f(z_1) = \ldots = f(z_7) = y$, then for $i = 1, \ldots, 7$, the vertex z_i would have a neighbor y in the independent set A_1, and thus $z_1, \ldots, z_7 \notin A_1$; however, the only appearance of colors $1, \ldots, 7$ in Q_x is on the vertices $z_1, \ldots, z_7$, and thus at most $c - 7$ colors would appear on A_1. We conclude that $|f(Z)| \geq |Z|/6$, and thus $t + 4 \geq |Q_x| \geq |Z| + |f(Z)| \geq \frac{7}{6}|Z| \geq \frac{7}{6}(2c - t - 21) \geq (6t + 25)/6$. This is a contradiction. ◀

Combining Lemma 18 with Theorem 17 (coloring $G[L]$ using at most $\chi(G)$ colors in linear time [1], using the fact that $G[L]$ has bounded tree-width, and coloring $G[C]$ using a disjoint set of colors), we obtain Theorems 4, 7, and 8.

Abstract

Given a set of obstacles and two points in the plane, is there a path between the two points that does not cross more than k different obstacles? This is a fundamental problem that has undergone a tremendous amount of work by researchers in various areas, including computational geometry, graph theory, wireless computing, and motion planning. It is known to be NP-hard, even when the obstacles are very simple geometric shapes (*e.g.*, unit-length line segments). The problem can be formulated and generalized into the following graph problem: Given a planar graph G whose vertices are colored by color sets, two designated vertices $s, t \in V(G)$, and $k \in \mathbb{N}$, is there an s-t path in G that uses at most k colors? If each obstacle is connected, the resulting graph satisfies the color-connectivity property, namely that each color induces a connected subgraph.

We study the complexity and design algorithms for the above graph problem with an eye on its geometric applications. We prove a set of hardness results, among which a result showing that the color-connectivity property is crucial for any hope for fixed-parameter tractable (FPT) algorithms, as without it, the problem is W[SAT]-hard parameterized by k. Previous results only implied that the problem is W[2]-hard. A corollary of this result is that, unless W[2] = FPT, the problem cannot be approximated in FPT time to within a factor that is a function of k. By describing a generic plane embedding of the graph instances, we show that our hardness results translate to the geometric instances of the problem.

We then focus on graphs satisfying the color-connectivity property. By exploiting the planarity of the graph and the connectivity of the colors, we develop topological results that allow us to prove that, for any vertex v, there exists a set of paths whose cardinality is upper bounded by a function of k, that "represents" the valid s-t paths containing subsets of colors from v. We employ these structural results to design an FPT algorithm for the problem parameterized by both k and the treewidth of the graph, and extend this result further to obtain an FPT algorithm for the parameterization by both k and the length of the path. The latter result generalizes and explains previous FPT results for various obstacle shapes, such as unit disks and fat regions.

1 Introduction

We consider the following problem: Given a set of obstacles and two designated points in the plane, is there a path between the two points that does not cross more than k obstacles? Equivalently, can we remove k obstacles so that there is an obstacle-free path between the two designated points? We refer to this problem as Obstacle Removal, and to its restriction to instances in which each obstacle is connected as Connected Obstacle Removal.

By considering the auxiliary plane graph that is the dual of the plane subdivision determined by the obstacles, Obstacle Removal was formulated and generalized into the following graph problem, referred to as Colored Path (see Figure 1 for illustrations):

Colored Path

Given: A planar graph G; a set of colors C; $\chi : V \longrightarrow 2^C$; two designated vertices $s, t \in V(G)$; and $k \in \mathbb{N}$

Question: Does there exist an s-t path in G that uses at most k colors?

Denote by Colored Path-Con the restriction of Colored Path to instances in which each color induces a connected subgraph of G.

As we discuss next, Connected Obstacle Removal and Colored Path are fundamental problems that have undergone a tremendous amount of work, albeit under different names and contexts, by researchers in various areas, including computational geometry, graph theory, wireless computing, and motion planning.

1.1 Related Work

In motion planning, the goal is generally to move a robot from a starting position to a final position, while avoiding collision with a set of obstacles. This is usually referred to as the *piano-mover*'s problem. Obstacle Removal is a variant of the piano-mover's

problem, in which the obstacles are in the plane and the robot is represented as a point. Since determining if there is an obstacle-free path for the robot in this case is solvable in polynomial time, if no such path exists, it is natural to seek a path that intersects as few obstacles as possible. Motivated by planning applications, Connected Obstacle Removal and Colored Path were studied under the name Minimum Constraint Removal [7, 9, 10, 11]. Connected Obstacle Removal has also been studied extensively, motivated by applications in wireless computing, under the name Barrier Coverage or Barrier Resilience [1, 2, 12, 13, 15, 16]. In such applications, we are given a field covered by sensors (usually simple shapes such as unit disks), and the goal is to compute a minimum set of sensors that need to fail before an entity can move undetected between two given sites.

Kumar *et al.* [13] were the first to study Connected Obstacle Removal. They showed that for unit-disk obstacles in some restricted setting, the problem can be solved in polynomial time. The complexity of the general case for unit-disk obstacles remains open. Several works showed the NP-hardness of the problem, even when the obstacles are very simple geometric shapes such as line segments (*e.g.*, see [1, 15, 16]). The complexity of the problem when each obstacle intersects a constant number of other obstacles is open [9, 11].

Bereg and Kirkpatrick [2] designed approximation algorithms when the obstacles are unit disks by showing that the length, referred to as the *thickness* [2] (*i.e.*, number of regions visited), of a shortest path that crosses k disks is at most $3k$; this follows from the fact that a shortest path does not cross a disk more than a constant number of times.

Korman *et al.* [12] showed that Connected Obstacle Removal is FPT parameterized by k for unit-disk obstacles, and extended this result to similar-size fat-region obstacles with a constant *overlapping number*, which is the maximum number of obstacles having nonempty intersection. Their result draws the observation, which was also used in [2], that for unit-disk (and fat-region) obstacles, the length of an optimal path can be upper bounded by a linear function of the number of obstacles crossed (*i.e.*, the parameter). This observation was then exploited by a branching phase that decomposes the path into subpaths in (simpler) restricted regions, enabling a similar approach to that of Kumar *et al.* [13].

Motivated by its applications to networking, among other areas, the problem of computing a minimum-colored path in a graph received considerable attention (*e.g.*, see [3, 17]). The problem was shown to be NP-hard in several works [3, 4, 11, 17]. Most of the NP-hardness reductions start from Set Cover, and result in instances of Colored Path (*i.e.*, planar graphs), as was also observed by [2]. These reductions are FPT-reductions, implying the W[2]-hardness of Colored Path. Moreover, these reductions imply that, unless P = NP, the minimization version of Colored Path cannot be approximated to within a factor of $c \lg n$, for any constant $c < 1$. Hauser [11], and Gorbenko and Popov [10], implemented exact and heuristic algorithms for the problem on general graphs. Very recently, Eiben *et al.* [7] designed exact and heuristic algorithms for Colored Path and Obstacle Removal, and proved computational lower bounds on their subexponential-time complexity, assuming the Exponential Time Hypothesis.

1.2 Our Results and Techniques

We study the complexity and parameterized complexity of Colored Path and Colored Path-Con, eyeing the implications on their geometric counterparts Obstacle Removal and Connected Obstacle Removal, respectively. The proofs of the hardness results we obtain are too long and technical to be included, and for those we refer to the full paper [8].

Clearly, Colored Path is in the parameterized class XP. We show that the color-connectivity property is crucial for any hope for an FPT-algorithm, since even very restricted instances and combined parameterizations of Colored Path are W[1]-complete:

▶ **Theorem 1.1.** Colored Path*, restricted to instances of pathwidth at most 4, and in which each vertex contains at most one color and each color appears on at most 2 vertices, is* W[1]-complete parameterized by k.

▶ **Theorem 1.2.** Colored Path*, parameterized by both k and the length of the sought path ℓ, is* W[1]-complete.

Without restrictions, the problem sits high in the parameterized complexity hierarchy:

▶ **Theorem 1.3.** Colored Path*, parameterized by k, is* W*[SAT]-hard and is in* W[P].

A corollary of Theorem 1.3 is that, unless W[2] = FPT, Colored Path cannot be approximated in FPT time to within a factor that is a function of k.

We can produce a generic construction [8] that can be used to realize any graph instance of Colored Path as a geometric instance of Obstacle Removal. Using this generic construction, the hardness results in Theorems 1.1–1.3, and the inapproximability result discussed above, translate to Obstacle Removal. Previously, Colored Path was only known to be W[2]-hard, via the standard reduction from Set Cover [3, 11, 17]. Our results refine the parameterized complexity and approximability of Colored Path and Obstacle Removal.

As it turns out, the color-connectivity property without planarity is hopeless: We can tradeoff planarity for color-connectivity by adding a single vertex that serves as a color-connector, thus establishing the W[SAT]-hardness of the problem on apex graphs.

The above hardness results show that we can focus our attention on Colored Path-Con. We show the following algorithmic result:

▶ **Theorem 1.4** (Theorem 4.7)**.** Colored Path-Con*, parameterized by both k and the treewidth ω of the input graph, is* FPT*.*

We remark that bounding the treewidth does not make Colored Path-Con much easier, as we can show that Colored Path-Con is NP-hard even for 2-outerplanar graphs of pathwidth at most 3 [8].

The folklore dynamic programming approach based on tree decomposition, used for the Hamiltonian Path/Cycle problems, does not work for Colored Path-Con to prove the result in Theorem 1.4 for the following reasons. As opposed to the Hamiltonian Path/Cycle problems, where it is sufficient to keep track of how the path/cycle interacts with each bag in the tree decomposition, this is not sufficient in the case of Colored Path-Con because we also need to keep track of which color sets are used on both sides of the bag. Although (by color connectivity) any subset of colors appearing on both sides of a bag must appear on vertices in the bag as well, there can be too many such subsets (up to $|C|^k$, where C is the set of colors), and certainly we cannot afford to enumerate all of them if we seek an FPT algorithm. To overcome this issue, we develop in Section 3 topological structural results that exploit the planarity of the graph and the connectivity of the colors to show the following. For any vertex $w \in V(G)$, and for any pair of vertices $u, v \in V(G)$, the set of (valid) u-v paths in $G - w$ that use colors appearing on vertices in the face of $G - w$ containing w can be "represented" by a minimal set of paths whose cardinality is a function of k.

In Section 4, we extend the notion of a minimal set of paths w.r.t. a single vertex to a "representative set" of paths w.r.t. a specific bag, and a specific enumerated configuration for the bag, in a tree decomposition of the graph. This enables us to use the upper bound on the size of a minimal set of paths, derived in Section 3, to upper bound the size of a

representative set of paths w.r.t. a bag and a configuration. This, in turn, yields an upper bound on the size of the table stored at a bag, in the dynamic programming algorithm, by a function of both k and the treewidth of the graph, thus yielding the desired result.

In Section 5, we extend the FPT result for Colored Path-Con in Theorem 1.4 w.r.t. the parameters k and ω, to the parameterization by both k and the length ℓ of the path:

▶ **Theorem 1.5** (Theorem 5.1). *Colored Path-Con, and hence Connected Obstacle Removal, parameterized by both k and ℓ is FPT.*

The dependency on both ℓ and k is *essential* for the result in Theorem 1.5, as we can show that if we parameterize only by k, or only by ℓ, then the problem becomes W[1]-hard [8].

The result in Theorem 1.5 generalizes and explains Korman *et al.*'s results [12] showing that Connected Obstacle Removal is FPT parameterized by k for unit-disk obstacles, which they also generalized to similar-size fat-region obstacles with bounded overlapping number. Their results exploit the obstacle shape to upper bound the length of the path by a linear function of k, and then use branching to reduce the problems to a simpler setting. Our result directly implies that, regardless of the (connected) obstacle shapes, as long as the path length is upper bounded by some function of k (Corollary 5.2), the problem is FPT. The FPT result in Theorem 1.5 also implies that:

▶ **Corollary 1.6** (Corollary 5.3). *For any computable function h, Colored Path-Con restricted to instances in which each color appears on at most $h(k)$ vertices, is FPT parameterized by k.*

The result in Corollary 1.6 has applications to Connected Obstacle Removal, in particular, to the interesting case when the obstacles are convex polygons, each intersecting a constant number of other polygons. The question about the complexity of this problem was posed in [9, 11], and remains open. The result in Corollary 1.6 implies that this problem is FPT.

We finally mention that it remains open whether Colored Path-Con and Connected Obstacle Removal are FPT parameterized by k only.

2 Preliminaries

We assume familiarity with graph theory and parameterized complexity. We refer the reader to the standard books [5, 6].

For a set S, we denote by 2^S the power set of S. Let $G = (V, E)$ be a graph, let $C \subset \mathbb{N}$ be a finite set of colors, and let $\chi : V \longrightarrow 2^C$. A vertex v in V is *empty* if $\chi(v) = \emptyset$. A color c *appears on*, or is *contained in*, a subset S of vertices if $c \in \bigcup_{v \in S} \chi(v)$. For two vertices $u, v \in V(G)$, $\ell \in \mathbb{N}$, a u-v path $P = (u = v_0, \ldots, v_r = v)$ in G is *ℓ-valid* if $|\bigcup_{i=0}^{r} \chi(v_i)| \leq \ell$; that is, if the total number of colors appearing on the vertices of P is at most ℓ. A color $c \in C$ is *connected* in G, or simply *connected*, if $\bigcup_{c \in \chi(v)} \{v\}$ induces a connected subgraph of G. The graph G is *color-connected*, if for every $c \in C$, c is connected in G.

For an instance (G, C, χ, s, t, k) of Colored Path or Colored Path-Con, if s and t are nonempty vertices, we can remove their colors and decrement k by $|\chi(s) \cup \chi(t)|$ because their colors appear on every s-t path. If afterwards k becomes negative, then there is no k-valid s-t path in G. Moreover, if s and t are adjacent, then the path (s, t) is a path with the minimum number of colors among all s-t paths in G. Therefore, we will assume:

▶ **Assumption 2.1.** *For an instance (G, C, χ, s, t, k) of Colored Path or Colored Path-Con, we can assume that s and t are nonadjacent empty vertices.*

3 Structural Results

Let G be a color-connected plane graph, C a set of colors, and $\chi : V \longrightarrow 2^C$. In this section, we present structural results that are the cornerstone of the FPT-algorithm for Colored Path-Con presented in the next section. We start by giving an intuitive description of the plan for this section.

As mentioned in Section 1, the main issue facing a dynamic programming algorithm based on tree decomposition, is how to upper bound, by a function of k and the treewidth, the number of k-valid paths between (any) two vertices u and v that use color sets contained in a certain bag. As it turns out, this number cannot be upper bounded as desired. Instead, we "represent" those paths using a minimal set $\mathcal{P}$ of k-valid u-v paths, in the sense that any k-valid u-v path can be replaced by a path from $\mathcal{P}$ that is not "worse" than it. To do so, it suffices to represent the k-valid u-v paths that use color sets contained in a third vertex w, by a set whose cardinality is a function of k. This will enable us to extend the notion of a minimal set of k-valid u-v paths w.r.t. a single vertex to a representative set for the whole bag, which is the key ingredient of the dynamic programming FPT-algorithm – based on tree decomposition – in the next section.

As it turns out, the paths that matter are those that use "external" colors w.r.t. w (defined below), since those colors have the potential of appearing on both sides of a bag containing w. Therefore, the ultimate goal of this section is to define a notion of a minimal set $\mathcal{P}$ of k-valid u-v paths with respect to w (Definition 3.5), and to upper bound $|\mathcal{P}|$ by a function of k. Upper bounding $|\mathcal{P}|$ by a function of k turns out to be quite challenging, and requires ideas and topological results that will be discussed later in this section.

Throughout this section, we shall assume that G is color-connected. We start with the following simple observation that holds because of this assumption:

▶ **Observation 3.1.** *Let $x, y \in V(G)$ be such that there exists a color $c \in \mathcal{C}$ that appears on both x and y. Then any x-y vertex-separator in G contains a vertex on which c appears.*

Let G' be a plane graph, let $w \in V(G')$, and let f be the face in $G' - w$ such that w is interior to f; we call f the *external face* w.r.t. w in $G' - w$, and the vertices incident to f *external vertices* w.r.t. w in $G' - w$. A color $c \in C$ is an *external color* w.r.t. w in $G' - w$, or simply *external* to w in $G' - w$, if c appears on an external vertex w.r.t. w in $G' - w$; otherwise, c is *internal* to w in $G' - w$. The following observation is easy to see:

▶ **Observation 3.2.** *Let G be a color-connected graph, and let $w \in V(G)$. Let H be any subgraph of $G - w$. If c is an external color to w in $G - w$ and c appears on some vertex in H, then c is an external color to w in H. This also implies that the set of internal colors to w in H is a subset of the set of internal colors to w in $G - w$.*

▶ **Definition 3.3.** Let s, t be two designated vertices in G, and let x, y be two adjacent vertices in G such that $\chi(x) = \chi(y)$. Define the following operation to x and y, referred to as a *color contraction* operation, that results in a graph G', a color function χ', and two designated vertices s', t' in G', obtained as follows:

- G' is obtained from G by contracting the edge xy, which results in a new vertex z;
- $s' = s$ (resp. $t' = t$) if $s \notin \{x, y\}$ (resp. $t \notin \{x, y\}$), and $s' = z$ (resp. $t' = z$) otherwise; and
- $\chi' : V(G') \longrightarrow 2^C$ is defined as $\chi'(w) = \chi(w)$ if $w \neq z$, and $\chi'(z) = \chi(x) = \chi(y)$.

G is *irreducible* if there does not exist two vertices in G to which the color contraction operation is applicable.

▶ **Lemma 3.4.** *Let G be a color-connected plane graph, C a color set, $\chi : V \longrightarrow 2^C$, $s,t \in V(G)$, and $k \in \mathbb{N}$. Suppose that the color contraction operation is applied to two vertices in G to obtain G', χ', s',t', as described in Definition 3.3. Then G' is a color-connected plane graph, and there is a k-valid s-t path in G if and only if there is a k-valid s'-t' path in G'.*

▶ **Definition 3.5.** Let $u,v,w \in V(G)$. A set $\mathcal{P}$ of k-valid u-v paths in $G-w$ is said to be *minimal* w.r.t. w if:

- **(i)** There does not exist two paths $P_1, P_2 \in \mathcal{P}$ such that $\chi(P_1) \cap \chi(w) = \chi(P_2) \cap \chi(w)$;
- **(ii)** there does not exist two paths $P_1, P_2 \in \mathcal{P}$ such that $\chi(P_1) \subseteq \chi(P_2)$; and
- **(iii)** for any $P \in \mathcal{P}$, there does not exist a u-v path P' in $G-w$ such that $\chi(P') \subsetneq \chi(P)$.

Clearly, for any $u,v,w \in V(G)$, a minimal set of k-valid u-v paths in $G-w$ exists.

▶ **Observation 3.6.** *Let $u,v,w \in V(G)$. Any set of u-v paths that is minimal w.r.t. w contains at most one path whose vertices contain* only *internal colors w.r.t. w in $G-w$.*

To derive an upper bound on the cardinality of a minimal set $\mathcal{P}$ of k-valid u-v paths w.r.t. a vertex w, we select a maximal set $\mathcal{M}$ of color-disjoint paths in $\mathcal{P}$. We first upper bound $|\mathcal{M}|$ by a function of k, which requires developing several results of topological nature. The key ingredient for upper bounding $|\mathcal{M}|$ is showing that the subgraph induced by the paths in $\mathcal{M}$ has a u-v vertex-separator of cardinality $O(k)$ (Lemma 3.10). We then upper bound $|\mathcal{M}|$ (Lemma 3.12) by upper bounding the number of different traces of the paths of $\mathcal{M}$ on this small separator, and inducting on both sides of the separator. Finally, we show (Theorem 3.13) that $|\mathcal{P}|$ is upper bounded by a function of $|\mathcal{M}|$, which proves the desired upper bound on $|\mathcal{P}|$. We proceed to the details.

For the rest of this section, let $u,v,w \in V(G)$, and let $\mathcal{P}$ be a set of minimal k-valid u-v paths in $G-w$. Let $\mathcal{M}$ be a set of minimal k-valid color-disjoint u-v paths in $G-w$, and let M be the subgraph of $G-w$ induced by the edges of the paths in $\mathcal{M}$.

▶ **Observation 3.7.** *If $P \in \mathcal{M}$ contains a color c that is external to w in M, then c appears on a vertex in P that is incident to the external face to w in M.*

▶ **Lemma 3.8.** *Let G' be a plane graph with a face f, let $u,v \in V(G')$, and let $u_1,\ldots,u_r$, $r \geq 3$, be the neighbors of u. Suppose that, for each $i \in [r]$, there exists a u-v path P_i containing u_i and a vertex incident to f different from v, and such that P_i does not contain any u_j, $j \in [r]$, $j \neq i$. Then there exist two paths P_i, P_j, $i,j \in [r]$, $i \neq j$, such that $V(P_i) \cup V(P_j) - \{v\}$ is a vertex-separator separating $\{u_1,\ldots,u_r\} \setminus \{u_i,u_j\}$ from v.*

▶ **Lemma 3.9.** *Let x,y be two vertices in an irreducible subgraph G' of G, and let f be a face in G'. Then there are at most two color-disjoint x-y paths in G' that contain only colors that appear on f.*

▶ **Lemma 3.10.** *Suppose that M is irreducible, then there exist paths $P_1,P_2,P_3 \in \mathcal{M}$ such that $M - P_1 - P_2 - P_3$ has a u-v vertex-separator of cardinality at most $2k+3$.*

Proof. By Observation 3.6 and Observation 3.2, $\mathcal{M}$ contains at most one path that contains only internal colors w.r.t. w in M. Therefore, it suffices to show that $\mathcal{M}$ contains two paths P_1,P_2 such that $M - P_1 - P_2$ has a u-v vertex-separator of cardinality at most $2k+3$, assuming that every path in $\mathcal{M}$ contains an external color w.r.t. w in M.

By Observation 3.7, every path in $\mathcal{M}$ passes through an external vertex w.r.t. w in M that contains a color external to w in M. Because the paths in $\mathcal{M}$ are pairwise color-disjoint

and u and v are empty vertices, every path in $\mathcal{M}$ passes through a vertex on the external face of w in M that is different from u and v. Let $u_1, \ldots, u_q$ be the neighbors of u in M, and note that since u is empty and M is irreducible, each u_i, $i \in [q]$, contains a color. Let $P_1, \ldots, P_q$ be the paths in $\mathcal{M}$ containing $u_1, \ldots, u_q$, respectively, and note that since the paths in $\mathcal{M}$ are color-disjoint, no P_i passes through u_j, for $j \neq i$. By Lemma 3.8, there are two paths in $P_1, \ldots, P_q$, say P_1, P_2 without loss of generality, such that $V_{12} = V(P_1) \cup V(P_2) - \{v\}$ is a vertex-separator that separates $\{u_3, \ldots, u_q\}$ from v.

We proceed by contradiction and assume that $M^- = M - P_1 - P_2$ does not have a u-v vertex-separator of cardinality $2k + 3$. By Menger's theorem [5], there exists a set $\mathcal{D}$ of $r' \geq 2k + 3$ vertex-disjoint u-v paths in M^-. Since V_{12} separates $\{u_3, \ldots, u_q\}$ from v in M, every u-v path in M^- intersects at least one of P_1, P_2 at a vertex other than v. It follows that there exists a path in $\{P_1, P_2\}$, say P_1, that intersects at least $k + 2$ paths in $\mathcal{D}$ at vertices other than v. Since the paths in $\mathcal{D}$ are vertex-disjoint and incident to u, we can order the paths in $\mathcal{D}$ that intersect P_1 around u (in counterclockwise order) as $\langle Q_1, \ldots, Q_r \rangle$, where $r \geq k + 2$, and Q_{i+1} is counterclockwise from Q_i, for $i \in [r - 1]$. P_1 intersects each path Q_i, $i \in [r]$, possibly multiple times. Moreover, since the paths in $\mathcal{M}$ are pairwise color-disjoint, each intersection between P_1 and a path Q_i, $i \in [r]$, must occur at an empty vertex. We choose $r - 1$ subpaths, $P_1^1, \ldots, P_1^{r-1}$, of P_1 satisfying the property that the endpoints of P_1^i are on Q_i and Q_{i+1}, for $i = 1, \ldots, r - 1$, and the endpoints of P_1^i are the only vertices on P_1^i that appear on a path Q_j, for $j \in [r]$. It is easy to verify that the subpaths $P_1^1, \ldots, P_1^{r-1}$ of P_1 can be formed by following the intersection of P_1 with the sequence of (ordered) paths $Q_1, \ldots, Q_r$.

Recall that the endpoints of $P_1^1, \ldots, P_1^{r-1}$ are empty vertices. Since M is irreducible, no two empty vertices are adjacent, and hence, each subpath P_1^i must contain an internal vertex v_i that contains at least one color. We claim that no two vertices v_i, v_j, $1 \leq i < j \leq r - 1$, contain the same color. Suppose not, and let v_i, v_j, $i < j$, be two vertices containing a color c. Since v_i, v_j are internal to P_1^i and P_1^j, respectively, $Q_1, \ldots, Q_r$ are vertex-disjoint u-v paths, and by the choice of the subpaths $P_1^1, \ldots, P_1^{r-1}$, the paths Q_i and Q_{i+1} form a Jordan curve, and hence a vertex-separator in G, separating v_i from v_j.

By Observation 3.1, color c must appear on a vertex in Q_p, $p \in \{i, i + 1\}$, and this vertex is clearly not in P_1 since P_1 intersects Q_p at empty vertices. Since every vertex in M appears on a path in $\mathcal{M}$, and c appears on $P_1 \in \mathcal{M}$ and on a vertex not in P_1, this contradicts that the paths in $\mathcal{M}$ are pairwise color-disjoint, and proves the claim.

Since no two vertices v_i, v_j, $1 \leq i < j \leq r$, contain the same color, the number $r - 1$ of subpaths $P_1^1, \ldots, P_1^{r-1}$ is upper bounded by the number of distinct colors that appear on P_1, which is at most k. It follows that r is at most $k + 1$, contradicting our assumption above and proving the lemma. ◀

▶ **Lemma 3.11.** *Let S be a minimal u-v vertex-separator in M. Let M_u, M_v be a partition of $M - S$ containing u and v, respectively, and such that there is no edge between M_u and M_v. For any vertex $x \in S$, M_u is contained in a single face of $M_v + x$.*

▶ **Lemma 3.12.** *$|\mathcal{M}| \leq g(k)$, where $g(k) = \mathcal{O}(c^k k^{2k})$, for some constant $c > 1$.*

Proof (sketch). By Observation 3.6, there is at most one path in $\mathcal{M}$ that contains only internal colors w.r.t. w in $G - w$. Therefore, it suffices to upper bound the number of paths in $\mathcal{M}$ that contain at least one external color to w in $G - w$. By Observation 3.2, every such path in $\mathcal{M}$ contains a color that is external to w in M.

The proof is by induction on k, over every color-connected plane graph G, every triplet of vertices u, v, w in G, and every minimal set $\mathcal{M}$ w.r.t. w of k-valid pairwise color-disjoint

u-v paths in $G - w$. If $k = 1$, any path in $\mathcal{M}$ contains exactly one external color w.r.t. w in M. By Lemma 3.9, at most two paths in $\mathcal{M}$ contain only external colors. Assume by the inductive hypothesis that, for each $1 \leq i < k$, we have $|\mathcal{M}| \leq g(i)$. We can assume that M is irreducible; otherwise, we can apply the color contraction operation and replace $\mathcal{M}$ with a set of paths satisfying the same properties.

By Lemma 3.10, there are (at most) 3 paths in $\mathcal{M}$, such that the subgraph of M induced by the remaining paths of $\mathcal{M}$ has a u-v vertex-separator S satisfying $|S| \leq 2k + 3$. Remove these 3 paths from $\mathcal{M}$, and now we can assume that M has a u-v vertex-separator S satisfying $|S| \leq 2k + 3$; we will add 3 to the upper bound on $|\mathcal{M}|$ at the end. We can assume that S is minimal. S separates M into two subgraphs M_u and M_v such that $u \in V(M_u)$, $v \in V(M_v)$, and there is no edge between M_u and M_v. We partition $\mathcal{M}$ into the following groups, where each group excludes the paths satisfying the properties of the groups defined before it: (1) The set of paths in $\mathcal{M}$ that contain a nonempty vertex in S; (2) the set of paths $\mathcal{M}_u^k$ consisting of each path P in $\mathcal{M}$ such that all colors on P appear on vertices in M_u (these colors could still appear on vertices in M_v as well); (3) the set of paths $\mathcal{M}_v^k$ consisting of each path P in $\mathcal{M}$ such that all colors on P appear on vertices in M_v; and (4) the set $\mathcal{M}^{<k}$ of remaining paths in $\mathcal{M}$, satisfying that each path contains a nonempty external vertex to w in M and contains less than k colors from each of M_u and M_v.

Since the paths in $\mathcal{M}$ are pairwise color-disjoint, no nonempty vertex in S appears on two distinct paths from group (1). Therefore, the number of paths in group (1) is at most $|S| \leq 2k + 3$. Observe that the vertices in S contained in any path from groups (2)-(4) are empty vertices. To upper bound the number of paths in group (2), for each path P, there is a last vertex x_P (*i.e.*, farthest from u) in P that is in S. Fix a vertex $x \in S$, and let us upper bound the number of paths P in group (2) for which $x = x_P$. Let P_v be the subpath of P from x to v. Note that since v is empty and all the vertices in S that are contained in paths in group (2) are empty, and since M is irreducible, P_v must contain at least one color. Since all colors appearing on P appear on vertices in M_u, all colors appearing on P_v appear in M_u. By Lemma 3.11, M_u is contained in a single face f of $M_v + x$. Since f is a vertex-separator that separates $V(M_u)$ from $V(P_v)$ in G, by Observation 3.1, every color that appears on P_v appears on f. By Lemma 3.9, there are at most two x-v paths that contain only colors that appear on f. This shows that there are at most two paths in group (2) for which x is the last vertex in S. Since $|S| \leq 2k + 3$, this upper bounds the number of paths in group (2) by $2(2k + 3) = 4k + 6$. By symmetry, the number of paths in group (3) is upper bounded by $4k + 6$.

To upper bound the number of paths in group (4), let $S = \{s_2, \ldots, s_{r-1}\}$, and extend S by adding the two vertices $s_1 = u$ and $s_r = v$ to form the set $A = \{s_1, s_2, \ldots, s_r\}$. For every two (distinct) vertices $s_j, s_{j'} \in A$, we define a set of paths $\mathcal{P}_{jj'}$ in $G - w$ whose endpoints are s_j and $s_{j'}$ as follows. For each path P in group (4), partition (the edges in) P into subpaths $P_1, \ldots, P_q$ satisfying the property that the endpoints of each P_i, $i \in [q]$, are in A, and no internal vertex to P_i is in A. For each P_i, $i \in [q]$, such that P_i contains a vertex that contains an external color to w in $G - w$, let P_i' (possibly P_i) be a subpath in $G - w$ between the endpoints of P_i satisfying that $\chi(P_i') \subseteq \chi(P_i)$ and $\chi(P_i')$ is minimal w.r.t. containment. Since P contains a vertex that contains an external color to w in $G - w$, it is easy to see that there exists an $i \in [q]$ such that P_i' contains a vertex containing an external color to w in $G - w$. Pick any $i \in [q]$ satisfying that P_i' contains a vertex containing an external color to w in $G - w$, associate P with P_i', and assign P_i' to the set of paths $\mathcal{P}_{jj'}$ such that s_j and $s_{j'}$ are the endpoints of P_i'. The map that takes each P to its P_i' is clearly a bijection.

Therefore, it suffices to upper bound the number of paths assigned to the sets $\mathcal{P}_{jj'}$. Fix a set $\mathcal{P}_{jj'}$. The paths in $\mathcal{P}_{jj'}$ have $s_j, s_{j'}$ as endpoints, and are pairwise color-disjoint. It is not difficult to show that $\mathcal{P}_{jj'}$ is a minimal set of $(k-1)$-valid s_j-$s_{j'}$ paths in $G-w$ w.r.t. w. By the inductive hypothesis, we have $|\mathcal{P}_{jj'}| \leq g(k-1)$. Since the number of sets $\mathcal{P}_{jj'}$ is at most $\binom{2k+5}{2}$, the number of paths in group (4) is $\mathcal{O}(k^2) \cdot g(k-1)$.

It follows that $|\mathcal{M}| \leq g(k)$, where $g(k)$ satisfies:

$$g(k) \leq 3 + (2k+3) + 2(4k+6) + \mathcal{O}(k^2) \cdot g(k-1) = \mathcal{O}(k^2) \cdot g(k-1),$$

where 3 accounts for the 3 paths removed from $\mathcal{M}$. Solving the aforementioned recurrence relation gives $g(k) = \mathcal{O}(c^k k^{2k})$, where $c > 1$ is a constant. ◀

Applying Lemma 3.12 to a maximal set $\mathcal{M}$ of color-disjoint paths in $\mathcal{P}$, and using an inductive proof, we can show the following theorem:

▶ **Theorem 3.13.** *Let G be a plane color-connected graph, and let $w \in V(G)$. Let G' be a subgraph of $G-w$, and let $u, v \in V(G')$. Every set $\mathcal{P}$ of minimal k-valid u-v paths in G' w.r.t. w satisfies $|\mathcal{P}| \leq h(k)$, where $h(k) = \mathcal{O}(c^{k^2} k^{2k^2+k})$, for some constant $c > 1$.*

4 The Algorithm

In this section, we highlight how the FPT algorithm for Colored Path-Con, parameterized by both k and the treewidth of the input graph works. As pointed out in Section 3, there can be too many (*i.e.*, more than FPT-many) subsets of colors that appear in a bag, and hence, that the algorithm may need to store/remember. To overcome this issue, we extend the notion of a minimal set of k-valid u-v paths w.r.t. a vertex – from the previous section – to a "representative set" of paths w.r.t. a specific bag and a specific enumerated configuration for the bag. This allows us to upper bound the size of the table, in the dynamic programming algorithm, stored at a bag by a function of both k and the treewidth of the graph.

Let (G, C, χ, s, t, k) be an instance of Colored Path-Con. Let $(\mathcal{V}, \mathcal{T})$ be a nice tree decomposition of G. By Assumption 2.1, we can assume that s and t are nonadjacent empty vertices. We add s and t to every bag in $\mathcal{T}$, and now we have $\{s,t\} \subseteq X_i$, for every bag $X_i \in \mathcal{T}$. For a bag X_i, we say that $v \in X_i$ is *useful* if $|\chi(v)| \leq k$. Let U_i be the set of all useful vertices in X_i and let $\overline{U_i} = X_i \setminus U_i$. We denote by V_i the set of vertices in the bags of the subtree of $\mathcal{T}$ rooted at X_i. For any two vertices $u, v \in X_i$, let $G^i_{uv} = G[(V_i \setminus X_i) \cup \{u, v\}]$. We extend the notion of a minimal set of k-valid u-v paths w.r.t. a vertex, developed in the previous section, to the set of vertices in a bag of $\mathcal{T}$.

▶ **Definition 4.1.** A set of k-valid u-v paths $\mathcal{P}_{uv}$ in G^i_{uv} is *minimal* w.r.t. X_i if it satisfies the following properties:

- **(i)** There does not exist two paths $P_1, P_2 \in \mathcal{P}_{uv}$ such that $\chi(P_1) \cap \chi(X_i) = \chi(P_2) \cap \chi(X_i)$;
- **(ii)** there does not exist two paths $P_1, P_2 \in \mathcal{P}_{uv}$ such that $\chi(P_1) \subseteq \chi(P_2)$; and
- **(iii)** for any $P \in \mathcal{P}_{uv}$ there does not exist a u-v path P' in G^i_{uv} such that $\chi(P') \subsetneq \chi(P)$.

The following lemma uses the upper bound on the cardinality of a minimal set of k-valid u-v paths w.r.t. a vertex, derived in Theorem 3.13 in the previous section, to obtain an upper bound on the cardinality of a minimal set of k-valid u-v paths w.r.t. a bag of $\mathcal{T}$:

▶ **Lemma 4.2.** *Let X_i be bag, $u, v \in X_i$, and $\mathcal{P}_{uv}$ a set of k-valid u-v paths in G^i_{uv} that is minimal w.r.t. X_i. Then the number of paths in $\mathcal{P}_{uv}$ is at most $h(k)^{|X_i|}$, where $h(k) = \mathcal{O}(c^{k^2} k^{2k^2+k})$, for some constant $c > 1$.*

▶ **Definition 4.3.** Let X_i be a bag in $\mathcal{T}$. A *pattern* π for X_i is a sequence $(v_1 = s, \sigma_1, v_2, \sigma_2, \ldots, \sigma_{r-1}, v_r = t)$, where $\sigma_i \in \{0,1\}$ and $v_i \in U_i$. For a bag X_i, and a pattern $(v_1 = s, \sigma_1, v_2, \sigma_2, \ldots, \sigma_{r-1}, v_r = t)$ for X_i, we say that a sequence of paths $\mathcal{S} = (P_1, \ldots, P_{r-1})$ *conforms* to (X_i, π) if:

- For each $j \in [r-1]$, $\sigma_j = 1$ implies that P_j is an induced path from v_j to v_{j+1} whose internal vertices are contained in $V_i \setminus X_i$ and P_j is empty otherwise; and
- $|\chi(\mathcal{S})| = |\bigcup_{j\in[r-1]} \chi(P_j)| \leq k$.

▶ **Definition 4.4.** Let X_i be a bag, π a pattern for X_i, and $\mathcal{S}_1, \mathcal{S}_2$ two sequences of paths that conform to (X_i, π). We write $\mathcal{S}_1 \preceq_i \mathcal{S}_2$ if $|\chi(\mathcal{S}_1) \cup (\chi(\mathcal{S}_2) \cap \chi(X_i))| \leq |\chi(\mathcal{S}_2)|$.

Using the relation $\preceq_i$ on the set of sequences that conform to (X_i, π), we can define the key notion of representative sets that makes the dynamic programming approach work:

▶ **Definition 4.5.** Let X_i be a bag and $\pi = (v_1, \sigma_1, v_2 \ldots, \sigma_{r-1}, v_r)$ a pattern for X_i. A set $\mathcal{R}_\pi$ of sequences that conform to (X_i, π) is a *representative* set for (X_i, π) if:

- **(i)** For every sequence $\mathcal{S}_1 \in \mathcal{R}_\pi$, and for every sequence $\mathcal{S}_2 \neq \mathcal{S}_1$ that conforms to (X_i, π), if $\mathcal{S}_1 \preceq_i \mathcal{S}_2$ then $\mathcal{S}_2 \notin \mathcal{R}_\pi$;
- **(ii)** for every sequence $\mathcal{S} \in \mathcal{R}_\pi$, and for every path $P \in \mathcal{S}$ between v_j and v_{j+1}, $j \in [r-1]$, there does not exist a v_j-v_{j+1} path P' in $G^i_{v_j v_{j+1}}$ such that $\chi(P') \subsetneq \chi(P)$; and
- **(iii)** for every sequence $\mathcal{S} \notin \mathcal{R}_\pi$ that conforms to (X_i, π) and satisfies that no two paths in $\mathcal{S}$ share a vertex that is not in X_i, there is a sequence $\mathcal{W} \in \mathcal{R}_\pi$ such that $\mathcal{W} \preceq_i \mathcal{S}$.

The following lemma uses the upper bound on the cardinality of a minimal set of k-valid u-v paths w.r.t. a bag X_i, derived in Lemma 4.2, to obtain an upper bound on the cardinality of a representative set w.r.t. a bag and a fixed pattern (X_i, π):

▶ **Lemma 4.6.** *Let X_i be bag, π a pattern for X_i, and $\mathcal{R}_\pi$ be a representative set for (X_i, π). Then the number of sequences in $\mathcal{R}_\pi$ is at most $h(k)^{|X_i|^2}$, where $h(k) = \mathcal{O}(c^{k^2} k^{2k^2+k})$, for some constant $c > 1$.*

For each bag X_i, we maintain a table Γ_i that contains, for each pattern for X_i, a representative set of sequences $\mathcal{R}_\pi$ for (X_i, π). The rest is a technical dynamic programming algorithm over $(\mathcal{V}, \mathcal{T})$ that computes the table Γ_i at a bag X_i for each bag type (introduce, forget, join) in the nice tree decomposition. We conclude with the following theorem:

▶ **Theorem 4.7.** *There is an algorithm that on input (G, C, χ, s, t, k) of* Colored Path-Con*, either outputs a k-valid s-t path in G or decides that no such path exists, in time $\mathcal{O}^\star(f(k)^{6\omega^2})$, where ω is the treewidth of G and $f(k) = \mathcal{O}(c^{k^2} k^{2k^2+k})$, for some constant $c > 1$. Therefore,* Colored Path-Con *parameterized by both k and the treewidth ω of the input graph is* FPT.

5 Extensions and Applications

In this section, we explain how to extend the FPT result for Colored Path-Con w.r.t. the parameterization by both k and the treewidth of the graph, to the parameterization by both k and the length ℓ of the sought path, and discuss important applications of this extended result. We formally define the problem w.r.t. the parameterization by k and ℓ:

Bounded-length Colored Path-Con

Given: A planar graph G; a set of colors C; $\chi : V \longrightarrow 2^C$; two designated vertices $s, t \in V(G)$; and $k, \ell \in \mathbb{N}$

Question: Does there exist a k-valid s-t path of length at most ℓ in G?

To extend Theorem 4.7, we repeatedly contract every edge uv incident to a vertex v whose distance to s is more than $\ell+1$; we assign the resulting vertex the color set $\chi(u) \cup \chi(v)$. (We do not delete such vertices in order to preserve the color-connectivity property.) Afterwards, the radius of G is at most $\ell+1$, and hence G has treewidth at most $3 \cdot (\ell+1)+1 = 3\ell+4$ [14]. Although the treewidth of G is bounded by a function of ℓ, we cannot use the FPT algorithm for Colored Path-Con, parameterized by k and the treewidth of G, to solve Bounded-length Colored Path-Con because a k-valid path returned by the algorithm for Colored Path-Con may have length more than ℓ. We can extend the FPT results for Colored Path-Con to Bounded-length Colored Path-Con to show the following:

▶ **Theorem 5.1.** Bounded-length Colored Path-Con *parameterized by both k and the length of the path is* FPT.

We now describe applications of Theorem 5.1. The first application is a direct consequence of this theorem.

▶ **Corollary 5.2.** *For any computable function h, the restriction of* Colored Path-Con *to instances in which the length of the path is at most $h(k)$ is* FPT *parameterized by k.*

We note that the above restriction of Colored Path-Con can be shown to be NP-hard.

Corollary 5.2 directly implies Korman *et al.*'s results [12], showing that Obstacle Removal is FPT for unit-disk obstacles and for similar-size fat-region obstacles with constant overlapping number. Using Bereg and Kirkpatrick's result [2], the length of a shortest k-valid path for unit-disk obstacles is at most $3k$ (see also Lemma 3 in Korman *et al.* [12]). By Corollary 2 in [12], the length of a shortest k-valid path for similar-size fat-region obstacles with constant overlapping number is linear in k. Corollary 5.2 generalizes these FPT results, which required quite some effort, and provides an explanation to why the problem is FPT for such restrictions, namely because the path length is upper bounded by a function of k.

The second application is related to an open question posed in [9, 11]. For an instance $I = (G, C, \chi, s, t, k)$ of Colored Path-Con, and a color $c \in C$, define the *intersection number* of c, denoted $\iota(c)$, to be the number of vertices in G on which c appears. Define the *intersection number* of G, $\iota(G)$, as $\max\{\iota(c) \mid c \in C\}$.

▶ **Corollary 5.3.** *For any computable function h,* Colored Path-Con *restricted to instances (G, C, χ, s, t, k) satisfying $\iota(G) \leq h(k)$ is* FPT *parameterized by k.*

Corollary 5.3 has applications pertaining to instances of Connected Obstacle Removal whose auxiliary graphs have intersection number bounded by a function of k. An interesting case that was studied is when the obstacles are convex polygons, each intersecting at most a constant number of other polygons. The complexity of this problem was posed as an open question in [9, 11], and remains unresolved. Corollary 5.3 implies that the problem is FPT, even for the more general setting in which the obstacles are arbitrary convex regions satisfying that the number of regions intersected by any region is a constant. (Note that convexity is important here.)

Abstract

We consider integer programming problems $\max\{c^T x : \mathcal{A}x = b, l \leq x \leq u, x \in \mathbb{Z}^{nt}\}$ where $\mathcal{A}$ has a (recursive) block-structure generalizing *n-fold* integer programs which recently received considerable attention in the literature. An n-fold IP is an integer program where $\mathcal{A}$ consists of n repetitions of submatrices $A \in \mathbb{Z}^{r \times t}$ on the top horizontal part and n repetitions of a matrix $B \in \mathbb{Z}^{s \times t}$ on the diagonal below the top part. Instead of allowing only two types of block matrices, one for the horizontal line and one for the diagonal, we generalize the n-fold setting to allow for arbitrary matrices in every block. We show that such an integer program can be solved in time $n^2 t^2 \varphi \cdot (r\, s\, \Delta)^{\mathcal{O}(rs^2+sr^2)}$ (ignoring logarithmic factors). Here Δ is an upper bound on the largest absolute value of an entry of $\mathcal{A}$ and φ is the largest binary encoding length of a coefficient of c. This improves upon the previously best algorithm of Hemmecke, Onn and Romanchuk that runs in time $n^3 t^3 \varphi \cdot \Delta^{\mathcal{O}(st(r+t))}$. In particular, our algorithm is not exponential in the number t of columns of A and B.

Our algorithm is based on a new upper bound on the ℓ_1-norm of an element of the *Graver basis* of an integer matrix and on a proximity bound between the LP and IP optimal solutions tailored for IPs with block structure. These new bounds rely on the *Steinitz Lemma*.

Furthermore, we extend our techniques to the recently introduced *tree-fold IPs*, where we again present a more efficient algorithm in a generalized setting.

1 Introduction

An *integer program (IP)* is an optimization problem of the form

$$\max\{c^T x : Ax = b,\, l \leq x \leq u,\, x \in \mathbb{Z}^n\} \tag{1}$$

which is described by a *constraint matrix* $A \in \mathbb{Z}^{m\times n}$, an *objective function* vector $c \in \mathbb{Z}^n$ a *right-hand side* vector $b \in \mathbb{Z}^m$ and *lower* and *upper bounds* $l \leq x \leq u$. Integer programming is one of the most important paradigms in the field of algorithms as a breadth of combinatorial optimization problems have an IP-model, see, e.g. [17, 20]. Since integer programming is NP-hard, there is a strong interest in restricted versions of integer programs that can be solved in polynomial time, while still capturing interesting classes of combinatorial optimization problems. A famous example is the class of integer programs with *totally unimodular* constraint matrix, capturing flow, bipartite matching, and shortest path problems for example. This setting has been extended to *bimodular* integer programming recently [1].

Another such polynomial-time solvable restriction is n-fold integer programming [6]. Given two matrices $A \in \mathbb{Z}^{r\times t}$ and $B \in \mathbb{Z}^{s\times t}$ and a vector $b \in \mathbb{Z}^{r+ns}$ for some $r, s, t, n \in \mathbb{Z}_+$. An n-fold Integer Program (n-fold IP) is an integer program (1) with constraint matrix

$$\mathcal{A} = \begin{pmatrix} A & A & \dots & A \\ B & 0 & \dots & 0 \\ 0 & B & & \vdots \\ \vdots & & \ddots & 0 \\ 0 & \dots & 0 & B \end{pmatrix} \tag{2}$$

Clearly, one can assume that $t \geq r$ and $t \geq s$ holds, as linearly dependent equations can be removed. Notice that the number of variables of an n-fold integer program is $t \cdot n$. The best known algorithm to solve an n-fold IP is due to Hemmecke, Onn and Romanchuk [10] with a running time of $\mathcal{O}(n^3t^3\varphi) \cdot \Delta^{\mathcal{O}(st(r+t))}$, where Δ is the absolute value of the largest entry in $\mathcal{A}$ and φ is the logarithm of the largest absolute value of a component of c. For fixed Δ, r, s and t, the running time depends only polynomially (cubic) on the number of variables and is therefore more efficient than applying algorithms for general IPs based on lattice-basis reduction [12, 16] or dynamic programming [7, 19].

The n-fold setting has gained strong momentum in the last years, especially in the fields of *parameterized complexity* and *approximation algorithms*. An algorithm is *fixed parameter tractable (fpt)* with respect to a parameter k derived from the input, if its running time is of the form $f(k) \cdot n^{O(1)}$ for some computable function f. The result of Hemmecke et al. [10] shows that integer programming is fixed parameter tractable with respect to Δ, s, r and t.

This opens the possibility to model combinatorial optimization problems with a fixed parameter as an n-fold integer program, see for instance [3, 13] and thereby obtain novel new results in the area of parameterized complixity. Very recently Jansen, Klein, Maack and Rau [11] used n-fold IPs to formulate an enhanced *configuration IP*, that is capable to track additional properties of configurations. With this enhanced IP they were able to develop approximation algorithms for several scheduling problems that involve setups. Not only for the scheduling problems, but also in the design of efficient algorithms for string and social choice problems, n-fold IPs have been successfully applied [14, 15].

A generalization of the classical n-fold IP, called *tree-fold* IP, was very recently introduced by Chen and Marx [2]. A matrix A is of tree-fold structure, if it is of recursive n-fold

structure, i.e. the matrices $B^{(i)}$ in IP (2) are of n'-fold structure themselves, and so on. Chen and Marx presented an algorithm to solve tree-fold IPs which runs in time $f(L) \cdot n^3 \varphi$, where φ is the encoding length and L involves parameters of the tree like the height of the tree and the number of variables and rows of the involved sub-matrices. They applied the tree-fold IP to a special case of the traveling salesman problem, where m clients have to visit every node of a weighted tree and the objective is to minimize the longest tour over all clients. Using the framework of tree-fold IPs, they obtained an fpt algorithm with a running time of $f(K) \cdot |V|^{\mathcal{O}(1)}$, where K is the longest tour of a client in the optimal solution and V is the set of vertices of the tree. However, the function f involves a term with a tower of K exponents.

1.1 Graver Bases and Augmentation Algorithms

Before we discuss our contributions, we have to review the core concepts of the algorithm of Hemmecke, Onn and Romanchuk [10] in a nutshell.

Suppose we are solving a general integer program (1) with constraint matrix $A \in \mathbb{Z}^{m \times n}$ and that we have a feasible solution z_0 at hand. Let $z^\star$ be an optimal solution. The vector $z^\star - z_0$ lies in the kernel of A, i.e., $A(z^\star - z_0) = 0$. An integer vector $y \in \ker(A)$ is called a *cycle* of A. Two vectors $u, v \in \mathbb{R}^n$ are said to be *sign compatible* if $u_i \cdot v_i \geq 0$ for each i. A cycle $y \in \ker(A)$ is *indecomposable* if it is not the sum of two sign-compatible and non-zero cycles of A. The set of indecomposable and integral elements from the kernel of A is called the *Graver basis* of A, [8], see also [18, 5].

A result of Cook, Fonlupt and Schrijver [4] implies that there exist $2n$ Graver-basis elements $g_1, \ldots, g_{2n} \in \ker(A)$ each sign compatible with $z^\star - z_0$ such that

$$z^\star - z_0 = \sum_{i=1}^{2n} \lambda_i g_i$$

holds for $\lambda_i \in \mathbb{N}_0$. For each i one has that $z_0 + \lambda_i g_i$ is a feasible integer solution of (1). Furthermore, there exists one i with $c^T(z^\star - z_0)/(2\,n) \leq \lambda_i c^T g_i$. Thus there exists an element g of the Graver basis of A and a positive integer $\lambda \in \mathbb{N}$ such that $z_0 + \lambda\, g$ is feasible and the gap to the optimum value has been reduced by a factor of $1 - 1/(2\,n)$.

Why should it be any simpler to find such an *augmenting vector* g as above? The crucial ingredient that is behind the power of this approach are *bounds* on the ℓ_1-norm of elements of the Graver basis of A. In some cases, these bounds are much more restrictive than the original lower and upper bounds $l \leq x \leq u$ and thus help in dynamic programming. In fact, each element g of the Graver basis of A has ℓ_1-norm bounded by $\|g\|_1 \leq \delta \cdot (n - m)$ where δ is the largest absolute value of a sub-determinant of A, see [18]. Applying the Hadamard bound, this means that

$$\|g\|_1 \leq m^{m/2} \Delta^m \cdot (n - m), \tag{3}$$

where Δ is a largest absolute value of an entry of A. Let us denote $m^{m/2}\Delta^m \cdot (n-m)$ by G_A. In order to find an augmenting solution which reduces the optimality gap by a factor of (roughly) $1 - 1/n$ one solves the following *augmentation integer program* with a *suitable* λ,

$$\max\{c^T y : Ay = 0,\, l - z_0 \leq \lambda \cdot y \leq u - z_0,\, \|y\|_1 \leq G_A, y \in \mathbb{Z}^n\}. \tag{4}$$

and replaces z_0 by $z_0 + \lambda \cdot y^\star$, where $y^\star$ is the optimal solution of (4). The number of augmenting steps can be bounded by $\mathcal{O}(n \log(c^T(z^\star - z_0)))$.

At first sight, it seems that one has not gained much with this approach, except that the right-hand side vector b has disappeared. In the case of n-fold integer programming however,

the ℓ_1-norm of an element of the Graver basis of $\mathcal{A}$ is bounded by a function in r, s, t and Δ and thus much smaller than the bound (3). This can be exploited in dynamic programming approaches.

Contributions of this paper. We present several elementary observations that, together, result in a much faster algorithm for integer programs with block structure including n-fold and tree-fold integer programs. We start with the following.

i) The ℓ_1-norm of an element of the Graver basis of a given matrix $A \in \mathbb{Z}^{m\times n}$ is bounded by $(2\,m\cdot\Delta+1)^m$, where Δ is an upper bound on the absolute value of each entry of A. This is shown with the Steinitz lemma and uses similar ideas as in [7]. Compared to the previous best bound (3), this new bound is independent on the number of columns n of A.

We then turn our attention to integer programming problems

$$\max\{c^T x : \mathcal{A}\,x = b,\, l \le x \le u,\, x \in \mathbb{Z}^{n\times t}\} \tag{5}$$

with constraint matrix of the form

$$\mathcal{A} = \begin{pmatrix} A^{(1)} & A^{(2)} & \dots & A^{(n)} \\ B^{(1)} & 0 & \dots & 0 \\ 0 & B^{(2)} & & \vdots \\ \vdots & & \ddots & 0 \\ 0 & \dots & 0 & B^{(n)} \end{pmatrix},$$

where $A^{(1)},\dots,A^{(n)} \in \mathbb{Z}^{r\times t}$ and $B^{(1)},\dots,B^{(n)} \in \mathbb{Z}^{s\times t}$ are arbitrary matrices. This is a more general setting than n-fold integer programming, since the matrices on the top line and on the diagonal respectively do not have to repeat. In this setting, we obtain the following results.

ii) The ℓ_1-norm of an element of the Graver basis of $\mathcal{A}$ is bounded by $\mathcal{O}(r\,s\,\Delta)^{(r+1)(s+1)}$ which is independent on the number of columns t of the $A^{(i)}$ and $B^{(i)}$.

iii) We next provide a special proximity bound for integer programs with block structure (5). Let $x^\star$ be an arbitrary optimal solution of the linear programming relaxation of (5). We show that there exists an optimal solution $z^\star$ of (5) with

$$\|x^\star - z^\star\|_1 \le n\,t\,(r\,s\,\Delta)^{\mathcal{O}(r\,s)}.$$

iv) We then exploit the bounds ii) and iii) in a new dynamic program to solve (5). Its running time is bounded by

$$n^2t^2\varphi\log^2 nt\cdot(rs\Delta)^{\mathcal{O}(r^2s+rs^2)} + \mathrm{LP}$$

where φ denotes the largest binary encoding length of c, and LP denotes the time needed to solve the LP relaxation of (5).

The main advantage of the running time of our algorithm is the improved dependency on the parameter t. In contrast, the previous best known algorithm by Hemmecke, Onn and Romanchuk [10] for classical n-fold IPs invovles a term $\Delta^{\mathcal{O}(st^2)}$ and therefore has an exponential dependency on t. Recall that we can assume that $t \ge r, s$ holds. The number of columns t can be very large. Even if we do not allow column-repetitions, t can be as large as Δ^{r+s} and in applications involving *configuration IPs* this is often the order of magnitude one is dealing with. Knop, Koutecky and Mnich [14] improved the dependency of t in a special

setting of n-fold to a factor $t^{\mathcal{O}(r)}$. In their setting, the matrix B on the diagonal consists of one line of ones only. Our running time is an improvement of their result also in this case.

Next, we generalize the notion of tree-fold IPs of [2] where we allow for arbitrary matrices at each node. This yields a rather natural description of a generalized tree-fold IP. We refer to Section 4 for the precise definition.

In this setting we obtain the following result.

v) We present an algorithm for generalized tree-fold IPs with a running time that is roughly doubly exponential in the height of the tree (for a precise running time we refer to Lemma 10). With this algorithm we improve upon the algorithm by Chen and Marx [2], which has a running time involving a term that has a tower of τ exponents, where τ is the height of the tree.

vi) Using the tree-fold IP formulation of [2], this implies an fpt algorithm for the the traveling salesman problem on trees with m clients with running time $2^{2^{poly(K)}} \cdot |V|^{O(1)}$, where K is the longest tour of an optimal solution over all clients.

Notation. We use the following notation throughout this paper. For positive numbers $n, r, s, t \in \mathbb{N}$ and index $i = 1, \ldots, n$, let $A^{(i)} \in \mathbb{Z}^{r \times t}$, $B^{(i)} \in \mathbb{Z}^{s \times t}$ with $\left|\left|A^{(i)}\right|\right|_\infty, \left|\left|B^{(i)}\right|\right|_\infty \leq \Delta$ for some constant Δ. Columns of matrices are denoted with a lower index, i.e. the j-th column of the matrix $A^{(i)}$ is denoted by $A^{(i)}_j$, and so on. With $\log x$, we denote the logarithm to the basis 2 of some number x.

We will often subdivide the set of entries in a vector $y \in \mathbb{R}^{nt}$ or a vector $\mathcal{A}y \in \mathbb{R}^{r+ns}$ into *bricks*. A vector $y \in \mathbb{R}^{nt}$ will consist of n bricks with t variables each, i.e.

$$y^T = \left((y^{(1)})^T, \quad (y^{(2)})^T, \quad \ldots, \quad (y^{(n)})^T\right)$$

with the brick $y^{(i)} \in \mathbb{R}^t$ corresponding to the block $B^{(i)}$. A vector $g = \mathcal{A}y \in \mathbb{R}^{r+ns}$ will consist of $n+1$ bricks,

$$(\mathcal{A}y)^T = \left((g^{(0)})^T, \quad (g^{(1)})^T, \quad \ldots, \quad (g^{(n)})^T\right),$$

where the first brick $g^{(0)} \in \mathbb{R}^r$ consists of the first r entries and corresponds to the block row $(A^{(1)}, \ldots, A^{(n)})$ of $\mathcal{A}$, and every other block $g^{(i)}$, $i \geq 1$, consists of s entries and corresponds to the block $B^{(i)}$. We will always use upper indices with brackets when referring to the bricks, and the indices will coincide with the index of the block $B^{(i)}$ they correspond to (except brick $g^{(0)}$). A simple but crucial observation we will use several times is the following. If y is a cycle of $\mathcal{A}$, then each brick $y^{(i)}$ is already a cycle of the matrix $B^{(i)}$.

2 The norm of a Graver-basis element

In this section, we provide the details of the contributions i) and ii). We will make use of the following lemma of Steinitz [9, 21]. Here $\|\cdot\|$ denotes an arbitrary norm.

▶ **Lemma 1** (Steinitz Lemma). *Let $v_1, \ldots, v_n \in \mathbb{R}^m$ be vectors with $||v_i|| \leq \Delta$ for $i = 1, \ldots, n$. If $\sum_{i=1}^n v_i = 0$, then there is a reordering $\pi \in S_n$ such that for each $k \in \{1, \ldots, n\}$ the partial sum $p_k := \sum_{i=1}^k v_{\pi(i)}$ satisfies $||p_k|| \leq m\Delta$ (for the same norm $\|\cdot\|$).*

▶ **Lemma 2.** *Let $A \in \mathbb{Z}^{m \times n}$ be an integer matrix, let Δ be an upper bound on the absolute value of each component of A, and let $y \in \mathbb{Z}^n$ be an element of the Graver basis of A. Then $\|y\|_1 \leq (2m\Delta + 1)^m$.*

Proof. We define a sequence of vectors $v_1, \dots, v_{\|y\|_1} \in \mathbb{Z}^m$ in the following manner. If $y_j \geq 0$, we add y_j copies of the j-th column of A to the sequence, if $y_j < 0$ we add $|y_j|$ copies of the negative of column j to the sequence.

Clearly, the v_i sum up to zero and their ℓ_∞-norm is bounded by Δ. Using Steinitz, there is a reordering $u_{\pi(1)}, \dots, u_{\pi(\|y\|_1)}$ of this sequence s.t. each partial sum $p_k := \sum_{j=1}^{k} u_{\pi(j)}$ is bounded by $m\Delta$ in the l_∞-norm. Clearly,

$$|\{x \in \mathbb{Z}^m : \|x\|_\infty \leq m\Delta\}| = (2m\Delta + 1)^m .$$

Thus, if $\|y\|_1 > (2m\Delta + 1)^m$, then two of these partial sums are the same and we have a sequence $u_{\pi(k)} + \dots + u_{\pi(k+\ell)} = 0$. But then we can decompose y into two vectors corresponding to this sequence and the remaining vectors $u_{\pi(i)}$. This shows the claim. ◀

We will now apply the Steinitz lemma to bound the ℓ_1-norm of an element of the Graver basis of

$$\mathcal{A} = \begin{pmatrix} A^{(1)} & A^{(2)} & \dots & A^{(n)} \\ B^{(1)} & 0 & \dots & 0 \\ 0 & B^{(2)} & & \vdots \\ \vdots & & \ddots & 0 \\ 0 & \dots & 0 & B^{(n)} \end{pmatrix},$$

where $A^{(1)}, \dots, A^{(n)} \in \mathbb{Z}^{r \times t}$ and $B^{(1)}, \dots, B^{(n)} \in \mathbb{Z}^{s \times t}$ are arbitrary matrices. Lemma 2 shows that the ℓ_1-norm of an element of the Graver basis of a matrix $B^{(i)}$ is bounded by $(2\,s\Delta + 1)^s =: L_B$.

▶ **Lemma 3.** *Let y be a Graver-basis element of $\mathcal{A}$, then*

$$||y||_1 \leq L_B\,(2r\Delta L_B + 1)^r =: L_{\mathcal{A}}.$$

Proof. Let g be a Graver basis element of $B^{(i)}$. Note that as $||g||_1 \leq L_B$ and $\left|\left|A^{(i)}\right|\right|_\infty \leq \Delta$, the infinity-norm of the vector $A^{(i)}g$ is bounded by

$$\left|\left|A^{(i)}g\right|\right|_\infty \leq \Delta L_B. \tag{6}$$

Now consider a Graver basis element $y \in \mathbb{Z}^{nt}$ of $\mathcal{A}$ and split it according to the matrices $B^{(i)}$ into bricks, i.e. $y^T = ((y^{(1)})^T, \dots, (y^{(n)})^T)$ with each $y^{(i)} \in \mathbb{Z}^t$ being a cycle of $B^{(i)}$. Hence, each $y^{(i)}$ can be decomposed into the sum of Graver basis elements $y_j^{(i)}$ of $B^{(i)}$, i.e. $y^{(i)} = y_1^{(i)} + \dots + y_{N_i}^{(i)}$. Thus, we have a decomposition

$$\begin{aligned} 0 &= (A^{(1)}, \dots, A^{(n)})y \\ &= A^{(1)}y^{(1)} + \dots + A^{(n)}y^{(n)} \\ &= A^{(1)}y_1^{(1)} + \dots + A^{(1)}y_{N_1}^{(1)} + \dots + A^{(n)}y_1^{(n)} + \dots + A^{(n)}y_{N_n}^{(n)} \\ &=: v_1 + \dots + v_N \in \mathbb{Z}^r \end{aligned}$$

for some $N = \sum_{i=1}^{n} N_i$ and $||v_i||_\infty \leq \Delta L_B$ for $i = 1, \dots, N$, using (6). Now we apply Steinitz to reorder the v_i s.t. each partial sum is bounded by $r\Delta L_B$ in the l_∞-norm. Again, if two partial sums were the same, we could decompose y, thus the number N of vectors

v_i is bounded by $(2r\Delta L_B + 1)^r$. Each v_i is of the form $A^{(j)}y_k^{(j)}$ for some j and k with $\|y_k^{(j)}\|_1 \leq L_B$, hence

$$\begin{aligned} ||y||_1 &\leq L_B \left(2r\Delta L_B + 1\right)^r \\ &= L_{\mathcal{A}}, \end{aligned}$$

finishing the proof. ◀

As $L_B \in \mathcal{O}(s\Delta)^s$ in our case, this shows $L_{\mathcal{A}} \in \mathcal{O}(rs\Delta)^{(r+1)(s+1)}$, as stated in point *ii*) in the previous chapter.

3 Solving the Generalized n-fold IP

Given a feasible solution x of the IP (5) we now follow the principle that we outlined in Section 1.1. There exists an element y of the Graver basis of $\mathcal{A}$ and a positive integer $\lambda \in \mathbb{N}$ such that $x + \lambda y$ is feasible and reduces the gap to the optimum value by a factor of $1 - 1/(2n)$. Suppose that we know λ. With our bound on $\|y\|_1 \leq L_A$ we will find an augmenting vector of at least this quality by solving (a relaxation of) the following *augmentation IP*:

$$\begin{aligned} \max\, & c^T y \\ & \mathcal{A}y = 0 \\ & ||y||_1 \leq L_{\mathcal{A}} \\ l - z \leq\, & \lambda y \leq u - z \\ & y \in \mathbb{Z}^{nt} \end{aligned} \tag{7}$$

The vector y we compute might violate the condition $||y||_1 \leq L_{\mathcal{A}}$, but we will have that $c^T y$ is at least as big as the optimum value of (7).

▶ **Lemma 4.** *Let λ be a fixed positive integer. In time $nt\,(rs\Delta)^{\mathcal{O}(r^2s+rs^2)}$, we can find an integral vector y with $Ay = 0$, $l - z \leq \lambda y \leq u - z$ and $c^T y \geq c^T y^\star$, where $y^\star$ is an optimum solution for (7).*

Proof. As λ is fixed, it will be convenient to rewrite the bounds on the variables as

$$\begin{aligned} & l^\star \leq y \leq u^\star \quad \text{with} \\ & l_i^\star = \max\left\{ \left\lceil \frac{l_i - z_i}{\lambda} \right\rceil, -L_{\mathcal{A}} \right\} \\ & u_i^\star = \min\left\{ \left\lfloor \frac{u_i - z_i}{\lambda} \right\rfloor, L_{\mathcal{A}} \right\}. \end{aligned} \tag{8}$$

In particular, $u^\star < \infty$. First observe that for each $y \in \mathbb{Z}^{nt}$ with $||y||_1 \leq L_{\mathcal{A}}$, one has

$$||\mathcal{A}y||_\infty \leq \Delta L_{\mathcal{A}}. \tag{9}$$

We can decompose $y = (y^{(1)}, \ldots, y^{(n)})$ into bricks according to the matrices $B^{(i)}$, and $B^{(k)}y^{(k)} = 0$ has to hold independently of the other variables. Let $U \subseteq \mathbb{Z}^{r+s}$ be the set of integer vectors of infinity norm at most $\Delta L_{\mathcal{A}}$. To find an optimal $y^\star$ for the augmentation IP (7) we construct the following acyclic digraph. There are two nodes 0_{start} and 0_{target}, together with nt copies of the set U, arranged in n blocks of t layers as

$$U_1^{(1)}, \ldots, U_t^{(1)}, U_1^{(2)}, \ldots, U_t^{(2)}, \ldots, U_1^{(n)} \ldots U_t^{(n)},$$

where the k-th block will correspond to the matrix

$$M^{(k)} := \begin{pmatrix} A^{(k)} \\ B^{(k)} \end{pmatrix}$$

(and thus to the brick $y^{(k)}$ of y). Writing $M^{(k)}_j$ for the j-th column of the matrix $M^{(k)}$, the arcs are given as follows. There is an arc from 0_{start} to $v \in U^{(1)}_1$ if there is an integer y_1 such that

$$v = y_1 M^{(1)}_1 \quad \text{and} \quad l^\star_1 \leq y_1 \leq u^\star_1$$

holds. The weight of this arc is $c_1 y_1$.

For two nodes $u \in U^k_{i-1}$ and $v \in U^k_i$ of two consecutive layers in the same block, we add an arc (u, v) if there is an integer $y_{(k-1)t+i}$ such that

$$v - u = y_{(k-1)t+i} M^{(k)}_i \quad \text{and} \quad l^\star_{(k-1)t+i} \leq y_{(k-1)t+i} \leq u^\star_{(k-1)t+i}$$

holds, i.e. if we can get from u to v by adding the i-th column of $\binom{A^{(k)}}{B^{(k)}}$ multiple times. The weight is $c_{(k-1)t+i} \cdot y_{(k-1)t+i}$. It remains to define the arcs between two blocks. If we fix a path through the whole block $U^{(k)}_1, \ldots, U^{(k)}_t$, this corresponds to fixing a brick $y^{(k)}$. Note that $M^{(k)} y^{(k)}$ has to be zero in the last s components, since continuing with this path in the next block will not change the entries of $\mathcal{A}y$ corresponding to $B^{(k)}$ any more. Thus, for placing an arc between two nodes $u \in U^k_t$ and $v \in U^{k+1}_1$ in two consecutive layers of different blocks, also the constraints $u_{r+1} = \cdots = u_{r+s} = 0$ have to be fulfilled.

Finally, we add arcs from $u \in U^{(n)}_t$ to 0_{target} if there exists an integer y_{nt} such that

$$-u = y_{nt} M^{(n)}_t \quad \text{and} \quad l^\star_{nt} \leq y_{nt} \leq u^\star_{nt}$$

holds. Again, the weight is $c_{nt} y_{nt}$.

Clearly, a longest $(0_{start} - 0_{target})$-path corresponds to an optimum solution of the augmentation IP (7), hence it is left to limit the time needed to find such a path.

The out-degree of each node is bounded by $u^\star_i - l^\star_i \leq 2L_{\mathcal{A}} + 1$ using (8). Therefore, the number of arcs is bounded by

$$\begin{aligned} nt \cdot |U| \cdot (2L_{\mathcal{A}} + 1) &= nt \left(2\Delta L_{\mathcal{A}} + 1\right)^{r+s} (2L_{\mathcal{A}} + 1) \\ &\leq nt \left(2\Delta L_{\mathcal{A}} + 1\right)^{r+s+1} \\ &\leq nt \left(2\Delta L_B \left(2r\Delta L_B + 1\right)^r + 1\right)^{r+s+1} \\ &= nt \cdot \mathcal{O}(\Delta r)^{r^2 s + r s^2 + o(r^2 s + r s^2)} \mathcal{O}(s)^{r^2 + rs + r}. \end{aligned}$$

We can find a shortest path by a Breadth-First Search in time linear in the number of edges. ◀

In the following lemma we consider the value $\Gamma := \max_i(u_i - l_i)$. In the case $u < \infty$, we can estimate $\Gamma \leq 2^\varphi$ and obtain a fixed running time in combination with Lemma 4. However, if there are variables present that are not bounded from above, we will combine this lemma with the proximity result of the next Section 3.1 which allows us to introduce artificial upper bounds $u' < \infty$.

▶ **Lemma 5.** *Consider the n-fold IP (5) with $u < \infty$. Let $\Gamma := \max_i(u_i - l_i)$. Given an initial feasible solution, we can find an optimum solution of the IP by solving the augmentation IP (7) for a constant $\lambda \in \mathbb{Z}_+$ at most*

$$\mathcal{O}\left(nt \log(\Gamma) \left(\log(nt\Gamma) + \varphi\right)\right)$$

times, where φ is the logarithm of the largest number occurring in the objective function c.

Proof (sketch). As previously discussed, for every feasible z there exists a pair (λ, y) s.t. $z + \lambda y$ is feasible and reducing the gap to the optimum value by $1 - 1/(2\,nt)$. This leads to roughly $nt \log(nt\,||c||_\infty \Gamma)$ iterations. If we only guess values for λ that are a power of 2, we only lose a constant factor but are able to limit the number of guesses. We refer to the full version of the paper for details. ◀

3.1 Proximity for n-fold IPs

If no explicit upper bounds are given (i.e. $u_i = \infty$ for some indices i), we cannot bound the number of necessary augmentation steps directly. To overcome this difficulty, we will present a proximity result in this section, stating that for an optimum rational solution $x^\star$, there exists an optimum integral solution $z^\star$ with $||x^\star - z^\star||_1 \leq ntL_{\mathcal{A}}$.

With this proximity result, we can first compute an optimum LP solution $x^\star$, and then introduce artificial box constraints $l(x^\star) \leq z \leq u(x^\star)$, depending on $x^\star$, knowing that at least one optimum IP solution lies within the introduced bounds.

▶ **Lemma 6.** *Let $x^\star$ be an optimum solution to the LP relaxation of (5). There exists an optimum integral solution $z^\star$ to (5) with*

$$||x^\star - z^\star||_1 \leq ntL_{\mathcal{A}} = nt(rs\Delta)^{\mathcal{O}(rs)}.$$

Proof. Let $x^\star$ be an optimum vertex solution of the LP relaxation of (5) and $z^\star$ be an optimum (integral) solution of (5) that minimizes the l_1-distance to $x^\star$.

We say a vector y *dominates* a cycle y' if they are sign-compatible and $|y'_i| \leq |y_i|$ for each i. The idea is to show that if the l_1-distance is too large, we can find a cycle dominated by $z^\star - x^\star$ and either add it to $x^\star$ or subtract it from $z^\star$ leading to a contradiction in both cases. However, as $z^\star - x^\star$ is fractional, we cannot decompose it directly but have to work around the fractionality.

To this end, denote with $\lfloor x^\star \rceil$ the vector $x^\star$ rounded towards $z^\star$ i.e. $\lfloor x^\star_i \rceil = \lfloor x^\star_i \rfloor$ if $z^\star_i \leq x^\star_i$ and $\lfloor x^\star_i \rceil = \lceil x^\star_i \rceil$ otherwise. Denote with $\{x^\star\}$ the fractional rest i.e. $\{x^\star\} = x^\star - \lfloor x^\star \rceil$. Consider the equation

$$\mathcal{A}\,(z^\star - x^\star) = \mathcal{A}\,(z^\star - \lfloor x^\star \rceil) - \mathcal{A}\{x^\star\} = 0.$$

Consider the integral vector $\mathcal{A}\{x^\star\}$. For each index i, we will obtain an integral vector w_i out of $\{x^\star\}_i \mathcal{A}_i$ by rounding the entries suitably such that

$$\mathcal{A}\{x^\star\} = \sum_{i=1}^{nt} (\{x^\star\}_i \mathcal{A}_i) = w_1 + \cdots + w_{nt}.$$

To be more formal, fix an index j and let $a_1, \ldots, a_{nt}$ denote the j-th entry of the vectors $\{x^\star\}_i \mathcal{A}_i$. Define $f := \left(\sum_{i=1}^{nt} a_i - \lfloor a_i \rfloor\right) \in \mathbb{Z}_+$ as the sum of the fractional parts. We round up f of the fractional entries a_i, and we round down all other fractional entries. If some a_i is integral already, it remains unchanged. After doing this for each component j, we obtain the vectors w_i as claimed. As $||\{x^\star\}||_\infty \leq 1$, each vector w_i is dominated by either $\mathcal{A}_i$ or $-\mathcal{A}_i$, in particular it inherits the zero entries.

Define the matrix

$$\mathcal{A}' := (w_1, \ldots, w_{nt})\,.$$

After permuting the columns, the matrix $(\mathcal{A}, -\mathcal{A}')$ has n-fold structure with parameters $r, s, 2t$. As Lemma 3 does not depend on t, the Graver basis elements of $(\mathcal{A}, -\mathcal{A}')$ are bounded

by $L_{\mathcal{A}}$ as well. We can now identify

$$\mathcal{A}(z^\star - x^\star) = (\mathcal{A}, -\mathcal{A}') \begin{pmatrix} z^\star - \lfloor x^\star \rceil \\ \mathbf{1}_{nt} \end{pmatrix} = 0,$$

and decompose the integral vector $\binom{z^\star - \lfloor x^\star \rceil}{\mathbf{1}_{nt}}$ into Graver basis elements of l_1-norm at most $L_{\mathcal{A}}$. But if

$$ntL_{\mathcal{A}} < ||z^\star - x^\star||_1 \leq \left|\left| \begin{pmatrix} z^\star - \lfloor x^\star \rceil \\ \mathbf{1}_{nt} \end{pmatrix} \right|\right|_1,$$

we obtain at least $nt + 1$ cycles. As $||\mathbf{1}_{nt}||_1 = nt$, this grants a cycle $\binom{\bar{y}}{\mathbf{0}_{nt}}$ and hence a cycle $\bar{y}$ of $\mathcal{A}$.

Case 1: $c^T\bar{y} \leq 0$: As $\bar{y}$ is dominated by $z^\star - \lfloor x^\star \rceil$, removing cycle $\bar{y}$ from the solution gives a new solution $\bar{z} = z^\star - \bar{y}$ with $c^T\bar{z} \geq c^T z^\star$, which is closer to the fractional solution $x^\star$. However, this contradicts the fact that $z^\star$ was chosen to be a solution with minimal distance $||x^\star - z^\star||_1$.

Case 2: $c^T\bar{y} > 0$: As we rounded $x^\star$ towards $z^\star$ and $\bar{y}$ is dominated by $z^\star - \lfloor x^\star \rceil$, we can add $\bar{y}$ to $x^\star$ and obtain a better solution, contradicting its optimality. ◀

We are now able to state our main theorem.

▶ **Theorem 7.** *The generalized n-fold IP (5) can be solved in time*

$$n^2t^2\varphi \log^2 nt \cdot (rs\Delta)^{\mathcal{O}(r^2s+rs^2)} + \boldsymbol{LP}$$

where φ denotes the logarithm of the largest number occurring in the input, and $\boldsymbol{LP}$ denotes the time needed to solve the LP relaxation of (5).

We refer to the full paper for a detailed analysis of the running time.

4 Tree-Fold IPs

Given matrices $A^{(i)} \in \mathbb{Z}^{m_i \times n}$ and vectors $b^{(i)} \in \mathbb{Z}^{m_i}$ for $i = 1, \ldots, N$ and $c, l, u \in \mathbb{Z}^n$ for some $n, N \in \mathbb{Z}_+$, $m_1, \ldots, m_N \in \mathbb{Z}^+$. We consider the following IP consisting of a system of (systems of) linear equations

$$\begin{aligned} \max\, & c^T x \\ & A^{(1)}x = b^{(1)} \\ & \qquad \vdots \\ & A^{(N)}x = b^{(N)} \\ & l \leq x \leq u \\ & x \in \mathbb{Z}^n. \end{aligned} \tag{10}$$

We call (10) a *tree-fold IP*, if for every matrix $A^{(i)}$ there is an index set $S(i)$ containing all indices of the non-zero columns of $A^{(i)}$, i.e.

$$S(i) \supseteq \left\{ j \mid A^{(i)}_j \neq 0 \right\},$$

such that the following two conditions hold. For all i, j, the sets $S(i), S(j)$ are either disjoint, or one of the sets is contained in the other. There is a matrix $A^{(i_0)}$ for which $S(i_0)$ contains all column indices.

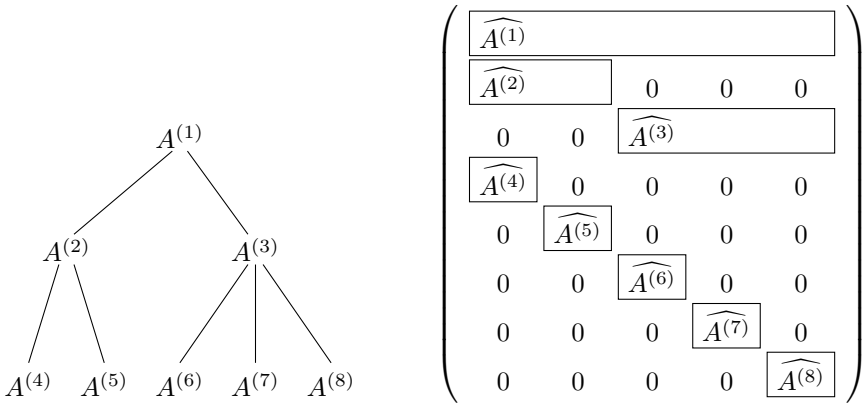

Figure 1 A matrix tree T and the induced tree-fold matrix $\mathcal{T}$, where $\widehat{A^{(i)}}$ denotes the part of $A^{(i)}$ that consists of the columns with index in $S(i)$. Note that if $A^{(1)}$ was not present, the set of columns of $\mathcal{T}$ could be bipartitioned into two sets orthogonal to each other.

Intuitively, the partial ordering induced by the sets $S(i)$ forms a tree T on the matrices $A^{(i)}$ (if the arcs stemming from transitivity are omitted). The root of this tree is the matrix $A^{(i_0)}$ with the largest set $S(i_0)$.

Analogously to our n-fold results, we will provide an upper bound on the l_1-norm of Graver basis elements of tree-fold matrices, together with a proximity result for optimum solutions. This will be sufficient to obtain an algorithm with a comparable running time.

Throughout this section, T will denote a tree as in Figure 1, we will denote the depth by τ and enumerate the layers starting at the deepest leaves (the leaves are not necessarily all in the same layer). The whole matrix induced by a tree-fold IP will be denoted by $\mathcal{T}$. This is, the IP (10) can be rewritten as

$$\begin{aligned} \max\, & c^T x \\ & \mathcal{T}x = b \\ & l \le x \le u \\ & x \in \mathbb{Z}^n \end{aligned} \tag{11}$$

▶ **Lemma 8.** *Let $\mathcal{T}$ be a tree-fold matrix where the corresponding matrix tree T has τ layers. Let the matrices of layer i have at most s_i rows and define $s = \prod_{i=1}^{\tau}(s_i+1)$ and $\Delta := ||\mathcal{T}||_\infty$. Then the Graver basis elements of $\mathcal{T}$ are bounded in their l_1-norm by*

$$L_\tau \le (3s\Delta)^{s-1}\,.$$

Proof (sketch). We enumerate the layers of T starting at the layer with the deepest leaves. We prove the claim by induction on the number τ of layers in the tree T. First observe that for $\tau = 1$, the claim follows by Lemma 2, as

$$L_1 \le (2s_1\Delta + 1)^{s_1} \le (3s\Delta)^{s-1}.$$

For the induction step, note that every child matrix $A^{(i)}$ of the root in T can be seen as the root matrix of a subtree T_i in T of depth $\tau - 1$ with at most $s_1, \dots, s_{\tau-1}$ rows in the corresponding layers. More formal, delete the root $A^{(1)}$ in T and let T_i be the connected component $A^{(i)}$ is in. Write

$$\widetilde{s} = \prod_{i=1}^{\tau-1}(s_i+1),$$

i.e. $s = \widetilde{s}(s_\tau + 1)$. By induction, we know that all Graver basis elements of the subtree-fold IPs $\mathcal{T}_i$ induced by T_i are bounded by

$$L_{\tau-1} \leq (3\widetilde{s}\Delta)^{\widetilde{s}-1} \leq (3s\Delta)^{\widetilde{s}-1}. \tag{12}$$

The rest of the induction step works similar to the proof of Lemma 3. We pick a cycle y of $\mathcal{T}$, decompose it into Graver basis elements for the subtree-fold matrices $\mathcal{T}_i$ and obtain a Steinitz sequence of vectors bounded by the induction hypothesis. However, due to space constraints, we omit the remaining part of this proof and refer to the full version of the paper. ◀

The following lemma states a proximity result for tree-fold IPs in the flavour of Lemma 6 for n-fold IPs. The proof uses that the bound in Lemma 8 only depends on the shape of the matrix but is independent of the number of columns in each block $A^{(i)}$, precisely as in Lemma 6. We refer to the full version of the paper for details on the proof.

▶ **Lemma 9.** *Let $\mathcal{T}$ be a matrix of tree-fold structure corresponding to the IP (10) and let $x^\star$ be an optimum solution to the LP relaxation of (10). There exists an optimum integral solution $z^\star$ to (10) with*

$$||x^\star - z^\star||_1 \leq nL_\tau.$$

We conclude with the following theorem that states the running time of our algorithm to solve a tree-fold IP. For a detailed analysis of the running time, we refer to the full version of the paper.

▶ **Theorem 10.** *Let $\mathcal{T}$ be of tree-fold structure with infinity-norm Δ and corresponding tree T. Let τ denote the number of layers of T and let the matrices of layer i have at most s_i rows.*

Define $s = \prod_{i=1}^{\tau}(s_i + 1)$ and $\sigma = \sum_{i=1}^{\tau} s_i$. Let n denote the number of columns of $\mathcal{T}$ and $l, u \in (\mathbb{Z} \cup \{\infty\})^n$. We can solve the IP (11),

$$\begin{aligned} \max\, & c^T x \\ & \mathcal{T}x = b \\ & l \leq x \leq u \\ & x \in \mathbb{Z}^n \end{aligned}$$

in time

$$n^2\varphi \log^2 n (s\Delta)^{\mathcal{O}(\sigma s)} + \boldsymbol{LP}$$

where φ denotes the logarithm of the largest number occurring in the input, and $\boldsymbol{LP}$ denotes the time needed to solve the LP relaxation of (11).

Abstract

In the Local Computation Algorithms (LCA) model, the algorithm is asked to compute a part of the output by reading as little as possible from the input. For example, an LCA for coloring a graph is given a vertex name (as a "query"), and it should output the color assigned to that vertex after inquiring about some part of the graph topology using "probes"; all outputs must be consistent with the same coloring. LCAs are useful when the input is huge, and the output as a whole is not needed simultaneously. Most previous work on LCAs was limited to bounded-degree graphs, which seems inevitable because probes are of the form "what vertex is at the other end of edge i of vertex v?". In this work we study LCAs for unbounded-degree graphs. In particular, such LCAs are expected to probe the graph a number of times that is significantly smaller than the maximum, average, or even minimum degree. We show that there are problems that have very efficient LCAs on any graph - specifically, we show that there is an LCA for the weak coloring problem (where a coloring is legal if every vertex has a neighbor with a different color) that uses $\log^* n + O(1)$ probes to reply to any query. As another way of dealing with large degrees, we propose a more powerful type of probe which we call a *strong* probe: given a vertex name, it returns a list of its neighbors. Lower bounds for strong probes are stronger than ones in the edge probe model (which we call *weak* probes). Our main result in this model is that roughly $\Omega(\sqrt{n})$ strong probes are required to compute a maximal matching.

Our findings include interesting separations between closely related problems. For weak probes, we show that while weak 3-coloring can be done with probe complexity $\log^* n + O(1)$, weak 2-coloring has probe complexity $\Omega(\log n / \log\log n)$. For strong probes, our negative result for *maximal* matching is complemented by an LCA for $(1-\epsilon)$-approximate *maximum* matching on regular graphs that uses $O(1)$ strong probes, for any constant $\epsilon > 0$.

1 Introduction

In classical algorithmic models, an algorithm is given an input and is required to compute an output. When dealing with truly massive data, such as the Internet, just reading the entire input may be impractical. The model of *local computation algorithms* (LCAs), as studied by Rubinfeld et al. [33], proposes the following approach. An algorithm in the LCA model is required to produce only a part of the output specified by a "query," and is expected to access only a small part of the input (without any pre-processing) using some simple "probes." For example, an LCA for maximal independent set (MIS) is given a vertex ID as a query, and is expected to return a "yes/no" answer, indicating whether the queried vertex is or is not in the MIS; all replies to queries must be consistent with the same MIS. To do that, the LCA can use probes of the form "which vertex is the ith neighbor of vertex v?", where v and i are the probe arguments. One of the main goals in LCA design is to minimize the number of probes required to produce an answer to a query.

In this paper we consider LCAs for graph problems. Almost exclusively, known LCAs for graph problems are efficient only for graphs of bounded degrees (with the notable exception of [20], which gives LCAs with polylog probe complexity for graphs with polylog degree). This may appear inevitable, because edge probes don't allow sublinear solutions to even learn a complete neighborhood of a linear-degree vertex. Our goal in this paper is to understand what *can* be done efficiently for graphs with unbounded degrees. We give two types of answers. First, we point to problems that admit efficient solutions for any graph. In particular, we give efficient LCAs for weak coloring [29], where the goal is to color vertices so that each vertex has a neighbor of a different color. Weak coloring has played a key role in the study of distributed algorithms e.g., [29, 10], in part due to its applications to resource allocations in distributed settings [25]. Hence it is natural that we study it in the context of LCAs. Moreover, this study has turned out to be worthwhile, because the results were unexpected: in our model there is a separation between weak 2-coloring and weak 3-coloring that was not observed in other models.

As another way of dealing with large degrees, we propose a more powerful probe model, where probing a vertex returns a list of all its neighbors. We call such probes "strong," as opposed to the "weak" edge probes. Lower bounds in this model consider the number of connections the LCA needs to make in order to probe the graph, even if communication along these channels is unbounded, and are stronger than lower bounds in the weak probe model. Strong probes can be thought of as an intermediate model that lies between the weak probe model and the distributed $\mathcal{LOCAL}$ model, and helps clarify the sources of differences between these two extremes. Our main negative result in this model is that approximately $\Omega(\sqrt{n})$ strong probes are required to compute a maximal matching.

Our results include the following. Let *WP* and *SP* stand for weak and strong probes, respectively and let n denote the number of nodes in the underlying graph. We give tight upper and lower bounds for weak 3-coloring. Our algorithm is deterministic and uses weak probes, whereas our lower bound holds also for randomized LCAs that may use strong probes.

▶ **Theorem 1.** *There exists a deterministic WP LCA for weak* 3*-coloring that uses* $\log^* n + O(1)$ *probes.*

▶ **Theorem 2.** *Every (randomized or deterministic) SP LCA for weak* 3*-coloring of the cycle graph requires* $\Omega(\log^* n)$ *probes.*

We describe a deterministic WP LCA for weak 2-coloring, and give a matching lower bound for graphs with maximal degree $d = O\left(\frac{\log n}{\log\log n}\right)$.

▶ **Theorem 3.** *There exists a deterministic WP LCA for weak* 2*-coloring that uses* $\log^* n + 2d_v + O(1)$ *weak probes, where* d_v *is the degree of the queried vertex.*

▶ **Theorem 4.** *Any deterministic WP LCA for weak* 2*-coloring* d*-regular graphs with* $d = O\left(\frac{\log n}{\log\log n}\right)$ *requires at least* $d/2$ *probes.*

We design a randomized LCA for weak 2-coloring, whose probe complexity is independent of the maximal degree and show how it can be implemented in both the strong and weak probe models.

▶ **Theorem 5.** *There exists a randomized WP LCA for weak* 2*-coloring that uses* $\Theta\left(\frac{\log^2 n}{\log\log n}\right)$ *probes, and a randomized SP LCA for weak* 2*-coloring that uses* $\Theta\left(\frac{\log n}{\log\log n}\right)$ *probes.*

We give a lower bound for vertex cover in the strong probe model. Specifically, we show that for high degree graphs, many strong probes are necessary to approximate a minimal vertex cover to any interesting precision.

▶ **Theorem 6.** *For any* $\epsilon < \frac{1}{2}$*, any randomized SP LCA that computes a vertex cover whose size is a* $(\frac{1}{2}n^{1-2\epsilon})$*-approximation to the size of the minimal vertex cover requires at least* ϵn^{ϵ} *probes.*

A corollary of Theorem 6 is the following.

▶ **Corollary 7.** *Any SP LCA for maximal matching on arbitrary graphs requires* $n^{1/2-o(1)}$ *probes.*

We describe an LCA that finds a matching that is a $(1-\epsilon)$-approximation to the maximum matching, for regular graphs, using a constant number of probes.

▶ **Theorem 8.** *There exists an SP LCA that finds a* $(1-\epsilon)$*-approximate maximum matching in expectation on* d*-regular graphs that uses* $\epsilon^{-O(\epsilon^{-2})}$ *probes per query.*

Finally, we show that for graphs with sufficiently high girth and degree, polynomially (in ϵ^{-1}) many strong probes suffice.

▶ **Theorem 9.** *There exists an SP LCA that finds a* $(1-\epsilon)$*-approximate maximum matching in expectation on* d*-regular graphs of girth* g*, with* $d \geq \epsilon^{-1}$ *and* $g \geq \epsilon^{-3}$*, that uses* $O(\epsilon^{-7})$ *probes per query.*

1.1 Overview of Our Techniques

Our main result in this abridged version is the proof of Theorem 6. We construct a family of bipartite graphs in which a large subset of vertices have "almost" the same view at distance 2. Exactly one of these vertices, v_0, needs to be added to the vertex cover; however, there are many vertices for which a small number of strong probes does not suffice in order to

verify that they are not v_0, and hence they must add themselves to the vertex cover. In our construction we use vertex naming schemes based on low degree polynomials to ensure that certain vertices do not share many neighbors. This result gives a separation between the SP model (and hence also the WP model) and the $\mathcal{LOCAL}$ model, as it is possible to compute a maximal matching in the $\mathcal{LOCAL}$ model in $O(\log n)$ rounds w.h.p. [24].

In the full version of the paper [9] we discuss deterministic and randomized methods of sampling a "parent" for each vertex. No matter how the parents are chosen, the resulting graph is a disjoint set of directed subgraphs, each one containing exactly one cycle. The main technical content of here is the analysis of the diameter of these subgraphs, depending on the choice of parent selection scheme.

We then address the problem of weak 3-coloring. Our LCA (the proof of Theorem 1) is based on the following approach. Given an arbitrary graph, the directed subgraphs formed by the parent relation (as above) span all vertices, and each of their connected components has at least two vertices. Hence any weak coloring of every component separately induces a weak coloring of the whole graph. Each component has one cycle, but it turns out that the 3-coloring algorithm for rooted trees of Goldberg, Plotkin and Shannon [13] can be adapted in order to legally 3-color (and hence also weakly 3-color) such a component. When implemented as an LCA, the upper bound of $\log^* n + O(1)$ on the number of probes follows from a similar upper bound on the number of rounds of the (modified) algorithm of [13]. To prove a nearly matching lower bound (Theorem 2) we use a reduction to the lower bound of Naor [28] (extending [21]) for distributed algorithms that legally 6-color a cycle. Adapting lower bounds from the distributed setting to the LCA setting also involves an argument of Göös et al. [15].

We show how to augment the previous algorithm in order to reduce the number of colors to 2, thus proving Theorem 3. It takes only one more probe to transform the weak 3-coloring to a weak 2-coloring that is legal for all vertices except for those vertices that do not serve as parents (which we refer to as *leaves*). The final step involves changing the colors of (some) leaves. In order to determine whether a vertex v is a leaf, we probe all of its neighbors, making the probe complexity linear in the degree of the queried vertex.

One natural method of proving lower bounds for LCAs is by reduction to the distributed $\mathcal{LOCAL}$ model, as was done in [15] (and as we do in the proof of Theorem 2). The relationship between LCAs and distributed algorithms has been studied before (e.g., [6, 31, 32, 33]) – given a distributed algorithm to a problem that takes t rounds, one immediately obtains an LCA that uses $O\left(d^t\right)$ probes (where d is the maximal degree), by probing all nodes within distance t. The inverse reduction doesn't work, as an LCA may probe remote (disconnected) nodes. Consider, for example, the following artificial problem: each vertex has to color itself blue if the node with ID 1 has an odd number of neighbors, and red otherwise. An LCA for this problem needs a single probe, while a distributed algorithm requires time proportional to the graph's diameter. Göös et al. [15] show that for many natural problems, probing remote vertices does not help. But even if we consider only probes to neighbors of discovered vertices, the best lower bound we can hope for using such a reduction is the distributed *time* lower bound: a lower bound of t rounds in the distributed model implies a lower bound of t probes in the LCA model (recall that an upper bound of t rounds in the distributed model implies an upper bound of $O\left(d^t\right)$ probes!). This suggests that we may need new tools to obtain stronger lower bounds. In the proof of Theorem 4, we iteratively construct families of d-regular graphs, where graphs in family F_i (for $i \leq d/2$) contain roughly d^i vertices, and we show that weak 2-coloring of graphs in family F_i requires at least i deterministic weak probes. Every graph G in family F_i is composed of d disjoint copies of graphs $H_1, \ldots, H_d$ from family

F_{i-1} and two auxiliary vertices a_i and b_i. From each graph H_j a single edge is removed, and instead one of its endpoints is connected to a_i and the other to b_i. Intuitively, it is reasonable to expect that a_i cannot decide on a color before it knows the color of at least one of its neighbors. Likewise, it is reasonable to expect that each neighbor, being a member of a graph in F_{i-1}, requires (by an induction hypothesis) $i-1$ probes. The combination of these two non-rigorous claims would imply that a_i requires at least i probes (one to determine the name of one of its neighbors, and $i-1$ probes so as to determine the color of that neighbor). Turning this informal intuition into a rigorous proof is nontrivial, and this is the main content of our proof of Theorem 4.

We design a randomized LCA for weak 2-coloring. A key aspect in our randomized LCA is that each vertex first chooses a random temporary color. This induces a weak 2-coloring for most vertices of the graph: each vertex whose temporary color differs from the temporary color of a neighbor can keep its color. Extending this weak 2-coloring to the remaining vertices is done by associating a parent with each vertex, with the intended goal that the color of the vertex will differ from the color of the parent (determining the color of the parent uses an inductive process). This aspect has several different implementations, leading to different probe complexities. Namely, for an arbitrary parent choice, the number of strong probes is $\Theta(\log n)$. If we implement the arbitrary choice using weak probes, the probe complexity is $\Theta(\log^2 n)$. For a more clever randomized choice of parent, we get that the strong probe complexity is $\Theta\left(\frac{\log n}{\log\log n}\right)$, and the weak probe complexity is $\Theta\left(\frac{\log^2 n}{\log\log n}\right)$. All these bounds on probe complexity hold with high probability.

We note that our results do not prove a separation between the complexities of deterministic and randomized WP LCAs for weak 2-coloring (although we conjecture that there is one), as our lower bound that is linear in the degree is proved only for regular graphs of degree at most $O\left(\frac{\log n}{\log\log n}\right)$, and our upper bound for randomized WP LCAs for weak 2-coloring is $O\left(\frac{\log^2 n}{\log\log n}\right)$.

Randomized LCAs generally use a pseudo-random generator in order to limit the number of bits that they use, while ensuring consistency (e.g., [1, 20, 32]). In order to explore the theoretical limitations of the probe complexity of LCAs, we assume that our randomized LCAs have unbounded access to random bits. Nevertheless, we show that one can implement the randomized WP LCA for weak 2-coloring (the one using the arbitrary parent choice scheme) using a pseudo-random generator with a seed of length $O(\log n)$.

We give an LCA for approximate maximum matching in regular graphs. We first describe an LCA for $(1-\epsilon)$ matching on graphs of degree bounded by d, that uses at most $\left(d+\frac{1}{\epsilon}\right)^{O\left(\epsilon^{-2}\right)}$ probes per query. (Alternatively, if we wish to have a better dependency on ϵ and are willing to have a dependency on n, then an LCA of Even, Medina and Ron [6] has probe complexity $d^{O\left(\frac{1}{\epsilon}\right)}+O\left(\frac{1}{\epsilon^2}\right)\log^* n$.) Our LCA $\mathcal{A}$ is a simple variation on a randomized LCA of Yoshida, Yamamoto and Ito [40]: whereas [40] does not limit the number of probes used by their LCA but instead analyze and provide upper bounds on the expected number of probes used by their LCA (expectation taken both other choice of random edge and randomness of the LCA), we run essentially the same LCA, but with a strict upper bound on the number of probes. This upper bound is a factor of $\frac{d}{\epsilon}$ larger than the expectation. Markov's inequality implies that this gives a $(1-\epsilon)$-approximation to the maximum matching in expectation.

To obtain an LCA for a d-regular graph G, if $d<\frac{1}{\epsilon^2}$ we use LCA $\mathcal{A}$. If $d>\frac{1}{\epsilon^2}$, we sparsify the graph: for some universal constant c (independent of ϵ), each edge remains in the graph with probability $\frac{c}{d\epsilon}$, and then all vertices that still have degree higher than $\frac{2c}{\epsilon}$ are removed from the graph. This results in a graph G' of degree bounded by $\frac{2c}{\epsilon}$. Every matching in G'

is a matching in G. Moreover, we show that the expected size of a maximum matching in G' (expectation taken over choice of random sparsification) is at least $(1 - \frac{\epsilon}{2})$ times the size of the maximum matching in G. Hence it suffices to find a $(1 - \frac{\epsilon}{2})$-approximate maximum matching in the bounded degree graph G', and it will serve as a $(1-\epsilon)$-approximate maximum matching in G. A sufficiently large matching in G' can be found by $\mathcal{A}$, using $\left(\frac{1}{\epsilon}\right)^{O\left(\frac{1}{\epsilon^2}\right)}$ probes to G' per query. To implement $\mathcal{A}$ on G', but using only probes to G, we show that each strong probe to G' can be simulated by $O(1/\epsilon)$ strong probes to G.

We show that we can find a $(1 - \epsilon)$-approximation to the maximum matching for regular graphs with sufficiently high degree and girth using polynomially (in $1/\epsilon$) many probes. Gamarnik and Goldberg [11] show that the randomized greedy algorithm finds a $(1 - \epsilon)$ approximation to the maximum matching on regular graphs with sufficiently high degree and girth. Similarly to the previous result, if the vertex degrees are sufficiently small (say, below $\frac{1}{\epsilon^3}$), we can use an LCA of [40] (an implementation of the randomized greedy algorithm that uses in expectation $O(d)$ probes in graphs of maximum degree d), while placing a strict upper bound on the number of probes (this upper bound is a factor of $\frac{1}{\epsilon^{O(1)}}$ larger than the expectation). If the degrees are large, our approach is once again to sparsify the graph G prior to using the LCA of [40] (modified to have a strict upper bound on the number of probes). Unfortunately, the resulting graph G' is only nearly regular but not actually regular. This requires us to extend the result of [11] from regular graphs to nearly regular graphs. We do so without relying on the proofs of [11], by the following approach. We add imaginary edges to G', making it regular (while maintaining high girth). The LCA now runs on a regular graph, and hence the bounds of [11] apply. The new problem that arises is that the matching that is output by the LCA might contain imaginary edges. However, we prove that the expected fraction of imaginary edges in that matching is similar to their fraction within the input graph (our proof uses both the high girth assumption and the fact that the randomized greedy algorithm is local in nature). This, combined with the fact that the fraction of imaginary edges in the input graph was small (because G' is nearly regular), implies that the imaginary edges can be discarded from the solution without significantly affecting the approximation ratio.

1.2 Related Work

Measures

There are several criteria by which one can measure the performance of LCAs. Rubinfeld et al. [33] focus on the time complexity of LCAs: how long it takes to reply to a query; Alon et al. [1] emphasize the space complexity, in particular, the length of the random seed used (randomized LCAs need a global random seed to ensure consistency). Mansour, Patt-Shamir and Vardi [26] introduce a unified model, that takes into account all four complexity measures: *probe complexity*, *time complexity* (per query) and space complexity, divided into *enduring memory* (in all known LCAs, this includes only the random seed) and *transient space* (the computational space used per query). They show that it is possible to obtain LCAs for which all of these are independent of n for certain problems, such as a $(1 - \epsilon)$ approximation to a maximal acyclic subgraph, using $d^{O(1/\epsilon)}$ probes, where d is the maximal degree of the graph. LCAs that do not use any enduring memory are called *stateless* [6]. Indeed, the deterministic algorithms in this paper are stateless. Another property that is considered desirable in LCAs is *query-obliviousness* [33]: the property that the replies to different queries do not depend on the order in which the queries are given. Again, the LCAs of this paper are all query-oblivious.

LCAs and high-degree graphs

As mentioned above, most known results assume bounded degrees. For example, Mansour et al. [27] describe LCAs for maximal matching and other problems that use polylogarithmic (in the size of the graph; exponential in the degree) time and space when the degrees of the graph are bounded by a constant. Even, Medina and Ron [6], focusing on probe complexity, give deterministic LCAs for MIS, maximal matching and $(d+1)$-coloring for graphs of degree bounded by a constant d, which use $d^{O(d^2)}\log^* n$ probes. Fraigniaud, Heinrich and Kosowski [10] investigate local conflict coloring, a general distributed labeling problem, and use their results to improve the probe complexity of $(d+1)$-vertex coloring to approximately $d^{O(\sqrt{d})}\log^* n$ probes.

Some papers allow for slightly super-constant degrees: Levi, Rubinfeld and Yodpinyanee [20] give LCAs for MIS and maximal matching for graphs of degree $2^{O(\sqrt{\log\log n})}$, using an improvement of Ghaffari [12]. Reingold and Vardi [32] give LCAs for MIS, maximal matching and other problems that apply to graphs that are sampled from some distribution. This limitation allows them to address graphs with higher maximal degree, as long as the average degree is $O(\log\log n)$, and the tail of the distribution is sufficiently light. If we restrict ourselves to LCAs that use polylogarithmic time and space, the approximate maximum matching LCA of [20] accommodates graphs of polylogarithmic degree. Levi, Ron and Rubinfeld [19] describe an LCA that constructs spanners using a number of probes polynomial in d.

Lower bounds

There are few explicit impossibility results LCAs. Göös et al. [15] show that any LCA for MIS requires $\Omega(\log^* n)$ probes, by showing that probing vertices that have not yet been discovered is not useful. This implies that, on a ring, the number of probes that an LCA needs to make is "roughly the same" as the number of rounds required by a distributed LOCAL algorithm, implying that the lower bounds of Linial [21] and Naor [28] hold for LCAs as well. Levi, Ron and Rubinfeld [19] show that an LCA that determines whether an edge belongs to a sparse spanning subgraph requires $\Omega(\sqrt{n})$ probes. Feige, Mansour and Schapire [8], adapting a lower bound from the property testing literature [14], show that approximating the minimum vertex cover in bounded degree bipartite graphs within a ratio of $1+\epsilon$ (for some explicit fixed $\epsilon > 0$) cannot be done with $o(\sqrt{n})$ probes.

Weak coloring

Weak coloring was introduced by Naor and Stockmeyer [29]. They give a LOCAL distributed algorithm that requires $\log^* d + O(1)$ rounds for weak 2-coloring graphs of maximal degree d, assuming all degrees are odd. In contrast, they show that there is no constant time LOCAL algorithm for weak c-coloring all graphs with vertices with even degrees, for constant c. Our deterministic weak 2-coloring LCA (Theorem 3) uses $\log^* n + O(d_v)$ probes, but when cast within the LOCAL model it takes $\log^* n + O(1)$ rounds (independently of d_v).

Additional LCA background

LCAs are not restricted to graphs. Well known examples include *locally-decodable codes* (LDCs) (e.g., [18, 39]) and local reconstruction (e.g., [17, 34]). LDCs are error-correcting codes that allow a single bit of the original message to be decoded with high probability by querying a small number of bits of a codeword. Local reconstruction involves recovering the

value of a function f for a particular input x given oracle access to a closely related function g. LCAs have recently been applied to solving convex problems in a distributed fashion [22]. Traditional methods for solving distributed optimization, such as iterative descent methods (e.g., [23]) and consensus methods (e.g., [4]), require global communication, and any edge failure or lag in the system immediately affects the entire solution, by delaying computation or causing it not to be computed at all; furthermore, if the network changes in a small way, the entire solution needs to be recomputed. If an LCA is used, most of the system remains unaffected by local changes or failures. Hence LCAs can be used to make systems more robust to edge failures, lag, and dynamic changes. LCAs have also been used in the context of mechanism design [16], machine learning [8], and designing distributed algorithms [7]. There are other situations when LCAs may be useful - say we wish to perform some computation on each of the vertices of an MIS of some huge graph. LCAs allow us to be able to begin work on some vertices before the entire MIS is computed, and guarantee that the local replies to the queries will be consistent with the same global solution, that will be available at some point in the future.

LCAs can also be used as subroutines in approximation algorithms e.g., [5, 31, 30, 40]. The goal of such algorithms is to output an approximation to the size of the solution to some combinatorial problem (such as Vertex Cover, Maximum Matching, Minimum Spanning Tree), in time sublinear in the input size. In particular, if one has an LCA whose running time is t that solves some problem, one can obtain an approximation to the size of the solution (with some constant probability) by executing this LCA on a sufficiently large (but constant) number of vertices k chosen uniformly at random, to obtain an approximation algorithm whose running time is kt (see e.g., [30, 36] for more details).

The concept of LCAs is related to but should not be confused with local algorithms as in [2, 3, 35]. The difference is that these local algorithms do not require the output for different probes to satisfy a global consistency property, but rather to satisfy some local criteria. For example, the goal might be for each vertex to output a small dense subgraph that contains it, without requiring two different vertices to agree on whether they share the same dense subgraph or not.

1.3 Paper Outline

Due to space restriction, we include a single result with complete proof in this version. See [9] for the full version of this paper.

2 Preliminaries

We denote the set of integers $\{1, 2, \ldots, n\}$ by $[n]$. All logarithms are base 2. Our input is a simple undirected graph $G = (V, E)$, $|V| = n$, in which every vertex has an ID and all IDs are distinct. For simplicity, we assume that the IDs are taken from the set $[n]$. The neighborhood of a vertex v, denoted $N(v)$, is the set of vertices that share an edge with v: $N(v) = \{u : (u, v) \in E\}$. The *degree* of a vertex v, is $|N(v)|$. The *girth* of G, denoted girth(G) is the length of the shortest cycle in G.

LCAs

Our definition of LCAs is slightly different from previous definitions in that it focuses on probe complexity. We do this so as not to introduce unnecessary notation. See [26, 36] for definitions that also take into account other complexity measures.

▶ **Definition 10** (Probe)**.** We assume that the input graph is represented as a two dimensional n by $d+1$ array, where d is the maximum degree. Rows are labeled from 1 to n by the vertex names. For any v, the cell $(v,0)$ specifies the degree d_v of v, the cell (v,j) for $1 \leq j \leq d_v$ specifies the name of the neighbor connected to v's jth port. Cells (v,j) for $d_v < j \leq d$ contain 0. We define strong and weak probes as follows.

- A *strong probe* (SP) specifies the ID of a vertex v; the reply to the probe is the entire row corresponding to v (namely, the list of all neighbors of v).
- A *weak probe* (WP) specifies a single cell (v,j) and receives its content (namely, only the j^{th} neighbor of v).

We note that knowing that u is v's i^{th} neighbor does not give us information regarding which one of u's ports v is connected to. This property is crucial for the proof of Theorem 4.

▶ **Definition 11** (Local computation algorithm)**.** A deterministic $p(n)$*-probe local computation algorithm* $\mathcal{A}$ for a computational problem is an algorithm that receives an input of size n. Given a query x, $\mathcal{A}$ makes at most $p(n)$ probes to the input in order to reply. $\mathcal{A}$ must be *consistent*; that is, the algorithm's replies to all of the possible queries combine to a single feasible solution to the problem.

A randomized $(p(n), s(n), \delta(n))$*-local computation algorithm* $\mathcal{A}$ differs from a deterministic one in the following aspects. Before receiving its input, it is allowed to write $s(n)$ random bits (referred to as the random *seed*) to memory.[4] Thereafter, it must behave like a deterministic LCA, except that when answering queries it may also read and use the random seed. For any input G, $|G| = n$, the probability (over the choice of random seed) that there exists a query in G for which $\mathcal{A}$ uses more than $p(n)$ probes is at most $\delta(n)$, which is called $\mathcal{A}$'s failure probability.

When LCA $\mathcal{A}$ is given input graph $G = (V, E)$ and queried on vertex $v \in V$, we denote this by $\mathcal{A}(G, v)$. An LCA $\mathcal{A}$ is said to *require* k probes on a graph $G = (V, E)$, if there is at least one query for which $\mathcal{A}$ uses k probes. We say that an LCA $\mathcal{A}$ requires k probes for a family F of graphs, if for some graph $G \in F$, $\mathcal{A}$ requires k probes.

▶ **Definition 12** (Approximation algorithm)**.** Given a maximization problem over graphs and a real number $0 \leq \alpha \leq 1$, a (possibly randomized) α-approximation algorithm $\mathcal{A}$ is guaranteed, for any input graph G, to output a feasible solution whose expected value is at least an α fraction of the value of an optimal solution (in expectation over the random bits used by $\mathcal{A}$).[5]

3 Lower Bound for Vertex Cover

In this section we prove Theorem 6:

▶ **Theorem 6.** *For any $\epsilon < \frac{1}{2}$, any randomized SP LCA that computes a vertex cover whose size is a $(\frac{1}{2}n^{1-2\epsilon})$-approximation to the size of the minimal vertex cover requires at least ϵn^{ϵ} probes.*

In order to prove Theorem 6 , we use the minimax theorem of Yao [38], by showing a lower bound on the expected number of probes required by a deterministic LCA when the input is selected from a certain distribution. To this end we construct, for infinitely many values of n, a family of graphs, parametrized by a constant $k \geq 3$.

[4] In this work, except where explicitly mentioned, we allow the random seed to be unbounded.
[5] The definition of approximation algorithms to minimization problems is analogous, with $\alpha \geq 1$.

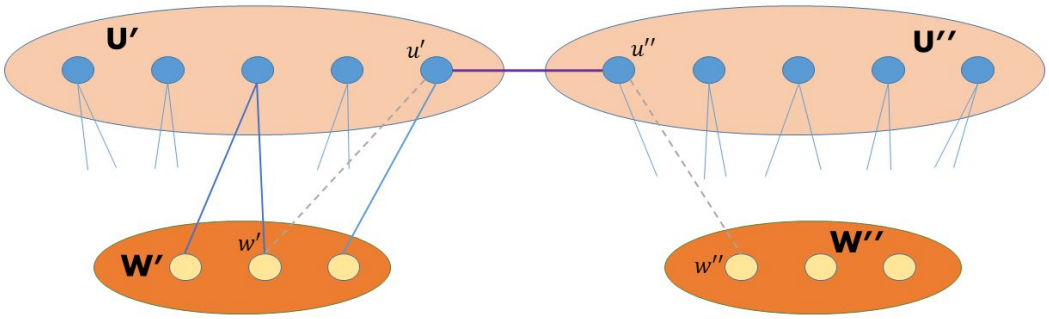

Figure 1 The graph fusion$(\mathbb{G}, (u', w'), (u'', w''))$. The dashed edges $e' = (u', w')$ and $e'' = (u'', v'')$ have been removed and the edge (u', u'') has been added.

Let p be a prime number, and $\mathbb{Z}(p)$ its associated field. Let $G^* = (U^* \cup W^*, E)$ be a bipartite graph, where $|U^*| = p^k$, $|W^*| = p^2$. Label each vertex in U^* by a k-tuple $(a_0, a_1, \ldots, a_{k-1})$, $a_i \in \mathbb{Z}(p), i \in \{0, 1, \ldots, k-1\}$ and the vertices in W^* by a pair (b_0, b_1), $b_i \in \mathbb{Z}(p), i \in \{0, 1\}$. Associate each vertex $u_j = (a_0, a_1, \ldots, a_{k-1}) \in U^*$ with the polynomial $f_j(x) = a_0 + a_1 x + \cdots + a_{k-1}x^{k-1}$. Connect $(b_0, b_1) \in W^*$ to u_j iff $b_1 = f_j(b_0)$.

▶ **Lemma 13.** *For every two different vertices $u_i, u_j \in U^*$, $N(u_i) \cap N(u_j) \leq k - 1$.*

Proof. Consider f_i and f_j, the polynomials associated with u_i and u_j respectively. Let $g(x) = f_i(x) - f_j(x)$. As g is not the zero polynomial, it has at most $k-1$ roots in $\mathbb{Z}(p)$. ◀

Let $\mathbb{G}$ to be a graph consisting of two identical copies of G^*. We denote these two copies by $G' = (U' \cup W', E')$ and $G'' = (U'' \cup W'', E'')$. Let $U = U' \cup U''$; let $W = W'' \cup W''$; let $n = |U \cup W| = 2(p^k + p^2)$.

We define the following operation on $\mathbb{G}$ (see Figure 1). Let e' and e'' be edges such that $e' = (u', w') : u' \in U', w' \in W'$ and $e'' = (u'', w'') : u'' \in U'', w'' \in W''$. Remove e' and e'' from $\mathbb{G}$, and add an edge $e = (u', u'')$. We call this operation fusion$(\mathbb{G}, e', e'')$, and call u and u' the *fusion vertices*. Note that there are p^{k+1} possible choices for e' and p^{k+1} possible choices for e''.

Given a graph $G =$ fusion$(\mathbb{G}, (u', w'), (u'', w''))$, the optimal size of the vertex cover of G is at most $2p^2 + 1$, as W and a fusion vertex constitute a vertex cover.

Note that a vertex can locally detect whether it is in U or in W just by looking at its own degree. However, to detect whether it is one of the fusion vertices, it needs to determine the degrees of its neighbors, which is impossible to do with number of probes significantly smaller than its degree.[6]

We now describe the graph family we use. Let $\mathbb{G} = (U \cup W, E)$ be as above. Let Π be the set of all possible namings of $U \cup W$ by the ID set $[n]$. Let $T = E' \times E''$. Given a naming $\pi \in \Pi$ and a pair of edges $\tau = (e', e'') \in T$, the graph $\mathbb{G}(\tau, \pi)$ is defined as follows:

1. The topology of $\mathbb{G}(\tau, \pi)$ is given by fusion$(\mathbb{G}, e', e'')$.
2. The vertices of $\mathbb{G}(\tau, \pi)$ are named according to π.

The family of graphs we consider is $\mathcal{G}(\Pi, T) = \{\mathbb{G}(\tau, \pi) \mid \tau \in T, \pi \in \Pi\}$. We now analyze the behavior of a given deterministic LCA A with proble complexity less than p/k on a

[6] Compare this with a distributed algorithm in the LOCAL model, for which one round suffices to determine this.

graph chosen uniformly at random from $\mathcal{G}(\Pi, T)$. We first make the following simplification. Suppose that A running on some $\mathbb{G}(\tau, \pi)$ is given v as a query. If A probes w'_τ or w''_τ, it knows that v is neither u'_τ nor u''_τ and hence A need not include v in the VC. For simplicity, we also assume that if A probes u'_τ or u''_τ, it knows not to add v to the VC. Note that this only strengthens A, hence we can make this assumption without loss of generality.

We use the following definition.

▶ **Definition 14** (View)**.** Let $\mathcal{A}$ be a deterministic SP LCA. We denote by $\textsc{View}(\mathcal{A}, G, v)$ the subgraph that $\mathcal{A}$ discovers when queried on vertex v in graph G, i.e., the set of all probed vertices and their neighbors.

▶ **Lemma 15.** *Let $\mathcal{A}$ be an SP LCA with probe complexity less than p/k. Let $G \in \mathcal{G}(\Pi, T)$. Assume that A is queried on G with vertex v. Then there is some vertex $w \in N(v)$ such that w has no neighbors except v in $\textsc{View}(\mathcal{A}, G, v)$. (That is, neither w nor any of its neighbors (except v) is probed in $\mathcal{A}(G, v)$.)*

Proof. $\mathcal{A}$ probes v and, say, a vertices from U and b vertices from W, for some $a, b \in \mathbb{N}$ such that $a + b < p/k$. From Lemma 13, A sees at most $a(k-1)$ vertices from $N(v)$ as a result of probing vertices in $U \setminus \{v\}$. Furthermore, A sees at most b vertices from $N(v)$ as a result of probing vertices in W. As $a(k-1) + b < p = |N(v)|$, at least one vertex in $N(v)$ is only seen once, while probing v. ◀

Consider an input graph $\mathbb{G}(\tau, \pi)$, where $\tau = ((u'_\tau, w'_\tau), (u''_\tau, w''_\tau))$. We use the following notation.

- A_v denotes the event that $\mathcal{A}$ is given v as a query. Note that A_v is independent of π and τ.
- $X_{\tau,\pi,i}$ denotes the event that none of $u'_\tau, w'_\tau, u''_\tau, w''_\tau$ is probed when A is queried on $i \in [n]$.

▶ **Lemma 16.** *Fix π and τ. Let v be a vertex in $U' \setminus \{u'_\tau\}$. If A_v and $X_{\tau,\pi,\pi(v)}$ hold, there exist $\pi_1 \in \Pi, \tau_1 \in T$ such that $\textsc{View}(\mathcal{A}, \mathbb{G}(\pi_1, \tau_1), u'_{\tau_1}) = \textsc{View}(\mathcal{A}, \mathbb{G}(\pi, \tau), v)$.*

Proof. By Lemma 15, there is some vertex $w \in N(v)$ that has no neighbors other than v in $\textsc{View}(\mathcal{A}, G(\pi, \tau), v)$. Let π_1 be identical to π except that v and u'_τ are interchanged. Set $\tau_1 = ((v, w), e''_\tau)$. The lemma follows. ◀

A symmetrical argument holds for $v \in U'' \setminus \{u''_\tau\}$.

▶ **Lemma 17.** *Fix $\mathbb{G}$, and let $i \in [n]$ be the ID of the vertex given to a deterministic SP LCA $\mathcal{A}$ as a query. If the probe complexity of $\mathcal{A}$ is less than p/k, then $\Pr[X_{\tau,\pi,i}] \geq 1 - \frac{1}{kp}$, where the probability is over the choice of π and τ.*

Proof. Fix π. If A probes a vertices in U and b vertices in W, it will hit one of $u'_\tau, w'_\tau, u''_\tau, w''_\tau$ with probability at most $\frac{a}{p^k} + \frac{b}{p^2}$, over the choice of τ. Since $a, b \geq 0$ and $a + b \leq p/k$, the probability is maximized for $a = 0, b = p/k$. As this bound holds for any π, the result follows. ◀

Lemma 16 and Lemma 17 imply that when a deterministic SP LCA is queried on a vertex $u \in U$ from a random graph in $\mathcal{G}(T, \Pi)$, it cannot discern in less than p/k probes whether u is a fusion vertex with probability greater than $\frac{1}{kp}$. Hence the LCA must add vertex u to the VC, because at least one fusion vertex *must* be in the VC. Therefore, the size of the VC that A computes is at least $p^k - O(1)$, whereas the optimal VC has size at most $p^2 + 1$:

▶ **Theorem 18.** *There does not exist a deterministic SP LCA A that computes a VC that is an $(\frac{1}{2}n^{1-2\epsilon})$-approximation to the optimal VC and uses fewer than ϵn^{ϵ} probes with probability greater than $\frac{1}{kp}$ on a graph chosen uniformly at random from $\mathcal{G}(\Pi, T)$.*

Proof. Let $\epsilon = 1/k$. Recall that $n = \Theta(p^k)$. We have shown that if the number of probes is less than $p/k = \Theta(n^{\epsilon} \cdot \epsilon)$, then the approximation ratio is at least $p^k/p^2 - o(1) = n^{1-2/k} - o(1)$. ◀

Applying Yao's principle [38] to Theorem 18 completes the proof of Theorem 6.

▶ **Corollary 19.** *Any SP LCA for maximal matching on arbitrary graphs requires $\Omega(n^{1/2-o(1)})$ probes.*

Proof. It is well known that, given any maximal matching, taking both end vertices of every edge gives a 2-approximation to the VC (e.g., [37]). Therefore, an LCA for maximal matching would immediately give a 2-approximation to the minimal vertex cover. Setting $2 = \Theta(n^{1-2\epsilon})$ in Theorem 6 gives $\epsilon = 1/2$. The result follows. ◀

Abstract

We study the classic BIN PACKING problem in a fully-dynamic setting, where new items can arrive and old items may depart. We want algorithms with low asymptotic competitive ratio *while repacking items sparingly* between updates. Formally, each item i has a *movement cost* $c_i \geq 0$, and we want to use $\alpha \cdot OPT$ bins and incur a movement cost $\gamma \cdot c_i$, either in the worst case, or in an amortized sense, for α, γ as small as possible. We call γ the *recourse* of the algorithm. This is motivated by cloud storage applications, where fully-dynamic BIN PACKING models the problem of data backup to minimize the number of disks used, as well as communication incurred in moving file backups between disks. Since the set of files changes over time, we could recompute a solution periodically from scratch, but this would give a high number of disk rewrites, incurring a high energy cost and possible wear and tear of the disks. In this work, we present optimal tradeoffs between number of bins used and number of items repacked, as well as natural extensions of the latter measure.

1 Introduction

Consider the problem of data backup on the cloud, where multiple users' files are stored on disks (for simplicity, of equal size). This is modeled by the BIN PACKING problem, where the items are files and the bins are disks, and we want to pack the items in a minimum number of bins. However, for the backup application, files are created and deleted over time. The storage provider wants to use a small number of disks, and also keep the communication costs incurred by file transfers to a minimum. Specifically, we want bounded "recourse", i.e., items should be moved sparingly while attempting to minimize the number of bins used in the packing. These objectives are at odds with each other, and the natural question is to give optimal tradeoffs between them.

Formally, an instance $\mathcal{I}$ of the BIN PACKING problem consists of a list of n items of sizes $s_1, s_2, \ldots, s_n \in [0, 1]$. A bin packing algorithm seeks to pack the items of $\mathcal{I}$ into a small number of unit-sized bins; let $OPT(\mathcal{I})$ be the minimum number of unit-sized bins needed to pack all of $\mathcal{I}$'s items. This NP-hard problem has been studied since the 1950s, with hundreds of papers addressing its many variations; see e.g., [18, Chapter 2] and [7] for surveys. Much of this work (e.g. [27, 39, 29, 30, 31, 37, 36, 33, 16, 2]) starting with [35] studies the *online* setting, where items arrive sequentially and are packed into bins immediately and irrevocably. While the offline problem is approximable to within an *additive* term of $\mathcal{O}(\log OPT)$ [17], in the online setting there is a 1.540-*multiplicative gap* between the algorithm and OPT in the worst case, even as $OPT \to \infty$ [2]. Given the wide applicability of the online problem, researchers have studied the problem where a small amount of repacking is allowed upon item additions and deletions. Our work focuses on the bounded recourse setting, and we give *optimal tradeoffs* between the number of bins used and amount of repacking required in the fully-dynamic setting for several settings.

A *fully-dynamic* BIN PACKING *algorithm* $\mathcal{A}$, given a sequence of item insertions and deletions, maintains at every time t a feasible solution to the BIN PACKING instance $\mathcal{I}_t$ given by items inserted and not yet deleted until time t. Every item i has a size s_i and a *movement cost* c_i, which $\mathcal{A}$ pays every time $\mathcal{A}$ moves item i between bins. Different approaches have been developed to measure the amount of repacking, in the context of data backup these measures corresponds to the communication or energy cost. For example, the movement cost c_i may be proportional to the size of the file (which is the communication cost if the files are all large), or may be a constant (if the files are small, and the overhead is entirely in setting up the connections), or may depend on the file in more complicated ways.

Formally, the fully-dynamic BIN PACKING problem is as follows.

▶ **Definition 1.1.** *A fully-dynamic algorithm $\mathcal{A}$ has (i) an* asymptotic competitive ratio α, *(ii)* additive term β *and (iii)* recourse γ, *if at each time t it packs the instance $\mathcal{I}_t$ in at most $\alpha \cdot OPT(\mathcal{I}_t) + \beta$ bins, while paying at most $\gamma \cdot \sum_{i=1}^{t} c_i$ movement cost until time t. If at each time t algorithm $\mathcal{A}$ incurs at most $\gamma \cdot c_t$ movement cost, for c_t the cost of the item updated at time t, we say $\mathcal{A}$ has* worst-case *recourse γ, otherwise we say it has* amortized *recourse γ.*

Any algorithm must pay $\frac{1}{2}\sum_{i=1}^{t} c_i$ movement cost just to insert the items, so an algorithm with γ recourse spends at most 2γ times more movement cost than the absolute minimum. The goal is to design algorithms which simultaneously have low asymptotic competitive ratio (a.c.r), additive term, and recourse. There is a natural tension between the a.c.r and recourse, so we want to find the optimal a.c.r-to-recourse trade-offs.

1.1 Related Work

Based on the classical BIN PACKING Problem [14], different online and dynamic variants have been developed and investigated. Due to space constraints we focus on the scenarios which share the most important properties with our model and only mention the best results for them. In the *Online Bin Packing Problem* [35], the items are unknown to the algorithm at the beginning and appear one after another. Balogh et al. [2] show a lower bound of 1.54037 for this problem and Seiden [33] presents an approximation algorithm with a competitive ratio of 1.58889. In the *Dynamic Bin Packing* setting [28], additionally to arrivals as in the Online Bin Packing Problem departures of items are also allowed. Here, a lower bound of 8/3 by Wong et al. [38] and an upper bound of 2.897 by Coffman et al. [28] exist.

We now turn our attention to the models which allow repacking of items. In the *Relaxed Online Bin Packing Problem*, first studied by Gambosi et al. [12, 13], online arrivals and no departures occur, but repacking of items is allowed. Repacking means that items can be assigned to another bin in the course of the execution, while in a setting without repacking decisions are irrevocable. Gambosi et al. gave a 4/3-a.c.r algorithm for the insertion-only setting which moves each item $\mathcal{O}(1)$ times, which in terms of recourse translates into $\mathcal{O}(1)$ amortized recourse for general movement costs. Following Sanders et al. [32], who studied makespan minimization with recourse, Epstein et al. [9] re-introduced the dynamic BIN PACKING problem with the movement costs c_i equaling the size s_i (the *size cost* setting, where worst-case recourse is also called *migration factor*). Epstein et al. gave a solution with a.c.r $(1+\varepsilon)$ and bounded (exponential in ϵ^{-1}) recourse for the insertion-only setting. Jansen and Klein [23] improved the recourse to $poly(\varepsilon^{-1})$ for insertion-only algorithms. The best known lower bound for an algorithm which uses only constant recourse in the *unit cost* model (i.e. $c_i = 1$ for all items) is originally given for our model, but it also applies to this setting with 1.3871 by Balogh et al. [4]. From the positive perspective Balogh et al. [5] give an approximation algorithm based on the Harmonic Fit Algorithm [29] for which they achieve a competitive ratio of $3/2$ and $\mathcal{O}(\varepsilon^{-1})$ movements per update. Since our algorithms are also applicable to this setting we improve this result to also close the gap between the lower and upper bound for this problem.

Our setting is the most powerful model among the presented ones, the *Fully-Dynamic Bin Packing* [21], in which we allow arrivals and departures of items as well as repacking. Ivković and Lloyd [21, 22] introduced the model of Fully-Dynamic Bin Packing and developed an algorithm called *Mostly Myopic Packing (MMP)* which achieves a $\frac{5}{4}$-competitive ratio. Their algorithm is based on an offline algorithm by Johnson [25, 26] and utilizes a technique whereby the packing of an item is done with a total disregard for already packed items of a smaller size. In contrast to our work, they use the concept of bundling smaller elements in their analysis, i.e. a group of items smaller than ε may be moved as a single item for unit costs. They can show that the number of single items or bundles of very small elements that need to be repacked is bounded by a constant. Additionally, Ivković [19] also gives a slightly simpler version of this algorithm, called *Myopic Packing (MP)*. It uses similar ideas but ignores one step of MMP that results in a much easier analysis and a competitive ratio of $\frac{4}{3}$. Berndt et al. [6] consider exactly the same setting, also allowing the bundling of very

small elements in the analysis. Their algorithm achieves a $1+\varepsilon$ approximation ratio and a bound of $\mathcal{O}\left(1/\varepsilon^4 \log\left(1/\varepsilon\right)\right)$ for the recourse in both the size costs and unit costs model.

In addition to the positive algorithmic results, researchers also explored lower bounds for this setting. All results assume that no bundling is allowed in the unit cost model (otherwise there can only be the trivial lower bound of one [6]), hence allowing only a constant number of shifted items per time step. Ivković and Lloyd [20] show a lower bound of $\frac{4}{3}$. Their construction uses the inability of an algorithm to react to insertions and deletions of items with size slightly larger than $\frac{1}{2}$ when the remaining items may be of arbitrarily small size. Balogh et al. [3, 4] improve this bound to roughly 1.3871. They extend the technique of the previous lower bound by constructing multiple lists of large items whose sizes are chosen through the construction of a linear program. Their results are the inspiration for some of the parameter choices in this work. For size costs, Berndt et al. [6] showed that any $(1+\varepsilon)$ a.c.r algorithm must have *worst-case recourse* $\Omega(\varepsilon^{-1})$. While these give nearly-tight results for "size costs" $c_i = s_i$, the unit cost ($c_i = 1$) and general cost cases were not so well understood prior to this work.

1.2 Our Results

We give (almost) tight characterizations for the recourse-to-asymptotic competitive ratio trade-off for fully-dynamic BIN PACKING under (a) unit movement costs, (b) general movement costs and (c) size movement costs. Our results are summarized in the following theorems. (See Tables 1 and 2 for a tabular listing of our results contrasted with the best previous results.) Note that an amortized recourse bound is a weaker (resp. stronger) upper (resp. lower) bound. In the context of sensitivity analysis (see [32]), our bounds provide a tight characterization of the *average* change between *approximately*-optimal solutions of slightly modified instances.

Unit Costs. Consider the most natural movement costs, *unit costs*, where $c_i = 1$ for all items i. Here we give tight upper and lower bounds. Let $\alpha = 1 - \frac{1}{W_{-1}(-2/e^3)+1} \approx 1.3871$ (here W_{-1} is the lower real branch of the Lambert W-function [8]). Balogh et al. [4] showed that α is a lower bound on the a.c.r with constant recourse. We present an alternative and simpler proof of this lower bound, also giving tighter bounds: doing better than α requires either *polynomial* additive term or recourse. Moreover, we give two matching algorithms proving α is tight for this problem: The first one uses directly the insights from the lower bound while the second one drives deeper into the structural insights of the current problem instance and reaches a slightly better result.

▶ **Theorem 1.2** (Unit Costs Tight Bounds). *For any $\varepsilon > 0$, there exists fully-dynamic* BIN PACKING *algorithms with amortized competitive ratio $(\alpha+\varepsilon)$ with worst case recourse $\mathcal{O}(\varepsilon^{-2})$ under unit movement costs and additive term $\mathcal{O}(\varepsilon^{-1})$. Conversely, any algorithm with a.c.r $(\alpha-\varepsilon)$ has additive term and amortized recourse whose product is $\Omega(\varepsilon^4 \cdot n)$ under unit movement costs.*

General Costs. Next, we consider the most general problem, with arbitrary movement costs. Theorem 1.2 showed that in the unit cost model, we can get a better a.c.r than for online BIN PACKING without repacking, whose optimal a.c.r is at least 1.540 ([2]). Alas, the fully-dynamic BIN PACKING problem with the general costs is not easier than the arrival-only online problem (with no repacking).

Table 1 Fully-dynamic bin packing with limited recourse: Positive results (Big-$\mathcal{O}$ notation dropped for notational simplicity)

▶ **Theorem 1.3** (Fully Dynamic as Hard as Online). *Any fully-dynamic* BIN PACKING *algorithm with bounded recourse under general movement costs has a.c.r at least as high as that of any online* BIN PACKING *algorithm. Given current bounds ([2]), this is at least* 1.540.

Given this result, is it conceivable that the fully-dynamic model is *harder* than the arrival-only online model, even allowing for recourse? We show this is likely not the case, as we can almost match the a.c.r of the current-best algorithm for online BIN PACKING.

▶ **Theorem 1.4** (Fully Dynamic Nearly as Easy as Online). *Any algorithm in the Super Harmonic family of algorithms can be implemented in the fully-dynamic setting with constant recourse under general movement costs. This implies an algorithm with a.c.r* 1.589 *using [33].*

The current best online BIN PACKING algorithm [1] is not from the Super Harmonic family but is closely related to it. It has an a.c.r of 1.578, so our results for fully-dynamic BIN PACKING are within a hair's width of the best bounds known for online BIN PACKING. It remains an open question as to whether our techniques can be extended to achieve the improved a.c.r bounds while maintaining constant recourse. While we are not able to give a black-box reduction from fully-dynamic algorithms to online algorithms, we conjecture that such a black-box reduction exists and that these problems' a.c.r are equal.

Size Costs. Finally, we give an extension of the already strong results known for the size cost model (where $c_i = s_i$ for every item i). We show that the lower bound known in the worst-case recourse model extends to the amortized model as well, for which it is easily shown to be tight.

▶ **Theorem 1.5** (Size Costs Tight Bounds). *For any $\varepsilon > 0$, there exists a $(1+\varepsilon)$-a.c.r algorithm with $\mathcal{O}(\varepsilon^{-2})$ additive term and $\mathcal{O}(\varepsilon^{-1})$ amortized recourse under size costs. Conversely, for infinitely many $\varepsilon > 0$, any $(1+\varepsilon)$-a.c.r algorithm with $o(n)$ additive term requires $\Omega(\varepsilon^{-1})$ amortized recourse under size costs.*

The hardness result above was previously only known for *worst-case* recourse [6]; this previous lower bound consists of a hard instance which effectively disallowed any recourse, while lower bounds against amortized recourse can of course not do so.

1.3 Techniques and Approaches

Unit Costs. For unit costs, our lower bound is based on a natural instance consisting of small items, to which large items of various sizes (greater than $\frac{1}{2}$) are repeatedly added/removed [4]. The near-optimal solutions oscillate between either having most bins containing both large and small items, or most bins containing only small items. Since small items can be moved rarely, this effectively makes them static, giving us hard instances. We can optimize for the lower bound arising thus via a *gap-revealing* LP, similar to [4]. However, rather than bound this LP precisely, we exhibit a near-optimal dual solution showing a lower bound of $\alpha - \varepsilon$.

For the first upper bound, the same LP now changes from a gap-revealing LP to a *factor-revealing* LP. The LP solution shows how the small items should be packed in order to "prepare" for arrival of large items, to ensure $(\alpha + \epsilon)$-competitiveness. An important building block of our algorithms is the ability to deal with (sub)instances made up solely of small items. In particular, we give fully-dynamic BIN PACKING algorithms with a.c.r $(1+\varepsilon)$ and only $\mathcal{O}(\varepsilon^{-2})$ *worst-case* recourse if all items have size $\mathcal{O}(\varepsilon)$. The ideas we develop are versatile, and are used, e.g., to handle the small items for general costs – we discuss them in more detail below. We then extend these ideas to allow for (approximately) packing items according to a "target curve", which in our case is the solution to the above LP. At this point the LP makes a re-appearance, allowing us to analyze a simple packing of large items "on top" of the curve (which we can either maintain dynamically using the algorithm of Berndt et al. [6] or recompute periodically in linear time); in particular, using this LP we are able to prove this packing of large items on top of small items has an optimal a.c.r of $\alpha + \mathcal{O}(\varepsilon)$. This implies that lazily repacking the large items near-optimally and packing them on top of the small items easily yields $\mathcal{O}(\varepsilon^{-2})$ amortized recourse. Relying on the fully-dynamic $poly(\varepsilon^{-1})$ migration factor AFPTAS algorithms of [6] with some additional ideas allows us to leverage this LP to obtain worst-case recourse bounds.

In the second upper bound, we take a different, more recourse-efficient method to pack the large items, which results in improved worst-case recourse. Specifically, we utilize an algorithm called Myopic Packing (MP) by Ivković [19]. This algorithm has a competitive ratio of $4/3$ (it is below the lower bound for our model since it uses bundling, i.e., it allows the repacking of a group of small items as one) and modifies only a constant number of bins per time step. Applying this algorithm to only items of a size of at least $\varepsilon/15$ restricts the amount of repacking to $\mathcal{O}(1/\varepsilon)$ per time step. We develop a new view of this algorithm to derive structural properties of the solution which are needed for the combination of major and minor items. Small items are handled similarly to the previous algorithm, however, we provide a fixed solution to the LP from before in order to use it in the analysis of the combined solution. Finally, the bins with small items are merged with the bins with large items by utilizing a greedy-like approach, where small chunks of reserved space and a big cumulative size of major items is prioritized in order to guarantee an efficient utilization of the reserved space. The combination has two main challenges: Firstly, we ensure that

this greedy process only has to modify $\mathcal{O}(1/\varepsilon)$ bins per time step. Secondly, we guarantee a space-efficient combination resulting in an overall good solution quality. The analysis carefully utilizes the structural insights about the solution for major items to estimate the solution quality within the bins that did not get merged.

General Costs. To transform any online lower bound to a lower bound for general costs even with recourse, we give the same sequence of items but with movement costs that drop sharply. This prohibits worst-case recourse, but since we allow amortized recourse, the large costs c_i for early items can still be used to pay for movement of the later items (with smaller c_i values). Hence, if the online algorithm moves an element e to some bin j, we delete all the elements after e and proceed with the lower bound based on assigning $e \mapsto j$. Now a careful analysis shows that for some sub-sequence of items the dynamic algorithm effectively performs no changes, making it a recourse-less online algorithm – yielding the claimed bound.

For the upper bound, we show how to emulate any algorithm in the *Super Harmonic* class of algorithms [33] even in the fully-dynamic case. We observe that the analysis for SH essentially relies on maintaining a stable matching in an appropriate compatibility graph. Now our algorithm for large items uses a subroutine similar to the Gale-Shapley algorithm. Our simulation also requires a solution for packing similarly-sized items. The idea here is to sort items by their cost (after rounding costs to powers of two), such that any insertion or deletion of items of this size can be "fixed" by moving at most one item of each smaller cost, yielding $\mathcal{O}(1)$ worst-case recourse.

The final ingredient of our algorithm is packing of small items into $(1-\epsilon)$-full bins. Unlike the online algorithm which can just use FirstFit, we have to extend the ideas of Berndt et al. [6] for the size-cost case. Namely we group bins into buckets of $\Theta(1/\epsilon)$ bins, such that all but one bin in a bucket are $1-\mathcal{O}(\epsilon)$ full, guaranteeing these bins are $1-\mathcal{O}(\epsilon)$ full on average. While for the size-cost case, bucketing bins and sorting the small items by size readily yields an $\mathcal{O}(\epsilon^{-1})$ recourse bound, this is more intricate for general case where size and cost are not commensurate. Indeed, we also maintain the small items in sorted order according to their size-to-movement-cost ratio (i.e., their *Smith ratio*), and only move items to/from a bin once it has $\Omega(\epsilon)$'s worth of volume removed/inserted (keeping track of erased, or "ghost" items). This gives an amortized $\mathcal{O}(\epsilon^{-2})$ recourse cost for the small items.

Size Costs. The technical challenge for size costs is in proving the lower bound with *amortized* recourse that matches the easy upper bound. Our proof uses item sizes which are roughly the reciprocals of the Sylvester sequence [34]. While this sequence has been used often in the context of bin packing algorithms, our sharper lower bound explicitly relies on its divisibility properties (which have not been used in similar contexts, to the best of our knowledge). We show that for these sizes, any algorithm $\mathcal{A}$ with a.c.r $(1+\epsilon)$ must, on an instance containing N items of each size, have $\Omega(N)$ many bins with one item of each size. In contrast, on an instance containing N items of each size *except the smallest size* ε, algorithm $\mathcal{A}$ must have some (smaller) $\mathcal{O}(N)$ many bins with more than one distinct size in them. Repeatedly adding and removing the N items of size ε, the algorithm must suffer a high amortized recourse.

We give a more in-depth description of our algorithms and lower bounds for unit, general and size costs, highlighting some salient points of their proofs in §2,§3 and §4, respectively. Due to space constraints we defer most proofs to the full versions of this paper ([15, 11]).

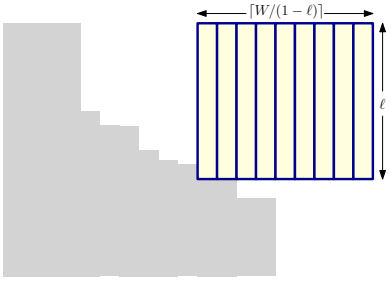

Figure 1 A packing of instance $\mathcal{I}_\ell$. The ℓ-sized items (in yellow) are packed "on top" of the small items (in grey).

2 Unit Movement Costs

We consider the natural unit movement costs model. First, we show that an a.c.r better than $\alpha = 1 - \frac{1}{W_{-1}(-2/e^3)+1} \approx 1.387$ implies either polynomial additive term or recourse. Next, we give tight $(\alpha+\epsilon)$-a.c.r algorithms, with both additive term and recourse polynomial in ϵ^{-1}. Our key idea is to use an LP that acts both as a *gap-revealing LP* for a lower bound, and also as a *factor-revealing LP* (as well as an inspiration) for our algorithm.

2.1 Impossibility results

Alternating between two instances, where both have $2n-4$ items of size $1/n$ and one instance also has 4 items of size $1/2 + 1/2n$, we get that any $\left(\frac{3}{2} - \varepsilon\right)$-competitive online BIN PACKING algorithm must have $\Omega(n)$ recourse. However, this only rules out algorithms with a *zero* additive term. Balogh et al. [4] showed that any $\mathcal{O}(1)$-recourse algorithm (under unit movement costs) with $o(n)$ additive term must have a.c.r at least $\alpha \approx 1.387$. We strengthen both this impossibility result by showing the need for a large additive term or recourse to achieve any a.c.r below α. Specifically, arbitrarily small polynomial additive terms imply near-linear recourse. Our proof is shorter and simpler than in [4]. As an added benefit, the LP we use to bound the competitive ratio will inspire our algorithm in the next section.

▶ **Theorem 2.1** (Unit Costs: Lower Bound). *For any $\varepsilon > 0$ and $\frac{1}{2} > \delta > 0$, for any algorithm $\mathcal{A}$ with a.c.r $(\alpha - \varepsilon)$ with additive term $o(\varepsilon \cdot n^\delta)$, there exists an dynamic bin packing input with n items on which $\mathcal{A}$ uses recourse at least $\Omega(\varepsilon^2 \cdot n^{1-\delta})$ under unit movement cost.*

The Instances: The set of instances is the a natural one, and was also considered by [4]. Let $1/2 > \delta > 0$, $c = 1/\delta - 1$, and let $W \geq 1/\varepsilon$ be a large integer. Our hard instances consist of *small* items of size $1/W^c$, and *large* items of size ℓ for all sizes $\ell \in \mathcal{S}_\varepsilon \triangleq \{\ell = 1/2 + i \cdot \varepsilon \mid i \in \mathbb{N}_{>0}, \ell \leq 1/\alpha\}$. Specifically, input $\mathcal{I}_s$ consists of $\lfloor W^{c+1} \rfloor$ small items, and for each $\ell \in \mathcal{S}_\varepsilon$, the input $\mathcal{I}_\ell$ consists of $\lfloor W^{c+1} \rfloor$ small items followed by $\lfloor \frac{W}{1-\ell} \rfloor$ size-ℓ items. The optimal bin packings for $\mathcal{I}_s$ and $\mathcal{I}_\ell$ require precisely $OPT(\mathcal{I}_s) = W$ and $OPT(\mathcal{I}_\ell) = \lceil \frac{W}{1-\ell} \rceil$ bins respectively. Consider any fully-dynamic bin packing algorithm $\mathcal{A}$ with limited recourse and bounded additive term. When faced with input $\mathcal{I}_s$, algorithm $\mathcal{A}$ needs to distribute the small items in the available bins almost uniformly. And if this input is extended to $\mathcal{I}_\ell$ for some $\ell \in \mathcal{S}_\varepsilon$, algorithm $\mathcal{A}$ needs to move many small items to accommodate these large items (or else use many new bins). Since $\mathcal{A}$ does not know the value of t beforehand, it cannot "prepare" simultaneously for all large sizes $\ell \in \mathcal{S}_\varepsilon$.

As a warm-up we show that the linear program (LP_ε) below gives a lower bound on the *absolute* competitive ratio α_ε of any algorithm $\mathcal{A}$ with no recourse. Indeed, instantiate the variables as follows. On input $\mathcal{I}_s$, let N_x be the number of bins in which $\mathcal{A}$ keeps free space in the range $[x, x+\varepsilon)$ for each $x \in \{0\} \cup \mathcal{S}_\varepsilon$. Hence the total volume packed is at most $N_0 + \sum_{x\in\mathcal{S}_\varepsilon}(1-x)\cdot N_x$. This must be at least $Vol(\mathcal{I}_s) \geq W - 1/W^c$, implying constraint ($\mathrm{Vol}_\varepsilon$). Moreover, as $OPT(\mathcal{I}_s) = W$, the α_ε-competitiveness of $\mathcal{A}$ implies constraint ($\mathrm{small}_\varepsilon$). Now if instance $\mathcal{I}_s$ is extended to $\mathcal{I}_\ell$, since $\mathcal{A}$ moves no items, these ℓ-sized items are placed either in bins counted by N_x for $x \geq \ell$ or in new bins. Since $\mathcal{A}$ is α_ε-competitive and $OPT(\mathcal{I}_\ell) \leq \lceil \frac{W}{1-\ell} \rceil$ we get constraint (CR_ε). Hence the optimal value of (LP_ε) is a valid lower bound on the competitive ratio α_ε.

$$
\begin{aligned}
&\text{minimize } \alpha_\varepsilon && && && (\mathrm{LP}_\varepsilon)\\
&\text{s.t. } N_0 + \textstyle\sum_{x\in\mathcal{S}_\varepsilon}(1-x)\cdot N_x && \geq W - 1/W^c && && (\mathrm{Vol}_\varepsilon)\\
&\quad N_0 + \textstyle\sum_{x\in\mathcal{S}_\varepsilon} N_x && \leq \alpha_\varepsilon \cdot W && && (\mathrm{small}_\varepsilon)\\
&\quad N_0 + \textstyle\sum_{x\in\mathcal{S}_\varepsilon, x\leq \ell-\varepsilon} N_x + \left\lceil \frac{W}{1-\ell} \right\rceil && \leq \alpha_\varepsilon \cdot \left\lceil \frac{W}{1-\ell} \right\rceil && \forall \ell \in \mathcal{S}_\varepsilon && (\mathrm{CR}_\varepsilon)\\
&\quad N_x \geq 0
\end{aligned}
$$

The claimed lower bound on the a.c.r of recourse-less algorithms follows from Lemma 2.2.

▶ **Lemma 2.2.** *The optimal value $\alpha^\star_\varepsilon$ of (LP_ε) satisfies $\alpha^\star_\varepsilon \in [\alpha - \mathcal{O}(\varepsilon), \alpha + \mathcal{O}(\varepsilon)]$.*

To extend the above argument to the fully-dynamic case, we observe that any solution to (LP_ε) defined by packing of $\mathcal{I}_s$ as above must satisfy some constraint (CR_ε) for some $\ell \in \mathcal{S}_\varepsilon$ with equality, implying a competitive ratio of at least α_ϵ. Now, to beat this bound, a fully-dynamic algorithm must move at least ϵ volume of small items from bins which originally had less than $x - \epsilon$ free space. As small items have size $1/W^c = 1/n^\delta$, this implies that $\Omega(\epsilon n^\delta)$ small items must be moved for every bin affected by such movement. This argument yields Lemma 2.3, which together with Lemma 2.2 implies Theorem 2.1.

▶ **Lemma 2.3.** *For all $\varepsilon > 0$ and $\frac{1}{2} > \delta > 0$, if $\alpha^\star_\varepsilon$ is the optimal value of (LP_ε), then any fully-dynamic* BIN PACKING *algorithm $\mathcal{A}$ with a.c.r $\alpha^\star_\varepsilon - \varepsilon$ and additive term $o(\varepsilon^2 \cdot n^\delta)$ has recourse $\Omega(\varepsilon^2 \cdot n^{1-\delta})$ under unit movement costs.*

2.2 Matching Algorithmic Results

As mentioned earlier, LP_ε also guides our algorithm. For the rest of this section, items smaller than ε are called *small*, and the rest are *large*. Items of size $s_i > 1/2$ are *huge*.

To begin, imagine a total of W volume of small items come first, followed by large items. Inspired by the LP analysis above, we pack the small items such that an N_ℓ/W fraction of bins have ℓ free space for all $\ell \in \{0\} \cup \mathcal{S}_\varepsilon$, where the N_ℓ values are near-optimal for (LP_ε). We call the space profile used by the small items the "curve"; see Figure 1. In the LP analysis above, we showed that this packing can be extended to a packing with a.c.r $\alpha + \mathcal{O}(\varepsilon)$ if $W/(1-\ell)$ items of size ℓ are added. But what if large items of *different* sizes are inserted and deleted? In §2.2.1 we show that this approach retains its $(\alpha + \mathcal{O}(\epsilon))$-a.c.r in this case too, and outline a linear-time algorithm to obtain such a packing.

The next challenge is that the small items may also be inserted and deleted. In §2.2.2 we show how to dynamically pack the small items with bounded recourse, so that the number of bins with any amount of free space $f \in \mathcal{S}_\varepsilon$ induce a near-optimal solution to LP_ε.

Finally, in §2.2.3 we combine the two ideas together to obtain our fully-dynamic algorithm.

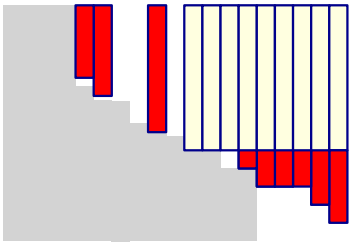

Figure 2 A packing of instance $\mathcal{I}'$. Large items are packed "on top" of the small items (in grey). Parts of large items not in the instance $\mathcal{I}_\ell^k$ are indicated in red.

2.2.1 LP_ε as a Factor-Revealing LP

In this section we show how we use the linear program LP_ε to analyze and guide the following algorithm: pack the small items according to a near-optimal solution to LP_ε, and pack the large items near-optimally "on top" of the small items.

To analyze this approach, we first show it yields a good packing if all large items are huge and have some common size $\ell > 1/2$. Consider an instance $\mathcal{I}_s$ consisting solely of small items with total volume W, packed using N_x bins with gaps in the range $[x, x+\varepsilon)$ for all $x \in \{0\} \cup \mathcal{S}_\varepsilon$, where $\{\alpha_\varepsilon, N_0, N_x : x \in \mathcal{S}_\varepsilon\}$ form a feasible solution for (LP_ε). We say such a packing is α_ε-*feasible*. By the LP's definition, any α_ε-feasible packing of small items can be extended to an α_ε-competitive packing for any extension $\mathcal{I}_\ell$ of $\mathcal{I}_s$ with $\ell \in \mathcal{S}_\varepsilon$, by packing the size ℓ items in the bins counted by N_x for $x \geq \ell$ before using new bins. In fact, this solution satisfies a similar property for any extension $\mathcal{I}_\ell^k$ obtained from $\mathcal{I}_s$ by adding *any* number k of items all of size ℓ. (Note that $\mathcal{I}_\ell$ is the special case of $\mathcal{I}_\ell^k$ with $k = \lfloor W/(1-\ell) \rfloor$.)

▶ **Lemma 2.4** (Huge Items of Same Size). *Any α_ε-feasible packing of small items of $\mathcal{I}_s$ induces an α_ε-competitive packing for all extensions $\mathcal{I}_\ell^k$ of $\mathcal{I}_s$ with $\ell > 1/2$ and $k \in \mathbb{N}$.*

Now, to pack the large items of the instance $\mathcal{I}$, we first create a similar new instance $\mathcal{I}'$ whose large items are all huge items. To do so, we first need the following observation.

▶ **Observation 2.5.** *For any input $\mathcal{I}$ made up of solely large items and function $f(\cdot)$, a packing of $\mathcal{I}$ using at most $(1+\varepsilon)\cdot OPT(\mathcal{I}) + f(\varepsilon^{-1})$ bins has all but at most $2\varepsilon \cdot OPT(\mathcal{I}) + 2f(\varepsilon^{-1}) + 3$ of its bins containing either no large items or being more than half-filled by large items.*

Now, consider a packing $\mathcal{P}$ of the large items of $\mathcal{I}$ using at most $(1+\varepsilon)\cdot OPT(\mathcal{I}) + f(\varepsilon^{-1})$ bins. By Observation 2.5, at most $2\varepsilon \cdot OPT(\mathcal{I}) + \mathcal{O}(f(\varepsilon^{-1}))$ bins in $\mathcal{P}$ are at most half full. We use these bins when packing $\mathcal{I}$. For each of the remaining bins of $\mathcal{P}$ we "glue" all large items occupying the same bin into a single item, yielding a new instance $\mathcal{I}'$ with only huge items, with any packing of $\mathcal{I}'$ "on top" of the small items of $\mathcal{I}$ trivially inducing a similar packing of $\mathcal{I}$ with the same number of bins. We pack the huge items of $\mathcal{I}'$ on top of the curve greedily, repeatedly packing the smallest such item in the fullest bin which can accommodate it. See §2.3.3 for a description of an implementation of this idea with limited recourse. Now, if we imagine we remove and decrease the size of some of these huge items, this results in a new (easier) instance of the form $\mathcal{I}_\ell^k$ for some k and $\ell > 1/2$, packed in no more bins than $\mathcal{I}'$ (see Figure 2). By Lemma 2.4, our packing of $\mathcal{I}'$ (and of $\mathcal{I}$) uses at most $\alpha_\varepsilon \cdot OPT(\mathcal{I}_\ell^k) \leq \alpha_\varepsilon \cdot OPT(\mathcal{I}') \leq (\alpha_\varepsilon + \mathcal{O}(\epsilon)) \cdot OPT(\mathcal{I}) + \mathcal{O}(f(\varepsilon^{-1}))$ bins. Performing the same while only near-optimally packing large items of size exceeding $1/4$, and packing the large items of size in the range $(\varepsilon, 1/4]$ so that we only open a new bin if all bins are at least $3/4$ full (in which case we would obtain a $4/3 < \alpha$ a.c.r) allows us to obtain even better recourse bounds. These ideas underlie the following theorem (a more complete proof of which appears in [15]).

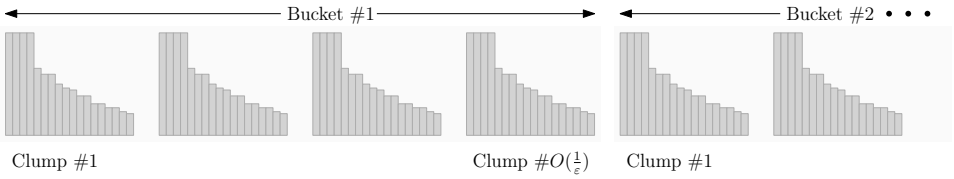

Figure 3 Buckets have $\mathcal{O}(\varepsilon^{-1})$ clumps, clumps have T bins.

▶ **Theorem 2.6.** *An α_ε-feasible packing of the small items of an instance $\mathcal{I}$ can be extended into a packing of $\mathcal{I}$ using at most $(\alpha_\epsilon + \mathcal{O}(\varepsilon)) \cdot OPT(\mathcal{I}) + \mathcal{O}(\varepsilon^{-2})$ bins in linear time. Moreover, given a fully-dynamic $(1+\varepsilon) \cdot OPT(\mathcal{I}) + f(\varepsilon^{-1})$ packing of items of size greater than $1/4$ of $\mathcal{I}_t$ and an α_ε-feasible packing of its small items, one can maintain a packing using $(\alpha_\epsilon + \mathcal{O}(\varepsilon)) \cdot OPT(\mathcal{I}_t) + \mathcal{O}(\max\{\varepsilon^{-2}, f(\varepsilon^{-1}))\}$ bins with $\mathcal{O}(\varepsilon^{-1})$ worst-case recourse per item move in the near-optimal dynamic packing of the items of size exceeding $1/4$.*

It remains to address the issue of maintaining an α_ε-feasible packing of small items dynamically using limited recourse.

2.2.2 Dealing With Small Items: "Fitting a Curve"

We now consider the problem of packing ε-small items according to an approximately-optimal solution of $(\mathrm{LP}_\varepsilon)$. We abstract the problem thus.

▶ **Definition 2.7** (Bin curve-fitting). *Given a list of bin sizes $0 \le b_0 \le b_1 \le \ldots, b_K \le 1$ and relative frequencies $f_0, f_1, f_2, \ldots, f_K$, such that $f_x \ge 0$ and $\sum_{x=0}^{K} f_x = 1$, an algorithm for the* bin curve-fitting problem *must pack a set of m of items with sizes $s_1, \ldots, s_m \le 1$ into a minimal number of bins N such that for every $x \in [0, K]$ the number of bins of size b_x that are used by this packing lie in $\{\lfloor N \cdot f_x \rfloor, \lceil N \cdot f_x \rceil\}$.*

If we have $K = 0$ with $b_0 = 1$ and $f_0 = 1$, we get standard BIN PACKING. We want to solve the problem only for (most of the) small items, in the fully-dynamic setting. We consider the special case with relative frequencies f_x being multiples of $1/T$, for $T \in \mathbb{Z}$; e.g., $T = \mathcal{O}(\varepsilon^{-1})$. Our approach is inspired by the algorithm of [23], and maintains bins in increasing sorted order of item sizes. The number of bins is always an integer product of T. Consecutive bins are aggregated into *clumps* of exactly T bins each, and clumps aggregated into $\Theta(\varepsilon^{-1})$ *buckets* each. Formally, each clump has T bins, with $f_x \cdot T \in \mathbb{N}$ bins of size b_x for $x = 0, \ldots, K$. The bins in a clump are ordered according to their capacity b_x, so each clump looks like its target curve. Each bucket except the last consists of some $s \in [1/\varepsilon, 3/\varepsilon]$ consecutive clumps (the last bucket may have fewer than $1/\epsilon$ clumps). See Figure 3. For each bucket, all bins except those in the last clump are full to within an additive ε.

Inserting an item adds it to the correct bin according to its size. If the bin size becomes larger than the target size for the bin, the largest item overflows into the next bin, and so on. Clearly this maintains the invariant that we are within an additive ε of the target size. We perform $\mathcal{O}(T/\epsilon)$ moves in the same bucket; if we overflow from the last bin in the last clump of the bucket, we add a new clump of T new bins to this bucket, etc. If a bucket contains too many clumps, it splits into two buckets, at no movement cost. An analogous (reverse) process happens for deletes. Loosely, the process maintains that on average the bins are full to within $\mathcal{O}(\varepsilon)$ of the target fullness – one loss of ε because each bin may have ε space, and another because an $\mathcal{O}(\varepsilon)$ fraction of bins have no guarantees whatsoever.

We now relate this process to the value of LP_ε. We first show that setting $T = \mathcal{O}(\varepsilon^{-1})$ and restricting to frequencies which are multiples of ε does not hurt us. Indeed, for us, $b_0 = 1$,

and $b_x = (1-x)$ for $x \in \mathcal{S}_\varepsilon$. Since ($\mathrm{LP}_\varepsilon$) depends on the total volume W of small items, and f_x may change if W changes, it is convenient to work with a normalized version normalized by W, which is essentially (LP_ε) with $W = 1$. Now $n_x = N_x/W$ can be interpreted as just being proportional to number of bins of size b_x, and we can define $f_x = n_x / \sum_x n_x$ to the fraction of bins of size b_x in our solution. However, we also need each f_x to be an integer multiple of $1/T$ for some integer $T = \mathcal{O}(\varepsilon^{-1})$. We achieve this by slightly modifying the LP solution, obtaining the following.

▶ **Lemma 2.8** (Multiples of ε). *For any optimal solution $\{n_x\}$ to (LP_ε) (with $W = 1$) with objective value α_ε, we can construct in linear time a solution $\{\tilde{n}_x\} \subseteq \varepsilon \cdot \mathbb{N}$ with objective value $\alpha_\varepsilon + \mathcal{O}(\varepsilon)$.*

Using a near-optimal solution to (LP_ε) as in the above lemma, we obtain a bin curve-fitting instance with $T = \mathcal{O}(\varepsilon^{-1})$. Noting that if we ignore the last bucket's $\mathcal{O}(T/\varepsilon^{-1}) = \mathcal{O}(\varepsilon^{-2})$ bins in our solution, we obtain an $(\alpha^\star_\varepsilon + \mathcal{O}(\varepsilon))$-feasible packing (with additive term $\mathcal{O}(\varepsilon^{-2})$) of the remaining items by our algorithm above, using $\mathcal{O}(\varepsilon^{-2})$ worst-case recourse. We obtain the following.

▶ **Lemma 2.9** (Small Items Follow the LP). *Let $\varepsilon \leq 1/6$. Using $\mathcal{O}(\varepsilon^{-2})$ worst-case recourse we can maintain packing of small items such that the content of all but $\mathcal{O}(\varepsilon^{-2})$ designated bins in this packing form an $(\alpha^\star_\varepsilon + \mathcal{O}(\varepsilon))$-feasible packing.*

2.2.3 Our Algorithm

From Lemma 2.8 and Lemma 2.9, we can maintain an $(\alpha^\star_\varepsilon + \mathcal{O}(\varepsilon))$-feasible packing of the small items (that is, a packing of inducing a solution to (LP_ε) with objective value $(\alpha^\star_\varepsilon + \mathcal{O}(\varepsilon))$), all while using $\mathcal{O}(\varepsilon^{-2})$ worst-case recourse. From Theorem 2.6, using a $(1+\varepsilon)$-a.c.r packing of the large items one can extend such a packing of the small items into an $(\alpha^\star_\varepsilon + \mathcal{O}(\varepsilon))$-approximate packing for $\mathcal{I}_t$, where $\alpha^\star_\varepsilon \leq \alpha + \mathcal{O}(\varepsilon)$, by Lemma 2.2. It remains to address the recourse incurred by extending this packing to also pack the large items.

Amortized Recourse. Here we periodically recompute in linear time the extension guaranteed by Theorem 2.6. Dividing the time into epochs and lazily addressing updates to large items (doing nothing on deletion and opening new bins on insertion) for $\varepsilon \cdot N$ steps, where N is the number of bins we use at the epoch's start, guarantees a $(\alpha + \mathcal{O}(\varepsilon))$-a.c.r throughout the epoch. Finally, as the number of large items at the end of an epoch of length $\epsilon \cdot N$ is at most $\mathcal{O}(N/\epsilon)$, repacking them incurs $\mathcal{O}(N/\varepsilon)/(\epsilon \cdot N) = \mathcal{O}(\epsilon^{-2})$ amortized recourse.

Worst Case Recourse. To obtain worst-case recourse we rely on the fully-dynamic $(1+\varepsilon)$-a.c.r algorithm of Berndt al. [6] to maintain a $(1+\varepsilon)$-approximate packing of the sub-instance made of items of size exceeding $1/4$ using $\tilde{O}(\varepsilon^{-3})$ size cost recourse, and so at most $\tilde{O}(\varepsilon^{-3})$ item moves (as these items all have size $\Theta(1)$). By Theorem 2.6, our $(\alpha + \mathcal{O}(\varepsilon))$-feasible solution for the small items of $\mathcal{I}_t$ can be extended dynamically to an $(\alpha + (\mathcal{O}(\varepsilon)))$-a.c.r packing of all of $\mathcal{I}_t$, using $\mathcal{O}(\varepsilon^{-1})$ worst-case recourse per item change in the dynamic packing of the items of size exceeding $1/4$ of $\mathcal{I}_t$, yielding an $\tilde{O}(\varepsilon^{-4})$ worst-case recourse bound overall.

From the above discussions we obtain this section's main result – tight algorithms for unit costs with polynomial additive term and recourse.

▶ **Theorem 2.10** (Unit Costs: Upper Bound). *There is a polytime fully-dynamic* BIN PACKING *algorithm which achieves $\alpha + \mathcal{O}(\varepsilon)$ a.c.r, additive term $\mathcal{O}(\varepsilon^{-2})$ and $\mathcal{O}(\varepsilon^{-2})$ amortized recourse, or additive term poly(ε^{-1}) and $\tilde{O}(\varepsilon^{-4})$ worst-case recourse, under unit movement costs.*

2.3 An Algorithm with Improved Worst-Case Recourse

In this section, we present a second algorithm for the Unit Costs model, which uses only $\mathcal{O}(\varepsilon^{-2})$ worst-case recourse. The previous algorithm mainly used the lower bound as borders, and then applied two different algorithms for small and large items, combining the two in a greedy fashion. A near-optimal packing of the large items "on top" of the small items yields the claimed competitive ratio. In this section, we show that a simple fully-dynamic $4/3$-competitive algorithm of Ivković [19] which has recourse only $\mathcal{O}(\varepsilon^{-1})$ for the large items (and only modifies a constant number of bins) combined in the same way yields the same $\alpha + \varepsilon$ a.c.r, but with better worst-case recourse.

For the remainder of the section, we refer to items of size at most $\delta = \varepsilon/15$ as *minor* items and items larger than this size as *major* items. In §2.3.1 we outline our packing of the minor items, which differs slightly from that of §2.2.2 (in particular it only incurs an $\mathcal{O}(\varepsilon^{-1})$, rather than $\mathcal{O}(\varepsilon^{-2})$, additive term). In §2.3.2 we outline Ivković's algorithm and some of its structural properties we rely on for our analysis. Finally, in §2.3.3 we prove that the combination of these solutions in a greedy manner as discussed in §2.2.1 yields an a.c.r of $\alpha + \mathcal{O}(\varepsilon)$. The full proofs of this section are deferred to [11].

The result of this section is summarized in the following theorem:

▶ **Theorem 2.11** (Unit Cost: Improved Upper Bound). *For each $\varepsilon \in (0, 1)$, there exists an algorithm for the Fully-Dynamic* BIN PACKING *Problem with a.c.r. $(1 + \varepsilon) \cdot \alpha$, additive term $\mathcal{O}(\varepsilon^{-1})$ and $\mathcal{O}(\varepsilon^{-2})$ worst-case recourse, under unit movement costs.*

2.3.1 Prospective Packing of Minor Items

For our improved recourse bound, our packing of small items here is essentially identical to that of 2.2.2, so we only highlight the differences here. As before, we pack the small items in bins which are sorted by item sizes, with bins partitioned into buckets of $\mathcal{O}(\varepsilon^{-1})$ clumps of size $\mathcal{O}(\varepsilon^{-1})$, with a prescribed height for each bin in the clump, and one "buffer" clump in each bucket which is potentially empty (with none of its bins exceeding its target filling height). Now, unlike the solution of 2.2.2, the number of bins of each target height will be the same in each clump, which will imply that the fraction of bins of type at most some j (i.e., filling height at most some w_j) is at most some $\mathcal{O}(\varepsilon)$ times the value assigned to it by the LP solution. This is sufficient to obtain the required competitive ratio for instances comprised solely of small items. The advantage of each clump having the same number of bins of each type however has the added benefit that it implies that once a particular clump is "full", (has all its bin of height at least its target height minus $\varepsilon/15$), we can begin packing major items "on top" of the obtained "curve". In particular this implies an additive term of $\mathcal{O}(\varepsilon^{-1})$, rather than $\mathcal{O}(\varepsilon^{-2})$. As before, the worst-case recourse is at most $\mathcal{O}(\varepsilon^{-2})$.

Choice of Parameters

What remains open in the description of the algorithm is the concrete assignment of bin types and the choice of the parameters k and T. Our choice of filling heights is inspired by the parameters from the lower bound by Balogh et al. [4] (or equivalently, of §2.1), but in order to get the desired upper bound instead, each filling height is essentially replaced by the next smaller filling height from the lower bound. Let $\alpha := 1 - 1/(W_{-1}(-2/e^3)+1) \approx 1.3871$ be the value of the lower bound.

For each bin clump of size T, we need to take care of the correct fraction of bins of a certain type j, which we implicitly determine by parameters z_j (for notational convenience, we also write $z'_j := \sum_{i=1}^{j} z_i$). For a minor item workload of W, we aim to create roughly

$z'_k \cdot W$ bins, where we choose $z'_k \coloneqq (1 + \varepsilon/4)\alpha$, hence achieving the desired tight bound for minor items. Note that the frequencies of each bin type as defined in 2.7 can be obtained by $f_i = z_i/z'_k$. The filling height corresponding to bin type k is defined as $w_k \coloneqq y_k \coloneqq (z'_k - 1)/z'_k$. Bins of this type have the largest remaining space, which is $1/z'_k$. Intuitively, the reason is that we do not need to reserve space for major items of size at least $1/z'_k$ as packing these items in exclusive bins still results in an approximation ratio of z'_k.

For the other bin types $j < k$, we now choose the parameters y_j according to the geometric series $y_j = \frac{1}{2}(2 \cdot y_k)^{\frac{j-1}{k-1}}$ (see also [4] for the background on why this is a good choice). The filling heights w_j of the different bin types depend almost directly on these parameters: We set $w_j \coloneqq y_j \ \forall j > 1$ and $w_1 \coloneqq 1 = y_1 + \frac{1}{2}$. This perceived inconsistency is due to the shift of the other w_j (w.r.t. the lower bound) as explained above.

The remaining values for z_j are set such that $z'_j \coloneqq y_k/(y_j(1-y_k))$ holds for all j. The values for z'_j are a result of optimizing the number of bins of type $\leq j$ against a class of bad instances where many items of size $1 - y_j + \varepsilon'$ (for some tiny $\varepsilon' > 0$) are inserted. These items can not be packed into the same bins with such types, however fit into bins of type $> j$. Note that the choice of these parameters results in $1/4 < 1 - 1/z'_k = y_k < \ldots < y_1 = 1/2$ and $3/4 < 2 \cdot (z'_k - 1) = z'_1 < \ldots < z'_k = (1 + \varepsilon/4) \cdot \alpha$.

Based on these parameters, a clump of T bins is organized as follows: We choose the size of a bin clump to be $T = \lceil 4z'_k/\varepsilon\alpha \rceil = \lceil 4/\epsilon \rceil + 1$ and the total number of bins of type $\leq j$ to be $\lceil z'_j/z'_k \cdot T \rceil$. Hence, the number of bins of type 1 is $\lceil z_1/z'_k \cdot T \rceil$, whereas for bin types $j > 1$, it is determined by $\lceil z'_j/z'_k \cdot T \rceil - \lceil z'_{j-1}/z'_k \cdot T \rceil$. Note that the rounding implies that the number of bins of some types may be zero.

Finally, we choose the number of bin types to be $k = \lceil 3/\varepsilon \rceil + 1$.

Analysis

The main goal of the upcoming analysis is to bound the number of bins used for a given payload W of minor items. In the following we state properties of the structure of the algorithm's solution.

In order to count the number of bins in our solution, we need the following technical lemma, which essentially resembles the volume constraint Vol_ε of LP_ε. Remember that $\delta = \varepsilon/15$ denotes the maximum size of a minor item.

▶ **Lemma 2.12.** *A set of full bins which consists of at least $z_j \cdot W$ bins of type j for each bin type j contains a workload of at least W of minor items; i.e., $\sum_{j=1}^{k} z_j W \cdot (w_j - \delta) \geq W$.*

▶ **Lemma 2.13.** *For all $1 \leq j \leq k$, the total number of bins of any type $i \leq j$ is at most $(z'_j + \frac{3}{4}\varepsilon\alpha)W$.*

This bound is mainly used for the analysis in §2.3.3, showing that a packing with the parameters as defined above indeed fits the target curve as desired. However, it also directly implies the approximation ratio for instances where only minor items are present (constraint small_ε in LP_ε).

▶ **Corollary 2.14.** *For an instance with only minor items, the algorithm achieves an a.c.r. of $z'_k + \frac{3}{4}\varepsilon\alpha = (1 + \varepsilon)\alpha$.*

▶ **Lemma 2.15.** *The recourse (regarding minor items) during an insertion or deletion of a minor item is bounded by $\mathcal{O}(\varepsilon^{-2})$.*

2.3.2 Dealing with Major Items

For major items, i.e. items with a size larger than $\delta = \varepsilon/15$, we use an algorithm called *Myopic Packing* (MP) by Ivković [19] which is a simplified version of the *MMP* algorithm by Ivković and Lloyd [21]. The algorithm is essentially a fully-dynamic variant of Johnson's First Fit Grouping Algorithm [24, 25]. For the sake of completeness, and since [19] is not freely available on the Internet and the algorithm is an essential component of our algorithm, we give a detailed description of this algorithm below.

We divide the major items in four sub-groups, depending on their size: A B (big) item has a size in $\left(\frac{1}{2}, 1\right]$, an L (large) item in $\left(\frac{1}{3}, \frac{1}{2}\right]$, an S (small) item in $\left(\frac{1}{4}, \frac{1}{3}\right]$ and an O (other) item in $\left(\frac{\varepsilon}{15}, \frac{1}{4}\right]$. Ignoring additional O items for now, the following bin types of interest can occur: BL, BS, B, LLS, LL, LSS and SSS. The name of the bin type represents the items of type B, L and S contained in that bin. The additional bin types LS, L, SS, S can only occur at most two times in a packing in total, so they induce an additive constant of at most 2 and thus can be ignored for the analysis. Each different type $\tau \in \mathcal{T} := \{BL, BS, B, LLS, LL, LSS, SSS\}$ is given a priority such that we have a total ordering $<$ on $\mathcal{T}$ which is $BL > BS > B > LLS > LL > LSS > SSS$. Out of the listed bin types above, the MP algorithm utilizes all but bins of type LSS.

The general idea of the algorithm is to insert items in a First Fit manner with disregard of items of a smaller type. This is realized by a recursive procedure which takes items out of a dedicated auxiliary storage and inserts them into the regular packing. When an item is inserted into a bin, items of lower types are removed from this bin and added to the auxiliary storage. It is important that the algorithm maintains a structural property called thoroughness, which reflects the structure of the packing as done by the First Fit Grouping Algorithm by Johnson. This property is formally defined in Lemma 2.16.

In more detail, the algorithm does the following: For an insertion of an item a, it is simply added to the auxiliary storage and a procedure to clear the storage is called. For a deletion of a, all items in the same bin as a are removed from the regular packing and added to the auxiliary storage. Then the procedure to clear the storage is called. At the end of an insert or delete operation, only a constant number of items remains in the auxiliary storage and is packed into at most 2 bins. The procedure to clear the auxiliary storage works as follows:

1. Every B item from the auxiliary storage is inserted into the regular packing. The thoroughness property is maintained by successively searching for fitting L and then S items in bins of a lower type to pair with the new B item. The remaining items from the bins from which the L or S item was removed are moved to the auxiliary storage.
2. L and S items from the auxiliary storage are paired with B bins from the regular packing whenever possible. Bins of the same or higher type are not changed in the process, i.e. an L item can only be paired with a B item of a BS or B bin. Other items from the bin in which these items are inserted are moved to the auxiliary storage.
3. As long as there are at least two L items in the auxiliary storage, they are inserted in a new bin and potentially paired with an S item either from the auxiliary storage or from an existing SSS bin to form an LLS bin. If no fitting S item exists, an LL bin is created. If an S item is taken from a regular bin, the remaining items are moved to the auxiliary storage.
4. As long as there are at least three S items in the auxiliary storage, new bins of type SSS are formed with these items and inserted into the regular packing. At the end of this step, the auxiliary storage contains at most one L item and two S items which can be packed into at most two bins.
5. All remaining O items in the auxiliary storage are moved to the regular packing in a first fit manner. This implies that bins that contain any other item type than O are prioritized over bins that exclusively contain O items.

Properties of the Algorithm

For our analysis of the packing, we mainly use the thoroughness property which is ensured by the algorithm and proven in [19]:

▶ **Lemma 2.16** ([19]). *A bin of type $\tau \in \mathcal{T}$ is* thorough *if there do not exist two bins B_1 and B_2 with lower types $\tau_1, \tau_2 \in \mathcal{T}$, $\tau_1, \tau_2 < \tau$ such that items from B_1 and B_2 can be used to form a bin of type τ. In the solution of the MP algorithm, bins of type BL, BS and LLS are thorough.*

We denote by ALG_τ and OPT_τ (e.g. ALG_{BL} and OPT_{BL}) the number of bins of type $\tau \in \mathcal{T}$ in ALG and OPT, respectively. The same notation is adapted for multiple types of bins (e.g. $\text{ALG}_{BL,LLS} = \text{ALG}_{BL} + \text{ALG}_{LLS}$). Using this notation, we get:
$\text{ALG} \leq \text{ALG}_{BL} + \text{ALG}_{BS} + \text{ALG}_B + \text{ALG}_{LLS} + \text{ALG}_{LL} + \text{ALG}_{SSS} + 2$, and
$\text{OPT} \geq \text{OPT}_{BL} + \text{OPT}_{BS} + \text{OPT}_B + \text{OPT}_{LLS} + \text{OPT}_{LL} + \text{OPT}_{SSS} + \text{OPT}_{LSS}$.

Note that the only reason these are not equalities is that the number of bins of type LS, L, SS or S is between 0 and 2.

We first argue that we may assume that no O items are part of the input: Consider the case that there is a bin containing only O items in ALG. Then every bin in ALG except one is filled with items of a cumulative size of at least $3/4$. Together with Lemma 2.13 we then directly get an approximation factor of $(1+\varepsilon)\alpha$ even if we would not combine our solutions for minor and major items at all. Regarding the case that there is no such O bin, since MP packs items in a myopic manner, it would produce the same solution if the O items were not part of the input. Hence we may compare the solution to an instance of the optimal solution, which does not need to consider any O items in its instance.

In order to ease the analysis of the algorithm, we introduce assumptions to the optimal solution and show that these do not increase the value of the optimal solution.

▶ **Lemma 2.17.** *Let* ALG *be the packing of the MP algorithm of a set of major items. For an optimal solution* OPT *of a packing of the same items, the following properties can be assumed without increasing the number of used bins in* OPT*:*

1. OPT *does not pack a BS bin containing a B item that is part of a BL bin in* ALG*.*
2. OPT *does not pack a B bin containing a B item that is part of a BL bin in* ALG*.*

We use the thoroughness of the MP algorithm (cf. Lemma 2.16) to show the following four statements that compare the solutions of ALG and OPT with each other. They will later be used in the analysis of the combination of our two approaches.

▶ **Lemma 2.18.** *Let* ALG *be the packing of the MP algorithm and* OPT *an optimal solution:*

1. $\text{ALG}_{BL} + \text{ALG}_{BS} + \text{ALG}_B = \text{OPT}_{BL} + \text{OPT}_{BS} + \text{OPT}_B$
2. $\text{ALG}_{BL} + \text{OPT}_{LSS} \geq 2\,(\text{ALG}_{LLS,LL} - \text{OPT}_{LLS,LL})$
3. $\text{ALG}_{BS} + \text{ALG}_{LL} + 2\text{OPT}_{LSS} \geq 3\,(\text{ALG}_{SSS} - \text{OPT}_{SSS})$
4. $\text{ALG}_{BS} + \text{OPT}_{LLS} + 2\text{OPT}_{LSS} \geq 3\,(\text{ALG}_{SSS} - \text{OPT}_{SSS})$

We finally determine the recourse that occurs during the insertion or deletion of a major item. Note that while considering this, we need to also account for possible O items.

▶ **Lemma 2.19.** *The recourse of the MP algorithm (for major items) is bounded by $\mathcal{O}(\varepsilon^{-1})$.*

2.3.3 Combining Major and Minor Items

The two presented approaches for the packing of minor and major items treat these items independently. These independent solutions now have to be combined into one to reach a good approximation guarantee. Assume we obtain these solutions as two sets of bins, where the bins $(B_1^{\min}, \dots, B_m^{\min})$ are the result of the algorithm for minor items and the bins $\left(B_1^{\text{maj}}, \dots, B_n^{\text{maj}}\right)$ are the result of the algorithm for major items. Note that although we temporarily ignored items of a size in $(\varepsilon/15, 1/4]$ in the analysis for the major items, the algorithm that combines the two solutions of course does not ignore the potential O items.

We first describe the structure of the packing we want to achieve and then show how to maintain that structure over time. The goal is to create pairs of bins with one bin from each solution while not modifying too many pairs in each time step. For ease of description, we still refer to two bins $B_i^{\min}$ and B_j^{maj} as two different bins even though their contents may be packed into the same bin. In such a case, we say that $B_i^{\min}$ is paired with B_j^{maj}.

We want to maintain a greedy-style combination of the two lists of bins, which can be described by the following combination process: The list of bins with minor items is (partially) sorted by their type $(1, \dots, k)$, i.e. bins potentially filled with more minor items appear earlier (the ordering here is different compared to the ordering in §2.3.1 when the minor items are actually packed). The list of bins with major items is sorted by their filling height in decreasing order (regardless of their type). The process iterates over the k bin types in the solution of minor items starting with type 2 (since there is no reserved space in bins of type 1) in increasing order. For each bin $B_i^{\min}$ of type j, we iterate over the bins with major items starting with the bins that have the largest filling height. We pair $B_i^{\min}$ with a bin with major items B_ℓ^{maj} that has a filling height of at most $1 - w_j$ and for which ℓ is minimal, i.e., the first bin with major items whose items fit into the reserved space of the respective (minor item) bin type.

Note that this process incorporates all bins of the minor solution that contain at least one item, including the ones that are part of a buffer clump. We do not use bins that contain no minor items at all (even if they are already present in the minor algorithm as part of a buffer clump). Such a greedy-style packing can be maintained while only modifying $\mathcal{O}(k)$ pairings per changed bin in either one of the two solutions. A major reason for this is that for the bins with minor items, only their type is of interest. The pairings of bins need to be changed if one of the following happens:

A change in the solution of major items: For each insertion or deletion of a major item, the solution of major items is modified independently first. The above described greedy process is then used to determine which bins with major items need to be matched with which types of bins of minor items. The combination is then modified to fit the new solution by switching out the major bins where needed, starting with those which are paired with bins of minor items of type 2.

A change in the solution of minor items: As for the major items, the solution of minor items is first modified independently upon insertion or deletion of a minor item. The modification may add or remove at most one bin of minor items. In this case, the above greedy approach is used to recalculate which bins with major items need to be matched with which types of bins of minor items. The solution is modified accordingly, starting with the matching with bins with minor items of type 2.

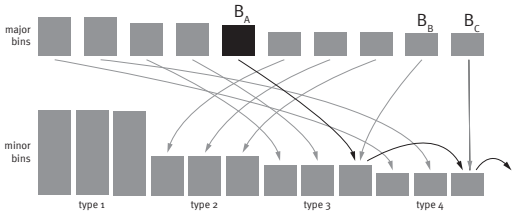

Figure 4 The gray bins represent current bins of the two solutions, the arrows indicate the current combination. The bin B_A is now inserted into the solution for the major items. B_A only fits into minor bins of type 3 or higher. The black arrows indicate the switching process. Bin B_A displaces B_B to a minor bin of type 4. Since there is no bin left for B_C, it is not combined with any minor bin after the changes.

Analysis

Due to the described greedy approach for changes and Lemma 2.15 and 2.19, we can bound the total recourse.

▶ **Lemma 2.20.** *The recourse is bounded by $\mathcal{O}(\varepsilon^{-2})$ for each insertion or deletion.*

▶ **Lemma 2.21.** *Let B^{min} be a bin with minor items of type j. If B^{min} is not combined with a bin of major items, all non-combined bins with major items have a filling height of at least $1 - w_j$.*

It remains to show that our algorithm achieves the desired approximation quality.

▶ **Lemma 2.22.** *Let* Alg *be the number of bins our algorithm uses for an arbitrary input sequence and* Opt *the number of bins used by an optimal solution. Then this yields* $\text{Alg} \leq (1+\varepsilon)\cdot\alpha\cdot\text{Opt}$.

Proof. We reuse the notation of Sections 2.3.1 and 2.3.2. For the bins with major items of Alg, we introduce a collection of bins called *L-S-quartet*, consisting of three LL bins and one SSS bin. The number of such collections is denoted by $Q^{\text{Alg}} := \left\lfloor \min\{\text{Alg}_{SSS}, \frac{1}{3}\text{Alg}_{LL}\} \right\rfloor$. We split the number of LL and SSS bins in Alg in the number of bins that can be put in such quartets, denoted by $\text{Alg}^{Q}_{LL} := 3Q^{\text{Alg}}$ and $\text{Alg}^{Q}_{SSS} := Q^{\text{Alg}}$, and the respective number of bins that cannot be put in such a collection, denoted by Alg^{-Q}_{LL} and Alg^{-Q}_{SSS}. Note that it therefore holds $\text{Alg}_{LL} = \text{Alg}^{Q}_{LL} + \text{Alg}^{-Q}_{LL}$ and $\text{Alg}_{SSS} = \text{Alg}^{Q}_{SSS} + \text{Alg}^{-Q}_{SSS}$. Furthermore, due to the definition of Q^{Alg}, it holds $\text{Alg}^{-Q}_{LL} \leq 2$ or $\text{Alg}^{-Q}_{SSS} = 0$.

Note that we assume that the solution of Alg for the major items does not contain bins with only O items, otherwise the approximation ratio would follow directly as argued in the previous section.

We estimate the optimal solution by adding up all the items which need to be packed. As before, we denote by W the cumulative size of all minor items. We estimate the cumulative size of major items by considering the different types of bins with major items $\tau \in \mathcal{T}$ and their minimal filling height $F(\tau)$ resulting from the minimum size of the respective items (e.g., for bins of type BL, we have $F(BL) = 1/2 + 1/3 = 5/6$). By incorporating the fact that all bins in quartets have an average filling height of $3/4$ we get

$$\text{Opt} \geq W + \sum_{\tau\in\mathcal{T}} F(\tau)\cdot\text{Alg}^{-Q}_{\tau} + \frac{3}{4}\text{Alg}^{Q}_{LL} + \frac{3}{4}\text{Alg}^{Q}_{SSS} \text{ as well as} \tag{1}$$

$$\text{Opt} \geq W + \sum_{\tau\in\mathcal{T}} F(\tau)\cdot\text{Alg}^{-Q}_{\tau} + 3Q^{\text{Alg}}. \tag{2}$$

From Lemma 2.21 we get the following: Suppose j is the maximum index such that a bin of type j is not combined with a bin of major items (pick $j = 1$ if such a bin does not exist). Then all remaining bins with major items must have a size of at least $1 - w_j$. Note that if $j = k$, then $\text{ALG} \leq (z'_k + \frac{3}{4}\varepsilon\alpha)W + z'_k \cdot W^{maj}$ directly follows, where W^{maj} is the workload of major items, and hence the approximation ratio. We assume $j < k$ in the following. We introduce $\text{ALG}^{\geq(1-w_j);-Q}_{BL,BS,B,LLS,LL,SSS}$ as the number of bins (with major items) of the given types used by our algorithm, limited to bins with a filling height of at least $1 - w_j$ and excluding all quartets. Hence we have

$$\begin{aligned}\text{ALG} &\leq (z'_j + \frac{3}{4}\varepsilon\alpha)W + \text{ALG}^{\geq(1-w_j);-Q}_{BL,BS,B,LLS,LL,SSS} + \text{ALG}^{Q}_{LL,SSS} \\ &\leq (z'_j + \frac{3}{4}\varepsilon\alpha)\text{OPT} + \sum_{\tau\in\mathcal{T}}(1 - z'_j \cdot F(\tau)) \cdot \text{ALG}^{\geq(1-w_j);-Q}_{\tau} + (1 - \frac{3}{4}z'_j)\text{ALG}^{Q}_{LL,SSS} \qquad (3)\end{aligned}$$

from (1) as well as

$$\begin{aligned}\text{ALG} &\leq (z'_j + \frac{3}{4}\varepsilon\alpha)W + \text{ALG}^{\geq(1-w_j);-Q}_{BL,BS,B,LLS,LL,SSS} + 4Q^{\text{ALG}} \\ &\leq (z'_j + \frac{3}{4}\varepsilon\alpha)\text{OPT} + \sum_{\tau\in\mathcal{T}}(1 - z'_j \cdot F(\tau)) \cdot \text{ALG}^{\geq(1-w_j);-Q}_{\tau} + (4 - 3z'_j)Q^{\text{ALG}}. \qquad (4)\end{aligned}$$

from (2). We use one of these estimations depending on Q^{ALG}.

Let $\hat{z}_j := z'_k - z'_j$. For the two cases with $\text{ALG}^{-Q}_{LL} \leq 2$ or $\text{ALG}^{-Q}_{SSS} = 0$ we show the following lemmas:

▶ **Lemma 2.23.** *Let* $\text{ALG}^{-Q}_{LL} \leq 2$. *Then it holds that*

$$\text{OPT} \geq \frac{1}{\hat{z}_j} \cdot \left(\sum_{\tau\in\mathcal{T}}(1 - z'_j \cdot F(\tau)) \cdot \text{ALG}^{\geq(1-w_j);-Q}_{\tau} + (1 - \frac{3}{4}z'_j)\text{ALG}^{Q}_{LL,SSS}\right).$$

▶ **Lemma 2.24.** *Let* $\text{ALG}^{-Q}_{SSS} = 0$. *Then it holds that*

$$\text{OPT} \geq \frac{1}{\hat{z}_j} \cdot \left(\sum_{\tau\in\mathcal{T}}(1 - z'_j \cdot F(\tau)) \cdot \text{ALG}^{\geq(1-w_j);-Q}_{\tau} + (4 - 3z'_j)Q^{\text{ALG}}\right).$$

Hence, from (3) together with Lemma 2.23 or (4) together with Lemma 2.24, we conclude

$$\text{ALG} \leq (z'_j + \frac{3}{4}\varepsilon\alpha)\text{OPT} + \hat{z}_j \cdot \text{OPT} \leq (z'_k + \frac{3}{4}\varepsilon\alpha)\text{OPT} = (1 + \varepsilon)\alpha\text{OPT}.$$

◀

Finally, Theorem 2.11 now directly follows from our analysis: Lemma 2.22 gives the approximation ratio of $(1 + \varepsilon) \cdot \alpha$ and Lemma 2.20 bounds the worst-case recourse to $\mathcal{O}(\varepsilon^{-2})$.

3 General Movement Costs

We now consider the case of general movement costs, and show a close connection with the (arrival-only) online problem. We first show that the fully-dynamic problem under general movement costs cannot achieve a better a.c.r than the online problem. Next, we match the a.c.r of any SUPER-HARMONIC algorithm for the online problem in the fully-dynamic setting.

3.1 Matching the Lower Bounds for Online Algorithms

Formally, an *adversary process* $\mathcal{B}$ for the online BIN PACKING problem is an adaptive process that, depending on the state of the system (i.e., the current set of configurations used to pack the current set of items) either adds a new item to the system, or stops the request sequence. We say that an adversary process shows a lower bound of c for online algorithms for BIN PACKING if for any online algorithm $\mathcal{A}$, this process starting from the empty system always eventually reaches a state where the a.c.r is at least c.

▶ **Theorem 3.1.** *Let $\beta \geq 2$. Any adversary process $\mathcal{B}$ showing a lower bound of c for the a.c.r of any online* BIN PACKING *algorithm can be converted into a fully-dynamic* BIN PACKING *instance with general movement costs such that any fully-dynamic* BIN PACKING *algorithm with amortized recourse at most β must have a.c.r at least c.*

Such a claim is simple for *worst-case* recourse. Indeed, given a recourse bound β, set the movement cost of the i-th item to be $(\beta + \varepsilon)^{n-i}$ for $\varepsilon > 0$. When the i-th item arrives we cannot repack *any* previous item because their movement costs are larger by a factor of $> \beta$. So this is a regular online algorithm. The argument fails, however, if we allow amortization.

To construct our lower bound instance, we start with an adversary process and create a dynamic instance as follows. Each subsequent arriving item has exponentially decreasing (by a factor β) movement cost. When the next item arrives, our algorithm could move certain existing items. These items would have much higher movement cost than the arriving item, and so, this process cannot happen too often. Whenever this happens, we *reset* the state of the process to an earlier time and remove all jobs arriving in the intervening period. This will ensure that the algorithm always behaves like an online algorithm which has not moved any of the existing items. Since it cannot move jobs too often, the set of existing items which have not been moved by the algorithm grow over time. This idea allows us to show: implies:

▶ **Corollary 3.2.** *No fully-dynamic* BIN PACKING *algorithm with bounded recourse under general movement costs and $o(n)$ additive term is better than* 1.540*-asymptotically competitive.*

3.2 (Nearly) Matching the Upper Bounds for Online Algorithms

We outline some of the key ingredients in obtaining an algorithm with competitive ratio nearly matching our upper bound of the previous section. The first is an algorithm to pack similarly-sized items.

▶ **Lemma 3.3** (Near-Uniform Sizes)**.** *There exists a fully-dynamic* BIN PACKING *algorithm with constant worst-case recourse which given items of sizes $s_i \in [1/k, 1/(k-1))$ for some integer $k \geq 1$, packs them into bins of which all but one contain $k-1$ items and are hence at least $1 - 1/k$ full. (If all items have size $1/k$, the algorithm packs k items in all bins but one.)*

Lemma 3.3 readily yields a 2-a.c.r algorithm with constant recourse (see [15]). We now discuss how to obtain 1.69-a.c.r based on this lemma and the HARMONIC algorithm [29].

The Harmonic Algorithm. The idea of packing items of nearly equal size together is commonly used in online BIN PACKING algorithms. For example, the HARMONIC algorithm [29] packs large items (of size $\geq \epsilon$) as in Lemma 3.3, while packing small items (of size $\leq \varepsilon$) into dedicated bins which are at least $1 - \varepsilon$ full on average, using e.g., FIRSTFIT. This algorithm uses $(1.69 + \mathcal{O}(\varepsilon)) \cdot OPT + \mathcal{O}(\varepsilon^{-1})$ bins [29]. Unfortunately, due to item removals, FIRSTFIT won't suffice to pack small items into nearly-full bins.

To pack small items in a dynamic setting we extend our ideas for the unit cost case, partitioning the bins into *buckets* of $\Theta(1/\epsilon)$ many bins, such that all but one bin in a bucket are $1-\mathcal{O}(\epsilon)$ full, and hence the bins are $1-\mathcal{O}(\epsilon)$ full on average. Since the size and cost are not commensurate, we maintain the small items in sorted order according to their *Smith ratio* (c_i/s_i). However, insertion of a small item can create a large cascade of movements throughout the bucket. We only move items to/from a bin once it has $\Omega(\epsilon)$'s worth of volume removed/inserted (keeping track of erased, or "ghost" items). A potential function argument allows us to show amortized $\mathcal{O}(\epsilon^{-2})$ recourse cost for this approach, implying the following lemma, and by [29], a $(1.69+\mathcal{O}(\varepsilon))$-a.c.r algorithm with $\mathcal{O}(\epsilon^{-2})$ recourse.

▶ **Lemma 3.4.** *For all $\varepsilon \leq \frac{1}{6}$ there exists an asymptotically $(1+\mathcal{O}(\varepsilon))$-competitive* BIN PACKING *algorithm with $\mathcal{O}(\varepsilon^{-2})$ amortized recourse if all items have size at most ε.*

Seiden's Super-Harmonic Algorithms. We now discuss our remaining ideas to match the bounds of any Super-Harmonic algorithm [33] in the fully-dynamic setting. A *Super-harmonic* (SH) algorithm partitions the unit interval $[0,1]$ into $K+1$ intervals $[0,\varepsilon], (t_0=\varepsilon, t_1](t_1,t_2], \ldots, (t_{K-1}, t_K=1]$. Small items (of size $\leq \varepsilon$) are packed into dedicated bins which are $1-\varepsilon$ full. A large item has type i if its size is in the range $(t_{i-1}, t_i]$. The algorithm also colors items blue or red. Each bin contains items of at most two distinct item types i and j. If a bin contains only one item type, all its items are colored the same. If a bin contains two item types $i \neq j$, all type i items are colored blue and type j ones are colored red (or vice versa). The SH algorithm is defined by four sequences $(\alpha_i)_{i=1}^K, (\beta_i)_{i=1}^K, (\gamma_i)_{i=1}^K$, and a bipartite *compatibility graph* $\mathcal{G}=(V,E)$. A bin with blue (resp., red) type i items contains at most β_i (resp., γ_i) items of type i, and is *open* if it contains less than this many type i items. The compatibility graph $\mathcal{G}=(V,E)$ has vertex set $V=\{b_i \mid i\in[K]\}\cup\{r_j \mid j\in[K]\}$, with an edge $(b_i,r_j)\in E$ indicating blue items of type i and red items of type j are *compatible* and may share a bin. In addition, an SH algorithm must satisfy the following invariants.

- **(P1)** The number of open bins is $\mathcal{O}(1)$.
- **(P2)** If n_i is the number of type-i items, the number of red type-i items is $\lfloor \alpha_i \cdot n_i \rfloor$.
- **(P3)** If $(b_i,r_j)\in E$ (blue type i items and red type j items are compatible), there is no pair of bins with one containing only blue type i items and one containing only red type j items.

Appropriate choice of $(t_i)_{i=1}^{K+1}, (\alpha_i)_{i=1}^K, (\beta_i)_{i=1}^K, (\gamma_i)_{i=1}^K$ and $\mathcal{G}$ allows one to bound the a.c.r of any SH algorithm. (E.g., Seiden gives an SH algorithm with a.c.r 1.589 [33].)

Simulating SH algorithms. In a sense, SH algorithms ignore the exact size of large items, so we can take all items of some type and color. This extends Lemma 3.3 to pack at most β_i or γ_i of them per bin to satisfy Properties 1 and 2. The challenge is in maintaining Property 3: consider a bin with β_i blue type i items and γ_j type-j items, and suppose the type i items are all removed. Suppose there exists an open bin with items of type $i' \neq i$ compatible with j. If the movement costs of both type j and type i' items are significantly higher than the cost of the type i items, we cannot afford to place these groups together, violating Property 3. To avoid such a problem, we use ideas from *stable matchings*. We think of groups of β_i blue type-i items and γ_j red type-j items as nodes in a bipartite graph, with an edge between these nodes if $\mathcal{G}$ contains the edge (b_i,r_j). We maintain a stable matching under updates, with priorities being the value of the costliest item in a group of same-type items packed in the same bin. The stability of this matching implies Property 3; we maintain this stable matching using (a variant of) the Gale-Shapley algorithm. Finally, relying on our solution for packing small items as in §3.2, we can pack the small items in bins which are $1-\varepsilon$ full on average. Combined with the SH bound of Seiden [33], we obtain the following:

▶ **Theorem 3.5.** *There exists a fully-dynamic* BIN PACKING *algorithm with a.c.r* 1.589 *and constant additive term using constant recourse under general movement costs.*

4 Size Movement Costs (Migration Factor)

In this section, we settle the optimal recourse to a.c.r tradeoff for size movement cost (referred to as *migration factor* in the literature); that is, $c_i = s_i$ for each item i. For worst-case recourse in this model (studied in [9, 23, 6]), $poly(\epsilon^{-1})$ upper and lower bounds are known for $(1+\epsilon)$-a.c.r. algorithms [6], though the optimal tradeoff remains elusive. We show that for amortized recourse the optimal tradeoff is $\Theta(\epsilon^{-1})$ recourse for $(1+\epsilon)$-a.c.r.

▶ **Fact 4.1.** *For all $\epsilon \leq 1/2$, there exists an algorithm requiring $(1+\mathcal{O}(\varepsilon))\cdot OPT(\mathcal{I}_t)+\mathcal{O}(\varepsilon^{-2})$ bins at all times t while using only $\mathcal{O}(\varepsilon^{-1})$ amortized migration factor.*

This upper bound is trivial – it suffices to repack according to an AFPTAS whenever the volume changes by a multiplicative $(1+\epsilon)$ factor. The challenge here is in showing this algorithm's a.c.r to recourse tradeoff is *tight*. We do so by constructing an instance where addition or removal of small items of size $\approx \varepsilon$ causes *every* near-optimal solution to be far from every near-optimal solution after addition/removal.

▶ **Theorem 4.2.** *For infinitely many $\epsilon > 0$, any fully-dynamic* BIN PACKING *algorithm with a.c.r $(1+\varepsilon)$ and additive term $o(n)$ must have* amortized *migration factor of $\Omega(\varepsilon^{-1})$.*

Our matching lower bound relies on the well-known Sylvester sequence [34], given by the recurrence relation $k_1 = 2$ and $k_{i+1} = \left(\prod_{j\leq i} k_j\right) + 1$, the first few terms of which are $2, 3, 7, 43, 1807, \ldots$ While this sequence has been used previously in the context of BIN PACKING, our proof relies on more fine-grained divisibility properties. In particular, letting c be a positive integer specified later and $\varepsilon := 1/\prod_{\ell=1}^{c} k_\ell$, we use the following properties:

(P1) $\frac{1}{k_1} + \frac{1}{k_2} + \ldots + \frac{1}{k_c} = 1 - \frac{1}{\prod_{\ell=1}^{c} k_\ell} = 1 - \varepsilon$.

(P2) If $i \neq j$, then k_i and k_j are relatively prime.

(P3) For all $i \in [c]$, the value $1/k_i = \prod_{\ell\in[c]\setminus\{i\}} k_\ell / \prod_{\ell=1}^{c} k_\ell$ is an integer product of ε.

(P4) If $i \neq j \in [c]$, then $1/k_i = \prod_{\ell\in[c]\setminus\{i\}} k_\ell / \prod_{\ell=1}^{c} k_\ell$ is an integer product of $k_j \cdot \epsilon$.

We define a vector of item sizes $\vec{s} \in [0,1]^{c+1}$ in our instances as follows: for $i \in [c]$ we let $s_i = \frac{1}{k_i} \cdot (1 - \frac{\varepsilon}{2})$, and $s_{c+1} = \varepsilon \cdot (\frac{3}{2} - \frac{\varepsilon}{2})$. The adversarial input sequence will alternate between two instances, $\mathcal{I}$ and $\mathcal{I}'$. For some large N a product of $\prod_{\ell=1}^{c} k_\ell$, Instance $\mathcal{I}$ consists of N items of sizes s_i for all $i \in [c+1]$. Instance $\mathcal{I}'$ consists of N items of all sizes but s_{c+1}.

Properties 1-4 imply on the one hand that $\mathcal{I}$ can be packed into completely full bins containing one item of each size, while any bin which does not contain exactly one item of each size has at least $\Omega(\varepsilon)$ free space. Similarly, an optimal packing of $\mathcal{I}'$ packs items of the same size in one set of bins, using up exactly $1 - \frac{\epsilon}{2}$ space, while any bin which contains items of at least two sizes has at least ϵ free space. These observations imply the following.

▶ **Lemma 4.3.** *Any algorithm $\mathcal{A}$ with $(1+\varepsilon/7)$-a.c.r and $o(n)$ additive term packs instance $\mathcal{I}$ such that at least $2N/3$ bins contain exactly one item of each size s_i, and packs instance $\mathcal{I}'$ such that at least $N/2$ bins contain items of exactly one size.*

Theorem 4.2 follows from Lemma 4.3 in a rather straightforward fashion. The full details of this proof and the lemmas leading up to it can be found in [15].

Abstract

We consider one-sided error property testing of $\mathcal{F}$-minor freeness in bounded-degree graphs for any finite family of graphs $\mathcal{F}$ that contains a minor of $K_{2,k}$, the k-circus graph, or the $(k \times 2)$-grid for any $k \in \mathbb{N}$. This includes, for instance, testing whether a graph is outerplanar or a cactus graph. The query complexity of our algorithm in terms of the number of vertices in the graph, n, is $\tilde{O}(n^{2/3}/\epsilon^5)$. Czumaj et al. (2014) showed that cycle-freeness and C_k-minor freeness can be tested with query complexity $\tilde{O}(\sqrt{n})$ by using random walks, and that testing H-minor freeness for any H that contains a cycles requires $\Omega(\sqrt{n})$ queries. In contrast to these results, we analyze the structure of the graph and show that either we can find a subgraph of sublinear size that includes the forbidden minor H, or we can find a pair of disjoint subsets of vertices whose edge-cut is large, which induces an H-minor.

1 Introduction

The study of graph minors began with the work of Wagner [18] and Kuratowski [14]. In a seminal work on graph minors, Robertson and Seymour [17] proved the Graph-Minor Theorem, which states that every family of graphs that is closed under forming minors is characterized by a finite list of forbidden minors. As a consequence of their work, they gave a classical decision algorithm with a running time of $\tilde{O}(n^3)$ to verify whether a fixed graph H is a minor of G.

If time complexity which is polynomial, or even linear, in n is considered too costly, then it is often useful to study a relaxed version of the decision problem. In graph property testing, the goal is to test whether a given input graph has a property or is far from the property (according to some metric) while looking at a very small part of the graph (sublinear in the number of vertices). This was first studied by Goldwasser, Goldreich and Ron [10], where the graph was represented as an adjacency matrix. While this model captures properties of dense graphs well, a more natural one for sparse graphs is the *bounded degree* model, first studied by Goldreich and Ron [12], where the graph is given as adjacency lists. In the bounded degree model, the metric is the fraction ϵ of edges of the input graph that have to be modified out of the maximum possible number of edges (the number of vertices times the bound on the maximum degree), and the *query complexity* of a tester is the number of adjacency list entries that the tester looks at. Two-sided (error) property testers are randomized algorithms that are allowed to err on all graphs, while one-sided (error) property testers are required to present a witness against the property when they reject (for more information on property testing, refer to [9, 8]).

In the setting of property testing, Benjamini, Schramm and Shapira [1] conjectured that for any fixed H, H-minor freeness can be tested with $\tilde{O}(\sqrt{n})$ queries by a one-sided tester on bounded degree graphs. Czumaj et al. [3] provided H-minor freeness testers with one-sided error. They showed that C_k-freeness is testable with $\tilde{O}(\sqrt{n})$ queries for bounded degree graphs for $k \geq 3$ and that any one-sided tester for H-minor freeness requires $\Omega(\sqrt{n})$ queries when H contains a cycle. When H is a forest, they showed that there is a one-sided tester for H-minor freeness whose query complexity depends only on ϵ. They consider the problem whether H-minor freeness can be tested with query complexity $o(n)$ for every minor H "the most begging open problem" [3] left open by their work. Apart from cycles and forests, the only further progress they make towards answering this question is for H which is the 4-vertex graph consisting of a triangle and an additional edge. In this paper we make a significant progress on answering this question and on closing the gap between the conjecture of Benjamini et al. [1] and what is known for one-sided error testing of general forbidden minors that contain a cycle.

1.1 Our results

We extend the study of testing H-minor freeness for a fixed graph H with one-sided error. For a finite family of minors $\mathcal{F}$, we say that a graph is $\mathcal{F}$-minor free if it is H-minor free for every $H \in \mathcal{F}$. We obtain a property tester with query complexity $\tilde{O}(n^{2/3}/\epsilon^5)$ for $\mathcal{F}$-minor freeness, where $\mathcal{F}$ is any family of forbidden minors that contains some graph H that is a minor of either the complete bipartite graph $K_{2,k}$, the k-circus graph (see [2]) or the $(k \times 2)$-grid. This implies, for example, that one can test with one-sided error whether a

graph is outerplanar or a cactus graph. We prove the following result (see Theorem 26 for a more general, technical version).

▶ **Theorem 1.** *Given a graph G with degree at most Δ, and a parameter ϵ, for every constant k, there is a one-sided (error) ϵ-tester with query complexity $\tilde{O}(n^{2/3}/\epsilon^5)$ for $\mathcal{F}$-minor freeness, where $\mathcal{F}$ is a family of forbidden minors such that there exists $H \in \mathcal{F}$ and H is a minor of $K_{2,k}$, the k-circus graph or the $(k \times 2)$-grid.*

Setting $\mathcal{F} = \{K_{2,3}, K_4\}$ and $\mathcal{F}$ to consist of the diamond graph (C_4 with a chord), it follows that outerplanarity, and being a cactus graph, can be tested with one-sided error, respectively.

▶ **Corollary 2.** *Testing outerplanarity with one-sided error has query complexity $\tilde{O}(n^{2/3}/\epsilon^5)$.*

▶ **Corollary 3.** *Testing the property of being a cactus graph with one-sided error has query complexity $\tilde{O}(n^{2/3}/\epsilon^5)$.*

1.2 Related Work

As described above, the work most closely related to ours is the paper by Czumaj et al. [3]. Other work in property testing on H-minor freeness studies two-sided error testers. Goldreich and Ron [12] showed that K_3-minor freeness (i.e. cycle-freeness) can be tested with two-sided error and query complexity that is a polynomial in $1/\epsilon$ only. Czumaj, Shapira and Sohler [4] studied a partitioning of graphs that have low expansion (like minor free graphs), which yields two-sided tests for hereditary properties. The problem of testing general H-minor freeness was studied by Benjamini, Schramm and Shapira in [1], where they showed that every minor-closed property of sparse graphs is testable with two-sided error and query complexity independent of the graph's size, although they could only give an upper bound on the query complexity that was triple-exponential in $1/\epsilon$. Hassidim et al. [13] used partition oracles to give an easier two-sided tester for the property of H-minor freeness with query complexity $2^{\text{poly}(1/\epsilon)}$. This was further improved by Levi and Ron [16] to obtain a two-sided tester with query complexity that is quasi-polynomial in $1/\epsilon$. Yoshida and Ito [19] provided testers with two-sided error for outerplanarity and being a cactus graph with query complexity which is only polynomial in $1/\epsilon$ and the bound on the maximum degree.

1.3 Challenges and Techniques

The results of Benjamini et al. [1] imply that the optimal complexity of a two-sided H-minor freeness tester may depend on the size of H (and ϵ and Δ) only. On the other hand, it was proved by Czumaj et al. [3] that the hardness of the one-sided error problem depends on the structure of H. Since all embeddings of H into G may be much larger than H itself, the challenge lies in exploring the proper subgraph to find a witness. However, finding a witness can be worthwhile because it can make the decision of the tester more comprehensible (cf. the discussion in [3]). In [3], the problem of finding C_k-minors is reduced to a tester for bipartiteness [11], which in turn finds odd cycles when two random walks that start from the same vertex collide.

Our algorithm is based on a different approach that employs a partitioning of the graph into sublinear parts. Specifically, the main ingredients in our algorithm are a method to employ a partition of the graph that is derived from a partition into connected parts of size roughly $n^{1/3}$ by Lenzen and Levi [15], and combinatorial lemmas about the existence of H-minors that depends on the number of cut edges between two parts.

In contrast to testing via partition oracles [13, 16], it is not sufficient to only approximate the number of edges between the parts of our partition and, in turn, to reject if this approximated value is too high. This would seem like a limitation to obtaining sublinear query complexity since we can no longer assume that the graph is $\Theta(\epsilon)$-far from being H-minor free after removing the edges going across the parts. In particular, we might have to find a minor that crosses the cut of two parts. An additional obstacle is that we cannot recover the part of a vertex in general because it can be rather large. However, we can show that if the input graph is ϵ-far from being H-minor free, then we can either find a large cut between two parts, which implies the existence of an H-minor, or we can recover a superset of a part that contains an H-minor.

Suppose that G is ϵ-far from being $\mathcal{F}$-minor free, where $\mathcal{F}$ is a family of forbidden minors as in Theorem 1. The algorithm uses a partition into *core clusters* and *remote clusters* of size $\tilde{O}(n^{1/3})$. We draw a uniform sample of edges of constant size (which contains an edge of a minor with constant probability) and distinguish two cases. If an edge belongs to a forbidden minor that is contained in a single cluster, then it suffices to check the cluster for this minor. For core clusters, we can do this by using a partition oracle, but for remote clusters we use a promise on the diameter of the cluster to recover a superset of the remote cluster.

The other case is that a forbidden minor lies across clusters. In particular, we argue that the minor must then lie across core clusters. We show that if the cut between two clusters is greater than some threshold $f = f(H)$, this implies an H-minor (recall that H is either $K_{2,k}$, the k-circus graph or the $(k \times 2)$-grid). In fact, we show that this is true for every pair of disjoint subsets of vertices such that their respective induced subgraphs are connected. Given that, we analyze the edge cut of a coarser partition into *super clusters* and show that if the total size of all cuts that exceed the above-mentioned threshold is small, then actually all edges between clusters can be removed. To obtain access to the partition into super clusters we make use of another coarser partition into *Voronoi cells* for which we also do not have a partition oracle but, roughly speaking, can answer membership queries efficiently.

While we do not attain the upper bound of $\tilde{O}(\sqrt{n})$ conjectured by Benjamini et al. [1], our techniques are significantly different from the ones of Czumaj et al. [3], which is the only other work that gives one-sided testers for minor freeness that we are aware of. Our work throws open two natural questions. The first is whether the technique of partitioning can be used to obtain a one-sided tester for H-minor freeness that matches the conjectured $\tilde{O}(\sqrt{n})$ upper bound. Roughly speaking, the complexity of the algorithm given in Theorem 1, in terms of n, results from the fact that the size of the parts is $\tilde{O}(n^{1/3})$, and the fact that checking to which part a vertex belongs to takes $\tilde{O}(n^{1/3})$ as well. The second question is whether similar techniques can be used to design one-sided testers for a larger class of minors with sublinear query complexity. The limitation of our current approach to the aforementioned minors arises from the inner structure of the parts that we can assume, namely connectivity and bounded diameter. Extending these guarantees, one may hope to find other minors, for example: $(k \times k)$-grid minors; or $K_{3,3}$, which implies testing planarity in sublinear time.

2 Preliminaries

The graphs we consider are simple, undirected, and have a known degree bound Δ. We denote the number of vertices in the graph at hand by n and we assume that each vertex v has a unique id, which for simplicity we also denote by v. There is a total order on the ids, i.e., given any two distinct ids u and v, we can decide whether $u < v$ or $v < u$. The

total order on the vertices induces a total order r on the edges of the graph in the following straightforward manner: $r(\{u,v\}) < r(\{u',v'\})$ if and only if $\min\{u,v\} < \min\{u',v'\}$ or $\min\{u,v\} = \min\{u',v'\}$ and $\max\{u,v\} < \max\{u',v'\}$. The total order over the vertices also induces an order over those vertices visited by a Breadth First Search (BFS) starting from any given vertex v, and whenever we refer to a BFS, we mean that it is performed according to this order. Whenever referring to one of the above orders, we may refer to the *rank* of an element in the respective order. This is simply the index of the respective element when listing all the elements according to the order starting with the smallest.

Let $G = (V,E)$ be a graph, where $V = [n]$. We will say that a graph G is ϵ-far from a property P if at least $\epsilon n\Delta$ edges of G have to be modified in order to convert it into a graph that satisfies the property P. In this paper, the property P that is of interest is H-minor freeness. We will assume that the graph G is represented by a function $f_G : [n] \times [\Delta] \to [n] \cup \{\star\}$, where $f(v,i)$ denotes the i^{th} neighbor of v if v has at least i neighbors. Otherwise, $f_G(v,i) = \star$. We will now define the notion of *one-sided* (error) property testers.

▶ **Definition 4** (One-sided testers)**.** A one-sided (error) ϵ-tester for a property P of bounded degree graphs with query complexity q is a randomized algorithm $\mathcal{A}$ that makes q queries to f_G for a graph G. The algorithm $\mathcal{A}$ accepts if G has the property P. If G is ϵ-far from P, then $\mathcal{A}$ rejects with probability at least $2/3$.

We denote the distance between two vertices u and v in G by $d_G(u,v)$. For vertex $v \in V$ and an integer r, let $\Gamma_r(v,G)$ denote the set of vertices at distance at most r from v. When the graph G is clear from the context, we shall use the shorthands $d(u,v)$ and $\Gamma_r(v)$ for $d_G(u,v)$ and $\Gamma_r(v,G)$, respectively. For a subset of vertices $S \subseteq V$, we denote by $G[S]$ the subgraph induced on S in G.

▶ **Definition 5** (Graph minors)**.** A graph H is a minor of G, if H can be obtained from G by a sequence of vertex deletions, edge deletions and *edge contractions*: For an edge $(u,v) \in G$, delete the vertices u,v, and create a new vertex w. For each neighbor z of either u or v in the graph, add a new edge (w,z).

▶ **Definition 6** ($(k\times 2)$-grid)**.** The $(k\times 2)$-grid is the graph whose vertex set is $\{x_i\}_{i=1}^{k} \cup \{y_i\}_{i=1}^{k}$ and edge set is $\{x_i, x_{i+1}\}_{i=1}^{k-1} \cup \{y_i, y_{i+1}\}_{i=1}^{k-1} \cup \{x_i, y_i\}_{i=1}^{k}$.

▶ **Definition 7** (k-circus graph ([2]))**.** The k-circus graph is the graph whose vertex set is $\{x\} \cup \{y_i\}_{i=1}^{k} \cup \{z_i\}_{i=1}^{k}$ and edge set is $\{(y_i,z_i)\}_{i=1}^{k} \cup \{z_i, z_{i+1}\}_{i=1}^{k-1} \cup \{x, y_i\}_{i=1}^{k}$.

For a graph $G = (V,E)$ and a pair of disjoint subsets of vertices $A \subset V$ and $B \subset V$ let $E_G(A,B) \stackrel{\text{def}}{=} \{(u,v) \in E \,|\, u \in A \wedge v \in B\}$. When it is clear from the context, we omit the subscript. We say that a pair of subsets of vertices A and B is *adjacent* if $E_G(A,B) \neq \emptyset$.

▶ **Definition 8** (Separability)**.** A graph $G = (V,E)$ is (f,g)-*separable* if for every disjoint sets of vertices A and B such that $G[A]$ and $G[B]$ are connected and the diameter of $G[A]$ is at most g it holds that $|E(A,B)| \leq f$.

We shall use the following theorem by Erdős and Szekeres.

▶ **Lemma 9** (Erdős and Szekeres [6])**.** *Given a sequence of natural numbers $S = (s_i)_{i\in[n]}$ of length n, there exists a subsequence of length $\sqrt{n}$ that is either monotonically increasing or monotonically decreasing.*

3 Separability and Evidence for Minors

In this section we prove combinatorial lemmas that give sufficient conditions for the existence of a $(k \times 2)$-grid minor, a k-circus minor and a $K_{2,k}$ minor in a graph. To that end, we will consider the following auxiliary graph, which is defined with respect to a partition of another graph's vertex set.

▶ **Definition 10.** Let $G = (V, E)$ be a graph and $\mathcal{P}$ a partition of its vertex set. The graph $G[\mathcal{P}]$ is defined as the graph with vertex set $\mathcal{P}$, and $\{P, P'\} \subseteq \mathcal{P}$ is an edge if and only if there are vertices $v \in P, u \in P'$ such that $\{u, v\} \in E$.

Notice that if $G[P]$ is connected for every $P \in \mathcal{P}$, then $G[\mathcal{P}]$ is isomorphic to the minor of G obtained by contracting every edge of $G[P]$, for all $P \in \mathcal{P}$, so we will often refer to this minor also by $G[\mathcal{P}]$.

▶ **Lemma 11.** *Given a tree $T = (V, E)$ of bounded degree Δ and a subset of* relevant *vertices $Q \subseteq V$, there exists a partitioning $\mathcal{P}$ of V such that $T[\mathcal{P}]$ is a path minor of T of length $\log_\Delta |Q|$ and for every $P \in \mathcal{P}$, it holds that $P \cap Q \neq \emptyset$.*

Proof. We will construct the claimed partition. Initially, let $\mathcal{P} = \{\{v\} \mid v \in V\}$. While there exists an edge $\{P, P'\}$ in $T[\mathcal{P}]$ such that P' does not contain a relevant vertex and the degree of P' is at most two, update $\mathcal{P} = \mathcal{P} \setminus P'$ and $P = P \cup P'$. Repeat this process until no such edges remain. Note that the resulting $T[\mathcal{P}]$ is still a tree of maximum degree Δ and that every part contains at most one relevant vertex, that is, $|P \cap Q| \leq 1$ for all $P \in \mathcal{P}$.

Since $T[\mathcal{P}]$ is a tree with at least $|Q|$ vertices, it has diameter $\ell \geq \log_\Delta |Q|$. Let $L = (P_1, P_2, \ldots, P_\ell)$ be a simple path in $T[\mathcal{P}]$ between a pair of leaves, of maximum length. For every part $P_i \in L$, let T_i be the subtree rooted at P_i in $T[\mathcal{P}]$ that is obtained by (virtually) removing the (at most two) edges between P_i and its neighbors in L. Every part $P_i \in L$ that contains no relevant vertex has at least one neighbor that is not in L, otherwise it is of degree at most two and would have been merged previously. For every such part, the tree T_i must contain at least one part that has non-empty intersection with Q, otherwise it would have been contracted. We update the partition by setting $P_i = \bigcup_{P \in T_i} P$ for every part $i \in [\ell]$ and setting $\mathcal{P} = \{P_i\}_{i=1}^{\ell}$.

Now, we have that for every $i \in [\ell]$, $P_i \cap Q \neq \emptyset$, and we have also not shortened the path. Therefore, $T[\mathcal{P}]$ is the desired path minor of T. ◀

▶ **Lemma 12.** *Given a rooted tree $T = (V, E)$ of bounded degree Δ with height h (for some $h \in \mathbb{N}$) and a subset of* relevant *vertices $Q \subseteq V$, there exists a partition, $\mathcal{P}$, of V such that $T[\mathcal{P}]$ is a star minor of T with $|Q|/(2h)$ leaves and for every $P \in \mathcal{P}$, it holds that $P \cap Q \neq \emptyset$.*

Proof. W.l.o.g., assume that the root is not in Q. Let S be the set of maximal paths in T that start at the root and end at some vertex in Q. The length of each path in S is bounded by h, and therefore there exist at least $|Q|/h$ such paths. Since all paths in S start at the same vertex and they are maximal, their end vertices are pairwise distinct. Removing all vertices that are not contained in any path of S and contracting all but the end edges of the paths in S, gives a star minor with at least $|Q|/h$ relevant leaves. Finally, we can contract an arbitrary leaf into the root to make the part of the root relevant. ◀

The common idea of the following proofs is to consider a partition of a graph into two parts such that there is a large cut, and to apply Lemma 11 and / or Lemma 12 to these parts in order to construct the desired minors.

▶ **Lemma 13.** *Let $G = (V, E)$ be a graph of bounded degree Δ that does not contain the $(k \times 2)$-grid as a minor. Then, G is $(\Delta^{1+\Delta^{k^2+1}}, n)$-separable.*

Proof. We prove the contrapositive of the statement of the lemma. Let $V_1 \dot\cup V_2$ be a partition of V such that $E(V_1, V_2) > \Delta^{1+\Delta^{k^2+1}}$. Let T_1 (resp. T_2) be a spanning tree of $G[V_1]$ (resp. $G[V_2]$). Let Q_1 be the set of vertices in V_1 that have a neighbor in V_2. Since $|E(V_1, V_2)| \geq \Delta^{1+\Delta^{k^2+1}}$, the size of the set Q_1 is at least $\Delta^{\Delta^{k^2+1}}$. By Lemma 11, there exists a partition $\mathcal{P}_1$ of V_1 such that $T_1[\mathcal{P}_1]$ is a path minor of T_1 of length $r \geq \log_\Delta |Q_1| \geq \Delta^{k^2+1}$. Let $(u_1, u_2, \cdots, u_r)$ be this path minor. For each vertex u_j in the path minor $T_1[\mathcal{P}_1]$, it holds that $|\Gamma(u_j) \cap V_2| \geq 1$. Now, for each vertex u_j in the path minor, remove all the edges to V_2 except the one of lowest rank, so that $|\Gamma(u_j) \cap V_2| = 1$.

Since the degree of G is at most Δ, the number of vertices in V_2 adjacent to Q_1 that remain after these edge deletions is at least Δ^{k^2}. Denote this set of vertices by Q_2. By Lemma 11, there exists a partition $\mathcal{P}_2$ of V_2 such that $T_2[\mathcal{P}_2]$ is a path minor of length $t \geq \log_\Delta |Q_2| \geq k^2$. Let $\{v_1, v_2, \cdots, v_t\}$ be this path. Since $|\Gamma(u_j) \cap T_2[\mathcal{P}_2]| = 1$ for all $u_j \in T_1[\mathcal{P}_1]$, we have $t \leq r$. Furthermore, each vertex $v_j \in T_2[\mathcal{P}_2]$ has at least one neighbor in $T_1[\mathcal{P}_1]$. Therefore, by Hall's theorem, there is matching of size at least k^2 between $T_1[\mathcal{P}_1]$ and $T_2[\mathcal{P}_2]$.

By Lemma 9, there is a set of k vertices, say $u_{i_1}, u_{i_2}, \cdots, u_{i_k}$ and $v_{j_1}, v_{j_2}, \cdots, v_{j_k}$, such that $i_1 \leq i_2 \leq \cdots \leq i_k$ and $j_1 \leq j_2 \leq \cdots \leq j_k$, and (u_{i_l}, v_{j_l}) is an edge in the matching. Contract the edges in the path to the vertices $u_{i_1}, u_{i_2}, \cdots, u_{i_k}$ and $v_{j_1}, v_{j_2}, \cdots, v_{j_k}$ to obtain the $(k \times 2)$-grid minor. ◀

▶ **Lemma 14.** *Let $G = (V, E)$ be a graph of bounded degree Δ that does not contain the k-circus as a minor. Then, G is $(2h\Delta^{2+k^2}, h)$-separable for every $h \in \mathbb{N}$.*

Proof. We prove the contrapositive of the statement of the lemma. This proof is very similar to the proof of Lemma 13. The only difference is that (i) we consider a partition $V_1 \dot\cup V_2$ of V such that $E(V_1, V_2) > 2h\Delta^{2+k^2}$ and the diameter of $G[V_1]$ is at most h and (ii) we apply Lemma 12 instead of Lemma 11 to $G[V_1]$. In particular, let T_1 (resp. T_2) be a spanning tree of $G[V_1]$ (resp. $G[V_2]$). Let Q_1 be the set of vertices in V_1 that have a neighbor in V_2. Since $|E(V_1, V_2)| \geq 2h\Delta^{2+k^2}$, the size of the set Q_1 is at least $2h\Delta^{1+k^2}$. By Lemma 12, there exists a partition $\mathcal{P}_1$ of V_1 such that $T_1[\mathcal{P}_1]$ is a star minor of T_1 with $r \geq \Delta^{1+k^2}$ leaves. Let $\{u_1, u_2, \cdots, u_r\}$ be the leaves of this star minor. For each leaf u_j of the star minor $T_1[\mathcal{P}_1]$, it holds that $|\Gamma(u_j) \cap V_2| \geq 1$. Now, for each leaf u_j in the star minor, remove all the edges to V_2 except the one of lowest rank, so that $|\Gamma(u_j) \cap V_2| = 1$. The remaining proof is analogous to the proof of Lemma 13. ◀

The proof of the following lemma appears in the arXiv version [7].

▶ **Lemma 15.** *Let $G = (V, E)$ be a graph of bounded degree Δ that does not contain the complete bipartite graph $K_{2,k}$ as a minor. Then, G is $(2\Delta kh, h)$-separable for every $h \in \mathbb{N}$.*

4 Underlying Partitions

In this section we describe a method to partition the graph into small connected parts with certain properties that enable us to apply Lemmas 13 to 15. The partition technique is very similar to the one that appears in [15], which is used for the local construction of sparse spanning subgraphs. We make minor adaptations to suit our needs. Omitted proofs appear in the arXiv version [7]. In Section 5, we will show how to utilize these partitions for testing the forbidden minors.

Three different partitions are described next, one of which is a refinement of the other two. As described in more detail in the next sections, the properties of these partitions are as follows. The refined partition into *core clusters* can be locally recovered. The edge cut of this partition is not necessarily small, even if the input graph excludes the forbidden minor. The second partition into *Voronoi cells* will be useful for checking the edge cut of the third partition into *super clusters*, which in turn is guaranteed to have a small edge cut in case the graph excludes the forbidden minor. See the arXiv version [7] for an illustration of the following definitions.

Parameters. The input parameters are α and γ. We sample ℓ uniformly at random from $[b \log n/\log(1+\gamma), b\log n/\log(1+\gamma) + \Delta/\gamma]$, and let $t \stackrel{\text{def}}{=} cn^{1/3}\ln n \cdot \ell\Delta/\alpha$ where c and b are sufficiently large constants. The parameter ℓ affects the diameter of the parts of the partition. It is picked randomly so as to ensure that only a small fraction of the edges are in the edge cut of the partition.

Centers. Pick a set $S \subset |V|$ of $\Theta(\alpha n^{2/3}/\ln n)$ vertices at random. We shall refer to the vertices in S as *centers*. For each vertex $v \in V$, its *center*, denoted by $c(v)$, is the center which is closest to v among all centers (break ties between centers according to the rank).

Remote Vertices. Define $R \stackrel{\text{def}}{=} \{v \mid \Gamma_\ell(v) \cap S = \emptyset\}$ where S is the set of centers. We call the vertices in R *remote* and abbreviate $\bar{R} \stackrel{\text{def}}{=} V \setminus R$.

Voronoi cells. The *Voronoi cell* of a vertex $v \in \bar{R}$ is $\mathsf{Vor}(v) \stackrel{\text{def}}{=} \{u \in \bar{R} \mid c(u) = c(v)\}$.

We deal with the partitioning of remote vertices later. Given a vertex $v \in \bar{R}$, one can determine its center by exploring its ℓ-hop neighborhood. However, it is much more costly to find all vertices that belong to its Voronoi cell, which may have size $\Omega(n)$. We now describe how to further refine the partition given by the Voronoi cells so that the number of vertices in each cluster is $\tilde{O}(n^{1/3}\Delta/\alpha)$.

Core clusters. For each Voronoi cell, consider the BFS tree spanning it, as described in Section 2, which is rooted at the respective center. For every $v \in V$, let $p(v)$ denote the *parent* of v in this BFS tree. If v is a center then $p(v) = v$. For every $v \in V \setminus S$, let $T(v)$ denote the subtree of v in the above-mentioned BFS tree when we remove the edge $\{v, p(v)\}$. Now consider a Voronoi cell. We define the *core cluster* of a vertex v as follows:

1. If $|\mathsf{Vor}(v)| \leq t$ then the core cluster of v is $\mathsf{Vor}(v)$.
2. If $|T(v)| \geq t$, where $|T(v)|$ denotes the number of vertices in $T(v)$, then the core cluster of v is the singleton $\{v\}$.
3. Otherwise, v has a unique ancestor u for which $|T(u)| < t$ and $|T(p(u))| \geq t$. The core cluster of v is the set of vertices in $T(u)$.

For a vertex $v \in \bar{R}$, let $\mathsf{cluster}(v)$ denote the cluster of v. For a cluster C, let $c(C)$ denote the center of the vertices in C (all the vertices in the cluster have the same center). Let $\mathsf{Vor}(C)$ denote the Voronoi cell of the vertices in C.

This describes a partition of V into R and $\bar{R}$, a refinement of $\bar{R}$ into Voronoi cells, and a refinement of this partition into core clusters. It was shown in [15] that the number of core clusters is not much higher than the number of Voronoi cells.

▶ **Lemma 16** (Lemma 1 in [15]). *The number of core clusters, denoted by s, is at most $|S| + n\ell(\Delta+1)/t$.*

Note that core clusters are, like Voronoi cells, connected.

▶ **Lemma 17.** *For every vertex $v \in \bar{R}$, $\mathsf{cluster}(v)$ is connected.*

Even more, Voronoi cells are still connected if one removes a cluster that is not a singleton.

▶ **Lemma 18.** *Let $v \in \bar{R}$ be a vertex such that $\mathsf{cluster}(v)$ is not a singleton. Then, $G[\mathsf{Vor}(v) \setminus \mathsf{cluster}(v)]$ is connected.*

In contrast to Voronoi cells, core clusters are guaranteed to be sufficiently small by construction, which allows us to fully explore them in an efficient manner. An explicit procedure for this is given in Section 5.1. However, it might still be possible for the overall edge cut to be large, even if there are only few edges in individual cuts between two core clusters. To this end, we group core clusters and consider the cut between pairs of a core cluster and such a resulting *super cluster* instead.

▶ **Definition 19.** For a core cluster A, define its *adjacent vertices* $\partial A \stackrel{\text{def}}{=} \{v \mid u \in A \wedge v \in \bar{R} \setminus A \wedge \{u, v\} \in E\}$, i.e., the set of vertices that are adjacent to a vertex in A, excluding A.

▶ **Definition 20.** Define the *adjacent centers* of a set of vertices $A \subseteq \bar{R}$ to be $\{c(v) \mid v \in A\}$.

Marked Clusters. Each center is *marked* independently with probability $p \stackrel{\text{def}}{=} 1/n^{1/3}$. If a center is marked, then we say that its Voronoi cell is marked and all the clusters in this cell are marked as well.

Super Clusters. Let A be a cluster which is not marked but is adjacent to at least one marked cluster. Let $\{u, v\}$ be the edge with minimum rank such that $u \in A$ and $v \in B$, where B is a marked cluster. We say that the cluster A *joins* the cluster B. The *super cluster* of B consists of B and all the clusters which join B.

After considering pairs of clusters and super clusters (and bounding the number of edges between them), only few pairs of core clusters (A, B) are left such that neither A nor B are member of a super cluster with high probability.

▶ **Lemma 21.** *With probability at least $1 - o(1)$, it holds that $|c(\partial A)| \leq n^{1/3} \log n$ for every core cluster A that is not adjacent to a marked cluster.*

This settles the three partitions of vertices from $\bar{R}$ into Voronoi cells, core clusters and super clusters. We now describe a way to partition the remote vertices into remote clusters such that (with high probability) the total number of edges that go out from each remote cluster is at most $O(\gamma n \Delta)$ even if the graph is far from being H-minor free. Basically, this implies that one can test a remote cluster isolated from the remaining graph because all outgoing edges can be removed such that G which was $(\alpha + \gamma)$-far from being H-minor free is still α-far from the property. The partitioning uses ideas of Elkin and Neiman [5].

Remote clusters. We will first describe the algorithm of Elkin and Neiman [5]. Given an integer h and a parameter $0 < \delta \leq 1$, each vertex v draws r_v according to the exponential distribution with parameter $\beta = \ln(n/\delta)/h$. By Claim 2.3 in [5], with probability at least $1 - \delta$, it holds that $r_v < h$ for all $v \in V$. Each vertex v receives r_u from every vertex u within distance at most h, and stores the values $m_u(v) = r_u - d(u, v)$. We use this technique to obtain a partition of R as follows. Every vertex $v \in R$ is *assigned* to the vertex $u \in R$ such that $m_u(v) = \max_{w \in R}\{m_w(v)\}$, if there is more than one such vertex, pick the one with minimum rank. We say that u is the *leader* of v denoted by $L(v)$ and that $\{w \in R \,|\, L(w) = L(v)\}$ is the *remote cluster* of v. We note that we run this algorithm on $G[R]$ (namely, we calculate $m_u(v) = r_u - d_{G[R]}(u, v)$), therefore a vertex u can not be assigned to a vertex on a different connected component in $G[R]$.

Like core clusters, remote clusters are also connected.

▶ **Lemma 22.** *For every $v \in R$, the subgraph induced on the remote cluster of v is connected.*

Similarly[5] as in [5], we define $C(v) = \{u \mid m_u(v) \geq \max_{w \in V}\{m_w(v) - 1\}\}$, for every $v \in R$. We will use an observation about the size of this set to argue that the number of cut-edges between remote clusters is small.

▶ **Lemma 23** (Proof of Lemma 2.2 in [5]). *For every $v \in R$, $\mathrm{Exp}[C(v)] \leq (n/\delta)^{1/h}$.*

For $\delta = 1/n^{b-1}$ and $h = \ell$, we obtain that $\mathrm{Exp}[C(v)] \leq (1+\gamma)$. Define the *edge-cut of R* to be $K = \{\{u,v\} \in E \mid v \in R \ \wedge u \in R \wedge (L(u) \neq L(v))\}$.

▶ **Lemma 24.** *With probability at least $99/100$, $|K| \leq 100\gamma\Delta|R| \leq 100\gamma\Delta n$.*

It remains to bound the number of edges between remote clusters and core clusters.

▶ **Lemma 25** (Lemma 6 in [15]). $\mathrm{Exp}[|E(R, \bar{R})|] \leq \gamma n$.

5 The Algorithm

We prove the following result. Theorem 1 follows by plugging in Lemmas 13 to 15.

▶ **Theorem 26.** *Let $\mathcal{F}$ be a finite family of graphs such that there exists $H \in \mathcal{F}$ and $f = f(n, \mathcal{F}, \Delta)$, $g = g(n, \mathcal{F}, \Delta), g \geq \ell$ (where ℓ is defined in Section 4) such that every n-vertex graph that is H-minor free is (f, g)-separable. For every $\epsilon > 0$, there is a one-sided ϵ-tester that given query access to an n-vertex graph, G, with maximum degree Δ, tests whether G is $\mathcal{F}$-minor free (i.e., G is R-minor free, for every $R \in \mathcal{F}$). The query complexity of the tester is $\tilde{O}(n^{2/3}f^3/\epsilon^5)$. If $\mathcal{F}$ includes a planar graph, then the running time is $\tilde{O}(n^{2/3}f^3/\epsilon^5)$ as well.*

We first analyze a global version of the tester (see Algorithm 1) and show how to turn it into a local algorithm in Section 5.1. Our tester draws $\Theta(f/\epsilon)$ edges at random from the input graph G. It follows that at least one of these edges is part of a forbidden minor with constant probability if G is ϵ-far from being $\mathcal{F}$-minor free. For the sake of this exposition, think of the graph being partitioned into core clusters and remote clusters. To reveal a forbidden minor from $\mathcal{F}$, the algorithm employs this partitioning.

We conduct the following case analysis. Either, an edge that is one out of many that connect a cluster A and an adjacent (disjoint) super cluster B will be sampled. Since non-remote clusters have diameter at most $\ell \leq g$, by the (f, g)-separability of $\mathcal{F}$-minor free graphs, a large cut between A and B implies the existence of H as a minor (see steps 2c and 2d). Otherwise, one can show that the total number of edges between clusters is at most $\epsilon n\Delta/2$. This implies that the edges between clusters can be removed such that the graph is still $\epsilon/2$-far from being $\mathcal{F}$-minor free. Then, it suffices to look for a minor-instance of a graph from $\mathcal{F}$ inside the clusters of each edge (see step 2b).

Therefore, it suffices to bound the number of edges between clusters under the promise that the edge-cut between every cluster and an adjacent (disjoint) super cluster is small. Since a naive bound over all pairs of clusters is quite costly, we classify edges and analyze each class independently. First, we observe that the total number of edges between remote clusters and clusters is $O(\epsilon n\Delta)$ with constant probability. It remains to bound the number of edges between core clusters. To this end, we analyze the total number of edges between core clusters within the same Voronoi cell, the total number of edges between two unmarked core clusters and the total number of edges between core clusters and super clusters separately.

[5] This set is defined slightly differently in [5], but Lemma 23 applies to this definition as well.

Algorithm 1 Test $\mathcal{F}$-minor freeness.

1. Partition V according to the partition described in Section 4 with parameters $\gamma = \Theta(\epsilon)$ and $\alpha = \Theta(\epsilon/f)$.
2. Sample $\Theta(f/\epsilon)$ random edges from G. For each sampled edge $\{u, v\}$:
   a. Find the cluster for each endpoint, denoted by C_v and C_u, respectively.
   b. If both u and v belong to the same cluster C, check that $G[C]$ is $\mathcal{F}$-minor free, if it is not, then return REJECT.
   c. If either for $w = u$ or for $w = v$ it holds that: $w \in \bar{R}$, $\mathsf{cluster}(w)$ is not a singleton, and $|E(\mathsf{Vor}(w) \setminus \mathsf{cluster}(w), \mathsf{cluster}(w))| > f$, then return REJECT.
   d. If both u and v are in $\bar{R}$ and and both C_u and C_v are not singletons then:
      i. If $|E(C_v, C_u)| > f$ then return REJECT.
      ii. If C_v (and symmetrically for C_u) joins a cluster $C \neq C_u$, then let $A \stackrel{\text{def}}{=} \bigcup_{v \in \partial C \setminus C_u} \mathsf{Vor}(v)$. If $|E((A \cup C) \setminus C_u, C_u)| > f$ then return REJECT.
3. Return ACCEPT.

This covers all relevant edges between clusters at least once and gives an upper bound on their total number.

Theorem 26 follows from the the efficient implementation (Section 5.1) and the correctness of the tester (Section 5.2).

The proof of the running time appears in the arXiv version [7].

5.1 Efficient Implementation

In this subsection we describe how Algorithm 1 can be implemented in query complexity $\tilde{O}(n^{2/3}f^3/\epsilon^5) \cdot \mathrm{poly}(\Delta)$. For a vertex $v \in V$, define $i_v \stackrel{\text{def}}{=} \min_i\{\Gamma_i(v) \geq y\}$ where $y \stackrel{\text{def}}{=} \Theta(n^{1/3}\log^2 n/\alpha)$. Let E denote the event that $\Gamma_{i_v}(v) \cap S \neq \emptyset$ for all $v \in V$. Since w.h.p. E occurs, henceforth we condition on this event. The following subroutines are sufficient in order to implement Algorithm 1:

1. Given a vertex $v \in \bar{R}$, finding $\mathsf{cluster}(v)$. The query complexity of finding $c(v)$ is bounded by $y \cdot \Delta$. That is, $c(v)$ is found after performing a BFS from v for at most i_v levels. Furthermore, the path connecting v and $c(v)$ in $T(c(v))$ is also found (this is the shortest path between v and $c(v)$ of smallest lexicographical order). Therefore it is possible to explore $T(c(v))$ with query complexity $O(y \cdot \Delta)$ per step. In order to determine $\mathsf{cluster}(v)$, it is sufficient to explore $T(v)$ and $T(a)$ up to t vertices, for any ancestor, a, of v. Therefore, the total query complexity is at most $O(\ell t y \Delta) = \tilde{O}(n^{2/3}f^2/\epsilon^4) \cdot \mathrm{poly}(\Delta)$ per iteration.
2. Given a subset of vertices A, finding $c(\partial A)$ can be done in query complexity $y \cdot \Delta$ times the total number of edges which are incident to vertices in A. If A is a cluster then the latter is bounded by $t\Delta$. Therefore we obtain a bound of $\tilde{O}(n^{2/3}f^2/\epsilon^3) \cdot \mathrm{poly}(\Delta)$ queries per iteration of step 2c and step 2(d)ii.
3. Finally, instead of finding the remote-cluster of a vertex $v \in R$ it suffices to find a connected induced subgraph that contains the remote-cluster of v. This is achievable by first finding the corresponding leader and then exploring the ℓ-hop neighborhood of the leader. To find the leader, it is sufficient to explore the ℓ-hop neighborhood of v and then for every vertex in it, to determine whether it is in R or not (determining whether a vertex is in R takes $O(y \cdot \Delta)$ time). With this at hand, it is possible to simulate the result of the leader-decomposition algorithm for v. Observe that both v and the leader of

v are in R, therefore (under the assumption that E occurred) it is possible to explore their ℓ-hop neigberhood in $O(y \cdot \Delta)$ time. The query complexity for each iteration of this step is bounded by $\tilde{O}(n^{2/3}f^2/\epsilon^2) \cdot \text{poly}(\Delta)$.

5.2 Correctness

▶ **Lemma 27.** *Algorithm 1 accepts every graph G that is $\mathcal{F}$-minor free.*

Proof. The completeness of the test is based on the separability of H-minor free graphs. We show that if the algorithm rejects, then G contains a graph from $\mathcal{F}$ as minor.

Step 2b rejects only if G contains a graph from $\mathcal{F}$ as a minor. To apply (f, g)-separability to step 2c, it suffices to note that for any $w \in \bar{R}$ such that $\mathsf{cluster}(w)$ is not a singleton, $G[\mathsf{Vor}[w] \setminus \mathsf{cluster}(w)]$ is connected by Lemma 18.

To apply the separability to step 2(d)i, it suffices to note that C_v and C_u are disjoint and that $G[C_v]$ and $G[C_u]$ are both connected by Lemma 17. To apply the separability to step 2(d)ii, we need to show that $G[(A \cup C) \setminus C_u]$ is connected, since it is clearly disjoint from C_u, the correctness then follows. There are two cases. If $(A \cup C) \cap C_u = \emptyset$, then $G[(A \cup C) \setminus C_u] = G[A \cup C]$ is connected. Otherwise, since C_u is not a singleton and since ∂C contains a vertex v which is in $\mathsf{Vor}(C_u) \setminus C_u$, the claim follows from Lemma 18. ◀

▶ **Lemma 28.** *Algorithm 1 rejects every graph G that is ϵ-far from being H-minor free with probability* 2/3.

Proof. Assume that G is ϵ-far from being H-minor free. Let $\mathcal{P}$ denote the partition obtained by the algorithm (namely, the partition of the entire graph as described in Section 4 with parameters $\gamma = \Theta(\epsilon)$ and $\alpha = \Theta(\epsilon/f)$). We say that an edge $e = \{u, v\}$ violates the separability property with respect to $\mathcal{P}$ if either:

1. There exist a core cluster $A \in \bar{R}$ and a cluster or a super cluster, $B \in \bar{R}$ such that $e \in E(A, B)$ and $|E(A, B)| > f$,
2. or, if either for $w = u$ or for $w = v$ it holds that: $w \in \bar{R}$, $\mathsf{cluster}(w)$ is not a singleton, and $|E(\mathsf{Vor}(w) \setminus \mathsf{cluster}(w), \mathsf{cluster}(w))| > f$.

Let $\mathcal{E}$ denote the set of edges which violate the f-separability property with respect to $\mathcal{P}$. If $|\mathcal{E}| > \alpha n\Delta$, then with probability at least 99/100, the algorithm finds a violation in one of the steps: step 2c, step 2(d)i or step 2(d)ii. Note that we do not need to check any edges between a core cluster and a remote cluster nor any edges between two remote clusters. By Markov's inequality and Lemma 25, with probability at least 99/100, $|E(R, \bar{R})| \leq 100\gamma n$. By Lemma 24, with probability at least 99/100, $|K| \leq 100\gamma n\Delta$. Thus, after removing these $|E(R, \bar{R}) \cup K| \leq \epsilon n\Delta/3$ edges, the graph is still $\epsilon/3$-far from being $\mathcal{F}$-minor free.

Assume that $|\mathcal{E}| \leq \alpha n\Delta$. We will show that with probability at least 96/100, we can separate G into clusters by removing at most $\alpha n\Delta \cdot 500f = \epsilon n\Delta/2$ edges. Therefore, the resulting graph is $\epsilon/2$-far from being $\mathcal{F}$-minor free, and with probability at least 2/3, the algorithm rejects in step 2b.

Separating G into clusters

1. As argued above, $|E(R, \bar{R}) \cup K| \leq 200\gamma n\Delta$ with probability at least 98/100. Therefore, we can separate G into $G[\bar{R}]$ and $G[R_1], \ldots, G[R_j]$, where $R_1, \ldots, R_j$ is the partition of R into remote clusters.
2. Next, we remove all the edges in $\mathcal{E}$ (at most $\alpha n\Delta$). In order to separate each Voronoi cell into its core clusters we simply remove all the edges between different clusters in

the same Voronoi cell. The number of edges which are incident to singleton clusters are at most Δs. Since we removed the edges in $\mathcal{E}$, for a cluster A which is not a singleton, we have that $E(A, \mathsf{Vor}(A) \setminus A) \leq f$. Therefore by removing at most $s(\Delta + f)$ edges we separate all the Voronoi cells into clusters.

3. By Lemma 21, with probability at least $1 - o(1)$, we can separate all the clusters, A, for which $c(\partial A)$ does not contain a marked center by removing at most $3sfp^{-1} \ln n$ edges.
4. The expected number of marked clusters is sp, therefore with probability at least $99/100$ the number of marked clusters is at most $100sp$. Thus, with probability at least $99/100$ the number of pairs $A, B \in \bar{R}$ such that A is a cluster and B is a super cluster is at most $s \cdot 100sp$. Since we removed all edges in $\mathcal{F}$, we have that $E(A, B) < f$ for each such pair. Therefore, the number of edges between clusters and super clusters is at most $100fs^2p$.

Recalling from Lemma 16 that $s = \Theta(\alpha n^{2/3}/\ln n)$, we can choose the constants in α and γ to be small enough such that

$$200\gamma n\Delta + \left[\alpha n\Delta + \Theta\left(\frac{\alpha n^{2/3}}{\ln n}\right)(\Delta + f)\right] + \Theta(\alpha n f) + \Theta\left(\frac{\alpha^2 n f}{\ln^2 n}\right) \leq \epsilon n\Delta/2.$$

Hence, with probability at least $96/100$, we can separate G into clusters and remote clusters by removing at most $\epsilon n\Delta/2$ edges. ◀

Abstract

We provide a number of algorithmic results for the following family of problems: For a given binary $m \times n$ matrix $\mathbf{A}$ and a nonnegative integer k, decide whether there is a "simple" binary matrix $\mathbf{B}$ which differs from $\mathbf{A}$ in at most k entries. For an integer r, the "simplicity" of $\mathbf{B}$ is characterized as follows.

- Binary r-Means: Matrix $\mathbf{B}$ has at most r different columns. This problem is known to be NP-complete already for $r = 2$. We show that the problem is solvable in time $2^{\mathcal{O}(k \log k)} \cdot (nm)^{\mathcal{O}(1)}$ and thus is fixed-parameter tractable parameterized by k. We also complement this result by showing that when being parameterized by r and k, the problem admits an algorithm of running time $2^{\mathcal{O}(r^{3/2} \cdot \sqrt{k \log k})}(nm)^{\mathcal{O}(1)}$, which is subexponential in k for $r \in o((k/\log k)^{1/3})$.
- Low GF(2)-Rank Approximation: Matrix $\mathbf{B}$ is of $\mathsf{GF}(2)$-rank at most r. This problem is known to be NP-complete already for $r = 1$. It is also known to be W[1]-hard when parameterized by k. Interestingly, when parameterized by r and k, the problem is not only fixed-parameter tractable, but it is solvable in time $2^{\mathcal{O}(r^{3/2} \cdot \sqrt{k \log k})}(nm)^{\mathcal{O}(1)}$, which is subexponential in k for $r \in o((k/\log k)^{1/3})$.
- Low Boolean-Rank Approximation: Matrix $\mathbf{B}$ is of Boolean rank at most r. The problem is known to be NP-complete for $k = 0$ as well as for $r = 1$. We show that it is solvable in subexponential in k time $2^{\mathcal{O}(r2^r \cdot \sqrt{k \log k})}(nm)^{\mathcal{O}(1)}$.

1 Introduction

In this paper we consider the following generic problem. Given a binary $m \times n$ matrix, that is a matrix with entries from domain $\{0,1\}$, $\mathbf{A} = (a_{ij}) \in \{0,1\}^{m \times n}$, the task is to find a "simple" binary $m \times n$ matrix $\mathbf{B}$ which approximates $\mathbf{A}$ subject to some specified constrains. One of the most widely studied error measures is the *Frobenius norm*, which for a matrix $\mathbf{A}$ is defined as

$$\|\mathbf{A}\|_F = \sqrt{\sum_{i=1}^{m}\sum_{j=1}^{n}|a_{ij}|^2}.$$

Here the sums are taken over $\mathbb{R}$. Then for a given nonnegative integer k, we want to decide whether there is a matrix $\mathbf{B}$ with certain properties such that $\|\mathbf{A}-\mathbf{B}\|_F^2 \leq k$.

We consider the binary matrix approximation problems when for a given integer r, the approximation binary matrix $\mathbf{B}$

(A1) has at most r pairwise-distinct columns,

(A2) is of $\mathsf{GF}(2)$-rank at most r, and

(A3) is of Boolean rank at most r.

Each of these variants is very well-studied. Before defining each of the problems formally and providing an overview of the relevant results, the following observation is in order. Since we approximate a binary matrix by a binary matrix, in this case minimizing the Frobenius norm of $\mathbf{A}-\mathbf{B}$ is equivalent to minimizing the ℓ_0-norm of $\mathbf{A}-\mathbf{B}$, where the measure $\|\mathbf{A}\|_0$ is the number of non-zero entries of matrix $\mathbf{A}$. We also will be using another equivalent way of measuring the quality of approximation of a binary matrix $\mathbf{A}$ by a binary matrix $\mathbf{B}$ by taking the sum of the Hamming distances between their columns. Let us recall that the *Hamming distance* between two vectors $\mathbf{x},\mathbf{y} \in \{0,1\}^m$, where $\mathbf{x} = (x_1,\ldots,x_m)^\intercal$ and $\mathbf{y} = (y_1,\ldots,y_m)^\intercal$, is $d_H(\mathbf{x},\mathbf{y}) = \sum_{i=1}^{m}|x_i - y_i|$ or, in words, the number of positions $i \in \{1,\ldots,m\}$ where x_i and y_i differ. Then for binary $m \times n$ matrix $\mathbf{A}$ with columns $\mathbf{a}^1,\ldots,\mathbf{a}^n$ and matrix $\mathbf{B}$ with columns $\mathbf{b}^1,\ldots,\mathbf{b}^n$, we define $d_H(\mathbf{A},\mathbf{B}) = \sum_{i=1}^{n} d_H(\mathbf{a}^i,\mathbf{b}^i)$. In other words, $d_H(\mathbf{A},\mathbf{B})$ is the number of positions with different entries in matrices $\mathbf{A}$ and $\mathbf{B}$. Then we have the following.

$$\|\mathbf{A}-\mathbf{B}\|_F^2 = \|\mathbf{A}-\mathbf{B}\|_0 = d_H(\mathbf{A},\mathbf{B}) = \sum_{i=1}^{n} d_H(\mathbf{a}^i,\mathbf{b}^i). \tag{1}$$

Problem (A1): Binary r-Means. By (1), the problem of approximating a binary $m \times n$ matrix $\mathbf{A}$ by a binary $m \times n$ matrix $\mathbf{B}$ with at most r different columns (problem (A1)) is equivalent to the following clustering problem. For given a set of n binary m-dimensional vectors $\mathbf{a}^1,\ldots,\mathbf{a}^n$ (which constitute the columns of matrix $\mathbf{A}$) and a positive integer r, Binary r-Means aims to partition the vectors in at most r clusters, as to minimize the sum of within-clusters sums of Hamming distances to their binary means. More formally,

Binary r-Means

Input: An $m \times n$ matrix $\mathbf{A}$ with columns $(\mathbf{a}^1,\ldots,\mathbf{a}^n)$, $r \in \mathbb{N}$ and a nonnegative integer k.

Question: Is there a positive integer $r' \leq r$, a partition $\{I_1,\ldots,I_{r'}\}$ of $\{1,\ldots,n\}$ and vectors $\mathbf{c}^1,\ldots,\mathbf{c}^{r'} \in \{0,1\}^m$ such that $\sum_{i=1}^{r'}\sum_{j\in I_i} d_H(\mathbf{c}^i,\mathbf{a}^j) \leq k$?

To see the equivalence of Binary r-Means and problem (A1), it is sufficient to observe that the pairwise different columns of an approximate matrix $\mathbf{B}$ such that $\|\mathbf{A}-\mathbf{B}\|_0 \leq k$ can be used as vectors $\mathbf{c}^1,\ldots,\mathbf{c}^{r'}$, $r' \leq r$. As far as the mean vectors are selected, a partition of columns of $\mathbf{A}$ can be obtained by assigning each column-vector $\mathbf{a}^i$ to its closest mean vector $\mathbf{c}^j$ (ties breaking arbitrarily). Then for such clustering the total sum of distances from vectors within cluster to their centers does not exceed k. Similarly, a solution to Binary r-Means can be used as columns (with possible repetitions) of matrix $\mathbf{B}$ such that $\|\mathbf{A}-\mathbf{B}\|_0 \leq k$. For that we put $\mathbf{b}^i = \mathbf{c}^j$, where $\mathbf{c}^j$ is the closest vector to $\mathbf{a}^i$.

This problem was introduced by Kleinberg, Papadimitriou, and Raghavan [37] as one of the examples of segmentation problems. Approximation algorithms for optimization versions of this problem were given by Alon and Sudakov [3] and Ostrovsky and Rabani [53], who referred to it as clustering in the Hamming cube. In bioinformatics, the case when $r = 2$ is known under the name Binary-Constructive-MEC (Minimum Error Correction) and was studied as a model for the Single Individual Haplotyping problem [13].

Binary r-Means can be seen as a discrete variant of the well-known k-Means Clustering. (Since in problems (A2) and (A3) we use r for the rank of the approximation matrix, we also use r in (A1) to denote the number of clusters which is commonly denoted by k in the literature on means clustering.) This problem has been studied thoroughly, particularly in the areas of computational geometry and machine learning. We refer to [1, 6, 39] for further references to the works on k-Means Clustering.

Problem (A2): Low GF(2)-Rank Approximation. Let $\mathbf{A}$ be a $m \times n$ binary matrix. In this case we view the elements of $\mathbf{A}$ as elements of $\mathsf{GF}(2)$, the Galois field of two elements. Then the $\mathsf{GF}(2)$-rank of $\mathbf{A}$ is the minimum r such that $\mathbf{A} = \mathbf{U} \cdot \mathbf{V}$, where $\mathbf{U}$ and $\mathbf{V}$ are $m \times r$ and $r \times n$ binary matrices respectively, and arithmetic operations are over $\mathsf{GF}(2)$. Equivalently, this is the minimum number of binary vectors, such that every column (row) of $\mathbf{A}$ is a linear combination (over $\mathsf{GF}(2)$) of these vectors. Then (A2) is the following problem.

Low GF(2)-Rank Approximation

Input: An $m \times n$-matrix $\mathbf{A}$ over $\mathsf{GF}(2)$, $r \in \mathbb{N}$ and a nonnegative integer k.
Question: Is there a binary $m \times n$-matrix $\mathbf{B}$ with $\mathsf{GF}(2)$-rank $\leq r$ and $\|\mathbf{A}-\mathbf{B}\|_F^2 \leq k$?

Low GF(2)-Rank Approximation arises naturally in applications involving binary data sets and serves as an important tool in dimension reduction for high-dimensional data sets with binary attributes, see [17, 35, 31, 38, 54, 57, 62] for further references and numerous applications of the problem.

Low GF(2)-Rank Approximation can be rephrased as a special variant (over $\mathsf{GF}(2)$) of the problem finding the rigidity of a matrix. (For a target rank r, the *rigidity* of a matrix A over a field $\mathbb{F}$ is the minimum Hamming distance between A and a matrix of rank at most r.) Rigidity is a classical concept in Computational Complexity Theory studied due to its connections with lower bounds for arithmetic circuits [29, 30, 58, 55]. We refer to [41] for an extensive survey on this topic.

Low GF(2)-Rank Approximation is also a special case of a general class of problems approximating a matrix by a matrix with a small non-negative rank. Already Non-negative Matrix Factorization (NMF) is a nontrivial problem and it appears in many settings. In particular, in machine learning, approximation by a non-negative low rank matrix has gained extreme popularity after the influential article in Nature by Lee and Seung [40]. NMF is an ubiquitous problem and besides machine learning, it has been independently introduced

and studied in combinatorial optimization [21, 61], and communication complexity [2, 42]. An extended overview of applications of NMF in statistics, quantum mechanics, biology, economics, and chemometrics, can be found in the work of Cohen and Rothblum [15] and recent books [12, 51, 25].

Problem (A3): Low Boolean-Rank Approximation. Let $\mathbf{A}$ be a binary $m \times n$ matrix. This time we view the elements of $\mathbf{A}$ as *Boolean* variables. The *Boolean rank* of $\mathbf{A}$ is the minimum r such that $\mathbf{A} = \mathbf{U} \wedge \mathbf{V}$ for a Boolean $m \times r$ matrix $\mathbf{U}$ and a Boolean $r \times n$ matrix $\mathbf{V}$, where the product is Boolean, that is, the logical $\wedge$ plays the role of multiplication and $\vee$ the role of sum. Here $0 \wedge 0 = 0$, $0 \wedge 1 = 0$, $1 \wedge 1 = 1$, $0 \vee 0 = 0$, $0 \vee 1 = 1$, and $1 \vee 1 = 1$. Thus the matrix product is over the Boolean semi-ring $(0, 1, \wedge, \vee)$. This can be equivalently expressed as the normal matrix product with addition defined as $1+1 = 1$. Binary matrices equipped with such algebra are called *Boolean matrices*. Equivalently, $\mathbf{A} = (a_{ij}) \in \{0,1\}^{m \times n}$ has the Boolean rank 1 if $\mathbf{A} = \mathbf{x}^\intercal \wedge \mathbf{y}$, where $\mathbf{x} = (x_1, x_2, \ldots, x_m) \in \{0,1\}^m$ and $\mathbf{y} = (y_1, y_2, \ldots, y_n) \in \{0,1\}^n$ are nonzero vectors and the product is Boolean, that is, $a_{ij} = x_i \wedge y_j$. Then the Boolean rank of $\mathbf{A}$ is the minimum integer r such that $\mathbf{A} = \mathbf{a^{(1)}} \vee \cdots \vee \mathbf{a^{(r)}}$, where $\mathbf{a^{(1)}}, \ldots, \mathbf{a^{(r)}}$ are matrices of Boolean rank 1; zero matrix is the unique matrix with the Boolean rank 0. Then Low Boolean-Rank Approximation is defined as follows.

Low Boolean-Rank Approximation

Input: A Boolean $m \times n$ matrix $\mathbf{A}$, $r \in \mathbb{N}$ and a nonnegative integer k.
Question: Is there a Boolean $m \times n$ matrix $\mathbf{B}$ of Boolean rank $\leq r$ and $d_H(\mathbf{A}, \mathbf{B}) \leq k$?

For $r = 1$ Low Boolean-Rank Approximation coincides with Low GF(2)-Rank Approximation but for $r > 1$ these are different problems.

Boolean low-rank approximation has attracted much attention, especially in the data mining and knowledge discovery communities. In data mining, matrix decompositions are often used to produce concise representations of data. Since much of the real data is binary or even Boolean in nature, Boolean low-rank approximation could provide a deeper insight into the semantics associated with the original matrix. There is a big body of work done on Low Boolean-Rank Approximation, see e.g. [7, 9, 17, 43, 48, 49].

P-Matrix Approximation. While at first glance Low GF(2)-Rank Approximation and Low Boolean-Rank Approximation look very similar, algorithmically the latter problem is more challenging. The fact that GF(2) is a field allows to play with different equivalent definitions of rank like row rank and column ranks. We exploit this strongly in our algorithm for Low GF(2)-Rank Approximation. For Low Boolean-Rank Approximation the matrix product is over the Boolean semi-ring and nice properties of the GF(2)-rank cannot be used here (see, e.g. [32]). Our algorithm for Low Boolean-Rank Approximation is based on solving an auxiliary $\mathbf{P}$-Matrix Approximation problem, where the task is to approximate a matrix $\mathbf{A}$ by a matrix $\mathbf{B}$ whose block structure is defined by a given pattern matrix $\mathbf{P}$. It appears, that $\mathbf{P}$-Matrix Approximation is also an interesting problem on its own.

More formally, let $\mathbf{P} = (p_{ij}) \in \{0,1\}^{p \times q}$ be a binary $p \times q$ matrix. We say that a binary $m \times n$ matrix $\mathbf{B} = (b_{ij}) \in \{0,1\}^{m \times n}$ is a $\mathbf{P}$-*matrix* if there is a partition $\{I_1, \ldots, I_p\}$ of $\{1, \ldots, m\}$ and a partition $\{J_1, \ldots, J_q\}$ of $\{1, \ldots, n\}$ such that for every $i \in \{1, \ldots, p\}$, $j \in \{1, \ldots, q\}$, $s \in I_i$ and $t \in J_j$, $b_{st} = p_{ij}$. In words, the columns and rows of $\mathbf{B}$ can be permuted such that the block structure of the resulting matrix is defined by $\mathbf{P}$.

P-Matrix Approximation

Input: An $m \times n$ binary matrix $\mathbf{A}$, a pattern binary matrix $\mathbf{P}$ and a nonnegative integer k.
Question: Is there an $m \times n$ $\mathbf{P}$-matrix $\mathbf{B}$ such that $\|\mathbf{A} - \mathbf{B}\|_F^2 \leq k$?

The notion of $\mathbf{P}$-matrix was implicitly defined by Wulff et al. [60] as an auxiliary tool for their approximation algorithm for the related monochromatic biclustering problem. Since Low GF(2)-Rank Approximation remains NP-complete for $r = 1$ [26], we have that $\mathbf{P}$-Matrix Approximation is NP-complete already for the very simple pattern matrix $P = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$.

1.1 Related work

In this subsection we give an overview of previous related algorithmic and complexity results for problems (A1)–(A3), as well as related problems. Since each of the problems has many practical applications, there is a tremendous amount of literature on heuristics and implementations. In this overview we concentrate on known results about algorithms with proven guarantee, with emphasis on parameterized complexity.

Problem (A1): Binary r-Means. Binary r-Means is trivially solvable in polynomial time for $r = 1$, and as was shown by Feige in [20], is NP-complete for every $r \geq 2$.

PTAS (polynomial time approximation scheme) for optimization variants of Binary r-Means were developed in [3, 53]. Approximation algorithms for more general k-Means Clustering is a thoroughly studied topic [1, 6, 39]. Inaba et al. [33] have shown that the general k-Means Clustering is solvable in time n^{mr+1} (here n is the number of vectors, m is the dimension and r the number of required clusters). We are not aware of any, except the trivial brute-force, exact algorithm for Binary r-Means prior to our work.

Problem (A2): Low GF(2)-Rank Approximation. When the low-rank approximation matrix $\mathbf{B}$ is not required to be binary, then the optimal Frobenius norm rank-r approximation of (not necessarily binary) matrix $\mathbf{A}$ can be efficiently found via the singular value decomposition (SVD). This is an extremely well-studied problem and we refer to surveys for an overview of algorithms for low rank approximation [36, 44, 59]. However, SVD does not guarantee to find an optimal solution in the case when additional structural constrains on the low-rank approximation matrix $\mathbf{B}$ (like being non-negative or binary) are imposed.

In fact, most of these constrained variants of low-rank approximation are NP-hard. In particular, Gillis and Vavasis [26] and Dan et al. [17] have shown that Low GF(2)-Rank Approximation is NP-complete for every $r \geq 1$. Approximation algorithms for the optimization version of Low Boolean-Rank Approximation were considered in [34, 35, 17, 38, 57, 10] among others.

Most of the known results about the parameterized complexity of the problem follows from the results for Matrix Rigidity. Fomin et al. have proved in [24] that for every finite field, and in particular GF(2), Matrix Rigidity over a finite field is W[1]-hard being parameterized by k. This implies that Low GF(2)-Rank Approximation is W[1]-hard when parameterized by k. However, when parameterized by k and r, the problem becomes fixed-parameter tractable. For Low GF(2)-Rank Approximation, the algorithm from [24] runs in time $2^{\mathcal{O}(f(r)\sqrt{k}\log k)}(nm)^{\mathcal{O}(1)}$, where f is some function of r. While the function $f(r)$ is not specified in [24], the algorithm in [24] invokes enumeration of all $2^r \times 2^r$ binary matrices of rank r, and thus the running time is at least double-exponential in r.

Meesum, Misra, and Saurabh [46], and Meesum and Saurabh [47] considered parameterized algorithms for related problems about editing of the adjacencies of a graph (or directed graph) targeting a graph with adjacency matrix of small rank.

Problem (A3): Low Boolean-Rank Approximation. It follows from the rank definitions that a matrix is of Boolean rank $r = 1$ if and only if its $\mathsf{GF}(2)$-rank is 1. Thus by the results of Gillis and Vavasis [26] and Dan et al. [17] Low Boolean-Rank Approximation is NP-complete already for $r = 1$.

While computing $\mathsf{GF}(2)$-rank (or rank over any other field) of a matrix can be performed in polynomial time, deciding whether the Boolean rank of a given matrix is at most r is already an NP-complete problem. Thus Low Boolean-Rank Approximation is NP-complete already for $k = 0$. This follows from the well-known relation between the Boolean rank and covering edges of a bipartite graph by bicliques [28]. Let us briefly describe this equivalence. For Boolean matrix $\mathbf{A}$, let G_A be the corresponding bipartite graph, i.e. the bipartite graph whose biadjacency matrix is $\mathbf{A}$. By the equivalent definition of the Boolean rank, $\mathbf{A}$ has Boolean rank r if and only if it is the logical disjunction of r Boolean matrices of rank 1. But for every bipartite graph whose biadjacency matrix is a Boolean matrix of rank at most 1, its edges can be covered by at most one biclique (complete bipartite graph). Thus deciding whether a matrix is of Boolean rank r is exactly the same as deciding whether edges of a bipartite graph can be covered by at most r bicliques. The latter Biclique Cover problem is known to be NP-complete [52]. Biclique Cover is solvable in time $2^{2^{\mathcal{O}(r)}}(nm)^{\mathcal{O}(1)}$ [27] and unless Exponential Time Hypothesis (ETH) fails, it cannot be solved in time $2^{2^{o(r)}}(nm)^{\mathcal{O}(1)}$ [11].

For the special case $r = 1$ Low Boolean-Rank Approximation and $k \leq \|A\|_0/240$, Bringmann, Kolev and Woodruff gave an exact algorithm of running time $2^{k/\sqrt{\|A\|_0}}(nm)^{\mathcal{O}(1)}$ [10]. (Let us remind that the ℓ_0-norm of a matrix is the number of its non-zero entries.) More generally, exact algorithms for NMF were studied by Cohen and Rothblum in [15]. Arora et al. [5] and Moitra [50], who showed that for a fixed value of r, NMF is solvable in polynomial time. Related are also the works of Razenshteyn et al. [56] on weighted low-rank approximation, Clarkson and Woodruff [14] on robust subspace approximation, and Basu et al. [8] on PSD factorization.

Observe that all these problems could be seen as matrix editing problems. For Binary r-Means, we can assume that $r \leq n$ as otherwise we have a trivial YES-instance. Then the problem asks whether it is possible to edit at most k entries of the input matrix, that is, replace some 0-s by 1-s and some 1-s by 0-s, in such a way that the obtained matrix has at most r pairwise-distinct columns. Respectively, Low GF(2)-Rank Approximation asks whether it is possible to edit at most k entries of the input matrix to obtain a matrix of rank at most r. In $\mathbf{P}$-Matrix Approximation, we ask whether we can edit at most k elements to obtain a $\mathbf{P}$-matrix. A lot of work in graph algorithms has been done on graph editing problems, in particular parameterized subexponential time algorithms were developed for a number of problems, including various cluster editing problems [19, 23].

1.2 Our results and methods

We study the parameterized complexity of Binary r-Means, Low GF(2)-Rank Approximation and Low Boolean-Rank Approximation. We refer to the recent books of Cygan et al. [16] and Downey and Fellows [18] for the introduction to Parameterized Algorithms and Complexity. Our results are summarized in Table 1.

Table 1 Parameterized complexity of low-rank approximation. GF(2) Approx stands for Low GF(2)-Rank Approximation and Bool Approx for Low Boolean-Rank Approximation. We omit the polynomial factor $(nm)^{\mathcal{O}(1)}$ in running times.

	k	r	$k+r$
Binary r-Means	$2^{\mathcal{O}(k \log k)}$, Thm 1	NP-c for $r \geq 2$ [20]	$2^{\mathcal{O}(r^{3/2} \cdot \sqrt{k \log k})}$, Thm 3
GF(2) Approx	W[1]-hard [24]	NP-c for $r \geq 1$ [26, 17]	$2^{\mathcal{O}(r^{3/2} \cdot \sqrt{k \log k})}$, Thm 4
Boolean Approx	NP-c for $k = 0$ [52]	NP-c for $r \geq 1$ [26, 17]	$2^{\mathcal{O}(r2^r \cdot \sqrt{k \log k})}$, Thm 2

Our first main result concerns Binary r-Means. We show (Theorem 1) that the problem is solvable in time $2^{\mathcal{O}(k \log k)} \cdot (nm)^{\mathcal{O}(1)}$. Therefore, Binary r-Means is FPT parameterized by k. Since Low GF(2)-Rank Approximation parameterized by k is W[1]-hard and Low Boolean-Rank Approximation is NP-complete for any fixed $k \geq 0$, we find Theorem 1 quite surprising. The proof of Theorem 1 is based on a fundamental result of Marx [45] about the complexity of a problem on strings, namely Consensus Patterns. We solve Binary r-Means by constructing a two-stage FPT Turing reduction to Consensus Patterns. First, we use the color coding technique of Alon, Yuster, and Zwick from [4] to reduce Binary r-Means to some special auxiliary problem and then show that this problem can be reduced to Consensus Patterns, and this allows us to apply the algorithm of Marx [45].

Our second main result concerns Low Boolean-Rank Approximation. As we mentioned above, the problem is NP-complete for $k = 0$, as well as for $r = 1$, and hence is intractable being parameterized by k or by r only. On the other hand, a simpler Low GF(2)-Rank Approximation is not only FPT parameterized by $k+r$, by [24] it is solvable in time $2^{\mathcal{O}(f(r)\sqrt{k} \log k)}(nm)^{\mathcal{O}(1)}$, where f is some function of r, and thus is *subexponential* in k. It is natural to ask whether a similar complexity behavior could be expected for Low Boolean-Rank Approximation. Our second main result, Theorem 2, shows that this is indeed the case: Low Boolean-Rank Approximation is solvable in time $2^{\mathcal{O}(r2^r \cdot \sqrt{k \log k})}(nm)^{\mathcal{O}(1)}$. The proof of this theorem is technical and consists of several steps. We first develop a subexponential algorithm for solving auxiliary **P**-Matrix Approximation, and then construct an FPT Turing reduction from Low Boolean-Rank Approximation to **P**-Matrix Approximation.

Let us note that due to the relation of Boolean rank computation to Biclique Cover, the result of [11] implies that unless Exponential Time Hypothesis (ETH) fails, Low Boolean-Rank Approximation cannot be solved in time $2^{2^{o(r)}} f(k)(nm)^{\mathcal{O}(1)}$ for any function f. Thus the dependence in r in our algorithm cannot be improved significantly unless ETH fails.

Interestingly, the technique developed for solving **P**-Matrix Approximation can be used to obtain algorithms of running times $2^{\mathcal{O}(r^{3/2} \cdot \sqrt{k \log k})}(nm)^{\mathcal{O}(1)}$ for Binary r-Means and Low GF(2)-Rank Approximation (Theorems 3 and 4 respectively). For Binary r-Means, Theorems 3 provides much better running time than Theorem 1 for values of $r \in o((k \log k)^{1/3})$.

For Low GF(2)-Rank Approximation, comparing Theorem 4 and the running time $2^{\mathcal{O}(f(r)\sqrt{k} \log k)}(nm)^{\mathcal{O}(1)}$ from [24], let us note that Theorem 4 not only slightly improves the exponential dependence in k by $\sqrt{\log k}$; it also drastically improves the exponential dependence in r, from 2^{2^r} to $2^{r^{3/2}}$.

Due to space restrictions, we only give high level descriptions of our algorithms. In Section 2 we sketch the algorithm for Binary r-Means parameterized by k, and in Section 3 we explain how we construct FPT algorithms for Binary r-Means and Low GF(2)-Rank Approximation parameterized by k and r that are subexponential in k. The full proofs and further results can be found in [22].

2 Binary r-Means parameterized by k

In this section we give a description of our FPT algorithm for Binary r-Means that runs in time $2^{\mathcal{O}(k \log k)} \cdot (nm)^{\mathcal{O}(1)}$ (Theorem 1).

Let $(\mathbf{A}, r, k)$ be an instance of Binary r-Means where $\mathbf{A}$ is a matrix with columns $(\mathbf{a}^1, \ldots, \mathbf{a}^n)$. We say that a partition $\{I_1, \ldots, I_{r'}\}$ of $\{1, \ldots, n\}$ for $r' \leq r$ is a *solution* for this instance if there are vectors $\mathbf{c}^1, \ldots, \mathbf{c}^{r'} \in \{0,1\}^m$ such that $\sum_{i=1}^{r'} \sum_{j \in I_i} d_H(\mathbf{c}^i, \mathbf{a}^j) \leq k$. We say that each I_i or, equivalently, the multiset of columns $\{\mathbf{a}^j \mid j \in I_i\}$ (some columns could be the same) is a *cluster* and $\mathbf{c}^i$ the *mean* of the cluster. Observe that given a cluster $I \subseteq \{1, \ldots, n\}$, one can easily compute an optimal mean $\mathbf{c} = (c_1, \ldots, c_m)^\intercal$ as follows. Let $\mathbf{a}^j = (a_{1j}, \ldots, a_{mj})^\intercal$ for $j \in \{1, \ldots, n\}$. For each $i \in \{1, \ldots, m\}$, consider the multiset $S_i = \{a_{ij} \mid j \in I\}$ and put $c_i = 0$ or $c_i = 1$ according to the *majority* of elements in S_i, that is, $c_i = 0$ if at least half of the elements in S_i are 0-s and $c_i = 1$ otherwise. We refer to this construction of $\mathbf{c}$ as the *majority rule*.

An *initial cluster* is an inclusion maximal set $I \subseteq \{1, \ldots, n\}$ such that all the columns in the initial cluster are equal. The property of initial clusters we build upon is that there is always an optimal solution that does not split any of the initial clusters. More formally, we say that a partition $\{I_1, \ldots, I_{r'}\}$ of the columns of matrix $\mathbf{A}$ is *regular* if for every initial cluster I, there is $i \in \{1, \ldots, r'\}$ such that $I \subseteq I_i$. Respectively, if $(\mathbf{A}, r, k)$ is a yes-instance of Binary r-Means, then there is a solution $\{I_1, \ldots, I_{r'}\}$ forming a regular partition and we call such a solution *regular*. In words, in a regular solution every two equal columns of $\mathbf{A}$ are placed in the same cluster. Thus in a regular solution $\{I_1, \ldots, I_{r'}\}$, each cluster I_i is either *simple*, that is, contains exactly one initial cluster and all its columns are equal, or I_i is *composite*, that is composed of several initial clusters. One can show that there is always an optimal solution to Binary r-Means that is regular.

Moreover, we can assume that a solution we seek for is not only regular but has stronger property. Indeed, let $\{I_1, \ldots, I_{r'}\}$ be a regular solution for instance $(\mathbf{A}, r, k)$. Denote by $\mathbf{c}^1, \ldots, \mathbf{c}^{r'}$ the corresponding means of the clusters. Let I_i be a composite cluster of $\{I_1, \ldots, I_{r'}\}$ that contains $h \geq 2$ initial clusters. Then $\sum_{j \in I_i} (\mathbf{c}^i, \mathbf{a}^j) \geq h - 1$. Therefore, for every yes-instance, a regular solution $\{I_1, \ldots, I_{r'}\}$ contains at most k composite clusters; all the remaining clusters are simple. Moreover, the total number of initial clusters used to form the composite clusters is at most $2k$. Note also that if I_i is a simple cluster then for $\mathbf{c}^i = \mathbf{a}^h$ for an arbitrary $h \in I_i$, we have that $\sum_{j \in I_i} (\mathbf{c}^i, \mathbf{a}^j) = 0$, that is, simple clusters do not contribute to the total cost of the solution.

Thus the essence of the problem is to find the way of composing initial clusters into composite ones. More precisely, for the instance $(\mathbf{A}, r, k)$, let $\mathcal{I}$ be the family of the initial clusters. Let $s = |\mathcal{I}|$. Then finding a solution for Binary r-Means is equivalent to finding a set $\mathcal{I}' \subseteq \mathcal{I}$ of size at most $2k$ such that $\mathcal{I}'$ can be used to form at most $r - s + |\mathcal{I}'|$ composite clusters. In other words, we are looking for $\mathcal{I}' \subseteq \mathcal{I}$ of size at most $2k$ such that there is a partition $\{P_1, \ldots, P_t\}$ of $\mathcal{I}'$ with $t \leq r - s + |\mathcal{I}'|$ (each set P_i says which initial clusters of $\mathcal{I}'$ are used to form a composite cluster) and vectors $\mathbf{s}^1, \ldots, \mathbf{s}^t \in \{0,1\}^m$ with the property that

$$\sum_{i=1}^{t} \sum_{I \in P_i} \sum_{j \in I} d_H(\mathbf{s}^i, \mathbf{a}^j) \leq k.$$

If $s \leq r$, then $(\mathbf{A}, r, k)$ is a trivial yes-instance of the problem with $\mathcal{I}$ being a solution. If $r + k < s$, then $(\mathbf{A}, r, k)$ is a trivial no-instance. From now on we assume that $r < s \leq r + k$.

If we color uniformly at random initial clusters with $2k$ colors, then with a "reasonable" probability each composite cluster is composed from initial clusters of different colors. This

will provide us with an additional structural information, which will bring us much closer to a solution. We use the classic *color coding* technique of Alon, Yuster, and Zwick from [4] to distinguish initial clusters of $\mathcal{I}'$ from each other. At the end we obtain a deterministic algorithm but, for simplicity, we describe a randomized Monte-Carlo algorithm here. We color the elements of $\mathcal{I}$ independently and uniformly at random by $2k$ colors $1,\ldots,2k$. Observe that if $(\mathbf{A},r,k)$ is a yes-instance, then at most $2k$ initial clusters in a solution that are included in composite clusters are colored by distinct colors with the probability at least $\frac{(2k)!}{(2k)^{2k}} \geq e^{-2k}$. We say that a solution $\{I_1,\ldots,I_{r'}\}$ for $(\mathbf{A},r,k)$ is a *colorful* solution if all initial clusters that are included in composite clusters of $\{I_1,\ldots,I_{r'}\}$ are colored by distinct colors. We construct an algorithm for finding a colorful solution (if it exists).

Let us fix some coloring of initial clusters in $2k$ colors. For $i\in\{1,\ldots,2k\}$, let $\mathcal{I}_i$ be the set of initial clusters colored by color i. Note that some sets $\mathcal{I}_i$ could be empty. We consider all possible partitions $\mathcal{P}=\{P_1,\ldots,P_t\}$ of nonempty subsets of $\{1,\ldots,2k\}$ such that each set of $\mathcal{P}$ contains at least two elements. Notice that if $(\mathbf{A},r,k)$ has a colorful solution $\{I_1,\ldots,I_{r'}\}$, then there is $\mathcal{P}=\{P_1,\ldots,P_t\}$ such that a cluster I_i of the solution is formed from initial clusters colored with colors P_j for some $j\in\{1,\ldots,t\}$. Moreover, two different composite clusters are colored with colors from different sets of $\mathcal{P}$. We go through all possible partitions $\mathcal{P}$, and if $(\mathbf{A},r,k)$ has a colorful solution, we will find the corresponding partition $\mathcal{P}$. Let us fix a partition $\mathcal{P}=\{P_1,\ldots,P_t\}$. If $s-|P_1|-\cdots-|P_t|+t>r$, we discard the current choice of $\mathcal{P}$. Assume from now that this is not the case. For each $i\in\{1,\ldots,t\}$, we do the following. Let $P_i=\{i_1,\ldots,i_p\}\subseteq\{1,\ldots,2k\}$. Then with this notation $\mathcal{I}_{i_j}$ is the set of initial clusters colored by color i_j. For $j\in\{1,\ldots,p\}$, we use $J^i_j=\bigcup_{I\in\mathcal{I}_{i_j}} I$ to denote the set of indices contained in clusters colored by i_j. We also define $J^i=J^i_1\cup\cdots\cup J^i_p$, which is the set of indices contained in clusters colored by colors from $\{i_1,\ldots,i_p\}$. Denote by $\mathbf{A}_i$ the submatrix of $\mathbf{A}$ containing the columns $\mathbf{a}^h$ with $h\in J^i$. We want to solve an auxiliary problem of finding the minimum integer $d_i\leq k$ such that there is a set of initial clusters $L^i_1,\ldots,L^i_p$ and a vector $\mathbf{s}^i\in\{0,1\}^m$ such that $L^i_j\subseteq J^i_j$ for $i\in\{1,\ldots,p\}$ and $\sum_{i=1}^p\sum_{j\in L^i_j} d_H(\mathbf{s}^i,\mathbf{a}^j)\leq d_i$. In words, for a set of colors $P_i=\{i_1,\ldots,i_p\}$, we want to find the best selection of initial clusters $L^i_1,\ldots,L^i_p$ such that each of the clusters L^i_j is colored by i_j; the best is in the sense that the total Hamming distance d_i from the columns corresponding to the selected set of clusters to their means is the minimum over all such selections.

Assume that we have an algorithm for this auxiliary problem. If such a value of d_i does not exist for some $i\in\{1,\ldots,t\}$, we discard the current choice of $\mathcal{P}$. Otherwise, we find the set of clusters $L^i_1,\ldots,L^i_p$ and $\mathbf{s}^i$. Let $L^i=L^i_1\cup\cdots\cup L^i_p$. We check whether $d_1+\cdots+d_t\leq k$. If it holds, we return the colorful solution with the composite clusters $L^1,\ldots,L^t$ whose means are $\mathbf{s}^1,\ldots,\mathbf{s}^t$ respectively and the remaining clusters are simple. Otherwise, we discard the choice of $\mathcal{P}$. If for one of the choices of $\mathcal{P}$ we find a colorful solution, we return it and stop. If we fail to find a solution for all possible $\mathcal{P}$, we return the answer NO and stop. If the described algorithm produces a solution, then because simple clusters do not contribute to the total cost of the solution it is possible to verify that the produced solution is a colorful solution to $(\mathbf{A},r,k)$.

So everything boils down to finding the optimal value d_i together with the corresponding initial clusters and their means. Let us remind that a regular partition $\{I_1,\ldots,I_p\}$ of $\{1,\ldots,n\}$ is a partition where any two indices corresponding to equal columns of $\mathbf{A}$ are assigned to the same cluster I_i. We call this the auxiliary problem Cluster Selection.

Cluster Selection

Input: An $m \times n$-matrix $\mathbf{A}$ with columns $\mathbf{a}^1, \ldots, \mathbf{a}^n$, a regular partition $\{I_1, \ldots, I_p\}$ of $\{1, \ldots, n\}$, and a nonnegative integer d.

Question: Is there a set of initial clusters $J_1, \ldots, J_p$ and a vector $\mathbf{c} \in \{0,1\}^m$ such that $J_i \subseteq I_i$ for $i \in \{1, \ldots, p\}$ and $\sum_{i=1}^{p} \sum_{j \in J_i} d_H(\mathbf{c}, \mathbf{a}^j) \leq d$?

Thus in Cluster Selection, for each cluster I_i, we have to select exactly one initial cluster J_i contained in I_i such that the total Hamming distance of the columns of the selected clusters to their means does not exceed d.

We prove that Cluster Selection is FPT when parameterized by d. The proof of this result is based on a reduction to the problem about strings. More precisely, we apply the result of Marx [45] about the Consensus Patterns problem. Recall that for two strings a and b of the same length, the *Hamming distance* $d_H(a, b)$ between strings is defined as the number of position where the strings differ.

Consensus Patterns

Input: A set of p strings $\{s_1, \ldots, s_p\}$ over an alphabet Σ, a positive integer t and a nonnegative integer d.

Question: Is there a string s of length t over Σ, and a length t substring s'_i of s_i for every $i \in \{1, \ldots, p\}$ such that $\sum_{i=1}^{p} d_H(\mathbf{s}, s'_i) \leq d$?

Marx proved in [45] that Consensus Patterns can be solved in time $\delta^{\mathcal{O}(\delta)} \cdot |\Sigma|^{\delta} \cdot L^9$ where $\delta = d/p$ and L the input size, i.e., the total length of all the strings in the input. This implies that Consensus Patterns can be solved in time $2^{\mathcal{O}(d \log d)} \cdot L^9$ if $|\Sigma|$ is fixed. We construct an FPT Turing reduction from Cluster Selection to Consensus Patterns. The reduction is technical but the rough idea is the following. We guess the number of elements in every cluster of the solution $J_1, \ldots, J_p$. For each guess, $(\ell_1 = |J_1|, \ldots, \ell_p = |J_p|)$, we delete from I_i all initial clusters which size is not equal to ℓ_i. Then for each I_i, we make ℓ_i equal strings. Each of theses strings consists of substrings corresponding to distinct columns of $\mathbf{A}$ with indices from I_i which are separated by special splitting substrings constructed by making use of two additional symbols. Thus in total we use alphabet Σ with 4 letters. This way, the choice of substrings corresponds to the choice of initial clusters.

Summarizing, our algorithm for Binary r-Means consists of two FPT Turing reductions. First, we design a reduction to Cluster Selection that, in its turn, is reduced to Consensus Patterns. This gives our first main result.

▶ **Theorem 1.** Binary r-Means *is solvable in time* $2^{\mathcal{O}(k \log k)} \cdot (nm)^{\mathcal{O}(1)}$.

3 Subexponential algorithms

The main result of this section is an FPT algorithm for Low Boolean-Rank Approximation parameterized by k and r that is subexponential in k. Note that Low Boolean-Rank Approximation is more complicated than Low GF(2)-Rank Approximation. The main reason to that is that the elements of the matrices do not form a field and thus many nice properties of matrix-rank cannot be used here. The way we handle this issue is to solve the $\mathbf{P}$-Matrix Approximation problem.

Let $\mathbf{A}$ be a Boolean $m \times n$-matrix with the Boolean rank $r \geq 1$. Then $\mathbf{A} = \mathbf{A}^{(1)} \vee \ldots \vee \mathbf{A}^{(r)}$ where $\mathbf{A}^{(1)}, \ldots, \mathbf{A}^{(r)}$ are matrices of Boolean rank 1. It implies that $\mathbf{A}$ has at most 2^r pairwise-distinct rows and at most 2^r pairwise-distinct columns. Hence, the Boolean rank of $\mathbf{A}$ is at most r if and only if there is a $2^r \times 2^r$-matrix $\mathbf{P}$ of Boolean rank at most r such that

$\mathbf{A}$ is a $\mathbf{P}$-matrix. Respectively, the Low Boolean-Rank Approximation problem can be reformulated as follows: Decide whether there is a $2^r \times 2^r$-pattern matrix $\mathbf{P}$ with the Boolean rank at most r and an $m \times n$ $\mathbf{P}$-matrix $\mathbf{B}$ such that $\|\mathbf{A} - \mathbf{B}\|_F^2 \leq k$. We generate all $2^r \times 2^r$-matrices $\mathbf{P}$ of Boolean rank at most r, and then for each matrix $\mathbf{P}$, we solve $\mathbf{P}$-Matrix Approximation for the instance $(\mathbf{A}, \mathbf{P}, k)$. We return YES if we obtain at least one yes-instance of $\mathbf{P}$-Matrix Approximation, and we return NO otherwise. Thus, using the algorithm for $\mathbf{P}$-Matrix Approximation from Theorem 5 (See later in this section), we obtain the following theorem.

▶ **Theorem 2.** Low Boolean-Rank Approximation *is solvable in* $2^{\mathcal{O}(r2^r\sqrt{k \log k})} \cdot (nm)^{\mathcal{O}(1)}$ *time.*

Now we sketch the main ideas behind our algorithm for $\mathbf{P}$-Matrix Approximation. In fact, we exploit the same ideas to construct subexponential in k time algorithms for Binary r-Means and Low GF(2)-Rank Approximation, and these algorithms are great deal less technical. Hence, we concentrate here on these problems.

Let $(\mathbf{A}, r, k)$ be an instance of Binary r-Means where $\mathbf{A}$ is a matrix with columns $(\mathbf{a}^1, \ldots, \mathbf{a}^n)$. Recall that given a solution $\{I_1, \ldots, I_{r'}\}$, one can compute the corresponding means $\mathbf{c}^1, \ldots, \mathbf{c}^{r'} \in \{0,1\}^m$ using the majority rule. Note that in the opposite direction, given a set of means $\mathbf{c}^1, \ldots, \mathbf{c}^{r'}$, we can construct clusters $\{I_1, \ldots, I_{r'}\}$ as follows: for each column $\mathbf{a}^j$, find the closest $\mathbf{c}^i$, $i \in \{1, \ldots, r'\}$, that is such that $d_H(\mathbf{c}^i, \mathbf{a}^j)$ is minimum and assign j to I_i. Note that this procedure does not guarantee that all clusters are nonempty but we can simply delete empty clusters. Hence, we can define a solution as a set of means $C = \{\mathbf{c}^1, \ldots, \mathbf{c}^{r'}\}$.

It can be observed that we can restrict ourself by considering only solutions of special type. Let $\mathbf{a}_1, \ldots, \mathbf{a}_m$ be the rows of $\mathbf{A}$. We say that a vector $\mathbf{c} = (c_1, \ldots, c_m)^\intercal \in \{0,1\}^m$ *agrees* with $\mathbf{A}$ if $c_i = c_j$ whenever $\mathbf{a}_i = \mathbf{a}_j$ for $i, j \in \{1, \ldots, m\}$. If $(\mathbf{A}, r, k)$ is a yes-instance of Binary r-Means, then it can be shown that $(\mathbf{A}, r, k)$ has a solution such that for each cluster of the solution its mean agrees with $\mathbf{A}$. Also it could be seen that if $(\mathbf{A}, r, k)$ is a yes-instance of Binary r-Means, then $\mathbf{A}$ has at most $r + k$ pairwise-distinct columns and at most $2^r + k$ pairwise-distinct rows. These observations allow us to construct a recursive branching algorithm for Binary r-Means.

First, we preprocess the instance $(\mathbf{A}, r, k)$: if $\mathbf{A}$ has at least $r + k + 1$ pairwise-distinct columns or at least $2^r + k + 1$ distinct rows, we return the answer NO and stop. Now on we assume that this is not the case.

Assume that we are given a partial clustering of some columns of $\mathbf{A}$ represented by a family of means $\{\mathbf{c}_1, \ldots, \mathbf{c}_s\}$, a budget d and the set I of remaining columns of $\mathbf{A}$ which have to be clustered. The algorithm tries to extend the partial solution by not exceeding the budget $d \leq k$. Some of the columns from I can go to the existing cluster and some can form new clusters. Suppose that we know the minimum Hamming distance $h \leq d$ from vectors in new clusters to their means (in the algorithm we consider all possible values of h). Then all vectors which are within distance less than h to the already existing means, can be assigned to the existing clusters. Then we will be basically left with two options. Either the number of columns to be assigned to new clusters does not exceed $\sqrt{d \log(2^r + d)} \leq \sqrt{k \log(2^r + k)}$; in this case we brute-force in all possible partitions of I. Or we can upper bound $h \leq \sqrt{d/\log(2^r + d)} \leq \sqrt{k/\log(2^r + k)}$. In the latter case we branch on all possible vectors that agree with $\mathbf{A}$ and are at distance at most h from one of the at most $r + k$ columns of I. Due to the fact that the number of distinct rows of $\mathbf{A}$ is at most $2^r + k$, the number of branches for each column of I is at most $(2^r + k)^h$. In each

branch of our algorithm, we add a new mean to the partial solution and call our algorithm recursively. Note that the depth of the recursion is upper bounded by r.

This way we obtain the following theorem.

▶ **Theorem 3.** Binary r-Means *is solvable in time* $2^{\mathcal{O}(r\sqrt{k\log(2^r+k)})}\cdot(nm)^{\mathcal{O}(1)}$.

The general idea of the subexponential time algorithm for Low GF(2)-Rank Approximation is similar but the algorithm is more complicated. Let $(\mathbf{A},r,k)$ be an instance of Low GF(2)-Rank Approximation where $\mathbf{a}^1,\ldots,\mathbf{a}^n$ are the columns of $\mathbf{A}$. We observe that $(\mathbf{A},r,k)$ is a yes-instance if and only if there is a positive integer $r'\leq r$ and linearly independent vectors $\mathbf{c}^1,\ldots,\mathbf{c}^{r'}\in\{0,1\}^m$ over $\mathsf{GF}(2)$ such that

$$\sum_{i=1}^{n}\min\{d_H(\mathbf{s},\mathbf{a}^i)\mid \mathbf{s}=\bigoplus_{j\in I}\mathbf{c}^j,\ I\subseteq\{1,\ldots,r'\}\}\leq k;$$

we use "$\bigoplus$" to denote the summation over $\mathsf{GF}(2)$. Respectively, we construct the recursive branching algorithm for Low GF(2)-Rank Approximation that tries to extend a partial solution represented by a family of linearly independent vectors. We use the properties that if $(\mathbf{A},r,k)$ is a yes-instance, then the number of pairwise distinct columns and rows is at most 2^r+k and we can select new vectors that agree with $\mathbf{A}$. We obtain the following theorem.

▶ **Theorem 4.** Low GF(2)-Rank Approximation *is solvable in time* $2^{\mathcal{O}(r\sqrt{k\log(2^r+k)})}\cdot(nm)^{\mathcal{O}(1)}$.

For $\mathbf{P}$-Matrix Approximation, we use the same approach based on the combination of branching and local search but because we have to follow the structure of the pattern matrix P, the algorithm becomes technical. We get the following running time for the problem.

▶ **Theorem 5.** $\mathbf{P}$-Matrix Approximation *is solvable in time* $2^{\mathcal{O}((p+q)\sqrt{k\log(p+k)+p\log p+q\log q+q\log(q+k)})}\cdot(nm)^{\mathcal{O}(1)}$.

Note that the running time in Theorem 5 is asymmetric in p and q due to the fact that we treat rows and columns in different way but, trivially, the instances $(\mathbf{A},\mathbf{P},k)$ and $(\mathbf{A}^\intercal,\mathbf{P}^\intercal,k)$ of $\mathbf{P}$-Matrix Approximation are equivalent.

4 Conclusion and open problems

In this paper we provide a number of parameterized algorithms for a number of binary matrix-approximation problems. Our results uncover some parts of the complexity landscape of these fascinating problems. We hope that our work will facilitate further investigation of this important and exciting area. We conclude with the following concrete open problems about bivariate complexity of Binary r-Means, Low GF(2)-Rank Approximation, and Low Boolean-Rank Approximation.

For Binary r-Means we have shown that the problem is solvable in time $2^{\mathcal{O}(k\log k)}\cdot(nm)^{\mathcal{O}(1)}$. A natural question is whether this running time is optimal. While the lower bound of the kind $2^{o(k)}\cdot(nm)^{\mathcal{O}(1)}$ or $2^{o(k\log k)}\cdot(nm)^{\mathcal{O}(1)}$ seems to be most plausible here, we do not know any strong argument against, say a $2^{o(k)}\cdot(nm)^{\mathcal{O}(1)}$-time algorithm. At least for the number of distinct columns $r\in o((k/\log k)^{1/3})$ we have a subexponential in k algorithm, so maybe we can solve the problem in time subexponential in k for any value of r?

For Low GF(2)-Rank Approximation we have an algorithm solving the problem in time $2^{\mathcal{O}(r^{3/2}\cdot\sqrt{k\log k})}(nm)^{\mathcal{O}(1)}$. Here, shaving off the $\sqrt{\log k}$ factor in the exponent seems to

be a reasonable thing. However, we do not know how to do it even at the cost of a worse dependence in r. In other words, could the problem be solvable in time $2^{\mathcal{O}(f(r)\cdot\sqrt{k})}(nm)^{\mathcal{O}(1)}$ for some function f? On the other hand, we also do not know how to rule out algorithms running in time $2^{o(r)\cdot o(k)}(nm)^{\mathcal{O}(1)}$.

For Low Boolean-Rank Approximation, how far is our upper bound $2^{\mathcal{O}(r2^r\cdot\sqrt{k\log k})}(nm)^{\mathcal{O}(1)}$ from the optimal? For example, we know that for any function f, the solvability of the problem in time $2^{2^{o(r)}}f(k)(nm)^{\mathcal{O}(1)}$ implies the failure of ETH. Could we rule out any $2^{o(\sqrt{k})}f(r)(nm)^{\mathcal{O}(1)}$ algorithm?

Abstract

Derandomization of blackbox identity testing reduces to extremely special circuit models. After a line of work, it is known that focusing on circuits with constant-depth and constantly many variables is enough (Agrawal,Ghosh,Saxena, STOC'18) to get to general hitting-sets and circuit lower bounds. This inspires us to study circuits with few variables, eg. logarithmic in the size s.

We give the first poly(s)-time blackbox identity test for $n = O(\log s)$ variate size-s circuits that have poly(s)-dimensional partial derivative space; eg. depth-3 diagonal circuits (or $\Sigma \wedge \Sigma^n$). The former model is well-studied (Nisan,Wigderson, FOCS'95) but no poly($s2^n$)-time identity test was known before us. We introduce the concept of *cone-closed* basis isolation and prove its usefulness in studying log-variate circuits. It subsumes the previous notions of rank-concentration studied extensively in the context of ROABP models.

1 Introduction

Polynomial Identity Testing (PIT) problem is to decide whether a multivariate polynomial is *zero*, where the input polynomial is given as an *algebraic circuit*. Algebraic circuits are the algebraic analog of boolean circuits that use ring operations $\{+, \times\}$ and computes polynomials (say) over a field. Since a polynomial computed by a circuit can have exponentially many

monomials wrt the circuit size, one cannot solve PIT in polynomial time by explicitly expanding the polynomial. On the other hand, using circuits we can efficiently evaluate polynomials at any point. This helps us to get a polynomial time randomized algorithm for PIT by evaluating the circuit at a random point, since any non-zero polynomial evaluated at a random point outputs a non-zero value with high probability [10, 58, 54]. However, finding a deterministic polynomial time algorithm for PIT is a longstanding open question in algebraic complexity theory. The PIT problem has been studied in two different paradigms: **1)** *whitebox* – allowed to see the internal structure of the circuit, and **2)** *blackbox* – can only use the circuit as an oracle to evaluate at points (from a small field extension). It has deep connections with both circuit lower bounds [29, 31, 1, 2] and many other algorithmic problems [41, 4, 35, 11, 13]. For more details on PIT, see the surveys [51, 52, 55] or review articles [56, 42].

Despite a lot of effort, little progress has been made on the PIT problem in general. However, efficient (deterministic poly-time) PIT algorithms are known for many special circuit models. For example, blackbox PIT for depth-2 circuits (or sparse polynomials) [8, 34, 39], PIT algorithms for subclasses of depth-3 circuits [33, 50, 53], subclasses of depth-4 circuits [5, 7, 46, 15, 36, 37, 45], read-once algebraic branching programs (ROABP) and related models [19, 6, 18, 3, 26, 25], certain types of symbolic determinants [12, 27], as well as non-commutative models [38, 22].

1.1 Our results

In the first result, *we give a polynomial time blackbox PIT algorithm of log-variate depth-*3 *diagonal circuits* $\Sigma \wedge \Sigma$ (i.e. number of variables is logarithmic wrt circuit size). Depth-3 diagonal circuits compute a sum of power of linear polynomials. This model was first introduced by [51] and has since drawn significant attention of PIT research community. Saxena [51] first gave a polynomial time whitebox algorithm and exponential lower bound for this model, by introducing a duality trick. In a subsequent work Kayal [32] gave an alternate polynomial time whitebox algorithm for depth-3 diagonal circuits based on the partial derivative method, which was first introduced by [44] to prove circuit lower bounds; as, $\Sigma \wedge \Sigma$ circuits have a low-dimension partial derivative space. However, one limitation of these approaches was that they depend on the characteristic of the underlying field. Later, [16] gave an alternative proof of duality trick which depends only on the field size (as mentioned in [24, Lem.4.7]) and Saptharishi [48, Chap.3] extended Kayal's idea for large enough field.

Although this model is very weak (it cannot even compute $x_1 \cdots x_n$ efficiently), studying this model has proved quite fruitful. Duality trick was crucially used in the work by [23], where they showed that depth-3 circuits, in some sense, capture the complexity of general arithmetic circuits.

Like whitebox PIT, a series of work has been done on *blackbox* PIT for depth-3 diagonal circuits. Both [6] and [19] gave two independent and different quasi-polynomial time blackbox PIT algorithms for this model. Later, [18] gave an $s^{O(\log\log s)}$-time (s is the circuit size) blackbox PIT algorithm for this model. Mulmuley [43, 40] related depth-3 diagonal blackbox PIT to construction of normalization maps for the invariants of the group SL_m for constant m. We can not give the detailed notation here and would like to refer to [40, Sec.9.3]. Despite a lot of effort, no polynomial time blackbox PIT for this model is known. After depth-2 circuits (or sparse polynomials), this can be thought of as the simplest model for which no polynomial time blackbox PIT is known. Because of its simplicity, this model is a good test case for generating new ideas for the PIT problem.

Log-variate models: Now we discuss why studying PIT for log-variate models is so important. The PIT algorithms in current literature always try to achieve a sub-exponential dependence on n, the number of variables. In a recent development, [2] showed that for some constant c a poly(s)-time blackbox PIT for size-s degree-s and $\log^{\circ c} s$-variate[1] circuits is sufficient to *completely* solve PIT. Most surprisingly, they also showed that a poly(s)-time blackbox PIT for size-s and $\log^{\star} s$-variate[2] $\Sigma \wedge \Sigma\Pi$ circuits will 'partially' solve PIT (in quasi-polynomial time) and prove that "either E$\not\subseteq$#P/poly or VP$\neq$VNP" (a weaker version of [2, Thm.21]). For example, even a poly(s)-time blackbox PIT for size-s and $(\log\log s)$-variate depth-4 circuits would be tremendous progress. A similar result also holds for $\Sigma \wedge^{a} \Sigma\Pi(n)$ circuits, where both a and n are 'arbitrarily small' unbounded functions (i.e. time-complexity may be arbitrary in terms of both a and n), see [2, Thm.21].

The above discussion motivates us to discover techniques and measures that are specialized to this low-variate regime. Many previous works are based on 'support size of a monomial' as a measure for rank-concentration [6, 18, 26]. For a monomial m, its *support* is the set of variables whose exponents are positive. We investigate a 'larger' measure: *cone-size* (see Definition 3) which is the number of monomials that divide m (also see [14]). Using cone-size as a measure for rank-concentration, we give a blackbox PIT algorithm for circuit models with 'low' dimensional partial derivative space.

▶ **Theorem 1.** *Let $\mathbb{F}$ be a field of characteristic 0 or greater than d. Let $\mathcal{P}$ be a set of n-variate d-degree polynomials, over $\mathbb{F}$, computed by circuits of bitsize s such that: $\forall P \in \mathcal{P}$, the dimension of the partial derivative space of P is at most k. Then, blackbox PIT for $\mathcal{P}$ can be solved in $(sdk)^{O(1)} \cdot (3n/\log k)^{O(\log k)}$ time.*

Note that for $n = O(\log k) = O(\log sd)$, the above bound is poly-time and we get a polynomial time blackbox PIT algorithm for log-variate circuits (i.e. number of variables is logarithmic wrt circuit size) with low-dimensional partial derivative space. This was not known before our work. Prior to our work, [18] gave a $(sdk)^{O(\log\log sdk)}$-time algorithm for $\mathcal{P}$, using support size as the measure in the proof. Unlike our algorithm, in the log-variate case their algorithm remains super-polynomial time.

In particular, diagonal depth-3 circuit is a prominent model with low partial derivative space. So, our method gives a polynomial time PIT algorithm for log-variate depth-3 diagonal circuits. No poly-time blackbox PIT for this model was known before our work; again, $s^{O(\log\log s)}$ was the prior best [18].

Structure of log-variate polynomials? In the second result, we investigate a structural property of polynomials over vector spaces. For a polynomial $f(\mathbf{x})$ with coefficients over $\mathbb{F}^k$, let sp(f) be the subspace spanned by its coefficients. Informally, in *rank concentration* we try to concentrate the rank of sp(f) to the coefficients of "few" monomials. It was first introduced by [6]. Many works in PIT achieve rank concentration on low-support monomials, mainly, in the ROABP model [6, 18, 26, 25]. One way of strengthening low-support concentration is through *low-cone concentration*, where rank is concentrated in the low cone-size monomials. This concept was not used before in designing PIT algorithms. Our first result (Theorem 1) can be seen from this point of view. There, we developed a method to get polynomial time blackbox PIT for log-variate models which satisfy 'low-cone concentration property'.

[1] The function $\log^{\circ c}$ denotes c times composition of the log function. For e.g. $\log^{\circ 2} s = \log\log s$.
[2] For any positive integer s, $\log^{\star} s = \min\{i \mid \log^{\circ i} s \leq 1\}$.

We introduce the concept of cone-closed basis, a much stronger notion of concentration than the previous ones. We say f has a cone-closed basis, if there is a set of monomials B whose coefficients form a basis of $\mathrm{sp}(f)$ and B is closed under sub-monomials. This definition is motivated by a special depth-3 diagonal model, which have this property naturally (see Lemma 18). We prove that this notion is a strengthening of both low-support and low-cone concentration ideas (see Lemma 11). Recently, and independently, this notion of closure has also appeared as an 'abstract simplicial complex' in [21].

In the following result, we relate cone-closed basis with 'basis isolating weight assignment' (Defn.12)– another well studied concept in PIT. It was first introduced by [3] and also used in many other subsequent works [26, 12, 28]. Here, we show that a general polynomial f over $\mathbb{F}^k$, when shifted by a basis isolating weight assignment [3], becomes cone-closed. It strengthens some previously proven properties; eg., a polynomial over $\mathbb{F}^k$ when shifted 'randomly' becomes low-support concentrated [17, Cor.3.22] (extended version of [18]) or, when shifted by a basis isolating weight assignment becomes low-support concentrated [26, Lem.5.2].

Notations. For any $n \in \mathbb{N}$, $[n]$ denotes the set of first n positive integers. By $\mathbf{x}$, we denote $(x_1, \ldots, x_n)$, a tuple of n-variables. For any $\mathbf{e} = (e_1, \ldots, e_n) \in \mathbb{N}^n$, $\mathbf{x}^{\mathbf{e}}$ denotes the monomial $\prod_{i=1}^{n} x_i^{e_i}$. For a polynomial f and a monomial m, $\mathrm{coef}_m(f)$ denotes the coefficient of the monomial m in f. An *weight assignment* $\mathbf{w}$ on the variables $\mathbf{x}$ is an n-tuple $(w_1, \ldots, w_n) \in \mathbb{N}^n$, where w_i is the weight assigned to the variable x_i.

▶ **Theorem 2.** *Let $f(\mathbf{x}) \in \mathbb{F}[\mathbf{x}]^k$ be an n-variate d-degree polynomial over $\mathbb{F}^k$ and char $\mathbb{F} = 0$ or $> d$. Let $\mathbf{w} = (w_1, \ldots, w_n) \in \mathbb{N}^n$ be a basis isolating weight assignment of $f(\mathbf{x})$. Then, $f(\mathbf{x} + t^{\mathbf{w}}) := f(x_1 + t^{w_1}, \ldots, x_n + t^{w_n})$ has a cone-closed basis over $\mathbb{F}(t)$.*

1.2 Proof ideas

Proof idea of Theorem 1: The proof of Theorem 1 has two steps. In the first step, we show that with respect to any monomial ordering (say lexicographic monomial ordering), the dimension k of the partial derivative space of a polynomial is lower bounded by the cone-size of its leading monomial. For a polynomial $f \in \mathbb{F}[\mathbf{x}]$, the leading monomial, wrt a monomial ordering, is the largest monomial in the set $\{\mathbf{x}^{\mathbf{e}} \mid \mathrm{coef}_{\mathbf{x}^{\mathbf{e}}}(f) \neq 0\}$. So, for every nonzero $P \in \mathcal{P}$ there is a monomial with nonzero coefficient and cone-size $\leq k$. The second step is to check whether the coefficients of all the monomials in P, with cone-size $\leq k$, are zero. We show that the number of such monomials is small (Lemma 5); the number is quasi-polynomial in general, but, merely polynomial in the log-variate case. Next, we give a new method to efficiently extract a monomial of cone-size$\leq k$, out of a potentially exponential space of monomials (Lemma 4). These facts, combined with the estimates stated in Theorem 1, prove Corollary 6; which gives a polynomial time blackbox PIT algorithm for log-variate circuits with low dimensional partial derivative space.

Next, we discuss the idea to get a polynomial time blackbox PIT algorithm for depth-3 diagonal circuits where *rank* of the linear polynomials is logarithmic wrt the circuit size (see Definition 7 & Theorem 9). Here, the proof has two steps. First, in Lemma 8, we show how to efficiently reduce a low-rank depth-3 diagonal circuit to a low-*variate* depth-3 diagonal circuit while preserving nonzeroness. This we do by a Vandermonde based linear map on the variables. Since a depth-3 diagonal circuit has low-dimensional partial derivative space (i.e. polynomial wrt circuit size), we apply Corollary 6 on the low-variate depth-3 diagonal circuits and get Theorem 9.

Proof idea of Theorem 2: First, wrt the weight assignment $\mathbf{w}$, we define an ordering among the set of bases (see Section 3). Then, we show that wrt the basis isolating weight assignment $\mathbf{w}$, there exists a *unique minimum basis* and its weight is strictly less than the weight of every other basis (Lemma 13). Let B be the set of monomials whose coefficients form the least basis, wrt $\mathbf{w}$, of f.

Now, we consider the set of all sub-monomials of those in B and identify a subset A that is cone-closed. We define A in an algorithmic way (see Algorithm 1). Besides the cone-closed property, A also satisfies an algebraic property (Lemma 17)— In the *transfer matrix* T, that captures the variable-shift transformation (Equation 3), the sub-matrix $T_{A,B}$ is *full* rank. We prove that A is exactly a basis of the shifted f by studying the action of the shift on the coefficient vectors. The properties proved above and Cauchy-Binet Formula [57] are crucially used in the study of the coefficient vectors after the variable-shift.

Theorem 2 has an immediate consequence that any polynomial f over $\mathbb{F}^k$, when shifted by formal (or random) variables, becomes cone-closed; since the weight induced by the formal variables on the monomials is a basis isolating weight assignment. This seems quite a nontrivial and an interesting property of general polynomials (over vector spaces).

2 Low-cone concentration and hitting-sets– Proof of Theorem 1

In this section we initiate a study of properties that are relevant for low-variate circuits (or the log-variate regime).

Notations. For a circuit C, $|C|$ denotes the size of C. For a monomial m, by $\text{coef}_m(C)$, we denote the coefficient of monomial m in the polynomial computed by C. For a circuit C, we also use C to denote the polynomial computed by C.

▶ **Definition 3** (Cone of a monomial)**.** A monomial $\mathbf{x}^{\mathbf{e}}$ is called a *sub-monomial* of $\mathbf{x}^{\mathbf{f}}$, if $\mathbf{e} \leq \mathbf{f}$ (i.e. coordinate-wise). We say that $\mathbf{x}^{\mathbf{e}}$ is a *proper sub-monomial* of $\mathbf{x}^{\mathbf{f}}$, if $\mathbf{e} \leq \mathbf{f}$ and $\mathbf{e} \neq \mathbf{f}$.

For a monomial $\mathbf{x}^{\mathbf{e}}$, the *cone of* $\mathbf{x}^{\mathbf{e}}$ is the set of all sub-monomials of $\mathbf{x}^{\mathbf{e}}$. The cardinality of this set is called *cone-size of* $\mathbf{x}^{\mathbf{e}}$. It equals $\prod(\mathbf{e}+\mathbf{1}) := \prod_{i\in[n]}(e_i+1)$, where $\mathbf{e} = (e_1, \ldots, e_n)$.

A set S of monomials is called *cone-closed* if for every monomial in S all its sub-monomials are also in S.

▶ **Lemma 4** (Coef. extraction)**.** *Let C be a blackbox circuit which computes an n-variate and degree-d polynomial over a field of size greater than d. Then for any monomial $m = \prod_{i\in[n]} x_i^{e_i}$, we have a $\text{poly}(|C|d, \text{cs}(m))$-time algorithm to compute the coefficient of m in C, where $\text{cs}(m)$ denotes the cone-size of m.*

Proof. Our proof is in two steps. First, we inductively build a circuit computing a polynomial which has two parts; one is $\text{coef}_m(C) \cdot m$ and the other one is a "junk" polynomial where every monomial is a proper super-monomial of m. Second, we construct a circuit which extracts the coefficient of m. In both these steps the key is a classic interpolation trick.

We induct on the variables. For each $i \in [n]$, let $m_{[i]}$ denote $\prod_{j\in[i]} x_j^{e_j}$. We will construct a circuit $C^{(i)}$ which computes a polynomial of the form,

$$C^{(i)}(\mathbf{x}) \;=\; \text{coef}_{m_{[i]}}(C) \cdot m_{[i]} \;+\; C^{(i)}_{\text{junk}} \tag{1}$$

where, for every monomial m' in the support of $C^{(i)}_{\text{junk}}$, $m_{[i]}$ is a proper submonomial of $m'_{[i]}$.

Base case: Since $C =: C^{(0)}$ computes an n-variate degree-d polynomial, $C(\mathbf{x})$ can be written as $C(\mathbf{x}) = \sum_{j=0}^{d} c_j x_1^j$ where, $c_j \in \mathbb{F}[x_2, \ldots, x_n]$. Let $\alpha_0, \ldots, \alpha_{e_1}$ be some $e_1 + 1$ distinct elements in $\mathbb{F}$. For every α_j, let $C_{\alpha_j x_1}$ denote the circuit $C(\alpha_j x_1, x_2, \ldots, x_n)$ which computes $c_0 + c_1\alpha_j x_1 + \ldots + c_{e_1}\alpha_j^{e_1} x_1^{e_1} + \cdots + c_d \alpha_j^d x_1^d$. Since

$$M = \begin{bmatrix} 1 & \alpha_0 & \ldots & \alpha_0^{e_1} \\ \vdots & \vdots & \vdots & \vdots \\ 1 & \alpha_{e_1} & \ldots & \alpha_{e_1}^{e_1} \end{bmatrix}$$

is an invertible Vandermonde matrix, one can find an $\mathbf{a} = [a_0, \ldots, a_{e_1}] \in \mathbb{F}^{e_1+1}$, $\mathbf{a} \cdot M = [\,0,\ 0,\ \ldots,\ 1\,]$. Using this $\mathbf{a}$, we get the circuit $C^{(1)} := \sum_{j=0}^{e_1} a_j C^{(0)}_{\alpha_j x_1}$. Its least monomial wrt x_1 has $\deg_{x_1} \geq e_1$, which is the property that we wanted.

Induction step $(i \to i+1)$*:* From induction hypothesis, we have the circuit $C^{(i)}$ with the properties mentioned in Eqn.1. The polynomial can also be written as $b_0 + b_1 x_{i+1} + \ldots + b_{e_{i+1}} x_{i+1}^{e_{i+1}} + \ldots b_d x_{i+1}^d$, where every b_j is in $\mathbb{F}[x_1, \ldots, x_i, x_{i+2}, \ldots, x_n]$. Like the proof of the base case, for $e_{i+1}+1$ distinct elements $\alpha_0, \ldots, \alpha_{e_{i+1}} \in \mathbb{F}$, we get $C^{(i+1)} = \sum_{j=0}^{e_{i+1}} a_j C^{(i)}_{\alpha_j x_{i+1}}$, for some $\mathbf{a} = [a_0, \ldots, a_{e_{i+1}}] \in \mathbb{F}^{e_{i+1}+1}$ and the structural constraint of $C^{(i+1)}$ is easy to verify, completing the induction.

Now we describe the second step of the proof. After first step, we get

$$C^{(n)}(\mathbf{x}) \;=\; \mathrm{coef}_m(C) \cdot m \;+\; C^{(n)}_{\mathrm{junk}}\,,$$

where for every monomial m' in the support of $C^{(n)}_{\mathrm{junk}}$, m is a proper submonomial of m'. Consider the polynomial $C^{(n)}(x_1 t, \ldots, x_n t)$ for a fresh variable t. Then, using interpolation wrt t we can construct a $O(|C^{(n)}| \cdot d)$-size circuit for $\mathrm{coef}_m(C) \cdot m$, by extracting the coefficient of $t^{\deg(m)}$, since the degree of every monomial appearing in $C^{(n)}_{\mathrm{junk}}$ is $> \deg(m)$. Now evaluating at $\mathbf{1}$, we get $\mathrm{coef}_m(C)$. The size, or time, constraint of the final circuit clearly depends polynomially on $|C|, d$ and $\mathrm{cs}(m)$. ◀

But, how many low-cone monomials can there be? Fortunately, in the log-variate regime they are not too many [47]. Though, in general, they are quasi-polynomially many.

▶ **Lemma 5** (Counting low-cones)**.** *The number of n-variate monomials with cone-size at most k is $O(rk^2)$, where $r := (3n/\log k)^{\log k}$.*

Proof. First, we prove that for any fixed support set, the number of cone-size $\leq k$ monomials is less than k^2. Next, we multiply by the number of possible support sets to get the estimate.

Let $T(k, \ell)$ denote the number of cone-size$\leq k$ monomials m with support set, say, exactly $\{x_1, \ldots, x_\ell\}$. Since the exponent of x_ℓ in such an m is at least 1 and at most $k-1$, we have the following by the disjoint-sum rule: $T(k, \ell) \leq \sum_{i=2}^{k} T\,(k/i, \ell - 1)$. This recurrence affords an easy inductive proof as, $T(k, \ell) < \sum_{i=2}^{k} (k/i)^2 < k^2 \cdot \sum_{i=2}^{k} \left(\frac{1}{i-1} - \frac{1}{i}\right) < k^2$.

From the definition of cone, a cone-size $\leq k$ monomial can have support size at most $\ell := \lfloor \log k \rfloor$. The number of possible support sets, thus, is $\sum_{i=0}^{\ell} \binom{n}{i}$. Using the binomial estimates [30, Chapter 1], we get $\sum_{i=0}^{\ell} \binom{n}{i} \leq (3n/\ell)^{\ell}$. ◀

The partial derivative space of polynomials was first used by Nisan and Wigderson [44] to prove circuit lower bounds. Later, it was used in many other works. For more details see the following surveys [9, 49]. Here, using cone-size as a measure, we describe a blackbox PIT algorithm for circuits models with low dimensional partial derivative space. This algorithm runs in polynomial time when we are in log-variate regime. For a polynomial $f(\mathbf{x}) \in \mathbb{F}[\mathbf{x}]$, by $\partial_{\mathbf{x}<\infty}(f)$ we denote the space generated all partial derivatives of f.

Proof of Theorem 1. The proof has two steps. First, we show that with respect to any monomial ordering $\prec$ (say lexicographic monomial ordering), for all nonzero $P \in \mathcal{P}$, the dimension of the partial derivative space of P is lower bounded by the cone-size of the leading monomial in P. Using this, we can get a blackbox PIT algorithm for $\mathcal{P}$ by testing the coefficients of all the monomials of P of cone-size $\leq k$ for zeroness. Next, we analyze the time complexity to do this.

The first part is the same as the proof of [14, Corollary 4.14] (with origins in [20]). Here, we give a brief outline. Let $LM(\cdot)$ be the *leading monomial* operator wrt the monomial ordering $\prec$. It can be shown that for any polynomial $f(\mathbf{x})$, the dimension of its partial derivative space $\partial_{\mathbf{x}^{<\infty}}(f)$ is the same as $D := \#\{LM(g) \mid g \in \partial_{\mathbf{x}^{<\infty}}(f)\}$ (see [14, Lemma 8.4.12]). This means that $\dim \partial_{\mathbf{x}^{<\infty}}(f)$ is lower-bounded by the cone-size of $LM(f)$ [14, Corollary 8.4.13], which completes the proof of our first part.

Next, we apply Lemma 4, on the circuit of P and a monomial m of cone-size $\leq k$, to get the coefficient of m in C in poly(sdk)-time. Finally, Lemma 5 tells that we have to access at most $k^2 \cdot (3n/\log k)^{\log k}$ many monomials m. Multiplying these two expressions gives us the time bound. ◀

This gives us immediately,

▶ **Corollary 6.** *Let $\mathbb{F}$ be a field of characteristic 0 or $> d$. Let $\mathcal{P}$ be a set of n-variate d-degree polynomials, over $\mathbb{F}$, computable by circuits of bitsize s; with $n = O(\log sd)$. Suppose that, for all $P \in \mathcal{P}$, the dimension of the partial derivative space of P is poly(sd). Then, blackbox PIT for $\mathcal{P}$ can be solved in poly(sd)-time.*

Now we discuss our result regarding depth-3 diagonal circuits $\Sigma \wedge \Sigma$.

▶ **Definition 7** (Depth-3 diagonal circuit and its rank)**.** A *depth-3 diagonal circuit* is of the form $\Sigma \wedge \Sigma$ (sum-power-sum). It computes a polynomial presented as $C(\mathbf{x}) = \sum_{i\in[k]} c_i \ell_i^{d_i}$, where ℓ_i's are linear polynomials over $\mathbb{F}$ and c_i's in $\mathbb{F}$.

By $\mathrm{rk}(C)$ we denote the linear rank of the polynomials $\{\ell_i\}_{i\in[k]}$.

The next lemma introduces an efficient *nonzeroness preserving variable reduction* map $(n \mapsto \mathrm{rk}(C))$ for depth-3 diagonal circuits. For a set of n-variate circuits $\mathcal{C}$ over $\mathbb{F}$, a *polynomial map* $\Psi : \mathbb{F}^m \to \mathbb{F}^n$ is called nonzeroness preserving variable reduction map for $\mathcal{C}$, if $m < n$ and for all $C \in \mathcal{C}$, $C \neq 0$ if and only if $\Psi(C) \neq 0$.

▶ **Lemma 8** (Variable reduction)**.** *Let $P(\mathbf{x})$ be an n-variate d-degree polynomial computed by a size-s depth-3 diagonal circuit over some sufficiently large field $\mathbb{F}$. Then, there exists a* poly(nds)*-time computable nonzeroness preserving variable reduction map which converts P to another $rk(P)$-variate degree-d polynomial computed by* poly(s)*-size depth-3 diagonal circuit.*

For proof, see the full version linked on the first page.

▶ **Theorem 9** (Log-rank $\Sigma \wedge \Sigma$)**.** *Let $\mathbb{F}$ be a field of characteristic 0 or $> d$. Let $\mathcal{P}$ be the set of n-variate d-degree polynomials P, computable by depth-3 diagonal circuits of bitsize s, with $rk(P) = O(\log sd)$. Then, blackbox PIT for $\mathcal{P}$ can be solved in poly(sd)-time.*

Proof. The above description gives us a non-zeroness preserving variable reduction $(n \mapsto \mathrm{rk}(P))$ method that reduces P to an $O(\log(sd))$-variate and degree-d polynomial P' computed by poly(s)-size depth-3 diagonal circuit.

Since the dimension of the partial derivative space of P' is poly(sd) [14, Lem.8.4.8], Corollary 6 gives us a poly(sd)-time hitting-set for P'. ◀

3 Cone-closed basis after shifting– Proof of Theorem 2

In this section we will consider polynomials over a vector space, say $\mathbb{F}^k$. This viewpoint has been useful in studying algebraic branching programs (ABP), eg. [6, 18, 3, 26]. Let $D \in \mathbb{F}^k[\mathbf{x}]$ and let $\mathrm{sp}(D)$ be the vector space spanned by its coefficients. Now, we formally define various kinds of rank concentrations of D.

▶ **Definition 10** (Rank Concentration)**.** We say that D has a

1. *cone-closed basis* if there is a cone-closed set of monomials B (see Definition 3) whose coefficients in D form a basis of $\mathrm{sp}(D)$.
2. *ℓ-support concentration*, if there is a set of monomials B with support size less than ℓ whose coefficients form a basis of $\mathrm{sp}(D)$.
3. *ℓ-cone concentration*, if there is a set of monomials B with cone size less than ℓ (see Definition 3) whose coefficients form a basis of $\mathrm{sp}(D)$.

In the next lemma, we show that cone-closed basis notion subsumes the other two notions.

▶ **Lemma 11.** *Let $D(\mathbf{x})$ be a polynomial in $\mathbb{F}^k[\mathbf{x}]$. Suppose that $D(\mathbf{x})$ has a cone-closed basis. Then, $D(\mathbf{x})$ has $(k+1)$-cone concentration and $(\lg 2k)$-support concentration.*

Proof. Let B be a cone-closed set of monomials forming the basis of $\mathrm{sp}(D)$. Clearly, $|B| \leq k$. Thus, each $m \in B$ has cone-size $\leq k$. In other words, D is $(k+1)$-cone concentrated.

Moreover, each $m \in B$ has support-size $\leq \lg k$. In other words, D is $(\lg 2k)$-support concentrated. ◀

Next, we define the notions which will be used in the proof of Theorem 2.

Basis & weights. Consider a weight assignment $\mathbf{w} = (w_1, \ldots, w_n) \in \mathbb{N}^n$ on the variables $\mathbf{x} = (x_1, \ldots, x_n)$. It extends to monomials $m = \mathbf{x}^{\mathbf{e}}$ as $\mathbf{w}(m) := \langle \mathbf{e}, \mathbf{w} \rangle = \sum_{i=1}^{n} e_i w_i$. Sometimes, we also use $\mathbf{w}(\mathbf{e})$ to denote $\mathbf{w}(m)$. Similarly, for a set of monomials B, the weight of B is $\mathbf{w}(B) := \sum_{m \in B} \mathbf{w}(m)$.

Let $B = \{m_1, \ldots, m_\ell\}$ resp. $B' = \{m'_1, \ldots, m'_\ell\}$ be an ordered set of monomials (non-decreasing wrt $\mathbf{w}$) that forms a basis of the span of coefficients of $f \in \mathbb{F}^k[\mathbf{x}]$. Let $\mathbf{w}$ be a weight assignment on the variables. We say that $B < B'$ wrt $\mathbf{w}$, if there exists $i \in [\ell]$ such that $\forall j < i,\ \mathbf{w}(m_j) = \mathbf{w}(m'_j)$ but $\mathbf{w}(m_i) < \mathbf{w}(m'_i)$.

We say that $B \leq B'$ if either $B < B'$ or if $\forall i \in [\ell],\ \mathbf{w}(m_i) \leq \mathbf{w}(m'_i)$. A basis B is called a *least basis*, if for any other basis B', $B \leq B'$. Next, we describe a condition on $\mathbf{w}$ such that least basis will be unique.

▶ **Definition 12.** (Basis Isolating Weight Assignment [3, Defn.5])**.** A weight assignment $\mathbf{w}$ is called a *basis isolating weight assignment* for a polynomial $f(\mathbf{x}) \in \mathbb{F}^k[\mathbf{x}]$ if there exists a set of monomials B such that:

1. the coefficients of the monomials in B form a basis for $\mathrm{sp}(f)$,
2. weights of all monomials in B are distinct, and
3. the coefficient of every $m \in \mathrm{supp}(f) \setminus B$ is in the linear span of $\{\mathrm{coef}_{m'}(f) \mid m' \in B, \mathbf{w}(m') < \mathbf{w}(m)\}$.

▶ **Lemma 13.** *If $\mathbf{w}$ is a basis isolating weight assignment for $f \in \mathbb{F}^k[\mathbf{x}]$, then f has a unique least basis B wrt $\mathbf{w}$. In particular, for any other basis B' of f, we have $\mathbf{w}(B) < \mathbf{w}(B')$.*

Algorithm 1 Finding cone-closed set.

Input: A subset B of the n-tuples M.
Output: A cone-closed $A \subseteq M$ with full rank $T_{A,B}$.
function FIND-CONE-CLOSED(B, n)
  if $n = 1$ **then**
    $s \leftarrow |B|$;
   return $\{0, \ldots, s-1\}$;
  else
    Let π_n be the map which projects the set of monomials B on the first $n-1$ variables;
    Let ℓ be the maximum number of preimages under π_n;
    $\forall i \in [\ell]$, F_i collects those elements in $\mathrm{Img}(\pi_n)$ whose preimage size$\geq i$;
    $A_0 \leftarrow \emptyset$;
    for $i \leftarrow 1$ to ℓ **do**
      $S_i \leftarrow$ FIND-CONE-CLOSED$(F_i, n-1)$;
      $A_i \leftarrow A_{i-1} \bigcup (S_i \times \{i-1\})$;
    end for
   return A;
  end if
end function

For proof, see the full version linked on the first page. Next, we want to study the effect of shifting f by a basis isolating weight assignment. To do that we require an elaborate notation. As before $f(\mathbf{x})$ is a n-variate and degree-d polynomial over $\mathbb{F}^k$. For a weight assignment $\mathbf{w}$, by $f(\mathbf{x} + t^{\mathbf{w}})$ we denote the polynomial $f(x_1 + t^{w_1}, \ldots, x_n + t^{w_n})$. For $\mathbf{a} = (a_1, \ldots, a_n)$ and $\mathbf{b} = (b_1, \ldots, b_n)$ in $\mathbb{N}^n$, $\binom{\mathbf{a}}{\mathbf{b}}$ denotes $\prod_{i=1}^{n} \binom{a_i}{b_i}$, where $\binom{a_i}{b_i} = 1$ for $b_i = 0$ and $\binom{a_i}{b_i} = 0$ for $a_i < b_i$. Let $M_{n,d} = \{\mathbf{a} \in \mathbb{N}^n : |\mathbf{a}|_1 \leq d\}$ corresponds to the set of all n-variate d-degree monomials. For every $\mathbf{a} \in M_{n,d}$, $\mathrm{coef}_{\mathbf{x}^{\mathbf{a}}}(f(\mathbf{x} + t^{\mathbf{w}}))$ can be expanded using the binomial expansion, and we get:

$$\sum_{\mathbf{b} \in M_{n,d}} \binom{\mathbf{b}}{\mathbf{a}} \cdot t^{\mathbf{w}(\mathbf{b}) - \mathbf{w}(\mathbf{a})} \cdot \mathrm{coef}_{\mathbf{x}^{\mathbf{b}}}(f(\mathbf{x}))\,. \tag{2}$$

We express this data in matrix form as

$$F' = D^{-1} T D \cdot F, \tag{3}$$

where the matrices involved are,

1. F and F': rows are indexed by the elements of $M_{n,d}$ and columns are indexed by $[k]$. In F resp. F' the $\mathbf{a}$-th row is $\mathrm{coef}_{\mathbf{x}^{\mathbf{a}}}(f(\mathbf{x}))$ resp. $\mathrm{coef}_{\mathbf{x}^{\mathbf{a}}}(f(\mathbf{x} + t^{\mathbf{w}}))$.
2. D: is a diagonal matrix with both the rows and columns indexed by $M_{n,d}$. For $\mathbf{a} \in M_{n,d}$, $D_{\mathbf{a},\mathbf{a}} := t^{\mathbf{w}(\mathbf{x}^{\mathbf{a}})}$.
3. T: both the rows and columns are indexed by $M_{n,d}$. For $\mathbf{a}, \mathbf{b} \in M_{n,d}$, $T_{\mathbf{a},\mathbf{b}} := \binom{\mathbf{b}}{\mathbf{a}}$. It is known as *transfer matrix*.

We will prove the following combinatorial property of T: For any $B \subseteq M_{n,d}$, there is a *cone-closed* $A \subseteq M_{n,d}$ such that the submatrix $T_{A,B}$ has full rank. Our proof is an involved double-induction, so we describe the construction of A as Algorithm 1.

▶ **Lemma 14** (Comparison). *Let B and B' be two nonempty subsets of M such that $B \subseteq B'$. Let $A =$ FIND-CONE-CLOSED(B, n) and $A' =$ FIND-CONE-CLOSED(B', n) in Algorithm 1. Then $A \subseteq A'$.*

▶ **Lemma 15** (Closure). *Let B be a nonempty subset of M. If $A = \text{FIND-CONE-CLOSED}(B, n)$ in Algorithm 1, then A is cone-closed. Moreover, $|A| = |B|$.*

For proofs of the above two lemmas, see the full version linked on the first page. Next, we recall a fact that has been used for ROABP PIT.

▶ **Lemma 16.** *[25, Claim 3.3] Let $a_1, \ldots, a_n$ be distinct non-negative integers and char $\mathbb{F} = 0$ or greater than the maximum of all a_is. Let A be an $n \times n$ matrix with, $i, j \in [n]$, $A_{i,j} := \binom{a_j}{i-1}$. Then, A is full rank.*

In the following lemma, we prove that the sub-matrix $T_{A,B}$ has full rank, where $B \subseteq M_{n,d}$ and A is the output of Algorithm 1 on input A. It requires char $\mathbb{F} = 0$ or greater than d.

▶ **Lemma 17** (Full rank). *If $A = \text{FIND-CONE-CLOSED}(B, n)$, then $T_{A,B}$ has full rank.*

Proof. The proof will be by double-induction– outer induction on n and an inner induction on iteration i of the 'for' loop (Algorithm 1).

Base case: For $n = 1$, the claim is true due to Lemma 16.

Induction step $(n-1 \to n)$*:* To show $T_{A,B}$ full rank, we prove that for any vector $\mathbf{b} \in \mathbb{F}^{|B|}$: if $T_{A,B} \cdot \mathbf{b} = 0$ then $\mathbf{b} = 0$. For this we show that the following invariant holds at the end of each iteration i of the 'for' loop (Algorithm 1). Here, we assume the coordinates of $\mathbf{b}$ are indexed by the elements of B and for all $\mathbf{f} \in B$, $\mathbf{b_f}$ denotes the value of $\mathbf{b}$ at coordinate $\mathbf{f}$.

Invariant (n-variate & i-th iteration): For each $\mathbf{f} \in B$ such that the preimage size of $\pi_n(\mathbf{f})$ is at most i, the product $T_{A_i,B} \cdot \mathbf{b} = 0$ implies that $\mathbf{b_f} = 0$. Here,

At the end of iteration $i = 1$, we have the vector $T_{A_1,B} \cdot \mathbf{b}$. Recall that $A_1 = S_1 \times \{0\}$ and $F_1 = \pi_n(B)$. So $T_{A_1,B} \cdot \mathbf{b} = T_{S_1,F_1} \cdot \mathbf{c}$, where $\mathbf{c} \in \mathbb{F}^{|F_1|}$ and for $\mathbf{e} \in F_1$, $\mathbf{c_e} := \sum_{(\mathbf{e},k) \in \pi_n^{-1}(\mathbf{e})} \binom{k}{0} \mathbf{b}_{(\mathbf{e},k)}$. Thus, $T_{A_1,B} \cdot \mathbf{b} = 0$ implies $T_{S_1,F_1} \cdot \mathbf{c} = 0$. Since $S_1 = \text{FIND-CONE-CLOSED}(F_1, n-1)$, using induction hypothesis, we get that $\mathbf{c} = 0$. This means that for $\mathbf{e} \in B$ such that the preimage size of $\pi_n(\mathbf{e})$ is at most 1, we have $\mathbf{c_e} = 0$. This proves our invariant at the end of the iteration $i = 1$.

$(i-1 \to i)$: Suppose that at the end of $(i-1)$-th iteration, the invariant holds. We show that it also holds at the end of the i-th iteration. For each $j \in [i]$, let $\mathbf{v}_j$ denote the projection of $T_{A_i,B} \cdot \mathbf{b}$ on the coordinates indexed by $S_j \times \{j-1\}$. By focusing on the rows of $T_{A_j,B}$, we can see that $\mathbf{v}_j = T_{S_j,F_1} \cdot \mathbf{c}_j$ where the vector $\mathbf{c}_j \in \mathbb{F}^{|F_1|}$ is defined as, for $\mathbf{e} \in F_1$,

$$\mathbf{c}_{j_\mathbf{e}} := \sum_{(\mathbf{e},k) \in \pi_n^{-1}(\mathbf{e})} \binom{k}{j-1} \cdot \mathbf{b}_{(\mathbf{e},k)} \,. \tag{4}$$

Suppose that $T_{A_i,B} \cdot \mathbf{b} = 0$. Because of the invariant at $i-1$th round, for all $\mathbf{f} \in B$ with preimage size of $\pi_n(\mathbf{f})$ is less than i, $\mathbf{b_f} = 0$. So all we have to argue is that for every $\mathbf{f} \in B$ such that the preimage size of $\mathbf{e} := \pi_n(\mathbf{f})$ is i, the coordinate $\mathbf{b_f} = 0$.

To prove our goal, first we show that each $\mathbf{c}_j$ is a zero vector. Since $T_{A_i,B} \cdot \mathbf{b} = 0$, its projection $\mathbf{v}_j = T_{S_j,F_1} \cdot \mathbf{c}_j$ is zero too. By induction hypothesis (on $i-1$), for each $\mathbf{e} \in F_1$ with preimage size $< i$, the coordinate $\mathbf{c}_{j\mathbf{e}} = 0$. Thus, the vector $T_{S_j,F_1} \cdot \mathbf{c}_j = T_{S_j,F_j} \cdot \mathbf{c}'_j$ where the vector $\mathbf{c}'_j \in \mathbb{F}^{|F_j|}$ is defined as, for $\mathbf{e} \in F_j$, $\mathbf{c}'_{j\mathbf{e}} := \mathbf{c}_{j\mathbf{e}}$. Consequently, $T_{S_j,F_j} \cdot \mathbf{c}'_j = 0$, for $j \in [i]$. By induction hypothesis (on $n-1$), we know that T_{S_j,F_j} is full rank. So $\mathbf{c}'_j = 0$, which tells us that $\mathbf{c}_j = 0$, for $j \in [i]$.

Fix an $\mathbf{e} \in F_1$, with preimage size $= i$, and let the preimages be $\{(\mathbf{e}, k_1), \ldots, (\mathbf{e}, k_i)\}$

where k_j's are distinct nonnegative integers. From Equation 4, we can write

$$\begin{bmatrix} \mathbf{c}_{1\mathbf{e}} \\ \mathbf{c}_{2\mathbf{e}} \\ \vdots \\ \mathbf{c}_{i\mathbf{e}} \end{bmatrix} = \begin{bmatrix} \binom{k_1}{0} & \binom{k_2}{0} & \cdots & \binom{k_i}{0} \\ \binom{k_1}{1} & \binom{k_2}{1} & \cdots & \binom{k_i}{1} \\ \vdots & \vdots & \cdots & \vdots \\ \binom{k_1}{i-1} & \binom{k_2}{i-1} & \cdots & \binom{k_i}{i-1} \end{bmatrix} \cdot \begin{bmatrix} \mathbf{b}_{(\mathbf{e},k_1)} \\ \mathbf{b}_{(\mathbf{e},k_2)} \\ \vdots \\ \mathbf{b}_{(\mathbf{e},k_i)} \end{bmatrix}.$$

Since for each $j \in [i]$, $\mathbf{c}_j$ is a zero vector, from the above equation we get

$$\begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \end{bmatrix} = \begin{bmatrix} \binom{k_1}{0} & \binom{k_2}{0} & \cdots & \binom{k_i}{0} \\ \binom{k_1}{1} & \binom{k_2}{1} & \cdots & \binom{k_i}{1} \\ \vdots & \vdots & \cdots & \vdots \\ \binom{k_1}{i-1} & \binom{k_2}{i-1} & \cdots & \binom{k_i}{i-1} \end{bmatrix} \cdot \begin{bmatrix} \mathbf{b}_{(\mathbf{e},k_1)} \\ \mathbf{b}_{(\mathbf{e},k_2)} \\ \vdots \\ \mathbf{b}_{(\mathbf{e},k_i)} \end{bmatrix}.$$

Now invoking Lemma 16, we get $\mathbf{b}_{(\mathbf{e},k_j)} = 0$ for all $j \in [i]$. In other words, for any $\mathbf{f} \in B$ such that the preimage size of $\pi_n(\mathbf{f})$ is i, the coordinate $\mathbf{b}_{\mathbf{f}} = 0$.

($i = \ell$): Since $A = A_\ell$, the output of FIND-CONE-CLOSED(B, n), using our invariant at the end of ℓ-th iteration we deduce that $T_{A,B} \cdot \mathbf{b} = 0$ implies $\mathbf{b} = 0$. Thus, $T_{A,B}$ has full rank. ◀

Now we are ready to prove our main theorem using the transfer matrix equation.

Proof of Theorem 2. As we mentioned in Equation 2, the shifted polynomial $f(\mathbf{x} + t^{\mathbf{w}})$ yields a matrix equation $F' = D^{-1}TD \cdot F$. Let k' be the rank of F. We consider the following two cases.

Case 1 ($k' < k$): We reduce this case to the other one where $k' = k$. Let S be a subset of k' columns such that $F_{M,S}$ has rank k'. The matrix $F_{M,S}$ denotes the polynomial $f_S(\mathbf{x}) \in \mathbb{F}[\mathbf{x}]^{k'}$, where $f_S(\mathbf{x})$ is the projection of the 'vector' $f(\mathbf{x})$ on the coordinates indexed by S. So, any linear dependence relation among the coefficients of $f(\mathbf{x})$ is also valid for $f_S(\mathbf{x})$. So $\mathbf{w}$ is also a basis isolating weight assignment for $f_S(\mathbf{x})$. Now from our Case 2, we can claim that $f_S(\mathbf{x}+t^{\mathbf{w}})$ has a cone-closed basis A. Thus, coefficients of the monomials, corresponding to A, in $f(\mathbf{x})$ form a basis of $\mathrm{sp}(f)$. This implies that $f(\mathbf{x} + t^{\mathbf{w}})$ has a cone-closed basis A.

Case 2 ($k' = k$): Let B be the least basis of $f(\mathbf{x})$ wrt $\mathbf{w}$ and A = FIND-CONE-CLOSED(B, n). We prove that the coefficients of monomials in A form a basis of the coefficient space of $f(\mathbf{x} + t^{\mathbf{w}})$. To prove this, we show that $\det(F'_{A,[k]}) \neq 0$. Define $T' := TDF$ so that $F' = D^{-1}T'$. Using Cauchy-Binet formula [57], we get that

$$\det(F'_{A,[k]}) = \sum_{C \in \binom{M}{k}} \det(D^{-1}_{A,C}) \cdot \det(T'_{C,[k]}).$$

Since for all $C \in \binom{M}{k} \setminus \{A\}$, the matrix $D^{-1}_{A,C}$ is singular, we have $\det(F'_{A,[k]}) = \det(D^{-1}_{A,A}) \cdot \det(T'_{A,[k]})$. Again applying Cauchy-Binet formula for $\det(T'_{A,[k]})$, we get

$$\det(F'_{A,[k]}) = \det(D^{-1}_{A,A}) \cdot \sum_{C \in \binom{M}{k}} t^{\mathbf{w}(C)} \det(T_{A,C}) \cdot \det(F_{C,[k]}).$$

From Lemma 13, we have that for all basis $C \in \binom{M}{k} \setminus \{B\}$, $\mathbf{w}(C) > \mathbf{w}(B)$. The matrix $T_{A,B}$ is nonsingular by Lemma 17, and the other one $F_{B,[k]}$ is nonsingular since B is a basis. Hence, the sum is a nonzero polynomial in t. In particular, $\det(F'_{A,[k]}) \neq 0$, which ensures that the coefficients of the monomials corresponding to A form a basis of $\mathrm{sp}_{\mathbb{F}(t)}(f(\mathbf{x} + t^{\mathbf{w}}))$. Since Lemma 15 says that A is also cone-closed, we get that $f(\mathbf{x} + t^{\mathbf{w}})$ has a cone-closed basis. ◀

3.1 Models with a cone-closed basis

We give a simple proof showing that a typical diagonal depth-3 circuit is already cone-closed. Consider the polynomial $D(\mathbf{x}) = (\mathbf{1} + \mathbf{a}_1 x_1 + \ldots + \mathbf{a}_n x_n)^d$ in $\mathbb{F}^k[\mathbf{x}]$, where $\mathbb{F}^k$ is seen as an $\mathbb{F}$-algebra with coordinate-wise multiplication.

▶ **Lemma 18.** *$D(\mathbf{x})$ has a cone-closed basis.*

Proof. Consider the n-tuple $L := (\mathbf{a}_1, \ldots, \mathbf{a}_n)$. Then for every monomial $\mathbf{x}^\mathbf{e}$, the coefficient of $\mathbf{x}^\mathbf{e}$ in D is $L^\mathbf{e} := \prod_{i=1}^n \mathbf{a}_i^{e_i}$, with some nonzero scalar factor (note: here we seem to need char($\mathbb{F}$) zero or large). We ignore this constant factor, since it does not affect linear dependence relations. Consider *deg-lex* monomial ordering, i.e. first order the monomials by lower to higher total degree, then within each degree arrange them according to a lexicographic order. Now we prove that the 'least basis' of $D(\mathbf{x})$ with respect to this monomial ordering is cone-closed.

We incrementally devise a monomial set B as follows: Arrange all the monomials in ascending order. Starting from least monomial, put a monomial in B if its coefficient cannot be written as a linear combination of its previous (thus, smaller) monomials. From construction, the coefficients of monomials in B form the least basis for the coefficient space of $D(\mathbf{x})$. Now we show that B is cone-closed. We prove it by contradiction.

Let $\mathbf{x}^\mathbf{f} \in B$ and let $\mathbf{x}^\mathbf{e}$ be its submonomial that is not in B. Then we can write

$$L^\mathbf{e} = \sum_{\mathbf{x}^\mathbf{b} \prec \mathbf{x}^\mathbf{e}} c_\mathbf{b} L^\mathbf{b} \quad \text{with } c_\mathbf{b}\text{'s in } \mathbb{F}\,.$$

Multiplying by $L^{\mathbf{f}-\mathbf{e}}$ on both sides, we get

$$L^\mathbf{f} = \sum_{\mathbf{x}^\mathbf{b} \prec \mathbf{x}^\mathbf{e}} c_\mathbf{b} L^{\mathbf{b}+\mathbf{f}-\mathbf{e}} = \sum_{\mathbf{x}^{\mathbf{b}'} \prec \mathbf{x}^\mathbf{f}} c'_{\mathbf{b}'} L^{\mathbf{b}'}\,.$$

Note that $\mathbf{x}^{\mathbf{b}'} \prec \mathbf{x}^\mathbf{f}$ holds true by the way a monomial ordering is defined. This equation contradicts the fact that $\mathbf{x}^\mathbf{f} \in B$, and completes the proof. ◀

4 Conclusion

Since it is known that one could focus solely on the PIT of VP circuits that depend only on the first $o(\log s)$ variables, we initiate a study of properties that are useful in that regime. These properties are– low-cone concentration and cone-closed basis. Their usefulness is proved in our monomial counting and coefficient extraction results. Using these concepts we solve an interesting special case of diagonal depth-3 circuits.

An open question is to make our approach work for field characteristic smaller than the degree. Another interesting problem is to employ the cone-closed basis properties of the $\Sigma \wedge \Sigma^n$ model to devise a poly-time blackbox PIT for general n.

In our second result, we proved that after shifting the variables by a basis isolating weight assignment, a polynomial has a cone-closed basis. Basis isolating weight assignment is much weaker than the one induced by lexicographic monomial ordering (or the Kronecker map). An interesting open question is to *efficiently* design a weight assignment (or, in general, polynomial map) that ensures a cone closed basis. Till now, no known blackbox PIT algorithm for ROABPs gives a polynomial time blackbox PIT algorithm for log (or sub-log) variate ROABPs. So, achieving cone-closed basis or low-cone concentration property (in polynomial time) for log (or sub-log) variate ROABPs is also interesting; then, the counting & extraction techniques developed in our first result will give a polynomial time blackbox PIT. This will solve some open problems posed in [2, Sec.6].

Abstract

We propose a new distribution-free model of social networks. Our definitions are motivated by one of the most universal signatures of social networks, triadic closure – the property that pairs of vertices with common neighbors tend to be adjacent. Our most basic definition is that of a *c-closed* graph, where for every pair of vertices u, v with at least c common neighbors, u and v are adjacent. We study the classic problem of enumerating all maximal cliques, an important task in social network analysis. We prove that this problem is fixed-parameter tractable with respect to c on c-closed graphs. Our results carry over to *weakly c-closed graphs*, which only require a vertex deletion ordering that avoids pairs of non-adjacent vertices with c common neighbors. Numerical experiments show that well-studied social networks tend to be weakly c-closed for modest values of c.

1 Introduction

There has been an enormous amount of important work over the past 15 years on models for capturing the special structure of social networks. This literature is almost entirely driven by the quest for generative (i.e., probabilistic) models. Well-known examples of such models include preferential attachment [6], the copying model [38], Kronecker graphs [13, 39], and the Chung-Lu random graph model [14, 15]. There is little consensus about which generative model is the "right" one. For example, already in 2006, the survey by Chakrabarti and Faloutsos [12] compares 23 different probabilistic models of social networks, and multiple new such models are proposed every year.

Generative models articulate a hypothesis about what "real-world" social networks look like, how they are created, and how they will evolve in the future. They are directly useful for generating synthetic data and can also be used as a proxy to study the effect of random processes on a network [3, 41, 43]. However, the plethora of models presents a quandary for the design of algorithms for social networks with rigorous guarantees: which of these models should one tailor an algorithm to? One idea is to seek algorithms that are tailored to *none* of them, and to instead assume only determinstic combinatorial conditions that share the spirit of the prevailing generative models. This is the approach taken in this paper.

There is empirical evidence that many NP-hard optimization problems are often easier to solve in social networks than in worst-case graphs. For example, lightweight heuristics are unreasonably effective in practice for finding the maximum clique of a social network [52]. Similar success stories have been repeatedly reported for the problem of recovering dense subgraphs or communities in social networks [60, 54, 42, 59]. To define our notion of "social-network-like" graphs, we turn to one of the most agreed upon properties of social networks – *triadic closure*, the property that when two members of a social network have a friend in common, they are likely to be friends themselves.

1.1 Properties of social networks

There is wide consensus that social networks have relatively predictable structure and features, and accordingly are not well modeled by arbitrary graphs. From a structural viewpoint, the most well studied and empirically validated statistical properties of social networks include heavy-tailed degree distributions [6, 11, 23], a high density of triangles [64, 53, 63] and other dense subgraphs or "communities" [26, 32, 46, 47, 40], low diameter and the small world property [35, 36, 37, 45], and triadic closure [53, 63, 56].

For the problem of finding cliques in networks, it does not help to assume that the graph has small diameter (every network can be rendered small-diameter by adding one extra vertex connected to all other vertices). Similarly, merely assuming a power-law degree distribution does not seem to make the clique problem easier [24]. On the other hand, as we show, the clique problem is tractable on graphs with strong triadic closure properties.

1.2 Our model: c-closed graphs

Motivated by the empirical evidence for triadic closure in social networks, we define the class of c-closed graphs. Figure 1 shows the triadic closure of the network of email communications at Enron [1] and other social networks have been shown to behave similarly [8]. In particular, the more common neighbors two vertices have, the more likely they are to be adjacent to each other. The definition of c-closed graphs is a coarse version of this property: we assert that *every* pair of vertices with c or more common neighbors must be adjacent to each other.

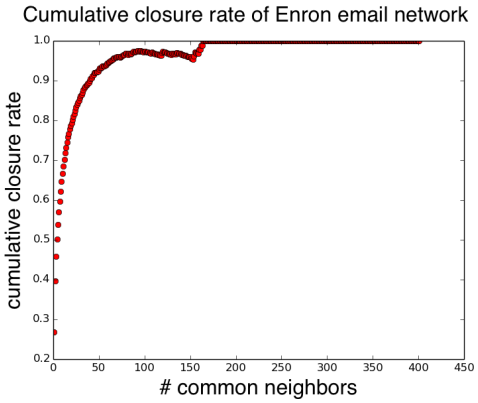

Figure 1 Triadic closure properties of the Enron email graph (36K nodes and 183K edges). Nodes of this network are Enron employees, and there is an edge connecting two employees if one sent at least one email to the other. Given an x value, the y-axis shows the cumulative closure rate: the fraction of pairs of nodes with *at least* x common neighbors that are themselves connected by an edge.

▶ **Definition 1** (c-closed graph)**.** For a positive integer c, an undirected graph $G = (V, E)$ is *c-closed* if, whenever two distinct vertices $u, v \in V$ have at least c common neighbors, (u, v) is an edge of G.

The parameter c interpolates between a disjoint unions of cliques (when $c = 1$) and all graphs (when $c = |V| - 1$). The class of 2-closed graphs is already non-trivial. These are exactly the graphs that do not contain $K_{2,2}$ or a diamond (K_4 minus an edge) as an induced subgraph. For example, graphs with girth at least 5, e.g. constant-degree expanders, are 2-closed. For every c, membership in the class of c-closed graphs can be checked by squaring the adjacency matrix in $O(n^\omega)$ time, where $\omega < 2.373$ is the matrix multiplication exponent.

While the definition of c-closed captures important aspects of triadic closure, it is fragile in the sense that a single pair of non-adjacent vertices with many common neighbors prevents the graph from being c-closed for a low value of c. To address this, we define the more robust notion of *weakly c-closed* graphs and show that our results carry over to these graphs. Well-studied social networks with thousands of vertices are typically weakly c-closed for modest values of c (see the full version [29] for experimental results).

▶ **Definition 2.** Given a graph and a value of c, a *bad pair* is a non-adjacent pair of vertices with at least c common neighbors.

▶ **Definition 3** (Weakly c-closed graph)**.** A graph is *weakly c-closed* if there exists an ordering of the vertices $\{v_1, v_2, \ldots, v_n\}$ such that for all i, v_i is in no bad pairs in the graph induced by $\{v_i, v_{i+1}, \ldots, v_n\}$.

A graph can be c-closed only for large c but weakly c-closed for much smaller c. Consider the graph G that is a clique of size k with one edge (u, v) missing. G is not c-closed for any $c < k - 2$. The only bad pair in G is (u, v). The vertex ordering that places u and v at the end demonstrates that G is weakly 1-closed. Also, the properties of being c-closed and weakly c-closed are hereditary, meaning that they are closed under taking induced subgraphs. We will use this basic fact often.

1.3 Our contributions

One can study a number of computational problems on c-closed (and weakly c-closed) graphs. We focus on the problem of enumerating all maximal cliques, an important problem in social network analysis [16, 58, 18, 21, 57]. We study *fixed-parameter tractability*[4] with respect to c. There is a rich literature on fixed-parameter tractability for other graph parameters including treewidth, arboricity, and the size of the output [17].

In a graph G, a *clique* is a subgraph of G in which there is an edge between every pair of vertices. A *maximal* clique in G is a clique that cannot be made any larger by the addition of some other vertex in G. In any graph, all maximal cliques can be listed in $O(mn)$ time per maximal clique [61]. We focus on the following two problems:

1. determining the maximum possible number of maximal cliques in a c-closed graph on n vertices.
2. finding algorithms to enumerate all maximal cliques in c-closed graphs (that run faster than $O(mn)$ time per maximal clique).

Our main result is that for constant c the number of maximal cliques in a c-closed graph on n vertices is $O(n^{2-2^{1-c}})$. More specifically, we prove the following bound.

▶ **Theorem 4.** *Any c-closed graph on n vertices has at most* $\min\{3^{(c-1)/3}n^2, 4^{(c+4)(c-1)/2}n^{2-2^{1-c}}\}$ *maximal cliques.*

For example, 3-closed, 4-closed, and 5-closed graphs have $O(n^{3/2})$, $O(n^{7/4})$, and $O(n^{15/8})$ maximal cliques respectively.

The proof of the first bound listed in Theorem 4 extends to weakly c-closed graphs, giving the following result.

▶ **Theorem 5.** *Any weakly c-closed graph on n vertices has at most $3^{(c-1)/3}n^2$ maximal cliques.*

See the full version [29] for experimental results showing that well-studied social networks are weakly c-closed for modest values of c. Note that Theorem 5 is exponential in the even smaller value of $(c-1)/3$.

Since in any graph all maximal cliques can be listed in $O(mn)$ time per maximal clique, Theorem 4 proves that listing all maximal cliques in a c-closed graph is fixed-parameter tractable (i.e. has running time $f(c)n^\alpha$ for constant α). We give an algorithm for listing all maximal cliques in a c-closed graph that runs faster than applying the $O(mn)$-per-clique algorithm as a black box. Our algorithm follows naturally from the proof of Theorem 4 and gives the following theorem, where $p(n, c)$ denotes the time to list all wedges (induced 2-paths) in a c-closed graph on n vertices. A result of Gąsieniec, Kowaluk, and Lingas [31] implies that $p(n, c) = O(n^{2+o(1)}c + c^{(3-\omega-\alpha)/(1-\alpha)}n^\omega + n^\omega \log n)$ where ω is the matrix multiplication exponent and $\alpha > 0.29$.

▶ **Theorem 6.** *In any c-closed graph, a set of cliques containing all maximal cliques can be generated in time $O(p(n, c) + 3^{c/3}n^2)$. The exact set of all maximal cliques in any c-closed graph can be generated in time $O(p(n, c) + 3^{c/3}2^c cn^2)$.*

Non-trivial lower bounds for the number of maximal cliques in a c-closed graph were previously known only for extreme values of c. A 2-closed graph can have $n^{3/2}$ maximal

[4] A problem is said to be fixed-parameter tractable with respect to a parameter k if there is an algorithm that solves it in time at most $f(k)n^\alpha$ where f can be an arbitrary function but α is a constant.

cliques [22]. The classic Moon-Moser graph (with additional isolated vertices) is $(n-2)$-closed and has $3^{\lfloor n/3 \rfloor}$ maximal cliques [44]. This graph consists of the complete multipartite graph with $\lfloor n/3 \rfloor$ parts of size 3, and possibly additional isolated vertices. By taking a disjoint union of $n/(c+2)$ Moon-Moser graphs on $(c+2)$ vertices, we can construct a c-closed graph on n vertices with $\Omega(c^{-1}3^{c/3}n)$ maximal cliques for all $n \geq c$. We give improved lower bounds for intermediate values of c.

▶ **Theorem 7.** *For any positive integer c, there are c-closed graphs with n vertices and $\Omega(c^{-3/2}2^{c/2}n^{3/2})$ maximal cliques.*

It is an open problem to determine the exact exponent of n (between $3/2$ and $2 - 2^{1-c}$) in the expression for the maximum number of maximal cliques in a c-closed graph.

1.4 Related work

There are only a few algorithmic results for graph classes motivated by social networks. Although a number of NP-hard problems remain NP-hard on graphs with a power-law degree distribution [25], several problems in P have been shown to be easier on such graphs. Brach, Cygan, Lacki, and Sankowski [10] give faster algorithms for transitive closure, maximum matching, determinant, PageRank and matrix inverse. Borassi, Crescenzi, and Trevisan [9] assume several axioms satisfied by real-world graphs, one being a power-law degree distribution, and give faster algorithms for diameter, radius, distance oracles, and computing the most "central" vertices. Motivated by triadic closure, Gupta, Roughgarden, and Seshadhri [33] define *triangle-dense* graphs and prove relevant structural results. Intuitively, they prove that if a constant fraction of two-hop paths are closed into triangles, then the graph must contain many dense clusters.

For general graphs, Moon and Moser prove that the maximum possible number of maximal cliques in a graph on n vertices is $3^{n/3}$ (realized by a complete $n/3$-partite graph) [44]. Tomita, Tanaka, and Takahashi prove that the time to generate all maximal cliques in any n-vertex graph is also $O(3^{n/3})$ [58].

The clique problem has been studied on 2-closed graphs (under a different name). Eschen, Hoang, Spinrad, and Sritharan [22] show that the maximum number of maximal cliques in a 2-closed graph is $O(n^{3/2})$. They also show a matching lower bound via a projective planes construction. Suppose $n = p^2 + p + 1$ for a positive integer p and consider a finite projective plane on n points (and hence with n lines, see e.g. [2]). Let G denote the bipartite graph representing the point-line incidence matrix. The defining properties of finite projective planes imply that no two vertices have two common neighbors, so the 2-closed condition is vacuously satisfied. Every vertex of G has degree $p+1$, so the graph has $\Theta(n^{3/2})$ edges, each a maximal clique.

The clique problem has also been studied on other special classes of graphs such as graphs embeddable on a surface [19] and graphs of bounded degeneracy [20]. Degeneracy is a measure of everywhere sparsity. More formally, the degeneracy of a graph G is the smallest value d such that every nonempty subgraph of G contains a vertex of degree at most d. Eppstein et al. show that the maximum number of maximal cliques in a graph of degeneracy d is $O(n3^{d/3})$. The degeneracy of a graph, however, can be much larger than its c-closure. For example, the degeneracy of a graph is at least the size of a maximum clique, while even in 1-closed graphs, the size of the maximum clique can be arbitrarily large.

Clique counting is a classical problem in extremal combinatorics. One fundamental question is to count the *minimum* number of cliques in graphs with fixed number of edges i.e. to show that graphs with few cliques must have few edges. This simple question turns

out to be a complex problem, and is settled for K_3 by Razborov [50] by flag algebra, K_4 by Nikiforov [48] by a combination of combinatorics and analytical arguments, and all K_t by Reiher [51] by generalizing the argument of flag algebra to all sizes of cliques.

There has also been a long line of work in combinatorics on counting (not necessarily maximal) cliques in graphs with certain excluded subgraphs, subdivisions, or minors. Most recently, Fox and Wei give an asymptotically tight bound on the maximum number of cliques in graphs with forbidden minors [28], and an upper bound on the maximum number of cliques in graphs with forbidden subdivisions or immersions [27].

Many problems in combinatorics can be phrased as counting the number of cliques or independent sets in a (hyper)graph. For example, the problems of finding the volume of the metric polytope and counting the number of n-vertex H-free graphs (for any fixed subgraph H) can be translated into clique counting problems. The recently developed "container method" [5, 55] is a powerful tool to bound the number of cliques in (hyper)graphs and can be used to tackle a great range of problems.

1.5 Organization

In Section 2 we prove the first bound listed in Theorem 4, state Theorem 5, and introduce the proof of Theorem 6. In Section 3 we prove the second bound listed in Theorem 4 (which has improved dependence on n). In Section 4 we prove Theorem 7.

See the full version [29] for the proof of Theorem 6.

1.6 Notation

All graphs $G(V, E)$ are simple, undirected and unweighted. For any $v \in V$, let $N(v)$ denote the neighborhood of v. When the current graph is ambiguous, $N_G(v)$ will denote the neighborhood of v in G. For any $S \subseteq V$, let $G[S]$ denote the subgraph of G induced by S.

2 Initial Bound and Algorithm

2.1 Bound on number of maximal cliques

In this section, we prove the following bound on the number of maximal cliques in a c-closed graph and show that this bound carries over to weakly c-closed graphs. Let $F(n, c)$ denote the maximum possible number of maximal cliques in a c-closed graph on n vertices. The following theorem uses a natural peeling process and obtain an initial upper bound on the number of maximal cliques. A more involved analysis, Theorem 11 which gives a tighter upper bound, is delayed to later.

▶ **Theorem 8** (restatement of part of Theorem 4). *For all positive integers c, n, we have $F(n, c) \leq 3^{(c-1)/3} n^2$.*

Proof. Let G be a c-closed graph on n vertices and let $v \in V(G)$ be an arbitrary vertex. Every maximal clique $K \subseteq G$ is of one of the following types:

1. The clique K does not contain vertex v; and K is maximal in $G \setminus \{v\}$.
2. The clique K contains vertex v; and $K \setminus \{v\}$ is maximal in $G \setminus \{v\}$.
3. The clique K contains vertex v; and $K \setminus \{v\}$ is not maximal in $G \setminus \{v\}$.

Bounding the number of maximal cliques of type 1 and 2 is straightforward because every such clique can be obtained by starting with a clique maximal in $G \setminus \{v\}$ and extending it to include vertex v if possible. Therefore, the number of maximal cliques of types 1 and 2 combined is at most $F(n-1, c)$.

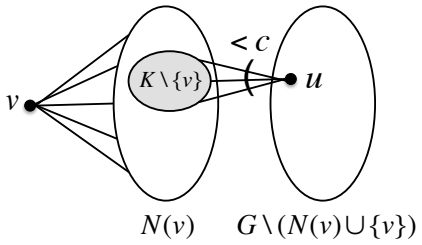

Figure 2 A maximal clique K of type 3: K contains vertex v and $K \setminus \{v\}$ is not maximal in $G \setminus \{v\}$. Property C asserts that there exists a vertex $u \notin N(v)$ whose neighborhood contains $K \setminus \{v\}$. Since G is c-closed, $|N(u) \cap N(v)| < c$.

Type 3 cliques are maximal in $N(v)$, but not in $G \setminus \{v\}$. We will prove that the number of maximal cliques of type 3 is at most $3^{(c-1)/3}n$, crucially using the c-closed property. Figure 2 shows a maximal clique K of type 3.

We claim that each type 3 maximal clique K satisfies the following three properties.

A) $K \setminus \{v\}$ is a clique in the neighborhood of v, and
B) $K \setminus \{v\}$ is not in the neighborhood of any other vertex in $N(v)$.
C) There exists a vertex $u \notin N(v)$ whose neighborhood contains $K \setminus \{v\}$.

Property A is clear since K is a clique containing v. Property B is true because if we can extend $K \setminus \{v\}$ to include some vertex $w \in N(v)$, then K can also be extended to include w which contradicts the fact that K is maximal. To see property C, note that since $K \setminus \{v\}$ is not a maximal clique in $G \setminus \{v\}$ we can extend the clique $K \setminus \{v\}$ to include some vertex in $G \setminus \{v\}$. By property B, we can extend $K \setminus \{v\}$ to include some vertex u not in $N(v)$.

Let u be as in property C. Then $K \setminus \{v\}$ must be a maximal clique in $G[N(v) \cap N(u)]$ because otherwise we could extend $K \setminus \{v\}$ to some other vertex in $N(v) \cap N(u)$, which contradicts property B.

Thus, the number of type 3 maximal cliques is at most

$$\sum_{u \in G \setminus (N(v) \cup \{v\})} F(|N(u) \cap N(v)|, c). \tag{1}$$

Since G is c-closed, $|N(u) \cap N(v)| < c$ for all vertices $u \notin N(v)$. Then since any k-vertex graph has at most $3^{k/3}$ maximal cliques [44],

$$F(|N(u) \cap N(v)|, c) \leq 3^{(c-1)/3}.$$

Thus, the number of type 3 maximal cliques in G is at most $3^{(c-1)/3}n$.

Counting all three types of maximal cliques, we have the following recursive inequality:

$$F(n, c) \leq F(n-1, c) + 3^{(c-1)/3}n.$$

By induction on n with the base case $F(1, c) = 1$, this gives

$$F(n, c) \leq 3^{(c-1)/3}\binom{n+1}{2} \leq 3^{(c-1)/3}n^2. \quad \blacktriangleleft$$

Note that v was chosen arbitrarily and the proof is valid as long as "$|N(u) \cap N(v)| < c$ for all vertices $u \notin N(v)$". Thus, in each recursive level, we only require the existence of a vertex v in no bad pairs. Equivalently, it suffices to have an ordering of the vertices $\{v_1, v_2, \ldots, v_n\}$ such that for all i, v_i is in no bad pairs in the graph induced by $\{v_i, v_{i+1}, \ldots, v_n\}$. This is exactly the definition of a weakly c-closed graph. Thus, we get the following theorem.

▶ **Theorem 9** (Restatement of Theorem 5). *For any positive integers c, n, there are at most $3^{(c-1)/3}n^2$ maximal cliques in an n-vertex weakly c-closed graph.*

2.2 Algorithm to generate all maximal cliques

Recall that $p(n, c)$ denotes the time to list all wedges (induced 2-paths) in a c-closed graph on n vertices. A result of Gąsieniec, Kowaluk, and Lingas [31] implies that $p(n, c) = O(n^{2+o(1)}c + c^{(3-\omega-\alpha)/(1-\alpha)}n^\omega + n^\omega \log n)$ where ω is the matrix multiplication exponent and $\alpha > 0.29$.

▶ **Theorem 10** (restatement of Theorem 6). *A superset of the maximal cliques in any c-closed graph can be generated in time $O(p(n, c) + 3^{c/3}n^2)$. The exact set of all maximal cliques in any c-closed graph can be generated in time $O(p(n, c) + 3^{c/3}2^c cn^2)$.*

The algorithm follows naturally from the proof of Theorem 8 with two additional ingredients:

- A preprocessing step to enumerate all wedges in the graph speeds up the later process of finding the intersection of the neighborhoods of two vertices (i.e. $N(u) \cap N(v)$ from the proof of Theorem 8).
- An algorithm of Tomita, Tanaka, and Takahashi [58] generates all maximal cliques in any n-vertex graph in time $O(3^{n/3})$. We apply this to the recursive calls on the small induced subgraphs $G[N(u) \cap N(v)]$, which have less than c vertices, that arise in handling the type 3 cliques in the proof of Theorem 8.

We defer the full algorithm description and runtime analysis to the full version [29].

3 Improved Bound

Recall that $F(n, c)$ is the maximum number of maximal cliques in a c-closed graph on n vertices.

▶ **Theorem 11** (restatement of part of Theorem 4). *For all positive integers c, n, we have $F(n, c) \leq 4^{(c+4)(c-1)/2}n^{2-2^{1-c}}$.*

The structure of the proof is similar to that of Theorem 8. We get an improved bound by a separate analysis depending on whether G has a vertex of "high" degree. This idea appears in the result of Eschen et al. [22], who prove the result for the $c = 2$ case.

We will require the following simple lemma.

▶ **Lemma 12.** *For any v, $G[N(v)]$ is a $(c-1)$-closed graph.*

Proof. Consider pair $x, y \in N(v)$ with $c-1$ common neighbors in $G[N(v)]$. Since vertex $v \notin N(v)$ is also a common neighbor of x and y, x and y have c common neighbors in G. Thus, (x, y) is an edge. ◀

Proof of Theorem 11. Let $G = (V, E)$ be a c-closed graph on n vertices with $F(n, c)$ maximal cliques. Let $\Delta(G)$ be the maximum degree of G.

Case 1: $\Delta(G) \leq n^{1/2}$.

By Lemma 12 for all $v \in V(G)$, $G[N(v)]$ is $(c-1)$-closed. Then, since the number of maximal cliques containing v is exactly the number of maximal cliques in $G[N(v)]$, we have

$$F(n, c) \leq nF(\Delta(G), c-1).$$

Case 2: $\Delta(G) > n^{1/2}$.

Let $v \in V$ be a vertex of degree $\Delta(G)$. We will count the maximal cliques containing at least one vertex in $N(v) \cup \{v\}$, delete $N(v) \cup \{v\}$, and recurse.

Since the number of maximal cliques containing v is exactly the number of maximal cliques in $G[N(v)]$, v is in at most $F(\Delta(G), c-1)$ maximal cliques. It remains to bound the number the maximal cliques that contain some vertex in $N(v)$ but not v itself. Such a clique must contain some vertex in $u \in V \setminus (N(v) \cup \{v\})$ (otherwise, it would not be maximal). Let $\mathcal{K}$ be the set of such cliques. We will bound $|\mathcal{K}|$ by grouping the maximal cliques K in $\mathcal{K}$ based on which vertices of $N(v)$ are in K. For nonempty $S \subseteq N(v)$, let $N(S)$ denote $\bigcap_{u \in S} N(u)$. Also, let $N_2(v)$ denote the set of vertices of distance *exactly* 2 from v. Let us bound the number of cliques $K \in \mathcal{K}$ such that $K \cap N(v) = S$. The other vertices in K must be in $N(S) \cap N_2(v)$. By Lemma 12, $G[N(S) \cap N_2(v)]$ is a $(c-1)$-closed graph. The number of cliques $K \in \mathcal{K}$ such that $K \cap N(v) = S$ is at most $F(|N(S) \cap N_2(v)|, c-1)$. Summing over all subsets $S \subseteq N(v)$, we have

$$|\mathcal{K}| \leq \sum_{S \subseteq N(v)} F(|N(S) \cap N_2(v)|, c-1). \tag{2}$$

For all $u \in N_2(v)$, since u and v are not adjacent, $|N(u) \cap N(v)| < c$ (because G is c-closed). Each vertex in $N_2(v)$ can be in $N(S)$ for only 2^{c-1} sets $S \subseteq N(v)$, implying

$$\sum_{S \subseteq N(v)} |N(S) \cap N_2(v)| \leq |N_2(v)| 2^{c-1} \leq \min\{(\Delta(G))^2, n\} 2^{c-1}. \tag{3}$$

We want to determine for all S the value of $|N(S) \cap N_2(v)|$ that maximizes the upper bound for $|\mathcal{K}|$ in Inequality (2) subject to the constraint in Inequality (3). Later, we prove our bound on F (from the theorem statement) by induction on n and c. In fact, we show that $F(n, c)$ is bounded by

$$F_0(n, c) = 4^{(c+4)(c-1)/2} n^{2-2^{1-c}},$$

the desired upper bound for $F(n, c)$ that we are trying to prove by induction. Since $F_0(n, c)$ is convex in n, by the inductive hypothesis we can apply Jenson's inequality on Inequality (2). Jenson's inequality implies that the upper bound on $|\mathcal{K}|$ is maximized by setting $|N(S) \cap N_2(v)|$ to be as large as possible (note that it cannot exceed $\Delta(G)$) for as many S as possible until the bound in Inequality (3) is met and setting the rest to be 0. By Inequality (3), the number of non-zero terms $|N(S) \cap N_2(v)|$ we sum over is at most $\Delta(G)^{-1} \min\{(\Delta(G))^2, n\} 2^{c-1} \leq \min\{\Delta(G), \frac{n}{\Delta(G)}\} 2^{c-1}$. Thus, we have the following continuation of Inequality (2).

$$|\mathcal{K}| \leq \sum_{S \subseteq N(v)} F(|N(S) \cap N_2(v)|, c-1) \leq \min\{\Delta(G), \frac{n}{\Delta(G)}\} 2^{c-1} F_0(\Delta(G), c-1). \tag{4}$$

Recall $|\mathcal{K}|$ is the number of maximal cliques that contain some vertex in $N(v)$ but not v itself, so we combine Inequality (4) with the observation (from the beginning of case 2) that v is in at most $F(\Delta(G), c-1)$ maximal cliques to conclude that the number of maximal cliques containing at least one vertex in $N(v) \cup \{v\}$ is at most

$$F_0(\Delta(G), c-1)(1 + \min\{\Delta(G), \frac{n}{\Delta(G)}\} 2^{c-1}) \leq F_0(\Delta(G), c-1) \min\{\Delta(G), \frac{n}{\Delta(G)}\} 2^c.$$

Then, recursing on $G \setminus (N(v) \cup \{v\})$, we have:

$$F(n, c) < F_0(\Delta(G), c-1) \min\{\Delta(G), \frac{n}{\Delta(G)}\} 2^c + F(n - \Delta(G), c).$$

Combining the low and high degree bounds on $F(n,c)$, we get the following recurrence.

$$F(n,1) = n, \quad F(1,c) = 1$$
$$F(n,c) \leq \begin{cases} nF(\Delta(G), c-1) & \Delta(G) \leq n^{1/2} \\ F_0(\Delta(G), c-1)\frac{n}{\Delta(G)}2^c + F(n-\Delta(G), c) & \Delta(G) > n^{1/2} \end{cases}$$

The remainder of the proof shows inductively that the recurrence implies the desired bound $F(n,c) \leq F_0(n,c) \leq n^{2-2^{1-c}}2^{(c+4)(c-1)/2}$. The desired bound holds in the two base cases. For the inductive case, we need to show that

$$n^{2-2^{1-c}}2^{(c+4)(c-1)/2} \geq \begin{cases} n\Delta(G)^{2-2^{2-c}}2^{(c+3)(c-2)/2} & \Delta(G) \leq n^{1/2} \\ \Delta(G)^{2-2^{2-c}}2^{(c+3)(c-2)/2}\frac{n}{\Delta(G)}2^c & \\ \quad +(n-\Delta(G))^{2-2^{1-c}}2^{(c+4)(c-1)/2} & \Delta(G) > n^{1/2}. \end{cases}$$

In the $\Delta(G) \leq n^{1/2}$ case, the expression is maximized when $\Delta(G) = n^{1/2}$. Thus,

$$n\Delta(G)^{2-2^{2-c}}2^{(c+3)(c-3)/2} \leq n^{1+\frac{1}{2}(2-2^{2-c})}2^{(c+3)(c-2)/2} < n^{2-2^{1-c}}2^{(c+4)(c-1)/2},$$

as desired.

For the $\Delta(G) > n^{1/2}$ case, the second term of the expression can be written as $(n(1-\frac{\Delta(G)}{n}))^{2-2^{1-c}}2^{(c+4)(c-1)/2}$. We use the following claim.

▶ **Claim 13.** *$(1-x)^k \leq 1 - \frac{xk}{2}$ for any $0 < x \leq 1/2$ and $1 \leq k \leq 2$*

Proof. For any $y \in (0,1)$, $(1-y) \leq e^{-y}$ and $e^{-y} \leq 1-y/2$. Thus, $(1-x)^k \leq e^{-xk} \leq 1-xk/2$. ◀

Applying the claim with $x = \frac{\Delta(G)}{n}$ and $k = 2-2^{1-c}$, it suffices to show that

$$n^{2-2^{1-c}}2^{(c+4)(c-1)/2} \geq \Delta(G)^{2-2^{2-c}}2^{(c+3)(c-2)/2}\frac{n}{\Delta(G)}2^c + n^{2-2^{1-c}}\left(1 - \frac{\Delta(G)(2-2^{1-c})}{2n}\right)2^{(c+4)(c-1)/2}.$$

or equivalently that

$$\Delta(G)^{2-2^{2-c}}2^{(c+3)(c-2)/2}\frac{n}{\Delta(G)}2^c - n^{2-2^{1-c}}\frac{\Delta(G)(2-2^{1-c})}{2n}2^{(c+4)(c-1)/2} \leq 0.$$

Simplifying the left-hand side of the above inequality and using the fact that $c \geq 1$:

$$\begin{aligned} &\Delta(G)^{2-2^{2-c}}2^{(c+3)(c-2)/2}\frac{n}{\Delta(G)}2^c - n^{2-2^{1-c}}\frac{\Delta(G)(2-2^{1-c})}{2n})2^{(c+4)(c-1)/2} \\ &= n\Delta(G)^{1-2^{2-c}}2^{(c^2+c-6)/2} - n^{1-2^{1-c}}\Delta(G)(1-2^{-c})2^{(c^2+3c-4)/2} \\ &\leq 2^{(c^2+c-6)/2}(n\Delta(G)^{1-2^{2-c}} - n^{1-2^{1-c}}\Delta(G)(1-2^{-c})2^{c+1}) \\ &= 2^{(c^2+c-6)/2}(n\Delta(G)^{1-2^{2-c}} - n^{1-2^{1-c}}\Delta(G)(2^{c+1}-2)) \\ &\leq 2^{(c^2+c-6)/2}(n\Delta(G)^{1-2^{2-c}} - n^{1-2^{1-c}}\Delta(G)) \\ &= 2^{(c^2+c-6)/2}n^{1-2^{1-c}}\Delta(G)^{1-2^{2-c}}(n^{2^{1-c}} - \Delta(G)^{2^{2-c}}) \leq 0. \end{aligned}$$

The last inequality holds because $\Delta \geq n^{1/2}$. ◀

Like the proof of the initial bound (Theorem 8), the proof of the improved bound (Theorem 11) also suggests an algorithm for generating the set of maximal cliques involving the preprocessing step of listing the set of all wedges in the graph. However, this algorithm is not asymptotically faster than the algorithm from Theorem 10 since its dependence on n still includes $p(n,c)$ and we omit it.

4 Lower bound

▶ **Theorem 14** (restatement of Theorem 7). *For any positive integer c, we can construct graphs which are c-closed and with $\Omega(c^{-3/2}2^{c/2}n^{3/2})$ maximal cliques.*

Construction

We suppose that c is even and n is a multiple of c. We can do this with only an absolute constant factor loss in the bound, which is allowable. We start with a graph H on $v = 2n/c$ vertices with girth 5 and the maximum possible number of edges, which is $\Omega(v^{3/2})$ [30].

We construct our c-closed graph G on n vertices from H in the following way. For each vertex $x \in V(H)$, we replace it with a vertex set U_x with $c/2$ vertices. Therefore, there are $|V(H)| \cdot c/2 = n$ vertices in G. The adjacency relation of G is as follows.

- Add all edges within each U_x so that U_x is a clique for all $x \in V(H)$.
- For any edge (x, y) of H, we place edges between the vertex sets U_x and U_y such that the bipartite graph between U_x and U_y consists of a complete bipartite graph minus a perfect matching.
- For any distinct and nonadjacent $x, y \in V(H)$, there are no edges between U_x and U_y.

Theorem 14 follows from the next two claims.

▶ **Claim 15.** *The graph G constructed is c-closed.*

Proof. It suffices to check that for any two non-adjacent vertices in G, they have at most $c - 1$ common neighbors. By the construction, there are only two types of non-adjacent vertices:

Case 1: The non-adjacent pair $u, v \in V(G)$ are such that $u \in U_x, v \in U_y$ and $x, y \in V(H)$ are disitinct and non-adjacent in H.

In this case, there are no edges between U_x, U_y, and the common neighbors of u, v are such that there is a vertex $z \in V(H)$ such that $(x, z), (y, z)$ are both edges in H. Since H has girth 5, there is at most one such $z \in H$ given x, y, as otherwise H would contain a C_4. Vertex $u \in V(G)$ is adjacent to exactly $|U_z| - 1 = (c/2) - 1$ vertices in U_z, so u, v can have at most $(c/2) - 1$ common neighbors.

Case 2: The non-adjacent pair $u, v \in V(G)$ is such that $u \in U_x, v \in U_y$ and $x, y \in V(H)$ are adjacent in H.

In this case, u and v are adjacent to all other vertices in $U_x \cup U_y$, so they have $c - 2$ common neighbors in $U_x \cup U_y$. Suppose for contradiction that u, v have some other common neighbor w and $w \in U_z$ for some $z \neq x, y$. This implies that $(w, x), (w, y)$ are both edges in H. However, (x, y) is already an edge in H by the assumption of this case. This implies that H contains a triangle, which contradicts the fact that H has girth 5.

Combining both cases, we know that G is c-closed. ◀

▶ **Claim 16.** *There are $\Omega(c^{-3/2}2^{c/2}n^{3/2})$ maximal cliques in G.*

Proof. For any edge (x, y) of H, picking one endpoint of each non-edge in $U_x \cup U_y$ gives a maximal clique. Thus for each edge (x, y) of H, there are exactly $2^{|U_x|} = 2^{c/2}$ maximal cliques.

There are $\Omega(|V(H)|^{3/2}) = \Omega((2n/c)^{3/2})$ edges in H. As each of the maximal cliques obtained are distinct, we obtain $\Omega(2^{c/2} \cdot (2n/c)^{3/2}) = \Omega(c^{-3/2}2^{c/2}n^{3/2})$ maximal cliques. ◀

5 Open problems and future directions

Direct improvement of our results

- Determine the exact dependence on n for the maximum possible number of of maximal cliques in a c-closed graph. We have proven (up to constant dependence on c) that this number is between $n^{3/2}$ and $n^{2-2^{1-c}}$.
- Find a faster algorithm for listing the set of all wedges (induced 2-paths) in a c-closed graph (this would improve the runtime of Algorithm from Theorem 10).

Further exploration of c-closed graphs

- Study the densest k-subgraph problem, a generalization of the clique problem, on c-closed graphs. The input to the problem is a graph G and a parameter k, and the goal is to to find the subgraph of G on k vertices with the most edges. Unlike the clique problem, densest k-subgraph is NP-hard even for 2-closed graphs (more specifically, for graphs of girth 6) [49]. For general graphs, the best-known approximation algorithm has approximation ratio roughly $O(n^{1/4})$ [7] and under certain average-case hardness assumptions (concerning the planted clique problem), constant-factor approximation algorithms do not exist [4].
- Determine which other NP-hard problems are fixed-parameter tractable with respect to c.
- Determine which problems in P have faster algorithms on c-closed graphs.

Other model-free definitions of social networks

- Explore other graph classes motivated by the well-established signatures of social networks (described in the introduction): heavy-tailed degree distributions, high triangle density, dense "communities", low diameter and the small world property, and triadic closure.
- Determine other model-free definitions of social networks, for example, those motivated by 4-vertex subgraph frequencies. Ugander et al. [62] and subsequently Seshadhri [34] computed 4-vertex subgraph counts in a variety of social networks and the frequencies observed are far different than what one would expect from a random graph. In particular, social networks tend to have far fewer induced 4-cycles than random graphs.

Abstract

We develop a framework for obtaining polynomial time approximation schemes (PTAS) for a class of stochastic dynamic programs. Using our framework, we obtain the first PTAS for the following stochastic combinatorial optimization problems:

1. *Probemax* [19]: We are given a set of n items, each item $i \in [n]$ has a value X_i which is an independent random variable with a known (discrete) distribution π_i. We can *probe* a subset $P \subseteq [n]$ of items sequentially. Each time after probing an item i, we observe its value realization, which follows the distribution π_i. We can *adaptively* probe at most m items and each item can be probed at most once. The reward is the maximum among the m realized values. Our goal is to design an adaptive probing policy such that the expected value of the reward is maximized. To the best of our knowledge, the best known approximation ratio is $1 - 1/e$, due to Asadpour *et al.* [2]. We also obtain PTAS for some generalizations and variants of the problem.
2. *Committed Pandora's Box* [24, 22]: We are given a set of n boxes. For each box $i \in [n]$, the cost c_i is deterministic and the value X_i is an independent random variable with a known (discrete) distribution π_i. Opening a box i incurs a cost of c_i. We can adaptively choose to open the boxes (and observe their values) or stop. We want to maximize the expectation of the realized value of the last opened box minus the total opening cost.
3. *Stochastic Target* [15]: Given a predetermined target $\mathbb{T}$ and n items, we can adaptively insert the items into a knapsack and insert at most m items. Each item i has a value X_i which is an independent random variable with a known (discrete) distribution. Our goal is to design an adaptive policy such that the probability of the total values of all items inserted being larger than or equal to $\mathbb{T}$ is maximized. We provide the first bi-criteria PTAS for the problem.
4. *Stochastic Blackjack Knapsack* [16]: We are given a knapsack of capacity $\mathbb{C}$ and probability distributions of n independent random variables X_i. Each item $i \in [n]$ has a size X_i and a profit p_i. We can adaptively insert the items into a knapsack, as long as the capacity constraint is not violated. We want to maximize the expected total profit of all inserted items. If the capacity constraint is violated, we lose all the profit. We provide the first bi-criteria PTAS for the problem.

1 Introduction

Consider an online stochastic optimization problem with a finite number of rounds. There are a set of tasks (or items, boxes, jobs or actions). In each round, we can choose a task and each task can be chosen at most once. We have an initial "state" of the system (called the value of the system). At each time period, we can select a task. Finishing the task generates some (possibly stochastic) feedback, including changing the value of the system and providing some profit for the round. Our goal is to design a strategy to maximize our total (expected) profit.

The above problem can be modeled as a class of stochastic dynamic programs which was introduced by Bellman [3]. There are many problems in stochastic combinatorial optimization which fit in this model, *e.g.,* the stochastic knapsack problem [9], the Probemax problem [19]. Formally, the problem is specified by a 5-tuple $(\mathcal{V}, \mathcal{A}, f, g, h, T)$. Here, $\mathcal{V}$ is the set of all possible values of the system. $\mathcal{A}$ is a finite set of items or tasks which can be selected and each item can be chosen at most once. This model proceeds for at most T rounds. At each round $t \in [T]$, we use $I_t \in \mathcal{V}$ to denote the current value of the system and $\mathcal{A}_t \subseteq \mathcal{A}$ the set of remaining available items. If we select an item $a_t \in \mathcal{A}_t$, the value of the system changes to $f(I_t, a_t)$. Here f may be stochastic and is assumed to be independent for each item $a_t \in \mathcal{A}$. Using the terminology from Markov decision processes, the state at time t is $s_t = (I_t, \mathcal{A}_t) \in \mathcal{V} \times 2^{\mathcal{A}}$. [1] Hence, if we select an item $a_t \in \mathcal{A}_t$, the evolution of the state is determined by the state transition function f:

$$s_{t+1} = (I_{t+1}, \mathcal{A}_{t+1}) = (f(I_t, a_t), \mathcal{A}_t \setminus a_t) \quad t = 1, \ldots, T. \tag{1}$$

Meanwhile the system yields a random profit $g(I_t, a_t)$. The function $h(I_{T+1})$ is the terminal profit function at the end of the process.

We begin with the initial state $s_1 = (I_1, \mathcal{A})$. We choose an item $a_1 \in \mathcal{A}$. Then the system yields a profit $g(I_1, a_1)$, and moves to the next state $s_2 = (I_2, \mathcal{A}_2)$ where I_2 follows the distribution $f(I_1, a_1)$ and $\mathcal{A}_2 = \mathcal{A} \setminus a_1$. This process is iterated yielding a random sequence

$$s_1, a_1, s_2, a_2, s_3, \ldots, a_T, s_{T+1}.$$

The profits are accumulated over T steps. [2] The goal is to find a policy that maximizes the

[1] This is why we do not call I_t the state of the system.

[2] If less than T steps, we can use some special items to fill which satisfy that $f(I, a) = I$ and $g(I, a) = 0$ for any value $I \in \mathcal{V}$.

expectation of the total profits $\mathbb{E}\Big[\sum_{t=1}^{T} g(I_t, a_t) + h(I_{T+1})\Big]$. Formally, we want to determine:

$$\mathrm{DP}^*(s_1) = \max_{\{a_1,\ldots,a_T\}\subseteq\mathcal{A}} \mathbb{E}\Big[\sum_{t=1}^{T} g(I_t, a_t) + h(I_{T+1})\Big] \qquad \text{(DP)}$$
$$\text{subject to: } I_{t+1} = f(I_t, a_t), \qquad t = 1, \ldots, T.$$

By Bellman's equation [3], for every initial state $s_1 = (I_1, \mathcal{A})$, the optimal value $\mathrm{DP}^*(s_1)$ is given by $\mathrm{DP}_1(I_1, \mathcal{A})$. Here DP_1 is the function defined by $\mathrm{DP}_{T+1}(I_{T+1}) = h(I_{T+1})$ together with the recursion:

$$\mathrm{DP}_t(I_t, \mathcal{A}_t) = \max_{a_t\in\mathcal{A}_t} \mathbb{E}\Big[\mathrm{DP}_{t+1}(f(I_t, a_t), \mathcal{A}_t \setminus a_t) + g(I_t, a_t)\Big], \quad t = 1, \ldots, T. \tag{2}$$

When the value and the item spaces are finite, and the expectations can be computed, this recursion yields an algorithm to compute the optimal value. However, since the state space $\mathcal{S} = \mathcal{V} \times 2^{\mathcal{A}}$ is exponentially large, this exact algorithm requires exponential time. Since this model can capture several stochastic optimization problems which are known (or believed) be #P-hard or even PSPACE-hard, we are interested in obtaining polynomial-time approximation algorithms with provable performance guarantees.

1.1 Our Results

In order to obtain a polynomial time approximation scheme (PTAS) for the stochastic dynamic program, we need the following assumptions.

▶ **Assumption 1.** *In this paper, we make the following assumptions.*

1. *The value space $\mathcal{V}$ is discrete and ordered, and its size $|\mathcal{V}|$ is a constant. W.l.o.g., we assume $\mathcal{V} = (0, 1, \ldots, |\mathcal{V}| - 1)$.*
2. *The function f satisfies that $f(I_t, a_t) \geq I_t$, which means the value is nondecreasing.*
3. *The function $h : \mathcal{V} \to R^{\geq 0}$ is a nonnegative function. The expected profit $\mathbb{E}[g(I_t, a_t)]$ is nonnegative (although the function $g(I_t, a_t)$ may be negative with nonzero probability).*

Assumption (1) seems to be quite restrictive. However, for several concrete problems where the value space is not of constant size (*e.g.,* Probemax in Section 1.2), we can discretize the value space and reduce its size to a constant, without losing much profit. Assumption (2) and (3) are quite natural for many problems. Now, we state our main result.

▶ **Theorem 1.** *For any fixed $\varepsilon > 0$, if Assumption 1 holds, we can find an adaptive policy in polynomial time $n^{2^{O(\varepsilon^{-3})}}$ with expected profit at least $\mathsf{OPT} - O(\varepsilon) \cdot \mathsf{MAX}$ where $\mathsf{MAX} = \max_{I\in\mathcal{V}} \mathrm{DP}_1(I, \mathcal{A})$ and OPT denotes the expected profit of the optimal adaptive policy.*

Our Approach: For the stochastic dynamic program, an optimal adaptive policy σ can be represented as a decision tree $\mathcal{T}$ (see Section 2 for more details). The decision tree corresponding to the optimal policy may be exponentially large and arbitrarily complicated. Hence, it is unlikely that one can even represent an optimal decision for the stochastic dynamic program in polynomial space. In order to reduce the space, we focus a special class of policies, called *block adaptive policy*. The idea of *block adptive policy* was first introduced by Bhalgat*et al.* [6] and further generalized in [17] to the context of the stochastic knapsack. To the best of our knowledge, the idea has not been extended to other applications. In this paper, we make use of the notion of block policy as well, but we target at the development

of a general framework. For this sake we provide a general model of block policy (see Section 3). Since we need to work with the more abstract dynamic program, our construction of block adaptive policy is somewhat different from that in [6, 17].

Roughly speaking, in a block adaptive policy, we take a batch of items simultaneously instead of a single one each time. This can significantly reduce the size of the decision tree. Moreover, we show that there exists a block-adaptive policy that approximates the optimal adaptive policy and has only a constant number of blocks on the decision tree (the constant depends on ε). Since the decision tree corresponding to a block adaptive policy has a constant number of nodes, the number of all topologies of the block decision tree is a constant. Fixing the topology of the decision tree corresponding to the block adaptive policy, we still need to decide the subset of items to place in each block. Again, there is exponential number of possible choices. For each block, we can define a *signature* for it, which allows us to represent a block using polynomially many possible signatures. The signatures are so defined such that two subsets with the same signature have approximately the same reward distribution. Finally, we show that we can enumerate the signatures of all blocks in polynomial time using dynamic programming and find a nearly optimal block-adaptive policy. The high level idea is somewhat similar to that in [17], but the details are again quite different.

1.2 Applications

Our framework can be used to obtain the first PTAS for the following problems.

1.2.1 The Probemax Problem

In the Probemax problem, we are given a set of n items. Each item $i \in [n]$ has a value X_i which is an independent random variable following a known (discrete) distribution π_i. We can *probe* a subset $P \subseteq [n]$ of items sequentially. Each time after *probing* an item i, we observe its value realization, which is an independent sample from the distribution π_i. We can *adaptively* probe at most m items and each item can be probed at most once. The reward is the maximum among the m realized values. Our goal is to design an adaptive probing policy such that the expected value of the reward is maximized.

Despite being a very basic stochastic optimization problem, we still do not have a complete understanding of the approximability of the Probemax problem. It is not even known whether it is intractable to obtain the optimal policy. For the non-adaptive Probemax problem (*i.e.,* the probed set P is just a priori fixed set), it is easy to obtain a $1 - 1/e$ approximation by noticing that $f(P) = \mathbb{E}[\max_{i \in P} X_i]$ is a submodular function (see e.g., Chen *et al.* [8]). Chen *et al.* [8] obtained the first PTAS. When considering the adaptive policies, Munagala [19] provided a $\frac{1}{8}$-approximation ratio algorithm by LP relaxation. His policy is essentially a non-adaptive policy (it is related to the contention resolution schemes [23, 10]). They also showed that the *adaptivity gap* (the gap between the optimal adaptive policy and optimal non-adaptive policy) is at most 3. For the Probemax problem, the best-known approximation ratio is $1 - \frac{1}{e}$. Indeed, this can be obtained using the algorithm for stochastic monotone submodular maximization in Asadpour *et al.* [2]. This is also a non-adaptive policy, which implies the adaptivity gap is at most $\frac{e}{e-1}$. In this paper, we provide the first PTAS, among all adaptive policies. Note that our policy is indeed adaptive.

▶ **Theorem 2.** *There exists a PTAS for the Probemax problem. In other words, for any fixed constant $\varepsilon > 0$, there is a polynomial-time approximation algorithm for the Probemax problem that finds a policy with the expected profit at least $(1-\varepsilon)\mathsf{OPT}$, where OPT denotes the expected profit of the optimal adaptive policy.*

Let the value I_t be the maximum among the realized values of the probed items at the time period t. Using our framework, we have the following system dynamics for Probemax:

$$I_{t+1} = f(I_t, i) = \max\{I_t, X_i\}, \quad g(I_t, i) = 0, \text{ and } h(I_{T+1}) = I_{T+1} \tag{3}$$

$t = 1, 2, \ldots, T$. Clearly, Assumption 1 (2) and (3) are satisfied. But Assumption 1 (1) is not satisfied because the value space $\mathcal{V}$ is not of constant size. We can discretize the value space and reduce its size to a constant. See full version for more details. If the reward is the summation of top-k values ($k = O(1)$) among the m realized values, we obtain the ProbeTop-k problem. Our techniques also allow us to derive the following result.

▶ **Theorem 3.** *For the ProbeTop-k problem where k is a constant, there is a polynomial time algorithm that finds an adaptive policy with the expected profit at least $(1-\varepsilon)\mathsf{OPT}$, where OPT denotes the expected profit of the optimal adaptive policy.*

1.2.2 Committed ProbeTop-k Problem

We are given a set of n items. Each item $i \in [n]$ has a value X_i which is an independent random variable with a known (discrete) distribution π_i. We can *adaptively* probe at most m items and choose k values in the committed model, where k is a constant. In the *committed* model, once we probe an item and observe its value realization, we must make an irrevocable decision whether to choose it or not, *i.e.,* we must either add it to the final chosen set C immediately or discard it forever. [3] If we add the item to the final chosen set C, the realized profit is collected. Otherwise, no profit is collected and we are going the probe the next item. Our goal is to design an adaptive probing policy such that the expected value $\mathbb{E}[\sum_{i\in C} X_i]$ is maximized, where C is the final chosen set.

▶ **Theorem 4.** *There is a polynomial time algorithm that finds a committed policy with the expected profit at least $(1-\varepsilon)\mathsf{OPT}$ for the committed ProbeTop-k problem, where OPT is the expected total profit obtained by the optimal policy.*

Let b_i^θ represent the action that we probe item i with the threshold θ (*i.e.,* we choose item i if X_i realizes to a value s such that $s \geq \theta$). Let I_t be the the number of items that have been chosen at the period time t. Using our framework, we have following transition dynamics for the ProbeTop-k problem.

$$I_{t+1} = f(I_t, b_i^\theta) = \begin{cases} I_t + 1 & \text{if } X_i \geq \theta, I_t < k, \\ I_t & \text{otherwise;} \end{cases} \quad g(I_t, b_i^\theta) = \begin{cases} X_i & \text{if } X_i \geq \theta, I_t < k, \\ 0 & \text{otherwise;} \end{cases} \tag{4}$$

for $t = 1, 2, \ldots, T$, and $h(I_{T+1}) = 0$. Since k is a constant, Assumption 1 is immediately satisfied. There is one extra requirement for the problem: in any realization path, we can choose at most one action b_i^θ from the set $\mathcal{B}_i = \{b_i^\theta\}_\theta$.

1.2.3 Committed Pandora's Box Problem

For Weitzman's "Pandora's box" problem [24], we are given n boxes. For each box $i \in [n]$, the probing cost c_i is deterministic and the value X_i is an independent random variable with a known (discrete) distribution π_i. Opening a box i incurs a cost of c_i. When we open the box i, its value is realized, which is a sample from the distribution π_i. The goal is to adaptively open

[3] In [10, 11], it is called the online decision model.

a subset $P \subseteq [n]$ to maximize the expected profit: $\mathbb{E}\left[\max_{i\in P}\{X_i\} - \sum_{i\in P} c_i\right]$. Weitzman provided an elegant optimal adaptive strategy, which can be computed in polynomial time. Recently, Singla [22] generalized this model to other combinatorial optimization problems such as matching, set cover and so on.

In this paper, we focus on the committed model, which is mentioned in Section 1.2.2. Again, we can *adaptively* open the boxes and choose at most k values in the committed way, where k is a constant. Our goal is to design an adaptive policy such that the expected value $\mathbb{E}\left[\sum_{i\in C} X_i - \sum_{i\in P} c_i\right]$ is maximized, where $C \subseteq P$ is the final chosen set and P is the set of opened boxes. Although the problem looks like a slight variant of Weitzman's original problem, it is quite unlikely that we can adapt Weitzman's argument (or any argument at all) to obtain an optimal policy in polynomial time. When $k = O(1)$, we provide the first PTAS for this problem. Note that a PTAS is not known previously even for $k = 1$.

▶ **Theorem 5.** *When $k = O(1)$, there is a polynomial time algorithm that finds a committed policy with the expected value at least $(1-\varepsilon)\mathsf{OPT}$ for the committed Pandora's Box problem.*

Similar to the committed ProbeTop-k problem, let b_i^θ represent the action that we open the box i with threshold θ. Let I_t be the number of boxes that have been chosen at the time period t. Using our framework, we have following system dynamics for the committed Pandora's Box problem:

$$I_{t+1} = f(I_t, b_i^\theta) = \begin{cases} I_t + 1 & \text{if } X_i \geq \theta, I_t < k, \\ I_t & \text{otherwise;} \end{cases} \quad g(I_t, b_i^\theta) = \begin{cases} X_i - c_i & \text{if } X_i \geq \theta, I_t < k, \\ -c_i & \text{otherwise;} \end{cases} \tag{5}$$

for $t = 1, 2, \cdots, T$, and $h(I_{T+1}) = 0$. Notice that we never take an action b_i^θ for a value $I_t < k$ if $\mathbb{E}[g(I_t, b_i^\theta)] = \Pr[X_t \geq \theta] \cdot \mathbb{E}[X_i \mid X_i \geq \theta] - c_i < 0$. Then Assumption 1 is immediately satisfied.

1.2.4 Stochastic Target Problem

İlhan *et al.* [15] introduced the following stochastic target problem. [4] In this problem, we are given a predetermined target $\mathbb{T}$ and a set of n items. Each item $i \in [n]$ has a value X_i which is an independent random variable with a known (discrete) distribution π_i. Once we decide to insert an item i into a knapsack, we observe a reward realization X_i which follows the distribution π_i. We can insert at most m items into the knapsack and our goal is to design an adaptive policy such that $\Pr[\sum_{i\in P} X_i \geq \mathbb{T}]$ is maximized, where $P \subseteq [n]$ is the set of inserted items. For the stochastic target problem, İlhan *et al.* [15] provided some heuristic based on dynamic programming for the special case where the random profit of each item follows a known normal distribution. In this paper, we provide an additive PTAS for the stochastic target problem when the target is relaxed to $(1-\varepsilon)\mathbb{T}$.

▶ **Theorem 6.** *There exists an additive PTAS for stochastic target problem if we relax the target to $(1-\varepsilon)\mathbb{T}$. In other words, for any given constant $\varepsilon > 0$, there is a polynomial-time approximation algorithm that finds a policy such that the probability of the total rewards exceeding $(1-\varepsilon)\mathbb{T}$ is at least $\mathsf{OPT} - \varepsilon$, where OPT is the resulting probability of an optimal adaptive policy.*

[4] [15] called the problem the adaptive stochastic knapsack instead. However, their problem is quite different from the stochastic knapsack problem studied in the theoretical computer science literature. So we use a different name.

Let the value I_t be the total profits of the items in the knapsack at time period t. Using our framework, we have following system dynamics for the stochastic target problem:

$$I_{t+1} = f(I_t, i) = I_t + X_i, \quad g(I_t, i) = 0, \text{ and } h(I_{T+1}) = \begin{cases} 1 & \text{if } I_{T+1} \geq \mathbb{T}, \\ 0 & \text{otherwise;} \end{cases} \tag{6}$$

for $t = 1, 2, \cdots, T$. Then Assumption 1 (2,3) is immediately satisfied. But Assumption 1 (1) is not satisfied for that the value space $\mathcal{V}$ is not of constant size. We can discretize the value space and reduce its size to a constant.

1.2.5 Stochastic Blackjack Knapsack

Levin *et al.* [16] introduced the *stochastic blackjack knapsack*. In this problem, we are given a capacity $\mathbb{C}$ and a set of n items, each item $i \in [n]$ has a size X_i which is an independent random variable with a known distribution π_i and a profit p_i. We can adaptively insert the items into a knapsack, as long as the capacity constraint is not violated. Our goal is to design an adaptive policy such that the expected total profits of all items inserted is maximized. The key feature here different from classic stochastic knapsack is that we gain zero if overflow, *i.e.,* we will lose the profits of all items inserted already if the total size is larger than the capacity. This extra restriction might induce us to take more conservative policies. Levin *et al.* [16] presented a non-adaptive policy with expected value that is at least $(\sqrt{2}-1)^2/2 \approx 1/11.66$ times the expected value of the optimal adaptive policy. Chen *et al.* [7] assumed each size X_i follows a known exponential distribution and gave an optimal policy for $n = 2$ based on dynamic programming. In this paper, we provide the first bi-criteria PTAS for the problem.

▶ **Theorem 7.** *For any fixed constant $\varepsilon > 0$, there is a polynomial-time approximation algorithm for stochastic blackjack knapsack that finds a policy with the expected profit at least $(1-\varepsilon)\mathsf{OPT}$, when the capacity is relaxed to $(1+\varepsilon)\mathbb{C}$, where OPT is the expected profit of the optimal adaptive policy.*

Denote $I_t = (I_{t,1}, I_{t,2})$ and let $I_{t,1}, I_{t,2}$ be the total sizes and total profits of the items in the knapsack at the time period t respectively. When we insert an item i into the knapsack and observe its size realization, say s_i, we define the system dynamics function to be

$$I_{t+1} = f(I_t, i) = (I_{t,1} + s_i, I_{t,2} + p_i), \quad h(I_{T+1}) = \begin{cases} I_{T+1,2} & \text{if } I_{T+1,1} \leq \mathbb{C}, \\ 0 & \text{otherwise;} \end{cases} \tag{7}$$

and $g(I_t, i) = 0$ for $t = 1, 2, \cdots, T$. Then Assumption 1 (2,3) is immediately satisfied. But Assumption 1 (1) is not satisfied for that the value space $\mathcal{V}$ is not of constant size. We can discretize the value space and reduce its size to a constant.

1.3 Related Work

Stochastic dynamic program has been widely studied in computer science and operation research (see, for example, [4, 20]) and has many applications in different fields. It is a natural model for decision making under uncertainty. In 1950s, Richard Bellman [3] introduced the "principle of optimality" which leads to dynamic programming algorithms for solving sequential stochastic optimization problems. However, Bellman's principle does not immediate lead to efficient algorithms for many problems due to "curse of dimensionality" and the large state space.

There are some constructive frameworks that provide approximation schemes for certain classes of stochastic dynamic programs. Shmoys *et al.* [21] dealt with stochastic linear programs. Halman *et al.* [12, 13, 14] studied stochastic discrete DPs with scalar state and action spaces and designed an FPTAS for their framework. As one of the applications, they used it to solve the stochastic ordered adaptive knapsack problem. As a comparison, in our model, the state space $\mathcal{S} = \mathcal{V} \times 2^{\mathcal{A}}$ is exponentially large and hence cannot be solved by previous framework.

Stochastic knapsack problem (SKP) is one of the most well-studied stochastic combinatorial optimization problem. We are given a knapsack of capacity $\mathbb{C}$. Each item $i \in [n]$ has a random value X_i with a known distribution π_i and a profit p_i. We can adaptively insert the items to the knapsack, as long as the capacity constraint is not violated. The goal is to maximize the expected total profit of all items inserted. For SKP, Dean *et al.* [9] first provide a constant factor approximation algorithm. Later, Bhalgat *et al.* [6] improved that ratio to $\frac{3}{8} - \varepsilon$ and gave an algorithm with ratio of $(1 - \varepsilon)$ by using ε extra budget for any given constant $\varepsilon \geq 0$. In that paper, the authors first introduced the notion of block adaptive policies, which is crucial for this paper. The best known single-criterion approximation factor is 2 [5, 17, 18].

The Probemax problem and ProbeTop-k problem are special cases of the general stochastic probing framework formulated by Gupta *et al.* [11]. They showed that the adaptivity gap of any stochastic probing problem where the outer constraint is prefix-closed and the inner constraint is an intersection of p matroids is at most $O(p^3 \log(np))$, where n is the number of items. The Bernoulli version of stochastic probing was introduced in [10], where each item $i \in U$ has a fixed value w_i and is "active" with an independent probability p_i. Gupta *et al.* [10] presented a framework which yields a $\frac{1}{4(k^{in}+k^{out})}$-approximation algorithm for the case when $\mathcal{I}_{in}$ and $\mathcal{I}_{out}$ are respectively an intersection of k^{in} and k^{out} matroids. This ratio was improved to $\frac{1}{(k^{in}+k^{out})}$ by Adamczyk *et al.* [1] using the iterative randomized rounding approach. Weitzman's Pandora's Box is a classical example in which the goal is to find out a single random variable to maximize the utility minus the probing cost. Singla [22] generalized this model to other combinatorial optimization problems such as matching, set cover, facility location, and obtained approximation algorithms.

2 Policies and Decision Trees

An instance of stochastic dynamic program is given by $\mathcal{J} = (\mathcal{V}, \mathcal{A}, f, g, h, T)$. For each item $a \in \mathcal{A}$ and values $I, J \in \mathcal{V}$, we denote $\Phi_a(I, J) := \Pr[f(I, a) = J]$ and $\mathcal{G}_a(I) := \mathbb{E}[g(I, a)]$. The process of applying a feasible adaptive *policy* σ can be represented as a decision tree $\mathcal{T}_\sigma$. Each node v on $\mathcal{T}_\sigma$ is labeled by a unique item $a_v \in \mathcal{A}$. Before selecting the item a_v, we denote the corresponding time index, the current value and the set of the remaining available items by t_v, I_v and $\mathcal{A}(v)$ respectively. Each node has several children, each corresponding to a different value realization (one possible $f(I_v, a_v)$). Let $e = (v, u)$ be the s-th edge emanating from $s \in \mathcal{V}$ where s is the realized value. We call u the s-child of v. Thus e has probability $\pi_e := \pi_{v,s} = \Phi_{a_v}(I_v, s)$ and weight $w_e := s$.

We use $\mathbb{P}(\sigma)$ to denote the expected profit that the policy σ can obtain. For each node v on $\mathcal{T}_\sigma$, we define $\mathcal{G}_v := \mathcal{G}_{a_v}(I_v)$. In order to clearly illustrate the tree structure, we add a dummy node at the end of each root-to-leaf path and set $\mathcal{G}_v = h(I_v)$ if v is a dummy node. Then, we recursively define the expected profit of the subtree $\mathcal{T}_v$ rooted at v to be

$$\mathbb{P}(v) = \mathcal{G}_v + \sum_{e=(v,u)} \pi_e \cdot \mathbb{P}(u), \tag{8}$$

if v is an internal node and $\mathbb{P}(v) = \mathcal{G}_v = h(I_v)$ if v is a leaf (*i.e.,* the dummy node). The expected profit $\mathbb{P}(\sigma)$ of the policy σ is simply $\mathbb{P}(\text{the root of } \mathcal{T}_\sigma)$. Then, according to Equation (2), we have

$$\mathbb{P}(v) \leq \mathrm{DP}_{t_v}(I_v, \mathcal{A}(v)) \leq \mathrm{DP}_1(I_v, \mathcal{A}) \leq \max_{I \in \mathcal{V}} \mathrm{DP}_1(I, \mathcal{A}) = \mathsf{MAX}$$

for each node v. For a node v, we say the path from the root to it on $\mathcal{T}_\sigma$ as the *realization path* of v, and denote it by $\mathcal{R}(v)$. We denote the probability of reaching v as $\Phi(v) = \Phi(\mathcal{R}(v)) = \prod_{e \in \mathcal{R}(v)} \pi_e$. Then, we have

$$\mathbb{P}(\sigma) = \sum_{v \in \mathcal{T}_\sigma} \Phi(v) \cdot \mathcal{G}_v. \tag{9}$$

We use OPT to denote the expected profit of the optimal adaptive policy. For each node v on the tree $\mathcal{T}_\sigma$, by Assumption 1 (2) that $f(I_v, a_v) \geq I_v$, we define $\mu_v := \Pr[f(I_v, a_v) > I_v] = 1 - \Phi_{a_v}(I_v, I_v)$. For a set of nodes P, we define $\mu(P) := \sum_{v \in P} \mu_v$.

▶ **Lemma 8.** *Given an policy σ, there is a policy σ' with profit at least $\mathsf{OPT} - O(\varepsilon) \cdot \mathsf{MAX}$ which satisfies that for any realization path $\mathcal{R}$, $\mu(\mathcal{R}) \leq O(1/\varepsilon)$, where $\mathsf{MAX} = \max_{I \in \mathcal{V}} \mathrm{DP}_1(I, \mathcal{A})$.*

W.l.o.g, we assume that all (optimal or near optimal) policies σ considered in this paper satisfy that for any realization $\mathcal{R}$, $\mu(\mathcal{R}) \leq O(1/\varepsilon)$.

3 Block Adaptive Policies

The decision tree corresponding to the optimal policy may be exponentially large and arbitrarily complicated. Now we consider a restrict class of policies, called block-adaptive policy. The concept was first introduced by Bhalgat *et al.* [6] in the context of stochastic knapsack. Our construction is somewhat different from that in [6, 17]. Here, we need to define an order for each block and introduce the notion of approximate block policy.

Formally, a block-adaptive policy $\hat{\sigma}$ can be thought as a decision tree $\mathcal{T}_{\hat{\sigma}}$. Each node on the tree is labeled by a *block* which is a set of items. For a block M, we choose an arbitrary order φ for the items in the block. According to the order φ, we take the items one by one, until we get a bigger value or all items in the block are taken but the value does not change (recall from Assumption 1 that the value is nondecreasing). Then we visit the child block which corresponds to the realized value. We use I_M to denote the current value right before taking the items in the block M. Then for each edge $e = (M, N)$, it has probability

$$\pi_e^\varphi = \sum_{a \in M} \left[\left(\prod_{\varphi_b < \varphi_a} \Phi_b(I_M, I_M) \right) \cdot \Phi_a(I_M, I_N) \right]$$

if $I_N > I_M$ and $\pi_e^\varphi = \prod_{a \in M} \Phi_a(I_M, I_M)$ if $I_N = I_M$.

Similar to Equation (8), for each block M and an arbitrary order φ for M, we recursively define the expected profit of the subtree $\mathcal{T}_M$ rooted at M to be

$$\mathbb{P}(M) = \mathcal{G}_M^\varphi + \sum_{e=(M,N)} \pi_e^\varphi \cdot \mathbb{P}(N) \tag{10}$$

if M is an internal block and $\mathbb{P}(M) = h(I_M)$ if M is a leaf (*i.e.,* the dummy node). Here $\mathcal{G}_M^\varphi$ is the expected profit we can get from the block which is equal to

$$\mathcal{G}_M^\varphi = \sum_{a \in M} \left[\left(\prod_{\varphi_b < \varphi_a} \Phi_b(I_M, I_M) \right) \cdot \mathcal{G}_a(I_M) \right].$$

Since the profit $\mathcal{G}_M^{\varphi}$ and the probability π_e^{φ} are dependent on the order φ and thus difficult to deal with, we define the approximate block profit and the approximate probability which do not depend on the choice of the specific order φ:

$$\widetilde{\mathcal{G}}_M = \sum_{a\in M} \mathcal{G}_a(I_M) \quad \text{and} \quad \widetilde{\pi}_e = \sum_{a\in M} \left[\left(\prod_{b\in M\setminus a} \Phi_b(I_M, I_M) \right) \cdot \Phi_a(I_M, I_N) \right] \tag{11}$$

if $I_N > I_M$ and $\widetilde{\pi}_e = \prod_{a\in M} \Phi_a(I_M, I_M)$ if $I_N = I_M$. Then we recursively define the approximate profit

$$\widetilde{\mathbb{P}}(M) = \widetilde{\mathcal{G}}_M + \sum_{e=(M,N)} \widetilde{\pi}_e \cdot \widetilde{\mathbb{P}}(N), \tag{12}$$

if M is an internal block and $\widetilde{\mathbb{P}}(M) = \mathbb{P}(M) = h(I_M)$ if M is a leaf. For each block M, we define $\mu(M) := \sum_{a\in M} [1 - \Phi_a(I_M, I_M)]$. Lemma 9 below can be used to bound the gap between the approximate profit and the original profit if the policy satisfies the following property.Then it suffices to consider the approximate profit for a block adaptive policy $\hat{\sigma}$ in this paper.

(P1) Each block M with more than one item satisfies that $\mu(M) \le \varepsilon^2$.

▶ **Lemma 9.** *For any block-adaptive policy $\hat{\sigma}$ satisfying Property (P1), we have*

$$\left(1 + O(\varepsilon^2)\right) \cdot \widetilde{\mathbb{P}}(\hat{\sigma}) \ge \mathbb{P}(\hat{\sigma}) \ge \left(1 - \varepsilon^2\right) \cdot \widetilde{\mathbb{P}}(\hat{\sigma}).$$

3.1 Constructing a Block Adaptive Policy

In this section, we show that there exists a block-adaptive policy that approximates the optimal adaptive policy. In order to prove this, from an optimal (or nearly optimal) adaptive policy σ, we construct a block adaptive policy $\hat{\sigma}$ which satisfies certain nice properties and can obtain almost as much profit as σ does. Thus it is sufficient to restrict our search to the block-adaptive policies. The construction is similar to that in [17].

▶ **Lemma 10.** *An optimal policy σ can be transformed into a block adaptive policy $\hat{\sigma}$ with approximate expected profit $\widetilde{\mathbb{P}}(\hat{\sigma})$ at least $\mathsf{OPT} - O(\varepsilon) \cdot \mathsf{MAX}$. Moreover, the block-adaptive policy $\hat{\sigma}$ satisfies Property (P1) and (P2):*

(P1) *Each block M with more than one item satisfies that $\mu(M) \le \varepsilon^2$.*

(P2) *There are at most $O(\varepsilon^{-3})$ blocks on any root-to-leaf path on the decision tree.*

Proof (sketch). For a node v on the decision tree $\mathcal{T}_\sigma$ and a value $s \in \mathcal{V}$, we use v_s to denote the s-child of v, which is the child of v corresponding to the realized value s (see Figure 1). We say an edge $e_{v,u}$ is *non-increasing* if $I_v = I_u$ and define the *leftmost path* of v to be the realization path which starts at v, ends at a leaf, and consists of only the non-increasing edges.

We say a node v is a *starting node* if v is the root or v corresponds to an increasing value of its parent v' (*i.e.,* $I_v > I_{v'}$). For each staring node v, we greedily partition the leftmost path of v into several segments such that for any two nodes u, w in the same segment M and for any value $s \in \mathcal{V}$, we have

$$|\mathbb{P}(u_s) - \mathbb{P}(w_s)| \le \varepsilon^2 \cdot \mathsf{MAX} \text{ and } \mu(M) \le \varepsilon^2. \tag{13}$$

For each root-to-leaf path $\mathcal{R}$, Equation (13) can yield at most $O(\varepsilon^{-3})$ blocks. Now, we are ready to describe the algorithm, which takes a policy σ as input and outputs a block adaptive

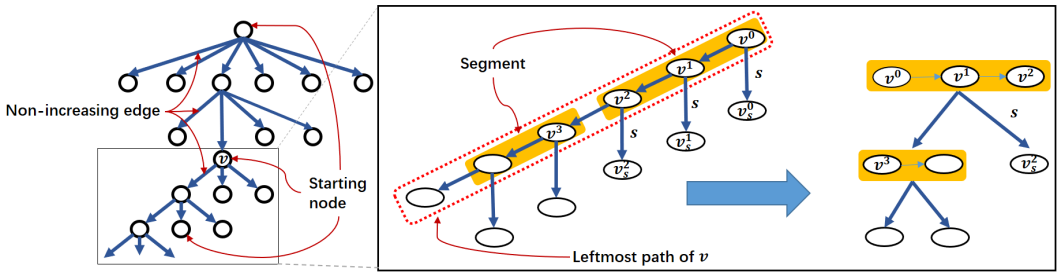

Figure 1 Decision tree and block policy.

Algorithm 1 A policy $\hat{\sigma}$.

Input: A policy σ.

1: We start at the root of $\mathcal{T}_\sigma$.
2: **repeat**
3: Suppose we are at node v on $\mathcal{T}_\sigma$. Take the items in $\mathsf{seg}(v)$ one by one in the original order (the order of items in policy σ) until some node u makes a transition to an increasing value, say s.
4: Visit the node $l(v)_s$, the s-child of $l(v)$ (*i.e.,* the last node of $\mathsf{seg}(v)$).
5: If all items in $\mathsf{seg}(v)$ have been taken and the value does not change, visit $l(v)_{I_v}$.
6: **until** A leaf on $\mathcal{T}_\sigma$ is reached.

policy $\hat{\sigma}$. For each node v, we denote its segment $\mathsf{seg}(v)$ and use $l(v)$ to denote the last node in $\mathsf{seg}(v)$. In Algorithm 1, we can see that the set of items which the policy $\hat{\sigma}$ attempts to take always corresponds to some realization path in the original policy σ. Property (P1) and (P2) hold immediately following from the partition argument. Then we can show that the expected profit $\mathbb{P}(\hat{\sigma})$ that the new policy $\hat{\sigma}$ can obtain is at least $\mathsf{OPT} - O(\varepsilon^2) \cdot \mathsf{MAX}$. ◀

3.2 Enumerating Signatures

To search for the (nearly) optimal block-adaptive policy, we want to enumerate all possible structures of the block decision tree. Fixing the topology of the decision tree, we need to decide the subset of items to place in each block. To do this, we define the *signature* such that two subsets with the same signature have approximately the same profit distribution. Then, we can enumerate the signatures of all blocks in polynomial time and find a nearly optimal block-adaptive policy. Formally, for an item $a \in \mathcal{A}$ and a value $I \in \mathcal{V} = (0, 1, \ldots, |\mathcal{V}| - 1)$, we define the *signature* of a on I to be the following vector

$$\mathsf{Sg}_I(a) = \left(\bar{\Phi}_a(I,0), \bar{\Phi}_a(I,1), \ldots, \bar{\Phi}_a(I,|\mathcal{V}|-1), \bar{\mathcal{G}}_a(I)\right),$$

where $\bar{\Phi}_a(I,J) = \left\lfloor \Phi_a(I,J) \cdot \frac{n}{\varepsilon^4} \right\rfloor \cdot \frac{\varepsilon^4}{n}$ and $\bar{\mathcal{G}}_a(I) = \left\lfloor \mathcal{G}_a(I) \cdot \frac{n}{\varepsilon^4 \mathsf{MAX}} \right\rfloor \cdot \frac{\varepsilon^4 \mathsf{MAX}}{n}$ for any $J \in \mathcal{V}$. [5] For a block M of items, we define the *signature* of M on I to be $\mathsf{Sg}_I(M) = \sum_{a \in M} \mathsf{Sg}_I(a)$.

▶ **Lemma 11.** *Consider two decision trees $\mathcal{T}_1, \mathcal{T}_2$ corresponding to block-adaptive policies with the same topology* (i.e., *$\mathcal{T}_1$ and $\mathcal{T}_2$ are isomorphic) and the two block adaptive policies*

[5] If $\mathsf{MAX} = \max_{I \in \mathcal{V}} \mathrm{DP}_1(I, \mathcal{A})$ is unknown, for some several concrete problems (*e.g.,* Probemax), we can get a constant approximation result for MAX, which is sufficient for our purpose. In general, we can guess a constant approximation result for MAX using binary search.

satisfy Property (P1) and (P2). If for each block M_1 on $\mathcal{T}_1$, the block M_2 at the corresponding position on $\mathcal{T}_2$ satisfies that $\mathsf{Sg}_I(M_1) = \mathsf{Sg}_I(M_2)$ where $I = I_{M_1} = I_{M_2}$, then $|\widetilde{\mathbb{P}}(\mathcal{T}_1) - \widetilde{\mathbb{P}}(\mathcal{T}_2)| \leq O(\varepsilon) \cdot \mathsf{MAX}$.

Since $|V| = O(1)$, the number of possible signatures for a block is $O\left((n/\varepsilon^4)^{|\mathcal{V}|}\right) = n^{O(1)}$, which is a polynomial of n. By Lemma 10, for any block decision tree $\mathcal{T}$, there are at most $(|\mathcal{V}|)^{O(\varepsilon^{-3})} = 2^{O(\varepsilon^{-3})}$ blocks on the tree which is a constant.

3.3 Finding a Nearly Optimal Block-adaptive Policy

In this section, we find a nearly optimal block-adaptive policy and prove Theorem 1. To do this, we enumerate over all topologies of the decision trees along with all possible signatures for each block. This can be done by a standard dynamic programming.

Consider a given tree topology $\mathcal{T}$. A configuration C is a set of signatures each corresponding to a block. Let t_1 and t_2 be the number of paths and blocks on $\mathcal{T}$ respectively. We define a vector $\mathsf{CA} = (u_1, u_2, \ldots, u_{t_1})$ where u_j is the upper bound of the number of items on the jth path. For each given $i \in [n], \mathsf{C}$ and CA, let $\mathcal{M}(i, \mathsf{C}, \mathsf{CA}) = 1$ indicate that we can reach the configuration C using a subset of items $\{a_1, \ldots, a_i\}$ such that the total number of items on each path j is no more than u_j and 0 otherwise. Set $\mathcal{M}(0, \mathbf{0}, \mathbf{0}) = 1$ and we compute $\mathcal{M}(i, \mathsf{C}, \mathsf{CA})$ in an lexicographically increasing order of $(i, \mathsf{C}, \mathsf{CA})$ as follows:

$$\mathcal{M}(i, \mathsf{C}, \mathsf{CA}) = \max\left\{\mathcal{M}(i-1, \mathsf{C}, \mathsf{CA}), \mathcal{M}(i-1, \mathsf{C}', \mathsf{CA}')\right\} \tag{14}$$

Now, we explain the above recursion as follows. In each step, we should decide how to place the item a_i on the tree $\mathcal{T}$. Notice that there are at most $t_2 = (|\mathcal{V}|)^{O(\varepsilon^{-3})} = 2^{O(\varepsilon^{-3})}$ blocks and therefore at most 2^{t_2} possible placements of item a_i and each placement is called *feasible* if there are no two blocks on which we place the item a_i have an ancestor-descendant relation. For a feasible placement of a_i, we subtract $\mathsf{Sg}(a_i)$ from each entry in C corresponding to the block we place a_i and subtract 1 from CA on each entry corresponding to a path including a_i, and in this way we get the resultant configuration C' and CA' respectively. Hence, the max is over all possible such $\mathsf{C}', \mathsf{CA}'$.

We have shown that the total number of all possible configurations on $\mathcal{T}$ is n^{t_2}. The total number of vectors CA is $T^{t_1} \leq n^{t_1} \leq n^{t_2} = n^{t_2}$ where T is the number of rounds. For each given $(i, \mathsf{C}, \mathsf{CA})$, the computation takes a constant time $O(2^{t_2})$. Thus we claim for a given tree topology, finding the optimal configuration can be done within $O(n^{2^{O(\varepsilon^{-3})}})$ time .

The proof of Theorem 1. Suppose σ^* is the optimal policy with expected profit $\mathbb{P}(\sigma^*) = \mathsf{OPT}$. We use the above dynamic programming to find a nearly optimal block adaptive policy σ. By Lemma 10, there exists a block adaptive policy $\hat{\sigma}$ such that

$$\widetilde{\mathbb{P}}(\hat{\sigma}) \geq \mathsf{OPT} - O(\varepsilon)\mathsf{MAX}.$$

Since the configuration of $\hat{\sigma}$ is enumerated at some step of the algorithm, our dynamic programming is able to find a block adaptive policy σ with the same configuration (the same tree topology and the same signatures for corresponding blocks). By Lemma 11, we have

$$\widetilde{\mathbb{P}}(\sigma) \geq \widetilde{\mathbb{P}}(\hat{\sigma}) - O(\varepsilon)\mathsf{MAX} \geq \mathsf{OPT} - O(\varepsilon)\mathsf{MAX}.$$

By Lemma 9, we have $\mathbb{P}(\sigma) \geq \left(1 - \varepsilon^2\right) \cdot \widetilde{\mathbb{P}}(\sigma) \geq \mathsf{OPT} - O(\varepsilon)\mathsf{MAX}$. Hence, the proof of Theorem 1 is completed. ◀

Abstract

We study k-means clustering in a semi-supervised setting. Given an oracle that returns whether two given points belong to the same cluster in a fixed optimal clustering, we investigate the following question: how many oracle queries are sufficient to efficiently recover a clustering that, with probability at least $(1-\delta)$, simultaneously has a cost of at most $(1+\epsilon)$ times the optimal cost and an accuracy of at least $(1-\epsilon)$?

We show how to achieve such a clustering on n points with $O((k^2 \log n) \cdot m(Q, \epsilon^4, \delta/(k \log n)))$ oracle queries, when the k clusters can be learned with an ϵ' error and a failure probability δ' using $m(Q, \epsilon', \delta')$ labeled samples in the supervised setting, where Q is the set of candidate cluster centers. We show that $m(Q, \epsilon', \delta')$ is small both for k-means instances in Euclidean space and for those in finite metric spaces. We further show that, for the Euclidean k-means instances, we can avoid the dependency on n in the query complexity at the expense of an increased dependency on k: specifically, we give a slightly more involved algorithm that uses $O(k^4/(\epsilon^2\delta) + (k^9/\epsilon^4)\log(1/\delta) + k \cdot m(\mathbb{R}^r, \epsilon^4/k, \delta))$ oracle queries.

We also show that the number of queries needed for $(1-\epsilon)$-accuracy in Euclidean k-means must linearly depend on the dimension of the underlying Euclidean space, and for finite metric space k-means, we show that it must at least be logarithmic in the number of candidate centers. This shows that our query complexities capture the right dependencies on the respective parameters.

1 Introduction

Clustering is a fundamental problem that arises in many learning tasks. Given a set P of data points, the goal is to output a k-partition $C_1 \dot\cup \ldots \dot\cup C_k$ of P according to some optimization criteria. In unsupervised clustering, the data points are unlabeled. The classic k-means problem and other well-studied clustering problems such as k-median fall into this category.

In a general k-means clustering problem, the input comprises a finite set of n points P that is to be clustered, a set of candidate centers Q, and a distance metric d giving the distances between each pair of points in $P \cup Q$. The goal is to find k cluster centers $c_1, \ldots, c_k \in Q$ that minimizes the cost, which is the sum of squared distances between each point in P and its closest cluster center. In this case, the clustering $\mathcal{C}$ is defined by setting $C_i = \{x \in P : c_i \text{ is the closest center to } x\}$ for all $i = 1, \ldots, k$ and breaking ties arbitrarily. Two widely studied special cases are the k-means problem in Euclidean space (where $P \subset \mathbb{R}^r, Q = \mathbb{R}^r$, and d is the Euclidean distance function) and the k-means problem in finite metric spaces (where $(P \cup Q, \mathrm{d})$ forms a finite metric space).

Despite its popularity and success in many settings, there are two known drawbacks of the unsupervised k-means problem:

1. Finding the centers that satisfy the clustering goal is computationally hard. For example, even the special case of 2-means problem in Euclidean space is NP-hard [8].
2. There could be multiple possible sets of centers that minimize the cost. However, in practical instances, not all such sets are equally meaningful, and we would like our algorithm to find one that corresponds to the concerns of the application.

Since k-means is NP-hard, it is natural to seek approximation algorithms. For the general k-means problem in Euclidean space, notable approximation results include the local search by Kanungo et al. [13] with an approximation guarantee of $(9 + \epsilon)$ and the recent LP-based 6.357-approximation algorithm by Ahmadian et al. [1]. On the negative side, Lee et al. [14] ruled out arbitrarily good approximation algorithms for the k-means problem on general instances. For several special cases, however, there exist PTASes. For example, in the case where k is constant, Har-Peled and Mazumdar [11] and Feldman et al. [9] showed how to get a PTAS using weak coresets, and in the case where the dimension d is constant, Cohen-Addad et al. [7] and Friggstad et al. [10] gave PTASes based on a basic local search algorithm. In addition, Awasthi et al. [4] presented a PTAS for k-means, assuming that the input is "clusterable" (satisfies a certain stability criterion).

Even if we leave aside the computational issues with unsupervised k-means, we still have the problem that there can be multiple different clusterings that minimize the cost. To see this, consider the 2-means problem on the set of vertices of an equilateral triangle. In this case, we have three different clusterings that give the same minimum cost, but only one of the clusterings might be meaningful. One way to avoid this issue is to have strong assumptions on the input. For example, Balcan et al. [5] considered the problem in a restricted setting where any c-approximation to the problem also classifies at least a $(1 - \epsilon)$ fraction of the points correctly.

Ashtiani et al. [3] recently proposed a different approach for addressing the aforementioned drawbacks. They introduced a semi-supervised active clustering framework where the algorithm is allowed to make queries of the form *same-cluster(x, y)* to a domain expert, and the expert replies whether the points x and y belong to the same cluster in some fixed optimal clustering. Under the additional assumptions that the clusters are contained inside k balls in $\mathbb{R}^r$ that are sufficiently far away from each other, they presented an algorithm that makes $O(k^2 \log k + k(\log n + \log(1/\delta)))$ same-cluster queries, runs in $O(kn \log n + k^2 \log(1/\delta))$ time,

and recovers the clusters with probability at least $(1-\delta)$. Their algorithm finds approximate cluster centers, orders all points by their distances to the cluster centers, and performs binary searches to determine the radii of the balls. Although it recovers the exact clusters, this approach works only when the clusters are contained inside well-separated balls. When the clusters are determined by a general Voronoi partitioning, and thus distances to the cluster boundaries can differ in different directions, this approach fails.

A natural question arising from the work of Ashtiani et al. [3] is whether such strong assumptions on the input structure are necessary. Ailon et al. [2] addressed this concern and considered the problem without any assumptions on the structure of the underlying true clusters. Their main result was a polynomial-time $(1+\epsilon)$-approximation scheme for k-means in the same semi-supervised framework as in Ashtiani et al. [3]. However, in contrast to Ashtiani et al. [3], their work gives no assurance on the accuracy of the recovered clustering compared to the true clustering. To achieve their goal, the authors utilized importance sampling to uniformly sample points from small clusters that significantly contribute to the cost. Their algorithm makes $O(k^9/\epsilon^4)$ same-cluster queries, runs in $O(nr(k^9/\epsilon^4))$ time, and succeeds with a constant probability.

In this work, we investigate the k-means problem in the same semi-supervised setting as Ailon et al. [2], but in addition to approximating the cost, we seek a solution that is also accurate with respect to the true clustering. We assume that the underlying true clustering minimizes the cost, and that there are no points on cluster boundaries (i.e., the margin between each pair of clusters can be arbitrarily small but not zero). This last assumption is what differentiates our setup from that of Ailon et al. [2]. It is reasonable to assume that no point lies on the boundary of two clusters, as otherwise, to achieve constant accuracy, we would have to query at least a constant fraction of the boundary points. Without querying each boundary point, we have no way of determining to which cluster it belongs.

Observe that if we label all the points correctly with respect to the true clustering, the resulting clustering automatically achieves the optimal cost. However, such perfect accuracy is difficult to achieve as there may be points that are arbitrarily close to each other but belong to different clusters. Using only a reasonable number of samples, the best we can hope for is to recover an approximately accurate solution. PAC (Probably Approximately Correct) learning helps us achieve this goal and provides a trade-off between the desired accuracy and the required number of samples.

Suppose that we have a solution where only a small fraction of the input points is incorrectly classified. In this case, one would hope that the cost is also close to the optimal cost. Unfortunately, the extra cost incurred by the incorrectly classified points can be very high depending on their positions, true labels, and the labels assigned to them. Our main concern in this paper is controlling this additional cost.

We show that if we start with a constant-factor approximation for the cost, we can refine the clustering using a PAC learning algorithm. This yields a simple polynomial-time algorithm that, given a k-means instance and $(\epsilon, \delta) \in (0,1)^2$ as parameters, with probability at least $(1-\delta)$ outputs a clustering that has a cost of at most $(1+\epsilon)$ times the optimal cost and that classifies at least a $(1-\epsilon)$ fraction of the points correctly with respect to the underlying true clustering. To do so, the algorithm makes $O((k^2 \log n) \cdot m(Q, \epsilon^4, \delta/(k \log n)))$ same-cluster queries. Here, $m(Q, \epsilon', \delta')$ is the sufficient number of labeled samples for a PAC learning algorithm to learn k clusters in a k-means instance with an ϵ' error and a failure probability δ' in the supervised setting (recall that Q is the set of candidate centers). We further show that our algorithm can be easily adapted to k-median and other similar problems that use the ℓ'th power of distances in place of squared distances for some fixed

$\ell > 0$. We formally present this result as Theorem 6 in Section 3. In Theorem 1 below, we give an informal statement for the case of k-means.

▶ **Theorem 1** (An informal version of Theorem 6). *There exists a semi-supervised learning algorithm that, given a k-means instance, oracle access to same-cluster queries that are consistent with some fixed optimal clustering, and parameters $(\epsilon, \delta) \in (0,1)^2$, outputs a clustering that, with probability at least $(1-\delta)$, correctly labels (up to a permutation of the labels) at least a $(1-\epsilon)$ fraction of the points and, simultaneously, has a cost of at most $(1+\epsilon)$ times the optimal cost. In doing so, the algorithm makes $O((k^2 \log n) \cdot m(Q, \epsilon^4, \delta/(k \log n)))$ same-cluster queries.*

Our algorithm is general and applicable to any family of k-means, k-median, or similar distance based clustering instances that can be efficiently learned with PAC learning. As discussed later in this work, these include Euclidean and general finite metric space clustering instances. In contrast, both Ashtiani et al. [3] and Ailon et al. [2], considered only the Euclidean k-means problem. To the best of our knowledge, ours is the first such result applicable to finite metric space k-means and both Euclidean and finite metric space k-median problems.

Ideally, we want $m(Q, \epsilon, \delta)$ to be small. Additionally, the analysis of our algorithm relies on two natural properties of learning algorithms. Firstly, we require PAC learning to always correctly label all the sampled points. Secondly, we also require it to not 'invent' new labels and only output labels that it has seen on the samples. We show that such learning algorithms with small $m(Q, \epsilon, \delta)$ exist both for k-means instances in Euclidean space and for those in finite metric spaces with no points on the boundaries of the optimal clusters. For r-dimensional Euclidean k-means, $m(Q = \mathbb{R}^r, \epsilon, \delta)$ has a linear dependency on r. For the case of finite metric spaces, $m(Q, \epsilon, \delta)$ has a logarithmic dependency on $|Q|$, which is the size of the set of candidate centers. In fact, these learning algorithms are applicable not only to k-means instances but also to instances of other similar center-based clustering problems (where clusters are defined by assigning points to their closest cluster centers). We discuss our learning algorithms in detail in the full version of this paper.

Our semi-supervised learning algorithm is inspired by the work of Feldman et al. [9] on weak coresets. Their construction of the weak coresets first obtains an intermediate clustering using a constant-factor approximation algorithm and refines each intermediate cluster by taking random samples. In order to get a good guarantee for the cost, their algorithm partitions each cluster into an inner ball that contains the majority of the points, and an outer region that contains the remaining points. We proceed similarly to this construction; however, we further partition the outer region into $O(\log n)$ concentric rings and use PAC learning to label the points in the inner ball and in each of the outer rings separately. For Euclidean k-means instances, the number of same-cluster queries needed by the algorithm has a logarithmic dependency on the number n of points, which is similar (up to a $\text{poly}(\log \log n)$ factor) to that of the algorithm by Ashtiani et al. [3]. The advantage of our algorithm is that it works for a much broader range of k-means instances whereas the applicability of the algorithm of Ashtiani et al. [3] is restricted to those instances whose clusters are contained in well-separated balls in Euclidean space.

This algorithm is effective in many natural scenarios where the number of clusters k is larger than $\log n$. However, as the size of the k-means instance (i.e., the number of points) becomes large, the $\log n$ factor becomes undesirable. In Euclidean k-means, the number of samples needed by the learning algorithm for an ϵ error and a failure probability δ does not depend on n. The $\log n$ dependency in the final query complexity is exclusively due to repeating the PAC learning step on $\Omega(k \log n)$ different partitions of P. To overcome

this problem, we present a second algorithm, which is applicable only to Euclidean k-means instances, inspired by the work of Ailon et al. [2]. This time, we start with a $(1+\epsilon)$-approximation for the cost and refine it using PAC learning. Unlike our first algorithm, we only run the PAC learning once on the whole input, and thus we completely eliminate the dependency on n. The disadvantages of this algorithm compared to our first algorithm are the slightly more involved nature of the algorithm and the increased dependency on k in its query complexity. Theorem 2 below formally states this result. We present our algorithm in Section 4 and discuss the key ideas that lead to its construction. The complete proof of Theorem 2 is given in the full version.

▶ **Theorem 2.** *There exists a polynomial-time algorithm that, given a k-means instance in r-dimensional Euclidean space, oracle access to same-cluster queries that are consistent with some fixed optimal clustering, and parameters $(\epsilon, \delta) \in (0,1)^2$, outputs a clustering that, with probability at least $(1-\delta)$, correctly labels (up to a permutation of the labels) at least a $(1-\epsilon)$ fraction of the points and, simultaneously, has a cost of at most $(1+\epsilon)$ times the optimal cost. The algorithm makes $O(k^4/(\epsilon^2\delta) + (k^9/\epsilon^4)\log(1/\delta) + k \cdot m(\mathbb{R}^r, \epsilon^4/k, \delta))$ same-cluster queries.*

For the Euclidean setting, the query complexities of both our algorithms have a linear dependency on the dimension of the Euclidean space. The algorithm of Ashtiani et al. [3] does not have such a dependency due to their strong assumption on the cluster structure, whereas the one by Ailon et al. [2] does not have that as it only approximates the cost. We show that, in our scenario, such a dependency is necessary to achieve the accuracy guarantees of our algorithms. For the finite metric space k-means, the query complexity of our general algorithm has an $O(\text{poly}(\log|P|, \log|Q|))$ dependency. The dependency on $|P|$ comes from the repeated application of the learning algorithm on $\Omega(k \log|P|)$ different partitions, and whether we can avoid this is an open problem. However, we show that an $\Omega(\log|Q|)$ query complexity is necessary for the accuracy. We formalize these results in Theorem 3 below (the proof is in the full version).

▶ **Theorem 3.** *Let K be a family of k-means instances. Let $\mathcal{A}$ be an algorithm that, given a k-means instance in K, oracle access to same-cluster queries for some fixed optimal clustering, and parameters $(\epsilon, \delta) \in (0,1)^2$, outputs a clustering that, with probability at least $(1-\delta)$, correctly labels (up to a permutation of the cluster labels) at least a $(1-\epsilon)$ fraction of the points. Then, the following statements hold:*

1. *If K is the family of k-means instances in r-dimensional Euclidean space that have no points on the boundaries of optimal clusters, $\mathcal{A}$ must make $\Omega(r)$ same-cluster queries.*
2. *If K is the family of finite metric space k-means instances that have no points on the boundaries of optimal clusters, $\mathcal{A}$ must make $\Omega(\log|Q|)$ same-cluster queries.*

The outline of this extended abstract is as follows. In Section 2 we introduce the notation, formulate the problem and present the learning theorems that we use in the subsequent sections. In Section 3 we present our first algorithm, which is simple and applicable to general k-means instances that admit efficient learning algorithms, but has a dependency of $\log n$ in its query complexity. Finally, in Section 4 we discuss how to remove the $\log n$ dependency in the query complexity for the special case of Euclidean k-means instances and present our second algorithm.

In the full version, we present formal proofs of all the stated results, where we also introduce the basic concepts and tools of PAC learning and explain how to design learning algorithms for Euclidean and finite metric space k-means instances.

2 Preliminaries

In this section, we introduce the basic notation and two common families of k-means instances, and formally define the k-means problem that we address in this work. We also introduce the notion of *learnability* for families of k-means instances and state two learning theorems that will be used in the later sections.

2.1 k-Means Problem in a Semi-supervised Setting

Let P and Q be two sets of points where $|P| = n$, and let $\mathrm{d} : (P \cup Q) \times (P \cup Q) \to \mathbb{R}_+$ be a distance metric. We denote a k-means instance by the triple (P, Q, d). Two common families of k-means instances we consider in this work are:

1. k-means instances in Euclidean space, where $P \subset \mathbb{R}^r$, $Q = \mathbb{R}^r$, and $\mathrm{d}(x_1, x_2) = \|x_1 - x_2\|$ is the Euclidean distance between x_1 and x_2, and
2. k-means instances in finite metric spaces, where $(P \cup Q, \mathrm{d})$ forms a finite metric space.

Let $[k] := \{1, \ldots, k\}$. We identify a k-clustering $\mathcal{C}$ of (P, Q, d) by a labeling function $f_{\mathcal{C}} : P \to [k]$, and a set of k centers, $c_1, \ldots, c_k \in Q$, associated with each label, $1, \ldots, k$. For each label $i \in [k]$ of a clustering $\mathcal{C}$, let $C_i := \{p \in P : f_{\mathcal{C}}(p) = i\}$ be the set of points whose label is i. For convenience, we may use the labeling function $f_{\mathcal{C}}$ or the set of clusters $\{C_1, \ldots, C_k\}$ interchangeably to denote a clustering $\mathcal{C}$.

For a subset $C \subseteq P$ and a point $q \in Q$, define $\mathrm{cost}(C, q) := \sum_{p \in C} \mathrm{d}^2(p, q)$. For each i, define center $c_i := \mathrm{argmin}_{q \in Q} \mathrm{cost}(C_i, q)$, i.e., each center is a point in Q that minimizes the sum of squared distances between itself and each of the points assigned to it. For a k-clustering $\mathcal{C}$, we define its *k-means cost* as $\mathrm{cost}(\mathcal{C}) := \sum_{i \in [k]} \mathrm{cost}(C_i, c_i)$. Let $\mathcal{C}^*$ be the set of all k-clusterings of (P, Q, d). Then, the optimal k-means cost of (P, Q, d) is defined as $OPT := \min_{\mathcal{C} \in \mathcal{C}^*} \mathrm{cost}(\mathcal{C})$. We say that a k-clustering $\mathcal{C}$ α-approximates the k-means cost if $\mathrm{cost}(\mathcal{C}) \leq \alpha OPT$.

Let $\mathcal{O}$ be a fixed k-clustering of (P, Q, d) that achieves the optimal k-means cost, and let $\mathcal{C}$ be any k-clustering of P. Let $f_{\mathcal{O}}$ and $f_{\mathcal{C}}$ be the labeling functions that correspond to $\mathcal{O}$ and $\mathcal{C}$ respectively. We assume that we have oracle access to the labeling function $f_{\mathcal{O}}$ of the optimal target clustering up to a permutation of the labels. We can simulate a single query to such an oracle with $O(k)$ queries to a same-cluster oracle (see the full version for details). A same-cluster oracle is an oracle that answers *same-cluster*(p_1, p_2) queries with 'yes' or 'no' based on whether p_1 and p_2 belong to the same cluster in the fixed optimal clustering $\mathcal{O}$.

The error of a clustering $\mathcal{C}$ with respect to the clustering $\mathcal{O}$ for a k-means instance (P, Q, d) is now defined as $\mathrm{error}(\mathcal{C}, \mathcal{O}) := \min_{\sigma} |\{p \in P : f_{\mathcal{O}}(p) \neq \sigma(f_{\mathcal{C}}(p))\}|$, where the minimization is over all permutations $\sigma : [k] \to [k]$. In other words, $\mathrm{error}(\mathcal{C}, \mathcal{O})$ is the minimum number of points incorrectly labeled by the clustering $\mathcal{C}$ with respect to the optimal clustering $\mathcal{O}$, considering all possible permutations of the cluster labels. The reason for defining error in this manner is because we use a simulated version of $f_{\mathcal{O}}$ (which is only accurate up to a permutation of the cluster labels) instead of the true $f_{\mathcal{O}}$ to learn cluster labels. We say that a k-clustering $\mathcal{C}$ is $(1 - \alpha)$-accurate with respect to $\mathcal{O}$ if $\mathrm{error}(\mathcal{C}, \mathcal{O}) \leq \alpha n$.

Given (P, Q, d), parameters k and $(\epsilon, \delta) \in (0, 1)^2$, and oracle access to $f_{\mathcal{O}}$, our goal is to output a k-clustering $\hat{\mathcal{O}}$ of (P, Q, d) that, with probability at least $(1 - \delta)$, satisfies $\mathrm{error}(\hat{\mathcal{O}}, \mathcal{O}) \leq \epsilon n$ and $\mathrm{cost}(\hat{\mathcal{O}}) \leq (1 + \epsilon) OPT$.

2.2 PAC Learning for k-Means

Let K be a family of k-means instances, and let $m(Q, \epsilon, \delta)$ be a positive integer-valued function. We say such a family K is *learnable* with *sample complexity* m if there exists a learning algorithm $\mathcal{A}_L$ such that the following holds: Let $\epsilon \in (0,1)$ be an error parameter and let $\delta \in (0,1)$ be a probability parameter. Let (P, Q, d) be a k-means instance that belongs to K. Let $\mathcal{O}$ be a fixed optimal k-means clustering and let $f_{\mathcal{O}}$ be the associated labeling function. Let T be a fixed subset of P, and let S be a multiset of at least $m(Q, \epsilon, \delta)$ independently and uniformly distributed samples from T. The algorithm $\mathcal{A}_L$, given input (P, Q, d) and $(s, f_{\mathcal{O}}(s))$ for all $s \in S$, outputs a function $h : P \to [k]$. Moreover, with probability at least $(1-\delta)$ over the choice of S, the output h agrees with $f_{\mathcal{O}}$ on at least a $(1-\epsilon)$ fraction of the points in T (i.e., $|\{p \in T : h(p) = f_{\mathcal{O}}(p)\}| \geq (1-\epsilon)|T|$). This simpler notion of learnability is sufficient for the purpose of this work although it deviates from that of the general PAC learnability, which concerns with samples drawn from arbitrary distributions.

We say that such a learning algorithm $\mathcal{A}_L$ has the *zero sample error* property if the output h of $\mathcal{A}_L$ assigns the correct label to all the sampled points (i.e., $h(s) = f_{\mathcal{O}}(s)$ for all $s \in S$). Furthermore, we say that such a learning algorithm $\mathcal{A}_L$ is *non-inventive* if it does not 'invent' labels that it has not seen. This means that the output h of $\mathcal{A}_L$ does not assign labels that were not present in the input (sample, label) pairs (i.e., if $h(x) = c$ for some $x \in P$, then for some sample point $s \in S$, $f_{\mathcal{O}}(s) = c$).

In Section 3, we present a simple algorithm for $(1+\epsilon)$-approximate and $(1-\epsilon)$-accurate k-means clustering for a family K of k-means instances, assuming that K is learnable with a zero sample error, non-inventive learning algorithm. In the analysis, zero sample error and non-inventive properties play a key role in the crucial step of bounding the cost of incorrectly labeled points in terms of that of correctly labeled nearby points.

We now present two learning theorems for the Euclidean setting and the finite metric space setting (see the full version for the proofs). Assuming no point lies on cluster boundaries, the theorems state that the labeling function $f_{\mathcal{O}}$ of the optimal clustering is learnable with a zero sample error, non-inventive learning algorithm in both settings. We say that a k-means instance (P, Q, d) has *no boundary points* if in any optimal clustering $\mathcal{O}$ with clusters $O_1, \ldots, O_k$ and respective centers $o_1, \ldots, o_k$, the closest center to any given point $p \in P$ is unique (i.e., if $p \in O_i$, $\mathrm{d}(p, o_i) < \mathrm{d}(p, o_j)$ for all $j \neq i$).

▶ **Theorem 4** (Learning k-Means in Euclidean Space). *Let* $\mathrm{d}(p_1, p_2) = \|p_1 - p_2\|$ *be the Euclidean distance function. Let* $K = \{(P, \mathbb{R}^r, \mathrm{d}) : P \subset \mathbb{R}, |P| < \infty, (P, \mathbb{R}^r, \mathrm{d})$ *has no boundary points*$\}$ *be the family of* k*-means instances that are in* r*-dimensional Euclidean space and that have no boundary points. The family* K *is learnable with sample-complexity*[1] $m(\mathbb{R}^r, \epsilon, \delta) = \tilde{O}((k^2 r \log(k^2 r)(\log(k^3 r/\epsilon)) + \log(1/\delta))/\epsilon)$.

▶ **Theorem 5** (Learning k-Means in Finite Metric Spaces). *Let* $K = \{(P, Q, \mathrm{d}) : (P \cup Q, \mathrm{d})$ *is a finite metric space, and* (P, Q, d) *has no boundary points*$\}$ *be the family of finite metric space* k*-means instances that have no boundary points. The family* K *is learnable with sample-complexity*[2] $m(Q, \epsilon, \delta) = \tilde{O}((k^2(\log k)(\log |Q|)(\log k + \log 1/\epsilon) + \log(1/\delta))/\epsilon)$.

3 A Simple Algorithm for $(1+\epsilon)$ Cost and $(1-\epsilon)$ Accuracy

Let K be a family of k-means instances that is learnable with sample complexity m using a zero sample error, non-inventive learning algorithm $\mathcal{A}_L$. Let $\mathcal{A}_\alpha$ be a constant-factor approximation algorithm (in terms of cost) for k-means, and let $\mathcal{A}_1$ be a polynomial-time algorithm for the 1-means problem (i.e., given $(P, Q, \mathrm{d}) \in K$, $\mathcal{A}_1$ finds $\operatorname{argmin}_{q \in Q} \operatorname{cost}(P, q)$ in polynomial time). We present a simple semi-supervised learning algorithm that, given a k-means instance (P, Q, d) of class K and oracle access to the labeling function $f_{\mathcal{O}}$ of a fixed optimal clustering $\mathcal{O}$ of (P, Q, d), outputs a clustering $\hat{\mathcal{O}}$ that, with probability at least $(1-\delta)$, satisfies $\operatorname{cost}(\hat{\mathcal{O}}) \leq (1+\epsilon)OPT$ and $\operatorname{error}(\hat{\mathcal{O}}, \mathcal{O}) \leq \epsilon|P|$. Our algorithm uses $\mathcal{A}_\alpha$, $\mathcal{A}_1$, and $\mathcal{A}_L$ as subroutines and makes $O((k \log |P|) \cdot m(Q, \epsilon^4, \delta/(k \log |P|)))$ oracle queries. We show that our algorithm can be easily modified for $(1+\epsilon)$-approximate and $(1-\epsilon)$-accurate k-median and other similar distance-based clustering problems. Towards the end of this section, we discuss several applications of this result, namely, for Euclidean and finite metric space k-means and k-median problems.

Let us start by applying the learning algorithm $\mathcal{A}_L$ to learn all the cluster labels. If we get perfect accuracy, the cost will be optimal. A natural question to ask in this case is: what happens to the cost if the learning output has ϵ error? In general, even a single misclassified point can incur an arbitrarily large additional cost. To better understand this, consider the following: Let $O_i, O_j \subseteq P$ be two distinct optimal clusters in the target clustering, and let o_i, o_j be their respective cluster centers. Let $p \in O_i$ be a point that is incorrectly classified and assigned label $j \neq i$ by $\mathcal{A}_L$. Also assume that the number of misclassified points is small enough so that the centers of the clusters output by the learning algorithm are close to those of the optimal clustering. Thus, in the optimal clustering, p incurs a cost of $\mathrm{d}^2(p, o_i)$, whereas according to the learning outcome, p incurs a cost that is close to $\mathrm{d}^2(p, o_j)$. In the worst case, $\mathrm{d}(p, o_j)$ can be arbitrarily larger than $\mathrm{d}(p, o_i)$.

Now suppose that, within distance ρ from p, there exists some point $q \in O_j$. In this case, we can bound the cost incurred due to the erroneous label of p using the true cost of p in the target clustering. To be more specific, using the triangle inequality, we get the following bound for any metric space: $\mathrm{d}(p, o_j) \leq \mathrm{d}(p, q) + \mathrm{d}(q, o_j) \leq \rho + \mathrm{d}(q, o_j)$. Furthermore, due to the optimality, $\mathrm{d}(q, o_j) \leq \mathrm{d}(q, o_i) \leq \mathrm{d}(q, p) + \mathrm{d}(p, o_i) \leq \rho + \mathrm{d}(p, o_i)$. Hence, it follows that $\mathrm{d}(p, o_j) \leq 2\rho + \mathrm{d}(p, o_i)$. To utilize this observation in an algorithmic setting, we need to make sure that, for every point that is misclassified into cluster j, there exists a correctly classified nearby point q that belongs to the optimal cluster O_j. Luckily, this is ensured by the combination of zero sample error and non-inventive properties of $\mathcal{A}_L$. If a point is misclassified into cluster j, the non-inventive property says that $\mathcal{A}_L$ must have seen a sample point q from cluster j. The zero sample error property ensures that q is labeled correctly by $\mathcal{A}_L$. To make sure that such correctly labeled points are sufficiently close to their incorrectly labeled counterparts, we run $\mathcal{A}_L$ separately on certain suitably bounded partitions of P.

The formal description of our algorithm is given in Algorithm 1. The outline is as follows: First, we run $\mathcal{A}_\alpha$ on (P, Q, d) and obtain an intermediate clustering $\mathcal{C} = \{C_1, \ldots, C_k\}$. For each C_i, we run $\mathcal{A}_1$ to find a suitable center c_i. Next, we partition each intermediate cluster C_i into an inner ball and $O(\log |P|)$ outer rings centered around c_i. We run the learning algorithm $\mathcal{A}_L$ separately on each of these partitions. We choose the inner and outer radii of the rings so that, in each partition, the points that are incorrectly classified by the learning algorithm only incur a small additional cost compared to that of the correctly classified points. The final output is a clustering $\hat{\mathcal{O}}$ that is consistent with the learning outputs on each of the partitions. For each cluster $\hat{O}_i$, we associate the output of running $\mathcal{A}_1$ on $(\hat{O}_i, Q, \mathrm{d})$ as

Algorithm 1: A simple algorithm for $(1+\epsilon)$-approximate $(1-\epsilon)$-accurate k-means.

Input : k-Means instance (P, Q, d), oracle access to $f_{\mathcal{O}}$, constant-factor approximation algorithm $\mathcal{A}_\alpha$ for k-means, 1-means algorithm $\mathcal{A}_1$, learning algorithm $\mathcal{A}_L$ with sample complexity m, accuracy parameter $0 < \epsilon < 1$, and failure probability $0 < \delta < 1$.

Output : The clustering $\hat{\mathcal{O}} = \{\hat{O}_1, \ldots, \hat{O}_k\}$ defined by the labeling $f_{\hat{\mathcal{O}}} : P \to [k]$ computed below. The respective cluster centers are $\hat{o}_i = \operatorname{argmin}_{q \in Q} \operatorname{cost}(\hat{O}_i, q)$, which can be found by running $\mathcal{A}_1$ on $(\hat{O}_i, Q, \mathrm{d})$.

1 Let $n = |P|$, and let $\gamma = \epsilon^2/(288\alpha)$.
2 Run $\mathcal{A}_\alpha$ and obtain an α-approximate k-means clustering $\mathcal{C} = \{C_1, \ldots, C_k\}$. For each $i \in [k]$, run $\mathcal{A}_1$ on (C_i, Q, d) and find centers $c_i = \operatorname{argmin}_{q \in Q} \operatorname{cost}(C_i, q)$.
3 **for** $C_i \in \mathcal{C}$ **do**
4 Let $r_i = \sqrt{\operatorname{cost}(C_i, c_i)/(\gamma |C_i|)}$.
5 Let $C_{i,0}$ be all points in C_i that are at most r_i away from c_i.
6 Let $C_{i,j}$ be the points in C_i that are between $2^{j-1} r_i$ and $2^j r_i$ away from c_i for $j = 1, \ldots, (\log n)/2$.
7 Let $m' = m(Q, \gamma^2, \delta/(k \log n))$.
8 **for** *each non-empty* $C_{i,j}$ **do**
9 Sample m' points $x_1, \ldots, x_{m'} \in C_{i,j}$ independently and uniformly at random.
10 Query the oracle on $x_1, \ldots, x_{m'}$ and let $S_{i,j} = \{(x_i, f_{\mathcal{O}}(x_i)) : i = 1, \ldots, m'\}$.
11 Run $\mathcal{A}_L$ on input (P, Q, d) and $S_{i,j}$, and obtain a labeling $h_{i,j} : C_{i,j} \to [k]$.
12 Output the clustering $\hat{\mathcal{O}}$ defined by the following labeling function:
13 **for** *each* i, j, $x \in C_{i,j}$ **do**
14 Set $f_{\hat{\mathcal{O}}}(x) = h_{i,j}(x)$.

its center. Note that, due to the accuracy requirements, the cluster center to which a point is assigned in the output may not be the cluster center closest to that point in the output. It remains an interesting problem to find an accurate clustering in which every point is always assigned to its nearest cluster center.

With probability at least $(1-\delta)$, Algorithm 1 outputs a $(1+\epsilon)$-approximately optimal, $(1-\epsilon)$-accurate k-means clustering (the complete analysis is in the full version). In Algorithm 1, instead of an exact algorithm $\mathcal{A}_1$ for the 1-means problem, we can also use a PTAS. Using a PTAS to approximate 1-means up to a $(1+\epsilon)$ factor will only cost an additional $(1+\epsilon)$ factor in our cost analysis. As a result, we get the same approximation and accuracy guarantees if we replace ϵ with $\epsilon/3$.

Algorithm 1 makes $O((k \log n) \cdot m(Q, \epsilon^4, \delta/(k \log n)))$ queries to the oracle $f_{\mathcal{O}}$ in total. Recall that simulating an oracle query to $f_{\mathcal{O}}$ takes $O(k)$ same-cluster queries. Therefore, the total number of same-cluster queries is $O((k^2 \log n) \cdot m(Q, \epsilon^4, \delta/(k \log n)))$.

Our definition of a learning algorithm in Section 2.2 has nothing to do with whether the input is a k-means instance or a k-median instance, which is similar to k-means except that the cost of a cluster C with respect to a center q is defined as $\operatorname{cost}(C, q) := \sum_{p \in C} \mathrm{d}(p, q)$. In fact, it applies to any similar clustering scenario where the cost is defined in terms of the ℓ'th power ($\ell > 0$) of distances instead of squared distances. The analysis of Algorithm 1 can be adapted to any fixed ℓ once we have a suitable triangle inequality. (For example, in k-means (i.e., when $\ell = 2$), we use $(a+b)^2 \le (1+\epsilon)a^2 + (1+1/\epsilon)b^2$. When $\ell \le 1$, we can simply use the trivial triangle inequality $(a+b)^\ell \le a^\ell + b^\ell$.) Thus, for such clustering problems, Algorithm 1, with a slight modification on choice of radii in Step 4 and a little adjustment to the parameter γ, will give the same guarantees. Hence, we have the following theorem which is the formal version of Theorem 1. The proof follows from the analysis of Algorithm 1.

▶ **Theorem 6.** *Let K be a family of k-means (k-median) instances. Suppose that K is learnable with sample complexity $m(Q, \epsilon, \delta)$ using a zero sample error, non-inventive learning*

algorithm $\mathcal{A}_L$. Let $\mathcal{A}_\alpha$ be a constant-factor approximation algorithm, and let $\mathcal{A}_1$ be a PTAS for the 1-means (1-median) problem. There exists a polynomial-time algorithm that, given an instance $(P, Q, \mathrm{d}) \in K$, oracle access to same-cluster queries for some fixed optimal clustering $\mathcal{O}$, and parameters $(\epsilon, \delta) \in (0,1)^2$, outputs a clustering that, with probability at least $(1-\delta)$, is $(1-\epsilon)$-accurate with respect to $\mathcal{O}$, and simultaneously has a cost of at most $(1+\epsilon)OPT$. The algorithm uses $\mathcal{A}_L$, $\mathcal{A}_\alpha$, and $\mathcal{A}_1$ as subroutines. The number of same-cluster queries made by the algorithm is

1. $O((k^2 \log |P|) \cdot m(Q, \epsilon^4, \delta/(k \log |P|)))$ *for the k-means setting and*
2. $O((k^2 \log |P|) \cdot m(Q, \epsilon^2, \delta/(k \log |P|)))$ *for the k-median setting.*

For k-means and k-median instances in Euclidean space and those in finite metric spaces, there exist several constant-factor approximation algorithms (for example, Ahmadian et al. [1] and Kanungo et al. [13]). Solving the 1-means problem in Euclidean space is straightforward: The solution to $\operatorname{argmin}_{q \in \mathbb{R}^r} \operatorname{cost}(P, q)$ is simply $q = (\sum_{p \in P} p)/|P|$. For the k-median problem in Euclidean space, the problem of 1-median does not have an exact algorithm but several PTASes exist (for example, Cohen et al. [6]). In a finite metric space, to solve $\operatorname{argmin}_{q \in Q} \operatorname{cost}(P, q)$, we can simply try all possible $q \in Q$ in polynomial time, and this holds for the k-median setting as well. Thus, for Euclidean and finite metric space k-means and k-median instances that have no boundary points, Theorem 6, together with Theorem 4 and Theorem 5, gives efficient algorithms for $(1+\epsilon)$-approximate, $(1-\epsilon)$-accurate semi-supervised clustering.

4 Removing the Dependency on Problem Size in the Query Complexity for Euclidean k-Means

For the family of Euclidean k-means instances, the query complexity of Algorithm 1 suffers from a $\tilde{O}(\log n)$ dependency (where n is the number of points in the input k-means instance, and $\tilde{O}$ hides $\operatorname{poly}(\log \log n)$ factors) due to the repeated use of the learning algorithm $\mathcal{A}_L$. Specifically, we run $\mathcal{A}_L$ with a failure probability of $\delta/(k \log n)$, $O(\log n)$ times per cluster. Note that the sample complexity of $\mathcal{A}_L$ itself, in the case of Euclidean k-means instances, does not have this dependency.

In this section, we show that we can avoid this dependency on n using a slightly more involved algorithm at the cost of increasing the query complexity by an extra $\operatorname{poly}(k)$ factor. Nevertheless, this algorithm has superior performance when the size of the input instance (i.e., the number of points) is very large (when $\log n = \Omega(k^{10})$ for example).

Recall that, for a set $C \subset \mathbb{R}^r$, $\operatorname{cost}(C, y)$ is minimized when y is the centroid of C, denoted by $\mu(C) = (\sum_{x \in C} x)/|C|$. Define the fractional size of an optimal cluster O_i as the fraction of points that belong to O_i, i.e., the ratio $|O_i|/n$. Suppose we only want to get a good approximation for the cost, and that we know that all the clusters in the target solution have sufficiently large fractional sizes. In this case, naive uniform sampling will likely pick a large number of samples from each of the clusters. This observation, together with Lemma 7, allows us to approximate the centroid and the cost of each cluster to any given accuracy.

▶ **Lemma 7** (Lemma 1 and Lemma 2 of Inaba et al. [12]). *Let $(\epsilon, \delta) \in (0,1)^2$, let $m \geq 1/(\epsilon\delta)$ be a positive integer, and let $S = \{p_1, \ldots, p_m\}$ be a multiset of m i.i.d. samples from the uniform distribution over some finite set $C \subset \mathbb{R}^r$. With probability at least $(1-\delta)$, $\mathrm{d}^2(\mu(S), \mu(C)) \leq \epsilon \cdot \operatorname{cost}(C, \mu(C))/|C|$ and $\operatorname{cost}(C, \mu(S)) \leq (1+\epsilon) \operatorname{cost}(C, \mu(C))$.*

However, the above approach fails when some clusters in the optimal target solution contribute significantly to the cost, but have small fractional sizes (that is because uniform

sampling is not guaranteed to pick sufficient numbers of samples from the small clusters). Ailon et al. [2] circumvented this issue with an algorithm that iteratively approximates the centers of the clusters using a distance-based probability distribution (D^2-sampling). We will refer to their algorithm as $\mathcal{A}^*$.

Note that when it comes to accuracy, we can totally disregard clusters with small fractional sizes; we only have to correctly label a sufficiently large fraction of the points in large clusters. With this intuition, we present the outline of our algorithm.

Let $(P, \mathbb{R}^r, \mathrm{d})$ be a k-means instance in Euclidean space that has no boundary points. For simplicity, we refer to the instance $(P, \mathbb{R}^r, \mathrm{d})$ by just P where possible, as for Euclidean k-means, the other two parameters are fixed. We start with a naive uniform sampling step that gives a good approximation for the centers of large clusters. Starting with these centers, we run a slightly modified version of algorithm $\mathcal{A}^*$ to approximate the centers of the remaining small clusters. Thus, at this point, we have a clustering with a good cost and we know which clusters are large. We now run the learning algorithm $\mathcal{A}_L$ on input P and obtain a labeling of the points. For each point, we assign its final label based on (1) the label assigned to it by the learning algorithm $\mathcal{A}_L$, and (2) its proximity to large cluster centers. In particular, if the output of $\mathcal{A}_L$ decides that a point p should be in some large cluster i, and if p is sufficiently close to the approximate center for cluster i, we label it according to the learning output; otherwise, we label it according to its nearest approximate center. We show that this approach retains a cost that is close to the cost of the clustering output by $\mathcal{A}^*$. The accuracy guarantee comes from the facts that a large fraction of the points are sufficiently close to the centers of large clusters, and that $\mathcal{A}_L$ labels most of them correctly with a good probability.

We now review the key properties of algorithm $\mathcal{A}^*$ (the algorithm of Ailon et al. [2]). Let $0 < \epsilon < 1$. We say a k-means instance P is (k, ϵ)-irreducible if no $(k-1)$-means clustering gives an $(1+\epsilon)$-approximation for the k-means problem, i.e., if OPT^k denotes the optimal k-means cost of P, then P is (k, ϵ)-irreducible if $OPT^{k-1} > (1+\epsilon)OPT^k$. Suppose that P is (k, ϵ)-irreducible. Let $\mathcal{O} = \{O_1, \ldots, O_k\}$ be the target optimal clustering, and let $o_1, \ldots, o_k$ be the respective centers. Let $C_i = \{c_1, \ldots, c_i\}$ denote a set of i centers and let $Z(i)$ denote the following statement: There exists a set of i distinct indices $j_1, \ldots, j_i$ such that, for all $r \in [i]$, $\mathrm{cost}(O_{j_r}, c_r) \leq (1 + \epsilon/16)\,\mathrm{cost}(O_{j_r}, o_{j_r})$. To put it differently, $Z(i)$ says that C_i is a set of good candidate centers for i-many distinct clusters in the target optimal solution. Assuming P is (k, ϵ)-irreducible, the algorithm $\mathcal{A}^*$ yields a method to incrementally construct sets $C_1, \ldots, C_k$ (i.e., $C_{i+1} = C_i \cup \{c_{i+1}\}$) such that, conditioned on $Z(i)$ being true, $Z(i+1)$ is true with probability at least $(1 - 1/k)$. Now suppose that P is $(k, \epsilon/(4k))$-irreducible. Then $\mathcal{A}^*$ gives a $(1+\epsilon/(4 \cdot 16k))$-approximation for k-means with probability at least $(1-1/k)^k \geq 1/4$. Otherwise, $\mathcal{A}^*$ gives a $(1+\epsilon/(4 \cdot 16k))$-approximation for the i-means problem for some $i < k$, where i is the largest integer such that P is $(i, \epsilon/4k)$-irreducible. In the latter case, it will give a $(1 + \epsilon/(4 \cdot 16k))(1 + \epsilon/(4k))^{k-i}$-approximation with probability at least $1/4$. In either case, the output of $\mathcal{A}^*$ is a $(1+\epsilon)$-approximation.

In our algorithm, we first find the centers of large clusters using uniform sampling, and then run $\mathcal{A}^*$ to find the remaining centers. This allows us to know which clusters are large, which is a crucial information needed for the final labeling. Suppose that in the target optimal solution we have $k_0 \leq k$ clusters whose fractional sizes are at least ϵ/k. Note that k_0 is at least 1 due to the Pigeonhole Principle, since at least one cluster should have a fractional size of at least $1/k > \epsilon/k$. By Lemma 7, using uniform sampling, we can approximate the centroid of each of these large clusters with a good accuracy. Hence, we can have a set C_{k_0} of k_0 centers such that $Z(k_0)$ is true with probability $(1 - \delta)$. Afterwards, we use $\mathcal{A}^*$ to

Algorithm 2: Algorithm whose query complexity is independent of n

Input : Point set $P \subset \mathbb{R}^r$, the oracle access to $f_{\mathcal{O}}$, parameter k, accuracy parameter ϵ, failure probability δ, and algorithms $\mathcal{A}_{cost}$ and $\mathcal{A}_L$.

Output : The clustering $\hat{\mathcal{O}} = \{\hat{O}_1, \ldots, \hat{O}_k\}$ defined by the labeling $f_{\hat{\mathcal{O}}} : P \to [k]$ computed below. For each $i \in [k]$, the respective cluster center $\hat{o}_i$ is the centroid of $\hat{O}_i$.

1 Draw $Q_1(k, \epsilon, \delta)$ samples from P independently and uniformly at random, and query $f_{\mathcal{O}}$ to get their true cluster labels in $\mathcal{O}$. Denote the set of sampled points by S, and for all $i \in [k]$, denote the set of sampled points that belong to class i by S_i.

2 Let k' be the number of distinct cluster labels with more than $(\epsilon/(2k))Q_1(k, \epsilon, \delta)$ samples. Let $C_{k'} := \{\mu(S_i) : |S_i| > (\epsilon/(2k))Q_1(k, \epsilon, \delta)\}$. Without loss of generality, assume that the class labels for centers in $C_{k'}$ are $1, \ldots, k'$.

3 Run the algorithm $\mathcal{A}_{cost}$, starting from $C_{k'}$ as the partial set of centers. This takes $Q_2(k, \epsilon, \delta)$ more queries. Let $C_k = \{c_1, \ldots, c_k\}$ be the output, and let OPT^* be the cost of the clustering obtained by assigning each point to its nearest c_i.

4 Use the PAC learning algorithm $\mathcal{A}_L$ on $Q_3(k, r, \epsilon^4/k, \delta)$ uniform i.i.d. samples from P to learn a classifier for the k classes that is $(1 - \epsilon^4/k)$-accurate with probability at least $(1 - \delta)$. Let $H_1, \ldots, H_k$ be the sets of points that are labeled $1, \ldots, k$ respectively by the classifier.

5 Output the clustering $\hat{\mathcal{O}}$ defined by the following labeling function: for each $i \in [k']$ and $p \in H_i$ such that $\mathrm{d}^2(p, c_i) \leq kOPT^*/(n\epsilon^3)$, set $f_{\hat{\mathcal{O}}}(p) = i$. For any other point p, set $f_{\hat{\mathcal{O}}}(p) = i$ if the nearest cluster center to p in C_k is c_i.

incrementally construct $C_{k_0+1}, \ldots, C_k$. Conditioned on $Z(k_0)$ being true, the output C_k will be a $(1 + \epsilon)$-approximation with probability $(1 - 1/k)^{k-k_0} \geq (1 - 1/k)^k \geq 1/4$ for $k \geq 2$. However, by independently running this incremental construction $O(\log(1/\delta))$ times and choosing the set of centers with the minimum total cost, we can boost this probability to $(1 - \delta)$. This observation gives the following generalization of Theorem 10 of Ailon et al. [2].

▶ **Theorem 8.** *Consider a Euclidean k-means instance $(P, \mathbb{R}^r, \mathrm{d})$. Let $O_1, \ldots, O_k$ be a fixed optimal clustering with respective centers $o_1, \ldots, o_k$. Let $k_0 \leq k$ and let $C_{k_0} = \{c_1, \ldots, c_{k_0}\}$ be a set of points such that, with probability at least p_0, $\mathrm{cost}(O_i, c_i) \leq (1 + \epsilon/(64k))\,\mathrm{cost}(O_i, o_i)$ for all $i \in [k_0]$. There exists an algorithm $\mathcal{A}_{cost}$ that, given P, C_{k_0}, and parameters $(\epsilon, \delta) \in (0, 1)^2$ as input, outputs a set of centers $C_k = C_{k_0} \cup \{c_{k_0+1}, \ldots, c_k\}$ such that $\sum_{i\in[k]} \mathrm{cost}(O_i, c_i) \leq (1 + \epsilon) \sum_{i\in[k]} \mathrm{cost}(O_i, o_i)$ with probability at least $p_0(1 - \delta)$. Moreover, $\mathcal{A}_{cost}$ uses $O((k^9/\epsilon^4)\log(1/\delta))$ same-cluster queries and runs in time $O(nr(k^9/\epsilon^4)\log(1/\delta))$.*

Theorem 8 implies a method to get a good approximation for the cost that also reveals which clusters are large. Specifically, we first perform uniform sampling over the whole set P and approximate the centers of the large clusters. If we get a sufficient number of samples, the approximate centers will satisfy the precondition of Theorem 8 with a good probability. Thus, using algorithm $\mathcal{A}_{cost}$ from Theorem 8, we get the desired approximation for the cost. What remains now is to use PAC learning and to appropriately label the points according to the learning outcome.

We present the pseudo-code of our algorithm in Algorithm 2, where we use the algorithm $\mathcal{A}_{cost}$ from Theorem 8 and the learning algorithm $\mathcal{A}_L$ guaranteed by Theorem 4. In Algorithm 2, $Q_1(k, \epsilon, \delta) = 256k^3/(\epsilon^2\delta)$ is the number of samples needed to ensure that we pick a sufficient number of samples from each of the clusters with fractional sizes of at least ϵ/k, $Q_2(k, \epsilon, \delta)$ is the sample complexity of the algorithm $\mathcal{A}_{cost}$, and $Q_3(k, r, \epsilon, \delta) = m(\mathbb{R}^r, \epsilon, \delta)$ is the sample complexity of the learning algorithm $\mathcal{A}_L$ for an error ϵ and a failure probability δ. As with Algorithm 1, the center that a point is assigned to in the final output may not be the closest center to that point.

With probability at least $(1 - \delta)$, the output of Algorithm 2 is $(1 + \epsilon)$-approximate and $(1 - \epsilon)$-accurate (refer to the full version for the complete analysis). As for the claim on the

query complexity, recall that we only need $O(k)$ same-cluster queries per single $f_{\mathcal{O}}$ query, and Algorithm 2 makes a total number of $Q_1(k,\epsilon,\delta) + Q_2(k,\epsilon,\delta) + Q_3(k,r,\epsilon^4/k,\delta)$ queries to $f_{\mathcal{O}}$. This observation together with the analysis of Algorithm 2 proves Theorem 2. We remark that the query complexity $Q_3(k,r,\epsilon^4/k,\delta)$ for learning Euclidean k-means instances is independent of P.

Abstract

We consider the problem of sketching the p-th frequency moment of a vector, $p > 2$, with multiplicative error at most $1 \pm \epsilon$ and *with high confidence* $1 - \delta$. Despite the long sequence of work on this problem, tight bounds on this quantity are only known for constant δ. While one can obtain an upper bound with error probability δ by repeating a sketching algorithm with constant error probability $O(\log(1/\delta))$ times in parallel, and taking the median of the outputs, we show this is a suboptimal algorithm! Namely, we show *optimal* upper and lower bounds of $\Theta(n^{1-2/p}\log(1/\delta) + n^{1-2/p}\log^{2/p}(1/\delta)\log n)$ on the sketching dimension, for any constant approximation. Our result should be contrasted with results for estimating frequency moments for $1 \leq p \leq 2$, for which we show the optimal algorithm for general δ is obtained by repeating the optimal algorithm for constant error probability $O(\log(1/\delta))$ times and taking the median output. We also obtain a matching lower bound for this problem, up to constant factors.

1 Introduction

The frequency moments problem is a very well-studied and foundational problem in the data stream literature. In the data stream model, an algorithm may use only sub-linear memory and a single pass over the data to summarize a data stream that appears as a sequence of incremental updates. A data stream may be viewed as a sequence of m records of the form $((i_1, v_1), (i_2, v_2), \ldots, (i_m, v_m))$, where, $i_j \in [n] = \{1, 2, \ldots, n\}$ and $v_j \in \mathbb{R}$. The record (i_j, v_j) changes the i_jth coordinate x_{i_j} of an underlying n-dimensional vector x to $x_{i_j} + v_j$. Equivalently, for $i \in [n]$, $x_i = \sum_{j:i_j=i} v_j$. Note that v_j may be positive or negative, which corresponds to the so-called turnstile model in data streams. Also, the i-th coordinate of x is sometimes referred to as the *frequency* of item i, though note that it can be negative in the turnstile model. The p-th moment of x is defined to be $F_p = \sum_{i\in[n]}|x_i|^p$, for a real number $p \geq 0$, which for $p \geq 1$ corresponds to the p-th power of the ℓ_p-norm $\|x\|_p^p$ of x.

The F_p estimation problem with approximation parameter ϵ and failure probability δ is: design an algorithm that makes one pass over the input stream and returns $\hat{F}_p$ such that $\Pr\left[|\hat{F}_p - F_p| \leq \epsilon F_p\right] \geq 1 - \delta$. Such an algorithm is also referred to as an (ϵ, δ)-approximation of F_p. This is a problem that is among the ones that has received the most attention

Table 1 Here, $g(p,n) = \min_{c \text{ constant}} g_c(n)$, where $g_1(n) = \log n$, $g_c(n) = \log(g_{c-1}(n))/(1-2/p)$. We start the upper bound timeline with [19], since that is the first work which achieved an exponent of $1-2/p$ for n. For earlier work which achieved worse exponents for n, see [1, 12, 14, 15].

F_p Algorithm	Sketching Dimension
[19]	$O(n^{1-2/p}\epsilon^{-O(1)}\log^{O(1)} n\log(1/\delta))$
[7]	$O(n^{1-2/p}\epsilon^{-2-4/p}\log n\log(M)\log(1/\delta))$
[31]	$O(n^{1-2/p}\epsilon^{-O(1)}\log^{O(1)} n\log(1/\delta))$
[3]	$O(n^{1-2/p}\epsilon^{-2-6/p}\log n\log(1/\delta))$
[8]	$O(n^{1-2/p}\epsilon^{-2-4/p}\log n\cdot g(p,n)\log(1/\delta))$
[2]	$O(n^{1-2/p}\log n\epsilon^{-O(1)}\log(1/\delta))$
[16], **Best upper bound**	$O(n^{1-2/p}\epsilon^{-2}\log(1/\delta)+n^{1-2/p}\epsilon^{-4/p}\log n\log(1/\delta))$

in the data stream literature, and we only give a partial list of work on this problem [1, 2, 3, 4, 6, 7, 8, 10, 12, 14, 15, 16, 20, 19, 25, 26, 27, 30, 31, 34].

We study the class of algorithms based on linear sketches, which store only a sketch $S \cdot x$ of the input vector x and a (possibly randomized) matrix A. This model is well-studied, both for the problem of estimating norms and frequency moments [4, 18, 30, 32], and for other problems such as estimating matrix norms [29], and matching size [5, 28]. The efficiency is measured in terms of the *sketching dimension* which is the maximum number of rows of a matrix S used by the algorithm. Since the algorithm is randomized, it may choose different S based on its randomness, so the maximum is taken over its randomness. Linear sketches are particularly useful for data streams since given an update (i_j, v_j), one can update Sx as $S(x + v_j e_{i_j}) = Sx + Sv_j e_{i_j}$, where e_{i_j} is the standard unit vector in the i_j-th direction. They are also used in distributed environments, since given $S \cdot x$ and618 $S \cdot y$, one can add these to obtain $S \cdot (x + y)$, the sketch of $x + y$.

When $0 < p \leq 2$, one can achieve a sketching dimension of $O(\epsilon^{-2}\log(1/\delta))$ independent of n [1, 25, 27], while for $p = 0$ the sketching dimension is $O(\epsilon^{-2}(\log(1/\epsilon) + \log\log n)\log(1/\delta))$ [26]. For $p = 2$ there is a sketching lower bound of $\Omega(\epsilon^{-2}\log(1/\delta))$ [24], which implies an optimal algorithm for general δ is to run an optimal algorithm with error probability $1/3$ and take the median of $O(\log(1/\delta))$ independent repetitions. As a side result, we show in the full version a lower bound of $\Omega(\epsilon^{-2}\log(1/\delta))$ for any $1 \leq p < 2$, which shows this strategy of amplifying the success probability by $O(\log 1/\delta)$ independent repetitions is also optimal for any $1 \leq p < 2$.

Perhaps surprisingly, for $p > 2$, the sketching dimension needs to be polynomial in n, as first shown in [32], with the best known lower bounds being $\Omega(n^{1-2/p}\log n)$ [4] for constant ϵ and δ, and $\Omega(n^{1-2/p}\epsilon^{-2})$ for constant δ [30]. Regarding upper bounds, we present the long list of bounds in Table 1. The best known upper bound is $O(n^{1-2/p}\epsilon^{-2}\log(1/\delta) + n^{1-2/p}\epsilon^{-4/p}\log n\log(1/\delta))$ [16]. This is tight only when ϵ and δ are constant, in which case it matches [4], or when δ is constant and $\epsilon < 1/\text{poly}(\log n)$, since it matches [30].

1.1 Our Contributions

In this work, we show *optimal* upper and lower bounds of $\Theta(n^{1-2/p}\log(1/\delta) + n^{1-2/p}\log^{2/p}(1/\delta)\log n)$ on the sketching dimension for F_p-estimation, for any $p > 2$, and for any constant ϵ. Our upper bound shows, perhaps surprisingly, that the optimal bound is *not* to run $O(\log(1/\delta))$ independent repetitions of a constant success probability algorithm and report the median of the outputs. Indeed, such an algorithm would give a worse $O(n^{1-2/p}\log(1/\delta)\log n)$ sketching dimension.

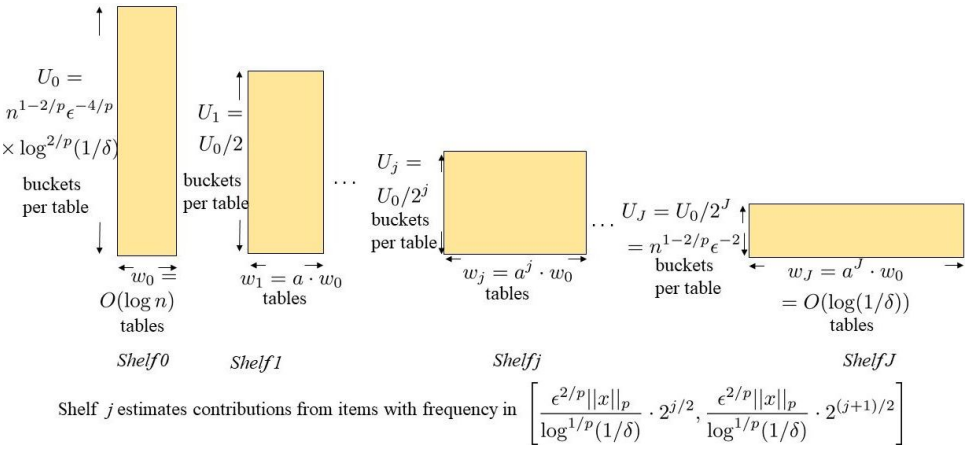

Figure 1 Shelf structure and level sets for each shelf index j whose contribution to F_p is estimated accurately.

For general ϵ, our upper bound is $O(n^{1-2/p}\epsilon^{-2}\log(1/\delta) + n^{1-2/p}\epsilon^{-4/p}\log^{2/p}(1/\delta)\log n)$ and our lower bound is $\Omega(n^{1-2/p}\epsilon^{-2}\log(1/\delta) + n^{1-2/p}\epsilon^{-2/p}\log^{2/p}(1/\delta)\log n)$, which differ by at most an $\epsilon^{-2/p}$ factor. Our results thus come close to resolving the complexity for general ϵ as well.

Our results should be contrasted to $1 \le p \le 2$, for which the optimal sketching dimension for such p is $\Theta(\epsilon^{-2}\log(1/\delta))$, and so for these p it is optimal to run $O(\log(1/\delta))$ independent repetitions of a constant probability algorithm. Here we strengthen the $\Omega(\epsilon^{-2}\log(1/\delta))$ bound for $p = 2$ of [24] by showing the same bound for $1 \le p \le 2$.

1.1.1 Overview of Upper Bound

In order to obtain a confidence of $1 - \delta$, we use the $d = \lceil \log(1/\delta) \rceil$th moment of an estimate $\hat{F}_p$ of F_p. Since we are unable to use the dth moment of the Taylor polynomial estimator of [17], we employ a different estimator X_i for estimating individual coordinates $|x_i|$ and use it as X_i^p to estimate $|x_i|^p$. This estimator is based on (a) using random qth roots of unity for sketches instead of standard Rademacher variables, and (b) taking the *average* of the estimates from those tables where the item does not collide with the set of top-k estimated heavy hitters.

The Shelf Structure. The algorithm uses two structures, namely, a GHSS-like structure from [17] and a new shelf structure , which is our main algorithmic novelty (both formally defined later). The shelf structure is necessary when the failure probability is $\delta = n^{-\omega(1)}$; otherwise, for $\delta = n^{-\Theta(1)}$, somewhat surprisingly the GHSS structure of [17] alone suffices with parameter $C = n^{1-2/p}(\epsilon^{-2}\log(1/\delta)/\log(n) + \epsilon^{-4/p}\log^{2/p}(1/\delta))$ and number of measurements $O(C\log n)$, which requires an intricate d-th moment analysis of the GHSS structure.

The shelf structure is partitioned into shelves, indexed from $j = 0, \ldots, J$, for a value J which is specified below. Each shelf consists of a pair of CountSketch like structures, HH_j and AvgEst_j. The number of buckets in the tables of the jth shelf is H_j and the number of tables in the jth shelf of the HH_j structure is w_j and of the AvgEst_j structure is $2w_j$. We set $H_J = \Theta(n^{1-2/p}\epsilon^{-2})$ and $w_J = \Theta(\log(1/\delta))$, while $H_0 = \Theta(n^{1-2/p}\epsilon^{-4/p}\log^{2/p}(1/\delta))$ and $w_0 = s = \Theta(\log n)$.

The input vector x is provided as input to all the shelves' structures. The table height $H_j = H_0 b^j$ decays geometrically with parameter $0 < b < 1$ and the table width $w_j = w_0 a^j$ increases geometrically with parameter $a > 1$. Note that the parameters a and b determine J. By requiring that $|1 - ab| = \Omega(1)$, we ensure that the total number of measurements of the shelf structure is $\sum_{j=0}^{J} H_j w_j = O(H_0 w_0 + H_J w_J)$, no matter which value of J we choose. For the shelf structure, frequency-wise thresholds are defined as $U_j = O(\hat{F}_2/H_j)^{1/2}$, for $j = 0, 1, \ldots, J$. The shelf frequency group corresponding to shelf j is $S_j = [U_j, U_{j+1})$, where, $U_{J+1} = \infty$ and $U_0 = T_0$. We sometimes conflate S_j with the set of items whose frequency belongs to S_j. The frequency group G_0 is defined as $[T_0, U_1]$ and coincides with S_0. See Figure 1.

So why a shelf structure? Suppose for simplicity that ϵ is a constant. Consider a vector x which has a constant number of "large" coordinates of value $\Theta(n^{1/p})$, and $\Theta(n)$ remaining "small" coordinates of absolute value $O(1)$. Then we need to find all the large coordinates to accurately estimate F_p up to a small constant factor. This is well-known to be possible with $\Theta(n^{1-2/p})$ buckets in the J-th shelf, since with probability $1 - \delta$, each of the large coordinates will not collide with any other large coordinate in more than a small constant fraction of tables. Note that in each table, in each bucket containing a large coordinate, the "noise" in the bucket from small coordinates will be $Cn^{1/p}$ for an arbitrarily small constant $C > 0$ with constant probability, and so this will happen in most buckets containing a large coordinate in most tables with probability $1 - \delta$.

However, now consider a vector x which has $\Theta(\log(1/\delta))$ "large-ish" coordinates of value $\Theta(n^{1/p}/\log^{1/p}(1/\delta))$, and $\Theta(n)$ remaining "small" coordinates of absolute value $O(1)$, as before. Then we again need to find most of the "large-ish" coordinates to accurately estimate F_p up to a constant factor. We also *cannot* subsample and try to estimate how many large-ish coordinates there are from a subsample. Indeed, since there are only $O(\log(1/\delta))$ total large-ish coordinates, sub-sampling would not accurately estimate this total with probability at least $1 - \delta$. However, to find these "large-ish" coordinates, we need to increase the number of buckets from $\Theta(n^{1-2/p})$ to $\Theta(n^{1-2/p} \cdot \log^{2/p}(1/\delta))$ just so that in a bucket containing one of these coordinates, with constant probability the noise will not be too large. But if we then want this to happen for a $1 - \delta$ fraction of tables, we still need $\Theta(\log(1/\delta))$ tables, which gives overall $\Theta(n^{1-2/p} \cdot \log^{1+2/p}(1/\delta))$ measurements, which is above our desired total of $O(n^{1-2/p}(\log(1/\delta) + \log(n)\log^{2/p}(1/\delta)))$ measurements.

So what went wrong? The key idea in our analysis is to relax the requirement of trying to recover all the larg-ish coordinates with probability $1 - \delta$. Suppose instead of $\Theta(\log(1/\delta))$ tables we just use $\Theta(\log n)$ tables. Then with probability $1 - 1/n$, there may be two large-ish coordinates which collide and cancel with each other in every single table, and we have no way of recovering them. However, we are able to show that with probability $1 - \delta$, only $O(\log(1/\delta)/\log n)$ large-ish coordinates will fall into this category, and neglecting this roughly $(1 - 1/\log n)$ fraction of the large-ish coordinates will not affect our estimate of F_p by more than a constant factor. And indeed, our 0-th shelf has exactly $\Theta(n^{1-2/p} \cdot \log^{2/p}(1/\delta))$ buckets and $\Theta(\log n)$ tables, so is exactly suited for finding these large-ish coordinates. In general, we can show that one of our shelves will be able to handle every vector with coordinates of magnitude between the large and large-ish coordinates. Again, by choosing the shelf structure carefully, the total number of measurements is dominated by that in the zero-th plus the J-th shelf, giving us $O(n^{1-2/p}(\log(1/\delta) + \log(n)\log^{2/p}(1/\delta)))$ total measurements, and explaining where the $\log^{2/p}(1/\delta)$ in the upper bound comes from.

The Non-Large-ish Coordinates. Our shelves are designed to estimate the contribution to F_p from all coordinates of absolute value at least $\Theta(n^{1/p}/\log^{1/p}(1/\delta))$. For coordinates of smaller value, we can now afford to sub-sample and apply the same 0-th shelf structure to estimate their contribution to F_p. We apply the GHSS structure, which is analogous to the structure presented in [17] and has $L+1$ levels corresponding to $l = 0, \ldots, L$, and consists of a pair of CountSketch like structures HH_l and AvgEst_l at each level. The sub-sampling technique and the associated frequency-wise thresholds and frequency groups are defined analogously (with new parameters) to [17].

A notable difference with [17] is that the AvgEst structures in the GHSS and shelf structures use complex qth roots of unity and return the average of table estimates instead of the median of table estimates used by CountSketch, which are novelties in this context, though have been used for other data stream problems [23]. We have that $\mathbf{E}[X_i^p] = |x_i|^p(1 \pm n^{-\Omega(1)})$ for our estimator X_i of $|x_i|$, and thus X_i^p provides a nearly unbiased estimator of $|x_i|^p$. Additionally, we use averaging in the definition of X_i instead of the median to allow for a tractable, though intricate calculation of the d-th moment of the sum of the p-th powers of X_i.

1.1.2 Overview of Lower Bounds

We give an overview for the case of constant ϵ. In both cases we start by applying Yao's minimax principle for which we fix S and then design a pair of distributions α and β which must be distinguished by an (ϵ, δ)-approximation algorithm for F_p. We can also assume the rows of S are orthonormal, since a change of basis to the row space of S can always be applied in post-processing.

Our $\Omega(n^{1-2/p}\epsilon^{-2/p}(\log^{2/p} 1/\delta)\log n)$ bound. This is our technically more involved lower bound. We first upper bound the variation distance using the χ^2-divergence as in [4] and work only with the latter. We let $\alpha = N(0, I_n)$ be an n-dimensional isotropic Gaussian distribution, while β is a distribution formed by sampling an $x \sim N(0, I_n)$, together with a random subset $T \subset [n]$ of size $O(\log(1/\delta))$, and outputting $z = x + \sum_{i \in T}(Cn^{1/p}/t^{1/p})e_i$, where e_i is the i-th standard unit vector and $C > 0$ is a constant. For $y \sim \alpha$ and $z \sim \beta$, one can show that with probability $1 - O(\delta)$, one has that $\|z\|_p^p$ is a constant factor larger than $\|y\|_p^p$, since $\|y\|_p^p$ and $\|x\|_p^p$ are concentrated at $\Theta(n)$, while $\sum_{i \in T} C^p n/t = \Theta(n)$.

A common technique in upper bounds, including our own, is the notion of subsampling, whereby a random fraction of roughly $1/2^i$ of the n coordinates are sampled, for each value of $i \in O(\log n)$, and information is then gathered for each i and combined into an overall estimate of F_p. We choose our hard distributions so that *subsampling does not help.* Indeed, if one subsamples half of the coordinates of $z \sim \beta$, with probability $\Omega(\delta)$ all of the coordinates in T will be removed, at which point z is indistinguishable from $y \sim \alpha$. Therefore, our pair of distributions suggests itself as being hard for $(\Theta(1), \delta)$-approximate F_p algorithms.

What drives our analysis is conditioning our distributions on an event $\mathcal{G}$ which only happens with probability $\Omega(\delta)$. Note that for any algorithm which can distinguish samples from α from those from β with probability at least $1 - \delta$, it must still have probability $9/10$, say, of distinguishing the distributions given an event $\mathcal{G}$ which occurs for samples drawn from β. The event $\mathcal{G}$ corresponds to every $i \in T$ having the property that the corresponding column S_i of our sketching matrix S has squared length at most $2r/n$, where r is the number of rows of S. By a Markov bound, half of the columns of S have this property, and since T has size $O(\log 1/\delta)$, with probability $\Omega(\delta)$, event $\mathcal{G}$ occurs.

We analyze the χ^2-divergence of the distributions α and β conditioned on $\mathcal{G}$. One technique helpful for this is an equality that we show in the full version, which states that for

p a distribution on $\mathbb{R}^n$, that $\chi^2(N(0,I_n)*p, N(0,I_n)) = \mathbf{E}[e^{\langle X,X'\rangle}]-1$, where X and X' are independently drawn from p. This equality was used in [4, 29, 35] among other places. In our case, the inner product of X and X' corresponds to an inner product P of two independent random sums of t columns of S, restricted to only those columns with squared length at most $2r/n$. Let the t columns forming X be denoted by T and the t columns forming X' be denoted by U.

Critical to our analysis is bounding $\mathbf{E}[P^j]$ for large powers of j, as shown in the lemma the full version. One can think of indexing the rows of S^TS by T and the columns of S^TS by U, where S^TS is an $n\times n$ matrix. Let M denote the resulting submatrix. The inner product of interest is then $e_T^TMe_U$, where $e_T=\sum_{i\in T}e_i$ and $e_U=\sum_{i\in U}e_i$.

Our bound, given in the above-referred to lemma in the full version, is very sensitive to minor changes. Indeed, if instead of showing $\mathbf{E}[P^j]\leq\left(\frac{t^2}{r^{1/2}}\right)\cdot\left(\frac{16r}{n}\right)^j$, we had shown $\mathbf{E}[P^j]\leq\left(\frac{t^2}{r^{1/2}}\right)\cdot\left(\frac{16rt}{n}\right)^j$ or $\mathbf{E}[P^j]\leq\left(\frac{t^2}{r^{1/2}}\right)\cdot\left(\frac{16r\log n}{n}\right)^j$, our resulting bound for the χ^2-divergence would be larger than 1. For instance, a natural approach is to instead consider $e_T=\sum_{i\in T}\sigma_ie_i$ and $e_U=\sum_{i\in U}\sigma_ie_i$ where the σ_i are independent random signs (i.e., $\Pr[\sigma_i=1]=\Pr[\sigma_i=-1]=1/2$), which would correspond to redefining the distribution β above to sample $z=x+\sum_{i\in T}(Cn^{1/p}/t^{1/p})\sigma_ie_i$. Without further conditioning the σ_i variables, the χ^2-divergence can be as large as $n^{\Theta(\log(1/\delta))}$. This is because with probability roughly 2^{-2t}, over the choice of the σ_i, one has $\sum_{i\in T}\sigma_ie_i$ and $\sum_{i\in U}\sigma_ie_i$ both being very well aligned with the top singular vector of M (if say, S were a random matrix with orthonormal rows), at which point our desired inner product is too large. Instead, by setting all $\sigma_i=1$, that is, by considering $e_T=\sum_{i\in T}e_i$ and $e_U=\sum_{i\in U}e_i$ as we do, we rule out this possibility.

We prove our lemma by expanding $\mathbf{E}[P^j]$ into a sum of products, each having the form $\prod_{w=1}^j|\langle S_{a_w},S_{b_w}\rangle|$ where the S_{a_w},S_{b_w} are columns of S. One thing that matters in such products is the multiplicities of duplicate columns that appear in a product. We split the summation by what we call *y-patterns*. We can think of a y-pattern as a partition of $\{1,2,\ldots,j\}$ into y non-empty pieces. We can also define a z-pattern as a partition of $\{1,2,\ldots,j\}$ into z non-empty pieces. We analyze the expectation for a particular pair P,Q, where P is a y-pattern and Q is a z-pattern for some $y,z\in\{1,2,\ldots,j\}$, that is, we only sum over pairs of j-tuples $a_1,\ldots,a_j$ and $b_1,\ldots,b_j$ for which for each non-empty piece $\{d_1,\ldots,d_\ell\}$ in P, where $d_i\in\{1,2,\ldots,j\}$ for all i and $\ell\leq j$, we have $a_{d_1}=a_{d_2}=\cdots=a_{d_\ell}$. Similarly for each $\{e_1,\ldots,e_m\}$ in Q, where $e_i\in\{1,2,\ldots,j\}$ for all i and $m\leq j$, we have $b_{e_1}=b_{e_2}=\cdots=b_{e_m}$. We also require if $d,d'\in\{1,2,\ldots,j\}$ are in different pieces of P, then $a_d\neq a_{d'}$. Similarly, if $e,e'\in\{1,2,\ldots,j\}$ are in different pieces of Q, then $b_e\neq b_{e'}$. Thus, each pair of j-tuples is valid for exactly one pair P,Q of patterns.

The valid pairs of j-tuples for P and Q define a bipartite multi-graph as follows. In the left partition we create a node for each non-empty piece of P, and in the right partition we create a node for each non-empty piece of Q. We include an edge from a node a in the left to a node b in the right if $i\in a$ and $i\in b$ for some $i\in\{1,2,\ldots,j\}$. If there is more than one such i, we include an edge with multiplicity corresponding to the number of such i. This bipartite graph only depends on P and Q. We consider a maximum matching in this multi-graph, and we upper bound the contribution of valid pairs for P and Q based on that matching. By summing over all pairs P,Q, we obtain our bound on $\mathbf{E}[P^j]$.

Our $\Omega(n^{1-2/p}\epsilon^{-2}\log(1/\delta))$ bound. This bound uses the same distributions α and β as in [30], where an $\Omega(n^{1-2/p}\epsilon^{-2})$ bound was shown, but we strengthen it to hold for general δ. To do so, we use an exact characterization of the variation distance between multi-variate

Gaussians with shifted mean by relating it to the univariate case (given in the full version), and a strong concentration of bounded Lipshitz functions with respect to the Euclidean norm (given in the full version). These enable us to show with probability $1 - O(\delta)$, vectors sampled from α and β have $\l_p$-norm differing by a $1 + \epsilon$ factor. By the definition of α and β, we can then reduce the problem to distinguishing an isotropic Gaussian from an isotropic Gaussian plus a small multiple of a fixed column of S, which typically has small norm since S has orthonormal rows. We then apply a bound as derived above (see full version).

Our $\Omega(\epsilon^{-2}\log(1/\delta))$ bound for $1 \leq p < 2$. This lower bound uses similar techniques to our lower bound of $\Omega(n^{1-2/p}\epsilon^{-2}\log(1/\delta))$, but considers distinguishing an isotropic Gaussian $N(0, I_n)$ from an $N(0, (1+\epsilon)I_n)$ random variable. Here we set $n = \Theta(\epsilon^{-2}\log(1/\delta))$, and show the p-norms of samples from the two distributions differ by a $(1+\epsilon)$-factor with probability $1 - \delta$. Using that S has orthonormal rows, the images of the two distributions under our sketching matrix S correspond to $N(0, I_r)$ and $N(0, (1+\epsilon)I_r)$, where r is the number of rows of S. The result then follows by using the product structure of Hellinger distance.

2 Our Lower Bounds

We first describe our lower bounds in a little more detail. Due to space constraints, we present a highly abridged version without proofs here (see full version). We defer both our $\Omega(n^{1-2/p}\epsilon^{-2}\log(1/\delta))$ lower bound for $p > 2$ and our $\Omega(\epsilon^{-2}\log(1/\delta))$ lower bound for $1 \leq p < 2$ entirely to the full version. Here we focus on our lower bound of $\Omega(n^{1-2/p}\epsilon^{-2/p}(\log^{2/p}(1/\delta))\log n)$ for $p > 2$. See also Section 1 for an overview of all of our lower bounds.

We assume δ-**Bound4**, which is that $\log(1/\delta) \leq (n^{1-2/p}\varepsilon^{-2/p}(\log^{2/p} 1/\delta)\log n)^{1/4}n^{-c'}$, for a sufficiently small constant $c' > 0$. Since $p > 2$ is an absolute constant, independent of n, this just states that $\delta \geq 2^{-n^{c''}}$ for a sufficiently small constant $c'' > 0$. There are other bounds - δ-**Bound1**, δ-**Bound2**, and δ-**Bound3** - see the full version, but these are not assumptions but rather implied by relations between the various parameters (e.g., otherwise the $\Omega(n^{1-2/p}\epsilon^{-2}\log(1/\delta))$ lower bound is stronger).

Let p and q be probability density functions of continuous distributions. The χ^2-divergence from p to q is $\chi^2(p, q) = \int_x \left(\frac{p(x)}{q(x)} - 1\right)^2 q(x)dx$.

▶ **Fact 1.** *([33], p.90) For any two distributions p and q, we have $D_{TV}(p, q) \leq \sqrt{\chi^2(p, q)}$.*

We need a fact about the distance between a Gaussian location mixture to a Gaussian distribution.

▶ **Fact 2.** *(p.97 of [21]) Let p be a distribution on $\mathbb{R}^n$. Then $\chi^2(N(0, I_n) * p, N(0, I_n)) = \mathbf{E}[e^{\langle X, X'\rangle}] - 1$, where X and X' are independently drawn from p.*

Let T be a sample of $t \stackrel{\text{def}}{=} \log_3(1/\sqrt{\delta})$ coordinates $i \in [n]$ without replacement.
Case 1: Suppose $y \sim N(0, I_n)$, and let α' be the distribution of y.
Case 2: Let $z = x + \sum_{i \in T} \frac{C'\epsilon^{1/p}E_{n-t}}{t^{1/p}}e_i$, where $x \sim N(0, I_n)$ and $E_{n-t} = \mathbf{E}_{x \sim N(0, I_{n-t})}[\|x\|_p]$. Note that x and T are independent. Also, $C' > 0$ is a sufficiently large constant. Let β' be the distribution of z.

In the full version we show that for the sketching algorithm to be correct, $D_{TV}(\bar{\alpha'}, \bar{\beta'}) \geq 1 - 2\delta$, where $\bar{\alpha'}$ is the distribution of $S \cdot y$ for $y \sim \alpha'$ and $\bar{\beta'}$ is the distribution of $S \cdot z$ for $z \sim \beta'$.

Fix an $r \times n$ matrix S with orthonormal rows. Important to our proof will be the existence of a subset W of $n/2$ of the columns for which $\|S_i\|^2 \leq 2r/n$ for all $i \in W$. To see that W exists, consider a uniformly random column S_i for $i \in [n]$. Then $\mathbf{E}[\|S_i\|^2] = r/n$ and so by Markov's inequality, at least a 1/2-fraction of columns S_i satisfy $\|S_i\|^2 \leq 2r/n$. We fix W to be an arbitrary subset of $n/2$ of these columns.

Suppose we sample t columns of S without replacement, indexed by $T \subset [n]$. Let $\mathcal{G}$ be the event that the set T of sampled columns belongs to the set W.

▶ **Lemma 3.** $\Pr[\mathcal{G}] \geq \sqrt{\delta}$.

Let $\alpha_G = \bar{\alpha}' \mid \mathcal{G}$ and $\beta_G = \bar{\beta}' \mid \mathcal{G}$. By the triangle inequality, $1 - 2\delta \leq D_{TV}(\bar{\alpha}', \bar{\beta}') \leq \Pr[\mathcal{G}] D_{TV}(\alpha_g, \beta_G) + 1 - \Pr[\mathcal{G}] \leq \frac{\sqrt{\delta}}{2} D_{TV}(\alpha_G, \beta_G) + 1 - \frac{\sqrt{\delta}}{2}$, which implies that $1 - 4\sqrt{\delta} \leq D_{TV}(\alpha_G, \beta_G)$. We can assume δ is less than a sufficiently small positive constant, and so it suffices to show for sketching dimension $r = o(n^{1-2/p}\varepsilon^{-2/p}(\log^{2/p} 1/\delta)\log n)$, that $D_{TV}(\alpha_G, \beta_G) \leq 1/2$. By Fact 1, it suffices to show $\chi^2(\alpha_G, \beta_G) \leq 1/4$.

Since S has orthonormal rows, $\bar{\alpha}'$ is distributed as $N(0, I_r)$. Note that, by definition of α, we in fact have $\bar{\alpha}' = \alpha_G$ since conditioning on $\mathcal{G}$ does not affect this distribution. On the other hand, β_G is a Gaussian location mixture, that is, it has the form $N(0, I_r) * p$, where p is the distribution of a random variable chosen by sampling a set T subject to event $\mathcal{G}$ occurring and outputting $\sum_{i \in T} \frac{C' \epsilon^{1/p} E_{n-t} S_i}{t^{1/p}}$. We can thus apply Fact 2 and it suffices to show for $r = o(n^{1-2/p}\varepsilon^{-2/p}(\log^{2/p} 1/\delta)\log n)$ that $\mathbf{E}[e^{\frac{(C')^2\epsilon^{2/p}E_{n-t}^2}{t^{2/p}}\langle \sum_{i\in T} S_i, \sum_{j \in U} S_j\rangle}] - 1 \leq \frac{1}{4}$, where the expectation is over independent samples T and U conditioned on $\mathcal{G}$. Note that under this conditioning T and U are uniformly random subsets of W.

To bound the χ^2-divergence, we define variables $x_{T,U}$, where $x_{T,U} = \frac{(C')^2\epsilon^{2/p}E_{n-t}^2}{t^{2/p}}\langle \sum_{i\in T} S_i, \sum_{j\in U} S_j\rangle$. Consider the following, where the expectation is over independent samples T and U conditioned on $\mathcal{G}$:

$$\begin{aligned}
\mathbf{E}\left[\exp\left\{\frac{(C')^2\epsilon^{2/p}E_{n-t}^2}{t^{2/p}}\langle \sum_{i\in T} S_i, \sum_{j\in U} S_j\rangle\right\}\right] &= \mathbf{E}\left[e^{x_{T,U}}\right] = \sum_{0 \leq j < \infty} \mathbf{E}\left[\frac{x_{T,U}^j}{j!}\right] \\
&= 1 + \sum_{j \geq 1} \frac{(C')^{2j}\varepsilon^{2j/p}E_{n-t}^{2j}}{t^{2j/p}j!}\mathbf{E}\left[\langle \sum_{i\in T} S_i, \sum_{j\in U} S_j\rangle^j\right] \\
&= 1 + \sum_{j \geq 1} \frac{O(1)^{2j}\varepsilon^{2j/p}n^{2j/p}}{t^{2j/p}j!}\mathbf{E}\left[\langle \sum_{i\in T} S_i, \sum_{j\in U} S_j\rangle^j\right].
\end{aligned}$$

The final equality uses that $E_{n-t} = \Theta(n^{1/p})$ and here $O(1)^{2j}$ denotes an absolute constant raised to the $2j$-th power. We can think of T as indexing a subset of rows of $S^T S$ and U indexing a subset of columns. Let M denote the resulting $t \times t$ submatrix of $S^T S$. Then $\langle \sum_{i\in T} S_i, \sum_{j\in U} S_j\rangle = \sum_{i,j\in[t]} M_{i,j} \leq \sum_{i,j\in[t]} |M_{i,j}| \stackrel{\text{def}}{=} P$, and we seek to understand the value of $\mathbf{E}[P^j]$ for integers $j \geq 1$.

The following lemma is the key to the argument; its proof is described in Section 1. The proof is based on defining y-patterns and looking at matchings in an associated bipartite multi-graph.

▶ **Lemma 4.** *For integers $j \geq 1$, $\mathbf{E}[P^j] \leq \left(\frac{t^2}{r^{1/2}}\right) \cdot \left(\frac{16r}{n}\right)^j$.*

Given the previous lemma, by δ-**Bound4**, we have $\frac{t^2}{r^{1/2}} = \frac{1}{n^{\Omega(1)}}$, and therefore Lemma 4 establishes that $\mathbf{E}[P^j] \leq \frac{1}{n^{\Omega(1)}} \cdot \left(\frac{16r}{n}\right)^j$. We thus have, $\mathbf{E}\left[\exp\left\{\frac{(C')^2\epsilon^{2/p}E_{n-t}^2}{t^{2/p}}\langle \sum_{i\in T} S_i, \sum_{j\in U} S_j\rangle\right\}\right] =$

$\mathbf{E}[e^{x_{T,U}}] = 1 + \frac{1}{n^{\Omega(1)}} \cdot \sum_{j \geq 1} \frac{O(1)^{2j} \epsilon^{2j/p} n^{2j/p}}{j! t^{2j/p}} \cdot \left(\frac{r}{n}\right)^j = 1 + \frac{1}{n^{\Omega(1)}} \cdot \sum_{j \geq 1} \frac{(c \log n)^j}{j!} \leq 1 + \frac{1}{n^{\Omega(1)}} \cdot e^{c(\log n)} \leq 1 + \frac{1}{4}$, since $c > 0$ is an arbitrarily small constant independent of the constant in the $n^{\Omega(1)}$. The proof is complete.

For $1 \leq p < 2$, we now show that the sketching dimension is $\Omega(\epsilon^{-2} \log(1/\delta))$, which as discussed in Section 1, matches known upper bounds up to a constant factor.

▶ **Theorem 5.** *The sketching dimension for (ϵ, δ)-approximating F_p for $1 \leq p < 2$ is $\Omega(\epsilon^{-2} \log(1/\delta))$.*

3 Algorithm

As outlined earlier, the algorithm uses two level-based structures, namely, GHSS, which is similar to the GHSS structure presented in [17], and the shelf structure. The shelf structure is needed only when $\delta = n^{-\omega(1)}$, otherwise, the GHSS structure suffices. The GHSS has $L + 1$ levels, corresponding to $l = 0, 1, \ldots, L$, and the shelf structure has J shelves numbered $0, 1, \ldots, J$. In particular, shelf 0 is identical to GHSS level 0.

3.1 Estimating F_p

GHSS *structure.* Corresponding to each GHSS level $l \in \{0, 1, \ldots, L-1\}$, a pair of CountSketch like structures named $\mathsf{HH}_l = \mathsf{HH}(C_l, s)$ (denoting that the number of buckets per table is $16C_l$ and number of independent repetitions is s) and $\mathsf{AvgEst}_l = \mathsf{AvgEst}(C_l, 2s)$ are kept. Here, $s = \Theta(\log n)$, recall $C = n^{1-2/p}(\epsilon^{-2} \log(1/\delta)/\log(n) + \epsilon^{-4/p} \log^{2/p}(1/\delta))$, $C = C_0 = \Theta(p^2 n^{1-2/p} \epsilon^{-4/p} \log^{2/p}(1/\delta))$ and $C_l = C_0 \alpha^l$, for $l = 0, 1, 2, \ldots, L-1$, where, $\alpha = 1 - (1 - 2/p)\nu$ and ν is a constant. The number of levels is $L = \lceil \log_{2\alpha}(n/C) \rceil$. The final level L of the GHSS structure uses an ℓ_2/ℓ_1 deterministic sparse-recovery algorithm [9, 13]. We will show that the number of items that are subsampled into level L is $O(C_L)$ with probability $1 - O(\delta)$ and therefore from [9, 13], by using $O(C_L \log(n/C_L))$ measurements, these item frequencies are recovered deterministically. Following [17], the GHSS structure subsamples the stream hierarchically using independent random hash functions $g_1, \ldots, g_L : [n] \to \{0, 1\}$. All items are mapped to level 0; an item is mapped to each of levels 1 through l iff $g_1(i) = \ldots = g_l(i) = 1$, where, the g_l's are $O(\log(1/\delta) + \log n)$-wise independent.

HH and AvgEst structures. The $\mathsf{HH}(C_l, s)$ is a CountSketch structure [11]. The $\mathsf{AvgEst}(C_l, 2s)$ structure is similar, except that instead of Rademacher sketches, it uses random qth roots of unity sketches, where, $q = O(\log(1/\delta) + \log n)$. At level l and for table indexed $r \in [2s]$, the corresponding hash function is $h_{lr} : [n] \to [16C_l]$, and the sketch for bucket index b is given by $T_{lr}[b] = \sum_{h_{lr}(i)=b} x_i \omega_{lr}(i)$, where, $\{\omega_{lr}(i)\}_{i \in [n]}$ is a random family of qth roots of unity that is $O(\log(1/\delta) + \log n)$-wise independent. The hash functions across the tables and distinct levels, and the seeds of the family of the random roots of unity, are independent.

Shelf structure. The shelves, indexed from $j = 0, \ldots, J$, each also consist of an analogous pair of structures, namely, $\mathsf{HH}(H_j, w_j)$ and $\mathsf{AvgEst}(H_j, 2w_j)$, where, $O(H_j)$ is the number of buckets per hash table in these structures, and there are $O(w_j)$ independent repetitions per structure. The AvgEst structures of the shelves also use sketches using qth roots of unity, instead of Rademacher sketches. In particular, $H_0 = C_0$ and $w_0 = s$, ensuring that shelf 0 coincides with level 0 of GHSS. Further, $H_J = \Theta(n^{1-2/p} \epsilon^{-2})$ and $w_J = O(\log(1/\delta))$. There are two cases, namely, (1) $H_J = \Omega(H_0)$, or, (2) $H_J = o(H_0)$. In the first case, $J = 1$ and there are only two shelves, considerably simplifying the analysis. The other case $H_J = o(H_0)$ is more interesting. Here, we let $H_j = H_0 b^j$, for a parameter $b < 1$ and $b = \Omega(1)$. The table

widths increase geometrically as $w_j = w_0 a^j$, for a parameter $a > 1$. The total measurements used by the shelf structure is $\sum_{j=0}^{J} H_j w_j = H_0 w_0 \sum_{j=0}^{J} (ab)^j = O(\max(H_0 w_0, H_J w_J))$, provided, $|1 - ab| = \Omega(1)$, or, $|\ln(ab)| = \Omega(1)$. The entire stream $\mathcal{S}$ is provided as input to each of the shelves $j = 0, 1, \ldots, J$.

Frequency groups, thresholds, estimates and samples. Let $B = \Theta(C)$ and $\bar{\epsilon} = (B/C)^{1/2} = \Theta(1/p)$. Let $\hat{F}_2$ be an estimate for $F_2 = \|x\|_2^2$ satisfying $F_2 \leq \hat{F}_2 \leq (1 + O(1/p))F_2$ with probability $1 - O(\delta)$. Define frequency thresholds for GHSS levels as follows: $T_0 = (\hat{F}_2/B)^{1/2}$, $T_l = (2\alpha)^{-l/2} T_0$ and $Q_l = T_l(1 - \bar{\epsilon})$, for $l \in [L - 1]$. Let $Q_L, T_L = 0^+$ (i.e., $a \geq T_L$ iff $a > 0$). For shelf $j = 0, \ldots, J$, let $E_j = \bar{\epsilon}^2 H_j$. For shelf j, define the frequency threshold $U_j = (\hat{F}_2/E_j)^{1/2}$ and let $U_{J+1} = \infty$. For GHSS level indices $l = 0, \ldots, L-1$, let $\hat{x}_{il}$ denote the estimate for x_i obtained using HH_l, and (overloading notation), for shelf indices, $j = 0, \ldots, J$, let $\hat{x}_{ij}$ denote the estimate for x_i obtained from the HH structure of shelf j. $\hat{x}_{iL}$ denotes the estimate returned from the ℓ_2/ℓ_1 sparse recovery structure at level L.

Discovering Items. We say that i is *discovered* at shelf $j \in [J]$, provided, $(1 - \bar{\epsilon})U_j \leq |\hat{x}_{ij}| \leq (1 + \bar{\epsilon})U_{j+1}$ and $j \in [J]$ is the *highest* numbered shelf with this property. We say that i is discovered at GHSS level $l \in \{0, \ldots, L\}$, if i is not discovered at any shelf indexed $j \in [J]$, and l is the *smallest* level such that $T_l(1 - \bar{\epsilon}) < \hat{x}_{il} \leq T_{l-1}(1 + \bar{\epsilon})$. If i is discovered at shelf j, then, i is included in the shelf sample $\bar{S}_j$. If i is discovered at level $l \in [0, 1, \ldots, L]$ and $|\hat{x}_{il}| \geq T_l$, then, i is included in the level sample $\bar{G}_l$. If i is discovered at level l and $T_l(1 - \bar{\epsilon}) < |\hat{x}_{il}| < T_l$ then, i is placed in $\bar{G}_{l+1}$ iff the random toss of an unbiased coin K_i lands heads; and upon tails, it is not placed in any sample group. The GHSS level sampling scheme is similar to [17].

The averaged estimator and NOCOLLISION. For each item i included in a group sample $\bar{G}_l$ or shelf sample $\bar{S}_j$, an estimate X_i for $|x_i|$ is obtained using the corresponding AvgEst structure of that level or shelf, provided the event NOCOLLISION(i) succeeds. If i is sampled into $\bar{G}_l$, then NOCOLLISION(i) holds if there is a set $R_l(i) \subset [2s]$ of table indices of the AvgEst_l structure such that for each $r \in R_l(i)$, i does not collide under the hash function h_{lr} with any of the items that are the top-C_l absolute estimated frequencies using HH_l. An analogous definition holds if i is included in the jth shelf sample. Assuming NOCOLLISION(i) holds, the estimate X_i is defined as the average of the estimates obtained from the tables whose indices are in the set $R_l(i)$ (resp. $R_j(i)$ if i was discovered in shelf j), that is, $X_i = (1/|R(i)|) \sum_{r \in R(i)} T_r[h_r(i)] \cdot \overline{\omega_r(i)} \cdot \mathrm{sgn}(\hat{x_i})$. Further, we check whether $(1 - \bar{\epsilon})T_l \leq X_i \leq (1 + \bar{\epsilon})T_{l-1}$ (resp. $(1 - \bar{\epsilon})U_j \leq X_i \leq (1 + \bar{\epsilon})U_{j+1}$, if i is in shelf j sample), otherwise, i is dropped from the sample.

Estimating F_p. The estimate for the pth frequency moment, $\hat{F}_p$, is the sum of the contribution from the shelf samples $\bar{S}_j, j \in [J]$, and the contribution from the sample groups $\bar{G}_l$, $l = 0, \ldots, L$. For an item $i \in \bar{G}_l$, let $l_d(i)$ be the level at which an item i is discovered. Let $\hat{F}_p^{\text{SHELF}} = \sum_{j=1}^{J} \sum \left\{ X_i^p \mid i \in \bar{S}_j, (1 - \bar{\epsilon})U_j \leq |X_j| \leq (1 + \bar{\epsilon})U_{j+1} \right\}$, and $\hat{F}_p^{\text{GHSS}} = \sum_{l=0}^{L} 2^L \sum \left\{ X_i^p \mid i \in \bar{G}_l, l_d(i) < L, (1 - \bar{\epsilon})T_{l_d} \leq X_i < (1 + \bar{\epsilon})T_{l_d - 1} \right\} + 2^L \sum_{l_d(i) = L} |\hat{x}_i|^p$. The final estimate is $\hat{F}_p = \hat{F}_p^{\text{SHELF}} + \hat{F}_p^{\text{GHSS}}$.

3.2 Analysis

Notation. Let $F_2^{\text{res}}(k)$ be the sum of the squares of all coordinates except the top-k absolute coordinates. For a GHSS level $l \in [L]$, $F_2^{\text{res}}(l, k)$ is the random k-residual second moment of the frequency vector in the sampled substream $\mathcal{S}_l$. Let (1) $\text{GOODF}_2 \equiv F_2 \leq \hat{F}_2 \leq (1 + 0.001/(2p))F_2$, (2) $\text{SMALLRES}_l \equiv F_2^{\text{res}}(2C_l, l) \leq 1.5 F_2^{\text{res}} \left(\lceil (2\alpha)^l C \rceil \right) / 2^{l-1}$, $l = 0, 1, \ldots, L$, (3) $\text{SMALLRES} \equiv \forall l \in \{0, 1, \ldots, L\}$ SMALLRES_l, (4) $\text{GOODLASTLEVEL} \equiv (\hat{f}_{iL} = f_i)$ and $\forall i \notin \mathcal{S}_L, (\hat{f}_{iL} = 0)$. We condition the analysis on the "good event" $\mathcal{G} \equiv \text{GOODF}_2 \wedge \text{SMALLRES} \wedge \text{GOODLASTLEVEL}$, that we show holds with probability $1 - \min(O(\delta), n^{-\Omega(1)})$.

▶ **Lemma 6.** *$\mathcal{G}$ holds with probability* $1 - \min(O(\delta), n^{-\Omega(1)})$.

The range of item frequencies is subdivided into frequency groups , so that each item belongs to exactly one shelf frequency group or to exactly one GHSS frequency group. The frequency group corresponding to the shelf j is $[U_j, U_{j+1})$, for $j = 1, \ldots, J$, where, $U_{J+1} = \infty$ and $U_0 = T_0$. The frequency group corresponding to level l of GHSS is $[T_l, T_{l-1})$, where, $T_L = 0$ and $T_{-1} = U_1$. Let S_j (resp. G_l) denote the set of items whose frequency belongs to the frequency group corresponding to shelf j (resp. group l). A few other events are used in the analysis. If $i \in G_l$, then, $\Pr[\text{NOCOLLISION}(i)] \geq 1 - \exp\{-\Theta(\log n)\}$ as shown in [17] (Lemma 30). If $i \in S_j$, $\Pr[\text{NOCOLLISION}(i)] \geq 1 - \exp\{-\Theta(w_j)\}$. We condition on the following events.

$$\text{GOODEST}(i) \equiv \forall l \in [0, \ldots, L], i \in \mathcal{S}_l \Rightarrow |\hat{x}_{il} - x_i| \leq \left(F_2^{\text{res}}\left(2C_l, l\right)/C_l\right)^{1/2} \quad (5)$$

$$\text{ACCUEST}(i) \equiv \forall l \in [0, \ldots, L], i \in \mathcal{S}_l \Rightarrow |\hat{x}_{il} - x_i| \leq \left(F_2^{\text{res}}\left((2\alpha)^l C\right)/(2(2\alpha)^l C)\right)^{1/2} . \quad (6)$$

As shown in [17], (a) GOODEST(i) and ACCUEST(i) each hold with probability $1 - n^{-\Omega(1)}$, and, (b) GOODEST$(i) \wedge$ SMALLRES imply the event ACCUEST(i). For an item i that is discovered at some shelf j, GOODEST(i) is the same as ACCUEST(i) and is defined as $|\hat{x}_{ij} - x_i| \leq \left(F_2^{\text{res}}\left(U_j\right)/U_j\right)^{1/2}$ and holds with probability $1 - \exp\{-\Theta(w_j)\}$.
Lemma 7 extends the approximate 2-wise independence property of the sampling scheme of [17] to an approximate d-wise independence property.

▶ **Lemma 7.** *Let* $I = \{i_1, \ldots, i_d\} \subset [n]$ *and* $1 \leq h \leq d$. *Let* ACCUEST$(\{i_1, \ldots, i_h\}) \equiv \bigwedge_{k=1}^{h}$ ACCUEST(i_k). *Then, assuming d-wise independence of the hash functions,* $\sum_{\substack{l_j=0,1,\ldots,L,\\ \forall j=1,2,\ldots,h}} 2^{l_1+l_2+\ldots+l_h} Pr\{\bigwedge_{j=1}^{h} i_j \in \bar{G}_{l_j} | \bigwedge_{j=h+1}^{d} i_j \in \mathcal{S}_{l_j}, \mathcal{G}, \text{ACCUEST}(\{i_1, \ldots, i_h\})\} \in \prod_{j=1}^{h}\left(1 \pm 2^{\text{level}(i_j)+1} n^{-c}\right)$.

Lemma 8 bounds $|X_i - \mathbf{E}[X_i]|$ using the $2d$th moment method.

▶ **Lemma 8.** *Suppose* $d \leq O(\log n)$ *and even and let* $s \geq 300\log(n)$. *Then we have that* $Pr\{|X_i - |x_i|| > \left(\frac{dF_2^{res}(2C)}{(s/9)C}\right)^{1/2} \mid \text{NOCOLLISION}, \text{GOODEST}\} < 2^{-2d+1}$.

▶ **Lemma 9** ([22]). $\left|\mathbf{E}[X_i^p] - |x_i|^p \mid \mathcal{G}, \text{GOODEST}, \text{NOCOLLISION}\right| \leq |x_i|^p n^{-\Omega(1)}$.

For $i \in [n]$, let x_{li} be an indicator variable that is 1 iff $i \in \mathcal{S}_l$. Let X_i denote $|\hat{x}_i|$ when $l_d(i) = L$ and otherwise, let its meaning be unchanged. Let z_{il} be an indicator variable that is 1 if $i \in \bar{G}_l$ and 0 otherwise. Define $\hat{F}_p = \sum_{i\in[n]} Y_i$. where, $Y_i = \sum_{l'=0}^{L} 2^{l'} z_{il'} X_i^p$. Let $\mathcal{H} = \mathcal{G} \cap$ NOCOLLISION $\cap$ GOODEST and $G' = \text{lmargin}(G_0) \cup_{l=1}^{L} G_l$.

▶ **Lemma 10.** *Let* $B \geq O(n^{1-2/p}\epsilon^{-4/p}\log^{2/p}(1/\delta)))$. *For integral* $0 \leq d_1, d_2 \leq \lceil\log(1/\delta)\rceil$, *we have,* $\mathbf{E}\left[\left(\sum_{i\in G'}(Y_i - \mathbf{E}[Y_i \mid \mathcal{H}])\right)^{d_1}\left(\sum_{i\in G'}(\overline{Y_i} - \mathbf{E}[\overline{Y_i} \mid \mathcal{H}])\right)^{d_2} | \mathcal{H}\right] \leq \left(\frac{\epsilon F_p}{20}\right)^{d_1+d_2}$.

3.3 Analysis for the case $\delta \geq n^{-O(1)}$

For the case $\delta = n^{-O(1)}$, the shelf structure is not needed. Redefine the group G_0 to correspond to the frequency range $[T_0, \infty]$. The lemmas in this section assume that the family $\{\omega_{lr}(i)\}_{i\in[n]}$ are $O(\log(1/\delta) + \log(n))$-wise independent, and independent across l, r and all hash functions are also $O(\log(1/\delta) + \log(n))$-wise independent.

▶ **Lemma 11.** *Let* $1 \le e, g \le \lceil \log(1/\delta) \rceil, l \in mid(G_0)$ *and* $|x_l| \ge \left(\frac{F_2^{res}(C)}{C}\right)^{1/2}$. *Then,* $\mathbf{E}\left[(Y_l - \mathbf{E}[Y_l \mid \mathcal{H}])^e \left(\overline{Y_l} - \mathbf{E}\left[\overline{Y_l} \mid H\right]\right) \mid \mathcal{H}\right]$ *is real and is at most* $\left(\frac{a|x_l|^{2p-2}F_2^{res}(C)}{\rho C}\right)^{(e+g)/2}$ *for some constant* a. *Further,* $\left|\mathbf{E}\left[(Y_l - \mathbf{E}[Y_l \mid \mathcal{H}])^e\right] \mid \mathcal{H}\right| \le |x_l|^{pe} n^{-\Omega(e)}$.

The calculation of the dth central moment for the contribution to $\hat{F}_p$ from the items in $\text{mid}(G_0)$ requires an upper bound on the following combinatorial sums. $Q(S_1, S_2) = \sum_{q=1}^{\min(S_1,S_2)} \sum_{\substack{e_1+\ldots+e_q=S_1 \\ e'_j s \ge 1}} \sum_{\substack{g_1+\ldots+g_q=S_2 \\ g'_j s \ge 1}} \binom{S_1}{e_1,\ldots,e_q}\binom{S_2}{g_1,\ldots,g_q}$, and
$R(S) = \sum_{q=1}^{\lfloor S/2 \rfloor} \sum_{h_1+\ldots+h_q=S, h'_j s \ge 2} \binom{S}{h_1,\ldots,h_q} \sum_{\{i_1,\ldots,i_q\}} \prod_{r\in[q]} |x_{i_r}|^{(p-1)h_r} \prod_{r\in[q]} h_r^{h_r/2}$.

▶ **Lemma 12.** $Q(S_1, S_2) \le R(S_1 + S_2) \le (16e(S_1 + S_2)F_{2p-2})^{(S_1+S_2)/2}$.

▶ **Lemma 13.** *Let* $C \ge O(n^{1-2/p}/\log(n))\epsilon^{-2}\log(1/\delta))$. *Then, for* $0 \le d_1, d_2 \le \log(1/\delta)$, $\mathbf{E}\left[\left(\sum_{i\in mid(G_0)}(Y_i - \mathbf{E}[Y_i \mid \mathcal{H}])\right)^{d_1}\left(\sum_{i\in mid(G_0)}(\overline{Y_i} - \mathbf{E}\left[\overline{Y_i} \mid H\right])\right)^{d_2} \mid \mathcal{H}\right] \le \left(\frac{\epsilon F_p}{10}\right)^{d_1+d_2}$.

▶ **Lemma 14.** *Let* $C \ge Kn^{1-2/p}\epsilon^{-2}\log(1/\delta)/\log(n) + Ln^{1-2/p}\epsilon^{-4/p}\log^{2/p}(1/\delta)$, *where,* K, L *are constants. Then, for* $d = \lceil \log(1/\delta) \rceil$, $\mathbf{E}\left[\left(\sum_{i\in S}(Y_i - \mathbf{E}[Y_i \mid \mathcal{H}])\right)^d\left(\sum_{i\in S}(\overline{Y_i} - \mathbf{E}\left[\overline{Y_i} \mid \mathcal{H}\right])\right)^d \mid \mathcal{H}\right] \le \left(\frac{\epsilon F_p}{5}\right)^{2d}$. *It follows that* $Pr\left[\left|\hat{F}_p - F_p\right| \ge (\epsilon/2)F_p\right] \le \delta$.

Since, $\mathcal{H}$ holds with probability $1 - 1/n^{-c}$, for any constant c by choosing $s = \Theta(\log n)$ appropriately, we have the following theorem.

▶ **Theorem 15.** *For each* $0 < \epsilon < 1$ *and* $7/8 \ge \delta \ge n^{-c}$, *for any constant* c, *there is a sketching algorithm that* (ϵ, δ)*-approximates* F_p *with sketching dimension* $O\left(n^{1-2/p}\left(\epsilon^{-2}\log(1/\delta) + \epsilon^{-4/p}\log^{2/p}(1/\delta)\log n\right)\right)$ *and update time (per stream update)* $O((\log n)\log(1/\delta)))$.

3.4 Analysis for the case $\delta = n^{-\omega(1)}$

We now extend the analysis for failure probability δ smaller than $n^{-\Theta(1)}$ and up to $\delta = 2^{-n^{\Omega(1)}}$. For the GHSS structure, NOCOLLISION and GOODEST may hold only with probability $1 - n^{-\Theta(1)}$. We first show that the number of items that fail to satisfy NOCOLLISION or GOODEST is at most $O(\log(1/\delta)/\log n)$ with probability $1 - O(\delta)$. The following lemmas assume the parameter sizes for B, C, C_l, H_J and H_j as described earlier.

▶ **Lemma 16.** *With probability* $1 - O(\delta)$, *the number of elements for which* GOODEST *or* NOCOLLISION *fails is at most* $O(\log(1/\delta))/(\log n)$.

Thus, it is possible that legitimate items are not discovered, or are dropped due to collisions, or mistakenly classified and their contribution added to samples. Let $\text{Error}^{\text{GHSS}}$ denote the total contribution of such items to $\hat{F}_p^{\text{GHSS}}$ and let $\text{Error}^{\text{SHELF}}$ denote the error arising in the estimate of $\hat{F}_p^{\text{SHELF}}$ due to analogous errors. As described earlier, we mainly emphasize the more interesting and complicated case when $H_J = o(H_0)$ (otherwise, $J = 1$).

▶ **Lemma 17.** $Error^{\text{GHSS}} \le O(\epsilon^2 F_p/\log n)$ *and* $Error^{\text{SHELF}} \le O(\max(\epsilon^2 F_p/(\log n), O(\epsilon^p F_p)))$, *each with probability* $1 - \delta/n^{\Omega(1)}$.

We first prove a refinement of Lemma 11.

▶ **Lemma 18.** *[Refinement of Lemma 11.] Let* $1 \le e, g \le \lceil \log(1/\delta) \rceil$, $l \in S_j$ *and* $\log(1/\delta) = \omega(\log n)$. *Assume that* ACCUEST$(l)$ *holds and* $H_j \ge \Omega(p^2 E_J)$ *and* $|x_l| \ge (F_2/E_j)^{1/2}$. *Then,* $\mathbf{E}\left[\left(\left(1 + \frac{Z_l}{|x_l|}\right)^p - 1\right)^e \left(\left(1 + \frac{\overline{Z_l}}{|x_l|}\right)^p - 1\right)^g \mid \mathcal{H}\right]$ *is real and bounded above by* $c^h |x_l|^{-h}\left(\frac{F_2}{H_j}\right)^{h/2}\left(\min\left(\frac{h}{w_j}, 1\right)\right)^{h/2}$, *where,* $h = e + g$ *and* c *is an absolute constant.*

Lemma 19 considers the $2d$th central moment of the contribution to $\hat{F}_p^{\text{SHELF}}$ from all but the outermost shelf, and from the set of outermost shelf items denoted S_J, separately. Let $S' = S_1 \cup \ldots \cup S_{J-1}$.

▶ **Lemma 19.** *Let $0 \leq d_1, d_2 \leq \lceil \log(1/\delta) \rceil$ and integral and c_1, c_2 be constants. Then,* $\mathbf{E}\left[\left(\sum_{i\in S'}(Y_i - \mathbf{E}\left[Y_i \mid \mathcal{H}\right])\right)^{d_1}\left(\sum_{i\in S'}(\overline{Y_i} - \overline{\mathbf{E}\left[Y_i \mid \mathcal{H}\right]})\right)^{d_2} \mid \mathcal{H}\right] \leq (c_1\epsilon F_p)^{d_1+d_2}$. $\mathbf{E}\left[\left(\sum_{i\in S_J}(Y_i - \mathbf{E}\left[Y_i \mid \mathcal{H}\right])\right)^{d_1}\left(\sum_{i\in S_J}(\overline{Y_i} - \overline{\mathbf{E}\left[Y_i \mid \mathcal{H}\right]})\right)^{d_2} \mid \mathcal{H}\right] \leq (c_2\epsilon F_p)^{d_1+d_2}$.

Combining Lemmas 10, 13 and 19 with Lemma 17, we obtain the following.

▶ **Lemma 20.** *$\exists$ constant c s.t. for $1 \leq d \leq \lceil \log(1/\delta) \rceil$,* $\mathbf{E}\left[\left(\sum_{i\in[n]}(Y_i - \mathbf{E}\left[Y_i \mid \mathcal{H}\right])\right)^{d}\left(\sum_{i\in[n]}(\overline{Y_i} - \mathbf{E}\left[\overline{Y_i} \mid \mathcal{H}\right])\right)^{d} \mid \mathcal{H}\right] \leq (c\epsilon F_p)^{2d}$. *Hence, $Pr\left[\left|\hat{F}_p - F_p\right| \leq \epsilon F_p)\right] < \delta$.*

▶ **Theorem 21.** *For each $0 < \epsilon < 1$ and $7/8 \geq \delta \geq 2^{-n^{\Omega(1)}}$, there is a sketching algorithm that (ϵ, δ)-approximates F_p with sketching dimension $O\big(n^{1-2/p}\big(\epsilon^{-2}\log(1/\delta) + \epsilon^{-4/p}\log^{2/p}(1/\delta)\log n\big)\big)$ and update time (per stream update) $O((\log n)\log(1/\delta))$.*

Quasi-PTAS for Scheduling with Precedences using LP Hierarchies

Shashwat Garg[1]
Eindhoven University of Technology, Netherlands
s.garg@tue.nl

Abstract

A central problem in scheduling is to schedule n unit size jobs with *precedence constraints* on m identical machines so as to minimize the makespan. For $m = 3$, it is not even known if the problem is NP-hard and this is one of the last open problems from the book of Garey and Johnson.

We show that for fixed m and ϵ, polylog(n) rounds of Sherali-Adams hierarchy applied to a natural LP of the problem provides a $(1+\epsilon)$-approximation algorithm running in quasi-polynomial time. This improves over the recent result of Levey and Rothvoss, who used $r = (\log n)^{O(\log \log n)}$ rounds of Sherali-Adams in order to get a $(1 + \epsilon)$-approximation algorithm with a running time of $n^{O(r)}$.

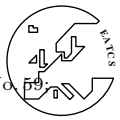
1 Introduction

A central problem in scheduling is the following: suppose we are given n unit jobs which have to be processed non-preemptively on m identical machines. There is also a precedence order among the jobs: if $i \prec j$, then job i has to be completed before j can begin. The goal is to find a schedule of the jobs with the minimum makespan, which is defined as the time by which all the jobs have finished.

This problem admits an easy $(2 - \frac{1}{m})$ approximation algorithm which was given by Graham [5] in the 60's and is one of the landmark results in scheduling. This algorithm is known as the *list-scheduling* algorithm and works as follows: at every time $t = 1, 2, \ldots$, if there is an empty slot on any of the m machines, schedule any *available* job there, where a job is available if it is not yet scheduled and all the jobs which must precede it have already been scheduled. This simple greedy algorithm is essentially the best algorithm for the problem and for almost half a century it was an open problem whether one can get a better approximation algorithm. In fact, this was one of the ten open problems in Schuurman and Woeginger's influential list of open problems in scheduling [11]. It was known since the 70's that it is NP-hard to get an approximation factor better than 4/3 [8]. Slight improvements were given

[1] Supported by the Netherlands Organisation for Scientific Research (NWO) under project no. 022.005.025.



by Lam and Sethi [6] who gave a $2 - \frac{2}{m}$ approximation algorithm, and Gengal and Ranade [3] who gave a $2 - \frac{7}{3m+1}$ approximation algorithm for $m \geq 4$. Finally in 2010, Svensson [13] showed that assuming a variant of Unique Games conjecture due to Bansal and Khot [1], for any constant $\epsilon > 0$ there is no $(2 - \epsilon)$ approximation algorithm for the problem.

However, this still leaves open the problem for the important case when m is a constant. In fact in practice, usually the number of jobs are very large but there are only a few machines. Surprisingly, for $m = 3$, it is not even known if the problem is NP-hard. This is one of the four problems from the book of Garey and Johnson [4] whose computational complexity is still unresolved.

In order to get a better algorithm for the case when m is a constant, a natural strategy is to write a linear program (LP), and for this problem, one such LP is the time-indexed LP (1), in which we first make a guess T of the makespan and then solve the LP. The value of the LP is the smallest T for which the LP is feasible, and the worst case ratio of the optimal makespan and the value of the LP is known as the integrality gap of the LP. It is well known that LP (1) has an integrality gap of at least $2 - \frac{2}{m+1}$ (see e.g. [9]), which suggests that one needs to look at stronger convex relaxations in order to get a better algorithm. Such a stronger convex relaxation can be obtained by applying a few rounds of a hierarchy to the LP, and in this paper, we will use the Sherali-Adams hierarchy [12]. It is known that just one round of Sherali-Adams hierarchy reduces the integrality gap to 1 for $m = 2$ and thus, the problem can be solved exactly in this case (credited to Svensson in [10]). Claire Mathieu in a workshop in Dagstuhl 2010 asked if one can get a $(1 + \epsilon)$-approximation algorithm using $f(\epsilon, m)$ rounds of Sherali-Adams hierarchy for some function f independent of n, which would imply a PTAS for the problem when m is a constant. This is also Open Problem 1 in Bansal's recent list of open problems in scheduling presented at MAPSP 2017.

To get some intuition behind why hierarchies should help in this problem, let us first look at the analysis for Graham's list-scheduling algorithm. At the end of this algorithm, the number of time slots which are busy, that is where all the m machines have some job scheduled on them, is a lower bound on the optimum. Also, the number of non-busy time slots is a lower bound on the optimum. This is because there must be a *chain* of jobs $j_1 \prec j_2 \prec \cdots \prec j_k$ such that one job from this chain is scheduled at each non-busy time, and the length of any chain in the instance is clearly a lower bound on the optimum. This implies that the makespan given by the algorithm, which is the sum of the number of busy and non-busy time slots, is a 2-approximation of the optimum makespan, and a slightly more careful argument gives the guarantee of $(2 - 1/m)$. Now the key idea is that if the instance given to us has a maximum chain length of at most ϵ times the optimal makespan, then Graham's list-scheduling algorithm already gives a $(1 + \epsilon)$-approximation, and hierarchies provide, via conditionings, a good way to "effectively" reduce the length of the chains in any given instance.

Though the question of whether one can get a $(1 + \epsilon)$-approximation algorithm using $f(\epsilon, m)$ rounds of Sherali-Adams hierarchy is still unresolved, a major breakthrough was made recently by Levey and Rothvoss [9], who gave a $(1 + \epsilon)$-approximation algorithm using $r = (\log n)^{O(m^2 \log\log n/\epsilon^2)}$ rounds of Sherali-Adams. This gives an algorithm with a running time of $n^{O(r)}$, which is faster than exponential time but worse than quasi-polynomial time.

1.1 Our Result

In this paper, we improve over the result of Levey and Rothvoss [9] by giving a $(1 + \epsilon)$-approximation algorithm which runs in quasi-polynomial time. Formally, we show the following:

▶ **Theorem 1.** *The natural LP* (1) *for the problem augmented with r rounds of Sherali-Adams hierarchy has an integrality gap of at most $(1+\epsilon)$, where $r = O_{m,\epsilon}(\log^{O(m^2/\epsilon^2)} n)$. Moreover, there is a $(1+\epsilon)$-approximation algorithm for this problem running in time $n^{O(r)}$.*

Throughout the paper, we use the notation $O_{m,\epsilon}(.)$ to hide factors depending only on m and ϵ. The natural LP for the problem is the following:

$$\begin{aligned}
\sum_{t=1}^{T} y_{jt} &= 1 && \forall j \in [n] \\
\sum_{j} y_{jt} &\leq m && \forall t \leq T \\
\sum_{t' \leq t} y_{jt'} &\geq \sum_{t' \leq t+1} y_{it'} && \forall t \leq T,\ \forall j \prec i \\
y_{jt} &\geq 0 && \forall t \leq T,\ \forall j \in [n]
\end{aligned} \tag{1}$$

Here T is our guess on the optimum makespan. In an integral solution, $y_{jt} = 1$ if job j is scheduled at time t, and 0 otherwise. The first constraint ensures that each job is scheduled at exactly one time and the second constraint ensures that no more than m jobs are scheduled at any time. The third constraint ensures that if $j \prec i$, then job i can only be scheduled at a time strictly later than job j.

1.2 Overview of Our Algorithm

Let us first give an overview of the algorithm of Levey-Rothvoss [9] since our algorithm builds up on it.

Previous approach

At a high-level, the algorithm of Levey-Rothvoss [9] works by constructing a laminar family of intervals, where the topmost level has one interval $[1, T]$ and each succeeding level is constructed by dividing each interval of the previous level into two equal sized intervals, as shown in the figure below. Thus, there are $(1 + \log T)$ levels where level ℓ contains 2^ℓ intervals, each of size $\frac{T}{2^\ell}$ for $\ell = 0, 1, \ldots, \log T$. This laminar family can be thought of as being a binary tree of depth $\log T$ with the interval $[1, T]$ as the root and the level ℓ intervals being vertices at depth ℓ.

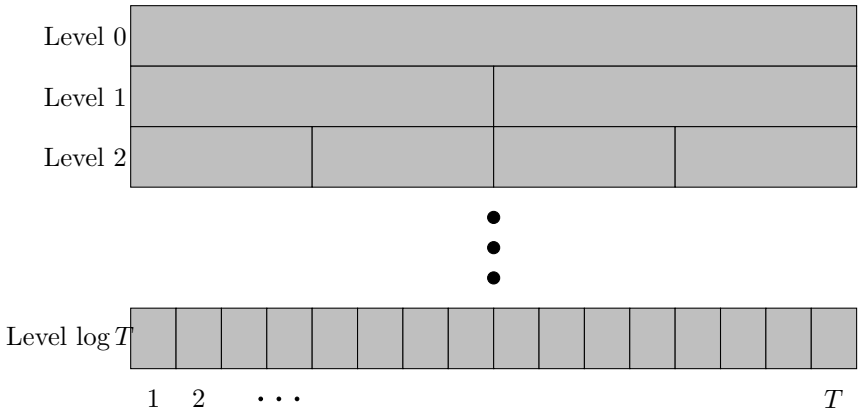


Figure 1 Construction of the laminar family used in the algorithm.

Each job j is first assigned to the smallest interval in this laminar family which fully contains the fractional support of j as per the solution of the LP. Let $k = O(\log \log n)$ and let us call the top k^2 levels in the laminar family as the *top levels* and the level succeeding it, that is the level k^2 as the *bottom level*. Their algorithm conditions (see Section 2 for the definition of conditioning) roughly 2^{k^2} times in order to reduce the maximum chain length among the jobs assigned to the top levels. Once the length of the chains in the top levels is reduced, the last k of the top levels are discarded from the instance, and the sub-instances corresponding to each interval in the bottom level is recursively solved in order to get a partial schedule for all the jobs except those assigned to the top levels. The discarding of the k levels is done in order to create a large gap between the top levels and the bottom level. Having such a gap makes it easier to schedule the remaining jobs in the top levels in the gaps of the partial schedule and Levey-Rothvoss [9] give an elegant algorithm to do this, provided that the maximum chain length among the jobs in the top levels is small. This step increases the makespan by at most a $(1 + \epsilon/\log n)$ factor, which adds up to a loss of a $(1 + \epsilon)$ factor in total over the at most $\log n$ depth of the recursion. Finally, one must also schedule the jobs in the k levels which were discarded; to do this without increasing the makespan by more than a $(1 + \epsilon)$ factor, it suffices to ensure that these k discarded levels contain at most an ϵ fraction of the jobs contained in the top levels. Let us call such a set of k consecutive levels, which contains at most an ϵ fraction of the number of jobs in the levels above it, as a *good batch*.

Now the reason they had to condition $2^{k^2} = 2^{O((\log \log n)^2)}$ times, which leads to the running time of $n^{O(2^{k^2})}$, comes from the fact that they condition on every interval in the top k^2 levels. And this is necessary to ensure that a good batch exists. For example, the number of jobs contained in the levels $[pk, (p + 1)k)$ may be about $e^{\epsilon p} \cdot (\epsilon T/\log n)$ for all $p < (1/\epsilon) \ln(m \log n) \approx k$, in which case there is no good batch in the first $o(k^2)$ levels.

Our approach

To get around the above issue, we observe the following: if, after conditioning on only the top Ck levels, where $C = O(1/\epsilon^2)$ is a big enough constant, there does not exist a good batch in the top Ck levels, then in fact a $(1 - \epsilon)$ fraction of the jobs in the top Ck levels must lie in the last $(1/\epsilon^2)k$ levels, that is, in levels from $Ck - (1/\epsilon^2)k$ to $Ck - 1$. This implies that we can discard the jobs in the first $Ck - (1/\epsilon^2)k$ levels by charging them to the jobs in the levels from $Ck - (1/\epsilon^2)k$ to $Ck - 1$, and in doing so we only discard an ϵ fraction of the total number of jobs.

Notice that we have only conditioned about $2^{Ck} = \text{polylog}(n)$ times till now as there are these many intervals in the top Ck levels. The next crucial observation is that after deleting the top $Ck - (1/\epsilon^2)k$ levels, the sub-instances defined by each of the subtrees rooted at the intervals on the level $Ck - (1/\epsilon^2)k$ can be solved independently of each other. This means that we can perform conditioning in parallel on each such sub-instance, and thus in total, we will condition at most $2^{Ck} \cdot \log T = \text{polylog}(n)$ times, since the depth of the recursion is at most the height of the tree.

Now it might also happen that we already find a good batch in the top Ck levels and in this case, we follow a strategy similar to Levey-Rothvoss [9] by recursing on the bottom intervals to find a partial schedule and fitting the jobs in the top levels in this partial schedule. This step might discard an ϵ fraction of the jobs in the top levels. These two cases, one where we recurse because there is no good batch in the top Ck levels and one where we recurse because there is a good batch in the top Ck levels, might interleave in a complicated manner. We show that the number of jobs ever discarded in the algorithm due to each type of recursion is at most an $O(\epsilon)$ fraction of the total number of jobs, which implies that we can achieve a makespan of $(1 + \epsilon)T$.

The above high-level description skims over a few important issues. One big challenge in the above approach is to ensure that the number of jobs discarded in the cases where we do not find a good batch stays small during the whole algorithm. Even though this is the case in one such recursive call, this might not happen over all the recursive calls taken together and we might end up discarding a constant fraction of the jobs. To get over this obstacle, we carefully control which interval each job is assigned to: if a job j is assigned to an interval I but after conditioning on some job $i \neq j$ which is assigned to a level lower than j, the fractional support of j shrinks to a sub-interval of I, then we will still keep j assigned to I, rather than moving it down the laminar family. This ensures that each job is not charged more than once for discarded jobs and thus the total number of discarded jobs is at most ϵn. This however slightly changes the way jobs are assigned to intervals and the techniques developed by Levey and Rothvoss [9] cannot be immediately applied to fit the jobs of the top levels in the partial schedule of the bottom levels in the case when a good batch exists. To tackle this issue, we will allow each job in the top levels to be scheduled outside of its (current) fractional support as long as it doesn't violate the precedence constraints with the jobs in the bottom levels. With this modification, we will be able to fit the jobs in the top levels in the partial schedule of the bottom levels without discarding more than an ϵ fraction of the top jobs. This implies that in both types of recursions, we only discard an $O(\epsilon)$ fraction of the jobs.

2 Preliminaries on Sherali-Adams Hierarchy

In this section, we state the basic facts about Sherali-Adams hierarchy which we will need. We refer the reader to the excellent surveys [7, 2, 10] for a more extensive introduction to hierarchies.

Consider a linear program with n variables $y_1, \ldots, y_n$ where for each $i \in [n]$, $0 \leq y_i \leq 1$. For $s \geq 0$, the s^{th}-round Sherali-Adams lift of this linear program is another linear program with variables $y_S^{(s)}$ for each $S \subseteq [n]$ satisfying $|S| \leq s+1$, and some additional constraints. We will often denote $y_{\{i\}}^{(s)}$ by $y_i^{(s)}$ for simplicity.

If we think of y_i as the probability that $y_i = 1$, intuitively the variables $y_S^{(s)}$ should equal the probability that each $i \in S$ has $y_i = 1$, that is we would like to have that $y_S^{(s)} = \Pi_{i \in S} y_i$. As these constraints are not convex, we can only impose some linear conditions implied by them. In particular, for every constraint $a^T y \leq b$ of the starting LP, we add, for every $S, T \subseteq [n]$ such that $|S| + |T| \leq s$, a new constraint given by

$$\sum_{T' \subseteq T} (-1)^{|T'|} \left(\sum_{i=1}^{n} a_i y_{S \cup T' \cup \{i\}}^{(s)} - b y_{S \cup T'}^{(s)} \right) \leq 0. \tag{2}$$

If $y_S^{(s)} = \Pi_{i \in S} y_i$ was indeed true for all $|S| \leq s+1$, then the above inequality can be succinctly written as $(a^T y - b) \cdot \Pi_{i \in S} y_i \cdot \Pi_{i \in T}(1 - y_i) \leq 0$, and are thus valid constraints for all $0-1$ solutions.

Observe that an s^{th}-round Sherali-Adams lift of an LP with n variables and m constraints is just another LP with $n^{O(s)}$ variables and $m \cdot n^{O(s)}$ constraints. Letting $y^{(s)}$ denote a feasible solution of the s^{th}-round Sherali-Adams lift, $y^{(s)}$ is also feasible for all $s' \leq s$ rounds of Sherali-Adams and in particular is a feasible solution of the starting LP.

Conditioning

Given a feasible solution $y^{(s)}$ of the s^{th}-round Sherali-Adams lift and $i \in [n]$ such that $y_i^{(s)} > 0$, then we can *condition on the event* $y_i = 1$ to get a feasible solution $z^{(s-1)}$ of the $(s-1)^{th}$-round Sherali-Adams lift defined as

$$z_S^{(s-1)} = \frac{y_{S\cup\{i\}}^{(s)}}{y_i^{(s)}} \qquad \forall S : |S| \leq s.$$

The fact that $z^{(s-1)}$ is a feasible solution of the $(s-1)^{th}$-round Sherali-Adams lift follows easily from (2). Moreover, z satisfies $z_i^{(s-1)} = 1$ and the following useful property:

▶ **Observation 2.** *If for some $j \in [n]$, $y_j^{(s)} = 0$ and we condition on $y_i = 1$ for any $i \in [n]$, then $z_j^{(s-1)} = 0$.*

Proof. Using the Sherali-Adams lift (2) of the constraint $y_i \leq 1$ with $S = \{j\}$ and $T = \phi$, we get $y_{\{i,j\}}^{(s)} \leq y_j^{(s)}$. This gives $z_j^{(s-1)} = \frac{y_{\{i,j\}}^{(s)}}{y_i^{(s)}} \leq \frac{y_j^{(s)}}{y_i^{(s)}} = 0$. ◀

One can think of the solution $z_S^{(s-1)}$ as giving the conditional probability of $y_S^{(s)} = 1$ given $y_i^{(s)} = 1$. By conditioning on a variable y_i to be 1, we will mean that we replace the current fractional solution $y^{(s)}$ with the fractional solution $z^{(s-1)}$ as in above. Observation 2 implies that conditioning can never increase the support of any variable, or in other words, if the probability that $y_j = 1$ is zero, then the conditional probability that $y_j = 1$ conditioned on $y_i = 1$, is also zero.

3 Algorithm

Before we describe our algorithm, we first develop some notation. Let T denote the value of the LP (1) and let $y^{(s)}$ denote the feasible solution of the s^{th}-round Sherali-Adams lift of the LP we get after we condition $r - s$ times in the algorithm. We will say that we are in *round* s of the algorithm if we have conditioned $r - s$ times so far. So we will start the algorithm in round r with solution $y^{(r)}$, and if we condition in round s, we go to round $s-1$ with solution $y^{(s-1)}$.

For each job j, define the *fractional support interval of j in round s* as $F_j^{(s)} := [r_j^s, d_j^s]$, where r_j^s is the smallest time t for which $y_{jt}^{(s)} > 0$ and d_j^s is the largest time for which $y_{jt}^{(s)} > 0$ (r_j and d_j are used to symbolize release time and deadline). In other words, $F_j^{(s)}$ is the minimal interval which fully contains the fractional support of job j in $y^{(s)}$. By Observation 2, upon conditioning, the fractional support interval can only shrink, that is $F_j^{(s-1)} \subseteq F_j^{(s)}$.

For each job j, we also define a *support interval* $S_j^{(s)}$. We will initially set $S_j^{(r)} := F_j^{(r)}$. In later rounds, we will update $S_j^{(s)}$ in such a way that $F_j^{(s)} \subseteq S_j^{(s)} \subseteq F_j^{(r)}$. Intuitively, $S_j^{(s)}$ reflects our knowledge in round s of where j can be scheduled. Notice that we might schedule j outside of the fractional support interval $F_j^{(s)}$.

A schedule of jobs is called a *feasible schedule* if it satisfies the precedence constraints among all the jobs and a *partial feasible schedule* if it schedules some of the jobs and satisfies the precedence constraints among them. In order to get a feasible schedule of all the jobs with a makespan of at most $(1+\epsilon)T$, it suffices to show the following:

▶ **Theorem 3.** *We can find a partial feasible schedule $\sigma : [n] \to [T] \cup \{DISCARDED\}$ such that $\sigma(j) = DISCARDED$ for at most ϵT jobs.*

Clearly a schedule σ as in Theorem 3 has makespan at most T. Having such a partial feasible schedule, we can easily convert it to a feasible schedule of all the n jobs with a makespan of at most $(1+\epsilon)T$: iterate through every job j discarded in σ and find the earliest time t by when all the jobs which must precede j have either already been scheduled or are as of yet discarded. Create a new time slot between times t and $t+1$ containing only job j. This increases the makespan by one for every job discarded in σ.

Laminar Family.

A laminar family of intervals is defined in the following manner. The topmost level, level 0, has one interval $[1, T]$. Each succeeding level is constructed by dividing each interval of the previous level into two equal sized intervals[2]. Thus there are $(1 + \log T)$ levels, where level ℓ contains 2^ℓ intervals each of size $\frac{T}{2^\ell}$ for $\ell = 0, 1, \ldots, \log T$. This laminar family can be thought of as being a binary tree of depth $\log T$ with the interval $[1, T]$ as the root, and the level ℓ intervals as being vertices at depth ℓ.

Let $\mathcal{I}_\ell$ denote the set of intervals at level ℓ of the laminar family. For an interval $I \in \mathcal{I}_\ell$, a *sub-interval of* I is any interval $I' \subseteq I$ of the laminar family, including I itself; and $I_{\text{left}}, I_{\text{right}}$ will denote the left and right sub-intervals respectively of I in $\mathcal{I}_{\ell+1}$. By the midpoint of I, we will mean the right boundary of I_{left}.

Job j is *assigned* to interval I in round s if I is the smallest interval in the laminar family such that $S_j^{(s)} \subseteq I$. This assignment of jobs to intervals depends on $S_j^{(s)}$ and will change as s and $S_j^{(s)}$ change during the algorithm. Let $I^{(s)}(j)$ denote the interval to which j is assigned in round s of the algorithm. For an interval I in the laminar family, let $\mathcal{J}^{(s)}(I)$ denote the set of jobs assigned to I, and let $\mathcal{J}^{(s)}(\mathcal{I}_\ell)$ denote the set of jobs assigned to intervals in $\mathcal{I}_\ell$ in round s of the algorithm.

Batches.

Let $k = \log(\frac{32m}{\epsilon} \cdot \log n)$. For $p \geq 0$, define the p^{th} batch as

$$\mathcal{B}_p = \{\mathcal{I}_{pk}, \mathcal{I}_{pk+1}, \ldots, \mathcal{I}_{(p+1)k-1}\}.$$

That is, it denotes the set of k consecutive levels starting from level pk till level $(p+1)k-1$. Let $\mathcal{J}^{(s)}(\mathcal{B}_p)$ denote the set of jobs assigned to intervals in batch p in round s. Batch $\mathcal{B}_p$ for $p \geq 1$ is called a *good batch with respect to* $[T]$ *in round* s if

$$|\mathcal{J}^{(s)}(\mathcal{B}_p)| \leq \frac{\epsilon}{4m} \sum_{i=0}^{p-1} |\mathcal{J}^{(s)}(\mathcal{B}_i)|. \tag{3}$$

We will omit the "with respect to $[T]$" if it is clear from the context that we start the summation in the right hand side of (3) from the first batch in $[T]$. Similarly, we will omit the "in round s" if s is clear from the context.

Algorithm.

We can now describe our algorithm and split its description in two steps for clearer exposition. Let $C = 2(4m/\epsilon)^2 + 1, k = \log(\frac{32m}{\epsilon} \cdot \log n)$ and $\delta = \frac{\epsilon}{8mCk2^{Ck}\log n}$. The reader can think of

[2] Without loss of generality, T is a power of 2. Otherwise, we can add a few dummy jobs at the end which must succeed all other jobs and which make T a power of 2.

these parameters as being $k = \Theta_{m,\epsilon}(\log\log n)$ and $\delta = \Theta_{m,\epsilon}(1/\text{polylog}(n))$. s will always denote the current round of the algorithm, unless otherwise specified. We initialise $s := r$ and for each job j, $S_j^{(r)} := F_j^{(r)}$.

Schedule($y^{(r)}, T$):[3]

1. **Step 1: Reducing chain length in the top $qk \leq Ck$ levels**

   In this step, we will reduce the length of the chains in each interval I in the top qk levels of the laminar family to at most $\delta|I|$, for some $q \leq C$. This is done by going down the levels, starting from level 0 till level $qk-1$, where q is chosen such that

   a. after having conditioned on all the levels from 0 to $qk-1$, $\mathcal{B}_{q-1}$ is a good batch, or

   b. we have already conditioned on the top Ck levels and found no good batch, in which case we set $q = C$.

   The conditioning on the levels and update of S_j's is done as follows. For $\ell = 0, 1, \ldots, qk-1$:

   - Let $s_{\text{old}} = s$ and for each j, let $\ell(j)$ denote the level of the interval $I^{(s_{\text{old}})}(j)$, that is the level to which j is assigned at the beginning of this iteration of the loop.
   - We go over every interval $I \in \mathcal{I}_\ell$ and do the following: if $\mathcal{J}^{(s)}(I)$ has a chain of length more than $\delta|I|$, let j be the first job in this chain. We condition on j lying in I_{right}. After every conditioning, update $s := s-1$ and set $S_j^{(s)}$ for every job j as follows:
     - if $\ell(j) < \ell$, let m_j denote the midpoint of $I^{(s_{\text{old}})}(j)$ and $[t_r, t_d] := F_j^{(s)}$. If $F_j^{(s)} \subseteq I_{\text{left}}$, then we set $S_j^{(s)} := [t_r, m_j + 1]$, and if $F_j^{(s)} \subseteq I_{\text{right}}$, then we set $S_j^{(s)} := [m_j, t_d]$. Otherwise, set $S_j^{(s)} := F_j^{(s)}$.
     - if $\ell(j) \geq \ell$, set $S_j^{(s)} := F_j^{(s)}$.

   That is, the support intervals $S_j^{(s)}$ are set such that if we condition on jobs in level ℓ, then the jobs assigned to a level $\ell' < \ell$ before the conditionings stay assigned to level ℓ', and for all other jobs, $S_j^{(s)}$ equals the fractional support interval $F_j^{(s)}$.

2. **Step 2: Recursion**

   There are two cases to consider here, depending on which of (a) or (b) took place in the previous step.

   (i) If (a) occurred, perform a recursion of type 1.

   This step is similar to the algorithm of [9]. We discard all the jobs in the good batch $\mathcal{B}_{q-1}$. Then for each interval $I \in \mathcal{I}_{qk}$, we recursively call Schedule$(y^{(s)}, I)$ to obtain a schedule $\tilde{\sigma}_I$, which are put together to form a partial feasible schedule $\tilde{\sigma}$ for the jobs assigned to a level $\ell \geq qk$.

   Then we fit the jobs in the top levels, that is the jobs in $\mathcal{J}^{(s)}(\mathcal{B}_0) \cup \cdots \cup \mathcal{J}^{(s)}(\mathcal{B}_{q-2})$ in the empty slots in $\tilde{\sigma}$. We give more details of how this is done in Section 4.2.1. Some jobs in the top levels will be discarded while doing this.

   Call this step a *recursion of type* 1. The number of jobs discarded in this step, that is the jobs in batch $\mathcal{B}_{q-1}$ along with the jobs in the top levels which are discarded, will be referred to as the jobs discarded due to this step. Notice that this does not include the jobs discarded in each recursive call to the intervals in $\mathcal{I}_{qk}$.

   (ii) If (b) occurred, perform a recursion of type 2.

   In this case, we discard all the jobs in $\mathcal{J}^{(s)}(\mathcal{B}_0) \cup \cdots \cup \mathcal{J}^{(s)}(\mathcal{B}_{C-(4m/\epsilon)^2-1})$. Then for each interval $I \in \mathcal{I}_{(C-(4m/\epsilon)^2)k}$, we recursively call Schedule$(y^{(s)}, I)$ to get a

[3] When the algorithm is called on an interval of length $L \leq 2^{Ck}$, we can just "brute force" by conditioning mL times to find an exact solution. We avoid writing this explicitly in the algorithm for simplicity.

schedule σ_I which are put together to form a partial feasible schedule σ for all the jobs assigned to a level $\ell \geq (C - (4m/\epsilon)^2)k$.

Call this step a *recursion of type 2*. The number of jobs discarded in this step, that is the jobs in batches $\mathcal{B}_0, \ldots, \mathcal{B}_{C-(4m/\epsilon)^2-1}$ will be referred to as the jobs discarded due to this step. Just like before, this does not include the jobs discarded in each recursive call to the intervals in $\mathcal{I}_{(C-(4m/\epsilon)^2)k}$.

In each type of recursion, we recurse on multiple sub-instances defined by intervals of some level. It is important that the recursions on these sub-instances are done independently of each other. That is, we pass the same (current) Sherali-Adams solution to each recursive call, and conditionings done in one recursive call are independent of conditionings done in any other recursive call, and thus do not affect the fractional solution of any other recursive call.

4 Analysis

In this section, we prove Theorem 3 which will imply Theorem 1. We split the analysis into two parts: in the first part, we give a bound on the number of rounds of Sherali-Adams needed in the algorithm. In the second part, we show that we discard at most ϵT jobs during the algorithm and schedule all other jobs by time T, thus proving Theorem 3.

But first, we need to show that the algorithm is well-defined.

▶ **Observation 4.** *In step* 1*, when we condition on an interval I by finding a chain $\mathcal{C}$ in I and conditioning the first job j in this chain to lie in I_{right}, this is possible to do. Moreover, this assigns every job in $\mathcal{C}$ to a sub-interval of I_{right}.*

Proof. For the first part of the observation, we need to show that $F_j^{(s)} \cap I_{\text{right}} \neq \phi$, where s is the round of the algorithm just before we condition on j in I. As j is assigned to I in round s, it must be that $S_j^{(s)} \cap I_{\text{right}} \neq \phi$. The support intervals are updated in a way such that we can only have $S_j^{(s)} \neq F_j^{(s)}$ after we condition on a level below that of j. But because we always condition on the levels from top to bottom, we must have $S_j^{(s)} = F_j^{(s)}$. This proves the first part of the observation.

The moreover part follows easily now since every other job $i \in \mathcal{C}$ satisfies $j \prec i$ and must start scheduling only after j. ◀

4.1 Bounding number of rounds of Sherali-Adams

Let $r(|I|)$ denote the number of rounds of Sherali-Adams the algorithm uses when run on the instance defined by the subtree rooted at interval I of the laminar family. Our goal in this subsection is to show $r(T) \leq r$ for $r = O_{m,\epsilon}(\log^{O(m^2/\epsilon^2)} n)$.

We first give an upper bound on the number of conditionings done in one interval I.

▶ **Lemma 5.** *The algorithm conditions at most m/δ times on any interval I in step* 1*.*

Proof. Let s_{old} denote the round of the algorithm just before we start to condition in I, and let $\ell \geq 0$ be such that $I \in \mathcal{I}_\ell$. Each time we condition in I, we assign at least $\delta|I|$ jobs in I to a sub-interval of I_{right} (by Observation 4).

Also, no job assigned to a level $\ell' < \ell$ in round s_{old} moves down the laminar family during conditionings done in I. And for all other jobs, they only get assigned to a sub-interval. Thus no new job is assigned to I while we are conditioning in I.

Using $F_j^{(s_{\text{old}})} \subseteq S_j^{(s_{\text{old}})}$ and the second constraint of LP (1), there can be at most $m|I|$ jobs in total assigned to I in round s_{old}. Thus, the number of times we condition in I is at most $\frac{m|I|}{\delta|I|} = \frac{m}{\delta}$. ◀

▶ **Lemma 6.** *The algorithm conditions at most $2^{Ck}m/\delta$ times in step 1 of the algorithm.*

Proof. By Lemma 5, we condition at most m/δ times per interval. As we condition on the topmost qk levels and hence on at most $2^{qk} \leq 2^{Ck}$ intervals, we condition at most $2^{Ck}m/\delta$ times in step 1. ◀

In step 2 of the algorithm, if we do a recursion of type 1 then we recurse on every interval at level $qk \geq k$. Otherwise, if we do a recursion of type 2 then we recurse on every interval at level $(C - (4m/\epsilon)^2)k \geq k$. In either case we recurse on every interval of some level $\ell \geq k$ and thus on an interval of size at most $T/2^k$. Because the conditionings done in one recursive call are done independently of the conditionings in any other recursive call, the total number of rounds of Sherali-Adams we need can be bounded by the following recurrence:

$$r(T) \leq \frac{2^{Ck}m}{\delta} + r(T/2^k)$$

where the base case is $r(2^{Ck}) = 2^{Ck}m$, and thus we get

$$r(T) \quad \leq \quad \frac{2^{Ck}m \log T}{\delta} \leq \frac{8m^2Ck(\log^2 n)2^{2Ck}}{\epsilon} = O_{m,\epsilon}((\log n)^{5+\frac{64m^2}{\epsilon^2}}) = r.$$

4.2 Bounding number of jobs discarded

In this subsection, we bound the number of jobs discarded in the algorithm and show that it is at most ϵT. We will separately bound the number of jobs discarded due to recursions of type 1 and recursions of type 2 and show that each is at most $\epsilon T/2$. The former uses a result proved by Levey and Rothvoss [9] but which needs to be heavily adapted to our algorithm. The latter uses a simple charging argument.

4.2.1 Jobs discarded due to recursions of type 1.

Suppose we perform a recursion of type 1 when the algorithm is called on the interval I of the laminar family. To be consistent with the notation of [9], we will call the set of jobs $\mathcal{J}^{(s)}(\mathcal{B}_{q-1})$ as $\mathcal{J}_{\text{middle}}$, the set of jobs $\mathcal{J}^{(s)}(\mathcal{B}_0) \cup \cdots \cup \mathcal{J}^{(s)}(\mathcal{B}_{q-2})$ as $\mathcal{J}_{\text{top}}$ and the jobs in the levels below these as $\mathcal{J}_{\text{bottom}}$ (here we are reindexing the batches such that the first level starts from interval I).

▶ **Claim 7.**

$$|\mathcal{J}_{middle}| \leq \frac{\epsilon}{4m}|\mathcal{J}_{top}|.$$

Proof. Follows from the fact that $\mathcal{B}_{q-1}$ is a good batch and (3). ◀

After discarding all the jobs in $\mathcal{J}_{\text{middle}}$, the algorithm recursively finds a partial feasible schedule $\tilde{\sigma}$ of the jobs in $\mathcal{J}_{\text{bottom}}$. Let $\mathcal{J}' \subseteq \mathcal{J}_{\text{bottom}}$ be the set of jobs scheduled by $\tilde{\sigma}$. The algorithm will then attempt to extend $\tilde{\sigma}$ to a schedule σ of the jobs in $\mathcal{J}_{\text{top}} \cup \mathcal{J}'$. We will be able to do this by discarding only a few jobs from $\mathcal{J}_{\text{top}}$. More formally:

▶ **Lemma 8.** *When the algorithm is called on an interval I, we can extend $\tilde{\sigma}$ to a feasible schedule σ of the jobs in $(\mathcal{J}_{top} \setminus \mathcal{J}_{discard}) \cup \mathcal{J}'$ where*

$$|\mathcal{J}_{discard}| \leq \frac{\epsilon |I|}{4 \log n}.$$

We defer the proof of Lemma 8 to the full version of the paper. We show below how Lemma 8 implies that we discard at most $\epsilon T/2$ jobs in all recursions of type 1.

▶ **Lemma 9.** *Total number of jobs discarded in all recursions of type 1 during the algorithm is at most $\epsilon T/2$.*

Proof. Using Claim 7 and Lemma 8, if we perform a recursion of type 1 when the algorithm is called on the interval I, the number of jobs discarded is at most

$$\frac{\epsilon}{4m} |\mathcal{J}_{\text{top}}| + \frac{\epsilon |I|}{4 \log n}.$$

Over all recursions of type 1, the first term sums up to at most $\epsilon n/4m \leq \epsilon T/4$. For any $\ell \geq 0$, the second term sums up to $\frac{\epsilon T}{4 \log n}$ over all intervals $I \in \mathcal{I}_\ell$. As there are at most $\log n$ levels, the second term also sums up to $\epsilon T/4$ over all recursions of type 1. ◀

4.2.2 Jobs discarded due to recursions of type 2.

Let $\epsilon' = \epsilon/4m$. Recall that in a recursion of type 2, we delete all the jobs assigned to levels 0 to $(C - (1/\epsilon')^2)k - 1$ and retain only the later $(1/\epsilon')^2$ batches. We show below that in such a case, at least a $(1 - \epsilon')$ fraction of the jobs in the top C batches are in the last $(1/\epsilon')^2$ batches and thus, by deleting the jobs in the first $C - (1/\epsilon')^2$ batches we only delete an ϵ' fraction of the jobs.

▶ **Lemma 10.** *If case (b) occurs in step 1 of the algorithm, then*

$$\sum_{i=0}^{C-(1/\epsilon')^2-1} |\mathcal{J}^{(s)}(\mathcal{B}_i)| \leq \epsilon' \sum_{i=C-(1/\epsilon')^2}^{C-1} |\mathcal{J}^{(s)}(\mathcal{B}_i)|. \tag{4}$$

Proof. Let $S = \sum_{i=0}^{C-(1/\epsilon')^2-1} |\mathcal{J}^{(s)}(\mathcal{B}_i)|$, the left hand side of (4). Case (b) occurs in step 1 of the algorithm if none of the batches $\mathcal{B}_p$ for $p \in [C - (1/\epsilon')^2, C - 1]$ are good. But then for $p \in [C - (1/\epsilon')^2, C - 1]$, we must have

$$|\mathcal{J}^{(s)}(\mathcal{B}_p)| > \epsilon' \sum_{i=0}^{p-1} |\mathcal{J}^{(s)}(\mathcal{B}_i)| \geq \epsilon' \sum_{i=0}^{C-(1/\epsilon')^2-1} |\mathcal{J}^{(s)}(\mathcal{B}_i)| = \epsilon' S.$$

This implies (4) as

$$\sum_{i=C-(1/\epsilon')^2}^{C-1} |\mathcal{J}^{(s)}(\mathcal{B}_i)| \geq \sum_{i=C-(1/\epsilon')^2}^{C-1} \epsilon' S = \left(\frac{1}{\epsilon'}\right)^2 \epsilon' S = \frac{S}{\epsilon'}.$$ ◀

This implies that when we discard the top $C - (1/\epsilon')^2$ batches, we are only discarding at most an ϵ' fraction of the jobs in the next $(1/\epsilon')^2$ batches. We can imagine this as putting a charge of ϵ' on every job in the last $(1/\epsilon')^2$ batches. Thus the total charge on all the jobs at the end of the algorithm is an upper bound on the number of jobs discarded in recursions of type 2 during the algorithm.

▶ **Lemma 11.** *For every job j, we put a charge on j at most once.*

Proof. Fix a job j and suppose we put a charge on j at least once. When we put a charge on j for the first time, then in some recursion of type 2 it must have been assigned to the lowest $(1/\epsilon')^2$ batches among the top C batches. The algorithm will then recurse on every interval at level $(C-(1/\epsilon')^2)k$ and thus job j is now in the top $(1/\epsilon')^2$ batches in one of the recursive calls.

Let $I \in \mathcal{I}_{(C-(1/\epsilon')^2)k}$ be such that j is assigned to a sub-interval of I. When we recursively call the algorithm on I, the first $(1/\epsilon')^2$ batches already satisfy the property that any interval I' in them has maximum chain length at most $\delta|I'|$. Thus in step 1 of the algorithm, we will not condition on any interval in the top $(1/\epsilon')^2$ batches. This implies that job j always stays assigned to the top $(1/\epsilon')^2$ batches; this is because the assignment of a job to an interval can only change when we condition on an interval at the same level or at a level above that of the job.

Now suppose we put a charge on j again. Then we must have once again done a recursion of type 2 within the recursive call to I. But j is assigned to the topmost $(1/\epsilon')^2$ batches in this instance and in a recursion of type 2, we delete the topmost $C-(1/\epsilon')^2 > (1/\epsilon')^2$ batches and put a charge on only the later $(1/\epsilon')^2$ batches, which leads to a contradiction. ◀

▶ **Lemma 12.** *Number of jobs discarded in recursions of type 2 throughout the algorithm is at most $\epsilon T/2$.*

Proof. Because the number of jobs discarded in recursions of type 2 throughout the algorithm is at most the total charge on all the jobs and by Lemma 11, each job is charged at most once, we get that the number of jobs discarded in recursions of type 2 is at most

$$\epsilon' n = \epsilon n/4m \leq \epsilon T/4 \leq \epsilon T/2.$$ ◀

Abstract

We study the computational complexity of Arrival, a zero-player game on n-vertex switch graphs introduced by Dohrau, Gärtner, Kohler, Matoušek, and Welzl. They showed that the problem of deciding termination of this game is contained in $\mathsf{NP} \cap \mathsf{coNP}$. Karthik C. S. recently introduced a search variant of Arrival and showed that it is in the complexity class PLS. In this work, we significantly improve the known upper bounds for both the decision and the search variants of Arrival.

First, we resolve a question suggested by Dohrau et al. and show that the decision variant of Arrival is in $\mathsf{UP} \cap \mathsf{coUP}$. Second, we prove that the search variant of Arrival is contained in CLS. Third, we give a randomized $\mathcal{O}(1.4143^n)$-time algorithm to solve both variants.

Our main technical contributions are (a) an efficiently verifiable characterization of the unique witness for termination of the Arrival game, and (b) an efficient way of sampling from the state space of the game. We show that the problem of finding the unique witness is contained in CLS, whereas it was previously conjectured to be FPSPACE-complete. The efficient sampling procedure yields the first algorithm for the problem that has expected runtime $\mathcal{O}(c^n)$ with $c < 2$.

1 Introduction

Variants of switch graphs have applications and are studied for example in combinatorics and in automata theory (cf. [11] and the references therein). Dohrau et al. [5] introduced Arrival, a natural computational problem on switch graphs, which they informally described as follows:

> Suppose that a train is running along a railway network, starting from a designated origin, with the goal of reaching a designated destination. The network, however, is of a special nature: every time the train traverses a switch, the switch will change its position immediately afterwards. Hence, the next time the train traverses the same switch, the other direction will be taken, so that directions alternate with each traversal of the switch.
> Given a network with origin and destination, what is the complexity of deciding whether the train, starting at the origin, will eventually reach the destination? [5]

The above rather straightforward question remains unresolved. Dohrau et al. [5] showed that deciding Arrival is unlikely to be NP-complete (by demonstrating that it is in NP ∩ coNP), but it is currently not known to be efficiently solvable.

To determine whether the train eventually reaches its destination, it is natural to consider a *run profile*, i.e., the complete transcript describing how many times the train traversed each edge. Dohrau et al. [5] presented a natural integer programming interpretation of run profiles called *switching flows*, which have the advantage of being trivial to verify. The downside of switching flows is that they do not guarantee to faithfully represent the number of times each edge has been traversed; a switching flow might contain superfluous circulations compared to a valid run profile. Nevertheless, Dohrau et al. [5] proved that the existence of a switching flow implies that the train reaches its destination, and thus a switching flow constitutes an NP witness for Arrival.

The coNP membership was shown by an insightful observation about the structure of switch graphs. Specifically, the train reaches its destination d if and only if it never enters a node from which there is no directed path to d. The railway network can thus be altered so that all such vertices point to an additional "dead-end" vertex $\bar{d}$. The coNP witness is then simply a switching flow from the origin to the dead-end $\bar{d}$.

Given that the decision variant of Arrival is in NP ∩ coNP, it is natural to study the search complexity of Arrival in the context of total search problems with the guaranteed existence of a solution, i.e., within the complexity class TFNP (which contains the search analogue of NP ∩ coNP). Total search problems are classified into subclasses of TFNP using the methodology proposed by Papadimitriou [13] that clusters computational problems according to the type of argument assuring the existence of a solution. Karthik C. S. [14] noticed that the search for a switching flow is a prime candidate to fit into the hierarchy of TFNP problems. He introduced S-Arrival, a search version of Arrival that seeks a switching flow to either the destination d or the dead-end vertex $\bar{d}$, and showed that it is contained in the complexity class PLS [10] of total problems amenable to local search.

Fearnley et al. [6] recently studied multiple variants of reachability games on switch graphs and as one of their results gave a lower bound on the complexity of deciding ARRIVAL. Specifically, they showed that Arrival is NL-hard.

1.1 Our Results

One of the open problems suggested by Dohrau et al. [5] was whether deciding the termination of Arrival is contained in UP ∩ coUP (recall that UP is a subclass of NP such that for each YES-instance there is a unique certificate). Recall that given a railway network with an origin o and a destination d, the transcript of the route of the train captured in the run profile from o to d (if it exists) is unique. We show that it is possible to efficiently decide whether a switching flow corresponds to a run profile, which provides a positive answer to the above question and places Arrival inside UP ∩ coUP. We similarly also improve the upper bound on the search complexity of Arrival: We show that S-Arrival is contained in the complexity class CLS. Daskalakis and Papadimitriou [4] introduced CLS to classify problems that can be reduced to local search over continuous domains. CLS contains multiple important search problems such as solving simple stochastic games, finding equilibria in congestion games, and solving linear complementarity problems on P-matrices. For all of these problems, as well as for S-Arrival, we currently do not have a polynomial time algorithm, and they are not known to be complete for some subclass of TFNP.

We establish the containment in CLS through a reduction to End-Of-Metered-Line (EOML), a total search problem that was recently introduced by Hubáček and Yogev [9] who also showed that it is in CLS. In EOML we are given a source in a directed graph with vertices of in-degree and out-degree at most one, and the task is to find a sink or a source different from the given trivial source. The access to the graph is given locally via information about the successor and predecessor of each vertex together with its distance from the trivial source (for the formal definition see Definition 18).

Our result makes it unlikely for S-Arrival to be PLS-hard, which was one of the possibilities suggested by the containment in PLS shown by Karthik C. S. [14]. This is due to known black-box separations among subclasses of TFNP [12, 2], which suggest that CLS is a proper subclass of PLS. Note that our reduction from S-Arrival to End-Of-Metered-Line results in instances with a significantly restricted structure: the End-Of-Metered-Line graph consists only of a single path and many isolated vertices. We believe that this structure may in future work be used to show that S-Arrival is contained in FP.

Our reduction from S-Arrival to End-Of-Metered-Line also implies that we can use an algorithm by Aldous [1] to solve S-Arrival. The algorithm is randomized and runs in $\mathcal{O}(2^{n/2}poly(n))$ expected time on switch graphs with n vertices. This is the first algorithm with expected runtime $\mathcal{O}(c^n)$ for $c < 2$. (A trivial $\mathcal{O}(2^n poly(n))$ time algorithm can be obtained by following the path of the train through the network.) Aldous' algorithm, in fact, solves any problem in PLS. It samples a large number of candidate solutions and then performs a local search from the best sampled solution. The advantage of our reduction is that the resulting search space for End-Of-Metered-Line is small enough to make Aldous' algorithm useful, unlike in the previous reduction by Karthik C. S. [14] that showed containment in PLS.

Fearnley et al. [7] recently gave a reduction from P-matrix linear complementarity problems (PLCP) to End-Of-Metered-Line. As in our case for Arrival, this implies that Aldous' algorithm can be used to solve PLCP. In fact this gives the fastest known randomized algorithm for PLCP, running in expected time $\mathcal{O}(2^{n/2}poly(n))$ for input matrices of dimension $n \times n$. Fearnley et al. do not make this observation themselves, but it is

straightforward to check that their reduction also gives an efficient representation of the search space. Although Aldous' algorithm is very simple, it non-trivially improves the best runtime of algorithms for multiple problems. We believe that this way of applying Aldous' algorithm is a powerful technique that will produce additional results in the future.

1.2 Technical remarks

Recall that a switching flow is a run profile with additional superfluous circulations compared to the valid run profile. Our main technical observation is a characterization of switching flows that correspond to the valid run profile. Given a switch graph G and a switching flow f, we consider the subgraph G^* induced over the railway network by the "last-used" edges; for every vertex v, we include in G^* only the outgoing edge that was, according to the switching flow, used by the train last time it left from v. Note that such last-used edges can be efficiently identified simply by considering the parity of the total number of visits at every vertex. When f is a valid run profile, then it is straightforward to see that the subgraph G^* is acyclic. We show that this property is in fact a characterization, i.e., any switching flow for which the induced graph G^* is acyclic must be a run profile. Given that this property is easy to check, we can use it to efficiently verify run profiles as UP witnesses. (The coUP witness is then a run profile to the dead-end at $\bar{d}$.)

For our reduction from S-Arrival to End-Of-Metered-Line we extend the above observation to partial switching flows that are not required to end at the destination. The vertices of the End-Of-Metered-Line graph created by our reduction correspond to partial switching flows in the S-Arrival instance. The directed edges connect partial run profiles to their natural successors and predecessors, i.e., the partial run extended or shortened by a single step of the train. Any switching flow that does not correspond to some partial run profile is an isolated vertex in the End-Of-Metered-Line graph. Finally, the trivial source is the empty switching flow, and the distance from it can be computed for any partial run simply as the number of steps taken by the train so far. Given that there is only a single path in the resulting End-Of-Metered-Line graph and that its sink is exactly the complete run, we get that the unique solution to the End-Of-Metered-Line instance gives us a solution for the original instance of S-Arrival.

To make the reduction efficiently computable, we need to address the verification of partial run profiles. As it turns out, partial run profiles can be efficiently verified using the graph G^*, in a similar way to complete run profiles discussed above. The main difference is that the graph of last-used edges for a partial run profile can contain a cycle, as the train might visit the same vertex multiple times on its route to the destination. However, we show that there is at most one cycle in G^*, which always contains the current end-vertex of the partial run. The complete characterization of partial run profiles (which covers also full run profiles) is given in Lemma 9, and the formal reduction is described in Section 4.2.1.

Finally, we show that every partial run profile is uniquely determined by its last-used edges and its end-vertex. This limits the size of the search space for the EOML instances that are produced by our reduction, which allows us to efficiently use Aldous' algorithm [1] to solve Arrival and S-Arrival.

2 Preliminaries

In the rest of the paper we use the following standard notation. For $k \in \mathbb{N}$, we denote by $[k]$ the set $\{1, \ldots, k\}$. For a graph $G = (V, E)$, we reserve $n = |V|$ for the number of vertices. The basic object that we study are switch graphs, as defined by Dohrau et al. [5].

Algorithm 1: RUN.

Input : a switch graph $G = (V, E, s_0, s_1)$ and two vertices $o, d \in V$
Output : for each edge $e \in E$, the number of times the train traversed e

```
1  v ← o                                                  // position of the train
2  ∀u ∈ V set s_curr[u] ← s_0(u) and s_next[u] ← s_1(u)
3  ∀e ∈ E set r[e] ← 0                                    // initialize the run profile
4  step ← 0 while v ≠ d do
5  |  (v, w) ← s_curr[v]                                 // compute the next vertex
6  |  r[s_curr[v]]++                                     // update the run profile
7  |  swap(s_curr[v], s_next[v])
8  |  v ← w                                              // move the train
9  |  step ← step + 1
10 return r
```

▶ **Definition 1** (switch graph). A *switch graph* is a tuple $G = (V, E, s_0, s_1)$ where $s_0, s_1 \colon V \to V$ and $E = \{(v, s_0(v)), (v, s_1(v)) \mid \forall v \in V\}$.[5] In order to avoid cumbersome notation, we slightly overload the use of s_0, s_1 and treat both as functions from vertices to edges; that is by $s_b(v)$ we denote the edge $(v, s_b(v))$ for $b \in \{0, 1\}$. We use this convention throughout the paper unless stated otherwise.

The ARRIVAL problem was formally defined by Dohrau et al. [5] as follows.

▶ **Definition 2** (Arrival [5]). Given a switch graph $G = (V, E, s_0, s_1)$ and two vertices $o, d \in V$, the ARRIVAL problem is to decide whether the algorithm RUN (Algorithm 1) terminates, i.e., whether the train reaches the destination d starting from the origin o.

To simplify theorem statements and our proofs, we assume without loss of generality that both $s_0(d)$ and $s_1(d)$ end in d.

A natural witness for termination of the RUN procedure considered in previous work (e.g. [5]) is a switching flow. We extend the definition of a switching flow to allow for partial switching flows that do not necessarily end in the desired destination d.

▶ **Definition 3** ((partial) switching flow, end-vertex). Let $G = (V, E, s_0, s_1)$ be a switch graph. For $o, d \in V$, we say that $\boldsymbol{f} \in \mathbb{N}^{2n}$ is a *switching flow from o to d* if the following two conditions hold.

Kirchhoff's Law (flow conservation):

$$\forall v \in V \colon \sum_{e=(u,v)\in E} \boldsymbol{f}_e - \sum_{e=(v,w)\in E} \boldsymbol{f}_e = [v = d] - [v = o] \ ,$$

where $[\cdot]$ is the indicator variable of the event in brackets.

Parity Condition:

$$\forall v \in V \colon \boldsymbol{f}_{s_1(v)} \leq \boldsymbol{f}_{s_0(v)} \leq \boldsymbol{f}_{s_1(v)} + 1 \ .$$

Kirchoff's law means that o emits one unit of flow, d absorbs one unit of flow, and at all other vertices, in-flow equals out-flow. If $d = o$, we have a circulation.

Given an instance $(G = (V, E, s_0, s_1), o, d)$ of ARRIVAL, we say that $\boldsymbol{f}$ is a *switching flow* if it is a switching flow from o to d. A vector $\boldsymbol{f} \in \mathbb{N}^{2n}$ is called a *partial switching flow* iff $\boldsymbol{f}$ is a switching flow from o to v for some vertex $v \in V$. We say that v is the *end-vertex* of the partial switching flow. We denote the end-vertex of $\boldsymbol{f}$ by $v_{\boldsymbol{f}}$.

[5] Whenever $s_0(v) = s_1(v)$ for some vertex $v \in V$ we depict them as multiple edges in figures.

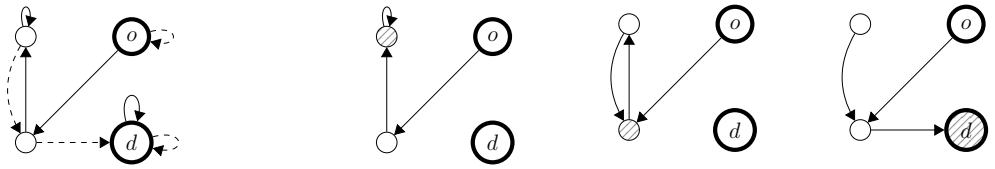

Figure 1 An example of a switch graph G and cycles in the graphs G^* corresponding to partial run profiles after 3, 4, and 5 steps of the train (respectively from left to right). We use hatching to highlight the current end-vertex.

▶ **Definition 4** ((partial) run profile)**.** A *run profile* is the switching flow $\boldsymbol{r}$ returned by the algorithm Run (Algorithm 1) upon termination. A *partial run profile* is a partial switching flow corresponding to some intermediate value of $\boldsymbol{r}$ in the algorithm Run (Algorithm 1).

▶ **Observation 5** (Dohrau et al. [5, Observation 1])**.** *Each (partial) run profile is a (partial) switching flow.*

▶ **Observation 6.** *An end-vertex $v_{\boldsymbol{f}}$ of a switching flow $\boldsymbol{f}$ is computable in polynomial time.*

Proof. It is sufficient to determine which vertex has a net in-flow of one. ◀

3 The Complexity of Run Profile Verification

Dohrau et al. [5] proved that it is possible to efficiently verify whether a given vector is a switching flow. In this section we show that we can also efficiently verify whether a switching flow is a run profile. Combining this with the results by Dohrau et al. [5], we prove that the decision problem of Arrival is in $\mathsf{UP} \cap \mathsf{coUP}$ (see Section 4.1) and that the search problem of Arrival lies in the complexity class CLS (see Section 4.2). As outlined in Section 1.2, our approach for verification of run profiles is based on finding a cycle in a natural subgraph of the railway network G defined below. Specifically, we consider the subgraph of G that contains only the last visited outgoing edge of each vertex, i.e., every vertex has out-degree at most one.

▶ **Definition 7** ($G^*_{\boldsymbol{f}}$)**.** Let $(G = (V, E, s_0, s_1), o, d)$ be an instance of Arrival, and let $\boldsymbol{f} \in \mathbb{N}^{2n}$ be a partial switching flow. We define a graph $G^*_{\boldsymbol{f}} = (V, E^*)$ as follows

$$E^* = \left\{ s_0(v) \colon \forall v \in V \text{ s.t. } \boldsymbol{f}_{s_0(v)} \neq \boldsymbol{f}_{s_1(v)} \right\} \cup \left\{ s_1(v) \colon \forall v \in V \text{ s.t. } \boldsymbol{f}_{s_0(v)} = \boldsymbol{f}_{s_1(v)} > 0 \right\}.$$

▶ **Observation 8.** *Given a partial switching flow $\boldsymbol{f}$, the graph $G^*_{\boldsymbol{f}}$ can be computed in polynomial time.*

▶ **Lemma 9.** *A partial switching flow $\boldsymbol{f}$ is a partial run profile iff $\boldsymbol{f}_{s_0(d)} = \boldsymbol{f}_{s_1(d)} = 0$ and one of the following two conditions holds:*

1. *There exists no cycle in $G^*_{\boldsymbol{f}}$.*
2. *There exists exactly one cycle in $G^*_{\boldsymbol{f}}$ and this cycle contains the end-vertex of $\boldsymbol{f}$.*

The main idea of the proof is based on the following fact: a switching flow f which is *not* a run profile must contain a circulation (as shown by Dohrau et al. [5]). Let f be a switching flow that we get from a run profile r by adding some flows on cycles, then the last added circulation (the last added cycle) must form a cycle in the corresponding graph G^*_f. On the

other hand, a cycle containing the end-vertex is formed in G^*_f whenever the train arrives to a previously visited vertex. An illustration of the graph G^* at consecutive steps of the algorithm Run, with the corresponding evolution of the end-vertices and cycles, is given in Figure 1.

The complete proof of Lemma 9 is provided in the full version [8].

▶ **Lemma 10.** *It is possible to verify in polynomial time whether a vector is a run profile.*

Proof. We can check that a vector $\boldsymbol{f}$ is a switching flow in polynomial time due to Dohrau et al. [5]. The construction of the graph $G^*_{\boldsymbol{f}}$ is polynomial by Observation 8. Lemma 9 gives us a polynomial time procedure to check if $\boldsymbol{f}$ is also a run profile as it is sufficient to check if $G^*_{\boldsymbol{f}}$ contains more than one cycle or whether it has a cycle not containing the end-vertex. This check can be done by a simple modification of the standard depth-first search on $G^*_{\boldsymbol{f}}$. ◀

4 The Computational Complexity of Arrival

In this section we use our efficient structural characterization of run profiles from Lemma 9 to improve the known results about the computational complexity of Arrival. Specifically, we show that the decision version of Arrival is in $\mathsf{UP} \cap \mathsf{coUP}$ and the search version is in CLS.

4.1 The Decision Complexity of Arrival

Our upper bound on the decision complexity of Arrival follows directly from the work of Dohrau et al. [5] by application of Lemma 10.

▶ **Theorem 11.** Arrival *is in* $\mathsf{UP} \cap \mathsf{coUP}$.

Proof. The unique UP certificate for a YES-instance of Arrival is the run profile $\boldsymbol{r}$ returned by the algorithm Run. Clearly, for each YES-instance there exists only one such vector $\boldsymbol{r}$ and $\boldsymbol{r}$ does not exist for NO-instances. By Lemma 10, we can determine whether a candidate switching flow $\boldsymbol{r}$ is a run profile in polynomial time.

The coUP membership follows directly from the reduction of NO-instances of Arrival to YES-instances of Arrival as suggested by Dohrau et al. [5]. The reduction adds to the original graph G a new vertex $\bar{d}$, and for each vertex $v \in V$ such that there is no directed path from v to the destination d, the edges $s_0(v)$ and $s_1(v)$ are replaced with edges $(v, \bar{d})$. This alteration of the original switch graph can be performed in polynomial time. Dohrau et al. [5] proved that the train eventually arrives either at d or $\bar{d}$. The unique coUP witness for Arrival is then a run profile from o to the dead-end $\bar{d}$. ◀

4.2 The Search Complexity of Arrival

The search complexity of Arrival was first studied by Karthik C. S. [14], who introduced a total search variant of Arrival as follows.

▶ **Definition 12** (S-Arrival [14])**.** Given a switch graph $G = (V, E, s_0, s_1)$ and a pair of vertices $o, d \in V$, define a graph G' as follows:

1. Add a new vertex $\bar{d}$.
2. For each vertex v such that there is no directed path from v to d, replace edges $s_0(v)$ and $s_1(v)$ with edges $(v, \bar{d})$.
3. Edges $s_0(d), s_1(d), s_0(\bar{d})$, and $s_1(\bar{d})$ are self-loops.

The problem S-Arrival is to find a switching flow in G' either from o to d or from o to $\bar{d}$.

The above Definition 12 is motivated by the proof of membership in NP ∩ coNP by Dohrau et al. [5]. Namely, in order to ensure that a solution for S-Arrival always exists, it was necessary to add to the switch graph G the dead-end vertex $\bar{d}$.

Note that our method for efficient verification of run profiles from Lemma 10 allows us to define a more natural version of S-Arrival directly on the graph G without any modifications. Instead of relying on the dead-end vertices, we can use the fact that a partial run profile with an edge that was visited for $2^n + 1$ times is an efficiently verifiable witness for NO-instances of Arrival.

▶ **Definition 13** (S-Arrival - simplified)**.** Given a switch graph $G = (V, E, s_0, s_1)$ and a pair of vertices $o, d \in V$, the S-Arrival problem asks us to find one of the following:

1. a run profile $\boldsymbol{r} \in \mathbb{N}^{[2n]}$ from o to d, or
2. a run profile $\boldsymbol{r} \in \mathbb{N}^{[2n]}$ from o to any $v \in V$ such that
   - $\boldsymbol{r}_{(u,v)} = 2^n + 1$, where u is the last vertex visited by the train before it reached the end-vertex v of $\boldsymbol{r}$, and
   - $\boldsymbol{r}_{e'} \leq 2^n$ for all $e' \neq (u, v)$.

The correspondence of the above version of S-Arrival to the original one follows formally from the following lemma.

▶ **Lemma 14** (Karthik C. S. [14, Lemma 1])**.** *For any $G = (V, E, s_0, s_1)$ and a pair of vertices $o, d \in V$. Let $\boldsymbol{r}$ be a run profile (thus $v_{\boldsymbol{r}} = d$), then $\boldsymbol{r}_e \leq 2^n$ for each edge $e \in E$.*

To argue membership of our version of S-Arrival in TFNP, we need to show that both types of solutions in Definition 13 can be verified efficiently. Solutions of the first type are simply run profiles, and we have already shown that they can be verified in polynomial time in Lemma 10. In order to be able to verify solutions of the second type, it remains to argue that for any partial run profile, the immediate predecessor of its end-vertex can be determined in polynomial time.

▶ **Lemma 15.** *Let $\boldsymbol{r}$ be a partial run profile after $R \geq 1$ steps and u be the vertex visited by the train at step $R - 1$. Then*

1. *either u is the unique predecessor of $v_{\boldsymbol{r}}$ in $G^*_{\boldsymbol{r}}$, or*
2. *there is a single cycle in $G^*_{\boldsymbol{r}}$ containing $v_{\boldsymbol{r}}$ and u is the predecessor of $v_{\boldsymbol{r}}$ on this cycle.*

Proof. First, note that if u is the end-vertex one step before $v_{\boldsymbol{r}}$ becomes the end-vertex then $G^*_{\boldsymbol{r}}$ must contain the edge $(u, v_{\boldsymbol{r}})$, as it is the last edge used by the train to leave u. Thus, in the first case (when $v_{\boldsymbol{r}}$ has only one predecessor in $G^*_{\boldsymbol{r}}$) the immediate predecessor of $v_{\boldsymbol{r}}$ in the partial run $\boldsymbol{r}$ is unambiguously given by the only predecessor of $v_{\boldsymbol{r}}$ in $G^*_{\boldsymbol{r}}$.

For the second case we show that $G^*_{\boldsymbol{r}}$ contains a directed cycle C (containing the end-vertex $v_{\boldsymbol{r}}$) and u is unambiguously given by the predecessor of $v_{\boldsymbol{r}}$ in $G^*_{\boldsymbol{r}}$ that lies on C. We find the cycle C by constructing the longest possible directed path $c_0 = v_{\boldsymbol{r}}, c_1, \ldots, c_k$ in $G^*_{\boldsymbol{r}}$ without repeating vertices. Note that it cannot happen that c_k has no outgoing edge in $G^*_{\boldsymbol{r}}$. Otherwise, $\boldsymbol{r}$ would have two different end-vertices $v_{\boldsymbol{r}}$ and c_k (as having no outgoing edge in $G^*_{\boldsymbol{r}}$ means that the train has never left this vertex). By Lemma 9, the directed edge from c_k has to end in the end-vertex $v_{\boldsymbol{r}}$, or else there would be a cycle in $G^*_{\boldsymbol{r}}$ that avoids $v_{\boldsymbol{r}}$.

The algorithm Run takes R steps to generate the run profile $\boldsymbol{r}$, i.e., $\sum_{e \in E} \boldsymbol{r}_e = R$. Let $t_{\boldsymbol{r}} \colon V \to \{0, 1, \ldots, R - 1\}$ be the function returning the last step after which a vertex was left by the train in the partial run profile $\boldsymbol{r}$. Observe that, except for the edge through which

the train arrived to $v_{\boldsymbol{r}}$,[6] it holds for all edges $(x, y) \in G^*_{\boldsymbol{r}}$ that $t_{\boldsymbol{r}}(x) < t_{\boldsymbol{r}}(x) + 1 \leq t_{\boldsymbol{r}}(y)$. However, the above inequality cannot hold for all edges on the cycle C, and thus C has to contain the last used edge and the train had to be in c_k at step $R - 1$. ◀

▶ **Observation 16.** S-Arrival *from Definition 12 reduces to simplified* S-Arrival *from Definition 13.*

Proof. Given a solution of the second type of the simplified S-Arrival, i.e., the long run profile, we can get a run profile $\boldsymbol{r}$ to $\bar{d}$ in polynomial time. For each vertex u we can determine whether there is an oriented path from it to the destination d, and if there is no such path we set $\boldsymbol{r}_{s_0(v)} = \boldsymbol{r}_{s_1(v)} = 0$. We compute the end vertex $v_{\boldsymbol{r}}$ and set $s_0(v_{\boldsymbol{r}}) = 1$. All other components of $\boldsymbol{r}$ are set according to the original solution of the simplified S-Arrival. ◀

4.2.1 S-Arrival is in CLS

Karthik C. S. [14] showed that S-Arrival is contained in the class PLS. We improve this result and prove that S-Arrival is in fact contained in CLS. As a by-product, we also obtain a randomized algorithm for S-Arrival with runtime $\mathcal{O}(1.4143^n)$ which is the first algorithm for this problem with expected runtime $\mathcal{O}(c^n)$ for $c < 2$.

The class of total search problems that are amenable to "continuous" local search was defined by Daskalakis and Papadimitriou [4] using the following canonical problem.

▶ **Definition 17** (CLS [4])**.** CLS is the class of total search problems reducible to the following problem called CLOpt.

Given two arithmetic circuits $f\colon [0,1]^3 \to [0,1]^3$ and $p\colon [0,1]^3 \to [0,1]$, and two real constants $\varepsilon, \lambda > 0$, find either a point $x \in [0,1]^3$ such that $p(f(x)) \leq p(x) + \varepsilon$ or a pair of points $x, x' \in [0,1]^3$ certifying that either p or f is not λ-Lipschitz.

Instead of working with CLOpt, we use as a gateway for our reduction a problem called End-Of-Metered-Line (EOML) which was recently defined and shown to lie in CLS by Hubáček and Yogev [9].

▶ **Definition 18** (End-Of-Metered-Line)**.** Given circuits $S, P\colon \{0,1\}^m \to \{0,1\}^m$, and $V\colon \{0,1\}^m \to [2^m] \cup \{0\}$ such that $P(0^m) = 0^m \neq S(0^m)$ and $V(0^m) = 1$, find a string $x \in \{0,1\}^m$ satisfying one of the following:

1. either $P(S(x)) \neq x$ or $S(P(x)) \neq x \neq 0^m$,
2. $x \neq 0^m$ and $V(x) = 1$,
3. either $V(x) > 0$ and $V(S(x)) - V(x) \neq 1$ or $V(x) > 1$ and $V(x) - V(P(x)) \neq 1$.

The circuits S, P from Definition 18 implicitly represent a directed graph with vertices labelled by binary strings of length m, where each vertex has both out-degree and in-degree at most one. The circuit P represents the predecessor and the circuit S represents the successor of a given vertex as follows: there is an edge from a vertex u to a vertex v iff $S(u) = v$ and $P(v) = u$. Finally, the circuit V can be thought of as an odometer that returns the distance from the trivial source at 0^m or value 0 for vertices lying off the path starting at the trivial source. The task in End-Of-Metered-Line is to find a sink or a source different from the trivial one at 0^m (the solutions of the second and of the third type in Definition 18 ensure that V behaves as explained above).

We are now ready to present our reduction from S-Arrival to End-Of-Metered-Line.

[6] The inequality does not hold for $v_{\boldsymbol{r}}$, since $t(v_{\boldsymbol{r}})$ has not been updated to the time R yet.

▶ **Theorem 19.** S-Arrival *can be reduced to* End-Of-Metered-Line*, and thus it is contained in* CLS*.*

Proof. Let (G, o, d) be an instance of S-Arrival. We construct an instance of EOML that contains a vertex for each candidate partial switching flow over the switch graph G, i.e., for each vector with $2n$ coordinates and values from $[2^n + 1] \cup \{0\}$. The EOML instance will comprise of a directed path starting at the initial (empty) partial run profile 0^{2n}. Each vertex on the path has an outgoing edge to its consecutive partial run profile. Any vertex that does not correspond to a partial run profile becomes a self-loop. Finally, the valuation circuit V returns either the number of steps in the corresponding partial run profile or the zero value if the vertex does not correspond to a partial run profile. Formal description of the circuits S, P, and V defining the above EOML graph is provided in the full version [8]. A polynomial bound on the size of the circuits S, P, and V follows directly from Observation 8 (computing G^*), Lemma 10 (testing whether a given vector is a partial run profile), Observation 6 (computing the end-vertex), and Lemma 15 (computing the previous position of the train).

Lemma 9 and Lemma 15 imply that the EOML graph indeed consists of a single directed path and isolated vertices with self-loops. By the construction of V (it outputs the number of steps of the train), there are no solutions of the second or the third type (cf. Definition 18). Thus, the EOML instance has a unique solution which has to correspond to a run profile in the original S-Arrival instance or to a partial run profile certifying that the train ran for too long (see the second type of solution in Definition 13). ◀

5 An $\mathcal{O}(1.4143^n)$ Algorithm for S-Arrival

Consider any problem that can be put into the complexity class PLS, i.e., can be reduced to the canonical PLS-complete problem LocalOpt (see also [14, Definition 1]):

▶ **Definition 20** (LocalOpt)**.** Given circuits $S\colon \{0,1\}^m \to \{0,1\}^m$, and $V\colon \{0,1\}^m \to [2^m] \cup \{0\}$, find a string $x \in \{0,1\}^m$ such that $V(x) \geq V(S(x))$.

Aldous [1] introduced the following simple algorithm that can be used to solve LocalOpt: pick $2^{m/2}$ binary strings uniformly and independently at random from $\{0,1\}^m$, and let $x_{\max}$ be the selected string that maximizes the value $V(x)$. Starting from $x = x_{\max}$, repeatedly move to the successor $S(x)$, until $V(x) \geq V(S(x))$. He showed that the expected number of circuit evaluations performed by the algorithm before finding a local optimum is at most $\mathcal{O}(m2^{m/2})$. Note that in the case of EOML it is possible that all sampled solutions are isolated vertices in the EOML graph. In this case the 0^m string has the best known value, and the search is started from there.

In the case of S-Arrival, the PLS membership proof of Karthik C. S. constructs the circuits for successor and valuation with $\mathcal{O}(n^2)$ input bits [14, Theorem 2]; the EOML instance constructed in Theorem 19 – proving CLS and in particular PLS membership – yields circuits of $\mathcal{O}(n^2)$ input bits as well. This number is too high to yield a randomized algorithm of non-trivial runtime.

This number of $\mathcal{O}(n^2)$ input bits comes from the obvious encoding of a partial run profile: each of the $2n$ edges has a nonnegative integer flow value of at most $2^n + 1$. But in fact, a *terminating* run has at most $n2^n$ partial run profiles, as no *vertex-state pair* (v, s_curr) can repeat in Algorithm 1. In other words, a partial run profile $\boldsymbol{f}$ is determined by its end-vertex $v_{\boldsymbol{f}}$ as well as the positions of all switches at the time of the corresponding visit of $v_{\boldsymbol{f}}$. This means that a partial run profile can be encoded with $n + \log_2 n$ bits, and if we had a PLS or CLS membership proof of S-Arrival with circuits of this many inputs only, we could solve S-Arrival in time $O(\text{poly}(n) \times 2^{n/2})$.

Next, we show that such membership proofs indeed exist. For this, we show that the above encoding (of a partial run profile by an end-vertex and the positions of all switches) can be efficiently decoded: given an end-vertex and the positions of all switches, we can efficiently compute a unique candidate for a corresponding partial run profile. The resulting encoding and decoding circuits can be composed with the ones in Theorem 19 to obtain PLS and CLS membership proofs with circuits of $n + \log_2 n$ input bits, and hence yield a randomized algorithm of runtime $O(\text{poly}(n) \times 2^{n/2}) = O(1.4143^n)$, as explained above.

5.1 Decoding Partial Run Profiles

We work with instances of S-Arrival as in Definition 12, i.e., there is always a run profile either to d or to $\bar{d}$. This is without loss of generality [5, 14].

▶ **Definition 21.** Let $G = (V, E, s_0, s_1)$ be a switch graph, and let $o, d, \bar{d} \in V$ be as in Definition 12. The *parity* of a run profile $\boldsymbol{f} \in \mathbb{N}^{2n}$ is the vector $\boldsymbol{p_f} \in \{0,1\}^{n-2}$ defined by $\boldsymbol{p}_v = \boldsymbol{f}_{s_0(v)} - \boldsymbol{f}_{s_1(v)} \in \{0,1\}$, $v \in V \setminus \{d, \bar{d}\}$.

Note that we do not care about (the parity of) the switches at d and $\bar{d}$, since the algorithm stops as soon as d or $\bar{d}$ is reached.

Here is the main result of this section. For a given target vertex $t \in V$ and given parity $\boldsymbol{p}$, there is exactly one candidate for a partial run profile from o to t with parity $\boldsymbol{p}$. Moreover, this candidate can be computed by solving a system of linear equations.

▶ **Lemma 22.** *Let $(G, o, d, \bar{d})$ be an instance of* S-Arrival*, let $t \in V$ and $\boldsymbol{p} \in \{0,1\}^{n-2}$. Then there exists exactly one vector $\boldsymbol{f} \in \mathbb{R}^{2(n-2)}$ such that the following conditions hold.*
Kirchhoff's Law (flow conservation):

$$\forall v \in V \setminus \{d, \bar{d}\}\colon \sum_{e=(u,v)\in E} \boldsymbol{f}_e - \sum_{e=(v,w)\in E} \boldsymbol{f}_e = [v = t] - [v = o] \tag{1}$$

where $[\cdot]$ is the indicator variable of the event in brackets.
Parity Condition: $\boldsymbol{p_f} = \boldsymbol{p}$*, i.e.,*

$$\forall v \in V \setminus \{d, \bar{d}\}\colon \boldsymbol{f}_{s_0(v)} - \boldsymbol{f}_{s_1(v)} = \boldsymbol{p}_v. \tag{2}$$

Before we prove Lemma 22, let us draw a crucial conclusion: The unique partial run profile $\boldsymbol{f} \in \mathbb{N}^{2n}$ with end-vertex t and parity $\boldsymbol{p}$ (if such f exists – note that we are only guaranteed a real-valued $\boldsymbol{f}$) necessarily satisfies (1) and (2). Hence, we may use Lemma 22 to get the entries $\boldsymbol{f}_e$ for all edges except the ones leaving d and $\bar{d}$. Only if all the entries are nonnegative and integral and satisfy (1) at d and $\bar{d}$ (under $\boldsymbol{f}_{s_0(d)} = \boldsymbol{f}_{s_1(d)} = \boldsymbol{f}_{s_0(\bar{d})} = \boldsymbol{f}_{s_1(\bar{d})} = 0$) do we have a candidate for a partial run profile. Hence, there is a unique candidate, and given t and a $\boldsymbol{p}$, this candidate can be efficiently found.

Proof of Lemma 22. Set $m = 2(n-2)$, $V' = V \setminus \{d, \bar{d}\}$ and let $A \in \mathbb{Z}^{m \times m}$ be the coefficient matrix of the linear system (1), (2) in the variables $\boldsymbol{f}_e$. We show that A is invertible.

Let $\boldsymbol{q} \in \mathbb{R}^m$ be the vector such that $\boldsymbol{q}_{(v,s_i(v))} = -1$ if $s_i(v) = d$ and $\boldsymbol{q}_{(v,s_i(v))} = 0$ otherwise. We show that $\boldsymbol{q}$ can be expressed as a linear combination of the rows of A in a unique way, from which invertibility of A and the statement of the lemma follow.

Let us use coefficients λ_v for each $v \in V'$ for the rows corresponding to the flow conservation constraints (1), and coefficients μ_v for each $v \in V'$ for the rows corresponding to the parity constraints (2). The column of A corresponding to variable $\boldsymbol{f}_{(v,s_i(v))}$, has a -1 entry from the flow conservation constraint at v, and a 1 entry (if $i = 0$) or a -1 entry (if

$i = 1$) from the parity constraint at v. If $s_i(v) \neq d, \bar{d}$, there is another 1 entry from the flow conservation constraint at $s_i(v)$. All other entries are zero. The equations that express $\boldsymbol{q}$ as a linear combination of rows of A are therefore the following.

$$\begin{aligned}\forall v \in V' :\ -\lambda_v + \mu_v + \lambda_{s_0(v)} \cdot [s_0(v) \neq d, \bar{d}] &= \boldsymbol{q}_{(v,s_0(v))},\\ \forall v \in V' :\ -\lambda_v - \mu_v + \lambda_{s_1(v)} \cdot [s_1(v) \neq d, \bar{d}] &= \boldsymbol{q}_{(v,s_1(v))}.\end{aligned}$$

Or equivalently:

$$\lambda_v - \mu_v = \begin{cases} \lambda_{s_0(v)}, & \text{if } s_0(v) \neq d, \bar{d} \\ 1, & \text{if } s_0(v) = d \\ 0, & \text{if } s_0(v) = \bar{d} \end{cases} \qquad v \in V', \tag{3}$$

$$\lambda_v + \mu_v = \begin{cases} \lambda_{s_1(v)}, & \text{if } s_1(v) \neq d, \bar{d} \\ 1, & \text{if } s_1(v) = d \\ 0, & \text{if } s_1(v) = \bar{d} \end{cases} \qquad v \in V'. \tag{4}$$

We now show that there are unique coefficients λ_v, μ_v satisfying these equations. Let us define $\lambda_d = 1$ and $\lambda_{\bar{d}} = 0$. Adding corresponding equations of (3) and (4) then yields

$$\lambda_d = 1, \quad \lambda_{\bar{d}} = 0, \quad \lambda_v = \frac{1}{2}\left(\lambda_{s_0(v)} + \lambda_{s_1(v)}\right), \quad \forall v \in V'.$$

These are exactly the equations for the vertex values in a *stoppping simple stochastic game* on the graph G with only average or degree-1 vertices and sinks d and $\bar{d}$ (stopping means that d or $\bar{d}$ are reachable from everywhere which is exactly what we require in a switch graph). Condon proved that these values are unique [3]. This also determines the μ_v's uniquely. ◀

6 Conclusion and Open Problems

We showed that candidate run profiles in Arrival can be efficiently verified due to their structure. This allowed us to improve the known upper bounds for the search complexity of Arrival and S-Arrival. Here we mention some natural questions arising from our work.

- Are there any non-trivial graph properties that make Arrival or S-Arrival efficiently solvable? Given that we currently do not know of any polynomial time algorithm for Arrival on general switch graphs, we could study the complexity of Arrival on some interesting restricted classes of switch graphs.
- Are there other natural problems in $\mathsf{UP} \cap \mathsf{coUP}$ such that their corresponding search variant is reducible to EOML? Does End-Of-Metered-Line capture the computational complexity of any TFNP problem with unique solution? Fearnley et al. [7] recently gave a reduction from the PLCP to EOML. Given that Arrival and PLCP can be both reduced to EOML, yet another intriguing question is whether there exists any reduction between the two.
- As mentioned in Section 1.1, the reduction from PLCP to EOML by Fearnley et al. [7] implies that PLCP can be solved faster with Aldous' algorithm [1] than with any other known algorithm. It would be interesting to see whether Aldous' algorithm can similarly give improved runtimes for other problems than Arrival and PLCP.

Improved Bounds for Shortest Paths in Dense Distance Graphs

Paweł Gawrychowski

Abstract

We study the problem of computing shortest paths in so-called *dense distance graphs*, a basic building block for designing efficient planar graph algorithms. Let G be a plane graph with a distinguished set ∂G of *boundary vertices* lying on a constant number of faces of G. A distance clique of G is a complete graph on ∂G encoding all-pairs distances between these vertices. A dense distance graph is a union of possibly many unrelated distance cliques.

Fakcharoenphol and Rao [7] proposed an efficient implementation of Dijkstra's algorithm (later called *FR-Dijkstra*) computing single-source shortest paths in a dense distance graph. Their algorithm spends $O(b \log^2 n)$ time per distance clique with b vertices, even though a clique has b^2 edges. Here, n is the total number of vertices of the dense distance graph. The invention of FR-Dijkstra was instrumental in obtaining such results for planar graphs as nearly-linear time algorithms for multiple-source-multiple-sink maximum flow and dynamic distance oracles with sublinear update and query bounds.

At the heart of FR-Dijkstra lies a data structure updating distance labels and extracting minimum labeled vertices in $O(\log^2 n)$ amortized time per vertex. We show an improved data structure with $O\left(\frac{\log^2 n}{\log^2 \log n}\right)$ amortized bounds. This is the first improvement over the data structure of Fakcharoenphol and Rao in more than 15 years. It yields improved bounds for all problems on planar graphs, for which computing shortest paths in dense distance graphs is currently a bottleneck.

1 Introduction

Finding a truly subquadratic, strongly polynomial algorithm for many of the most basic real-weighted graph problems like the single-source shortest paths or the maximum flow on sparse digraphs seems to be very difficult. However, the situation changes significantly if we restrict ourselves to planar digraphs, which constitute an important class of sparse graphs. In this regime the ultimate goal is to obtain linear or almost linear time complexity.

In their breakthrough paper, Fakcharoenphol and Rao gave the first nearly-linear time algorithm for single-source shortest paths in real-weighted planar graphs [7]. Their algorithm had $O(n \log^3 n)$ time complexity. Although their upper bound was eventually improved to $O\left(n \frac{\log^2 n}{\log \log n}\right)$ by Mozes and Wulff-Nilsen [22], the techniques introduced in [7] proved very useful in obtaining not only nearly-linear time algorithms for other static planar graph problems, but also first sublinear dynamic algorithms for shortest paths and maximum flows.

A major contribution of Fakcharoenphol and Rao was introducing the general concept of a *dense distance graph*. Let G be a real-weighted plane digraph and let ∂G denote some subset of its vertices, called *boundary vertices*, such that there exist $\ell = O(1)$ faces $f_1, \ldots, f_\ell$ of G satisfying $\partial G \subseteq V(f_1) \cup \ldots V(f_\ell)$. Such graphs with a topologically nice boundary typically emerge after decomposing a plane graph using a cycle separator. For example, by using a cycle separator of Miller [19], one can decompose any n-vertex triangulated plane graph H into two subgraphs H_{in} and H_{out} such that (i) $H_{\text{in}} \cup H_{\text{out}} = H$, (ii) H_{in} and H_{out} are smaller than H by a constant factor, (iii) the set $\partial H_{\text{in}} = \partial H_{\text{out}} = V(H_{\text{in}}) \cap V(H_{\text{out}})$ has size $O(\sqrt{n})$ and lies both on a single face of H_{in} and on a single face of H_{out}.

We define a *distance clique* of G, denoted $\mathrm{DC}(G)$, to be a complete graph on ∂G such that the weight of an edge uv is equal to the length of the shortest path from u to v in G. A dense distance graph is a union of possibly many unrelated distance cliques.

We note that such a definition of a dense distance graph (also used in [23]) is a bit more general than that of Fakcharoenphol and Rao [7], who defined it only with respect to a recursive decomposition of G using cycle-separators. In fact, subsequently dense distance graphs have been also defined a bit differently with respect to so-called r-divisions [13], and even the two sides of a cycle-separator [15] (i.e., $\mathrm{DC}(H_{\text{in}}) \cup \mathrm{DC}(H_{\text{out}})$ in the above example). The definition we assume in this paper captures all these cases.

Suppose we are given q distance cliques $\mathrm{DC}(G_1), \ldots, \mathrm{DC}(G_q)$ explicitly. Let $\mathrm{DDG} = \bigcup_{i=1}^{q} \mathrm{DC}(G_i)$, $V = \partial G_1 \cup \ldots \cup \partial G_q$ and $n = |V|$. Clearly, DDG has $\sum_{i=1}^{q} |\partial G_i|^2$ edges in total. Fakcharoenphol and Rao showed how to compute single-source shortest paths in such graph DDG with non-negative edge weights in only $O\left(\sum_i |\partial G_i| \log^2 n\right)$ time, i.e., for each $\mathrm{DC}(G_i)$ one only needs to spend time nearly-linear in the number of *vertices* of $\mathrm{DC}(G_i)$, as opposed to its number of edges, i.e., $|\partial G_i|^2$. Their method is often called the *FR-Dijkstra*, as it follows the overall approach of Dijkstra's algorithm. Whereas Dijkstra's algorithm uses a priority queue to maintain its distance labels and extract a non-visited vertex with minimum label, a much more sophisticated data structure is used in FR-Dijkstra. This data structure is capable of relaxing many edges in a single step, by leveraging the fact that certain submatrices of the adjacency matrix of a distance clique are *Monge matrices*.

Applications of Dense Distance Graphs and FR-Dijkstra. Fakcharoenphol and Rao originally employed FR-Dijkstra to construct their dense distance graph recursively and answer distance queries on it. However, the applications of FR-Dijkstra proved much broader and thus it has become an important planar graph primitive used to obtain numerous breakthrough results in recent years. We briefly cover the most important of these results below.

The dense distance graphs and FR-Dijksta have been used to break the long-standing $O(n \log n)$ barrier for computing minimal s,t-cuts [12] in undirected planar graphs and global min-cuts in both undirected [17] and directed [20] planar graphs. Borradaile et al. [5] developed an oracle answering arbitrary min s,t-cut queries in an weighted undirected planar graph after only near-linear preprocessing. This result has been later generalized to bounded-genus graphs [3], thus proving the usefulness of FR-Dijkstra in more general graph classes.

The most sophisticated applications of FR-Dijkstra are probably those related to computing maximum flow in directed planar graphs. Borradaile et al. [4] gave a nearly-linear time max-flow algorithm for the case of multiple source and multiple sinks and maximum bipartite matching. Later, Łącki et al. [18] gave a nearly-linear time algorithm computing the maximum flow values between a specified source and all possible sinks.

Most recently, Asathulla et al. [2] used FR-Dijkstra to break through the $O(n^{3/2})$ barrier for minimum-cost bipartite weighted matching with integer weights. Cabello [6] showed the first truly subquadratic algorithm for computing a diameter of a weighted planar graph. Even though it mainly builds on a new concept of additively weighted Voronoi diagrams for planar graphs, dense distance graphs and FR-Dijkstra are still used extensively in his work. The diameter algorithm was later improved by Gawrychowski et al. [9] to run in $O(n^{5/3} \operatorname{polylog} n)$. Currently, [9] does not require FR-Dijkstra, but it seems that using it would be again required if one gave a more efficient Voronoi diagrams construction algorithm for planar graphs. Last but not least, FR-Dijkstra has been instrumental to obtaining virtually all *exact* dynamic algorithms for shortest paths, maximum flows and minimum cuts in planar graphs, with sublinear update/query bounds [7, 12, 13, 14, 17].

Significance. Dense distance graphs are pivotal in designing efficient planar graph algorithms, and therefore obtaining fine-grained bounds for computing and manipulating them is an important direction. Although a better algorithm (in comparison to the recursive method of [7]) running in $O((|V| + |\partial G|^2) \log n)$ time has been proposed for computing a distance clique [14], improving the FR-Dijkstra itself proved very challenging and no progress over [7] has been made so far in the most general setting that we study.

Related Work. For the important case of a *dense distance graph over an r-division*, i.e., when the individual graphs G_i are the pieces of an *r-division with few holes* of a single planar graph (see e.g., [16]), Mozes et al. [21] gave an algorithm for computing single source shortest paths in $O\left(\frac{n}{\sqrt{r}} \log^2 r\right)$ time. The original FR-Dijkstra runs in $O\left(\frac{n}{\sqrt{r}} \log n \log r\right)$ time in that case. Hence, [21] does not improve over it in the case of $r = \operatorname{poly} n$, which emerges in many important applications, e.g., [2, 3, 4, 13, 18]. However, dense distance graphs over r-divisions with $r = \operatorname{polylog}(n)$ have also found applications, most notably in $O(n \log \log n)$ algorithms for minimum cuts [12, 17, 20]. Computing shortest paths in dense distance graphs is not a bottleneck in those algorithms, though. For other applications of dense distance graphs over r-divisions with small r, consult [21].

Our Contribution. In this paper we show an algorithm for computing single-source shortest paths in a DDG in $O\left(\sum_{i=1}^{q} |\partial(G_i)| \frac{\log^2 n}{\log^2 \log n}\right)$ time, which is asymptotically faster than FR-Dijkstra in *all* cases. Specifically, for a dense distance graph defined over an r-division, the algorithm runs in $O\left(\frac{n}{\sqrt{r}} \frac{\log^2 n}{\log^2 \log n}\right)$ time.

We treat the problem of computing shortest paths in DDG from a purely data-structural perspective. At a high level, instead of developing an entirely new shortest paths algorithm,

we propose a new data structure for maintaining distance labels and extracting minimum labeled vertices in amortized $O\left(\frac{\log^2 n}{\log^2 \log n}\right)$ time, as opposed to $O(\log^2 n)$ time in [7].

In [7], a distance clique is first partitioned into *square* Monge matrices, each handling a subset of its edges. For any such matrix, a separate data structure is used for relaxing the corresponding edges and extracting the labels possibly induced by these edge relaxations. Recall that in the case of Dijkstra's algorithm, the improvement from $O(m \log n)$ to $O(m + n \log n)$ is obtained by noticing that relaxing edges is cheaper than extracting minimum labeled vertices. Consequently, one can use a Fibonacci heap [8] in place of a binary heap. We show that in the case of the data structure originally used in [7] for handling Monge matrices, the situation is in a sense the opposite: label extractions can be made cheaper than edge relaxations. We make use of this fact by proposing a biased scheme of partitioning distance cliques into *rectangular* (as opposed to square) Monge matrices, different than in [7]. Whereas in [7], the partition follows from a very natural idea of splitting face boundary into halves, our partition is tailored to exploit this asymmetry between the cost of processing a row and the cost of processing a column.

Our result implies an immediate improvement by a factor of $O(\log^2 \log n)$ in the time complexity for a number of planar digraph problems such as multiple-source multiple-sink maximum flows, maximum bipartite matching [4], single-source all-sinks maximum flows [18], for which the best known time bounds were $O(n \log^3 n)$, i.e., already nearly-linear. It also yields polylog-logarithmic speed-ups to both preprocessing and query/update algorithms of dynamic algorithms for shortest paths and max-flows [12, 13, 14]. More generally, we make polylog-logarithmic improvements to all previous results (such as [2]). for which the bottleneck of the best known algorithm is computing shortest paths in a dense distance graph. A more detailed discussion on the implications of our result and on how FR-Dijkstra is used in different algorithms for planar graphs can be found in the full version [11].

It should be noted that for small values of r, such as $r = \text{polylog}(n)$, our algorithm does not improve on [21] for the case of a dense distance graph over an r-division.

Model of Computation. We assume the standard word-RAM model with word size $\Omega(\log n)$. However, we stress that our algorithm works in the very general case of *real* edge lengths, i.e., we are only allowed to perform arithmetical operations on lengths and compare them.

Outline of the Paper. In Section 2 we introduce the matrix notation that we use and state some important properties of Monge matrices. In Section 3 we give an overview of our shortest paths algorithm and also discuss the main ideas behind the improved data structure for reporting column minima of a staircase Monge matrix in an online fashion.

In Sections 4, 5 and 6 we develop the increasingly more powerful data structures for reporting column minima in online Monge matrices. Each of these data structures is used in a black-box manner in the following section.

Due to space limitations, many technical details, most proofs and discussion of the applications can be found in the full version [11].

2 Monge Matrices and Their Minima

In this paper we define a *matrix* to be a partial function $\mathcal{M} : R \times C \to \mathbb{R}$, where R (called *rows*) and C (called *columns*) are some totally ordered finite sets. Set $R = \{r_1, \ldots, r_k\}$ and $C = \{c_1, \ldots, c_l\}$, where $r_1 \leq \ldots \leq r_k$ and $c_1 \leq \ldots \leq c_l$. If for $r_i, r_j \in R$ we have $r_i \leq r_j$, we

also say that r_i is (weakly) *above* r_j and r_j is (weakly) *below* r_i. Similarly, when c_i, c_j we have $c_i < c_j$, we say that c_i is *to the left* of c_j and c_j is *to the right* of c_i.

For some matrix $\mathcal{M}$ defined on rows R and columns C, for $r \in R$ and $c \in C$ we denote by $\mathcal{M}_{r,c}$ an *element* of $\mathcal{M}$. An element is the value of $\mathcal{M}$ on pair (r, c), if defined.

For $R' \subseteq R$ and $C' \subseteq C$ we define $\mathcal{M}(R', C')$ to be a *submatrix* of $\mathcal{M}$. $\mathcal{M}(R', C')$ is a partial function on $R' \times C'$ satisfying $\mathcal{M}(R', C')_{r,c} = \mathcal{M}_{r,c}$ for any $(r, c) \in R' \times C'$ such that $\mathcal{M}_{r,c}$ is defined. We sometimes abuse this notation by writing $\mathcal{M}(R', c')$ or $\mathcal{M}(r', C')$ when R' or C' are single-element, i.e., when $R' = \{r'\}$ or $C' = \{c'\}$.

The *minimum* of a matrix $\min\{\mathcal{M}\}$ is defined as the minimum value of the partial function $\mathcal{M}$. The *column minimum* of $\mathcal{M}$ in column c is defined as $\min\{\mathcal{M}(R, \{c\})\}$.

We call a matrix $\mathcal{M}$ *rectangular* if $\mathcal{M}_{r,c}$ is defined for every $r \in R$ and $c \in C$. A matrix is called *staircase* (*flipped staircase*) if $|R| = |C|$ and $\mathcal{M}_{r_i,c_j}$ is defined iff $i \le j$ ($i \ge j$ resp.).

Finally, a *subrectangle* of $\mathcal{M}$ is a rectangular matrix $\mathcal{M}(\{r_a, \ldots, r_b\}, \{c_x, \ldots, c_y\})$ for $1 \le a \le b \le k$, $1 \le x \le y \le l$. We define a *subrow* to be a subrectangle with a single row.

For a matrix $\mathcal{M}$ and a function $d : R \to \mathbb{R}$, define the *offset matrix* $\mathrm{off}(\mathcal{M}, d)$ to be a matrix $\mathcal{M}'$ such that for all r, c such that $\mathcal{M}_{r,c}$ is defined, we have $\mathcal{M}'_{r,c} = \mathcal{M}_{r,c} + d(r)$.

We say that a matrix $\mathcal{M}$ with rows R and columns C is a *Monge matrix*, if for each $r_1, r_2 \in R$, $r_1 \le r_2$ and $c_1, c_2 \in C$, $c_1 \le c_2$ such that all elements $\mathcal{M}_{r_1,c_1}, \mathcal{M}_{r_1,c_2}, \mathcal{M}_{r_2,c_1}, \mathcal{M}_{r_2,c_2}$ are defined, the *Monge property* holds, i.e., we have

$$\mathcal{M}_{r_2,c_1} + \mathcal{M}_{r_1,c_2} \le \mathcal{M}_{r_1,c_1} + \mathcal{M}_{r_2,c_2}.$$

▶ **Fact 1.** *Let $\mathcal{M}$ be a Monge matrix. For any $R' \subseteq R$ and $C' \subseteq C$, $\mathcal{M}(R', C')$ is also a Monge matrix.*

▶ **Fact 2.** *Let $\mathcal{M}$ be a rectangular Monge matrix. Assume that for some $c \in C$ and $r \in R$, $\mathcal{M}_{r,c}$ is a column minimum of c. Then, for each column c^- to the left of c, there exists a row $r^- \ge r$, such that $\mathcal{M}_{r^-,c^-}$ is a column minimum of c^-. Similarly, for each column c^+ to the right of c, there exists a row $r^+ \le r$, such that $\mathcal{M}_{r^+,c^+}$ is a column minimum of c^+.*

▶ **Fact 3.** *Let $\mathcal{M}$ be a Monge matrix and let $d : R \to \mathbb{R}$. Then $\mathrm{off}(\mathcal{M}, d)$ is also Monge.*

▶ **Fact 4.** *Let $\mathcal{M}$ be a rectangular Monge matrix and assume R is partitioned into disjoint blocks $\mathcal{R} = R_1, \ldots, R_a$ such that each R_i is a contiguous group of subsequent rows and each R_i is above R_{i+1}. Assume also that the set C is partitioned into blocks $\mathcal{C} = C_1, \ldots, C_b$ so that C_i is to the left of C_{i+1}. Then, a matrix $\mathcal{M}'$ with rows $\mathcal{R}$ and columns $\mathcal{C}$ defined as $\mathcal{M}'_{R_i,C_j} = \min\{\mathcal{M}(R_i, C_j)\}$, is also a Monge matrix.*

▶ **Fact 5.** *Let $\mathcal{M}$ be a rectangular Monge matrix. Let $r \in R$ and $C = \{c_1, \ldots, c_l\}$. The set of columns $C_r \in C$ having one of their column minima in row r is contiguous, that is either $C_r = \emptyset$ or $C_r = \{c_a, \ldots, c_b\}$ for some $1 \le a \le b \le l$.*

3 Shortest Paths in a Dense Distance Graph: an Overview

Recall that we are explicitly given q graphs $\mathrm{DC}(G_1), \ldots, \mathrm{DC}(G_q)$, such that each $\mathrm{DC}(G_i)$ is a complete digraph encoding the distances between boundary vertices ∂G_i of a plane digraph G_i. Additionally, we assume that ∂G_i is distributed into some $O(1)$ faces of G_i. We also assume that the distances between the boundary vertices of G_i are non-negative.

Let $\mathrm{DDG} = \mathrm{DC}(G_1) \cup \ldots \cup \mathrm{DC}(G_q)$, $V = \partial G_1 \cup \ldots \cup \partial G_q$ and $n = |V|$. Our goal is to find an efficient algorithm for computing single-source shortest paths in DDG.

As the graphs $\mathrm{DC}(G_i)$ are given explicitly, we can assume that we are allowed to preprocess each $\mathrm{DC}(G_i)$ once in time asymptotically no more than the time used to construct it, which is clearly $\Omega(|\partial G_i|^2)$. To the best of our knowledge, in all known applications this time is $\Theta((|V(G_i)| + |\partial G_i|^2) \log |V(G_i)|)$, which is the running time of Klein's algorithm [14]. After the preprocessing stage, we may need to handle multiple shortest-path queries.

In order to obtain the speedup over FR-Dijkstra we use a subtle combination of techniques. The single-source shortest paths in DDG are computed with an optimized implementation of Dijkstra's algorithm. Recall that Dijkstra's algorithm run from the source s grows a set S of *visited* vertices of the graph such that the lengths $d(v)$ of the shortest paths $s \to v$ for $v \in S$ are already known. Initially $S = \{s\}$ and we repeatedly choose a vertex $y \in V \setminus S$ such that the value (a distance estimate) $z(y) := \min_{x \in S}\{d(x) + \ell(x, y) : (x, y) \in E\}$ is the smallest. The vertex y is then added to S with $d(y) = z(y)$. The vertices $y \in V \setminus S$ are typically stored in a priority queue with keys $z(y)$, which allows to choose the best y efficiently.

Since the vertices of ∂G_i lie on $O(1)$ faces of a planar digraph G_i, we can exploit the fact that many of the shortest paths represented by $\mathrm{DC}(G_i)$ have to cross. Formally, this is captured by the following lemma. Denote by $\mathrm{DC}(G_i)[u, v]$ the weight of uv in $\mathrm{DC}(G_i)$.

▶ **Lemma 1** ([22]). *Each $DC(G_i)$ can be decomposed into $O(1)$ (possibly flipped) staircase Monge matrices D_i of at most $|\partial G_i|$ rows and columns. For each $u, v \in \partial G_i$ we have:*

- *for each $\mathcal{M} \in D_i$ such that $\mathcal{M}_{u,v}$ is defined, $\mathcal{M}_{u,v} \geq DC(G_i)[u, v]$.*
- *there exists $\mathcal{M} \in D_i$ such that $\mathcal{M}_{u,v}$ is defined and $\mathcal{M}_{u,v} = DC(G_i)[u, v]$.*

The decomposition can be computed in $O(|\partial G_i|)^2)$ time if ∂G_i is a subset of a single face of G_i and in $O((|V(G_i)| + |\partial G_i|^2) \log |V(G_i)|)$ time otherwise.

In other words, the adjacency matrix of $\mathrm{DC}(G_i)$ can be partitioned into a constant number of staircase Monge matrices. Consequently, a natural approach to maintaining the minimum distance estimate $z(y)$, for $y \notin S$, is to split the work needed to accomplish this task between the individual matrices $\mathcal{M} \in \bigcup_{i=1}^{q} D_i$ that encode the edges of DDG. Then, it is sufficient to design a data structure reporting the column minima of the offset matrix $\mathrm{off}(\mathcal{M}, d)$ in an online fashion. Specifically, the data structure has to handle *row activations* intermixed with extractions of the column minima in non-decreasing order. Once Dijkstra's algorithm establishes the distance $d(v)$ to some vertex v, the row of $\mathrm{off}(\mathcal{M}, d)$ corresponding to v is activated and becomes available to the data structure. This row contains values $d(v) + \ell(v, w)$, where $\ell(v, w)$ is, by Lemma 1, no less than the length of the edge vw in DDG. Alternatively, a minimum in some column corresponding to v (in the revealed part of $\mathrm{off}(\mathcal{M}, d)$) may be used by Dijkstra's algorithm to establish a new distance label $z(v) = d(v)$, even though not all rows of $\mathrm{off}(\mathcal{M}, d)$ have been revealed so far. In this case, we can guarantee that all the inactive rows of $\mathrm{off}(\mathcal{M}, d)$ contain entries not smaller than $d(v)$ and hence we can safely extract the column minimum of $\mathrm{off}(\mathcal{M}, d)$.

Such an approach was also used by Fakcharoenphol and Rao [7] and Mozes et al. [21], who both dealt with staircase Monge matrices by using a recursive partition into *square* Monge matrices, which are easier to handle. In particular, Fakcharoenphol and Rao showed that a sequence of row activations and column minima extractions can be performed on an $m \times m$ square Monge matrix in $O(m \log m)$ time. The recursive partition assigns each row and column to $O(\log |\partial G_i|)$ square Monge matrices. As a result, in [7], the total time for handling all the square matrices is $O(|\partial G_i| \log^2 |\partial G_i|)$. The details and the pseudocode of the above shortest path algorithm can be found in the full version [11].

The Data Structure. Developing an improved data structure reporting the column minima of an online offset staircase Monge matrix is the main contribution of this paper. This goal is achieved in three steps, presented in the following three sections in a bottom-up fashion. Below we sketch the main ideas behind these steps.

Our first component is a refined data structure for handling row activations and column minima extractions on a *rectangular* Monge matrix, described in Section 4. We show a data structure supporting any sequence of operations on a $k \times l$ matrix in $O\left(k\frac{\log m}{\log\log m} + l\log m\right)$ total time, where $m = \max(k, l)$. In comparison to [7], we do not map all the columns to active rows containing the current minima. Instead, the columns are assigned *potential row sets* of bounded size that are guaranteed to contain the "currently optimal" rows. This relaxed notion allows to remove the seemingly unavoidable binary search at the heart of [7] and instead use the SMAWK algorithm [1] to split the potential row sets once they become too large. The maintenance of a priority queue used for reporting the column minima in order is possible with the recent efficient data structure supporting subrow minimum queries in Monge matrices [10] and priority queues with $O(1)$ time Decrease-Key operation [8].

The second step is to relax the requirements posed on a data structure handling rectangular $k \times l$ Monge matrices. It is motivated by the following observation. Let $\Delta > 0$ be an integer. Imagine we have found the minima of l/Δ evenly spread, *pivot* columns $c_1, \ldots, c_{l/\Delta}$. Denote by $r_1, \ldots, r_{l/\Delta}$ some rows containing the corresponding minima. A well-known property of Monge matrices implies that for any column c' lying between c_i and c_{i+1}, we only have to look for a minimum of c' in rows $r_i, \ldots, r_{i+1}$. Thus, the minima in the remaining columns can be found in $O(k\Delta + l)$ total time. In Section 5 we show how to adapt this idea to an online setting that fits our needs. The columns are partitioned into $O(l/\Delta)$ *blocks* of size at most Δ. Each block is conceptually contracted to a single column: an entry in row r is defined as the minimum in row r over the contracted columns. For sufficiently small values of Δ, such a minimum can be computed in $O(1)$ time using the data structure of [10]. Locating a block minimum can be seen as an introduction of a new pivot column. We handle the block matrix with the data structure of Section 4 and prove that the total time needed to correctly report all the column minima is $O\left(k\frac{\log m}{\log\log m} + k\Delta + l + \frac{l}{\Delta}\log m\right)$. In particular, for $\Delta = \log^{1-\epsilon} m$, this bound becomes $O\left(k\frac{\log m}{\log\log m} + l\log^{\epsilon} m\right)$.

Finally, in Section 6 we exploit the asymmetry of per-row and per-column costs of the developed block data structure for rectangular matrices by using a different partition of a staircase Monge matrix. Our partition is biased towards columns, i.e., the matrix is split into *rectangular* (as opposed to square) Monge matrices, each with roughly poly-logarithmically more columns than rows. Consequently, the total number of rows in these matrices is $O\left(|\partial G_i|\frac{\log|\partial G_i|}{\log\log|\partial G_i|}\right)$, whereas the total number of columns is only slightly larger, i.e., $O\left(|\partial G_i|\log^{1+\epsilon}|\partial G_i|\right)$. This yields a data structure handling staircase Monge matrices in $O\left(|\partial G_i|\frac{\log^2|\partial G_i|}{\log^2\log|\partial G_i|}\right)$ total time. By plugging this data structure into our shortest path algorithm, we obtain the following theorem.

▶ **Theorem 2.** *The single-source shortest paths computations in DDG can be performed in* $O\left(\sum_{i=1}^{q}|\partial G_i|\frac{\log^2 n}{\log^2\log n}\right)$ *time. The required preprocessing time per each* G_i *is* $O(|\partial G_i|^2)$ *if* ∂G_i *lies on a single face of* G_i*, and* $O\left(|V(G_i)| + |\partial G_i|^2)\log|V(G_i)|\right)$ *otherwise.*

4 Online Column Minima of a Rectangular Offset Monge Matrix

Let $\mathcal{M}_0$ be a rectangular $k \times l$ Monge matrix. Let $R = \{r_1, \ldots, r_k\}$ and $C = \{c_1, \ldots, c_l\}$ be the sets of rows and columns of $\mathcal{M}_0$, respectively. Set $m = \max(k, l)$.

Let $d : R \to \mathbb{R}$ be an offset function and set $\mathcal{M} = \text{off}(\mathcal{M}_0, d)$. By Fact 3, $\mathcal{M}$ is also a Monge matrix. Our goal is to design a data structure capable of reporting the column minima of $\mathcal{M}$ in increasing order of their values. However, the function d is not entirely revealed beforehand, as opposed to the matrix $\mathcal{M}_0$. There is an initially empty, growing set $\overline{R} \subseteq R$ containing the rows for which $d(r)$ is known. Alternatively, the set $\overline{R}$ can be seen as "active" rows of $\mathcal{M}$ that can be accessed by the data structure. There is also a set $\overline{C} \subseteq C$ containing the remaining columns for which we have not reported the minima yet. Initially, $\overline{C} = C$ and $\overline{C}$ shrinks over time. We also provide a mechanism to guarantee that the rows that have not been revealed do not influence the smallest of the column minima of $\mathcal{M}(R, \overline{C})$.

The exact set of operations we support is the following:

- ACTIVATE-ROW(r), where $r \in R \setminus \overline{R}$ – add r to the set $\overline{R}$.
- LOWER-BOUND() – compute the number $\min\{\mathcal{M}(\overline{R}, \overline{C})\}$.
- ENSURE-BOUND-AND-GET() – inform the data structure that we indeed have $\min\{\mathcal{M}(R \setminus \overline{R}, C)\} \geq \min\{\mathcal{M}(\overline{R}, \overline{C})\} = $ LOWER-BOUND(), that is, the smallest element of $\mathcal{M}(R, \overline{C})$ does not depend on the values of $\mathcal{M}$ located in rows $R \setminus \overline{R}$.
  Observe that such claim implies that for some column $c \in \overline{C}$ we have $\min\{\mathcal{M}(R, c)\} = \min\{\mathcal{M}(\overline{R}, \overline{C})\}$, which in turn means that we are able to find the minimum element in column c. The function returns any such c and removes it from the set $\overline{C}$.
- CURRENT-MIN-ROW(c), where $c \in C$ – compute r, where $r \in \overline{R}$ is a row such that $\min\{\mathcal{M}(\overline{R}, c)\} = \mathcal{M}_{r,c}$. If $\overline{R} = \emptyset$, return **nil**. Note that c is not necessarily in $\overline{C}$.
  Additionally, we require CURRENT-MIN-ROW to have the following property: once the column c is moved out of $\overline{C}$, CURRENT-MIN-ROW(c) always returns the same row. Moreover, for $c_1, c_2 \in C$, $c_1 < c_2$, we have CURRENT-MIN-ROW$(c_1) \geq$ CURRENT-MIN-ROW(c_2).

Note that ACTIVATE-ROW increases the size of $\overline{R}$ and thus cannot be called more than k times. Analogously, ENSURE-BOUND-AND-GET decreases the size of $\overline{C}$ so it cannot be called more than l times. Actually, in order to reveal all the column minima with this data structure, the operation ENSURE-BOUND-AND-GET has to be called *exactly* l times.

4.1 The Components

The Subrow Minimum Query Data Structure. Given $r \in \overline{R}$ and a, b, $1 \leq a \leq b \leq l$, a subrow minimum query $S(r, a, b)$ computes a column $c \in \{c_a, \ldots, c_b\}$ such that $\mathcal{M}_{r,c} = \min\{\mathcal{M}(r, \{c_a, \ldots, c_b\})\}$. We use the following theorem of Gawrychowski et al. [10].

▶ **Theorem 3** ([10]). *Given a $k \times l$ rectangular Monge matrix $\mathcal{M}$, a data structure supporting subrow minimum queries in $O(\log\log(k + l))$ time can be constructed in $O(l \log k)$ time.*

Recall that $\mathcal{M} = \text{off}(\mathcal{M}_0, d)$. Adding the offset $d(r)$ to all the elements in row r of $\mathcal{M}_0$ does not change the relative order of elements in row r. Hence, the answer to a subrow minimum query $S(r, a, b)$ in $\mathcal{M}$ is the same as the answer to $S(r, a, b)$ in $\mathcal{M}_0$.

Therefor, by building a data structure of Theorem 3 for $\mathcal{M}_0$ we can answer any subrow minimum query in $\mathcal{M}$ in $O(\log\log m)$ time.

The Column Groups. The set C is internally partitioned into disjoint, contiguous *column groups* $\mathcal{C}_1, \ldots, \mathcal{C}_q$ (where $\mathcal{C}_1$ is the leftmost and $\mathcal{C}_q$ is the rightmost), so that $\bigcup_i \mathcal{C}_i = C$. For each $c \notin \overline{C}$, there is a group consisting of a single element c. Such a group is called *done*.

As the groups constitute contiguous segments of columns, we can represent the partition with a subset $F \subseteq C$ containing the first columns of individual groups. Each group is identified with its leftmost column. We use a dynamic predecessor data structure [24] for maintaining the set F. Such representation also allows to split groups and merge neighboring groups in $O(\log \log m)$ time.

The Potential Row Sets. For each $\mathcal{C}_i$ we store a set $P(\mathcal{C}_i) \subseteq \overline{R}$, called a *potential row set*. Between consecutive operations, the potential row sets satisfy the following invariants:

P.1 For any $c \in \mathcal{C}_i$ there exists a row $r \in P(\mathcal{C}_i)$ such that $\min\{\mathcal{M}(\overline{R}, c)\} = \mathcal{M}_{r,c}$.

P.2 The size of any set $P(\mathcal{C}_i)$ is less than 2α, where $\alpha = \sqrt{\log m}$.

P.3 For any $i < j$ and any $r \in P(\mathcal{C}_i)$, $r' \in P(\mathcal{C}_j)$, we have $r \geq r'$.

The sets $P(\mathcal{C}_i)$ are stored as balanced binary search trees, sorted bottom to top. Intuitively, invariant 3 can be maintained because, by Fact 1, $\mathcal{M}(\overline{R}, C)$ is a Monge matrix, so Fact 2 applies. Then, we have $|P(\mathcal{C}_i) \cap P(\mathcal{C}_{i+1})| \leq 1$, so the sum of sizes of sets $P(\mathcal{C}_i)$ is $O(k + l)$.

▶ **Lemma 4.** *An insertion or deletion of some r to $P(\mathcal{C}_i)$ (along with the update of the auxiliary structures) can be performed in $O(\log \alpha + \log \log m)$ time.*

Clearly, one can answer the Current-Min-Row(c) query by finding the relevant group $\mathcal{C}_i$, $c \in \mathcal{C}_i$, and examining the entries $\mathcal{M}_{r,c}$ for $r \in P(\mathcal{C}_i)$. This takes $O(\log \log m + \alpha)$ time.

Upon activation of a new row r, we first merge the groups $\mathcal{C}_j$ such that r contains a current minimum for each column in $\mathcal{C}_j$. The potential row set of the newly formed group is set to $\{r\}$. Next, we insert r to some (at most two) of the existing potential row sets. This might make some $P(\mathcal{C}_i)$ break invariant 2. In such case the group $\mathcal{C}_i$ along with $P(\mathcal{C}_i)$ is split, so that the resulting potential row sets are of size α. The splitting algorithm summarized by the following lemma which leverages the SMAWK algorithm [1] to decrease the per-row cost of a split.

▶ **Lemma 5.** *Let $\mathcal{M}$ be a $u \times v$ rectangular Monge matrix with rows $\{r_1, \ldots, r_u\}$ and columns $C = \{c_1, \ldots, c_v\}$. For any $i \in [1, u]$, in $O\left(u \frac{\log v}{\log u}\right)$ time we can find such $c_s \in C$ that:*

1. *Some minima of columns $c_1, \ldots, c_s$ lie in rows $r_{i+1}, \ldots, r_u$.*
2. *Some minima of columns $c_{s+1}, \ldots, c_v$ lie in rows $r_1, \ldots, r_i$.*

As the split of some fixed $P(\mathcal{C}_i)$ happens at most once per α insertions, we charge the $O\left(\alpha \frac{\log m}{\log \alpha}\right)$ cost of splitting $P(\mathcal{C}_i)$ to the α elements inserted since the last split of $P(\mathcal{C}_i)$. The total number of insertions performed on the potential row sets is $O(k + l)$.

The Priority Queue. A priority queue H contains an element c for each $c \in \overline{C}$. The queue H satisfies the following invariants between any two operations.

H.1 For each $c \in \overline{C}$, the key of c in H is greater than or equal to $\min\{\mathcal{M}(\overline{R}, c)\}$.

H.2 For each group $\mathcal{C}_j$ that is not done, there exists such column $c_j \in \mathcal{C}_j$ that the key of c_j in H is equal to $\min\{\mathcal{M}(\overline{R}, c_j)\} = \min\left\{\mathcal{M}(\overline{R}, \mathcal{C}_j)\right\}$.

Note that by invariants 1 and 2, the key at the top of H is in fact equal to $\min\{\mathcal{M}(\overline{R}, \overline{C})\}$. Hence, Lower-Bound can be implemented trivially in $O(1)$ time. The following lemma follows easily from invariant 1 and Theorem 3.

▶ **Lemma 6.** *We can ensure 2 is satisfied for a single group $\mathcal{C}_j$ in $O(\alpha \log \log m)$ time.*

The detailed description of how the individual operations are implemented can be found in the full version [11]. The performance of our data structure can be summarized as follows.

▶ **Lemma 7.** *Let $\mathcal{M}$ be a $k \times l$ offset Monge matrix. There exists a data structure built in $O(k + l \log m)$ time, supporting* Lower-Bound *in $O(1)$ time and both* Current-Min-Row *and* Ensure-Bound-And-Get *in $O(\log m)$ time. Additionally, any sequence of operations* Activate-Row *is performed in $O\left((k+l)\frac{\log m}{\log\log m}\right)$ total time, where $m = \max(k, l)$.*

5 Online Column Minima of a Block Monge Matrix

Let $\mathcal{M} = \text{off}(\mathcal{M}_0, d)$, R, C, l, k, m be defined as in Section 4. In this section we consider the problem of reporting the column minima of a rectangular offset Monge matrix, but in a slightly different setting. Again, we are given a fixed rectangular Monge matrix $\mathcal{M}_0$ and we also have an initially empty, growing set of rows $\overline{R} \subseteq R$ for which the offsets $d(\cdot)$ are known. Let $\Delta > 0$ be an integral parameter not larger than l. We partition C into a set $\mathcal{B} = \{B_1, \ldots, B_b\}$ of at most $\lceil l/\Delta \rceil$ blocks, each of size at most Δ. The columns in each B_i constitute a contiguous fragment of $c_1, \ldots, c_l$, and each block B_i is to the left of B_{i+1}. We also maintain a shrinking subset $\overline{\mathcal{B}} \subseteq \mathcal{B}$ containing the blocks B_i, such that the minima $\min\{\mathcal{M}(R, B_i)\}$ are not yet known. More formally, for each $B_i \in \mathcal{B} \setminus \overline{\mathcal{B}}$, we have $\min\{\mathcal{M}(R, B_i)\} = \min\{\mathcal{M}(\overline{R}, B_i)\}$. Initially $\overline{\mathcal{B}} = \mathcal{B}$.

For each $c \in C$ not contained in the blocks of $\overline{\mathcal{B}}$, the data structure explicitly maintains the *current minimum*, i.e., the value $\min\{\mathcal{M}(\overline{R}, c)\}$. Moreover, when a new row is activated, we provide the user with columns of $\bigcup(\mathcal{B} \setminus \overline{\mathcal{B}})$ for which the current minima have changed.

For blocks $\overline{\mathcal{B}}$, the data structure only maintains the value $\min\{\mathcal{M}(\overline{R}, \bigcup\overline{\mathcal{B}})\}$. Once the user can guarantee that $\min\{\mathcal{M}(R, \bigcup\overline{\mathcal{B}})\}$ does not depend on the "hidden offsets" of rows $R \setminus \overline{R}$, the data structure moves a block $B_i \in \overline{\mathcal{B}}$ such that $\min\{\mathcal{M}(R, \bigcup\overline{\mathcal{B}})\} = \min\{\mathcal{M}(\overline{R}, B_i)\}$ out of $\overline{\mathcal{B}}$ and makes it possible to access the current minima in the columns of B_i.

More formally, we support the following set of operations:

- Activate-Row(r), where $r \in R \setminus \overline{R}$ – add r to the set $\overline{R}$.
- Block-Lower-Bound() – return $\min\{\mathcal{M}(\overline{R}, \bigcup\overline{\mathcal{B}})\}$.
- Block-Ensure-Bound() – tell the data structure that indeed $\min\{\mathcal{M}(R \setminus \overline{R}, C)\} \geq$ Block-Lower-Bound() $= \min\{\mathcal{M}(\overline{R}, B_i)\}$, for some $B_i \in \overline{\mathcal{B}}$, i.e., the smallest element of $\mathcal{M}(R, \bigcup\overline{\mathcal{B}})$ does not depend on the entries of $\mathcal{M}$ located in rows $R \setminus \overline{R}$.
  As the minimum of $\mathcal{M}(R, B_i)$ can now be computed, B_i is removed from $\overline{\mathcal{B}}$.
- Current-Min(c), where $c \in C$ – for $c \in \bigcup(\mathcal{B} \setminus \overline{\mathcal{B}})$, return the explicitly maintained value $\min\{\mathcal{M}(\overline{R}, \{c\})\}$. For $c \in \bigcup\overline{\mathcal{B}}$, set Current-Min$(c) = \infty$.

Additionally, the data structure provides access to the queue Updates containing the columns $c \in \bigcup(\mathcal{B} \setminus \overline{\mathcal{B}})$ such that the most recent call to either Activate-Row or Block-Ensure-Bound resulted in a change (or an initialization, if $c \in B_i$ and the last update was Block-Ensure-Bound, which moved B_i out of $\overline{\mathcal{B}}$) of the value Current-Min(c).

Note that there can be at most k calls to Activate-Row and no more than $\lceil l/\Delta \rceil$ calls to Block-Ensure-Bound.

5.1 The Data Structure

An Infrastructure for Short Subrow Minimum Queries. In this section we assume that for any $r \in R$ and $1 \leq i, j \leq l$, $j - i + 1 \leq \Delta$, it is possible to compute an answer to a subrow minimum query $S(r, i, j)$ (see Section 4) on matrix $\mathcal{M}_0$ (equivalently: $\mathcal{M}$) in constant time. We call such a subrow minimum query *short*.

The Block Minima Matrix. Define a $k \times b$ matrix $\mathcal{M}'$ with rows R and columns $\mathcal{B}$, such that for all $r_i \in R$ and $B_j \in \mathcal{B}$, $\mathcal{M}'_{r_i,B_j} = \min\{\mathcal{M}(r_i, B_j)\}$. We build the data structure of Section 4 for matrix $\mathcal{M}'$.

▶ **Lemma 8.** *$\mathcal{M}'$ is a Monge matrix and its entries can be accessed in $O(1)$ time.*

The Exact Minima Array. For each column $c \in \bigcup(\mathcal{B} \setminus \overline{\mathcal{B}})$, the value $\texttt{cmin}(c) = \min\{\mathcal{M}(\overline{R}, c)\}$ is stored explicitly. The operation Current-Min(c) returns $\texttt{cmin}(c)$.

Rows Containing the Block Minima. For each $B_j \in (\mathcal{B} \setminus \overline{\mathcal{B}})$ we store the value $y_j = \mathcal{M}'$.Current-Min-Row(B_j). Note that the data structure of Section 4 guarantees that for $B_i, B_j \in (\mathcal{B} \setminus \overline{\mathcal{B}})$ such that $i < j$, we have $y_i \geq y_j$. The set of defined y_j's grows over time.

The Row Candidate Sets. Two subsets D_0 and D_1 of $\overline{R}$ are maintained. The set D_q for $q = 0, 1$ contains the rows of $\overline{R}$ that may still prove useful when computing the initial value of $\texttt{cmin}(c)$ for $c \in \bigcup\{B_i : B_i \in \overline{\mathcal{B}} \wedge i \bmod 2 = q\}$. For each such c, D_q contains a row r such that $\min\{\mathcal{M}(\overline{R}, c)\} = \mathcal{M}_{r,c}$. The sets D_q are also stored in dynamic predecessor structures.

Implementation. We now sketch how the data structure's components are used. Clearly, a call to Block-Lower-Bound translates into a single call Lower-Bound executed on $\mathcal{M}'$. When Block-Ensure-Bound is called, some block B_i is moved out of $\overline{\mathcal{B}}$. Apart from calling Ensure-Bound-And-Get on $\mathcal{M}'$, we have to initialize the values $\texttt{cmin}(c)$ for $c \in B_i$. For each such c, we examine multiple rows of $D_{i \bmod 2}$ when looking for minima, but it can be shown that most of these rows can be discarded from $D_{i \bmod 2}$ afterwards. This in turn allows us to charge the work to the insertions into row candidate sets.

When Activate-Row is called, one has to call Activate-Row on $\mathcal{M}'$ first. Moreover, the values $\texttt{cmin}(c)$ for some $c \in \bigcup(\mathcal{B} \setminus \overline{\mathcal{B}})$ have to be updated. It turns out that all such columns reside in at most two blocks and thus only $O(\Delta)$ additional time is needed.

The detailed implementation of each operation can be found in the full version [11].

▶ **Lemma 9.** *Let $\mathcal{M} = \mathit{off}(\mathcal{M}_0, d)$ be a $k \times l$ rectangular offset Monge matrix. Let Δ be the block size. Assume we can perform subrow minima queries spanning at most Δ columns of $\mathcal{M}_0$ in $O(1)$ time. There exists a data structure initialized in $O(k + l + \frac{l}{\Delta} \log m)$ time and supporting both* Block-Lower-Bound *and* Current-Min *in $O(1)$ time. Any sequence of* Activate-Row *and* Block-Ensure-Bound *operations can be performed in $O\left(k\left(\frac{\log m}{\log\log m} + \Delta\right) + l + \frac{l}{\Delta}\log m\right)$ time, where $m = \max(k, l)$.*

6 Online Column Minima of a Staircase Offset Monge Matrix

In this section we show a data structure supporting a similar set of operations as in Section 4, but in the case when the matrices $\mathcal{M}_0$ and $\mathcal{M} = \mathrm{off}(\mathcal{M}_0, d)$ are staircase Monge matrices with m rows $R = \{r_1, \ldots, r_m\}$ and m columns $C = \{c_1, \ldots, c_m\}$. We still aim at reporting the column minima of $\mathcal{M}$, while the set $\overline{R}$ of revealed rows is extended and new bounds on $\min\{\mathcal{M}(R \setminus \overline{R}, C)\}$ are available.

In comparison to the data structure of Section 4, we loosen the conditions posed on the operations Lower-Bound and Ensure-Bound-And-Get. Now, Lower-Bound might return a value smaller than $\min\{\mathcal{M}(\overline{R}, \overline{C})\}$ and a single call to Ensure-Bound-And-Get might not report any new column minimum at all. However, Ensure-Bound-And-Get can

still only be called if $\min\{\mathcal{M}(R \setminus \overline{R}, C)\} \geq$ Lower-Bound() and the data structure we develop in this section guarantees that a bounded number of calls to Ensure-Bound-And-Get suffices to report all the column minima of $\mathcal{M}$. The exact set of supported operations is:

- Activate-Row(r), where $r \in R \setminus \overline{R}$ – add r to the set $\overline{R}$.
- Lower-Bound() – return a number v such that $\min\{\mathcal{M}(\overline{R}, \overline{C})\} \geq v$.
- Ensure-Bound-And-Get() – tell the data structure that the inequality $\min\{\mathcal{M}(R \setminus \overline{R}, C)\} \geq$ Lower-Bound() holds.
  With this knowledge, the data structure may report some column $c \in \overline{C}$ such that $\min\{\mathcal{M}(R, c)\}$ is known. However, it's also valid to not report any new column minimum (in such case **nil** is returned) and only change the known value of Lower-Bound().
- Current-Min(c), where $c \in C$ – if $c \in C \setminus \overline{C}$, return the known minimum in column c.

6.1 The Data Structure

The Short Subrow Minimum Queries Infrastructure. Let $\Delta = \lceil \log^{1-\epsilon/2} m \rceil$. The following lemma allows us to use the data structure of Lemma 9 with block size Δ.

▶ **Lemma 10.** *The staircase Monge matrix $\mathcal{M}_0$ can be preprocessed in $O(m\Delta \log m)$ time so that subrow minimum queries on $\mathcal{M}_0$ spanning at most Δ columns take $O(1)$ time.*

The Partition of $\mathcal{M}$ into Rectangular Matrices $\mathcal{M}_1, \ldots, \mathcal{M}_q$. We partition the staircase Monge matrix $\mathcal{M}$ into $O(m \log^{\epsilon/2} m)$ non-overlapping *rectangular* Monge matrices $\mathcal{M}_1, \ldots, \mathcal{M}_q$ using the below lemma. Each $\mathcal{M}_i$ is a subrectangle of $\mathcal{M}$, each row r (column c) appears in a set W_r (W^c, resp.) of $O\left(\frac{\log m}{\log \log m}\right)$ ($O\left(\frac{\log^{1+\epsilon/2} m}{\log \log m}\right)$, resp.) subrectangles.

▶ **Lemma 11.** *For any $\epsilon \in (0, 1)$, a staircase matrix $\mathcal{M}$ with m rows and m columns can be partitioned in $O(m)$ time into $O(m \log^{\epsilon/2} m)$ non-overlapping rectangular matrices so that each row appears in $O\left(\frac{\log m}{\log \log m}\right)$ matrices of the partition, whereas each column appears in $O\left(\frac{\log^{1+\epsilon} m}{\log \log m}\right)$ matrices of the partition.*

We build the block data structure of Section 5 for each $\mathcal{M}_i$. For each $\mathcal{M}_i$ we use the same block size Δ. As each $\mathcal{M}_i$ is a subrectangle of $\mathcal{M}$, Lemma 10 guarantees that we can perform subrow minimum queries on $\mathcal{M}_i$ spanning at most Δ columns in $O(1)$ time. Recall that the blocks of the matrix $\mathcal{M}_i$ are partitioned into two sets $\overline{\mathcal{B}}_i$ and $\mathcal{B}_i \setminus \overline{\mathcal{B}}_i$. Denote by $block(\mathcal{M}_i)$ the submatrix $\mathcal{M}_i(\overline{R}_i, \bigcup \overline{\mathcal{B}}_i)$ and by $exact(\mathcal{M}_i)$ the submatrix $\mathcal{M}_i(\overline{R}_i, \bigcup(\mathcal{B}_i \setminus \overline{\mathcal{B}}_i))$. Here, R_i and C_i denote the row and column sets of $\mathcal{M}_i$, respectively.

The Priority Queue H. The core of our data structure is a priority queue H. At any time, H contains an element c for each $c \in \overline{C}$ and at most one element $\mathcal{M}_i$ for each matrix $\mathcal{M}_i$. Thus the size of H never exceeds $O(m \log^{\epsilon/2} m)$. We maintain the following invariants after the initialization and each call Activate-Row or Ensure-Bound-And-Get resulting in $\overline{C} \neq \emptyset$:

H.1 For each $c \in \overline{C}$, the key of c in H is equal to $\min\{\mathcal{M}_i.\text{Current-Min}(c) : \mathcal{M}_i \in W^c\}$.

H.2 For each $\mathcal{M}_i$ such that $block(\mathcal{M}_i)$ is not empty, the key of $\mathcal{M}_i$ in H is equal to $\min\{block(\mathcal{M}_i)\} = \mathcal{M}_i.\text{Block-Lower-Bound}()$.

▶ **Lemma 12.** *Assume invariants 1 and 2 are satisfied. Then H.Min-Key() $\leq \mathcal{M}(\overline{R}, \overline{C})$.*

Implementation. The data structure always returns the top key of H when Lower-Bound is called. Each call to Ensure-Bound-And-Get removes the top element e of H. If e is a column c, the minimum of c is reported. Otherwise $e = \mathcal{M}_i$ and it can be seen that $\mathcal{M}_i$.Block-Ensure-Bound can now be called. Afterwards, $\mathcal{M}_i$ is reinserted into H. Note that the number of times some $\mathcal{M}_j$ gets reinserted into H is no more than the total number of blocks in the matrices $\mathcal{M}_1, \ldots, \mathcal{M}_q$, i.e., $O(m \log^{\epsilon} m)$. The row activations are propagated to the relevant matrices $\mathcal{M}_j$ of the partition.

Both Ensure-Bound-And-Get and Activate-Row may make invariants 1 and 2 violated. However, the keys in H may only need to be decreased. Given that each operation Decrease-Key on H takes only $O(1)$ time, the time needed to update H is dominated by the cost of operations on the individual matrices $\mathcal{M}_j$.

The detailed implementation of the individual operations and analysis can be found in the full version [11]. The following lemma summarizes the performance of our data structure.

▶ **Lemma 13.** *Let $\mathcal{M} = \mathit{off}(\mathcal{M}_0, d)$ be an $m \times m$ offset staircase Monge matrix and let $\epsilon \in (0, 1)$. There exists a data structure that can be initialized in $O\left(m \log^{2-\epsilon} m\right)$ time, supporting both* Lower-Bound *and* Current-Min *in $O(1)$ time. Any sequence of* Activate-Row *and* Ensure-Bound-And-Get *operations takes $O\left(m \frac{\log^2 m}{\log^2 \log m}\right)$ total time. All the column minima are computed after $O(m \log^{\epsilon} m)$ calls to* Ensure-Bound-And-Get.

Abstract

Computing the distance between a given pattern of length n and a text of length m is defined as calculating, for every m-substring of the text, the distance between the pattern and the substring. This naturally generalizes the standard notion of exact pattern matching to incorporate dissimilarity score. For both Hamming and L_1 distance only relatively slow $\widetilde{\mathcal{O}}(n\sqrt{m})$ solutions are known for this generalization. This can be overcome by relaxing the question. For Hamming distance, the usual relaxation is to consider the k-bounded variant, where distances exceeding k are reported as ∞, while for L_1 distance asking for a $(1 \pm \varepsilon)$-approximation seems more natural. For k-bounded Hamming distance, Amir et al. [J. Algorithms 2004] showed an $\widetilde{\mathcal{O}}(n\sqrt{k})$ time algorithm, and Clifford et al. [SODA 2016] designed an $\widetilde{\mathcal{O}}((m + k^2) \cdot n/m)$ time solution. We provide a smooth time trade-off between these bounds by exhibiting an $\widetilde{\mathcal{O}}((m + k\sqrt{m}) \cdot n/m)$ time algorithm. We complement the trade-off with a matching conditional lower bound, showing that a significantly faster *combinatorial* algorithm is not possible, unless the combinatorial matrix multiplication conjecture fails. We also exhibit a series of reductions that together allow us to achieve essentially the same complexity for k-bounded L_1 distance. Finally, for $(1 \pm \varepsilon)$-approximate L_1 distance, the running time of the best previously known algorithm of Lipsky and Porat [Algorithmica 2011] was $\widetilde{\mathcal{O}}(\varepsilon^{-2}n)$. We improve this to $\widetilde{\mathcal{O}}(\varepsilon^{-1}n)$, thus essentially matching the complexity of the best known algorithm for $(1 \pm \varepsilon)$-approximate Hamming distance.

1 Introduction

The basic question in algorithms on strings is pattern matching, which asks for reporting (or detecting) occurrences of a given pattern P of length m in a text T of length n. A particularly relevant variant of this fundamental question is approximate pattern matching, where the goal is to detect fragments of the text that are *similar* to the pattern. This can be restated as computing the text-to-pattern distance, defined as the distance between P and every m-substring of T. If both P and T are over an integer alphabet Σ, two most natural distance functions are Hamming and L_1. Abrahamson [1] showed how to compute the text-to-pattern Hamming distance with a clever application of boolean convolution: a single convolution can be used to count matches generated by a particular letter in time close to linear, and by carefully partitioning the letters into frequent and non-frequent the overall running time can be guaranteed to be $\mathcal{O}(n\sqrt{m \log m})$. With a somewhat similar approach, the same complexity can be achieved for L_1 distance [5]. Naturally, one would like to design

an $\widetilde{\mathcal{O}}(n)$ time algorithm. However, an unpublished result attributed to Indyk [6] is that any significant improvement for Hamming distance by a *combinatorial* algorithm implies a significant improvement for *combinatorial matrix multiplication*, which is believed to be very hard. Later, a direct reduction from Hamming distance to L_1 distance was shown [14], as well as a reverse reduction [8] together with a full suite of two-way reductions between these two metrics and other functions, linking the corresponding complexities (up to poly-logarithmic factors).

A natural relaxation of computing the text-to-pattern distance is to ask for its $(1 \pm \varepsilon)$-approximation. Karloff [10] showed how to use random $\Sigma \to \{0, 1\}$ projections together with boolean convolution to approximate the Hamming distance in $\mathcal{O}(\varepsilon^{-2} n \log^3 m)$. The ε^{-2} dependency was believed to be tight, given the similarly looking lower bound for sketching Hamming distance [16, 9, 4], but Porat and Kopelowitz [11] refuted this by exhibiting a (complicated) $\mathcal{O}(\varepsilon^{-1} n \log \varepsilon^{-1} \log n \log m \log |\Sigma|)$ time algorithm. Later, they presented a much simpler solution with a slightly better complexity of $\mathcal{O}(\varepsilon^{-1} n \log n \log m)$ [12]. For approximating the L_1 distance, it was only known how to achieve $\mathcal{O}(\varepsilon^{-2} n \log m \log |\Sigma|)$ time complexity [15], and breaking the ε^{-2} barrier was open.

Another natural relaxation is to cap the distances at k, that is, return ∞ if the distance exceeds k. We will call this variant the k-bounded distance. For k-bounded Hamming distance, the classical solution by Landau and Vishkin [13] works in $\mathcal{O}(nk)$ time by checking every m-substring with $k+1$ constant-time longest common extension queries (also known as "kangaroo jumps"). Later, Amir et al. [2] improved this to $\mathcal{O}(n\sqrt{k \log k})$ using boolean convolution similarly as in the classical algorithm of Abrahamson, and also showed an $\mathcal{O}((k^3 \log k + m) \cdot n/m)$ time algorithm. Later, Clifford et al. [7] introduced a new repertoire of tools allowing them to further improve the latter complexity to $\mathcal{O}((k^2 \log k + m \operatorname{polylog} m) \cdot n/m)$. In particular, this is near linear-time for $k = \mathcal{O}(\sqrt{m})$. At a very high level, the improvement was obtained by partitioning both the pattern and the text into $\mathcal{O}(k)$ subpatterns and subtexts, such that the total number of blocks in their run-length encoding is small. This reduces the original problem to $\mathcal{O}(k^2)$ instances of pattern matching with mismatches on run-length encoded inputs, which can be solved in $\widetilde{\mathcal{O}}(k^2)$ total time, leading to an $\widetilde{\mathcal{O}}((k^2 + m) \cdot n/m)$ time algorithm. For k-bounded L_1 distance, only an $\mathcal{O}(n\sqrt{k \log k})$ time algorithm was known [3], and designing an almost linear-time algorithm for polynomially large (in m) values of k was open.

Our results. We provide a smooth transition between the $\widetilde{\mathcal{O}}(n\sqrt{k})$ time algorithm of Amir et al. [2] and the $\widetilde{\mathcal{O}}((m + k^2) \cdot n/m)$ solution given by Clifford et al. [7] for k-bounded Hamming distance. This is obtained by reducing k-bounded Hamming distance to $\mathcal{O}(k)$-RLE Hamming distance, in which the run-length encodings of both the pattern and the text consist of $\mathcal{O}(k)$ blocks, and then designing an efficient algorithm for the latter.

▶ **Theorem 1.** *There is a deterministic algorithm that outputs k-bounded text-to-pattern Hamming distance in time $\mathcal{O}((m \log^2 m \log |\Sigma| + k\sqrt{m \log m}) \cdot n/m)$.*

The complexity from Theorem 1 matches the previous solutions at the extreme points $k = \mathcal{O}(\sqrt{m})$ and $k = \Omega(m)$, but provides a better trade-off in-between. See Figure 1. Furthermore, we prove that this trade-off is essentially the best possible. More precisely, we complement the algorithm with a matching conditional lower bound, showing that a significantly faster *combinatorial* algorithm is not possible, unless the popular combinatorial matrix multiplication conjecture fails.

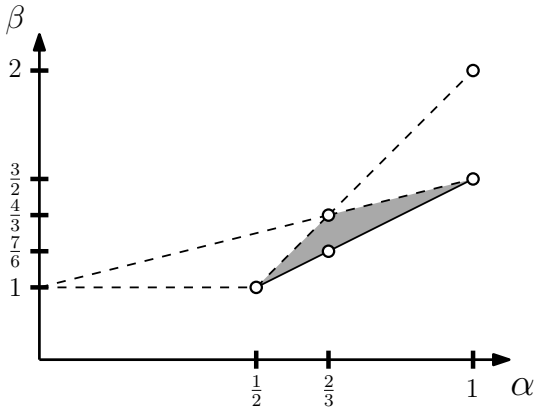

Figure 1 Running time $\mathcal{O}(m^\beta)$ of algorithm from Theorem 1 on instances with $n = \Theta(m)$ and $k = m^\alpha$. Previous algorithms are represented by dashed lines and our algorithm is represented by the solid line. For example, for $k = \Theta(m^{2/3})$ we improve the complexity from $\widetilde{\mathcal{O}}(m^{4/3})$ to $\widetilde{\mathcal{O}}(m^{7/6})$.

▶ **Theorem 2.** *For any positive $\varepsilon, \alpha, \kappa$, such that $\frac{1}{2}\alpha \le \kappa \le \alpha \le 1$ there is no* combinatorial *algorithm solving pattern matching with $k = \Theta(n^\kappa)$ mismatches in time $\mathcal{O}((k\sqrt{m})^{1-\varepsilon} \cdot n/m)$ for a text of length n and a pattern of length $m = \Theta(n^\alpha)$, unless the combinatorial matrix multiplication conjecture fails.*

Next, we move to computing L_1 distance. For computing $(1 \pm \varepsilon)$-approximate text-to-pattern L_1 distance we are able to break the quadratic dependency on $1/\varepsilon$ present in the previous algorithms by designing an $\widetilde{\mathcal{O}}(\varepsilon^{-1}n)$ solution, thus making the complexities of the best known algorithms for $(1 \pm \varepsilon)$-approximate text-to-pattern L_1 distance and Hamming distance essentially equal.

▶ **Theorem 3.** *There is a randomized Monte Carlo algorithm that outputs $(1 \pm \varepsilon)$-approximation of L_1 distance in time $\mathcal{O}(\varepsilon^{-1} n \log^3 n \log m)$. The algorithm is correct with high probability.*

For k-bounded L_1 distance we are able to obtain essentially the same trade-off as for k-bounded Hamming distance.

▶ **Theorem 4.** *There is a deterministic algorithm that outputs k-bounded text-to-pattern L_1 distance in time $\mathcal{O}((m \log^3 m + m \log^2 n + k\sqrt{m \log m} \cdot \log^2 n) \cdot n/m)$.*

In fact, instead of designing a new algorithm for k-bounded L_1 distance we exhibit a series of generic reductions that together allow us to reduce computing k-bounded L_1 distance to computing k-bounded Hamming distance.

▶ **Theorem 5.** *Let $T(n, m, k)$ be the complexity for k-bounded text-to-pattern Hamming distance. Then k-bounded L_1 text-to-pattern distance can be computed in time $\mathcal{O}(n \log^3 m + T(m, m, \mathcal{O}(k)) \cdot \log^2 n \cdot n/m)$.*

Thus, if k-bounded Hamming distance can be computed in time $\widetilde{\mathcal{O}}(n + (k\sqrt{m})^{1-\delta} \cdot n/m)$ for some $\delta \ge 0$ then k-bounded L_1 distance can be computed in time $\widetilde{\mathcal{O}}(n + (k\sqrt{m})^{1-\delta} \cdot n/m)$ as well. Together with a reduction from k-RLE to k-bounded Hamming distance this gives us a clear (although not yet complete) picture of connections between k-bounded and k-RLE text-to-pattern distance under Hamming and L_1 distance summarized in Figure 2.

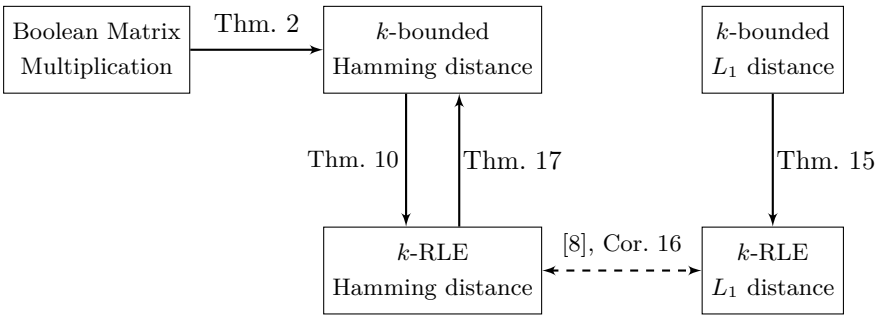

Figure 2 Existing (dashed lines) and new (solid lines) reductions.

Overview of the techniques. Our algorithm for k-bounded Hamming distance (and then also L_1 distance), is a refinement of the approach of Clifford et al. [7]. The general idea is to first consider the periodic structure of the pattern. If the pattern is not very periodic, then m-substrings of the text with a small distance to the pattern cannot occur too often. This allows us to filter the possible occurrences with an algorithm for $(1 \pm \varepsilon)$-approximate Hamming distance and then manually verify the remaining possibilities. Otherwise, the problem can be reduced to multiple smaller instances, in which both the pattern and the text are highly compressible, i.e. their run-length encodings consist of only $\mathcal{O}(k)$ blocks. The first new insight is that, instead of many small instances, it is possible to obtain a single instance of $\mathcal{O}(k)$-bounded Hamming distance, in which the run-length encoding of both the pattern and the text consist of $\mathcal{O}(k)$ blocks. The second observation is that, because the pattern and the text are still of length $\mathcal{O}(m)$, it (again) makes sense to partition the letters into frequent and non-frequent, except that now the threshold is defined with respect to the number of blocks of the pattern containing that letter. For non-frequent letters, we produce a compact representation of their contribution by iterating through every block of the pattern and every block of the text. For frequent letters, we essentially uncompress the corresponding fragments and run the classical convolution.

Our algorithm for $(1 \pm \varepsilon)$-approximate L_1 distance is based on generalized weighted mismatches, similarly as in the previous work [15]: given an arbitrary weight function $\sigma : \Sigma \times \Sigma \to \mathbb{Z}$, we output an array S_σ such that $S[i] = \sum_{j=1}^{m} \sigma(t_{i+j}, p_j)$. This can be computed as follows. For every letter $c \in \Sigma$, construct a new text T^c by setting $T^c[i] = 1$ if $t_i = c$ and $T^c[i] = 0$ otherwise. Similarly, construct a new pattern P^c such that $P^c[i] = \sigma(c, p_i)$. Then, $\sigma(t_{i+j}, p_j) = \sum_{c \in \Sigma} T^c[i + j] \cdot P^c[j]$, so S_σ can be computed with $|\Sigma|$ convolutions in $\mathcal{O}(|\Sigma| n \log m)$ time.

To connect the complexities of computing the text-to-pattern Hamming and L_1 distance we use the recently introduced notion of linearity preserving reductions [8] as a formalization of previously existing reductions between metrics (cf. [14]). The main idea is that in order to show a reduction between two pattern-matching problems, one can represent them as a $(+, \diamond)$ convolution and a $(+, \square)$ convolution, and show how to represent $\square$ as a linear combination of many copies of $\diamond$.

2 Preliminaries

Distance between strings. Let $X = x_1 x_2 \dots x_n$ and $Y = y_1 y_2 \dots y_n$ be two strings over an integer alphabet $[M]$, for some $M = \text{poly}(n)$. We define their L_1 distance as $L_1(X, Y) = \sum_i |x_i - y_i|$, and their Hamming distance as $\text{Ham}(X, Y) = |\{i : x_i \neq y_i\}|$.

Text-to-pattern distance. The text-to-pattern distance between a text $T = t_1 t_2 \dots t_n$ and a pattern $P = p_1 p_2 \dots p_m$ is defined as an array S such that, for every i, $S[i] = d(T[i+1 \,..\, i+m], P)$. Thus, for L_1 distance $S[i] = \sum_{j=1}^{m} |t_{i+j} - p_j|$, while for Hamming distance $S[i] = |\{j \in \{1, \dots, m\} : t[i+j] \neq p[j]\}|$. Then, $(1 \pm \varepsilon)$-approximate distance is an array S_ε such that, for every i, $(1-\varepsilon) \cdot S[i] \leq S_\varepsilon[i] \leq (1+\varepsilon) \cdot S[i]$. Finally, k-bounded distance is an array S_k such that, for every i, $S_k[i] = S[i]$ when $S[i] \leq k$ and $S_k[i] = \infty$ otherwise. Finally, in k-RLE distance we assume that the run-length encoding of both the pattern and the text consist of $\mathcal{O}(k)$ blocks, that is, they contain only $\mathcal{O}(k)$ maximal runs of identical letters.

Model. We assume the standard word RAM model, in which arithmetic operations on integers from $[M]$ take constant time.

Linearity preserving reductions. Say that we want to show a reduction between binary operators $\diamond$ and $\square$. In order for such a reduction to be relevant in the convolutional setting, it needs to be of a specific form. Let t be a fixed integer called the size of the reduction, and suppose there exist integer coefficients $\alpha_1, \dots, \alpha_t$, and functions $f_1, \dots, f_t, g_1, \dots, g_t$ such that, for any x and y, there is $x \square y = \sum_{\ell=1}^{t} \alpha_\ell \cdot (f_\ell(x) \diamond g_\ell(y))$. Then $(+, \square)$-convolution of T and P is computed as a linear combination of $(+, \diamond)$-convolutions $f_\ell(T)$ with $g_\ell(P)$, where $f(X) = f(x_1)f(x_2)\dots f(x_n)$ for $X = x_1 x_2 \dots x_n$. That is, a following equality holds $\sum_{i+j=k} x[i] \square y[j] = \sum_{\ell=1}^{t} \alpha_\ell \cdot \left(\sum_{i+j=k} x[i] \diamond y[j] \right)$.

3 k-bounded Distance

The goal of this section is to prove Theorem 1. We first show how to reduce k-bounded Hamming distance to $\mathcal{O}(n/m)$ instances of $\mathcal{O}(k)$-RLE Hamming distance on inputs of length $\mathcal{O}(m)$. We start with the standard trick of reducing the original problem to $\lceil n/m \rceil$ instances with pattern P of length m and text T of length $2m$ and work with such formulation from now on. Thus, now we need to reduce one such instance to an instance of $\mathcal{O}(k)$-RLE Hamming distance on inputs of length $\mathcal{O}(k)$.

We now highlight the kernelization technique of Clifford et al. [7]. An integer $\pi > 0$ is an x-period of a string $S[1, m]$ if $\mathrm{Ham}(S[\pi+1, m], S[1, m-\pi]) \leq x$ (cf. Definition 1 in [7]). Note that compared to the original formulation, we drop the condition that π is minimal from the definition.

▶ **Lemma 6** (Fact 3.1 in [7]). *If the minimal $2x$-period of the pattern is ℓ, then the starting positions of any two occurrences with x mismatches of the pattern are at distance at least ℓ.*

The first step of the algorithm is to determine the minimal $\mathcal{O}(k)$-period of the pattern. More specifically, we run the $(1+\varepsilon)$-approximate algorithm of Karloff [10] with $\varepsilon = 1$ matching the pattern P against itself. Since Karloff's algorithm is convolution-based, it can be adapted to computing mismatches for partial alignments, that is, between suffixes and prefixes of equal length of the same string. This takes $\mathcal{O}(m \log^2 m \log |\Sigma|)$ time and, by looking at the approximate outputs for offsets not larger than k, allows us to distinguish between two cases: (1) every $4k$-period of the pattern is at least k, or (2) there is an $8k$-period of the pattern that is at most k. Then we run the appropriate algorithm as described below.

No small $4k$-period. We again run Karloff's algorithm with $\varepsilon = 1$, but now we match the pattern with the text. We look for positions i where the 2-approximate algorithm reports at most k mismatches, meaning that $\mathrm{Ham}(P, T[i, i+m-1]) \leq 2k$. By Lemma 6, there

Figure 3 Example of rearranging the text and the pattern with $\ell = 4$.

are $\mathcal{O}(m/k)$ such positions, and we can safely discard all the others. Then, we test every such position using the "kangaroo jumps" technique of Landau and Vishkin [13], using $\mathcal{O}(k)$ constant-time operations per position, in total $\mathcal{O}(m)$ time.

Small $8k$-period. Let $\ell \leq k$ be any $8k$-period of the pattern. For a string S and $1 \leq i \leq \ell$, let $\{S\}_{\ell,i} = S[i]S[i+\ell]S[i+2\ell]\dots$ up until end of S. We denote by $\{S\}_\ell$ an ℓ-encoding of S, that is the string $\{S\}_{\ell,1}\{S\}_{\ell,2}\dots\{S\}_{\ell,\ell-1}, \{S\}_{\ell,\ell}$. Let runs$(S)$ be the number of runs in S. Denote $\text{runs}_\ell(S) = \sum_{i=1}^{\ell} \text{runs}(\{S\}_{\ell,i})$, and observe that it upperbounds the number of runs in $\{S\}_\ell$.

▶ **Lemma 7** (Lemma 6.1 in [7]). *If P has an $8k$-period ℓ for $\ell \leq k$, then* $\text{runs}_\ell(P) \leq 9k$.

We proceed with the kernelization argument. Let T_L be the longest suffix of $T[1,m]$ such that $\text{runs}_\ell(T_L) \leq 11k$. Similarly, let T_R be the longest prefix of $T[m+1,2m]$ such that $\text{runs}_\ell(T_R) \leq 11k$. Let $T' = T_L T_R$. Obviously, $\text{runs}_\ell(T') \leq 22k$.

▶ **Lemma 8** (Lemma 6.2 in [7]). *Every $T[i,i+m-1]$ that is an occurrence of P with k mismatches is fully contained in T'.*

Thus we see that k-mismatch pattern matching is reduced to a kernel where the ℓ-encoding of both the text and the pattern have few runs, that is, they both compress well with RLE.

From now on assume that both T' and P are of lengths divisible by ℓ. If this is not the case, we can pad them separately with at most $\ell - 1 < k$ characters each, not changing the complexity of our solution. Let m_1 and m_2 be integers such that $m_1 \cdot \ell = |T'|$ and $m_2 \cdot \ell = |P|$, $m_1 \geq m_2$.

We rearrange both P and T' to take advantage of their regular structure. That is, we define $T^\star = \{T'\}_\ell\{T''\}_\ell$, where $T'' = T'[\ell+1, m_1 \cdot \ell]\ \#^\ell$. Observe that $T^\star$ is a string of length $2m_1 \cdot \ell$, composed first of m_1 blocks of the form $T'[i]T'[i+\ell]\dots T'[i+(m_1-1)\ell]$ for $1 \leq i \leq \ell$, and then of m_1 blocks of the form $T'[i+\ell]\dots T'[i+(m_1-1)\ell]\ \#$. Similarly, we define $P^\star = \{P\ \$^{(m_1-m_2)\ell}\}_\ell$. Again we observe that $P^\star$ is the string of length $m_1 \cdot \ell$, composed of blocks of the form $P[i]P[i+\ell]\dots P[i+(m_2-1)\ell]\ \$^{m_1-m_2}$ for $1 \leq i \leq \ell$. An example of this reduction is presented in Figure 3.

Next we show that $T^\star$ and $P^\star$ preserve the Hamming distance between P and any m-substring of T' in the following sense:

▶ **Lemma 9.** *For any integer $0 \leq \alpha \leq (m_1 - m_2)\ell$, let $x = \lfloor \alpha/\ell \rfloor$ and $y = \alpha \bmod \ell$. Let $\beta = x + y \cdot m_1$. Then*

$$\text{Ham}(T'[\alpha+1, \alpha+m_2\cdot\ell], P) = \text{Ham}(T^\star[\beta+1, \beta+m_1\cdot\ell], P^\star) - (m_1 - m_2)\cdot\ell.$$

Proof. Observe that

$$\mathrm{Ham}(T'[\alpha+1,\alpha+m_2\cdot\ell],P)=\sum_{i=0}^{m_2-1}\sum_{j=1}^{\ell}\delta(T'[x\ell+y+i\ell+j],P[i\ell+j]), \tag{1}$$

where δ is indicator of character inequality. Observe that $P[i\ell+j])=P^\star[i+j\cdot m_1]$, for $1\le j\le \ell-y$ there is $T'[x\ell+y+i\ell+j]=T^\star[(x+i)+(y+j)m_1]$, and for $\ell-y<j\le\ell$ there is $T'[x\ell+y+i\ell+j]=T''[(x+i)\ell+(y+j-\ell)]=T^\star[(x+i)+(y+j-\ell)m_1+\ell m_1]=T^\star[(x+i)+(y+j)m_1]$. Additionally, for $m_2\le i<m_1$, $P^\star[i+j\cdot m_1]=\$$, which always generates a mismatch with any character in $T^\star$. Thus

$$(1)=\sum_{i=0}^{m_2-1}\sum_{j=1}^{\ell}\delta(T^\star[(x+i)+(y+j)m_1],P^\star[i+j\cdot m_1])=$$
$$=-(m_1-m_2)\ell+\sum_{i=0}^{m_1-1}\sum_{j=1}^{\ell}\delta(T^\star[(x+i)+(y+j)m_1],P^\star[i+j\cdot m_1]).$$ ◀

We see that it is enough to find all occurrences of $P^\star$ in $T^\star$ with $(k+(m_1-m_2)\cdot\ell)$ mismatches, where $k+(m_1-m_2)\cdot\ell\le 2k$, $|P^\star|=|T'|\le m$ and $|T^\star|=2|T'|\le 2m$. Additionally, $\mathrm{runs}(P^\star)\le 9k+\ell\le 10k$ and $\mathrm{runs}(T^\star)\le 22k+\ell\le 23k$. This gives us the following theorem.

▶ **Theorem 10.** *k-bounded text-to-pattern Hamming distance reduces in $\mathcal{O}(n\log^3 m)$ time to $\mathcal{O}(n/m)$ instances of $\mathcal{O}(k)$-RLE text-to-pattern Hamming distance on inputs of length $\mathcal{O}(m)$.*

Now we describe how to solve an instance of $\mathcal{O}(k)$-RLE Hamming distance.

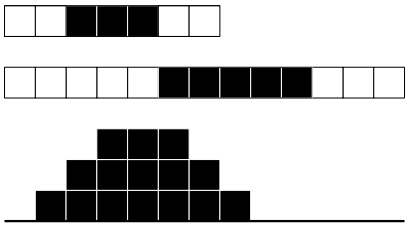
▶ **Lemma 11.** *There is a deterministic algorithm that outputs k-RLE Hamming text-to-pattern distance on inputs of length $\mathcal{O}(m)$ in time $\mathcal{O}(m+k\sqrt{m\log m})$.*

Proof. Consider a letter $c\in\Sigma$. For a string S, we denote by $\mathrm{runs}(S,c)$ the number of runs in S consisting of occurrences of c. Fix a parameter t. Call a letter c such that $\mathrm{runs}(P^\star,c)>t$ a heavy letter, and otherwise call it light. Now we describe how to count the number of mismatches for each type of letters. This is reminiscent to a trick originally used by Abrahmson [1] and later refined by Amir et al. [2].

Heavy letters. For every heavy letter c separately we use a convolution scheme. Since both $P^\star$ and $T^\star$ are of size $\mathcal{O}(m)$, this takes time $\mathcal{O}(m\log m)$ per every such letter. Since $\sum_{c\in\Sigma}\mathrm{runs}(P^\star,c)=\mathrm{runs}(P^\star)\le 10k$, there are $\mathcal{O}(k/t)$ heavy letters, making the total time $\mathcal{O}(mk/t\cdot\log m)$.

Light letters. First, we preprocess $P^\star$, and for every light letter c we compute a list of runs consisting of occurrences of c. Our goal is to compute the array $A[0,|T^\star|-|P^\star|]$, where $A[i]$ counts the number of matching occurrences of light letters in $T^\star[i+1,i+|P^\star|]$ and $P^\star$.

We scan $T^\star$, and for every run of a particular light letter, we iterate through the precomputed list of runs of this letter in $P^\star$. Observe that, given a run of the same letter in $P^\star$ and in $T^\star$, denoted $T^\star[u,v]$ and $P^\star[y,z]$, respectively, their corresponding matches can be seen as a piecewise linear function. More precisely, for all integers $u\le i\le v$ and $y\le j\le z$, we need to increase $A[i-j]$ by one. To see that we can process pair of runs in constant time, we work with discrete derivative, instead of original arrays.



$DA =$ | 1 | 0 | 0 | -1 |

$DB =$ | 1 | 0 | 0 | 0 | 0 | -1 |

$D^2(A \cdot B) =$ | 1 | 0 | 0 | -1 | 0 | -1 | 0 | 0 | 1 |

Figure 4 Left: a run in the pattern and a run in the text (both represented by black boxes) consisting of the same character and a histogram of the matches they generate. Right: first derivatives of the indicator arrays and second derivative of the match array, without padding zeroes.

Given a sequence F, we define its discrete derivative DF as follows: $(DF)[i] = F[i] - F[i-1]$. Correspondingly, if we consider a generating function $F(x) = \sum_i F[i]x^i$, then $(DF)(x) = F(x) \cdot (1-x)$ (for convenience, we assume that arrays are indexed from $-\infty$ to ∞).

Now consider indicator sequences $T_{u,v}[i] = \mathbf{1}(u \le i \le v)$ and $P_{y,z}[j] = \mathbf{1}(-z \le j \le -y)$. To perform the update, we set $A[i+j]$ += $T_{u,v}[i] \cdot P_{y,z}[j]$ for all i, j, or simpler using generating functions:

$$A(x) \mathrel{+}= T_{u,v}(x) \cdot P_{y,z}(x), \tag{2}$$

where $T_{u,v}(x) = \sum_{i=u}^{v} x^i$ and $P_{y,z}(x) = \sum_{j=y}^{z} x^{-j}$. However, we observe that $DT_{u,v}$ and $DP_{y,z}$ have particularly simple forms: $DT_{u,v}(x) = x^u - x^{v+1}$ and $DP_{y,z}(x) = x^{-z} - x^{-y+1}$. Thus it is easier to maintain second derivative of A, and (2) becomes:

$$D^2A(x) \mathrel{+}= x^{u-z} - x^{v-z+1} - x^{u-y+1} + x^{v-y+2}.$$

All in all, we can maintain D^2A in constant time per pair of runs, or in $\mathcal{O}(k \cdot t)$ total time, since every list of runs is of length at most t, and there are at most $23k$ runs in $T^\star$. Additionally, in $\mathcal{O}(m)$ time we can compute $A[0]$ and $A[1]$, allowing us to recover all other $A[i]$s from the formula $A[i] = (D^2A)[i] + 2A[i-1] - A[i-2]$.

Setting $t = \sqrt{m \log m}$ gives the total running time $\mathcal{O}(k\sqrt{m \log m})$ in both cases as claimed. ◀

Combining the reduction from Theorem 10 with Lemma 11 gives us Theorem 1.

4 Lower Bound for k-bounded Hamming Distance

In this section, we present a conditional lower bound for computing k-bounded Hamming distance. The main idea expands upon the proof attributed to Indyk [6], except that we use rectangular matrices instead of square, and use the padding accordingly. We pad using the same character in both text and pattern, increasing the number of mismatches only by a factor of 2.

Recall the combinatorial matrix multiplication conjecture stating that, for any $\varepsilon > 0$, there is no *combinatorial*[1] algorithm for multiplying two $n \times n$ boolean matrices working in time $\mathcal{O}(n^{3-\varepsilon})$. The following formulation is equivalent to this conjecture.

[1] It is not clear what does combinatorial mean *precisely*. However, FFT and so boolean convolution often used in algorithms on strings are considered not to be combinatorial.

▶ **Conjecture 12** (Combinatorial matrix multiplication). *For any $\alpha, \beta, \gamma, \varepsilon > 0$, there is no combinatorial algorithm for multiplying an $n^\alpha \times n^\beta$ matrix with an $n^\beta \times n^\gamma$ matrix in time $\mathcal{O}(n^{\alpha+\beta+\gamma-\varepsilon})$.*

The equivalence can be seen by simply cutting the matrices into square blocks (in one direction) or in rectangular blocks (in the other direction).

Now, consider two boolean matrices, A of dimension $M' \times N$ and B of dimension $N \times M$, for $M' \geq M \geq N$. We encode A as a text T by writing down its elements row-by-row and adding some padding. Namely:

$$T = \#^{M^2} r_1 \ \#^{M-N+1} \ r_2 \ \#^{M-N+1} \ \dots \ \#^{M-N+1} \ r_{M'} \#^{M^2}$$

where $r_i = r_{i,1} \dots r_{i,N}$ and $r_{i,j} = 0$ when $A_{i,j} = 0$ and $r_{i,j} = j$ when $A_{i,j} = 1$. Similarly, we encode B as a pattern P by writing down its elements column-by-column, except that here the padding is shorter by one character:

$$P = c_1 \ \#^{M-N} \ c_2 \ \#^{M-N} \ \dots \ \#^{M-N} \ c_M$$

where $c_j = c_{1,j} \dots c_{N,j}$ and $c_{i,j} = 0'$ when $B_{i,j} = 0$ and $c_{i,j} = i$ when $B_{i,j} = 1$.

Observe that, since we encode 0s from A and B using different symbols, and encoding of 1s is position-dependent, r_i and c_j will generate a match only if they are perfectly aligned and there is k such that $r_{i,k} = c_{k,j}$, or equivalently $A_{i,k} = B_{k,j} = 1$. Since each block (encoded row plus following padding) is either of length $N+1$ for rows or N for columns, there will be at most one aligned row-column pair for each pattern-text alignment.

The total number of mismatches, for each alignment, is at most $2NM$ (since there are at most MN non-# text characters that are aligned with pattern, and at most MN non-# pattern characters). We can determine whether any given entry of $A \cdot B$ is a 1, since if so the number of mismatches for the corresponding alignment is decreased by 1.

We have $|T| = \Theta(M'M)$ and $|P| = \Theta(M^2)$. By setting $M = \sqrt{m}$, $M' = \frac{n}{\sqrt{m}}$ and $N = \frac{k}{\sqrt{m}}$ we obtain Theorem 2.

If we denote by $\omega(\alpha, \beta, \gamma)$ the exponent of fastest algorithm to multiply a matrix of dimension $n^\alpha \times n^\beta$ with a matrix of dimension $n^\beta \times n^\gamma$, we also have:

▶ **Corollary 13.** *For any positive $\varepsilon, \alpha, \kappa$, such that $\frac{1}{2}\alpha \leq \kappa \leq \alpha \leq 1$ there is no algorithm solving pattern matching with $\Theta(n^\kappa)$ mismatches in time $\mathcal{O}(n^{\omega(2-\alpha, 2\kappa-\alpha, \alpha)/2-\varepsilon})$ for a text of length n and a pattern of length $\Theta(n^\alpha)$.*

5 $(1 \pm \varepsilon)$-approximation of L_1 Distance

In this section we prove Theorem 3. We use a procedure `generalized_weighted_matching` $(T, P, \texttt{score})$ that computes, for a text $T = t_1 t_2 \dots t_n$ and a pattern $P = p_1 p_2 \dots p_m$ and an arbitrary weight function $\sigma : \Sigma \times \Sigma \to \mathbb{Z}$, the array S_σ such that $S[i] = \sum_{j=1}^{m} \sigma(t_{i+j}, p_j)$ in in $\mathcal{O}(|\Sigma| n \log m)$ time.

Let $\delta = \frac{\varepsilon}{24 \cdot (3 + \log M)} = \Theta(\varepsilon / \log n)$, and let b be the smallest positive integer such that $2^b \geq 1/\delta$. We claim that with such parameters, Algorithm 1 outputs the desired $(1 \pm \varepsilon)$-approximation in the claimed time. Let S_ε be its output.

▶ **Theorem 14.** *For any i, $S[i] \cdot (1 - \varepsilon) \leq S_\varepsilon[i] \leq S[i] \cdot (1 + \varepsilon)$ with probability at least $2/3$.*

Proof. Consider first $x = x_a$ and $y = y_b$, two characters of the input. We analyze how well Algorithm 1 approximates $|x - y| = \operatorname{sgn}(x - y) \cdot (x - y)$ in the consecutive calls of `generalized_weighted_matching`. First, fix value of Δ and consider the binary representations of $x' = x + \Delta$ and $y' = y + \Delta$. More precisely, let $x' = \sum_i 2^i \cdot \alpha_i$ and $y' = \sum_i 2^i \cdot \beta_i$ for

Algorithm 1: $(1 \pm \varepsilon)$-approximation of text-to-pattern L_1 distance.

Input: Integer strings T and P.
Output: Score vector S_ε.

```
def score(x, y):
    x_0 ← x mod 2
    y_0 ← y mod 2
    if x_0 = y_0 then
        return 0
    else if sgn(x − y) = sgn(x_0 − y_0) then
        return 1
    else
        return −1

def approximate(T, P):
    Δ ← u.a.r. integer from 0 to 2^⌈log M⌉ − 1
    T' ← T + Δ
    P' ← P + Δ
    S_ε ← [0 ... 0]
    for i ← 0 to ⌈log M⌉ do
        T'' ← ⌊T'/2^i⌋ mod 2^b
        P'' ← ⌊P'/2^i⌋ mod 2^b
        S ← generalized_weighted_matching(T'', P'', score)
        S_ε ← S_ε + S · 2^i
    return S_ε
```

some $\alpha_i, \beta_i \in \{0, 1\}$. Algorithm 1 in essence estimates $|x-y| = \operatorname{sgn}(x-y)\sum_i 2^i(\alpha_i - \beta_i)$ with $C = \sum_i 2^i\gamma_i$ where $\gamma_i \in \{-1, 0, 1\}$ is the estimation of a contribution of $(\alpha_i - \beta_i) \cdot \operatorname{sgn}(x - y)$ to $(x' - y')$ and depends only on values of $\alpha_j - \beta_j \in \{-1, 0, 1\}$ for $i \le j < i + b$ in the following way:

- If, for every $i \le j < i + b$ we have $\alpha_j = \beta_j$, then $\gamma_i = 0$.
- Otherwise, let j' be the largest j such that $i \le j < i+b$ and $\alpha_j \neq \beta_j$. If $\alpha_{j'} - \beta_{j'} = 1$, then the local estimation is that $x' > y'$ and so $\gamma_i = \alpha_i - \beta_i$, and otherwise $\gamma_i = -1 \cdot (\alpha_i - \beta_i)$.

Consider $c = \max\{i : \alpha_i \neq \beta_i\}$ and $d = \max\{i : 2^i \le (x' - y')\}$, that is c is the position of the highest bit on which x' and y' differ, and d is the position of the highest bit of $x' - y'$. In general, $c \ge d$, and we say that pair x', y' is *t-bad*, if $c - d = t$.

We first observe that for a x, y pair to be at least t-bad, a following condition must be met: $\lfloor x'/2^{d+t} \rfloor \neq \lfloor y'/2^{d+t} \rfloor$. Since Δ is chosen uniformly at random from a large enough range of integers, there is

$$\sum_{\tau \ge t} \Pr(x', y' \text{ is } \tau\text{-bad} \mid x, y) \le |x - y|/2^{d+t} \le 2^{-t+1}.$$

We also observe following: for any pair x', y', in C, all the coefficients $\gamma_c, \gamma_{c-1}, \ldots, \gamma_{c-b+1}$ are computed correctly, since for any j such that $c \ge j \ge c - b + 1$ there is $j' = c$, and then $\gamma_j = (\alpha_j - \beta_j) \cdot \operatorname{sgn}(x - y)$. Therefore

$$\big|C - |x' - y'|\big| = \left|\sum_{i \le c-b} 2^i(\gamma_i - (\alpha_i - \beta_i) \cdot \operatorname{sgn}(x - y))\right| \le \sum_{i \le c-b} 2 \cdot 2^i < 2 \cdot 2^{c-b+1}.$$

If a pair x', y' is t-bad, it immediately follows that the absolute error of estimation is at most $2^{c-b+2} = 2^{d+t-b+2} \leq |x'-y'|2^{t+2}\delta$.

We now estimate expected error in estimation based on choice of Δ. If a particular pair x, y is t-bad, then $t \leq 1 + \lceil \log M \rceil$. Using the previous observations, we have

$$\mathbb{E}\Big[\big|C - \big|x'-y'\big|\big| \;\Big|\; x,y\Big] = \sum_t \Pr(x',y' \text{ is } t\text{-bad} \mid x,y) \cdot \mathbb{E}\Big[\big|C - \big|x'-y'\big|\big| \;\Big|\; x',y' \text{ is } t\text{-bad}\Big]$$
$$\leq \sum_{t=0}^{1+\lceil \log M \rceil} 2^{-t+1}|x-y|2^{t+2}\delta = (3+\log M)8\delta|x-y| = \frac{\varepsilon}{3}|x-y|.$$

By linearity of expectation $\mathbb{E}\Big[\big|S_\varepsilon[i] - S[i]\big|\Big] \leq \frac{\varepsilon}{3}S[i]$, and by Markov's inequality the claim follows. ◀

Now, a standard amplification technique applies: it is enough to repeat Algorithm 1 independently p times and take the median value from $S_\varepsilon^{(1)}[i], S_\varepsilon^{(2)}[i], \ldots, S_\varepsilon^{(p)}[i]$ as the final estimate $\widehat{S}_\varepsilon[i]$. Taking $p = \Theta(\log n)$ to be large enough makes the final estimate good with high probability, and by the union bound whole $\widehat{S}_\varepsilon$ is a good estimate of S.

The complexity of Algorithm 1 is dominated by `generalized_weighted_matching` being invoked $\mathcal{O}(\log n)$ times on alphabet of size $2^b = \Theta(\varepsilon^{-1}\log n)$. Each such invocation takes $\mathcal{O}(2^b n \log m) = \mathcal{O}(\varepsilon^{-1} n \log n \log m)$, and Algorithm 1 takes $\mathcal{O}(\varepsilon^{-1} n \log^2 n \log m)$ time and the total time for computing $(1 \pm \epsilon)$-approximation is $\mathcal{O}(\varepsilon^{-1} n \log^3 n \log m)$.

6 Reductions

In this section we design a series of reductions to complete the picture from Figure 2. We start with an L_1 version of Theorem 10.

▶ **Theorem 15.** *k-bounded text-to-pattern L_1 distance problem reduces in $\mathcal{O}(n \log^3 m)$ time to $\mathcal{O}(n/m)$ instances of $\mathcal{O}(k)$-RLE text-to-pattern L_1 distance on inputs of length $\mathcal{O}(m)$, where both the pattern and the text might contain wildcards.*

Proof. As in the proof of Theorem 10, we can assume that the length of T is $2m$. We observe that if the L_1 distance of an m-substring of T is at most k, so must be its Hamming distance. Therefore, we can use exactly the same filtering approach. In the case of no small $4k$-period, after filtering m-substrings with more than $2k$ mismatches we are left with $\mathcal{O}(m/k)$ possibilities, which are then verified using the "kangaroo jumps" technique of Landau and Vishkin [13]. The only required modification is that now for every found mismatch we calculate the corresponding increase in the L_1 distance. In the case of a small $8k$-period, we use the same transformation, except that all special characters become identical wildcards $*$ with L_1 distance 0 to every letter. This preserves the L_1 distance by the same argument. ◀

Then, instead of designing an algorithm for computing k-RLE L_1 distance, we apply the following reduction.

▶ **Corollary 16** (Theorem 2.1, Theorem 2.2 and Lemma A.1 in [8]). *For any $M \geq 0$, there is a linearity preserving reduction from L_1 distance between integers from $[M]$ to $\mathcal{O}(\log^2 M)$ instances of Hamming distance. There is a converse reduction from Hamming distance to $\mathcal{O}(1)$ instances of L_1 distance. Both reductions allow for wildcards in the input and output wildcard-less instances.*

By inspecting the proof of the above reduction we see that it does not create any new runs, that is, allows us to reduce k-RLE L_1 distance to $\mathcal{O}(\log^2 M)$ instances of k-RLE Hamming distance. Therefore, together with Theorem 15 and Lemma 11, we obtain an $\mathcal{O}((m + k\sqrt{m \log m}) \cdot \log^2 n + n \log^3 m)$ time algorithm for k-bounded L_1 distance as claimed in Theorem 4.

To complete the picture, we show a reduction from k-RLE Hamming distance to $2k$-bounded Hamming distance, that is, a converse to Theorem 10.

▶ **Theorem 17.** *k-RLE text-to-pattern Hamming distance on inputs of length $\mathcal{O}(m)$ reduces to $\mathcal{O}(1)$ instances of $2k$-bounded Hamming distance on inputs of length $\mathcal{O}(m)$.*

Proof. We proceed similarly as in Lemma 11. We observe that it is enough to compute the second discrete derivative of the output array S, that is D^2S defined as $(D^2S)[i] = S[i+2] - 2S[i+1] + S[i]$, since D^2S and two initial values of S (computed naively in time $\mathcal{O}(m)$) are enough to recover S. For any two blocks $t_u t_{u+1} \dots t_{v-1} t_v$ and $p_y p_{y+1} \dots p_{z-1} p_z$ of the same letter, D^2S needs to be updated in only 4 places, that is $D^2S[u - z] += 1$, $D^2S[v - z + 1] -= 1$, $D^2S[u - y + 1] -= 1$ and $D^2S[v - y + 2]$. We now explain how to deal with the first kind of updates, with the other three being implemented similarly.

We first reduce the problem to *k-sparse text-to-pattern Hamming distance*, where the text and the pattern are of length $\mathcal{O}(m)$ and have each at most k regular characters, with every other character being wildcard $*$ (special character having distance 0 to every other character). We construct sparse instance as follows: for every position t_u in T that starts a block, we set $T_{\text{sparse}}[u] = t_u$, and similarly in pattern for a position p_z (that ends a block), we set $P_{\text{sparse}}[z] = p_z$. Observe, that if $t_u \neq p_z$, then in the answer there is $S_{\text{sparse}}[u - z] += 1$, and if $t_u = p_z$ then S_{sparse} remains unchanged. That is, the answer counts mismatches, while we want to count matches. To invert the answer, we create T_{bin} such that $T_{\text{bin}}[i] = 1$ iff $T_{\text{sparse}}[i] \neq *$ and $T_{\text{bin}}[i] = 0$ otherwise, and P_{bin} in an analogous manner. Convolving T_{bin} and P_{bin} gives us, for every alignment, the total number of non-special text characters aligned with non-special pattern characters, and we obtain the answer with a single subtraction.

To reduce from k-sparse instances of Hamming distance to $2k$-bounded Hamming distance, we follow an analogous reduction from Lemma A.1 in [8] that reduces Hamming distance on $\mathbb{N}^+ + \{*\}$ to Hamming distance on $\mathbb{N}$. First, create a new text T_1 such that $T_1[i] = T[i]$ iff $T[i] \neq *$ and $T_1[i] = 0$ iff $T[i] = *$, and similarly to obtain P_1. Second, create a new text T_2 such that $T_2[i] = 1$ iff $T_2[i] \neq *$ and $T_2[i] = 0$ iff $T[i] = *$, and similarly to obtain P_2. Now we observe that $\text{Ham}(T[i], P[j]) = \text{Ham}(T_1[i], P_1[j]) - \text{Ham}(T_2[i], P_2[j])$, thus it is enough to compute exact Hamming text-to-pattern distances on these two instances and subtract them. However, we observe that in both of them, there are in total at most $2k$ characters different than 0, thus $2k$-bounded Hamming distance works just as fine. ◀

7 Conclusion and Open Problems

Showing a reduction from either *bounded RLE* L_1 distance, or *sparse* L_1 distance to k-approximated L_1 distance would suffice in completing a converse to Theorem 5, and prove that complexity of k-bounded L_1 and Hamming distances is the same, up to poly-logarithmic factors.

Abstract

A consensus tree is a phylogenetic tree that captures the similarity between a set of conflicting phylogenetic trees. The problem of computing a consensus tree is a major step in phylogenetic tree reconstruction. It is also central for predicting a species tree from a set of gene trees, as indicated recently in [Nature 2013].

This paper focuses on two of the most well-known and widely used consensus tree methods: the greedy consensus tree and the frequency difference consensus tree. Given k conflicting trees each with n leaves, the previous fastest algorithms for these problems were $\mathcal{O}(kn^2)$ for the greedy consensus tree [J. ACM 2016] and $\widetilde{\mathcal{O}}(\min\{kn^2, k^2n\})$ for the frequency difference consensus tree [ACM TCBB 2016]. We improve these running times to $\widetilde{\mathcal{O}}(kn^{1.5})$ and $\widetilde{\mathcal{O}}(kn)$ respectively.

1 Introduction

A *phylogenetic tree* describes the evolutionary relationships among a set of n species called taxa. It is an unordered rooted tree whose leaves represent the taxa and whose inner nodes represent their common ancestors. Each leaf has a distinct label from $[n]$. The inner nodes are unlabelled and have at least two children.

Numerous phylogenetic trees, reconstructed from data sources like fossils or DNA sequences, have been published in the literature since the early 1860s. However, the phylogenetic trees obtained from different data sources or using different reconstruction methods result in conflicts (similar though not identical phylogenetic trees over the same set $[n]$ of leaf labels). The conflicts between phylogenetic trees are usually measured by their difference in *signatures*: The signature of a phylogenetic tree T is the set $\{\mathsf{L}(u) : u \in T\}$ where $\mathsf{L}(u)$ denotes the set of labels of all leaves in the subtree rooted at node u of T (the set $\mathsf{L}(u)$ is sometimes called a *cluster*). To deal with the conflicts between k phylogenetic trees in a

systematic manner, the concept of a *consensus tree* was invented. Informally, the consensus tree is a single phylogenetic tree that summarizes the branching structure (signatures) of all the conflicting trees. That is, given a collection of k phylogenetic trees with the same set of leaf labels $[n]$, we would like to build a single phylogenetic tree that captures as much of their structure as possible (in practice, we might want to relax this assumption and only require that each set of leaf labels is a subset of $[n]$, but we assume that it is exactly $[n]$ as in the previous theoretical work). Of course, there are many possibilities of how this single phylogenetic tree should be chosen.

Many different types of consensus trees have been proposed in the literature. For almost all of them, optimal or near-optimal $\widetilde{\mathcal{O}}(kn)$ time constructions are known. These include Adam's consensus tree [1], strict consensus tree [27], loose consensus tree [4, 13], majority-rule consensus tree [17, 13], majority-rule (+) consensus tree [11], and asymmetric median consensus tree [20, 21][2]. Two of the most notable exceptions are the frequency difference consensus tree [10] and the greedy consensus tree [5, 9] whose running time remains quadratic in either k or n. In particular, the former can be constructed in $\widetilde{\mathcal{O}}(\min\{kn^2, k^2n\})$ time [11] and the later in $\mathcal{O}(kn^2)$ time [13]. For more details about different consensus trees and their advantages and disadvantages see the survey in [5], Chapter 30 in [8], and Chapter 8.4 in [31].

In this paper we propose novel worst-case efficient algorithms for the frequency difference consensus tree problem and the greedy consensus tree problem.

First, we present an $\mathcal{O}(kn \log^2 n)$ time deterministic labeling method. The labeling method counts the frequency (number of occurrences) of every cluster S in the input trees. Based on this labeling method, we obtain an $\mathcal{O}(kn \log^2 n)$ time construction of the frequency difference consensus tree. Then, for the greedy consensus tree, we present our main technical contribution: a method that uses micro-macro decomposition to verify if a cluster S is compatible with a tree T in $\mathcal{O}(n^{0.5} \log n)$ time and, if so, modify T to include S in $\mathcal{O}(n^{0.5} \log n)$ amortized time. Using this procedure, we obtain an $\mathcal{O}(kn^{1.5} \log n)$ time construction of the greedy consensus tree.

The frequency difference consensus tree. The frequency $f(S)$ of a cluster S (a set of labels of all leaves in some subtree) is the number of trees that contain S. A cluster is said to be *compatible* with another cluster if they are either disjoint or one is included in the other. A *frequent* cluster is a cluster that occurs in more trees than any of the clusters that are incompatible with it. The frequency difference consensus tree is a tree whose signature is exactly all the frequent clusters. Such a tree always exists because, for any pair of incompatible clusters, at most one will be included, and so all included clusters are pairwise compatible.

The frequency difference consensus tree was initially proposed by Goloboff et al. [10], and its relationship with other consensus trees was studied in [7]. In particular, it can be seen as a refinement of the majority-rule consensus tree [17, 13]. Moreover, it is known to give less noisy branches than the greedy consensus tree defined below. Steel and Velasco [30] concluded that "the frequency difference method is worthy of more widespread usage and serious study". A naive construction of the frequency difference consensus tree takes $\mathcal{O}(k^2n^2)$ time. The free software TNT [10] has implemented a heuristics method to construct it more efficiently. However, its time complexity remains unknown.

[2] Constructing the asymmetric median consensus tree was proven to be NP-hard for $k > 2$ [20] and solvable in $\widetilde{\mathcal{O}}(n)$ time for $k = 2$ [21].

Recently, Jansson et al. [11] presented an $\mathcal{O}(\min\{kn^2, k^2n + kn\log^2 n\})$ time construction (implemented in the FACT software package [12]). Their algorithm first computes the frequency $f(S)$ of every cluster S with non-zero frequency. This is done in total $\mathcal{O}(\min\{kn^2, k^2n\})$ time. They then show that given these computed frequencies, the frequency difference consensus tree can be computed in additional $\mathcal{O}(kn\log^2 n)$ time. In Section 2 we show how to compute all frequencies in total $\mathcal{O}(kn\log^2 n)$ time leading to the following theorem:

▶ **Theorem 1.** *The frequency difference consensus tree of k phylogenetic trees $T_1, T_2, \ldots, T_k$ on the same set of leaves $[n]$ can be computed in $\mathcal{O}(kn\log^2 n)$ time.*

To prove the above theorem, we first develop an $\mathcal{O}(kn\log^2 n)$ time algorithm for assigning a number $\mathsf{id}(u) \in [kn]$ to every $u \in T_i$ such that $\mathsf{id}(u) = \mathsf{id}(u')$ iff $\mathsf{L}(u) = \mathsf{L}(u')$. With these numbers in hand, we can then compute the frequencies of all clusters in $\mathcal{O}(kn)$ time using counting sort (since there are only kn clusters with non-zero frequencies, and each was assigned an integer bounded by kn). Notice that this also generates a sorted list of all clusters with non-zero frequencies.

The greedy consensus tree. We say that a given collection $\mathcal{C}$ of subsets of $[n]$ is *consistent* if there exists a phylogenetic tree T such that the signature of T is exactly $\mathcal{C}$. The greedy consensus tree is defined by the following procedure: We begin with an initially empty $\mathcal{C}$ and then consider all clusters S in decreasing order of their frequencies. In this order, for every S, we check if $\mathcal{C} \cup \{S\}$ is consistent, and if so we add S to $\mathcal{C}$.

The greedy consensus tree is one of the most well-known consensus trees. It has been used in numerous papers such as [6, 23, 14, 18, 2, 24, 29, 19, 3, 15, 16, 26, 33] to name a few. For example, in a recent landmark paper in Nature [23], it was used to construct the species tree from 1000 gene trees of yeast genomes, and in [6] it was asserted that *"The greedy consensus tree offers some robustness to gene-tree discordance that may cause other methods to fail to recover the species tree. In addition, the greedy consensus method outperformed our other methods for branch lengths outside the too-greedy zone."*.

The greedy consensus tree is a refinement of the majority-rule consensus tree, and is sometimes called the extended majority-rule consensus (eMRC) tree. It is implemented in popular phylogenetics software packages like PHYLIP [9], PAUP* [32], MrBayes [22], and RAxML [28]. A naive construction of the greedy consensus tree requires $\mathcal{O}(kn^3)$ time [5]. To speed this up, these software packages often use hashing to improve the running time. Thus, if one is interested in analyzing worst-case complexity of the algorithms used in these packages, it would be necessary to allow randomization, as otherwise there is no guarantee on the efficiency of hashing. Even with randomization, the worst-case time complexities of these solutions are not known. Recently, Jansson et al. [13] gave the best known provable construction with an $\mathcal{O}(kn^2)$ deterministic running time (their implementation is also part of the FACT package). In Section 3 we present our main contribution, a deterministic $\widetilde{\mathcal{O}}(kn^{1.5})$ construction as stated by the following theorem:

▶ **Theorem 2.** *The greedy consensus tree of k phylogenetic trees $T_1, T_2, \ldots, T_k$ on the same set of leaves $[n]$ can be computed in $\mathcal{O}(kn^{1.5}\log n)$ time.*

To prove the above theorem, we develop a generic procedure that takes any ordered list of clusters $S_1, S_2, \ldots, S_\ell \subseteq [n]$ and tries adding them one-by-one to the current solution $\mathcal{C}$. We assume that every cluster S_i is specified by providing a tree T_i and a node $u_i \in T_i$ such that $S_i = \mathsf{L}(u_i)$. Our procedure requires $\mathcal{O}(n^{0.5}\log n)$ time per cluster (to add this cluster to $\mathcal{C}$ or assert that it cannot be added) and needs not to assume anything about the order of the clusters. In particular, it does not rely on the clusters being sorted by frequencies.

2 Computing the Identifiers

We process the nodes of every T_i in a bottom-up order. For every node $u \in T_i$, we compute the identifier $\mathsf{id}(u)$ by updating the following structure called the *dynamic set equality structure*:

▶ **Lemma 3** (the dynamic set equality structure)**.** *There exists a data structure that maintains a set of integers under the following operations: (1) create a new empty set in constant time, (2) add $x \in [n]$ to the set in $\mathcal{O}(\log^2 n)$ time, (3) return the identifier of the set in constant time, and (4) list all ℓ elements of the set in $\mathcal{O}(\ell)$ time. The structure ensures that the identifiers are bounded by the total number of update operations performed so far, and that two sets are equal iff their identifiers are equal.*

Proof. To allow for listing all elements of the current set S, we store them in a list. Before adding the new element x to the list, we need to check if $x \in S$. This will be done using the representation described below.

Conceptually, we work with a complete binary tree B on n leaves labelled with $0, 1, \ldots, n-1$ when read from left to right (without losing generality, n is a power of 2), where every node u corresponds to a set $D(u) \subseteq [n]$ defined by the leaves in its subtree (note that $D(u) = \{i, i+1, \ldots, j\}$, where $0 \leq i \leq j < n$). Now, any set S is associated with a binary tree B, where we write 1 in a leaf if the corresponding element belongs to S and 0 otherwise. Then, for every node we define its characteristic vector by writing down the values written in the leaves of its subtree in the natural order (from left to right). Clearly, the vector of an inner node is obtained by concatenating the vector of its children. We want to maintain identifiers of all nodes, so that the identifiers of two nodes are equal iff their characteristic vectors are identical. If we can keep the identifiers small, then the identifier of the current set can be computed as the identifiers of the root of B.

Assume that we have already computed the identifiers of all nodes in B and now want to add x to S. This changes the value in the leaf u corresponding to x and, consequently, the characteristic vectors of all ancestors of u. However, it does not change the characteristic vectors of any other node. Therefore, we traverse the ancestors of u starting from u and recompute their identifiers. Let v be the current node. If we have never seen the characteristic vector of v before, we can set the identifier of v to be the largest already used identifier plus one. Otherwise, we have to set the identifier of v to be the same as the one previously used for a node with such a characteristic vector. As mentioned above, the characteristic vector of an inner node v is the concatenation of the characteristic vectors of its children v_ℓ and v_r. We maintain a dictionary mapping a pair consisting of the identifier of v_ℓ and the identifier of v_r to the identifier of v. The dictionary is global, that is, shared by all instances of the structure. Then, assuming that we have already computed the up-to-date identifiers of v_ℓ and v_r, we only need to query the dictionary to check if the identifier of v should be set to the largest already used identifier plus one (which is exactly when the dictionary does not contain the corresponding pair) or retrieve the appropriate identifier. Therefore, adding x to B reduces to $\log n$ queries to the dictionary. By implementing the dictionary with balanced search trees, we therefore obtain the claimed $\mathcal{O}(\log^2 n)$ time for adding an element.

We are not completely done yet, because creating a new complete binary tree B takes $\mathcal{O}(n)$ time and therefore the initialization time is not constant yet. However, we can observe that it does not make sense to explicitly maintain a node u of B such that $S \cap D(u) = \emptyset$, because we can assume that the identifier of such an u is 0. In other words, we can maintain only the part of B induced by the leaves corresponding to S. Adding an element $x \in S$ is implemented as above, except that we might need to create (at most $\mathcal{O}(\log n)$) new nodes

on the leaf-to-root path corresponding to x (if such a leaf already exists, we terminate the procedure as $x \in S$ already) and then recompute the identifiers on the whole path as described above. ◀

Armed with Lemma 3, we process every T_i bottom-up. Consider an inner node $v \in T_i$ and let $v_1, v_2, \ldots, v_d$ be its children ordered so that $|\mathsf{L}(v_1)| = \max_j |\mathsf{L}(v_j)|$, that is, the subtree rooted at v_1 is the largest. Assuming that we have already stored every $\mathsf{L}(v_j)$ in a dynamic set equality structure, we construct a dynamic set equality structure storing $\mathsf{L}(v)$ by simply inserting all elements of $\mathsf{L}(v_2) \cup \mathsf{L}(v_3) \cup \cdots \cup \mathsf{L}(v_d)$ into the structure of $\mathsf{L}(v_1)$. This takes $\mathcal{O}(\log^2 n)$ time per element. Then, we set $\mathsf{id}(u)$ to be the identifier of the obtained structure. By a standard argument (heavy path decomposition), every leaf of T_i is inserted into at most $\log n$ structures and therefore the whole T_i is processed in $\mathcal{O}(n \log^3 n)$ time. This gives us the claimed $\mathcal{O}(kn \log^3 n)$ total time.

We now proceed with a faster $\mathcal{O}(kn \log^2 n)$ total time solution. While this is irrelevant for our $\mathcal{O}(kn^{1.5} \log n)$ time construction of the greedy consensus tree, it implies a better complexity for constructing the frequency difference consensus tree.

We start with a high-level intuition. Lemma 3 is, in a sense, more than we need, as it is not completely clear that we need to immediately compute the identifier of the current set. Indeed, applying heavy path decomposition we can partially delay computing the identifiers by proceeding in $\mathcal{O}(\log n)$ phases. In each phase, we can then replace the dynamic dictionary used to store the mapping with a radix sort. Intuitively, this shaves one log from the time complexity. We proceed with a detailed explanation.

▶ **Theorem 4.** *The numbers $\mathsf{id}(u)$ can be found for all nodes of the k phylogenetic trees $T_1, T_2, \ldots, T_k$ in $\mathcal{O}(kn \log^2 n)$ total time.*

Proof. For a node $v \in T_i$, define its level $\mathsf{level}(v)$ to be ℓ, such that $2^\ell \leq |\mathsf{L}(v)| < 2^{\ell+1}$. Thus, the levels are between 0 and $\log n$, level of a node is at least as large as the levels of its children, and a node on level ℓ has at most one child on the same level. We work in phases $\ell = 0, 1, \ldots, \log n$. In phase ℓ, we assume that the numbers $\mathsf{id}(v)$ are already known for all nodes v, such that $\mathsf{level}(v) < \ell$, and want to assign these numbers to all nodes v, such that $\mathsf{level}(v) = \ell$. We will show how to achieve this in $\mathcal{O}(kn \log n)$ time, thus proving the theorem.

Consider all nodes v, such that $\mathsf{level}(v) = \ell$. Because every such v has at most one child at the same level, all level-ℓ nodes in T_i can be partitioned into maximal paths of the form $p = v_1 - v_2 - \ldots - v_s$, where the level of the parent of v_1 is larger than ℓ (or v_1 is the root of T_i), and the levels of all children of v_j (except for v_{j+1}, if defined) are smaller than ℓ. v_1 is called the head of p and denoted $\mathsf{head}(p)$. Now, our goal is to find $\mathsf{id}(v_j)$ with the required properties for every $j = 1, 2, \ldots, s$. We will actually achieve a bit more. The sets $\mathsf{L}(\mathsf{head}(p))$ are disjoint in every tree T_i, and thus we can define, for every i, a partition $\mathcal{P}_i = \{P_i(1), P_i(2), \ldots, P_i(t_i)\}$ of the set of leaves $[n]$, where every $P_i(z)$ corresponds to a level-ℓ path $p = v_1 - v_2 - \ldots - v_s$ in T_i, such that $\mathsf{L}(\mathsf{head}(p)) = P_i(z)$. The elements of $P_i(z)$ are then ordered, and we think that $P_i(z)$ is a sequence of length $|P_i(z)|$. The ordering is chosen so that, for every $j = 1, 2, \ldots, s$, the set $\mathsf{L}(v_j)$ corresponds to some prefix of $P_i(z)$. $P_i(z)[1..r]$ denotes the prefix of $P_i(z)$ of length r. We will assign identifiers to all such prefixes $P_i(z)[1..r]$, for every $i = 1, 2, \ldots, k$, $z = 1, 2, \ldots, t_i$ and $r = 1, 2, \ldots, |P_i(z)|$, with the property that the identifiers of two prefixes are equal iff the sets of leaves appearing in both of them are equal. Then, we can extract the required $\mathsf{id}(v_j)$ in constant time each by taking the identifiers of some $P_i(z)[1..r]$.

Recall that in the slower solution we worked with a complete binary tree B on n leaves. For every set S in the collection and every $u \in B$, we computed an identifier of the set $S \cap D(u)$. This was possible, because if u_ℓ and u_r are the left and the right child of u,

respectively, then the identifier of $S \cap D(u)$ can be found using the identifiers of $S \cap D(u_\ell)$ and $S \cap D(u_r)$. We need to show that retrieving these identifiers can be batched.

Fix a node $u \in B$ and, for every $i = 1, 2, \ldots, k$ and $z = 1, 2, \ldots, t_i$, consider all prefixes $P_i(z)[1..r]$ for $r = 1, 2, \ldots, |P_i(z)|$. We create a *version* of u for every such prefix. The version corresponds to the set containing all elements of $D(u)$ occurring in the prefix $P_i(z)[1..r]$. We want to assign identifiers to all versions of u. First, observe that we only have to create a new version if $P_i(z)[r] \in D(u)$, as otherwise the set is the same as for $r-1$. Thus, the total number of required versions, when summed over all nodes $u \in B$ on the same depth in B, is only kn, as a leaf of T_i creates exactly one new version for some u. For every node $u \in B$, we will store a list of all its versions. A version consists of its identifier (such that the identifier of two versions is the same iff the corresponding sets are equal) together with the indices i, z and r. We describe how to create such a list for every node $u \in B$ at the same depth d given the lists for all nodes at depth $d+1$ next.

Let u_1 and u_2 be the left and the right child of $u \in B$, respectively. Then, we need to create a new version of u for every new version of u_1 and every new version of u_2, because for the set corresponding to u to change either the set corresponding to u_1 or the set corresponding to u_2 must change, and every change is adding one new element. Fix i and z and consider all versions of u_1 corresponding to i and z sorted according to r. Let the sorted list of their r's be $a_1 < a_2 < \ldots$. Similarly, consider all versions of u_2 corresponding to i and z sorted according to r, and let the sorted list of their r's be $b_1 < b_2 < \ldots$. For every $x \in \{a_1, a_2, \ldots\} \cup \{b_1, b_2, \ldots\}$, we create a new version of u corresponding to i, z, and r equal to x. This is done by retrieving the version of u_1 with r equal to a_p, such that $a_p \leq x$ and p is maximized, and the version of u_2 with r equal to b_q, such that $b_q \leq x$ and q is maximized. Then, the identifier of the new version of u can be constructed from the pair consisting of the identifiers of these versions of u_1 and u_2 (this is essentially the same reasoning as in the slower solution). We could now use a dictionary to map these pairs to identifiers. However, we can also observe that, in fact, we have reduced finding the identifiers of all versions of all nodes $u \in B$ at the same depth d to identifying duplicates on a list of kn pairs of numbers from $[kn]$. This can be done by radix sorting all pairs in linear time (more precisely, $\mathcal{O}(kn)$ time and $\mathcal{O}(kn)$ space), and then sweeping through the sorted list while assigning the identifiers. This takes only $\mathcal{O}(kn)$ time for every depth d, so $\mathcal{O}(kn \log n)$ for every level as claimed. ◀

The proof of Theorem 1 follows immediately from Theorem 4.

3 Simulating the Greedy Algorithm

We consider k trees $T_1, \ldots, T_k$ on the same set of leaves $[n]$, and assume that every node u has an identifier $\mathsf{id}(u)$ such that $\mathsf{id}(u) = \mathsf{id}(u')$ iff $\mathsf{L}(u) = \mathsf{L}(u')$. We next develop a general method for maintaining a solution $\mathcal{C}$ (i.e., a set of compatible identifiers) so that, given any node $u \in T_i$, we are able to efficiently check if $\mathsf{L}(u)$ is compatible with $\mathcal{C}$, meaning that $\mathcal{C} \cup \mathsf{L}(u)$ is consistent, and if so add $\mathsf{L}(u)$ to $\mathcal{C}$. Our method does not rely on the order in which the sets arrive and in particular can be used to run the greedy algorithm.

We represent $\mathcal{C}$ with a phylogenetic tree T_c such that $\mathcal{C} = \{\mathsf{L}(u) : u \in T_c\}$. T_c is called the *current consensus tree*. By Lemma 2.2 of [13], S is compatible with $\mathcal{C}$ iff the node $v \in T_c$ defined as the lowest common ancestor of all leaves with labels from S has the property that, for every child v' of v, either $\mathsf{L}(v') \cap S = \emptyset$ or $\mathsf{L}(v') \subseteq S$. Recall that the lowest common ancestor (lca) of u and v is the deepest node w that is an ancestor of both u and v. Also, adding $\mathsf{L}(u)$ to $\mathcal{C}$ can be done by creating a new child w of v and reconnecting every original child v' of v such that $\mathsf{L}(v') \subseteq S$ to the new w. This is illustrated in Figure 1 (left).

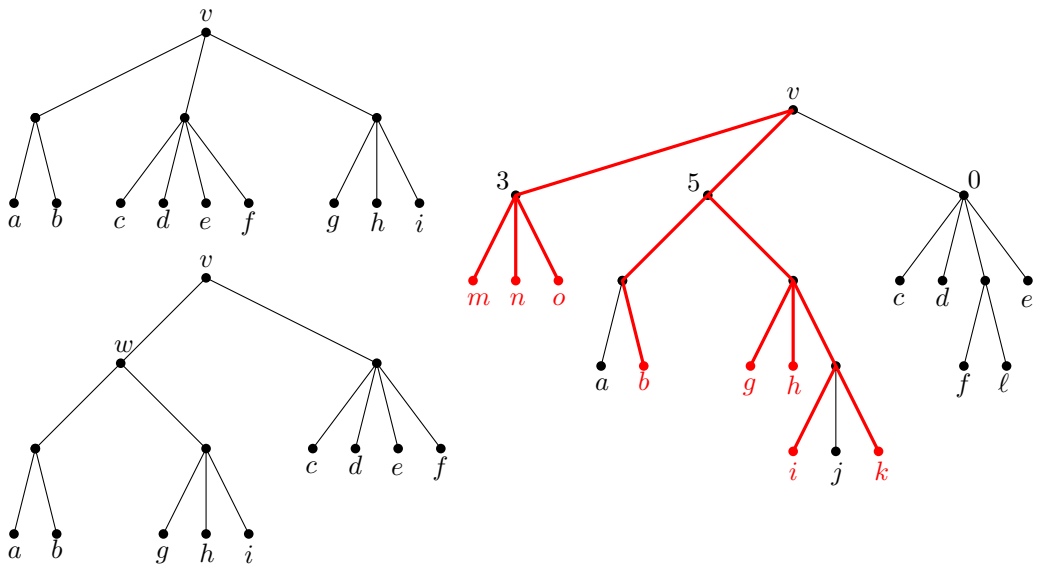

Figure 1 Left: adding $\{a, b, g, h, i\}$ to S. Right: checking if $S = \{m, n, o, b, g, h, i, k\}$ is compatible with T_c. Leaves corresponding to the elements of S are shown in red and their lca is v. S is not compatible with T_c because the counter of the middle child of v is equal to 5 yet there are 7 leaves in its subtree.

Initially, T_c consists only of n leaves attached to the common root (which corresponds to $\mathcal{C} = \{\{x\} : x \in [n]\}$). Our goal is to maintain some additional information so that given any node $u \in T_i$, we can check if $\mathsf{L}(u)$ is compatible with $\mathcal{C}$ in $\mathcal{O}(n^{0.5} \log n)$ time. After adding $\mathsf{L}(u)$ to $\mathcal{C}$ the information will be updated in amortized $\mathcal{O}(kn^{0.5} \log n)$ time. To explain the intuition, we first show how to check if $\mathsf{L}(u)$ is compatible with $\mathcal{C}$ in roughly $\mathcal{O}(|\mathsf{L}(u)|)$ time.

Let $\mathsf{L}(u) = \{\ell_1, \ell_2, \ldots, \ell_s\}$ and let u_i be the leaf of T_c labelled with ℓ_i. Let v be the lowest common ancestor of $u_1, u_2, \ldots, u_s$ found by asking $s - 1$ lca queries: we start with u_1 and then iteratively jump to the lca of the current node and u_i. Assuming that we represent T_c in such a way that an lca query can be answered efficiently, this takes roughly $\mathcal{O}(s)$ time. Then, we need to decide if for every child v' of v it holds that $\mathsf{L}(v') \subseteq \mathsf{L}(u)$ or $\mathsf{L}(v') \cap \mathsf{L}(u) = \emptyset$. This can be done by computing, for every such v', how many u_i's belong to the subtree rooted at v', and then checking if this number is either 0 or $|\mathsf{L}(v')|$. To compute these numbers, we maintain a counter for every v'. Then, for every u_i we retrieve the child v' of v such that u_i belongs to the subtree rooted at v' and increase the counter of v'. Assuming that we represent T_c so that such v' can be retrieved efficiently, this again takes roughly $\mathcal{O}(s)$ time. Finally, we iterate over all u_i again, retrieve the corresponding v' and check if its counter is equal to $|\mathsf{L}(v')|$ (so our representation of T_c should also allow retrieving the number of leaves in a subtree). If not, then $\mathsf{L}(u)$ is not compatible with $\mathcal{C}$, see Figure 1 (right). Otherwise, we create the new node w and reconnect to w all children v' of v, such that the counter of v' is equal to $|\mathsf{L}(v')|$.

We would like to avoid explicitly iterating over all elements of $\mathsf{L}(u)$. This will be done by maintaining some additional information, so that we only have to iterate over up to $n^{0.5}$ elements. To explain what is the additional information we need the (standard) notion of a *micro-macro decomposition*. Let b be a parameter and consider a binary tree on n nodes. We want to partition it into $\mathcal{O}(n/b)$ node-disjoint subtrees called *micro trees*. Each micro tree is of size at most b and contains at most two *boundary nodes* that are adjacent to nodes

in other micro trees. One of these boundary nodes, called the top boundary node, is the root of the whole micro tree, and the other is called the bottom boundary node. Such a partition is always possible and can be found in $\mathcal{O}(n)$ time.

We binarize every T_i to obtain T_i' (this could be avoided by working with edge-disjoint subtrees in the decomposition, but we find node-disjoint subtrees easier to think about; binarization adds a number of artificial nodes u for which we do not check if $\mathsf{L}(u)$ is compatible with $\mathcal{C}$)). Then, we find a micro-macro decomposition of T_i' with $b = n^{0.5}$ (where b has been chosen as to minimize the total running time). By properties of the decomposition we have the following:

▶ **Proposition 5.** *For any $u \in T_i$ such that $|\mathsf{L}(u)| > n^{0.5}$, there exists a boundary node $v \in T_i'$ such that $\mathsf{L}(u)$ can be obtained by adding at most $n^{0.5}$ elements to $\mathsf{L}(v)$. Furthermore, v and these up to $n^{0.5}$ elements can be retrieved in $\mathcal{O}(n^{0.5})$ time after $\mathcal{O}(n)$ preprocessing.*

The total number of boundary nodes is only $\mathcal{O}(kn^{0.5})$. For each such boundary node u, we maintain a pointer to a node $\mathsf{finger}(u) \in T_c$ called the *finger* of u, defined as the lowest common ancestor in T_c of all leaves with labels belonging to $\mathsf{L}(u)$. Additionally, the children of $\mathsf{finger}(u)$ are partitioned into three groups: (1) v_i such that $\mathsf{L}(v_i) \subseteq \mathsf{L}(u)$, (2) v_i such that $\mathsf{L}(v_i) \cap \mathsf{L}(u) = \emptyset$, and (3) the rest. We call them full, empty, and mixed, respectively (with respect to u). For each group we maintain a list storing all nodes in the group, every node knows its group, and the group knows it size. Additionally, every group knows the total number of leaves in all subtrees rooted at its nodes.

We also need to augment the representation T_c to allow for efficient *extended lca queries*. An extended lca query, denoted $\mathsf{lca\_ext}(u, v)$, returns the first edge on the path from the lca of u and v to u, and -1 if u is an ancestor of v. For example, in Figure 1 (right), $\mathsf{lca\_ext}(v, k) = -1$ whereas $\mathsf{lca\_ext}(h, k)$ is the edge between v and its leftmost child. The following lemma follows by slightly tweaking the link/cut trees of Sleator and Tarjan [25].

▶ **Lemma 6.** *We can maintain a collection of rooted trees under: (1) create a new tree consisting of a single node, (2) make the root of one tree a child of a node in another tree, (3) delete an edge from a node to its parent, (4) count leaves in the tree containing a given node, and (5) extended lca queries, all in $\mathcal{O}(\log n)$ amortized time, where n is the total size of all trees in the collection.*

We next show how to efficiently check for any u if $\mathsf{L}(u)$ is compatible with $\mathcal{C}$. By the following lemma, this can be done in $\mathcal{O}(n^{0.5} \log n)$ time, assuming we have stored the required additional information. Recall that this additional information includes:

1. The tree T_c maintained using Lemma 6.
2. For every boundary node w, we store $\mathsf{finger}(w)$.
3. For every boundary node w, we store three lists containing the full, the mixed, and the empty children of $\mathsf{finger}(w)$ respectively. Each list also stores the total number of leaves in all subtrees rooted at its nodes.

▶ **Lemma 7.** *Assuming access to the above additional information, given any node $u \in T_i$ we can check if $\mathsf{L}(u)$ is compatible with $\mathcal{C}$ in $\mathcal{O}(n^{0.5} \log n)$ time.*

Proof. By Lemma 2.2 of [13], to check if $\mathsf{L}(u)$ is compatible with $\mathcal{C}$ we need to check if, for a node v defined as the lowest common ancestor of all leaves with labels belonging to $\mathsf{L}(u)$, it holds that for every child v' of v either $\mathsf{L}(v') \cap \mathsf{L}(u) = \emptyset$ or $\mathsf{L}(v') \subseteq \mathsf{L}(u)$. By properties of the micro-macro decomposition, we can retrieve a boundary node w and a set S of up to $n^{0.5}$ labels such that $\mathsf{L}(u) = \mathsf{L}(w) \cup S$ (if $|\mathsf{L}(u)| < n^{0.5}$, there is no w). See Figure 2. Then, the

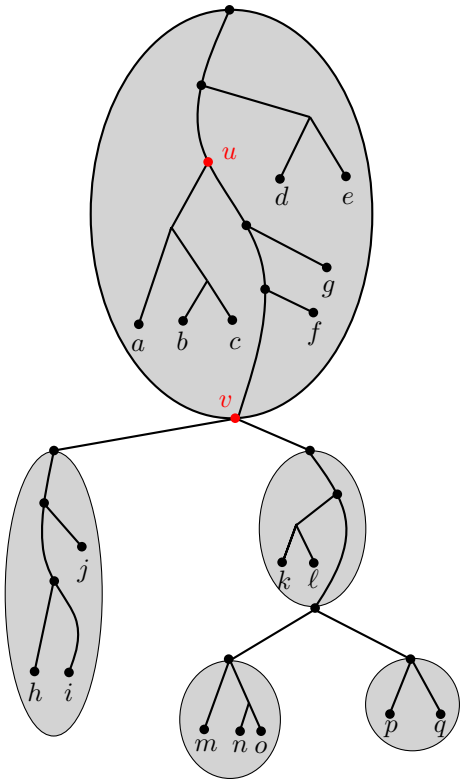

Figure 2 A schematic illustration of the micro-macro decomposition. v is a boundary node and $\mathsf{L}(v) = \{h, i, j, k, \ell, m, n, o, p, q\}$. Then, $\mathsf{L}(u) = \{a, b, c, f, g, h, i, j, k, \ell, m, n, o, p, q\}$ so $\mathsf{L}(u) = \mathsf{L}(v) \cup \{a, b, c, f, g\}$.

lowest common ancestor of all leaves with labels belonging to $\mathsf{L}(u)$ is the lowest common ancestor of $\mathsf{finger}(w)$ and all leaves with labels belonging to S. Therefore, v can be found with $|S|$ lca queries in $\mathcal{O}(n^{0.5} \log n)$ time. Second, to check if $\mathsf{L}(v_i) \cap \mathsf{L}(u) = \emptyset$ or $\mathsf{L}(v_i) \subseteq \mathsf{L}(u)$ for every child v_i of v we distinguish two cases:

(1) If v is a proper ancestor of $\mathsf{finger}(w)$ we can calculate $|\mathsf{L}(v_i) \cap \mathsf{L}(u)|$ for every v_i in $\mathcal{O}(|S| \log n) = \mathcal{O}(n^{0.5} \log n)$ time as follows. Every edge has its associated counter. We assume that all counters are set to zero before starting the procedure and will make sure that they are cleared at the end. First, we use an $\mathsf{lca\_ext}(w, v)$ query to access the edge leading to the subtree containing w and set its counter to $|\mathsf{L}(w)|$. Then, we iterate over all $\ell \in S$, retrieve the leaf u of T_c labelled with ℓ, and use an $\mathsf{lca\_ext}(u, v)$ query to access the edge leading to the subtree of v containing u and increase its counter by one. Additionally, whenever we access an edge for the first time (in this particular query), we add it to a temporary list Q. After having processed all $\ell \in S$, we iterate over $(v, v_i) \in Q$ and check if the counter of (v, v_i) is equal to the number of leaves in the subtree rooted at v_i (which requires retrieving the number of leaves). If this condition holds for every $(v, v_i) \in Q$ then $\mathsf{L}(u)$ is compatible with $\mathcal{C}$ and furthermore, the nodes v_i such that $(v, v_i) \in Q$ are exactly the ones that should be reconnected. Finally, we iterate over the edges in Q again and reset their counters.

(2) If $v = \mathsf{finger}(w)$ the situation is a bit more complicated because we might not have enough time to explicitly iterate over all children of v that should be reconnected. Nevertheless, we can use a very similar method. Every edge has its associated counter (again,

we assume that the counter are set to zero before starting the procedure and will make sure that they are cleared at the end). We also need a global counter g, that is set to the total number of leaves in all subtrees rooted at either full or mixed children of v decreased by $|\mathsf{L}(w)|$. g can be initialized in constant time in the first step of the procedure due to the additional information stored with every list of children. Intuitively, g is how many leaves not belonging to $\mathsf{L}(w)$ we still have to see to conclude that indeed $\mathsf{L}(v_i) \cap \mathsf{L}(u) = \emptyset$ or $\mathsf{L}(v_i) \subseteq \mathsf{L}(u)$ for every child v_i of v. We iterate over $\ell \in S$ and access the edge (v, v_i) leading to the subtree containing u labelled with ℓ. We decrease g by one and, if v_i is an empty child of v and this is the first time we have seen v_i (in this query) then we add the number of leaves in the subtree rooted at v_i to g. If, after having processed all $\ell \in S$, $g = 0$ then we conclude that $\mathsf{L}(u)$ is compatible with $\mathcal{C}$. The whole process takes $\mathcal{O}(|S| \log n) = \mathcal{O}(n^{0.5} \log n)$ time. ◀

Before explaining the details of how to update the additional information, we present the intuition. Recall that adding $\mathsf{L}(u)$ to $\mathcal{C}$ is done by creating a new child v' of v and reconnecting some children of v to v'. Let the set of all children of v be C and the set of children that should be reconnected be C_r. Note that if $|C_r| = 1$ or $|C| = |C_r|$ then we do not have to change anything in T_c. Otherwise, updating T_c can be implemented using two different methods:

1. Delete edges from nodes in C_r to v. Create a new tree consisting of a single node v' and make it a child of v. Then, make all nodes in C_r children of v'.
2. Delete edges from nodes in $C \setminus C_r$ to v. Delete the edge from v to its parent w. Create a new tree consisting of a single node v' and make it a child of w. Then, make v a child of v' and also make all nodes in $C \setminus C_r$ children of w. See Figure 3.

Thus, by using C_r or $C \setminus C_r$, the number of operations can be either $\mathcal{O}(|C_r|)$ or $\mathcal{O}(|C| - |C_r|)$. We claim that by choosing the cheaper option we can guarantee that the total time for modifying the link-cut tree representation of T_c is $\mathcal{O}(n \log^2 n)$. Intuitively, every edge of the final consensus tree participates in $\mathcal{O}(\log n)$ operations, and there are at most n such edges. This is formalized in the following lemma.

▶ **Lemma 8.** $\min\{|C_r|, |C| - |C_r|\}$ *summed over all updates of* T_c *is* $n \log n$.

Proof. We assume that $2 \leq |C_r| < |C|$ in every update, as otherwise there is nothing to change in T_c. Then, there are at most n updates, as each of them creates a new inner node and there are never any nodes with degree 1 in T_c.

We bound the sum of $\min\{|C_r|, |C| - |C_r|\}$ by assigning credits to inner nodes of T_c. During the execution of the algorithm, a node u with b siblings should have $\log b$ credits. Thus, whenever we create a new inner node we need at most $\log n$ new credits, thus the total number of allocated credits is $n \log n$. It remains to argue that, whenever we create a new child v' of v and reconnect some of its children, the original credits of v can be used to pay for the update and make sure that all children of v and v' have enough credits after the update.

Denoting $x = |C_r|$ and $y = |C| - |C_r|$, the cost of the update is $\min\{x, y\}$. The total number of credits of all children of v before the update is $(x + y) \log(x + y - 1)$. After the update, the number of credits of all children of v is $(y + 1) \log y \leq y \log y + \log n$ and the number of credits of all children of v' is $x \log(x - 1)$. Ignoring the $\log n$ new credits allocated to v', the number of available credits is thus:

$$(x + y) \log(x + y - 1) - y \log y - x \log(x - 1) = x \log(1 + y/(x - 1)) + y \log(1 + (x - 1)/y)$$

which is at least $\min\{x, y\}$ for $x \geq 2$, so enough to pay $\min\{|C_r|, |C| - |C_r|\}$ for the update. Hence, the sum is at most $n \log n$. ◀

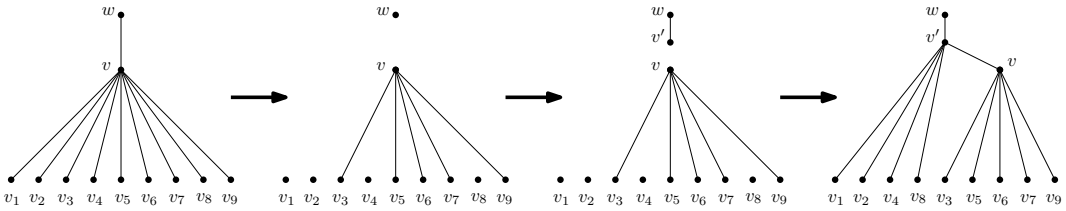

Figure 3 Reconnecting children v_3, v_5, v_6, v_7, v_9 of v using the second method.

Before presenting the whole update procedure, we need one more technical lemma.

▶ **Lemma 9.** *The procedure for checking if* $\mathsf{L}(u)$ *is compatible with* $\mathcal{C}$ *can be requested to return* C_r *in* $\mathcal{O}(|C_r| + n^{0.5})$ *time or* $C \setminus C_r$ *in* $\mathcal{O}(|C| - |C_r| + n^{0.5})$ *time.*

Proof. By inspecting the proof of Lemma 7, we see that there are two cases depending on whether v is a proper ancestor of $\mathsf{finger}(w)$ or not.

1. If v is a proper ancestor of $\mathsf{finger}(w)$ then C_r can be obtained from Q. More precisely, for every $(v, v_i) \in Q$ we add v_i to C_r in $\mathcal{O}(|C_r|)$ total time. We can also obtain $C \setminus C_r$ in $\mathcal{O}(|C|) = \mathcal{O}(|C \setminus C_r| + |S|) = \mathcal{O}(|C| - |C_r| + n^{0.5})$ time.
2. If $v = \mathsf{finger}(w)$ then, while iterating over $\ell \in S$, if this is the first time we have seen v_i then we add v_i to C_r. Additionally, we add all full children of v to C_r. Thus, C_r can be generated in $\mathcal{O}(|C_r|)$ time. Similarly, $C \setminus C_r$ consists of all empty children of v without the nodes v_i seen when iterating over $\ell \in S$, and so can be generated in $\mathcal{O}(|C \setminus C_r| + |S|) = \mathcal{O}(|C| - |C_r| + n^{0.5})$ time.

Thus, we can always generate C_r in $\mathcal{O}(|C_r| + n^{0.5})$ time and $C \setminus C_r$ in $\mathcal{O}(|C| - |C_r| + n^{0.5})$ time. ◀

To add $\mathsf{L}(u)$ to $\mathcal{C}$, we will need to iterate over either C_r or $C \setminus C_r$ (depending on which is smaller). After paying additional $\mathcal{O}(n^{0.5})$ time we can assume that we have access to a list of the elements in the appropriate set. The additional time sums up to $\mathcal{O}(n^{1.5})$, because there can be only n distinct new sets added to $\mathcal{C}$.

▶ **Lemma 10.** *If* $\mathsf{L}(u)$ *is compatible with* $\mathcal{C}$ *then, after adding* $\mathsf{L}(u)$ *to* $\mathcal{C}$ *and modifying* T_c *we can update all additional information in amortized* $\mathcal{O}(kn^{0.5} \log n)$ *time assuming that we add* n *such sets.*

Proof. Recall that T_c is maintained using the data structure from Lemma 6, and adding $\mathsf{L}(u)$ to $\mathcal{C}$ is implemented by creating a new child v' of v and reconnecting some of the children of v to v'. C is the set of all children of v and C_r is the set of children of v that are reconnected to v'. If $|C_r| \leq |C| - |C_r|$ we iterate over C_r and reconnect them one-by-one. If $|C_r| > |C| - |C_r|$ we iterate over $C \setminus C_r$ and reconnect them to a new node w that is inserted between v and its parent. To iterate over either C_r or $C \setminus C_r$, we extend the query procedure as explained in Lemma 9. This adds $\mathcal{O}(n^{0.5})$ to the time complexity, but then we can assume that the requested set can be generated in time proportional to its size. To unify the case of $|C_r| \leq |C| - |C_r|$ and $|C_r| > |C| - |C_r|$, we think that v is replaced with two nodes v' and v'', where v' is the parent of v''. All nodes in C_r become children of v'' while all nodes of $C \setminus C_r$ become children of v' after iterating over either C_r or $C \setminus C_r$, depending on which set is smaller, so by Lemma 8 in the whole process we iterate over sets of total size $n \log n$, so only amortized $\log n$ assuming that we add n sets $\mathsf{L}(u)$.

Consider a boundary node u. If $\mathsf{finger}(u) \neq v$ then there is no need to update the additional information concerning u. If $\mathsf{finger}(u) = v$ then we need to decide if the finger of u should be set to v' or v'' and update the partition of the children of $\mathsf{finger}(u)$ accordingly.

$\mathsf{finger}(u)$ should be set to v' exactly when, for any $w \in C \setminus C_r$, $\mathsf{L}(w) \cap \mathsf{L}(u) = \emptyset$ or, in other words, all nodes in $C \setminus C_r$ are empty with respect to u. The groups should be updated as follows:

1. If $\mathsf{finger}(u)$ is set to v'' then we should remove all nodes in $C \setminus C_r$ from the list of empty nodes with respect to u (as they are no longer children of $\mathsf{finger}(u)$). Other groups remain unchanged.
2. If $\mathsf{finger}(u)$ is set to v' then we should remove all nodes in C_r from the lists. Additionally, we need to insert v'' into the appropriate group: full if all nodes in C_r were full, empty if all nodes in C_r were empty, and mixed otherwise.

We need to show that all these conditions can be checked by either iterating over the nodes of C or over the nodes of $C \setminus C_r$, because we want to iterate over the smaller of these. This then guarantees that the amortized cost of updating the additional information for a boundary node is only $\mathcal{O}(\log n)$, so amortized $\mathcal{O}(kn^{0.5} \log n)$ overall.

To check if all nodes in $C \setminus C_r$ are empty with respect to u, we can either iterate over the nodes in $C \setminus C_r$ or iterate over all nodes in C_r and check if all nodes in C that are full or empty in fact belong to C_r (this is possible because we also keep the total number of full and empty nodes in C). Thus, we can check if $\mathsf{finger}(u)$ should be set to v'.

If $\mathsf{finger}(u)$ is set to v' we need to decide where to put v''. We only explain how to decide if all nodes in C_r are full, as the procedure for empty is symmetric. We can either iterate over all nodes in C_r and check that they are full or iterate over all nodes in $C \setminus C_r$ and check that all nodes in C that are empty or mixed in fact belong to $C \setminus C_r$ (and thus do not belong to C_r, so all nodes in C_r are full). Finally, we add the number of leaves in the subtree rooted at v'' (extracted in $\mathcal{O}(\log n)$ time) to the appropriate sum.

It remains to describe how to remove all unnecessary nodes from the lists. Here we do not worry about having to iterate over the smaller set, because there are only $\mathcal{O}(n)$ new edges created during the whole execution of the algorithm, so we can afford to explicitly iterate over the nodes that should be removed, that is, over C or $C \setminus C_r$. For every removed node, we also subtract the number of leaves in its subtree (extracted in $\mathcal{O}(\log n)$ time) from the appropriate sum. Overall, this adds $\mathcal{O}(n \log n)$ per boundary node to the time complexity, so only amortized $\mathcal{O}(kn^{0.5} \log n)$ overall. ◀

Abstract

Given a set $W = \{w_1, \ldots, w_n\}$ of non-negative integer weights and an integer C, the #Knapsack problem asks to count the number of distinct subsets of W whose total weight is at most C. In the more general integer version of the problem, the subsets are multisets. That is, we are also given a set $\{u_1, \ldots, u_n\}$ and we are allowed to take up to u_i items of weight w_i.

We present a deterministic FPTAS for #Knapsack running in $O(n^{2.5}\varepsilon^{-1.5}\log(n\varepsilon^{-1})\log(n\varepsilon))$ time. The previous best deterministic algorithm [FOCS 2011] runs in $O(n^3\varepsilon^{-1}\log(n\varepsilon^{-1}))$ time (see also [ESA 2014] for a logarithmic factor improvement). The previous best randomized algorithm [STOC 2003] runs in $O(n^{2.5}\sqrt{\log(n\varepsilon^{-1})} + \varepsilon^{-2}n^2)$ time. Therefore, for the case of constant ε, we close the gap between the $\tilde{O}(n^{2.5})$ randomized algorithm and the $\tilde{O}(n^3)$ deterministic algorithm.

For the integer version with $U = \max_i\{u_i\}$, we present a deterministic FPTAS running in $O(n^{2.5}\varepsilon^{-1.5}\log(n\varepsilon^{-1}\log U)\log(n\varepsilon)\log^2 U)$ time. The previous best deterministic algorithm [TCS 2016] runs in $O(n^3\varepsilon^{-1}\log(n\varepsilon^{-1}\log U)\log^2 U)$ time.

1 Introduction

Given a set $W = \{w_1, \ldots, w_n\}$ of non-negative integer weights and an integer C, the #Knapsack problem asks to count the number of distinct subsets of W whose total weight is at most C. This problem is the counting version of the well known Knapsack problem and is #P-hard. While there are many, celebrated, randomized polynomial-time algorithms for approximately counting #P-hard problems, the #Knapsack problem is one of the few examples where there is also a deterministic approximation algorithm (other notable examples are [8, 14, 1]).

From a geometric view, the #Knapsack problem is equivalent to finding the number of vertices of the n-dimensional hypercube that lie on one side of a given n-dimensional hyperplane. The problem is also related to pseudorandom generators for halfspaces (see

e.g. [2, 9, 11]) as these imply deterministic (though not polynomial-time) approximation schemes for #Knapsack by enumerating over all input seeds to the generator.

Approximately counting knapsack solutions. The #Knapsack problem can be solved with the following simple recursion: $S(i,j) = S(i-1,j) + S(i-1,j-w_i)$ where $S(i,j)$ is the number of subsets of $\{w_1, ..., w_i\}$ whose weight sums to at most j. This recurrence immediately implies a pseudo-polynomial $O(nC)$ time algorithm. More interestingly, this recurrence is the basis of all existing fully polynomial-time approximation schemes (FPTAS). That is, algorithms that for any $\varepsilon > 0$ estimate the number of solutions to within relative error $(1 \pm \varepsilon)$ in time polynomial in n and in $1/\varepsilon$.

Dyer et al. [4] were the first to show how to approximate this recurrence with random sampling. They gave a randomized sub-exponential $2^{O(\sqrt{n}\log^{2.5} n))}\epsilon^{-2}$ time algorithm. Using a more complicated random sampling (with a rapidly mixing Markov chain), Morris and Sinclair [10] obtained the first FPRAS (fully-polynomial *randomized* approximation scheme) running in $O(n^{4.5+\epsilon} + \epsilon^{-2}n^2)$ time. Dyer [3] further improved this to $O(n^{2.5}\sqrt{\log(n\varepsilon^{-1})} + \epsilon^{-2}n^2)$ by using a surprisingly simple sampling procedure (combined with randomized rounding). This to date is the fastest known randomized solution. As for deterministic solutions, the fastest solution to date is by Rizzi and Tomescu [12] and runs in $O(n^3\epsilon^{-1}\log\epsilon^{-1}/\log n)$ time. It is a logarithmic factor improvement (obtained by discretizing the recursion $S(i,j)$ with floating-point arithmetic) over the previous fastest $O(n^3\epsilon^{-1}\log(n\varepsilon^{-1}))$ time solutions of Gopalan et al. [6] (who used read-once branching programs inspired by related work on pseudorandom generators for halfspaces [9]) and of Štefankovič et al. [13] (who approximated a "dual" recursion $S^*(i,j)$ defined as the smallest capacity c such that there exist at least j subsets of $\{w_1, \ldots, w_i\}$ with weight c).

Approximately counting integer knapsack solutions. In the more general integer version of #Knapsack, the subsets are multisets. That is, in addition to $W = \{w_1, \ldots, w_n\}$ we are also given a set $\{u_1, \ldots, u_n\}$ and we are allowed to take up to u_i items of weight w_i.

The first (randomized) FPRAS for counting integer knapsack solution was given by Dyer [3] who presented a strongly polynomial $O(n^5 + n^4\varepsilon^{-2})$ time algorithm. A (deterministic) FPTAS for this problem was then given by Gopalan et al. [6] with a running time of $O(n^5\varepsilon^{-2}\log^2 U \log w)$ (see also [5]) where $U = \max_i\{u_i\}$ and $w = \sum_i w_i u_i + C$. The fastest solution to date is by Halman [7] with a running time of $O(n^3\varepsilon^{-1}\log(n\varepsilon^{-1}\log U)\log^2 U)$.

Our results. In this paper we present improved algorithms for both #Knapsack and its integer version. Our algorithms improve the previous best algorithms by polynomial factors. For constant ε, we close the gap between the $\tilde{O}(n^{2.5})$ randomized and the $\tilde{O}(n^3)$ deterministic running times. More formally, with the standard assumption of constant time arithmetics on the input numbers, we prove the following two theorems:

▶ **Theorem 1.** *There is a FPTAS running in $O(n^{2.5}\varepsilon^{-1.5}\log(n\varepsilon^{-1})\log(n\varepsilon))$ time and $O(n^{1.5}\varepsilon^{-1.5})$ space for counting knapsack solutions.*

▶ **Theorem 2.** *There is a FPTAS running in $O(n^{2.5}\varepsilon^{-1.5}\log(n\varepsilon^{-1}\log U)\log(n\varepsilon)\log^2 U)$ time and $O(n^{1.5}\varepsilon^{-1.5}\log U)$ space for counting integer knapsack solutions.*

Our algorithm is the first algorithm to deviate from the standard recursion. In particular, on large enough sets, instead of recursing on all but the last item, we recurse in the middle and use convolution to merge the two sub-solutions. This requires extending the recent technique of *K-approximation sets and functions* used by Halman [7] and introduced in [8].

Our extended technique (which we call *sum approximations*) is simple to state and leads to a surprisingly simple solution to #Knapsack with an improved running time. In a nutshell, for any function $f : \mathbb{Z}^+ \to \mathbb{Z}^+$ (think of $f(x) =$ the number of subsets with total weight exactly x) let $f^{\leq}$ denote the function $f^{\leq}(x) = \sum_{y \leq x} f(y)$ (hence $f^{\leq}(x) =$ the number of subsets with total weight at most x). Then, in order to approximate the function $f^{\leq}$ it is enough to find any function F such that $F^{\leq}$ approximates $f^{\leq}$.

We examine the properties of such sum approximations F in Section 2, and introduce a number of useful computational primitives on sum approximations. With these primitives in hand, we give a simplified version of Halman's algorithm for #Knapsack in Section 3. Then, in Section 4 we present an improved divide and conquer algorithm based on convolutions of sum approximations. Finally, in Section 5 we adapt our algorithm to the integer version, where every item has a corresponding multiplicity. Instead of the *binding constraints* approach used by Halman [7], we show that it is enough to perform a single scan of a sum approximation using nothing more than a standard binary search tree.

2 Approximation of a Function

Consider the following two functions: $f(x) =$ the number of subsets with total weight exactly x, and $f^{\leq}(x) =$ the number of subsets with total weight at most x. More generally:

▶ **Definition 3.** Given a function $f : \mathbb{Z}^+ \to \mathbb{Z}^+$ we define the function $f^{\leq}(x)$ as

$$f^{\leq}(x) = \sum_{y \leq x} f(y).$$

Our goal is to approximate $f^{\leq}(C)$ but we will actually approximate the entire function $f^{\leq}(x)$ for all x. We now describe what it means to approximate a function and present some properties of such approximations.

▶ **Definition 4** ($(1+\varepsilon)$-approximation of a function)**.** Given a function $f : \mathbb{Z}^+ \to \mathbb{Z}^+$ and a parameter $\varepsilon > 0$, a function $F : \mathbb{Z}^+ \to \mathbb{Z}^+$ is a $(1+\varepsilon)$-*approximation of* f if for every x,

$$f(x) \leq F(x) \leq (1+\varepsilon) f(x).$$

The above definition is similar to the definition of K-approximation sets [7] for $K = (1+\varepsilon)$.

▶ **Definition 5** ($(1+\varepsilon)$-sum approximation of a function)**.** Given a function $f : \mathbb{Z}^+ \to \mathbb{Z}^+$ and a parameter $\varepsilon > 0$, a function $F : \mathbb{Z}^+ \to \mathbb{Z}^+$ is a $(1+\varepsilon)$-*sum approximation of* f if $F^{\leq}$ is a $(1+\varepsilon)$-approximation of $f^{\leq}$.

We next examine some useful properties of sum approximations. For a function $f : \mathbb{Z}^+ \to \mathbb{Z}^+$ define its *shift* by w as follows:

$$f|_w(x) = \begin{cases} f(x-w), & x \geq w, \\ 0 & x < w, \end{cases}$$

and for two functions $f, g : \mathbb{Z}^+ \to \mathbb{Z}^+$ define their *convolution* to be:

$$(f * g)(w) = \sum_{x+y=w} f(x) g(y).$$

The following lemma describes four operations on sum approximations. The first three are similar to the ones used in [7, Property 2.1]. The fourth operation (convolution) is novel.

▶ **Lemma 6** (operations on sum approximations). *Let F be a $(1+\varepsilon)$-sum approximation of f and G be a $(1+\varepsilon)$-sum approximation of g, then the following properties hold:*

Approximation: *A $(1+\delta)$-sum approximation of F is a $(1+\delta)(1+\varepsilon)$-sum approximation of f.*

Summation: *$(F+G)$ is a $(1+\varepsilon)$-sum approximation of $(f+g)$.*

Shifting: *$F|_w$ is a $(1+\varepsilon)$-sum approximation of $f|_w$ for any $w>0$.*

Convolution: *$(F*G)$ is a $(1+\varepsilon)^2$-sum approximation of $(f*g)$.*

Proof.

Approximation: Let F' be a $(1+\delta)$-approximation of F. For every x, $f^{\leq}(x) \leq F^{\leq}(x) \leq (1+\varepsilon)f^{\leq}(x)$ and $F^{\leq}(x) \leq F'^{\leq}(x) \leq (1+\delta)F^{\leq}(x)$. We therefore have that $f^{\leq}(x) \leq F'^{\leq}(x) \leq (1+\delta)(1+\varepsilon)f^{\leq}(x)$.

Summation: For every x we have that $f^{\leq}(x) \leq F^{\leq}(x) \leq (1+\varepsilon)f^{\leq}(x)$ and $g^{\leq}(x) \leq G^{\leq}(x) \leq (1+\varepsilon)g^{\leq}(x)$, adding these two equations we get $(f+g)^{\leq}(x) \leq (F+G)^{\leq}(x) \leq (1+\varepsilon)(f+g)^{\leq}(x)$.

Shifting: For $x<w$, $f|_w(x) = 0 = F|_w(x)$. For $x \geq w$ let $y = x-w$. Since $y \geq 0$ we have that $f^{\leq}(y) \leq F^{\leq}(y) \leq (1+\varepsilon)f^{\leq}(y)$ and therefore $f|_w^{\leq}(x) \leq F|_w^{\leq}(x) \leq (1+\varepsilon)f|_w^{\leq}(x)$.

Convolution: We first prove that $(F*G)^{\leq}(w) \geq (f*g)^{\leq}(w)$:

$$\begin{aligned}
(F*G)^{\leq}(w) &= \sum_{x+y\leq w} F(x)G(y) = \sum_{x\leq w}\sum_{y\leq w-x} F(x)G(y) = \sum_{x\leq w}\left[F(x)\sum_{y\leq w-x} G(y)\right] \\
&= \sum_{x\leq w} F(x)G^{\leq}(w-x) \geq \sum_{x\leq w} F(x)g^{\leq}(w-x) = \sum_{x\leq w} F(x)\sum_{y\leq w-x} g(y) \\
&= \sum_{x+y\leq w} F(x)g(y) = \sum_{y\leq w}\sum_{x\leq w-y} F(x)g(y) = \sum_{y\leq w}\left[g(y)\sum_{x\leq w-y} F(x)\right] \\
&= \sum_{y\leq w} g(y)F^{\leq}(w-y) \geq \sum_{y\leq w} g(y)f^{\leq}(w-y) = \sum_{y\leq w} g(y)\sum_{x\leq w-y} f(x) \\
&= \sum_{x+y\leq w} f(x)g(y) = (f*g)^{\leq}(w).
\end{aligned}$$

Next we prove that $(F*G)^{\leq}(w) \leq (1+\varepsilon)^2(f*g)^{\leq}(w)$:

$$\begin{aligned}
(F*G)^{\leq}(w) &= \sum_{x+y\leq w} F(x)G(y) = \sum_{x\leq w}\sum_{y\leq w-x} F(x)G(y) = \sum_{x\leq w}\left[F(x)\sum_{y\leq w-x} G(y)\right] \\
&= \sum_{x\leq w} F(x)G^{\leq}(w-x) \leq \sum_{x\leq w} F(x)(1+\varepsilon)g^{\leq}(w-x) = \\
&= (1+\varepsilon)\sum_{x\leq w} F(x)\sum_{y\leq w-x} g(y) = (1+\varepsilon)\sum_{x+y\leq w} F(x)g(y) \\
&= (1+\varepsilon)\sum_{\leq w}\sum_{x\leq w-y} F(x)g(y) = (1+\varepsilon)\sum_{y\leq w}\left[g(y)\sum_{x\leq w-y} F(x)\right] \\
&= (1+\varepsilon)\sum_{y\leq w} g(y)F^{\leq}(w-y) \leq (1+\varepsilon)\sum_{y\leq w} g(y)(1+\varepsilon)f^{\leq}(w-y) = \\
&= (1+\varepsilon)^2\sum_{y\leq w} g(y)\sum_{x\leq w-y} f(x) = (1+\varepsilon)^2\sum_{x+y\leq w} f(x)g(y) \\
&= (1+\varepsilon)^2(f*g)^{\leq}(w).
\end{aligned}$$

◀

We next describe the way that we represent functions.

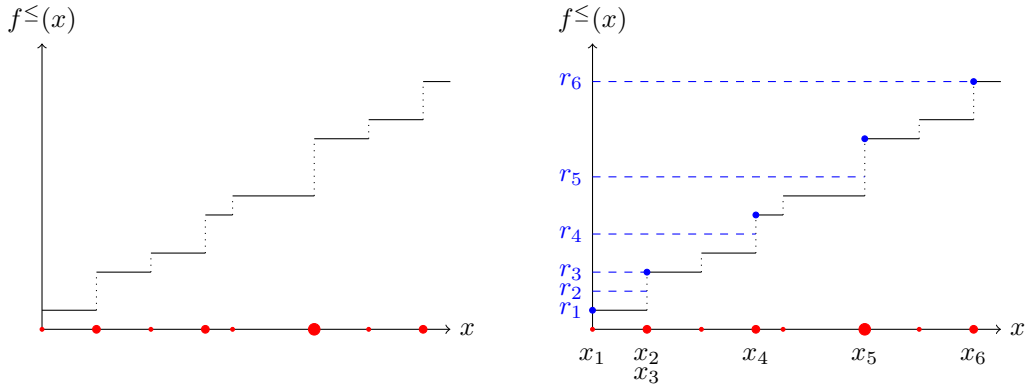

Figure 1 On the left, $f^{\leq}(x)$ compared to $f(x)$. The red point at position x is wider as $f(x)$ is larger. On the right, the blue points are the first entries that have value of at least r_i.

▶ **Definition 7** (a function representation)**.** Given a function $f : \mathbb{Z}^+ \to \mathbb{Z}^+$, the *representation of* f is defined to be a list of all the pairs $(x, f(x))$ where $f(x) > 0$. The list is kept sorted by the x value. The *size* of f (denoted by $|f|$) is the number of pairs in the representation of f. To simplify our presentation, we allow the representation to include multiple pairs with the same value of x. This can be easily fixed with a single scan over the representation.

In the following paragraphs we show how to efficiently implement the following operations on functions: *sparsification*, *summation*, *shifting*, *convolution*, and *query*. The output of each operation is a sum approximation.

Sparsification. Sparsification is the operation of constructing a $(1+\delta)$-sum approximation of f (see Definition 5). The input is a function $f : \mathbb{Z}^+ \to \mathbb{Z}^+$ and a sparsification parameter $\delta > 0$, the output is a function $F : \mathbb{Z}^+ \to \mathbb{Z}^+$ that is a $(1+\delta)$-sum approximation of f. The goal is to construct a function F that has a compact representation (i.e. a small number of points with non-zero values). The general idea is based on the one in [7] (function *Compress*) but tailored towards our particular application. We partition the values of $f^{\leq}$ into segments with elements belonging to $[r_i, r_{i+1})$ (see Figure 1), where:

$$r_0 = 0,$$
$$r_{i+1} = \max\{r_i + 1, \lfloor (1+\delta) r_i \rfloor\}.$$

We call $x_i = \min_x \left\{ f^{\leq}(x) \geq r_i \right\}$ the i-th *breakpoint*. For any x, let $\mathrm{succ}(x)$ be the strict successor of x among $\{x_i\}$, i.e. $\mathrm{succ}(x) = \min_i \{x_i > x\}$ We define the function $\tilde{f^{\leq}}$ (see Figure 2) as:

$$\tilde{f^{\leq}}(x) = f^{\leq}(\mathrm{succ}(x) - 1),$$

where $\tilde{f^{\leq}}(x) = \lim_{x \to \inf} f^{\leq}(x)$ if $\mathrm{succ}(x) = \infty$.

▶ **Lemma 8.** *$\tilde{f^{\leq}}$ is a $(1+\delta)$-approximation of $f^{\leq}$.*

Proof. First observe that $f^{\leq}(x) \leq \tilde{f^{\leq}}(x)$ (since $\mathrm{succ}(x) > x$ and $f^{\leq}$ is monotone). Consider any x and let i be the unique index such that $r_i \leq f^{\leq}(x) < r_{i+1}$. If $\mathrm{succ}(x) = \infty$ then $\tilde{f^{\leq}}(x) = \lim_{x \to \inf} f^{\leq}(x) < r_{i+1}$. Otherwise, $x_{i+1} > x$ and $\tilde{f^{\leq}}(x) = f^{\leq}(x_{i+1} - 1) < r_{i+1}$. We need to consider two cases: If $r_{i+1} \leq (1+\delta) r_i$, then $\tilde{f^{\leq}}(x) < r_{i+1} \leq (1+\delta) f^{\leq}(x)$. If $r_{i+1} = r_i + 1$ and because the values of $\tilde{f^{\leq}}(x)$ are integer, $\tilde{f^{\leq}}(x) \leq r_{i+1} - 1 = r_i$. So in both cases $\tilde{f^{\leq}}(x) \leq (1+\delta) f^{\leq}(x)$. ◀

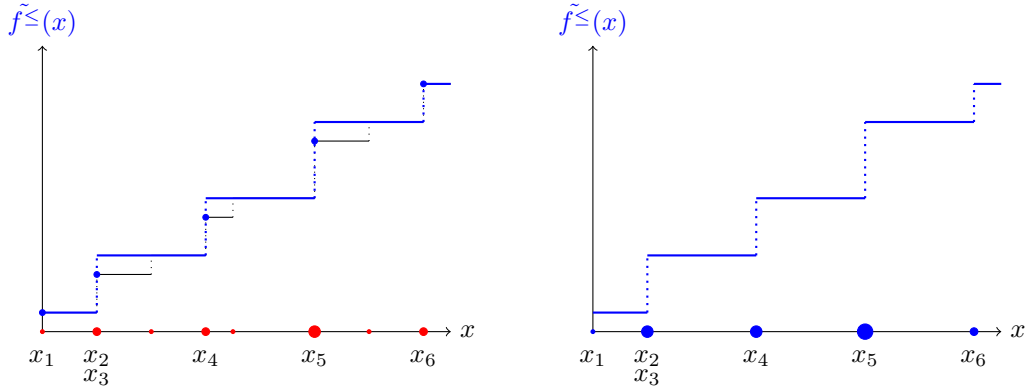

Figure 2 On the left, $\tilde{f^{\leq}}$ (in blue) is defined from $f^{\leq}$ and has the same value in any segment $[x_i, x_{i+1})$. On the right, the construction of $F(x)$. The blue points are only at positions x_i and are wider as $F(x_i)$ is larger.

Algorithm 1 SPARSIFY(f, δ).

Input: a function f represented by a sorted list of all pairs $(x, f(x))$ where $f(x) > 0$ and a sparsification parameter $\delta > 0$.

Output: a function F that is a $(1+\delta)$-sum approximation of f and is represented by a sorted list of at most $\log_{1+\delta} M$ pairs (where M is the maximum value of $f^{\leq}$).

initialize $r = accum = prevaccum = prevx = 0$
for every pair $(x, f(x))$ in sorted order **do**
  $r \leftarrow \max\{r+1, \lfloor(1+\delta)r\rfloor\}$
  while $accum < r$ **do**
    $accum \leftarrow accum + f(x)$
    get the next pair $(x, f(x))$ in the list
  end while
  add the pair $(prevx, accum - f(x) - prevaccum)$ to F
  $prevaccum \leftarrow accum - f(x)$
  $prevx \leftarrow x$
end for

We can now define the function F (the $(1+\delta)$-sum approximation of f). Observe that by Lemma 8, every F such that $F^{\leq} = \tilde{f^{\leq}}$ is a $(1+\delta)$-sum approximation. We define F as the discrete derivative of $\tilde{f^{\leq}}$. That is,

$$F(x) = \begin{cases} \tilde{f^{\leq}}(x) - \tilde{f^{\leq}}(x-1) & x > 0, \\ \tilde{f^{\leq}}(x) & x = 0. \end{cases}$$

It is easy to see that $F^{\leq} = \tilde{f^{\leq}}$. It is also easy to construct the representation of F in linear time with a single scan over the representation of f (see Algorithm 1). Let M be the maximum value of $f^{\leq}$. Notice that $\tilde{f^{\leq}}$ can have at most $|\{x_i\}| = |\{r_i\}| = \log_{1+\delta} M$ different values. This means that $|F|$ is at most $\log_{1+\delta} M$. The total running time is therefore $O(|f| + \log_{1+\delta} M)$.

Summation. Given two $(1+\varepsilon)$-sum approximations F and G of functions f and g respectively, we wish to construct the function $F + G$ (that is a $(1+\varepsilon)$-sum approximation of $f + g$

by Lemma 6). We construct $F+G$ naively by setting $(F+G)(x) = F(x)+G(x)$. The sorted list of $F+G$ can be obtained in linear time given two sorted lists of F and of G. The total space and time is therefore $O(|F|+|G|)$.

Shifting. Given a $(1+\varepsilon)$-sum approximation F of f, the function shifted by w, $F|_w$ is a $(1+\varepsilon)$-sum approximation of $f|_w$ by Lemma 6. In order to create $F|_w$, we take every pair in the representation of F, namely $(x, y = F(x))$ and change it to $(x+w, y)$. $F|_w(x)$ will be the sum of all the pairs where the first coordinate is x. The total space and time is $O(|F|)$.

Convolution. The convolution $F * G$ contains all the combinations of taking some x value from F and some y value from G. For every pair x, y such that $F(x) \neq 0$ and $G(x) \neq 0$ we add the value $F(x)G(y)$ to the value of $F * G$ at point $x+y$.

We sort these pairs in order to get the representation of $F * G$. For a certain y we have all the points $(x+y, F(x))$ sorted already, those are $|G|$ sorted sequences that we have to merge. The total space of the output $F * G$ is at most the number of such pairs x, y, that is $|F| \cdot |G|$. But it is possible to obtain a stream of the sorted pairs with their value using less space, by using a heap to merge the lists. Assuming without loss of generality that $|G| \leq |F|$, each list is a value y and a pointer to a point in F, and the heap extracts the minimum value of the sum of y and the value in the pointer. The total time to create $F * G$ is therefore $O(|F| \cdot |G| \cdot \log(\min\{|F|, |G|\}))$ and the space $O(|F|+|G|)$.

Query. Given a $(1+\varepsilon)$-sum approximation F of f and a point x, we can query the value $F^{\leq}(x)$ that satisfies $f^{\leq}(x) \leq F^{\leq}(x) \leq (1+\varepsilon)f^{\leq}(x)$ in time $O(|F|)$. This is because computing the function $F^{\leq}(x) = \sum_{y \leq x} F(y)$ takes $O(|F|)$ time by considering every y. Moreover, if we store the representation of F in a balanced binary search tree T then a query can be done in $O(\log |F|)$ time with a prefix sum query on T.

3 The Algorithm of Halman [7] (Simplified)

In this section we present a simplified version of the algorithm of Halman [7] for #Knapsack using sum approximations. The running time of this simple deterministic algorithm is $O(n^3\varepsilon^{-1})$ and the space is $O(n^2\varepsilon^{-1})$.

For a set of weights S, let $k_S(x)$ denote the number of subsets of S with total weight exactly x. The output of the algorithm is the function K_W that is a $(1+\varepsilon)$-sum approximation of k_W. The desired answer, $K_W^{\leq}(C)$, can then be easily obtained using the query operation.

Recall that $k_S|_w(x) = k_S(x-w)$ if $x \geq w$ and 0 otherwise. The algorithm is based on the following observation:

▶ **Lemma 9.** *Let S be a set of integer weights and w be an additional integer weight, then:*

$$k_{S\cup\{w\}} = k_S + k_S|_w$$

Proof. Any subset of $S \cup \{w\}$ with weight x either includes w (the number of such solutions is $k_S(x-w)$) or does not include w (the number of such solutions is $k_S(x)$). Since these options are disjoint, we have that $k_{S\cup\{w\}}(x) = k_S(x) + k_S|_w(x)$. ◀

The algorithm. The algorithm uses the above lemma to construct the set S by inserting one element at a time (until $S = W$), keeping K_S updated. The algorithm starts by setting $K_\emptyset(0) = 1$ and $K_\emptyset(x) = 0$ for any $x \neq 0$. In the i-th step, we compute the function

$K_{\{w_1,\dots,w_i\}}$ from $K_{\{w_1,\dots,w_{i-1}\}}$. Computing $K_{\{w_1,\dots,w_i\}}$ can be done with one shifting and one summation operation: $K_{\{w_1,\dots,w_i\}} = K_{\{w_1,\dots,w_{i-1}\}} + K_{\{w_1,\dots,w_{i-1}\}}|_{w_i}$. Notice that the size $|K_{\{w_1,\dots,w_i\}}| = 2|K_{\{w_1,\dots,w_{i-1}\}}|$ doubles from the summation operation. To overcome this blowup, at the end of each step of the algorithm, we sparsify with parameter $\delta = (1+\varepsilon)^{\frac{1}{n}} - 1$.

Correctness. From Lemmas 6 and 9, it follows that if K_S is a $(1+\alpha)$-sum approximation of k_S, then $K_S + K_S|_w$ is a $(1+\alpha)$-sum approximation of $k_{S\cup\{w\}}$. Furthermore, the approximation factor of $K_{\{w_1,\dots,w_i\}}$ after the sparsification is the approximation factor of $K_{\{w_1,\dots,w_{i-1}\}}$ multiplied by $(1+\delta)$. We get that K_W is a $((1+\varepsilon)^{\frac{1}{n}})^n$-sum approximation of k_W, as required.

Time complexity. The size of $K_{\{w_1,\dots,w_i\}}$ after the sparsification is bounded by $\log_{1+\delta} 2^i$. The time complexity is therefore:

$$\sum_{i=1}^{n} O\big(\log_{1+\delta} 2^i\big) = O\left(\sum_{i=1}^{n} \frac{i}{\log(1+\delta)}\right) = O\left(\frac{1}{\frac{1}{n}\log(1+\varepsilon)} \sum_{i=1}^{n} i\right) = O\big(n^3\varepsilon^{-1}\big)\,.$$

Space complexity. The space is $O(|K_W|) = O(\log_{1+\delta} 2^n) = O\Big(\frac{n}{\log(1+\delta)}\Big) = O\Big(\frac{n^2}{\log(1+\varepsilon)}\Big) = O(n^2\varepsilon^{-1})$, where we have used that $\ln(1+\varepsilon) \geq \varepsilon/2$ for $\varepsilon \in (0,1)$.

4 The Algorithm for Counting Knapsack Solutions

In this section we present a deterministic $O(n^{2.5}\varepsilon^{-1.5}\log(n\varepsilon^{-1})\log(n\varepsilon))$ time $O(n^{1.5}\varepsilon^{-1.5})$ space algorithm for counting knapsack solutions. The algorithm is based upon a similar observation to the one in Lemma 9:

▶ **Lemma 10.** *Let S and T be two sets of integer weights, then:*

$$k_{S\cup T} = k_S * k_T$$

Proof. A subset of $S\cup T$ of weight w must be obtained by taking a subset of weight w_S from S and a subset of weight w_T from T where $w_S + w_T = w$. Thus, $k_S(w_S)$ subsets of S of weight w_S and $k_T(w_T)$ subsets of T weight w_T generate $k_S(w_S)k_T(w_T)$ subsets of $S\cup T$ of weight $w_S + w_T$. Overall, we get that $k_{S\cup T}(w) = \sum_{w_S+w_T=w} k_S(w_S)k_T(w_T) = (k_S * k_T)(w)$. ◀

The algorithm. As in Section 3, our algorithm computes a $(1+\varepsilon)$-sum approximation K_W of k_W recursively. This time however, we do two things differently: (1) The value of the approximation factor is different for each recursion depth. In a recursive call of depth i, we are given a set S and we compute a $(1+\varepsilon_i)$-sum approximation K_S of k_S for some ε_i to be chosen later. (2) Given a set S we recurse differently depending on the size of S:

1. If $|S| > \sqrt{n/\varepsilon}$, then we partition the set S into two sets A and B each of size $|S|/2 = n/2^i$ and make two recursive calls: One computes a $(1+\varepsilon_{i+1})$-sum approximation K_A of k_A and the other computes a $(1+\varepsilon_{i+1})$-sum approximation K_B of k_B. We then find K_S by computing the convolution $K_A * K_B$ and sparsifying with parameter

$$\delta_i = \frac{\varepsilon^{3/4}}{2c\cdot 2^{i/2}\cdot n^{1/4}},$$

where ε is the original approximation parameter and $c = \frac{\sqrt{2}}{\sqrt{2}-1}$.

2. If $|S| \leq \sqrt{n/\varepsilon}$, then we apply the algorithm from Section 3 on the set S with parameter $\delta_{\log(\sqrt{n\varepsilon})} = \Omega(\sqrt{\varepsilon/n})$. Observe that in such a case the recursion depth is at least $\log(\sqrt{n\varepsilon})$.

Correctness. From Lemmas 6 and 10, it follows that if K_A is a $(1+\varepsilon_{i+1})$-sum approximation of k_A and K_B is a $(1+\varepsilon_{i+1})$-sum approximation of k_B, then K_S is a $(1+\varepsilon_{i+1})^2(1+\delta_i)$-sum approximation of k_S. This means that ε_i satisfies the following relation:

$$(1+\varepsilon_i) = (1+\varepsilon_{i+1})^2(1+\delta_i)$$

From the above equation and since on the bottom of the recursion with $\delta_i = \delta_{\log(\sqrt{n\varepsilon})}$, the final approximation factor of K_W is:

$$(1+\varepsilon_0) = (1+\delta_{\log(\sqrt{n\varepsilon})})^{\sqrt{n\varepsilon}} \prod_{i=0}^{\log(\sqrt{n\varepsilon})-1} (1+\delta_i)^{2^i} = \prod_{i=0}^{\log(\sqrt{n\varepsilon})} (1+\delta_i)^{2^i}$$

We need to prove that the above product is not larger than $(1+\varepsilon)$. Since $\sum_{i=0}^{x} 2^{i/2} < \frac{\sqrt{2}}{\sqrt{2}-1} \cdot 2^{x/2} = c \cdot 2^{x/2}$ and $(1+\delta_i)^{2^i} = (1+\delta_i)^{1/\delta_i \cdot 2^i \delta_i} \leq e^{2^i\delta_i} = e^{\frac{\varepsilon^{3/4}}{2c} n^{-1/4} 2^{i/2}}$ we obtain:

$$\prod_{i=0}^{\log(\sqrt{n\varepsilon})} (1+\delta_i)^{2^i} \leq e^{\frac{\varepsilon^{3/4}}{2c} n^{-1/2} \sum_{i=0}^{\log(\sqrt{n\varepsilon})} 2^{i/2}} < e^{\frac{\varepsilon^{3/4}}{2} n^{-1/4} 2^{\log(\sqrt{n\varepsilon})/2}} = e^{\frac{\varepsilon}{2}} \leq (1+\varepsilon),$$

where the last inequality follows from $\ln(1+\varepsilon) \geq \varepsilon/2$ for $\varepsilon \in (0,1)$. Moreover, since the recursion changes at depth $\log(\sqrt{n\varepsilon})$ we further need to assume that $\varepsilon \geq 1/n$. These assumptions are without loss of generality since for $\varepsilon > 1$ we could simply use $\varepsilon = 1$ and for $\varepsilon < 1/n$ the previous algorithms are faster.

Time complexity. We analyze the time complexity of every recursion depth i. For depth $i = \log(\sqrt{n\varepsilon})$, we apply the simple algorithm from Section 3 $\lfloor\sqrt{n\varepsilon}\rfloor$ times on sets of size $\Theta(\sqrt{n/\varepsilon})$ with $\delta_{\log(\sqrt{n\varepsilon})} = \Omega(\sqrt{\varepsilon/n})$, the running time is therefore $O(n^{2.5}\varepsilon^{-1.5})$.

For depth $i < \log(\sqrt{n\varepsilon})$, we apply 2^i convolutions and sparsifications. The time of the convolutions is dominant. The total running time is therefore:

$$\begin{aligned}\sum_{i=0}^{(\log\sqrt{n\varepsilon})-1} 2^i \left(\frac{n}{2^{i+1}\cdot\delta_{i+1}}\right)^2 \log\left(\frac{n}{2^{i+1}\cdot\delta_{i+1}}\right) &\leq \frac{1}{2}\sum_{i=1}^{\log\sqrt{n\varepsilon}} 2^i \left(\frac{n}{2^i\cdot\delta_i}\right)^2 \log(n\varepsilon^{-1}) \\ &= O\left(\sum_{i=1}^{\log\sqrt{n\varepsilon}} \frac{n^{2.5}}{\varepsilon^{1.5}} \log(n\varepsilon^{-1})\right) \\ &= O(n^{2.5}\varepsilon^{-1.5}\log(n\varepsilon^{-1})\log(n\varepsilon)).\end{aligned}$$

Space complexity. Since each recursive call makes at most two recursive calls, we do not need to keep more than two representation of sum approximations on every level of the recursion. We have seen in Section 2 that it is possible to construct sparsification of convolution in linear space. The space complexity of all recursive calls of depth $i < \log(\sqrt{n\varepsilon})$ is therefore:

$$\sum_{i=0}^{\log(\sqrt{n\varepsilon})} \left(2\cdot\frac{n}{2^i\cdot\delta_i}\right) = O\left(\sum_{i=0}^{\log(\sqrt{n\varepsilon})} \frac{n^{1.25}}{2^{i/2}\cdot\varepsilon^{0.75}}\right) = O\left(n^{1.25}\varepsilon^{-0.75}\right)$$

One call to the algorithm from Section 3 uses $O\left(\frac{\left(\sqrt{n/\varepsilon}\right)^2}{\delta_{\log(\sqrt{n\varepsilon})}}\right) = O\left(\frac{\left(\sqrt{n/\varepsilon}\right)^2}{\sqrt{\varepsilon/n}}\right) = O(n^{1.5}\varepsilon^{-1.5})$ space, and therefore the total space complexity is $O(n^{1.5}\varepsilon^{-1.5})$.

5 The Algorithm for Counting Integer Knapsack Solutions

In this section we show how to generalize the algorithms of Sections 3 and 4 to the integer version of counting knapsack solutions.

5.1 Generalizing the algorithm of Section 3

In Section 3 we showed how to insert into a set S a single item with weight w. We now need to show how to insert a single item with weight w and multiplicity u. The proof of the following lemma is similar to that of Lemma 9.

▶ **Lemma 11.** *Let S be a set of integer pairs representing weights and multiplicity of items, and let (w, u) be the weight and multiplicity of an additional item, then:*

$$k_{S\cup\{(w,u)\}} = k_S + k_S|_w + k_S|_{2w} + \ldots + k_S|_{u\cdot w}$$

We will describe a new operation on sum approximations that creates the sparsification of $G = (K_S + K_S|_w + K_S|_{2w} + \ldots + K_S|_{u\cdot w})$ without actually computing G, i.e. without actually computing all the points with non-zero value.

Events. Observe that a point (x, y) with non-zero value $y = K_S(x)$ implies $u + 1$ points in the above sum: $(x, y), (x + w, y), (x + 2w, y), \ldots, (x + u \cdot w, y)$. We call the first point (x, y) a *start event* (with position x and value y) and the last point $(x + u \cdot w, y)$ an *end event* (with position $x + u \cdot w$ and value y). Overall, for every x with non-zero value $y = K_S(x)$ there are two events, a total of $2|K_S|$ events. It is possible to sort in linear time the sequence of events by their positions $\{x\}_i \cup \{x + u \cdot w\}_i$ because K_S is given sorted. We call the sorted list of events the *event list*.

Similarly to Algorithm 1, we could construct the sparsification of $G = (K_S + K_S|_w + K_S|_{2w} + \ldots + K_S|_{u\cdot w})$ by scanning all points in G. This however would be too costly. Instead, we next present a new operation that constructs the sparsification of G while only scanning the $O(|K_S|)$ events in the event list.

InsertAndSparsify. While scanning the event list, when we see a start event (x, y) then we say that this event is an *active event* and that all the points $(x, y), (x + w, y), (x + 2w, y), \ldots, (x + u \cdot w, y)$ are *active points*. These points will become inactive when we will see the end event $(x + u \cdot w, y)$. As in Algorithm 1, we would like to accumulate the values of all points seen so far. When the accumulator is larger than r, we introduce a new breakpoint (i.e., output a new point to the sparsification of G) and set the new r to be $\max\{r + 1, \lfloor(1 + \delta)r\rfloor\}$. During the scan, apart from the accumulator, we also maintain a value Y = the sum of values of all currently active events.

When we scan a start event (x, y), we add the value y to both the accumulator and to Y. This is not enough. We also need to add to the accumulator the values of all active points whose position is x. These are precisely the points whose start events were at positions $x - w, x - 2w, \ldots, x - u \cdot w$. Notice that all these points have the same start position modulo w. For this reason, we maintain a balanced binary search tree T that stores all active events keyed by their start position modulo w. Each node v in T with key $r \in \{0, \ldots, w - 1\}$ stores a field Y_v = the sum of values of all active points whose start position is x such that $x = r \pmod w$. When we see a start event (x, y), we search in T for the node v with key $x \bmod w$ (or create one if no such node exists), we increase the node's Y_v field by y, and increase the accumulator by y. If (x, y) is an end event we subtract y from Y_v and from Y.

After processing event (x, y) as explained above, we want to process the next event (x', y') in the event list. Before doing so, we need to: (1) increase the accumulator by the total value of all points in the segment $[x, x')$, and (2) if the updated accumulator is larger than r, find and output the (possibly many) new breakpoints whose positions are between x and x'.

(1) We partition the segment $[x, x')$ into three segments: $[x, k_1w), [k_1w, k_2w), [k_2w, x')$ such that the lengths of the first and last segments are smaller than w, and the length of the middle segment is a multiple of w. Notice that every segment of length w contains an active point from every active event exactly once. Therefore, to obtain the total value of points in the segment $[x, x')$ we query T for the total value in segment $[x, k_1w)$ (with a *suffix sum* query on the Y_v values) and in segment $[k_2w, x')$ (with a *prefix sum* query on the Y_v values), and add to it $Y \cdot (k_2 - k_1)$ (the total value in segment $[k_1w, k_2w)$).

(2) After increasing the accumulator by the above total value, if the accumulator becomes larger than r, then we will find all the new breakpoints in $[x, x')$ in $O(\log |K_S|)$ time per breakpoint. Suppose the accumulated value at x was *prevaccum*. To find the first breakpoint in the segment $[x, k_1w)$ we query T for the the first node after $x \bmod w$ such that the sum of Y_v values between $x \bmod w$ and that node is at least $r - prevaccum$ (we call this a *succeeding sum* query on T, and we symmetrically define a *preceding sum* query in which we seek the first node before $x \bmod w$ rather than after). We then output this breakpoint, set *prevaccum* to be the accumulated value in this breakpoint, set $r = \max\{r + 1, \lfloor (1 + \delta)r \rfloor\}$, and continue in the same way to find the next breakpoint in the segment $[x, k_1w)$. Next, we find the breakpoints in the segment $[k_1w, k_2w)$. Since this segment is composed of $(k_2 - k_1)$ subsegments of length w, and since each of these subsegments contributes exactly Y to the accumulator, it is easy (in $O(1)$ time) to find which subsegment contains the next breakpoint. On this subsegment we proceed similarly as on $[x, k_1w)$. Finally, we need to find the breakpoints in segment $[k_2w, x')$, again similarly as in $[x, k_1w)$. See Algorithm 2.

Time and space complexity. Each operation on the binary search tree T takes $O(\log |K_S|)$ time thus the total time for InsertAndSparsify is $O\big((|K_{S\cup\{(w,u)\}}| + |K_S|) \cdot \log |K_S|\big)$. If $S = \{w_1, \ldots, w_i\}$ then $|K_S| = \log_{1+\delta} U^i$ and $|K_{S\cup\{(w,u)\}}| = O\big(\log_{1+\delta} U^i\big)$. The total time complexity of the algorithm is therefore:

$$\begin{aligned}
\sum_{i=1}^{n} O\big(\log_{1+\delta} U^i \cdot \log(\log_{1+\delta} U^i)\big) &= O\left(\sum_{i=1}^{n} \frac{i \log U}{\log(1+\delta)} \cdot \log\left(\frac{i \log U}{\log(1+\delta)}\right)\right) \\
&= O\left(\frac{\log U}{\frac{1}{n}\log(1+\varepsilon)} \cdot \log\left(\frac{n \log U}{\frac{1}{n}\log(1+\varepsilon)}\right) \sum_{i=1}^{n} i\right) \\
&= O\big(n^3 \varepsilon^{-1} \log U \log\left(n\varepsilon^{-1} \log U\right)\big)\,.
\end{aligned}$$

The space complexity is $O(|K_W|) = O\big(\log_{1+\delta} U^n\big) = O\Big(\frac{n \log U}{\log(1+\delta)}\Big) = O(n^2\varepsilon^{-1} \log U)$.

5.2 Generalizing the algorithm of Section 4

The only change to the algorithm of Section 4 is that when the set size is small (i.e. when we call the algorithm of Section 3) we use InsertAndSparsify as in the previous subsection.

Time and space complexity. We observe that the size of the representation of a $(1+\varepsilon)$-sum approximation has been changed to $|K_S| = \log_{1+\delta} U^{|S|} = \frac{|S| \log U}{\delta}$. As in Section 4, we

Algorithm 2 InsertAndSparsify(K_S, w, u, δ).

Input: a sum approximation K_S of k_S, a new item with weight of w and multiplicity u, and a sparsification parameter δ.

Output: a function G that is a $(1+\delta)$-sum approximation of $k_{S\cup(w,u)}$.

initialize T as an empty binary search tree of pairs (x, y) indexed by $(x \bmod w)$
initialize $Y = x = accum = prevaccum = 0$, and $r = 1$
for every event (x', y') in sorted order **do**
  $k_1 \leftarrow \lceil \frac{x}{w} \rceil$, $k_2 \leftarrow \lfloor \frac{x'}{w} \rfloor$
  while $accum + T.\mathsf{suffixSum}(x) + Y \cdot (k_2 - k_1) + T.\mathsf{prefixSum}(x' - 1) \geq r$ **do**
    if $accum + T.\mathsf{suffixSum}(x) \geq r$ **then**
      $bp \leftarrow T.\mathsf{succeedingSum}(x, r - accum)$
      $accum \leftarrow accum + T.\mathsf{suffixSum}(x) - T.\mathsf{suffixSum}(bp)$
    else
      $k_3 \leftarrow k_1 + \lfloor (r - accum - T.\mathsf{suffixSum}(x))/Y \rfloor$
      $bp \leftarrow T.\mathsf{precedingSum}(x', r - (accum + T.\mathsf{suffixSum}(x) + Y \cdot (k_3 - k_1)))$
      $accum \leftarrow accum + T.\mathsf{suffixSum}(x) + Y \cdot (k_3 - k_1) + T.\mathsf{prefixSum}(bp - 1)$
    end if
    add the pair $(x', accum - prevaccum - T[bp \bmod w])$ to G
    $prevaccum \leftarrow accum$, $x \leftarrow bp$, $k_1 \leftarrow \lceil \frac{x}{w} \rceil$, $r \leftarrow \max\{r+1, \lfloor (1+\delta)r \rfloor\}$
  end while
  if (x', y') is a start event **then**
    $Y \leftarrow Y + y'$, $T[x' \bmod w] \leftarrow T[x' \bmod w] + y'$
  else
    $Y \leftarrow Y - y'$, $T[x' \bmod w] \leftarrow T[x' \bmod w] - y'$
  end if
  $accum \leftarrow accum + T.\mathsf{suffixSum}(x) + Y \cdot (k_2 - k_1) + T.\mathsf{prefixSum}(x' - 1)$
  $x \leftarrow x'$
end for

calculate the total time complexity for depth $\log(\sqrt{n\varepsilon})$:

$$O\left(\sqrt{n\varepsilon} \cdot \left(\left(\sqrt{n/\varepsilon}\right)^3 \left(\sqrt{\varepsilon/n}\right)^{-1} \log U \log\left(\sqrt{n\varepsilon}\left(\sqrt{\varepsilon/n}\right)^{-1} \log U\right)\right)\right)$$

which is $O\big(n^{2.5}\varepsilon^{-1.5} \log U \log(n\varepsilon^{-1} \log U)\big)$. The total time for depths $i < \log(\sqrt{n\varepsilon})$ is:

$$\begin{aligned}
&\sum_{i=0}^{(\log\sqrt{n\varepsilon})-1} 2^i \left(\frac{n \log U}{2^{i+1} \cdot \delta_{i+1}}\right)^2 \log\left(\frac{n \log U}{2^{i+1} \cdot \delta_{i+1}}\right) \\
&\leq \frac{1}{2} \sum_{i=1}^{\log\sqrt{n\varepsilon}} 2^i \left(\frac{n \log U}{2^i \cdot \delta_i}\right)^2 \log(n\varepsilon^{-1} \log U) \\
&= O\left(\sum_{i=1}^{\log\sqrt{n\varepsilon}} \frac{n^{2.5} \log^2 U}{\varepsilon^{1.5}} \log(n\varepsilon^{-1} \log U)\right) \\
&= O(n^{2.5}\varepsilon^{-1.5} \log(n\varepsilon^{-1} \log U) \log(n\varepsilon) \log^2 U).
\end{aligned}$$

The space complexity is dominated by the space used for InsertAndSparsify on a set of size $\sqrt{n/\varepsilon}$ and $\delta = \sqrt{\varepsilon/n}$, that is $O(n^{1.5}\varepsilon^{-1.5} \log U)$.

Abstract

Recently, there has been a growing focus in solving approximate pattern matching problems in the streaming model. Of particular interest are the pattern matching with k-mismatches (KMM) problem and the pattern matching with w-wildcards (PMWC) problem. Motivated by reductions from these problems in the streaming model to the *dictionary matching problem*, this paper focuses on designing algorithms for the dictionary matching problem in the *multi-stream model* where there are several independent streams of data (as opposed to just one in the streaming model), and the memory complexity of an algorithm is expressed using two quantities: (1) a read-only *shared memory* storage area which is shared among all the streams, and (2) local *stream memory* that each stream stores separately.

In the dictionary matching problem in the multi-stream model the goal is to preprocess a dictionary $D = \{P_1, P_2, \ldots, P_d\}$ of $d = |D|$ patterns (strings with maximum length m over alphabet Σ) into a data structure stored in shared memory, so that given multiple independent streaming texts (where characters arrive one at a time) the algorithm reports occurrences of patterns from D in each one of the texts as soon as they appear.

We design two efficient algorithms for the dictionary matching problem in the multi-stream model. The first algorithm works when all the patterns in D have the same length m and costs $O(d \log m)$ words in shared memory, $O(\log m \log d)$ words in stream memory, and $O(\log m)$ time per character. The second algorithm works for general D, but the time cost per character becomes $O(\log m + \log d \log\log d)$. We also demonstrate the usefulness of our first algorithm in solving both the KMM problem and PMWC problem in the streaming model. In particular, we obtain the first almost optimal (up to poly-log factors) algorithm for the PMWC problem in the streaming model. We also design a new algorithm for the KMM problem in the streaming model that, up to poly-log factors, has the same bounds as the most recent results that use different techniques. Moreover, for most inputs, our algorithm for KMM is significantly faster on average.

1 Introduction

In the popular *streaming* model [2, 48] the input is given as a sequence of elements (the data stream) that may be scanned only once, the storage space is limited, and the amount of time spent on each element needs to be minimized. In many problems there is also a preprocessing phase involved. For example, in the basic streaming pattern matching problem, the goal is to find occurrences of a given pattern (to be preprocessed) of size m in the data stream [52, 18]. The preprocessing phase receives the pattern and creates a sub-linear sized data structure that is used to locate the pattern in streaming input. Following the breakthrough result of Porat and Porat [52], there has recently been a rising interest in solving pattern matching problems in the streaming model [18, 30, 47, 19, 42, 23, 24, 37, 38].

Approximate Streaming Pattern Matching. While Porat and Porat [52] and Breslauer and Galil [18] addressed the exact match case, which is the purest form of streaming pattern matching, several papers have focused on *approximate* versions in the streaming model. The term *approximate pattern matching* refers to any pattern matching problem that is not exact matching. Examples include pattern matching with up to k-mismatches [46, 53, 11, 22, 21, 27, 24, 26, 28], pattern matching with w-wildcards [33, 49, 41, 43, 29, 20, 37], pattern matching with up to e-edits [56], parameterized pattern matching [6, 12, 42, 15, 16, 17, 39], function pattern matching [13, 4], swapped matching [10, 3, 5] and many more.

Remarkably, recent results in the streaming model for both the pattern matching with k-mismatches (KMM) problem [24] and the pattern matching with w-wildcards (PMWC) problem [37] (both formally defined below) use a similar approach which, in particular, reduce the approximate pattern matching problem in the streaming model that is being solved to the *dictionary matching* (DM) problem in the streaming model. In the dictionary matching problem ([23, 31, 8, 9, 45, 34, 14, 35, 32, 7, 38]) the goal is to preprocess a *dictionary* $D = \{P_1, P_2, \ldots, P_d\}$ of $d = |D|$ patterns (strings over alphabet Σ) so that given a text T we quickly report all of the occurrences of patterns from D in T. In the streaming model [23, 38] the text T arrives online, one character at a time, and the goal is to report, for each arriving character, the id of the longest pattern ending at this character[1]. Moreover, a pattern must be reported as soon as it appears.

The motivation for this paper is due to realizing that the reductions to the dictionary matching problem mentioned above all suffer from an inefficiency that is due reducing a single stream approximate pattern matching problem to several instances of the dictionary matching problem, where all of the instances use the same dictionary but have different input texts. The results in [24] and [37] use a separate block of space for each instance of the dictionary matching, even though the dictionaries are the same. If it would be possible to share the space usage representing the dictionary among all of the instances then that would imply an immediate improvement in the total space usage. More formally, we introduce the *dictionary matching in the multi-stream model* that captures this challenge.

Dictionary matching in the multi-stream model. In the dictionary matching in the multi-stream (DMMS) problem the input is a dictionary D to be processed, there are s independent input streams of text $T_1, T_2, \ldots, T_s$, and the goal is to report all of the occurrences of

[1] This is a common simplification in which one must only report the longest pattern that has arrived (if several patterns end at the same text location), since converting such a solution to one that reports all the patterns is straightforward, and this way the focus is on the time cost that is independent from the output size.

patterns from D in any T_i, for $1 \leq i \leq s$, as soon as the occurrence arrives. An algorithm for the DMMS problem is allowed to set up a read-only block of *shared memory* during a preprocessing phase, whose contents depend solely on D, and s blocks of *stream memory*, one for each text stream, to be used privately for each text stream as the text is being processed. Notice that it is enough to describe an algorithm that works on one stream, as long as the description details which data is stored in each type of memory. Also notice that a naïve algorithm would be to use a separate solution for dictionary matching in one stream for each one of the text streams, where each instance is stored completely in stream memory and there is no use of the shared memory. The most efficient algorithm for dictionary matching in the streaming model is due to Golan and Porat [38] using $O(d \log m)$ words and the time per character is $O(\log\log|\Sigma|)$, which could be as large as $O(\log\log(m \cdot d))$. All of these complexities are in the worst-case, and their algorithm is correct with high probability. With the naïve method, the algorithm of [38] implies a solution for DMMS that uses a total of $O(s \cdot d \log m)$ words. This space complexity is inherent in the algorithm of [38] since, in particular, their algorithm always stores the last $\Theta(d \log m)$ text characters in each stream, which does not benefit from shared memory. Thus, algorithms are only of interest if they can beat this naïve method.

1.1 Our Results

We introduce a new algorithm for the dictionary matching problem in the multi-stream model, which is summarized in the following theorem.

▶ **Theorem 1.** *There exists an algorithm for the multi-stream dictionary matching problem where each pattern has length m that uses $O(d \log m)$ words of shared memory, $O(\log m \log d)$ words of stream memory, and $O(\log m)$ time per character. All of these complexities are in the worst-case, and the algorithm is correct with high probability.*

Notice that we focus on the case where all of the patterns in D have the same length m, since this case suffices for our applications. Due to space limitations, the following extension of the results to different length patterns is left for the full version.

▶ **Theorem 2.** *There exists an algorithm for the multi-stream dictionary matching problem that uses $O(d \log m)$ words of shared memory, $O(\log m \log d)$ words of stream memory, and $O(\log m + \log d \log\log d)$ time per character, where $m = m_D$ is the length of the longest pattern in D. All of these complexities are in the worst-case, and the algorithm is correct with high probability.*

Thus, if there are s streams of data, the total space usage becomes $O(d \log m + s \log m \log d)$ words, which is substantially less than the total space usage of the naïve method. By using the algorithm of Theorem 1 we are able to reduce the space usage for solving several approximate streaming pattern matching problems, as we discuss next.

Streaming pattern matching with w wildcards. A *wildcard* character, denoted by $'?' \notin \Sigma$, is a special character that matches every character in Σ. In the streaming PMWC problem the goal is to preprocess a pattern $P[1..m]$ that contains w wildcard characters, so that given a streaming text T the algorithm reports, for each arriving character, whether the current text suffix of length m matches the pattern. The most efficient known algorithm for the PMWC problem was given in [37] where we introduced a trade-off algorithm, which for every $0 \leq \delta \leq 1$ uses $\tilde{O}(w^{1-\delta})$ amortized time per character and $\tilde{O}(w^{1+\delta})$ words of space, where $\tilde{O}$ hides poly-logarithmic factors. Our results use a reduction from the PMWC problem to the DMMS problem. Using Theorem 1 we are able to obtain the following result which is optimal, up to $polylog(m, w)$ factors.

▶ **Theorem 3.** *There exists a randomized Monte Carlo algorithm for the pattern matching with w-wildcards problem in the streaming model that succeeds with high probability, uses $\tilde{O}(w)$ words of space and spends $\tilde{O}(1)$ time per arriving text character. Moreover, any algorithm which solves the streaming pattern matching with w wildcards with high probability must use $\Omega(w)$ bits of space.*

The proof of the upper bound for Theorem 3 is obtained by directly plugging the algorithm from Theorem 1 into the reduction of [37]. The lower bound is based on a straightforward reduction from the communication complexity INDEXING problem the proof of Theorem 3 is left for the full version.

Streaming pattern matching with k-mismatches. Another application is the KMM problem in the streaming model. In this problem the goal is to preprocess a pattern $P[1..m]$ so that given a streaming text T the algorithm reports for each arriving character whether the number of mismatches between P and the current text suffix of length m is at most k, and if so then the algorithm also reports the number of mismatches. The most efficient algorithm currently published for this problem is by Clifford et al. [24]. This algorithm uses $O(k^2 \operatorname{polylog} m)$ words of space and takes $O(\sqrt{k} \log k + \operatorname{polylog} m)$ time per character. Their results use a reduction from the streaming KMM problem to the DMMS problem. Using Theorem 1 we are able to obtain the following result.

▶ **Theorem 4.** *There exists a randomized Monte Carlo algorithm for the streaming k-mismatch problem that succeeds with high probability, uses $\tilde{O}(k)$ words of space and spends $\tilde{O}(k)$ time per arriving text character.*

A proof of Theorem 4 is obtained by plugging the algorithm from Theorem 1 into the reduction of [24] (with some minor details) which uses group testing techniques [54, 53, 51, 50, 36]. The space usage of this algorithm is optimal up to $\operatorname{polylog} m$ factors [40]. Clifford, Kociumaka and Porat [26] recently posted another algorithm that obtains the same complexities (ignoring poly-logarithmic factors) but using different techniques. Nevertheless, we provide a second stronger result.

k-mismatches and periodicity. Clifford et al. [24] introduced the notion of x-period which captures the generalization of periodicity to work with a bounded number of mismatches. The number of mismatches between two equal length strings S and S' is known as the Hamming Distance and is denoted by $\mathsf{Ham}(S, S')$. The x-period of a string P of length m is the smallest integer $\pi > 0$ such that $\mathsf{Ham}(P[1+\pi..m], P[1..m-\pi]) \leq x$. Notice that for small x, most strings have a high x-period.

▶ **Theorem 5.** *There exists a randomized Monte Carlo algorithm for the streaming k-mismatch problem that succeeds with high probability, uses $\tilde{O}(k)$ words of space and spends $\tilde{O}(k)$ time per arriving text character. Moreover, if the $4k$-period of P is $\Omega(k)$, then the algorithm spends an average of $\tilde{O}(1)$ time per character.*

Since the typical assumption is that k is fairly small, the algorithm of Theorem 5 spends an average of $\tilde{O}(1)$ time per character for most patterns. Notice that Theorem 5 immediately implies Theorem 4. Due to space considerations, the proof of Theorem 5 is left for the full version.

Organization. In the rest of this paper we give an overview focusing on intuition and the general ideas of how to prove Theorem 1. The missing proofs and details are left for the full version.

1.2 Related Work

As mentioned above, the current most efficient algorithm for DM in the streaming model is due to Golan and Porat [38] where the space usage is $O(d \log m)$ words and the time per character in T is $O(\log \log |\Sigma|)$. Another relevant result is that of Clifford et al. [25], which deals with pattern matching (one pattern) in multiple streams, but not in the classic streaming model (since the space usage is not sublinear). They show how for s streams and a pattern of size m, one can report occurrences of the pattern in all of the streams, concurrently, using $O(m + s)$ words of space.

We emphasize that the Aho-Corasick automata [1] is not a multi-stream solution for the dictionary matching problem since the shared memory usage is not sub-linear. However, the stream memory usage is $O(1)$ words.

2 Preliminaries

A string S of length $|S| = \ell$ is a sequence of characters $S[1]S[2] \dots S[\ell]$ over alphabet Σ. A *substring* of S is denoted by $S[x..y] = S[x]S[x+1] \dots S[y]$ for $1 \leq x \leq y \leq \ell$. If $x = 1$ the substring is called a *prefix* of S, and if $y = \ell$, the substring is called a *suffix* of S.

A prefix of S of length $y \geq 1$ is called a *period* of S if and only if $S[i] = S[i+y]$ for all $1 \leq i \leq \ell - y$. The shortest period of S is called *the principal period* of S, and its length is denoted by ρ_S. If $\rho_S \leq \frac{|S|}{2}$ we say that S is *periodic*.

Fingerprints For a natural number n we denote $[n] = \{1, 2, \dots, n\}$. For the following let $u, v \in \bigcup_{i=0}^{n} \Sigma^i$ be two strings of size at most n. Porat and Porat [52] and Breslauer and Galil [18] extended the fingerprint method of Karp and Rabin [44], and proved that for every constant $c > 1$ there exists a *fingerprint function* $\phi : \bigcup_{i=0}^{n} \Sigma^i \to [n^c]$, such that:

1. If $|u| = |v|$ and $u \neq v$ then $\phi(u) \neq \phi(v)$ with high probability (at least $1 - \frac{1}{n^{c-1}}$).
2. *The sliding property:* Let w=uv be the concatenation of u and v. If $|w| \leq n$ then given the length and the fingerprints of any two strings from u,v and w, one can compute the fingerprint of the third string in constant time.

For two strings u and v and a fingerprint function ϕ, we say that the *fingerprint concatenation* of $\phi(u)$ and $\phi(v)$ is $\phi(uv)$. If we are given the lengths of u and v then computing the fingerprint concatenation takes constant time due to the sliding property.

Remark. Our algorithm often uses fingerprints in order to quickly test if two strings are equal or not. To ease presentation, in the rest of the paper we assume that fingerprints never give false positives. This assumption is acceptable since the algorithm is allowed to fail with small probability.

3 Same Length Patterns – Proof of Theorem 1

Throughout the paper, let q denote the current index of the last character in T. The algorithm initially considers every text location as a *candidate* for an occurrence of a pattern. Conceptually, a text location c is considered to be a candidate until the algorithm encounters proof that there cannot be any pattern in D that appears at location c. This leads to a naïve solution which stores all of the candidates, and each time a new character arrives the candidates are tested to see if they are still candidates. Regardless of the method of testing, this solution is too expensive, in terms of both space and time, since the number of candidates could be $\Omega(m)$.

In order to reduce the time cost per character, we borrow a technique introduced in [52] which considers prefixes of the dictionary strings of exponentially growing length. This technique has been extensively used for streaming pattern matching algorithms [30, 18, 23, 24, 37, 38, 42, 26, 55], but in our case the details are more delicate than usual. Our algorithm makes use of an increasing sequence of $O(\log m)$ shift values $\Delta = (\delta_0, \delta_1, \ldots, \delta_{|\Delta|-1})$ where

$$\delta_k = \begin{cases} 25 & \text{if } k = 0 \\ \min(5\lfloor \frac{6}{25}\delta_{k-1} \rfloor, m) & \text{otherwise.} \end{cases}$$

Notice that for $1 \leq k < |\Delta| - 1$ we have $\delta_k - \delta_{k-1} \leq \delta_k/5$. Denote $\ell_k = \delta_k/5$. For each $0 \leq k \leq |\Delta| - 1$ let $D_k = \{P[1..\delta_k] | P \in D\}$ be the set of prefixes of patterns from D of length δ_k. Let $F_k = \{\phi(P) | P \in D_k\}$ be the set of fingerprints of patterns in D_k.

The intuition behind the sets D_k for $\delta_k \in \Delta$ is that our algorithm first finds occurrences of patterns from D_{k-1}, and those occurrences are then used for finding occurrences of patterns from D_k. Notice that D_0 contains only constant sized prefixes of patterns (of length 25). It is straightforward to find occurrences of these prefixes using $O(d)$ words in shared memory, $O(1)$ words in stream memory and $O(1)$ time per text character. Also notice that $D_{|\Delta|-1} = D$, and so once a pattern from $D_{|\Delta|-1}$ is found, it is reported immediately. Most of the technical work is on patterns in D_k for $1 \leq k < |\Delta| - 1$. Thus, the rest of the discussion primarily focuses on $\delta_1, \delta_2, \ldots, \delta_{|\Delta|-2}$.

Testing candidates. Testing whether a candidate c is still a candidate takes place only when $q = c + \delta_k - 1$ for some $\delta_k \in \Delta$ (so there are only $O(\log m)$ tests per each arrival of a text character). At this point in time, the suffix of T starting at location c is of length δ_k. Notice that for c to end up being an occurrence of some pattern it must be that $T[c..q] \in D_k$. The *text fingerprint* $\phi(T[1..q])$ is the fingerprint of the text up to the last character that has arrived, and is maintained with $O(1)$ space and in $O(1)$ time per character. The *candidate fingerprint* $\phi(T[1..c-1])$ is the fingerprint of the text prefix up to location c. With access to the candidate fingerprint (which we describe below) and the text fingerprint, the algorithm uses the sliding property to compute in constant time the fingerprint $\phi(T[c..q])$, and then tests whether $\phi(T[c..q]) \in F_k$ (thereby testing whether $T[c..q] \in D_k$) via a static hash table.

One almost trivial way of providing access to the candidate fingerprints is to store (in local stream memory) the candidates via a linked list together with some additional $O(1)$ information per candidate to help compute the candidate fingerprint. Unfortunately, the number of candidates could be as large as $\Omega(m)$, and so we cannot afford to store explicit information for each candidate. Instead, we devise a new method for implicitly storing the candidates so that whenever a new text character arrives we can quickly infer which candidates need to be tested (if any), and then quickly extract the candidate fingerprints of the tested candidates. This task is accomplished with the aid of *guiding graphs*.

The guiding graph. For each D_k the algorithm stores a directed edge-weighted graph G_k in shared memory, called a *guiding graph*. In order to simplify the presentation, we focus on a simplified version of the guiding graph. A *pseudo-forest* is an undirected graph where each connected component contains at most one cycle. G_k is a directed pseudo-forest in which the out-degree of each vertex is at most 1. Each edge e in G_k has a weight $w(e)$ and label $\lambda(e)$ such that there exists a non-empty *edge string* S_e where $\lambda(e) = \phi(S_e)$ and $w(e) = |S_e| \geq 1$. For each $P \in D_k$ there is an associated vertex $v_P \in G_k$. The total size of G_k is $O(|D_k|) = O(d)$.

The algorithmic usefulness of G_k is due to a *directed path* (DP) property which captures the combinatorial guarantees given by the guiding graph. We first state a stronger version of the DP property, which unfortunately we do not know how to guarantee as stated. In Section 4 we give a weaker version, which we do know how to guarantee, but the weaker version introduces an extra $O(\log d)$ factor in stream memory.

▶ **Property 1** (Strong Directed Path Property). *Let S be a string where $\delta_k \leq |S| < \delta_{k+1}$, such that the prefix and suffix of S of length δ_k are $P_b, P_e \in D_k$, respectively. Then there exists a single directed path π in G_k from v_b to v_e (which may contain cycles) such that the concatenation of the edge strings for the sequence of edges on π is exactly $S[1..|S| - \delta_k]$, which is the prefix of S until the occurrence of the suffix P_e.*

If $P \in D_k$ is a substring *of S at location h, then the path starting from v_b with total edge weight $h - 1$ must exist and end at v_P, so $v_P \in \pi$[2]. Moreover, for any prefix of π, with total edge weight w, the concatenation of the edge strings on this path prefix is $S[1..w]$.*

The intuition behind the usage of the guiding graph is that the guiding graph cleverly represents all possible linked lists of candidates in the *text interval* $I_k = (q-\delta_{k+1}+1, q-\delta_k+1]$ that can ever be encountered by the algorithm. For a location c in I_k, let the *entrance prefix* of c be $T[c..c + \delta_k - 1]$. Notice that c is a candidate if and only if the entrance prefix of c is some pattern $P \in D_k$. For a candidate c with entrance prefix $P \in D_k$, we denote $v_c = v_P$. Thus, all of the candidates in I_k are the candidates c for which the last verification took place when the character $T[c + \delta_k - 1]$ arrived, and so the entrance prefixes of candidates in I_k are patterns from D_k. Let L be the list of candidates in I_k. Let c_b (c_e) be the first (last) candidate in L, and let $P_b \in D_k$ ($P_e \in D_k$) be the string of length δ_k occurring at location c_b (c_e) in T. Both c_b and c_e are in I_k, and so $c_e - c_b < \delta_{k+1} - \delta_k$. Since $|P_b| = |P_e| = \delta_k$, the substring $S = T[c_b..c_e + |P_e| - 1]$ has P_b and P_e as its prefix and suffix, respectively, and $\delta_k \leq |S| < \delta_{k+1}$. Thus, by the strong DP property, there exists a path π_L in G_k from v_{c_b} to v_{c_e}, and the concatenation of edge strings on π_L is exactly $S[1..|S| - \delta_k] = T[c_b..c_e - 1]$. Moreover, for any candidate c in L we have $v_c \in \pi_L$ and the concatenation of the edge strings on a prefix π_c of π_L from v_{c_b} to v_c is exactly $S[1..c - c_b] = T[c_b..c - 1]$. Being that $T[1..c - 1]$ is the concatenation of $T[1..c_b - 1]$ and $T[c_b..c - 1]$, the candidate fingerprint of c is derivable from the candidate fingerprint of c_b and concatenation of the edge strings on π_c. Thus, if G_k is stored in shared memory, then we are able to recover the candidate fingerprints of all of the candidates in L by storing, in stream memory, a pointer to the beginning and of π_L together with locations c_b, c_e[3], and the fingerprint candidate of c_b. In some sense this feature allows us to access information about the history of the text stream, although this information is not stored explicitly.

Phantom Candidates. While the strong DP property guarantees that every candidate c in L has a corresponding vertex in π_L, the property does not guarantee that every vertex in π_L corresponds to a candidate in L. In particular, let $\pi_L = (v_1, v_2, \ldots, v_x)$ and notice that π_L may contain duplicate vertices (since π_L may contain a cycle). By the strong DP property, if the ordered list of candidates in L is $(c_1, c_2 \ldots, c_y)$ then there exist indices $1 = i_1 < i_2 < \cdots < i_y = x$ such that for all $1 \leq j \leq y$, v_{i_j} corresponds to c_j. However, for

[2] Notice that if π contains a cycle, then there may be several prefixes of π ending at v_P but only one of them can have a specific weight.

[3] The reason for storing c_e is in order to know where π_L ends. This is particularly important when G_k contains a cycle.

every $1 \leq z \leq x$ such that for every $1 \leq j \leq y$, $z \neq i_j$, we have that v_z at location z in the list[4] does not correspond to a candidate in L. This means that the implicit representation of L through π_L may contain irrelevant information.

To overcome this issue, we allow the vertices on π_L that do not correspond to candidates to be considered *as if* they are candidates, which we call *phantom* candidates. A phantom candidate is a text location that failed a test in the past, but now is implicitly considered again because its corresponding vertex lies on a directed path that is implicitly stored via the path's endpoints. A crucial aspect of phantom candidates is that they do *not* affect the complexity bounds or correctness of our algorithm. This will be made clear in the complexity analysis. If c is a phantom candidate due to vertex $v_i \in \pi_L$, we say that $v_c = v_i$.

Updating π_L. If L is empty and a new candidate c enters I_k, then π_L becomes the single vertex v_c. If L is not empty, let c_b and c_e be the first and last candidates in L, respectively. At this time it is possible that c_b is a phantom candidate, but we guarantee that c_e is not. Assume by induction that π_L is currently the path from v_{c_b} to v_{c_e} where the sum of the weights on edges of π_L is $c_e - c_b$.

If a new candidate c enters I_k then by the strong DP property there must exist a path from v_{c_e} to v_c. Moreover, by the strong DP property, the concatenation of edge strings (as seen when traversing π_L) from v_{c_e} to v_c is $T[c_e..c-1]$. Thus, the only change in memory needed for storing π_L is changing the stored location of the last candidate in I_k to be c, which is not a phantom candidate.

If c_b leaves I_k, then v_{c_b} is removed from the beginning of π_L. If c_b was the only candidate in I_k then π_L becomes empty and we are back to the base case. Otherwise, the new first candidate c in I_k is reached by following the single outgoing edge $e = (v_{c_b}, v_c)$ in G_k. By the strong DP property, $c = c_b + w(e)$, and $\phi(T[1..c-1])$ is the fingerprint concatenation of $\phi(T[1..c_b - 1])$ and $\lambda(e)$.

Information stored in shared memory. For each D_k the data structure stores the guiding graph G_k. In addition the data structure stores the fingerprints in F_k via a perfect hash table that maps each fingerprint $\phi(P)$ to the id of P. Since the space usage per each $\delta \in \Delta$ is $O(d)$ words, the total space used in shared memory is $O(d \log m)$ words.

Information stored in stream memory. The algorithm maintains the text fingerprint of the entire text which is the fingerprint of the text up to the last character that has arrived. This information is updated in constant time per each new character arrival, using the sliding property of ϕ.

The algorithm uses a separate data structure for each of the $O(\log m)$ text intervals. The data structure for text interval I_k maintains all the candidates in I_k by storing a pointer to the beginning of π_L, the locations of the first and last candidates in I_k, and the candidate fingerprint of the first candidate.

Thus, the total space usage per each text interval I_k is $O(1)$, and the total amount of stream memory used is $O(\log m)$.

Character Arrival. We now describe the fairly straightforward processing of a new text character. In particular, we show that the algorithm spends $O(1)$ time per text interval each time a text character arrives, for a total of $O(\log m)$ time per character. Let $T[q]$ be

[4] The reason for addressing the index of v_z directly is due to the possibility of cycles.

the new character that arrives to the stream of text T. The algorithm first updates the text fingerprint of T in the stream memory, and if $\phi(T[q-24..q]) \in F_0$ then the algorithm inserts $q-24$ as a candidate into the first text interval (recall that the last 25 characters in the text are dealt with via maintaining their fingerprint for this purpose). The candidate fingerprint for $q-24$ is computed via the sliding window property from the text fingerprint and $\phi(T[q-24..q])$.

For $\delta_k \in \Delta$ the algorithm checks for the existence of a candidate $c = q - \delta_k + 1$ by probing the head of the path for I_k. If so, the algorithm has to (1) test c, (2) remove c from I_k, and (3) if c is still a candidate and $k \leq |\Delta| - 3$ then add c to the data structure for I_{k+1}, while if $k = |\Delta| - 2$ then use $F_{|\Delta|-1}$ to report the id of a pattern occurrence.

To test a candidate $c = q - \delta_k + 1$ the algorithm uses the sliding property of ϕ to compute $\phi(T[c..q])$ from the candidate fingerprint of c (which is stored in stream memory) and the text fingerprint. This takes constant time. We assume from now that c is a candidate. The process for removing a candidate from I_k and adding a candidate to I_{k+1} is described above, and costs $O(1)$ time.

Phantom candidates do not affect complexities and correctness. The treatment of phantom candidates is exactly the same as the treatment of non-phantom candidates since in our algorithm we cannot distinguish between the two. In particular, a location $c = q - \delta_{k+1} + 1$ that was a *phantom* candidate before the last character arrived is tested to see if c is an occurrence of a pattern in D_{k+1}. Since c is a phantom candidate this test **must** fail and c will not be added to the data structure of D_{k+1} (but c could potentially become a phantom candidate again later on). Thus, allowing for phantom candidates does not affect the correctness of the algorithm. Notice that allowing for phantom candidates to exist does not increase the space or time complexities: the space usage is unaffected since the phantom candidates are maintained implicitly within the directed paths, and the time complexity is unaffected since for each arriving character and for each $\delta \in \Delta$, at most one candidate (phantom or not) needs to be considered.

4 Constructing Guiding Graphs

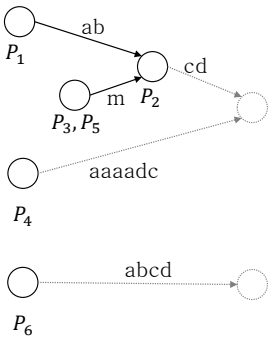
The main technical difficulty is in constructing the guiding graphs. We focus on the construction of the guiding graph for D_k. Recall that $\ell_k = \frac{\delta_k}{5}$ and that the length of every string in D_k is δ_k. A string $P \in D_k$ whose prefix of length $3\ell_k$ appears at least twice in P is said to be of type τ_{pr}, (the "pr" stands for "prefix repetition"). Since the goal here is to convey the main ideas and intuition of how to construct G_k we begin by making a simplifying assumption that there are no strings in D_k of type τ_{pr}. Removing this assumption requires introducing periodicity properties of strings, which we briefly address at the end of this section.

We define the *distance* between two strings $P, P' \in D_k$ to be the smallest possible distance between an occurrence of P and an occurrence of P' in any text. Notice that distances are never negative, and they do not define a metric (P may be at distance 1 from P' and P' may be at distance 1 from P'' but P and P'' might be at distance much larger than 2).

Intuition. The general idea is based on the following observation: if two strings in D_k are within distance at most ℓ_k in the text, then the two strings must share a common substring of length at least $4\ell_k$. However, the converse is not true. That is, not every two strings that share a common substring of length at least $4\ell_k$ have distance at most ℓ_k; see Figure 1.

P_1 = pref**sharedsubstring**suf
P_2 = ef**sharedsubstring**suffi
P_3 = in**sharedsubstring**abcde
P_4 = min**sharedsubstring**abcd
P_5 = abcde**sharedsubstring**xy

Figure 1 An example of strings in the same cluster. Notice that P_1 and P_2 could occur in a text within distance 2. Similarly P_3 and P_4 could occur in a text within distance 1. However, every other pair of strings cannot appear in any text within distance less than 15.



P_1 = abcdxyzxyzxyzxyaab
P_2 = cdxyzxyzxyzxyaabbc
P_3 = mcdxyzxyzxyzxyaabx
P_4 = aaaadcxyzxyzxyzxyx
P_5 = mcdxyzxyzxyzxyxyx
P_6 = abcdxxxxxxxxxxxxba

Figure 2 Examples of tries for clusters of strings of type τ_{npr}.

Nevertheless, we would still benefit from clustering the strings in D_k in a way that guarantees the following two properties: (1) if two strings from D_k are at distance at most ℓ_k then these strings appear in the same cluster, and (2) all of the strings in the same cluster share a common substring (possibly at different locations) of length $3\ell_k$ which we call the *seed* of the cluster. Notice that a string in a cluster may contain more than one occurrence of the seed. In order for seeds to be useful, we require that for a given seed of a cluster and a string P in that cluster, the location of the seed in P is the location of the *first* occurrence of the seed in P.

Given such a clustering, for each cluster separately we construct part of the guiding graph as follows (for an example, see Figure 2). For any pair of strings in the same cluster with distance at most ℓ_k, the algorithm synchronizes the two strings, based on the position of the seed in each one of the strings, as follows. Consider the prefix of each such string up to the occurrence of the seed. Then one of the prefixes must be a suffix of the other prefix. Thus, we consider all of the prefixes of all of the strings in a cluster, where each prefix of a string ends right before the occurrence of the seed in that string. We then construct a compacted trie from the reversal of all of the prefixes and associate each string $P \in D_k$ with the vertex in the trie corresponding to the reverse prefix of P. Each vertex in the trie has a single outgoing edge e to its parent (the root has out-degree 0), and the edge string of e is exactly the string corresponding to that edge in the compacted trie. Let T be a text and let c and c' be any two non-phantom candidates in I_k. Let P and P' be the entrance prefixes of c and c', respectively. The distance between P and P' is at most $c' - c \leq \ell_k$, and so P and P' must be in the same cluster. Moreover, $T[c..(c'-1)]$ corresponds exactly to the concatenation of the labels in the compacted trie on the single path from v_P to $v_{P'}$[5].

[5] Notice that if we were to allow strings of type τ_{pr} then this statement would no longer be true.

4.1 Creating Clusters

We consider two separate cases for the strings in D_k that are not of type τ_{pr}. The first are strings in $P \in D_k$ that have a substring of length $3\ell_k$ that occurs at least twice, but since we do not consider strings from type τ_{pr} then the prefix of P of length $3\ell_k$ does not occur more than once in P. Such strings are said to be of type τ_{npr} (the "npr" stands for "non-prefix repetition"). The second are strings that do not have a substring of length $3\ell_k$ that occurs at least twice. Such strings are said to be of type τ_{nr} (the "nr" stands for "no repetition").

Clustering for type τ_{npr}. Notice that a string P of type τ_{npr} could potentially have several substrings of length $3\ell_k$ such that each one of them appears at least twice in P. In order to remove the ambiguity, we treat the leftmost repeated string of length $3\ell_k$ in P as the *only* one that counts, and call it the *base* of P.

We cluster the strings of type τ_{npr} according to their base. That is, all of the strings in the same cluster have the same base, and this base is the seed of the cluster. Thus, we only need to show that if two strings of type τ_{npr} are at distance at most ℓ_k then these strings appear in the same cluster. The proof that this property holds is based on periodicity properties and is left for the full version.

Clustering for type τ_{nr}. Unfortunately, for type τ_{nr} it is impossible to guarantee both desired clustering properties at the same time. To see this, consider $S_1, S_2, S_3, \ldots, S_7 \in D_k$ and a text that contains all of these 7 strings, where for every $1 \leq i \leq 6$, the occurrence of S_i is exactly $\ell_k - 1$ positions before the occurrence of S_{i+1}. Then based on the properties that we are aiming for, all of these strings must appear in the same cluster. However, it is straightforward to construct such an example in which S_1 and S_7 do not share a single common character.

To solve this problem we modify the definition of guiding graphs by generalizing the definition of v_P for $P \in D_k$, using a weaker version of the DP property, and refining the properties that we require from the clustering. Instead of requiring each $P \in D_k$ to have a single associated vertex v_P, we now allow P to be associated with a set of vertices V_P. Recall that it is possible for a vertex to be associated with more than one string.

▶ **Property 2** (Weak Directed Path Property). *Let S be a string where $\delta_k \leq |S| < \delta_k + \left\lfloor \frac{\ell_k}{\log d} \right\rfloor$, such that the prefix and suffix of S of length δ_k are $P_b, P_e \in D_k$, respectively, where P_b and P_e are of type τ_{nr}. Then there exists $v_b \in V_b$ to $v_e \in V_e$ such that there exists a single directed path π in G_k from v_b to v_e and the concatenation of the edge strings for the sequence of edges on π is exactly $S[1..|S| - \delta_k]$, which is the prefix of S until the occurrence of the suffix P_e.*

If $P \in D_k$ of type τ_{nr} is a substring *of S at location h, then the path starting from v_b with total edge weight $h - 1$ must exist and end at a vertex $v_P \in V_P$, so $v_P \in \pi$. Moreover, for any prefix of π with total edge weight w, the concatenation of the edge strings on this prefix is $S[1..w]$.*

The *strong* DP property refers to strings of distance up to $\delta_{k+1} - \delta_k$, but the *weak* DP property only refers to strings of distance up to $\left\lfloor \frac{\ell_k}{\log d} \right\rfloor \leq \left\lfloor \frac{\delta_{k+1} - \delta_k}{\log d} \right\rfloor$. Thus, the algorithm uses $O(\log d)$ separate paths in order to cover the candidates in I_k which is of length $\delta_{k+1} - \delta_k$. This increases the space usage by a $O(\log d)$ factor, but the time cost remains the same.

Finally, the two properties we require from the clustering for type τ_{nr} are: (1) if two strings of type τ_{nr} are at distance at most $\lfloor \frac{\ell_k}{\log d} \rfloor$ then these strings appear together in *some* cluster, and (2) all of the strings in a cluster share a common seed of length $3\ell_k$. The details for finding such a clustering are non-obvious and are left for the full version.

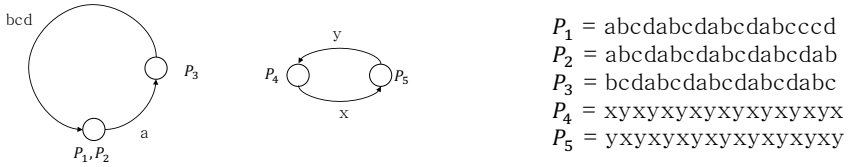


Figure 3 Example of connected components for clusters of pattern prefixes of type τ_{pr}.

Clustering for type τ_{pr}. The general idea for treating strings of type τ_{pr} is based on the following properties. Recall the definition of *base* from the clustering of τ_{npr}. Let $P \in D_k$ be of type τ_{pr}. Notice that Since P is of length $5\ell_k$ and the base of P is of length $3\ell_k$, then the two leftmost occurrences of the base in P (one of which is the prefix of P) must overlap. Denote the location of the second occurrence of the base by $r(P) + 1$. We prove (in the full version) that the prefix of P which ends after the *second* occurrence of the base in P (that is at location $r(P) + 3\ell_k$) must be periodic, and the principal period of this prefix is exactly the prefix $P[1..r(P)]$, which is the prefix of P up to the second occurrence of the base. Using periodicity techniques we are able to prove that for every two strings $P, P' \in D_k$ of type τ_{pr}, if the distance between the strings is at most $\ell_k \geq \delta_{k+1} - \delta_k$, then: (1) $r(P) = r(P')$, and (2) $P[1..r(P')]$ is a cyclic shift of $P'[1..r(P')]$. Thus, we cluster the strings in τ_{pr} such that for every two strings P and P' in the same cluster: (1) $r(P) = r(P')$, and (2) $P[1..r(P')]$ is a cyclic shift of $P'[1..r(P')]$. This will help us guarantee that the *strong* DP property holds. Finally, the cyclic shift naturally defines a directed cycle in G_k which captures the synchronization between the strings in a cluster, see Figure 3. Notice that it is possible that the same string will occur several times in a text at locations in a range shorter than ℓ_k. This case occurs only for strings that have a short period (less than ℓ_k), and is straightforward to show that all of these strings must be of type τ_{pr}. Thus, the cyclic graph description captures the relationship between possible occurrences of such a periodic string in the text, but also leads to the possibility of having a non-simple path represent many candidates.

Combining the three types. For type τ_{nr} we are able to guarantee the weak DP property, while for τ_{npr} and τ_{pr} we are able to guarantee the strong DP property, but for each type separately. That is, for two strings $P, P' \in D_k$ of different types, there is no path in G_k from a vertex corresponding to P to a vertex corresponding to P'. Thus, our algorithm creates a separate instance for each one of the three types, and runs them concurrently. Notice that it is possible for a candidate c to be of one type when c is in I_k and of a different type when c enters I_{k+1}. This is permissable since there are separate graphs for different values of k.

Abstract

We consider the problem of constructing a cyclic listing of all bitstrings of length $2n+1$ with Hamming weights in the interval $[n+1-\ell, n+\ell]$, where $1 \leq \ell \leq n+1$, by flipping a single bit in each step. This is a far-ranging generalization of the well-known middle two levels problem ($\ell = 1$). We provide a solution for the case $\ell = 2$ and solve a relaxed version of the problem for general values of ℓ, by constructing cycle factors for those instances. Our proof uses symmetric chain decompositions of the hypercube, a concept known from the theory of posets, and we present several new constructions of such decompositions. In particular, we construct four pairwise edge-disjoint symmetric chain decompositions of the n-dimensional hypercube for any $n \geq 12$.

1 Introduction

Gray codes are named after Frank Gray, a researcher at Bell Labs, who described a simple method to generate all 2^n bitstrings of length n by flipping a single bit in each step [8], now known as the binary reflected Gray code. This code found widespread use, e.g., in circuit design and testing, signal processing and error correction, data compression, etc.; many more applications are mentioned in the survey [28]. The binary reflected Gray code is also implicit in the well-known *Towers of Hanoi* puzzle and the *Chinese ring* puzzle that date back to the 19th century. The theory of Gray codes has developed considerably in the last decades, and the term is now used more generally to describe an exhaustive listing of any class of combinatorial objects where successive objects in the list differ by a

small amount. In particular, such generation algorithms have been developed for several fundamental combinatorial objects of interest for computer scientists, such as bitstrings, permutations, partitions, trees, etc., all of which are covered in depth in the most recent volume of Knuth's seminal series *The Art of Computer Programming* [20].

Since the discovery of the binary reflected Gray code, there has been continued interest in developing Gray codes for bitstrings of length n that satisfy various additional constraints. For instance, a Gray code with the property that each bit is flipped (almost) the same number of times was first constructed by Tootill [35]. Goddyn and Gvozdjak constructed an n-bit Gray code in which any two flips of the same bit are almost n steps apart [7], which is best possible. These are only two examples of a large body of work on possible Gray code transition sequences; see also [3, 5, 34]. Savage and Winkler constructed a Gray code that generates all 2^n bitstrings such that all bitstrings with Hamming weight k appear before all bitstrings with weight $k+2$, for each $0 \leq k \leq n-2$ [29], where the *Hamming weight* of a bitstring is the number of its 1-bits. They used this construction to tackle the infamous *middle two levels problem*, which asks for a cyclic listing of all bitstrings of length $2n+1$ with weights in the interval $[n, n+1]$ by flipping a single bit in each step. This problem was raised in the 1980s and received considerable attention in the literature (a detailed historic account is given in [22]). A general existence proof for such a Gray code for any $n \geq 1$ has been found only recently [12, 22], and an algorithm for computing it using $\mathcal{O}(1)$ amortized time and $\mathcal{O}(n)$ space was subsequently presented in [23]. The starting point of this work is the following more general problem raised in [13, 27].

▶ **Problem M** (middle 2ℓ levels problem)**.** *For any $n \geq 1$ and $1 \leq \ell \leq n+1$, construct a cyclic listing of all bitstrings of length $2n+1$ with Hamming weights in the interval $[n+1-\ell, n+\ell]$ by flipping a single bit in each step.*

The special case $\ell = 1$ of Problem M is the middle two levels problem mentioned before. The case $\ell = n+1$ is solved by the binary reflected Gray code discussed in the beginning. Moreover, the cases $\ell = n$ and $\ell = n-1$ were settled in [6, 21] and [13], respectively.

A natural framework for studying such Gray code problems is the *n-dimensional hypercube* Q_n, or n-cube for short, the graph formed by all bitstrings of length n, with an edge between any two bitstrings that differ in exactly one bit. The 5-cube is illustrated in Figure 1 (a). The *kth level* of the n-cube is the set of all bitstrings with Hamming weight exactly k. In this terminology, Problem M asks for a Hamilton cycle in the subgraph of the $(2n+1)$-cube induced by the middle 2ℓ levels.

The most general version of this problem is whether the subgraph of the n-cube induced by all levels in an arbitrary weight interval $[a, b]$ has an (almost) Hamilton cycle. This was solved in [11] for all possible values of $n \geq 1$ and $0 \leq a \leq b \leq n$, except in the cases when the length n of the bitstrings is odd and the levels a and b are symmetric around the middle, which is exactly Problem M. For all other cases that paper provides algorithms that generate each bitstring in those Gray codes in constant time.

1.1 Our results

In this work we solve the case $\ell = 2$ of Problem M, i.e., we construct a cyclic listing of all bitstrings of length $2n+1$ with Hamming weights in the interval $[n-1, n+2]$.

▶ **Theorem 1.** *For any $n \geq 1$, the subgraph of the $(2n+1)$-cube induced by the middle four levels has a Hamilton cycle.*

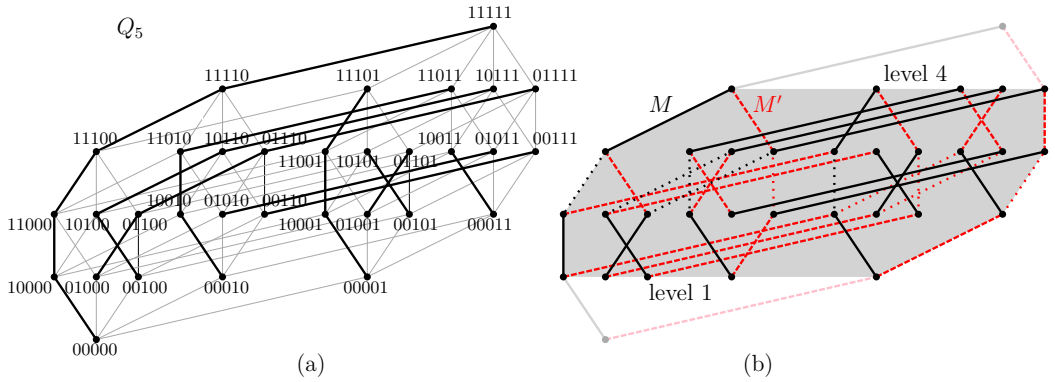

Figure 1 (a) The 5-cube with the (standard) symmetric chain decomposition $\mathcal{D}_0$, where the edges along the chains are highlighted by thick lines. (b) Building a cycle factor through the middle four levels of the 5-cube as explained in the proof of Theorem 2 with SCDs $\mathcal{D} := \mathcal{D}_0$ (black) and $\mathcal{D}' := \overline{\mathcal{D}_0}$ (red). The edges that are removed from $\mathcal{D}$ and $\mathcal{D}'$ are dotted, so the solid and dashed edges are the two matchings M and M' whose union forms the cycle factor. It has three cycles of lengths 4, 4 and 22, visiting all 30 bitstrings with Hamming weight in the interval $[1, 4]$.

Combining Theorem 1 with the results from [11] shows more generally that the subgraph of the n-cube induced by any four consecutive levels has an 'almost' Hamilton cycle.[1]

As another partial result towards Problem M, we show that the subgraph of the $(2n+1)$-cube induced by the middle 2ℓ levels has a cycle factor. A *cycle factor* is a collection of disjoint cycles which together visit all vertices of the graph. In particular, a Hamilton cycle is a cycle factor consisting only of a single cycle. Note here that the existence of a cycle factor for general values of ℓ is not an immediate consequence of Hall's theorem, which is applicable only for $\ell = 1$ and $\ell = n+1$, as only in those cases all vertices of the underlying graph have the same degree.

▶ **Theorem 2.** *For any $n \geq 1$ and $1 \leq \ell \leq n+1$, the subgraph of the $(2n+1)$-cube induced by the middle 2ℓ levels has a cycle factor.*

Our proof of Theorem 2 is concise and illustrative, and it motivates the subsequent discussion, so we present it right now. It uses a well-known concept from the theory of partially ordered sets (posets), a so-called symmetric chain decomposition. Here we define this term for the n-cube using graph-theoretic language. A *symmetric chain* in Q_n is a path $(x_k, x_{k+1}, \ldots, x_{n-k})$ in the n-cube where x_i is from level i for all $k \leq i \leq n-k$, and a *symmetric chain decomposition*, or SCD for short, is a partition of the vertices of Q_n into symmetric chains. For illustration, an SCD of Q_5 is shown in Figure 1 (a). We say that two SCDs are *edge-disjoint* if the corresponding paths in the graph Q_n are edge-disjoint, i.e., if there are no two consecutive vertices in one chain of the first SCD that are also contained in one chain of the second SCD. There is a well-known construction of two edge-disjoint SCDs in the n-cube for any $n \geq 1$ [31], which we will discuss momentarily.

[1] If the four levels are not symmetric around the middle, then this subgraph of the n-cube has two partition classes of different sizes, and thus cannot have a Hamilton cycle. However, it was shown in [11] that in those cases the graph has a cycle that visits all vertices in the smaller partition class, and also a cyclic listing of all vertices in which only few transitions flip two instead of one bit, where 'few' means only as many as the difference in size between the two partition classes. Both of these notions are natural generalizations of a Hamilton cycle.

Figure 2 The parenthesis matching approach for constructing the symmetric chain containing a bitstring x, yielding the symmetric chain decomposition $\mathcal{D}_0$. The highlighted bits are the leftmost unmatched 0 and the rightmost unmatched 1 in each bitstring.

Proof of Theorem 2. The proof is illustrated in Figure 1 (b). Consider two edge-disjoint SCDs $\mathcal{D}$ and $\mathcal{D}'$ in the $(2n+1)$-cube. Let $\mathcal{R}$ and $\mathcal{R}'$ be the chains obtained from $\mathcal{D}$ and $\mathcal{D}'$, respectively, by restricting them to the middle 2ℓ levels, so chains that are longer than $2\ell-1$ get shortened on both sides. As all chains in $\mathcal{R}$ and $\mathcal{R}'$ start and end at symmetric levels and the dimension $2n+1$ is odd, all these paths have odd length (possible lengths are $1, 3, \ldots, 2\ell-1$). Therefore, by taking every second edge on every path from $\mathcal{R}$ and $\mathcal{R}'$, we obtain two perfect matchings M and M' in the subgraph of the $(2n+1)$-cube induced by the middle 2ℓ levels. As the paths in $\mathcal{R}$ and $\mathcal{R}'$ are edge-disjoint, the matchings M and M' are also edge-disjoint. Therefore, the union of M and M' is the desired cycle factor. ◀

This proof motivates the search for a large collection of pairwise edge-disjoint SCDs in the n-cube. We can then use any two of them to construct a cycle factor as described in the previous proof, and use this cycle factor as a starting point for building a Hamilton cycle. This two-step approach of building a Hamilton cycle via a cycle factor proved to be very successful for such problems (see e.g. [15, 16, 17, 18, 22, 24, 30]). Consequently, for the rest of this section we focus on edge-disjoint SCDs in the n-cube.

There is a well-known construction of an SCD for the n-cube that is best described by the following parenthesis matching approach pioneered by Greene and Kleitman [9]; see Figure 2. For any vertex x of the n-cube, we interpret the 0s in x as opening brackets and the 1s as closing brackets. By matching closest pairs of opening and closing brackets in the natural way, the chain containing x is obtained by flipping the leftmost unmatched 0 to move up the chain, or the rightmost unmatched 1 to move down the chain, until no more unmatched bits can be flipped. It is easy to see that this indeed yields an SCD of the n-cube for any $n \geq 1$. We denote this standard SCD by $\mathcal{D}_0$; it is shown in Figure 1 (a) for $n = 5$.

By taking complements, we obtain another SCD, which we denote by $\overline{\mathcal{D}_0}$. It is not hard to see that $\mathcal{D}_0$ and $\overline{\mathcal{D}_0}$ are in fact edge-disjoint for any $n \geq 1$ [31]. Figure 1 (b) shows both SCDs for $n = 5$, and how they are used for building a cycle factor. Apart from this standard construction, we are not aware of any other construction of an SCD in the n-cube, even though there are several different ways to describe the same SCD (see e.g. [1, 4, 36]).

Our next result is a simple construction of another SCD in the n-cube for *even* values of $n \geq 2$, which we call $\mathcal{D}_1$. This construction is based on lattice paths and will be explained in Section 4 below. It has the additional feature that $\mathcal{D}_0$, $\overline{\mathcal{D}_0}$, $\mathcal{D}_1$ and $\overline{\mathcal{D}_1}$ are pairwise edge-disjoint for $n \geq 6$.

▶ **Theorem 3.** *For any even $n \geq 6$, the n-cube contains four pairwise edge-disjoint SCDs.*

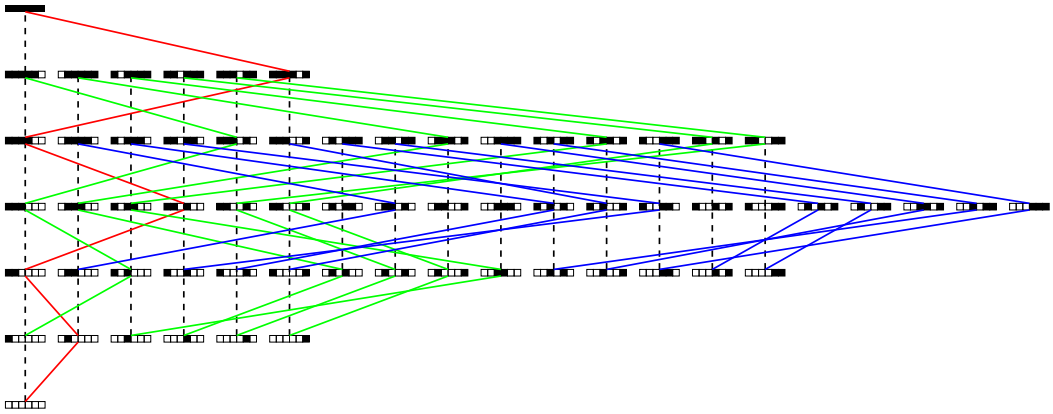

Figure 3 The edge-disjoint SCDs $\mathcal{D}_0$ (dashed vertical paths) and $\mathcal{D}_1$ (solid paths; chains of the same length are drawn with the same color) in the 6-cube. The bitstrings are drawn with white squares representing 0s and black squares representing 1s.

Table 1 Known pairwise edge-disjoint SCDs in the n-cube for $n = 1, 2, \ldots, 11$. The definitions of $\mathcal{X}_5, \mathcal{Y}_5, \mathcal{Z}_5$ and $\mathcal{X}_7, \mathcal{Y}_7$ are given in Section 4.3.

n	1	2	3	4	5	6	7	8	9	10	11
$\lfloor n/2 \rfloor + 1$	1	2	2	3	3	4	4	5	5	6	6
SCDs	$\mathcal{D}_0$	$\mathcal{D}_0, \overline{\mathcal{D}_0}$	$\mathcal{D}_0, \overline{\mathcal{D}_0}$	$\mathcal{D}_0, \overline{\mathcal{D}_0}$, $\mathcal{D}_1$	$\mathcal{X}_5, \mathcal{Y}_5$, $\mathcal{Z}_5$	$\mathcal{D}_0, \overline{\mathcal{D}_0}$, $\mathcal{D}_1, \overline{\mathcal{D}_1}$	$\mathcal{X}_7, \overline{\mathcal{X}_7}$ $\mathcal{Y}_7, \overline{\mathcal{Y}_7}$	$\mathcal{D}_0, \overline{\mathcal{D}_0}$, $\mathcal{D}_1, \overline{\mathcal{D}_1}$	$\mathcal{D}_0, \overline{\mathcal{D}_0}$	$\mathcal{D}_0, \overline{\mathcal{D}_0}$, $\mathcal{D}_1, \overline{\mathcal{D}_1}$	$\mathcal{D}_0, \overline{\mathcal{D}_0}$

Figure 3 shows the SCDs $\mathcal{D}_0$ and $\mathcal{D}_1$ in Q_6. Their complements $\overline{\mathcal{D}_0}$ and $\overline{\mathcal{D}_1}$ are not shown for clarity. Note that four edge-disjoint SCDs are best possible for Q_6, as they use up all edges incident with the middle level.

For odd values of n, we can still construct four edge-disjoint SCDs in the n-cube (except in a few small cases). However, the construction is not as direct and explicit as for even n.

▶ **Theorem 4.** *For $n = 7$ and any odd $n \geq 13$, the n-cube contains four pairwise edge-disjoint SCDs.*

For odd n, we can combine any two of the four edge-disjoint SCDs in the n-cube guaranteed by Theorem 4 to a cycle factor in the middle 2ℓ levels, as explained before, yielding in total $\binom{4}{2} = 6$ distinct cycle factors, four of which are non-isomorphic. To prove Theorem 4, we construct four edge-disjoint SCDs in the 7-cube in an ad hoc fashion and then apply the following product construction.

▶ **Theorem 5.** *If Q_a and Q_b each contain k pairwise edge-disjoint SCDs, then Q_{a+b} contains k pairwise edge-disjoint SCDs.*

Theorem 5 shows in particular that from k edge-disjoint SCDs in a hypercube of fixed dimension n, we obtain k edge-disjoint SCDs for infinitely many larger dimensions $2n, 3n, 4n, \ldots$.

We conjecture that the n-cube has $\lfloor n/2 \rfloor + 1$ pairwise edge-disjoint SCDs, but so far we only know that this holds for $n \leq 7$. Clearly, finding this many edge-disjoint SCDs would be best possible, as they use up all middle edges of the cube. Maximum sets of pairwise edge-disjoint SCDs in the n-cube we found for $n = 1, 2, \ldots, 11$ are shown in Table 1, together with the aforementioned upper bound.

1.2 Related work

Apart from building Gray codes, symmetric chain decompositions have many other interesting applications, e.g., to construct rotation-symmetric Venn diagrams for n sets when n is a prime number [14, 26], and to solve the Littlewood-Offord problem on sums of vectors [2].

A notion that is closely related to edge-disjoint SCDs is that of *orthogonal* chain decompositions, which were first considered by Shearer and Kleitman [31]. Two chain decompositions are called *orthogonal* if every pair of chains has at most one vertex in common, where one also allows chains that are not symmetric around the middle or chains that skip some levels. Shearer and Kleitman showed in their paper that $\mathcal{D}_0$ and $\overline{\mathcal{D}_0}$ are almost orthogonal (only the longest chains have two elements in common), and they conjectured that the n-cube has $\lfloor n/2 \rfloor + 1$ pairwise orthogonal chain decompositions where each decomposition consists of $\binom{n}{\lfloor n/2 \rfloor}$ many chains. Spink recently made some progress towards this conjecture, by showing that the n-cube has three orthogonal chain decompositions [32].

Pikhurko showed via a parenthesis matching argument that all edges of the n-cube can be decomposed into symmetric chains [25]. However, it is not clear whether these chains contain a subset that forms an SCD. Another interesting construction relating Hamilton cycles and SCDs in the n-cube was presented by Streib and Trotter [33]. They inductively construct a Hamilton cycle in the n-cube for any $n \geq 2$ that can be partitioned into symmetric chains forming an SCD. This Hamilton cycle has the minimal number of 'peaks' where the differences in the Hamming weight change sign.

1.3 Outline of this paper

In Section 2 we introduce several definitions that will be used throughout this paper. In Section 3 we sketch the main ideas for proving Theorem 1. The full proof is omitted due to space constraints and can be found in the preprint [10]. In Section 4 we present the proofs of Theorems 3–5, and we describe the construction of the SCD $\mathcal{D}_1$ and of the SCDs in Q_5 and Q_7 referred to in Table 1. We conclude in Section 5 with some open problems.

2 Preliminaries

We begin by introducing some terminology that is used throughout the following sections.

2.1 Bitstrings and lattice paths

We use $L_{n,k}$ to denote the set of all bitstrings of length n with Hamming weight k, so this is exactly the kth level of Q_n. For any bitstring x, we write $\overline{x}$ for its complement and $\mathrm{rev}(x)$ for the reversed bitstring. We often interpret a bitstring x as a path in the integer lattice $\mathbb{Z}^2$ starting at the origin $(0, 0)$, where every 1-bit is interpreted as an $\nearrow$-step that changes the current coordinate by $(+1, +1)$ and every 0-bit is interpreted as a $\searrow$-step that changes the current coordinate by $(+1, -1)$; see Figure 4. Note that for any bitstring x, the inverted bitstring $\overline{x}$ corresponds to mirroring the lattice path horizontally, and the inverted and reversed bitstring $\overline{\mathrm{rev}}(x)$ corresponds to mirroring the lattice path vertically.

2.2 Lexical matchings

We now introduce certain matchings between two consecutive levels of the hypercube, which were first described by Kierstead and Trotter [19]. Originally, these matchings were defined and analyzed for the graph between the middle two levels of the $(2n + 1)$-cube in an attempt

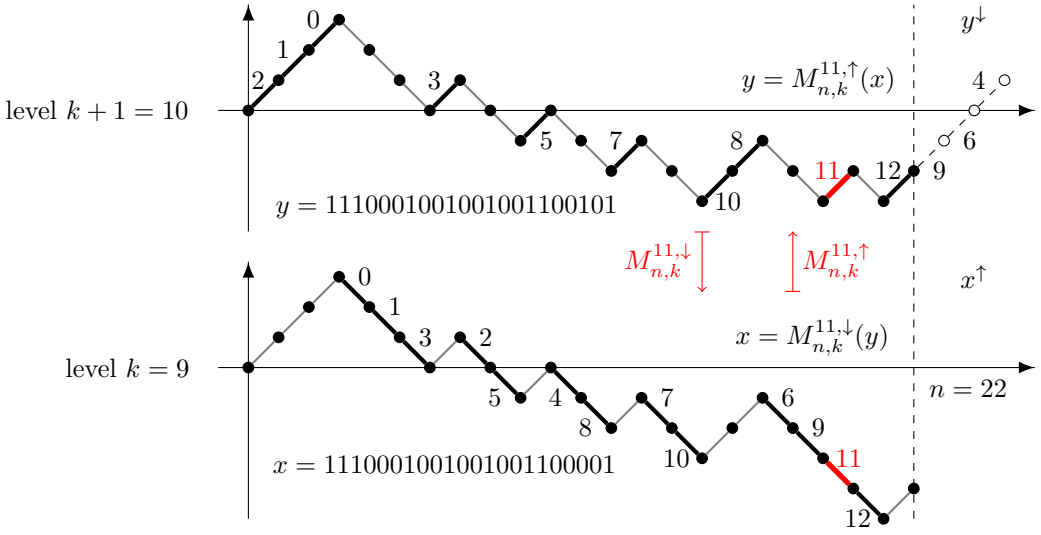

Figure 4 Definition of i-lexical matchings between levels 9 and 10 of Q_{22}, where steps flipped along the i-lexical matching edge are marked with i. Between those two levels, the vertex x is incident with i-lexical matching edges for each $i \in \{0, 1, \ldots, 12\}$, and the vertex y is incident with i-lexical matching edges for each $i \in \{0, 1, \ldots, 12\} \setminus \{4, 6, 9\}$.

to tackle the middle two levels problem. We first generalize them to the n-cube for arbitrary n and an arbitrary pair of consecutive levels k and $k+1$. For $i \in \{0, 1, \ldots, n-1\}$ the *i-lexical matching* is defined as follows; see Figure 4. We interpret a bitstring x as a lattice path, and we let $x^{\uparrow}$ denote the lattice path that is obtained by appending $\searrow$-steps to x until the resulting path ends at height -1. If x ends at a height less than -1, then $x^{\uparrow} := x$. Similarly, we let $x^{\downarrow}$ denote the lattice path obtained by appending $\nearrow$-steps to x until the resulting path ends at height $+1$. If x ends at a height more than $+1$, then $x^{\downarrow} := x$. We define the matching by two partial mappings $M_{n,k}^{i,\uparrow} \colon L_{n,k} \to L_{n,k+1}$ and $M_{n,k}^{i,\downarrow} \colon L_{n,k+1} \to L_{n,k}$ defined as follows: For any $x \in L_{n,k}$ we consider the lattice path $x^{\uparrow}$ and scan it row-wise from top to bottom, and from right to left in each row. The partial mapping $M_{n,k}^{i,\uparrow}(x)$ is obtained by flipping the ith $\searrow$-step encountered in this fashion, where counting starts with $0, 1, \ldots$, if this $\searrow$-step is part of x; otherwise x is left unmatched. Similarly, for any $x \in L_{n,k+1}$ we consider the lattice path $x^{\downarrow}$ and scan it row-wise from top to bottom, and from left to right in each row. The partial mapping $M_{n,k}^{i,\downarrow}(x)$ is obtained by flipping the ith $\nearrow$-step encountered in this fashion if this $\nearrow$-step is part of x; otherwise x is left unmatched. It is straightforward to verify that these two partial mappings are inverse to each other, so they indeed define a matching between levels k and $k+1$ of Q_n, which we denote by $M_{n,k}^{i}$.

The following properties of lexical matchings are direct consequences of these definitions.

▶ **Lemma 6.** *Let $0 \le k \le n-1$ and $l := \max\{k, n-k-1\}$. The lexical matchings defined before have the following properties.*

- **(i)** *For every $0 \le i \le l$, the matching $M_{n,k}^{i}$ saturates all vertices in the smaller of the two levels k and $k+1$.*
- **(ii)** *The matchings $M_{n,k}^{i}$, $i = 0, 1, \ldots, l$, form a partition of all edges of the subgraph of Q_n between levels k and $k+1$.*
- **(iii)** *For every $0 \le i \le l$ we have $\overline{M_{n,k}^{i}} = M_{n,n-k-1}^{l-i}$ and $\mathrm{rev}(M_{n,k}^{i}) = M_{n,k}^{l-i}$. Consequently, we have $\overline{\mathrm{rev}}(M_{n,k}^{i}) = M_{n,n-k-1}^{i}$.*

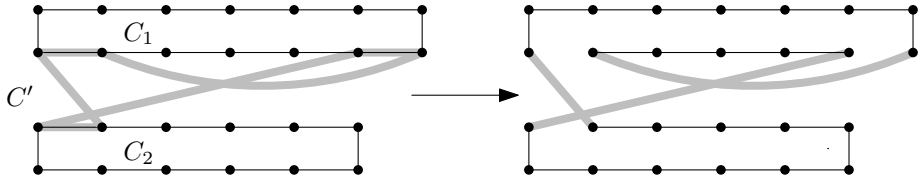

Figure 5 Joining two cycles C_1 and C_2 (black) from our cycle factor by taking the symmetric difference with a 6-cycle C' (gray).

Property (i) holds as in the smaller of the two levels k and $k+1$, no steps are appended to the lattice paths when computing the i-lexical matching between those levels. Property (ii) holds as the vertices in the smaller of the two levels k and $k+1$ have degree $l+1$ and the matchings $M^i_{n,k}$, $i = 0, 1, \ldots, l$, are all disjoint. Property (iii) follows from the observation that complementing a bitstring corresponds to mirroring the lattice path horizontally, and reverting a bitstring corresponds to mirroring the lattice path horizontally and vertically.

3 The middle four levels problem

In this section we outline the main steps for proving Theorem 1. The proof proceeds similarly as the proof of the middle two levels problem [12, 22]. In a first step, we construct a cycle factor in the middle four levels of the $(2n+1)$-cube, and in a second step we modify the cycles in the factor locally to join them to a Hamilton cycle. The cycle factor is constructed by taking the union of the following edge sets: all n-lexical and $(n+1)$-lexical matching edges between the upper two levels $n+1$ and $n+2$ and between the lower two levels $n-1$ and n, as well as certain carefully chosen edges from the $(n-2)$-lexical, the $(n-1)$-lexical, and the n-lexical matching between the middle two levels n and $n+1$. The most technical step here is to choose an appropriate set of edges between the middle two levels, so that the resulting subgraph has degree two at every vertex. When this is accomplished, we define a set of 6-cycles between levels $n+1$ and $n+2$ such that any two of these 6-cycles are edge-disjoint and every such 6-cycle C' intersects with two cycles C_1 and C_2 from our cycle factor as shown in Figure 5. Consequently, taking the symmetric difference of the edge sets of C_1, C_2, and C' results in a single cycle on the same vertex set as C_1 and C_2. We repeat this joining process until we end up with a single Hamilton cycle. In this process, we exploit that all of the 6-cycles used for the joining are edge-disjoint, and that on any cycle of the factor, no pairs of edges that two 6-cycles have in common with this cycle are interleaved, so there are never any conflicts between them. The main advantage of this two-step approach to proving Hamiltonicity is that it effectively reduces the problem of proving that a graph has a Hamilton cycle to the problem of proving that a suitably defined auxiliary graph is connected, which is much easier. All details of this proof can be found in [10].

4 Pairwise edge-disjoint SCDs

We proceed to prove Theorems 3–5.

4.1 Proof of Theorem 3

To prove Theorem 3, we first give an equivalent definition of the SCD $\mathcal{D}_0$ defined in the introduction via the parenthesis matching approach, which is valid only for even values of $n \geq 2$; recall Figure 1 (a) and Figure 2.

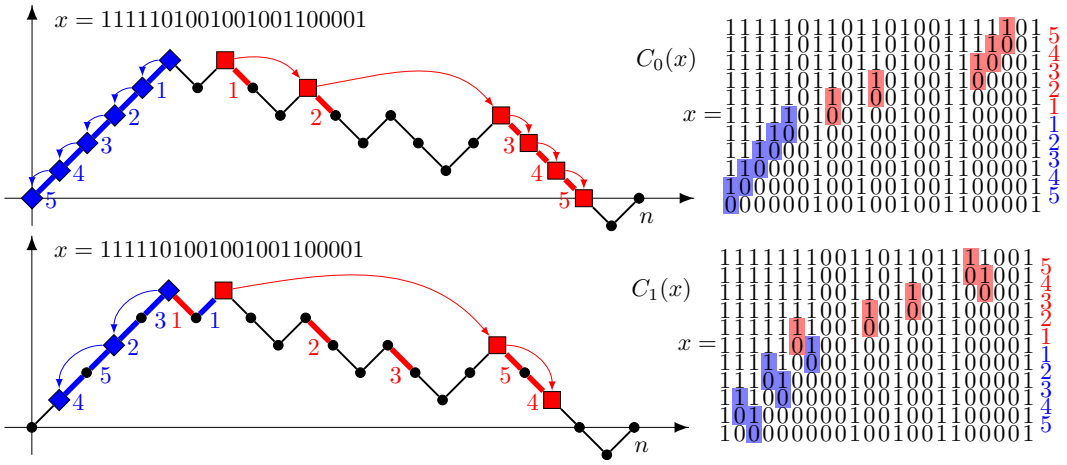

Figure 6 The labeling procedures that define the symmetric chains $C_0(x)$ (top) and $C_1(x)$ (bottom). The markers that define the upward and downward steps of the chains are drawn as a square and a diamond, respectively. The chain $C_0(x)$ is the same as the one shown in Figure 2.

For even $n \geq 2$, we consider a vertex $x \in L_{n,n/2}$ in the middle level $n/2$ of Q_n, and we define the sequence of vertices reached from x when moving up the corresponding chain, and the sequence of vertices reached when moving down the chain. For this we consider the lattice path corresponding to the bitstring x. This lattice path ends at the coordinate $(n, 0)$ as the number of 0s equals the number of 1s. We now label a subsequence of $\searrow$-steps of this lattice path with integers $j = 1, 2, \ldots$ according to the following procedure; see the top part of Figure 6 for an illustration:

(a0) We place a marker at the rightmost highest point of x and set $j := 1$.

(b0) If the marker is at height $h \geq 1$, we label the $\searrow$-step starting at the marker with j, and we move the marker to the starting point of the rightmost $\searrow$-step starting at height $h - 1$. We set $j := j + 1$ and repeat.

(c0) If the marker is at height $h = 0$, we stop.

Flipping the $\searrow$-steps of x marked with $1, 2, \ldots$ in this order yields the sequence of vertices reached from x when moving up the chain containing x. An analogous labeling procedure obtained by interchanging left and right, $\searrow$-steps and $\nearrow$-steps, and starting with ending points yields the sequence of vertices reached from x when moving down this chain. We denote this chain by $C_0(x)$. Observe that $C_0(x)$ is a symmetric chain, as the height of the marker decreases by 1 in each step, so the number of edges we move up from x equals the number of edges we move down from x. It is easy to verify that the SCD $\mathcal{D}_0$ defined before via the parenthesis matching approach satisfies $\mathcal{D}_0 = \bigcup_{x \in L_{n,n/2}} C_0(x)$.

Proof of Theorem 3. We first define a set $\mathcal{D}_1$ of chains in Q_n for even values of $n \geq 2$ via a labeling rule similar to the rule for $\mathcal{D}_0$ described before. From this definition it follows immediately that all chains in $\mathcal{D}_1$ are symmetric. We then use an equivalent characterization of $\mathcal{D}_0$ and $\mathcal{D}_1$ as the unions of certain lexical matchings to show that the chains in $\mathcal{D}_1$ form a partition of all vertices of Q_n, proving that $\mathcal{D}_1$ is an SCD, and that $\mathcal{D}_0$, $\overline{\mathcal{D}_0}$, $\mathcal{D}_1$, and $\overline{\mathcal{D}_1}$ are pairwise edge-disjoint.

For even $n \geq 2$, we consider a vertex $x \in L_{n,n/2}$ in the middle level of Q_n. We interpret it as a lattice path, and label some of its $\searrow$-steps as follows; see the bottom part of Figure 6:

(a1) We place a marker at the rightmost highest point of x and set $j := 1$. If there is a $\searrow$-step to the left of the marker starting at the same height, we label the nearest such step with 1 and set $j := 2$.

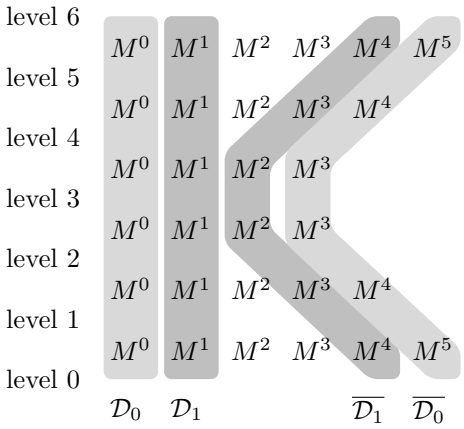

Figure 7 Unions of lexical matchings $M^i = M^i_{n,k}$ yielding edge-disjoint chain decompositions in Q_n for $n = 6$. The resulting chains in $\mathcal{D}_0$ and $\mathcal{D}_1$ in Q_6 are shown in Figure 3.

(b1) If the marker is at height $h \geq 2$, we label the rightmost $\searrow$-step starting at height $h-1$ with j. We consider all $\searrow$-steps starting at height $h-2$ to the right of the labeled step and the $\searrow$-step starting at the marker, we label the second step from the right from this set with $j+1$, and we move the marker to the starting point of the rightmost $\searrow$-step starting at height $h-2$. We set $j := j+2$ and repeat.

(c1) If the marker is at height $h = 1$ or $h = 0$, we stop.

We let $C_1(x)$ denote the chain obtained by flipping bits according to this labeling rule and the corresponding symmetric rule obtained by interchanging left and right, $\searrow$-steps and $\nearrow$-steps, and starting with ending points. Observe that $C_1(x)$ is a symmetric chain, as the height of the marker decreases by 2 in each iteration (and we label two steps in each iteration) and the conditional marking in step (a1) occurs if and only if the highest point of x is unique, so the number of edges we move up from x equals the number of edges we move down from x. At this point it is not clear yet that the chains $C_1(x)$, $x \in L_{n,n/2}$, are disjoint, nor that they cover all vertices of Q_n. This is what we will argue about next, which will prove that

$$\mathcal{D}_1 := \bigcup\nolimits_{x \in L_{n,n/2}} C_1(x) \tag{1}$$

is actually an SCD of Q_n.

By property (i) from Lemma 6, for any sequence $\mathbf{i} := (i_0, i_1, \ldots, i_{n-1})$ of indices $i_k \in \{0, 1, \ldots, \max\{k, n-k-1\}\}$ the union

$$\mathcal{D}_\mathbf{i} := \bigcup\nolimits_{k=0}^{n-1} M^{i_k}_{n,k} \tag{2}$$

is a chain decomposition of Q_n. The resulting chains are not necessarily symmetric, though. From the definitions in Section 2.2 it also follows that $\mathcal{D}_0$ equals the union of the 0-lexical matchings, and that for even $n \geq 2$, $\mathcal{D}_1$ as defined in (1) equals the union of the 1-lexical matchings; formally we have

$$\mathcal{D}_0 = \mathcal{D}_{(0,0,\ldots,0)} = \bigcup\nolimits_{k=0}^{n-1} M^0_{n,k} \quad , \quad \mathcal{D}_1 = \mathcal{D}_{(1,1,\ldots,1)} = \bigcup\nolimits_{k=0}^{n-1} M^1_{n,k} \quad .$$

Consequently, $\mathcal{D}_1$ is indeed a chain decomposition, and by the definition of $\mathcal{D}_1$ via the labeling procedure, all chains in this decomposition are symmetric, so $\mathcal{D}_1$ is indeed an SCD. The fact that $\mathcal{D}_0$, $\overline{\mathcal{D}_0}$, $\mathcal{D}_1$, and $\overline{\mathcal{D}_1}$ are pairwise edge-disjoint can be seen by applying property (iii) from Lemma 6 and by observing that by property (ii), $\mathcal{D}_\mathbf{i}$ and $\mathcal{D}_\mathbf{j}$ as defined in (2) are edge-disjoint if and only if the sequences $\mathbf{i}$ and $\mathbf{j}$ differ in every position; see Figure 7. ◀

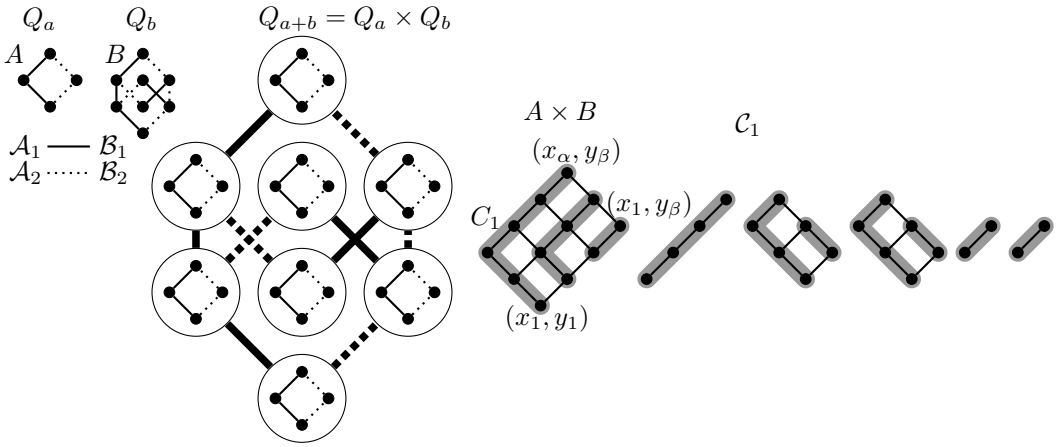

Figure 8 Illustration of the proof of Theorem 5. Construction of two edge-disjoint SCDs in Q_5 from two edge-disjoint SCDs in Q_2 and two edge-disjoint SCDs in Q_3. The chains of the SCD $\mathcal{C}_1$ of Q_5 as constructed in the proof are highlighted in gray.

Clearly, $\mathcal{D}_{(0,0,\ldots,0)}$ as defined in (2) equals $\mathcal{D}_0$ for *every* $n \geq 1$, so the union of all 0-lexical matchings forms an SCD in any dimension. In contrast to that, the union of all 1-lexical matchings $\mathcal{D}_{(1,1,\ldots,1)}$ only forms an SCD for *even* $n \geq 2$.

4.2 Proof of Theorem 5

Proof of Theorem 5. For the reader's convenience, this proof is illustrated in Figure 8. Let $\mathcal{A}_1, \mathcal{A}_2, \ldots, \mathcal{A}_k$ and $\mathcal{B}_1, \mathcal{B}_2, \ldots, \mathcal{B}_k$ denote k pairwise edge-disjoint SCDs of Q_a and Q_b, respectively. We will think of Q_{a+b} as the Cartesian product $Q_a \times Q_b$ of Q_a and Q_b. We show how to construct for every $i \in [k]$ an SCD $\mathcal{C}_i$ of $Q_{a+b} = Q_a \times Q_b$ which uses only edges of the form $((u, v), (u', v'))$ where (u, u') is an edge from $\mathcal{A}_i$ or (v, v') is an edge from $\mathcal{B}_i$. From this it follows that the SCDs $\mathcal{C}_1, \mathcal{C}_2, \ldots, \mathcal{C}_k$ are pairwise edge-disjoint.

The SCD $\mathcal{C}_i$ of Q_{a+b} is defined as follows: The Cartesian products $A \times B$ of chains $A \in \mathcal{A}_i$ and $B \in \mathcal{B}_i$ partition the vertices of Q_{a+b} into two-dimensional grids. $\mathcal{C}_i$ is obtained by partitioning each of those grids into symmetric chains in the natural way; see Figure 8 (cf. [4]): Specifically, let $A =: (x_1, \ldots, x_\alpha)$ and $B =: (y_1, \ldots, y_\beta)$ be the vertices in the chains A and B from bottom to top. As A and B are symmetric, we know that $|x_1| + |x_\alpha| = a$ and $|y_1| + |y_\beta| = b$, where $|x|$ denotes the Hamming weight of the bitstring x. This implies that $|(x_1, y_1)| + |(x_\alpha, y_\beta)| = |x_1| + |y_1| + |x_\alpha| + |y_\beta| = a + b$, i.e., the bottom and top vertex of the grid $A \times B$ are on symmetric levels in Q_{a+b}. We may therefore decompose $A \times B$ into disjoint symmetric chains C_j, $j = 1, 2, \ldots, \min\{\alpha, \beta\}$, by setting

$$C_j := \big((x_1, y_j), (x_2, y_j), \ldots, (x_{\alpha-j+1}, y_j), (x_{\alpha-j+1}, y_{j+1}), \ldots, (x_{\alpha-j+1}, y_\beta)\big) \ . \qquad \blacktriangleleft$$

4.3 Proof of Theorem 4

We begin by constructing the SCDs in Q_5 and Q_7 mentioned in Table 1.

▶ **Lemma 7.** *Q_5 contains three pairwise edge-disjoint SCDs, Q_7 contains four pairwise edge-disjoint SCDs, and this is best possible.*

Proof. We consider the graph Q_n with the two vertices in the outermost levels 0 and n removed, and we identify all bitstrings that differ only by rotation into so-called *necklaces*.

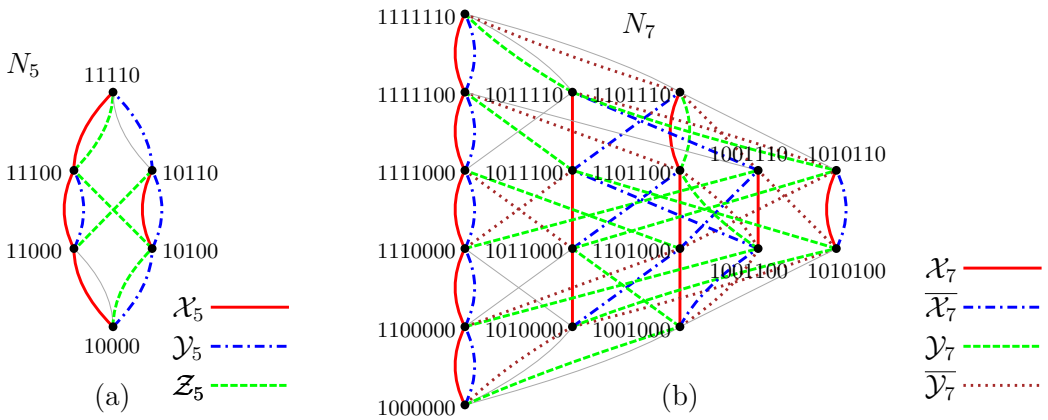

Figure 9 Illustration of the three edge-disjoint SCDs in N_5 (a) and four edge-disjoint SCDs in N_7 (b). The names of the SCDs correspond to the ones used in Table 1.

The resulting graph N_n is a multigraph version of the cover graph of the *necklace poset*. Specifically, the multiplicity of the edges in N_n corresponds to the number of ways a bit from a necklace can be flipped to reach the corresponding adjacent necklace. E.g., in N_5 the necklace $x := 10000$ has two edges leading to $y := 11000$, as we can flip the second or the fifth bit in x to reach y. This way, a necklace on level k has $n-k$ edges going up, and k edges going down, like the vertices in Q_n. The multigraphs N_5 and N_7 are shown in Figure 9. If n is prime, then every SCD in N_n corresponds to an SCD in Q_n, by turning each chain from N_n into n chains in Q_n obtained by rotating a representative of each necklace in all possible ways. Moreover, one of the chains of length $n-2$ needs to be extended by the all-zero and all-one bitstring to a chain of length n in Q_n. Observe that in this way, k edge-disjoint SCDs in N_n give rise to k edge-disjoint SCDs in Q_n.

As $n = 5$ and $n = 7$ are prime, we thus obtain three edge-disjoint SCDs in Q_5 from the SCDs in N_5 shown in Figure 9 (a), and four edge-disjoint SCDs in Q_7 from the SCDs in N_7 shown in Figure 9 (b). These SCDs use up all middle edges, so this is best possible. ◀

Proof of Theorem 4. For $n = 7$ the statement follows from Lemma 7. For odd $n \geq 13$ we apply Theorem 5 to Q_{n-7} and Q_7, using the four edge-disjoint SCDs in Q_{n-7} given by Theorem 3 (note that $n - 7 \geq 6$), and the four edge-disjoint SCDs in Q_7 given by Lemma 7. ◀

5 Open problems

- Understanding the structure of the cycle factors constructed as in the proof of Theorem 2 is an important step towards a general solution of Problem M. We performed some computer experiments in this direction; see [10]. What is the number and length of cycles in these factors? Is there a combinatorial interpretation of those numbers?
- Are there other explicit constructions of SCDs in the n-cube, different from $\mathcal{D}_0$, $\mathcal{D}_1$, and their complements?
- We conjecture that the n-cube has $\lfloor n/2 \rfloor + 1$ pairwise edge-disjoint SCDs. The main difficulty here is that we are missing a simple criterion like Hall's matching condition guaranteeing the existence of an SCD. Even finding five edge-disjoint SCDs in the n-cube for some small fixed n would be interesting, as this solution would extend to infinitely many larger values of n by Theorem 5. Beyond that, it would be very nice to construct more than constantly many edge-disjoint SCDs in the n-cube as n grows.

Abstract

We give a new fpt algorithm testing isomorphism of n-vertex graphs of tree width k in time $2^{k \operatorname{polylog}(k)} \operatorname{poly}(n)$, improving the fpt algorithm due to Lokshtanov, Pilipczuk, Pilipczuk, and Saurabh (FOCS 2014), which runs in time $2^{\mathcal{O}(k^5 \log k)} \operatorname{poly}(n)$. Based on an improved version of the isomorphism-invariant graph decomposition technique introduced by Lokshtanov et al., we prove restrictions on the structure of the automorphism groups of graphs of tree width k. Our algorithm then makes heavy use of the group theoretic techniques introduced by Luks (JCSS 1982) in his isomorphism test for bounded degree graphs and Babai (STOC 2016) in his quasipolynomial isomorphism test. In fact, we even use Babai's algorithm as a black box in one place. We give a second algorithm which, at the price of a slightly worse run time $2^{\mathcal{O}(k^2 \log k)} \operatorname{poly}(n)$, avoids the use of Babai's algorithm and, more importantly, has the additional benefit that it can also be used as a canonization algorithm.

1 Introduction

Already early on in the beginning of research on the graph isomorphism problem (which asks for structural equivalence of two given input graphs) a close connection to the structure and study of the automorphism group of a graph was observed. For example, Mathon [11] argued that the isomorphism problem is polynomially equivalent to the task of computing a generating set for the automorphism group and also to computing the size of the automorphism group.

With Luks's polynomial time isomorphism test for graphs of bounded degree [10], the striking usefulness of group theoretic techniques for isomorphism problems became apparent and they have been exploited ever since (e.g. [2, 12, 15, 13]). In his algorithm, Luks shows and uses that the automorphism group of a connected graph of bounded degree, after a vertex has been fixed, has a very restricted structure. More precisely, the group is in the class Γ_k of all groups whose composition factors are isomorphic to a subgroup of the symmetric group $\mathrm{Sym}(k)$.

Most recently, Babai's quasipolynomial time algorithm for general graph isomorphism [1] adds several novel techniques to tame and manage the groups that may appear as the automorphism group of the input graphs.

A second approach towards isomorphism testing is via decomposition techniques (e.g. [3, 5, 7]). These decompose the graph into smaller pieces while maintaining control of the complexity of the interplay between the pieces. When taking this route it is imperative to decompose the graph in an isomorphism-invariant fashion so as not to compare two graphs that have been decomposed in structurally different ways.

A prime example of this strategy is Bodlaender's isomorphism test [3] for graphs of bounded treewidth. Bodlaender's algorithm is a dynamic programming algorithm that takes into account all k-tuples of vertices that separate the graph, leading to a running time of $\mathcal{O}(n^{k+c})$ to test isomorphism of graphs of tree width at most k.

Only recently, Lokshtanov, Pilipczuk, Pilipczuk, and Saurabh [9] designed a fixed-parameter tractable isomorphism test for graphs of bounded tree width which has a running time of $2^{\mathcal{O}(k^5 \log k)}\,\mathrm{poly(n)}$. This algorithm first "improves" a given input graph G to a graph G^k by adding an edge between every pair of vertices between which more than k pairwise internally vertex disjoint paths exist. The improved graph G^k isomorphism-invariantly decomposes along clique separators into clique-separator free parts, which we will call *basic* throughout the paper. The decomposition can in fact be extended to an isomorphism-invariant tree decomposition into basic parts, as was shown in [4] to design a logspace isomorphism test for graphs of bounded tree width. For the basic parts, Lokshtanov et al. [9] show that, after fixing a vertex of sufficiently low degree, is it possible to compute an isomorphism-invariant tree decomposition whose bags have a size at most exponential in k and whose adhesion is at most $\mathcal{O}(k^3)$. They use this invariant decomposition to compute a canonical form essentially by a brute-force dynamic programming algorithm.

The problem of computing a canonical form is the task to compute, to a given input graph G, a graph G' isomorphic to G such that the output G' depends only on the isomorphism class of G and not on G itself.

The isomorphism problem reduces to the task of computing a canonical form: for two given input graphs we compute their canonical forms and check whether the canonical forms are equal (rather than isomorphic).

As far as we know, computing a canonical form could be algorithmically more difficult than testing isomorphism. It is usually not very difficult to turn combinatorial isomorphism tests into canonization algorithms, sometimes the algorithms are canonization algorithms in the first place. However, canonization based on group theoretic isomorphism tests is more challenging. For example, it is still open whether there is a graph canonization algorithm running in quasipolynomial time.

Our Results

Our main result is a new fpt algorithm testing isomorphism of graphs of bounded tree width.

▶ **Theorem 1.** *There is a graph isomorphism test running in time* $2^{k\,\mathrm{polylog}(k)}\,\mathrm{poly}(n)$*, where* n *is the size and* k *the minimum tree width of the input graphs.*

In the first part of the paper, we analyze the structure of the automorphism group of a graph G of tree width k. Following [9] and [4], we pursue a two-stage decomposition strategy for graphs of bounded tree width, where in the first step we decompose the improved graph along clique separators into basic parts. We observe that these basic parts are essential for understanding the automorphism groups. We show (Theorem 8) that with respect to a fixed vertex v of degree at most k, we can construct for each basic graph H an isomorphism-invariant tree decomposition of width at most $2^{\mathcal{O}(k \log k)}$ and adhesion at most $\mathcal{O}(k^2)$ where, in addition, each bag is equipped with a graph of small degree which is defined in an isomorphism-invariant way and gives us insight about the structure of the bag. In particular, using Luks's results [10], this also restricts the structure of the automorphism group.

Our construction is based on a similar construction of an isomorphism-invariant tree decomposition in [9]. Compared to that construction, we improve the adhesion (that is, the maximum size of intersections between adjacent bags of the decomposition) from $\mathcal{O}(k^3)$ to $\mathcal{O}(k^2)$. More importantly, we expand the decomposition by assigning a group and a graph to each bag.

Using these groups, we can prove that $\mathrm{Aut}(H)_v$ (the group of all automorphisms of H that keep the vertex v fixed) is a Γ_{k+1} group. This significantly restricts possible automorphism groups. Moreover, using the graph structure assigned to each bag, we can also compute the automorphism group of a graph of tree width k within the desired time bounds. The first, already nontrivial step towards computing the automorphism group, is a reduction from arbitrary graphs of tree width k to basic graphs. The second step reduces the problem of computing the automorphism group of a basic graph to the problem of computing the automorphism group of a structure that we call an *expanded d-ary tree*. In the reduction, the parameter d will be polynomially bounded in k. Then as the third step, we can apply a recent result [6] due to the first three authors that allows us to compute the automorphism groups of such expanded d-ary trees. This result is heavily based on techniques introduced by Babai [1] in his quasipolynomial isomorphism test. In fact, it even uses Babai's algorithm as a black box in one place.

We prove a second result that avoids the results of [6, 1] and even allows us to compute canonical forms, albeit at the price of an increased running time.

▶ **Theorem 2.** *There is a graph canonization algorithm running in time $2^{\mathcal{O}(k^2 \log k)} \mathrm{poly}(n)$, where n is the size and k the tree width of the input graph.*

Even though it does not employ Babai's new techniques, this algorithm still heavily depends on the group theoretic machinery. As argued above, the design of group theoretic canonization algorithms often requires extra work, and can be slightly technical, compared to the design of an isomorphism algorithm. Here, we need to combine the group theoretic canonization techniques going back to Babai and Luks [2] with graph decomposition techniques, which poses additional technical challenges and requires new canonization subroutines.

2 Preliminaries

Graphs. We use standard graph notation. All graphs $G = (V, E)$ considered are undirected finite simple graphs. We denote an edge $\{u, v\} \in E$ by uv. Let $U, W \subseteq V$ be subsets of vertices. We write $E(U, W)$ for the edges with one vertex in U and the other vertex from W, whereas $E(U)$ are the edges with both vertices in U. By $N(U)$, we denote the neighborhood of U, i.e., all vertices outside U that are adjacent to U. For the induced subgraph on U, we write $G[U]$, whereas $G - U$ is the induced subgraph on $V \setminus U$. A *rooted graph* is a

triple $G = (V, E, r)$ where $r \in V$ is the *root* of the graph. For two vertices $v, w \in V$ we denote by $\mathrm{dist}_G(v, w)$ the distance between v and w, i.e. the length of the shortest path from v to w. The *depth* of a rooted graph is the maximum distance from a vertex to the root, that is, $\mathrm{depth}(G) = \max_{v \in V} \mathrm{dist}_G(r, v)$. The *forward-degree* of a vertex $v \in V$ is $\mathrm{fdeg}(v) = |\{w \in N(v) \mid \mathrm{dist}(w, r) = \mathrm{dist}(v, r) + 1\}|$. Note that $|V| \leq (d+1)^{\mathrm{depth}(G)}$ where $d = \max_{v \in V} \mathrm{fdeg}(v)$ is the maximal forward-degree.

Separators. A pair (A, B) where $A \cup B = V(G)$ is called a *separation* if $E(A \setminus B, B \setminus A) = \emptyset$. In this case we call $A \cap B$ a *separator*. A separation (A, B) is an (L, R)-*separation* if $L \subseteq A$ and $R \subseteq B$ and in this case $A \cap B$ is called an (L, R)-*separator*. A separation (A, B) is a called a *clique separation* if $A \cap B$ is a clique and $A \setminus B \neq \emptyset$ and $B \setminus A \neq \emptyset$. In this case we call $A \cap B$ a *clique separator*.

Tree Decompositions. A *tree decomposition* of a graph G is a pair (T, β), where T is a rooted tree and $\beta : V(T) \to \mathrm{Pow}(V(G))$ is a mapping into the power set of $V(G)$ such that:

1. for each vertex $v \in V(G)$, the set $\{t \in V(G) \mid v \in \beta(t)\}$ induces a nonempty and connected subtree of T, and
2. for each edge $e \in E(G)$, there exists $t \in V(T)$ such that $e \subseteq \beta(t)$.

Sets $\beta(t)$ for $t \in V(T)$ are called the *bags* of the decomposition, while sets $\beta(s) \cap \beta(t)$ for $st \in E(T)$ are called the *adhesions sets*. The *width* of a tree decomposition T is equal to its maximum bag size decremented by one, i.e. $\max_{t \in V(T)} |\beta(t)| - 1$. The *adhesion width* of T is equal to its maximum adhesion size, i.e. $\max_{st \in E(T)} |\beta(s) \cap \beta(t)|$. The *tree width* of a graph, denoted by $\mathrm{tw}(G)$, is equal to the minimum width of its tree decompositions.

A graph G is k-*degenerate* if every subgraph of G has a vertex with degree at most k. It is well known that every graph of tree width k is k-degenerate.

Groups. For a function $\phi \colon V \to V'$ and $v \in V$ we write v^ϕ for the image of v under ϕ, that is, $v^\phi = \phi(v)$. We write composition of functions from left to right, e.g, $v^{(\sigma\rho)} = (v^\sigma)^\rho = \rho(\sigma(v))$. By $[t]$ we denote the set of natural numbers from 1 to t. By $\mathrm{Sym}(V)$ we denote the symmetric group on a set V and we also write $\mathrm{Sym}(t)$ for $\mathrm{Sym}([t])$. We use upper case Greek letters $\Delta, \Phi, \Gamma, \Theta$ and Ψ for permutation groups.

Labeling cosets. A *labeling coset* of a set V is a set of bijective mappings $\tau\Delta$ where τ is a bijection from V to $[|V|]$ and Δ is a subgroup of $\mathrm{Sym}(|V|)$. By $\mathrm{Label}(V)$, we denote the labeling coset $\tau\,\mathrm{Sym}(|V|)$. We say that $\tau\Delta$ is a *labeling subcoset* of a labeling coset $\rho\Theta$, written $\tau\Delta \leq \rho\Theta$, if $\tau\Delta$ is a subset of $\rho\Theta$ and $\tau\Delta$ forms a labeling coset again. Sometimes we will choose a single symbol to denote a labeling coset $\tau\Delta$. For this will usually use the Greek letter Λ. Recall that Γ_k denotes the class of all finite groups whose composition factors are isomorphic to subgroups of $\mathrm{Sym}(k)$. Let $\widetilde{\Gamma}_k$ be the class of all labeling cosets $\Lambda = \tau\Delta$ such that $\Delta \in \Gamma_k$.

Orderings on sets of natural numbers. We extend the natural ordering of the natural numbers to finite sets of natural numbers. For two such sets M_1, M_2 we define $M_1 \prec M_2$ if $|M_1| < |M_2|$ or if $|M_1| = |M_2|$ and the smallest element of $M_1 \setminus M_2$ is smaller than the smallest element of $M_2 \setminus M_1$.

Isomorphisms. In this paper we will always define what the isomorphisms between our considered objects are. But this can also be done in a more general context. Let $\phi : V \to V'$. For a vector $(v_1, \dots, v_k)$ we define $(v_1, \dots, v_k)^\phi$ as $(v_1^\phi, \dots, v_k^\phi)$ inductively. Analogously, for a set we define $\{v_1, \dots, v_n\}^\phi$ as $\{v_1^\phi, \dots, v_n^\phi\}$. For a labeling coset $\Lambda \leq \mathrm{Label}(V)$ we write Λ^ϕ for $\phi^{-1}\Lambda$. In the paper we will introduce isomorphisms $\mathrm{Iso}(X, X')$ for various objects X and X'. Unless otherwise stated these are all $\phi : V \to V'$ such that $X^\phi = X'$ where we apply ϕ as previously defined. For example, the isomorphism between two graphs G and G' are all $\phi : V \to V'$ such that $G^\phi = G'$ which means that G has an edge uv, if and only if G' has the edge $u^\phi v^\phi$.

3 Clique separators and improved graphs

To perform isomorphism tests of graphs of bounded tree width, a crucial step in [9] is to deal with clique separators. For this step the concept of a k-improved graph is the key.

▶ **Definition 3** ([9]). The *k-improvement* of a graph G is the graph G^k obtained from G by connecting every pair of non-adjacent vertices v, w for which there are more than k pairwise internally vertex disjoint paths connecting v and w. We say that a graph G *is k-improved* when $G^k = G$.

A graph is *k-basic* if it is k-improved and does not have any separating cliques. In particular, a k-basic graph is connected.

We summarize several structural properties of G^k.

▶ **Lemma 4** ([9]). *Let G be a graph and $k \in \mathbb{N}$.*

1. *The k-improvement G^k is k-improved, i.e., $(G^k)^k = G^k$.*
2. *Every tree decomposition (T, β) of G of width at most k is also a tree decomposition of G^k.*
3. *There exists an algorithm that, given G and k, runs in $\mathcal{O}(k^2 n^3)$ time and either correctly concludes that $\mathrm{tw}(G) > k$, or computes G^k.*

Since the construction of G^k from G is isomorphism-invariant, the concept of the improved graph can be exploited for isomorphism testing and canonization. A k-basic graph has severe limitations concerning its structure as we explore in the following sections. In the canonization algorithm from [9] a result of Leimer [8] is exploited that says that every graph has a tree decomposition into clique-separator free parts, and the family of bags is isomorphism-invariant. While it is usually sufficient to work with an isomorphism-invariant set of bags (see [14]) we actually require an isomorphism invariant decomposition, which can indeed be obtained.

▶ **Theorem 5** ([8],[4]). *There is an algorithm that, given a connected graph G, computes a tree decomposition (T, β) of G, called clique separator decomposition, with the following properties.*

1. *For every $t \in V(T)$ the graph $G[\beta(t)]$ is clique-separator free (and in particular connected).*
2. *Each adhesion set of (T, β) is a clique.*
3. *$|V(T)| \in \mathcal{O}(|V(G)|)$.*
4. *For each bag $\beta(t)$ the adhesion sets of the children are all equal to $\beta(t)$ or the adhesion sets of the children are all distinct.*

The algorithm runs in polynomial time and the output of the algorithm is isomorphism-invariant (w.r.t. G).

4 Decomposing basic graphs

In this section, we shall construct bounded-width tree decompositions of k-basic graphs of tree width at most k. Crucially, these decompositions will be isomorphism-invariant after fixing one vertex of the graph. Our construction refines a similar construction of [9].

Let us define three parameters c_{S}, c_{M}, and c_{L} (small, medium and large) that depend on k: $c_{\mathrm{S}} \coloneqq 6(k+1) \in \mathcal{O}(k)$, $c_{\mathrm{M}} \coloneqq c_{\mathrm{S}}+c_{\mathrm{S}}(k+1) \in \mathcal{O}(k^2)$ and $c_{\mathrm{L}} \coloneqq c_{\mathrm{M}}+2(k+1)\binom{c_{\mathrm{M}}}{k+2}^2 \in 2^{\mathcal{O}(k \log k)}$.

The interpretation of these parameters is that c_{M} will bound the size of the adhesion sets and c_{L} will bound the bag size. The parameter c_{S} is used by the algorithm which in certain situations behaves differently depending on sets being larger than c_{S} or not.

The bound $c_{\mathrm{M}} \in \mathcal{O}(k^2)$ improves the corresponding bound $c_{\mathrm{M}} \in \mathcal{O}(k^3)$ in [9]. However, the more significant extension of the construction in [9] is that in addition to the tree decomposition we also construct both an isomorphism-invariant graph of bounded forward-degree and depth and an isomorphism-invariant Γ_{k+1}-group associated with each bag.

The *weight* of a set $S \subseteq V(G)$ with respect to a (weight) function $w : V(G) \to \mathbb{N}$ is $\sum_{v \in S} w(v)$. The *weight* of a separation (A, B) is the weight of its separator $A \cap B$. For sets $L, R \subseteq V(G)$, among all (L, R)-separations (A, B) of minimal weight there exists a unique separation with an inclusion minimal A. For this separation we call $A \cap B$ the *leftmost minimal separator* and denote it by $S_{L,R}(w)$. Moreover, we define $S_{L,R} = S_{L,R}(\mathbf{1})$ where $\mathbf{1}$ denotes the function that maps every vertex to 1.

For $U \subseteq V(G)$ we define a weight function $w_{U,k}$ such that $w_{U,k}(u) = k$ for all $u \in U$ and $w_{U,k}(v) = 1$ for all $v \in V \setminus U$. Given a weight function w, using Menger's theorem and the Ford-Fulkerson algorithm it is possible to compute $S_{L,R}(w)$. The following lemma generalizes Lemma 3.2 of [9]. Through this generalization we obtain the adhesion bound $\mathcal{O}(k^2)$ for our decomposition.

▶ **Lemma 6.** *Let G be a graph, let $S \subseteq V(G)$ be a subset of vertices, and let $\{T_i \subseteq V(G)\}_{i \in [t]}$ and $\{w_i : V(G) \to \mathbb{N}\}_{i \in [t]}$ be families where each T_i is a minimum weight (L_i, R_i)-separator with respect to w_i for some $L_i, R_i \subseteq S$. Let $w : V(G) \to \mathbb{N}$ be another weight function such that for all $i \in [t]$:*

1. *$w(v) = w_i(v)$ for all $v \in V(G) \setminus S$, and*
2. *$w(v) \geq w_i(v)$ for all $v \in V(G)$.*

Let $D \coloneqq S \cup \bigcup_{i \in [t]} T_i$. Suppose that Z is the vertex set of any connected component of $G - D$. Then $w(N(Z)) \leq w(S)$.

The lemma can be used to extend a set of vertices S that is not a clique separator to a set D in an isomorphism-invariant fashion while controlling the size of the adhesion sets of the components of $G - D$. It will be important for us that we can also extend a labeling coset of S to a labeling coset of D and furthermore construct a graph of bounded forward-degree and depth associated with D and S.

▶ **Lemma 7.** *Let $k \in \mathbb{N}$ and let G be a graph that is k-improved. Let $S \subseteq V(G)$ and let $\Lambda \leq \mathrm{Label}(S)$ be a labeling coset such that*

1. *$\emptyset \subsetneq S \subsetneq V(G)$,*
2. *$|S| \leq c_M$,*
3. *S is not a clique,*
4. *$G - S$ is connected,*
5. *$S = N_G(V(G) \setminus S)$, and*
6. *$\Lambda \in \widetilde{\Gamma}_{k+1}$.*

There is an algorithm that either correctly concludes that $tw(G) > k$, or finds a proper superset D of S and a labeling coset $\widehat{\Lambda} \leq \mathrm{Label}(D)$ and a connected rooted graph H with the following properties:

(A) $D \supsetneq S$,
(B) $|D| \leq c_L$,
(C) $\widehat{\Lambda} \in \widetilde{\Gamma}_{k+1}$,
(D) *if Z is the vertex set of any connected component of $G - D$, then $|N(Z)| \leq c_M$,*
(E) $D \subseteq V(H)$, $\operatorname{depth}(H) \leq k+3$ *and* $\operatorname{fdeg}(v) \in k^{\mathcal{O}(1)}$ *for all* $v \in V(H)$.

The algorithm runs in time $2^{\mathcal{O}(k \log k)}|V(G)|^{\mathcal{O}(1)}$ and the output $(D, \widehat{\Lambda}, H)$ is isomorphism-invariant (w.r.t. the input data G, S, Λ and k).

Here, the output of an algorithm $\mathcal{A}$ is isomorphism-invariant if all isomorphisms between two input data (G, S, Λ, k) and (G', S', Λ', k') extend to an isomorphism between the output $(D, \widehat{\Lambda}, H)$ and $(D', \widehat{\Lambda}', H')$ (an isomorphism between (G, S, Λ, k) and (G', S', Λ', k') is a mapping $\phi : V(G) \to V(G')$ such that $(G, S, \Lambda, k)^\phi = (G', S', \Lambda', k')$ where we apply ϕ as defined in the preliminaries).

Proof. We consider two cases depending on the size of S.

Case $|S| \leq c_S$: Let $\mathcal{I} := \{(\{x\}, \{y\}) \mid x, y \in S, x \neq y, xy \notin E(G)\}$ and let $D = S \cup \bigcup_{(L,R)\in\mathcal{I}} S_{L,R}(w_{L\cup R, k+1})$. We set $w := w_{S,k+1}$ and then we have the following for every vertex set Z of a connected component of $G - D$ by Lemma 6.

$$|N(Z)| \leq w(N(Z)) \overset{6}{\leq} w(S) \leq c_S(k+1) \leq c_M.$$

For every $xy \notin E(G)$ there is a $(\{x\}, \{y\})$-separator of size at most k disjoint from $\{x, y\}$, because G is k-improved. Thus $|D| \leq |S| + k|S|^2 \leq c_S + kc_S^2 \leq c_L$. Moreover, since $G - S$ is connected and $S = N_G(V(G) \setminus S)$, for all distinct $x, y \in S$ every minimum weight $(\{x\}, \{y\})$-separator contains a vertex that is not in S. It follows that $D \neq S$.

Case $c_S < |S| \leq c_M$: Let $\mathcal{I} := \{(L, R) \mid |L| = |R| \leq k+2, |S_{L,R}| \leq k+1\}$ and $D = S \cup \bigcup_{(L,R)\in\mathcal{I}} S_{L,R}$.

The properties of D follow from similar arguments as in the first case. The fact that $\mathcal{I}$ is nonempty follows from the existence of a *balanced* separation (for details see [9]). Next, we show how to find $\widehat{\Lambda}$ in both cases. To each $x \in D \setminus S$ we associate the set $A_x := \{(L, R) \in \mathcal{I} \mid x \in S_{L,R}\}$. Two vertices x and y occur in exactly the same separators if $A_x = A_y$. In this case we call them equivalent and write $x \equiv y$. Let $A_1, \ldots, A_t \subseteq D \setminus S$ be the equivalence classes of "$\equiv$". Since each x is contained in some separator of size at most $k+1$ we conclude that the size of each A_i is at most $k+1$.

For each labeling $\lambda \in \operatorname{Label}(S)$ we choose an extension $\widehat{\lambda} : D \to \{1, \ldots, |D|\}$ such that $\widehat{\lambda}|_S = \lambda$ and for $x, y \in D \setminus S$ we have $x^{\widehat{\lambda}} < y^{\widehat{\lambda}}$ if $A_x^\lambda \prec A_y^\lambda$. (Recall that $\prec$ is the linear order of subsets of $\mathbb{N}$ as defined in the preliminaries). Inside each equivalence class A_i, the ordering is chosen arbitrarily. Define $\widehat{\Lambda} := (\{\mathrm{id}_S\} \times \operatorname{Sym}(A_1) \times \ldots \times \operatorname{Sym}(A_t)) \cdot \{\widehat{\lambda} \mid \lambda \in \Lambda\} \leq \operatorname{Label}(D)$. By construction the coset $\widehat{\Lambda}$ does not depend on the choices of the extensions $\widehat{\lambda}$. Since $|A_i| \leq k+1$ for all $1 \leq i \leq t$ we conclude that $\widehat{\Lambda} \in \widetilde{\Gamma}_{k+1}$, as desired.

It remains to explain how to efficiently compute $\widehat{\Lambda}$. For this we simply remark that it suffices to use a set of extensions $M \subseteq \Lambda$ such that Λ is the smallest coset containing all elements of M (i.e., we can use a coset analogue of a generating set). We conclude that $\widehat{\Lambda}$ can be computed in polynomial time in the size of $\mathcal{I}$.

Last but not least, we show how to construct the graph H. The Case $|S| \leq c_S$ is easy to handle. In this case we define H as the complete graph on the set $D \cup \{r\}$ where r is some new vertex, which becomes the root of H. The forward-degree of r is bounded by $|D|$ which in turn is bounded by $k^{\mathcal{O}(1)}$. We consider the Case $c_S < |S| \leq c_M$. We define $V(H) := \{(L, R) \mid L, R \subseteq S, |L| = |R| \leq k+2\} \cup D$. Clearly, we have $\mathcal{I} \subseteq V(H)$. For the root we choose $(\emptyset, \emptyset) \in V(H)$. We define the edges $E(H) := \{(L, R)(L', R') \mid L \subseteq L', R \subseteq R', |L| +$

$1 = |R|+1 = |L'| = |R'|\} \cup \{x(L,R) \mid x \in D, x \in S_{L,R}, (L,R) \in \mathcal{I}\}$. Since for each pair (L,R) there are at most $|S|^2$ different extensions (L',R') with $|L|+1 = |R|+1 = |L'| = |R'|$ and since each separator $S_{L,R}$ contains at most $k+1$ vertices, we conclude that the forward-degree of each vertex in H is bounded by $|S|^2+k+1 \in k^{\mathcal{O}(1)}$. The depth of H is at most $k+3$. ◀

A *labeled tree decomposition* (T,β,α,η) is a 4-tuple where (T,β) is a tree decomposition and α is a function that maps each $t \in V(T)$ to a labeling coset $\alpha(t) \leq \text{Label}(\beta(t))$ and η is a function that maps each $t \in V(T)$ to a graph $\eta(t)$.

The previous lemma can be used as a recursive tool to compute our desired isomorphism-invariant labeled tree decomposition.

▶ **Theorem 8.** *Let $k \in \mathbb{N}$ and let G be a k-basic graph and let v be a vertex of degree at most k. There is an algorithm that either correctly concludes that $\text{tw}(G) > k$, or computes a labeled tree decomposition (T,β,α,η) with the following properties.*

1. *the width of (T,β) is bounded by c_L,*
2. *the adhesion width of (T,β) is bounded by c_M,*
3. *the degree of T is bounded by kc_L^2 and the number of children of t with common adhesion set is bounded by k for each $t \in V(T)$,*
4. *$|V(T)|$ is bounded by $\mathcal{O}(|V(G)|)$,*
5. *for each bag $\beta(t)$ the adhesion sets of the children are all equal to $\beta(t)$ or the adhesion sets of the children are all distinct. In the former case the bag size is bounded by c_M,*
6. *for each $t \in V(T)$ the graph $\eta(t) = H_t$ is a connected rooted graph such that $\beta(t) \cup \beta(t)^2 \subseteq V(H_t)$ and for each adhesion set S there is a corresponding vertex $S \in V(H_t)$, $\text{depth}(H_t) \in \mathcal{O}(k)$ and $\text{fdeg}(v) \in k^{\mathcal{O}(1)}$ for all $v \in V(H_t)$, and*
7. *$\alpha(t) \in \widetilde{\Gamma}_{k+1}$.*

The algorithm runs in time $2^{\mathcal{O}(k^2 \log k)}|V(G)|^{\mathcal{O}(1)}$ and the output (T,β,α,η) of the algorithm is isomorphism invariant (w.r.t. G, v and k). Furthermore, if we drop Property 7 as a requirement, the triple (T,β,η) can be computed in time $2^{\mathcal{O}(k \log k)}|V(G)|^{\mathcal{O}(1)}$.

Here, the output of an algorithm $\mathcal{A}$ is isomorphism-invariant, if all isomorphisms between two input data extend to an isomorphism between the output. More precisely, an isomorphism $\phi \in \text{Iso}((G,v,k),(G',v',k'))$ extends to an isomorphism between (T,β,α,η) and $(T',\beta',\alpha',\eta')$ if there is a bijection between the tree decompositions $\phi_T : V(T) \to V(T')$ and for each node $t \in V(T)$ a bijection between the vertices of graphs $\phi_t : V(\eta(t)) \to V(\eta'(\phi_T(t)))$ which extends ϕ, i.e. $\phi_t(x) = x^\phi$ for all $x \in \beta(t) \cup \beta(t)^2 \cup 2^{\beta(t)}$ where we naturally apply ϕ as defined in the preliminaries. Furthermore, these extensions define an isomorphism between the output data, i.e. for all nodes $t \in V(T)$ we have that $\beta(t)^\phi = \beta'(\phi_T(t))$, $\alpha(t)^\phi = \alpha'(\phi_T(t))$ and $\eta(t)^{\phi_t} = \eta'(\phi_T(t))$.

▶ Remark. We later use the isomorphism-invariance of the labeled tree decomposition (T,β,α,η) from the previous theorem in more detail. Let $t \in V(T)$ be a non-root node and let $S \subseteq V(G)$ be the adhesion set to the parent node of t and let $I_t = (T_t,\beta_t,\alpha_t,\eta_t)$ be the decomposition of the subtree rooted at t and G_t the graph corresponding to I_t. Then η_t is isomorphism-invariant w.r.t. T_t, β_t, G_t and S.

5 Coset-Hypergraph-Isomorphism

After having computed isomorphism-invariant tree decompositions in the previous sections we now want to compute the set of isomorphisms from one graph to another in a bottom up fashion. Let G_1, G_2 be the two input graphs and suppose we are given isomorphism-invariant

tree decompositions (T_1, β_1) and (T_2, β_2). For a node $t \in V(T_i)$ we let $(G_i)_t$ be the graph induced by the union of all bags contained in the subtree rooted at t. The basic idea is to compute for all pairs $t \in V(T_1), t' \in V(T_2)$ the set of isomorphisms from $(G_1)_t$ to $(G_2)_{t'}$ (in addition the isomorphisms shall also respect the underlying tree decomposition) in a bottom up fashion.

The purpose of this section is to give an algorithm that solves this problem at a given bag (assuming we have already solved the problem for all pairs of children of t and t'). Let us first give some intuition for this task. Suppose we are looking for all bijections from $\beta_1(t)$ to $\beta_2(t')$ that can be extended to an isomorphism from $(G_1)_t$ to $(G_2)_{t'}$. Let $t_1, \dots, t_\ell$ be the children of t and $t'_1, \dots, t'_\ell$ the children of t'. Then we essentially have to solve the following two problems. First, we have to respect the edges appearing in the bags $\beta_1(t)$ and $\beta_2(t')$. But also, every adhesion set $\beta(t) \cap \beta(t_i)$ has to be mapped to another adhesion set $\beta(t') \cap \beta(t'_j)$ in such a way that the corresponding bijection (between the adhesion sets) extends to an isomorphism from $(G_1)_{t_i}$ to $(G_2)_{t'_j}$. In order to solve this problem we first consider the case in which the adhesion sets are all distinct and define the following abstraction.

An instance of *coset-hypergraph-isomorphism* is an 8-tuple $\mathcal{I} = (V_1, V_2, \mathcal{S}_1, \mathcal{S}_2, \chi_1, \chi_2, \mathcal{F}, \mathfrak{f})$ such that

1. $\mathcal{S}_i \subseteq \mathrm{Pow}(V_i)$,
2. $\chi_i \colon \mathcal{S}_i \to \mathbb{N}$ is a coloring,
3. $\mathcal{F} = \{\Theta_S \leq \mathrm{Sym}(S) \mid S \in \mathcal{S}_1\}$, and
4. $\mathfrak{f} = \{\tau_{S_1,S_2} \colon S_1 \to S_2 \mid S_1 \in \mathcal{S}_1, S_2 \in \mathcal{S}_2 \text{ such that } \chi_1(S_1) = \chi_2(S_2)\}$ such that
   a. every $\tau_{S_1,S_2} \in \mathfrak{f}$ is bijective, and
   b. for every color $i \in \mathbb{N}$ and every $S_1, S'_1 \in \chi_1^{-1}(i)$ and $S_2, S'_2 \in \chi_2^{-1}(i)$ and $\theta \in \Theta_{S_1}, \theta' \in \Theta_{S'_1}$ it holds that

$$\theta \tau_{S_1,S_2} (\tau_{S'_1,S_2})^{-1} \theta' \tau_{S'_1,S'_2} \in \Theta_{S_1} \tau_{S_1,S'_2}. \tag{N}$$

The instance is *solvable* if there is a bijective mapping $\phi \colon V_1 \to V_2$ such that

1. $S \in \mathcal{S}_1$ if and only if $S^\phi \in \mathcal{S}_2$ for all $S \in \mathrm{Pow}(V_1)$,
2. $\chi_1(S) = \chi_2(S^\phi)$ for all $S \in \mathcal{S}_1$, and
3. for every $S \in \mathcal{S}_1$ it holds that $\phi|_S \in \Theta_S \tau_{S,S^\phi}$.

In this case we call ϕ an *isomorphism* of the instance $\mathcal{I}$. Moreover, let $\mathrm{Iso}(\mathcal{I})$ be the set of all isomorphisms of $\mathcal{I}$. Observe that property (N) describes a consistency condition: if we can use σ_1 to map S_1 to S_2, σ_2 to map S'_1 to S_2, and σ_3 to map S'_1 to S'_2, then the mapping $\sigma_1 \sigma_2^{-1} \sigma_3$ can be used to map S_1 to S'_2. As a result the set of all isomorphisms of the instance $\mathcal{I}$ forms a coset, that is $\mathrm{Iso}(\mathcal{I}) = \Theta\phi$ for some $\Theta \leq \mathrm{Sym}(V_1)$ and $\phi \in \mathrm{Iso}(\mathcal{I})$.

In the application in the main recursive algorithm, the sets $V_i = \beta(t_i)$, the hyperedges $\mathcal{S}_i$ are the adhesion sets of t_i (and we will also encode the edges appearing in the bag in this way), and the cosets $\Theta_{S_1} \tau_{S_1,S_2}$ tell us which mappings between the adhesion sets S_1 and S_2 extend to an isomorphism between the corresponding subgraphs. The colorings χ_1 and χ_2 are used to indicate which subgraphs can not be mapped to each other (and also to distinguish between the adhesion sets and edges of the bags which will both appear in the set of hyperedges).

The next Lemma gives us one of the central subroutines for our recursive algorithm.

▶ **Lemma 9.** *Let $\mathcal{I} = (V_1, V_2, \mathcal{S}_1, \mathcal{S}_2, \chi_1, \chi_2, \mathcal{F}, \mathfrak{f})$ be an instance of coset-hypergraph-isomorphism. Moreover, suppose there are isomorphism-invariant rooted graphs $H_1 = (W_1, E_1, r_1)$ and $H_2 = (W_2, E_2, r_2)$ such that*

1. *$V_i \cup \mathcal{S}_i \subseteq W_i$,*
2. *$\mathrm{fdeg}(w) \leq d$ for all $w \in W_i$,*

3. $\operatorname{depth}(H_i) \leq h$, *and*
4. $|S| \leq d$ *for all* $S \in \mathcal{S}_i$

for all $i \in \{1, 2\}$. *Then a representation for the set* $\operatorname{Iso}(\mathcal{I})$ *can be computed in time* $2^{\mathcal{O}(h \cdot (\log d)^c)}$ *for some constant* c.

Here, isomorphism-invariant means that for every isomorphism $\phi \in \operatorname{Iso}(\mathcal{I})$ there is an isomorphism ϕ_H from H_1 to H_2 such that $v^\phi = v^{\phi_H}$ for all $v \in V_1$ and $\{v^\phi \mid v \in S\} = S^{\phi_H}$ for all $S \in \mathcal{S}_1$.

The proof of this lemma is based on the following theorem.

▶ **Theorem 10** ([6]). *Let* $\mathfrak{x}, \mathfrak{y} \colon V \to \Sigma$ *be two strings, let* $\Gamma \leq \operatorname{Sym}(V)$ *be a* Γ_d*-group and* $\gamma \in \operatorname{Sym}(V)$. *Then one can compute a representation of the set of all permutations* $\gamma' \in \Gamma\gamma$ *mapping* $\mathfrak{x}$ *to* $\mathfrak{y}$ *in time* $n^{\mathcal{O}((\log d)^c)}$ *for some constant* c *where* $n = |V|$.

Actually, we shall only need the following corollary. A rooted tree $T = (V, E, r)$ is *d-ary* if every node has at most d children. An expanded rooted tree is a tuple (T, C) where $T = (V, E, r)$ is a rooted tree and $C \colon L(T)^2 \to \operatorname{rg}(C)$ is a coloring of pairs of leaves of T ($L(T)$ denotes the set of leaves of T). Isomorphisms between expanded trees (T, C) and (T, C') are required to respect the colorings C and C'.

▶ **Corollary 11.** *Let* (T, C) *and* (T', C') *be two expanded* d*-ary trees and let* $\Gamma \leq \operatorname{Aut}(T)$ *and* $\gamma \in \operatorname{Iso}(T, T')$. *Then one can compute a representation of the set* $\{\phi \in \Gamma\gamma \mid (T, C)^\phi = (T', C')\}$ *in time* $n^{\mathcal{O}((\log d)^c)}$ *for some constant* c.

Proof sketch of Lemma 9. The proof essentially proceeds in three steps. First, the two graphs H_i ($i = 1, 2$) are extended by adding a vertex (S_i, v) for every $S_i \in \mathcal{S}_i$, $v \in S_i$ which is connected to the vertex S_i. Moreover, we compute the tree unfoldings T_i of both extended graphs.

Then, in the second step, we compute the set of isomorphisms γ from T_1 to T_2 such that for every $S \in \mathcal{S}_1$ the set $\{S\} \times S$ is mapped to $(\{S\} \times S)^\gamma$ according to the restrictions given by the cosets from the instance $\mathcal{I}$. This is possible since all the sets may be mapped independently of each other. In particular, at this point, identical elements $v \in V_1$ appearing in different sets $S, S' \in \mathcal{S}_1$ may be mapped to different elements $v', v'' \in V_2$.

To resolve this problem we use the coloring on the pairs of leaves of T_1 and T_2 to encode which elements in the tree unfolding correspond to identical elements in the original graph. The set of isomorphisms respecting these additional constraints can be computed using Corollary 11. ◀

Looking at the properties of the tree decompositions computed in Theorem 5 and 8 we have for every node t that either the adhesion sets to the children are all equal or they are all distinct. Up to this point we have only considered the problem that all adhesion sets are distinct (i.e. the coset-hypergraph-isomorphism problem). Next we consider the case that all adhesion sets are equal. Towards this end we define the following variant.

An instance of *multiple-colored-coset-isomorphism* is a 6-tuple $\mathcal{I} = (V_1, V_2, \chi_1, \chi_2, \mathcal{F}, \mathfrak{f})$ such that

1. $\chi_i \colon [t] \to \mathbb{N}$ is a coloring,
2. $\mathcal{F} = \{\Theta_i \leq \operatorname{Sym}(V) \mid i \in [t]\}$, and
3. $\mathfrak{f} = \{\tau_{i,j} \colon V_1 \to V_2 \mid i, j \in [t] \text{ such that } \chi_1(i) = \chi_2(j)\}$ such that
   a. every $\tau_{i,j} \in \mathfrak{f}$ is bijective, and
   b. for every color $i \in \mathbb{N}$ and every $j_1, j_1' \in \chi_1^{-1}(i)$ and $j_2, j_2' \in \chi_2^{-1}(i)$ and $\theta \in \Theta_{j_1}, \theta' \in \Theta_{j_1'}$ it holds that

$$\theta \tau_{j_1, j_2} \tau_{j_1', j_2}^{-1} \theta' \tau_{j_1', j_2'} \in \Theta_{j_1} \tau_{j_1, j_2'}. \tag{N2}$$

The instance is *solvable* if there is a bijective mapping $\phi\colon V_1 \to V_2$ and a $\pi \in \mathrm{Sym}(t)$ such that

1. $\chi_1(i) = \chi_2(\pi(i))$ for all $i \in [t]$, and
2. for every $i \in [t]$ it holds that $\phi \in \Theta_i \tau_{i,\pi(i)}$.

The set $\mathrm{Iso}(\mathcal{I})$ is defined analogously.

▶ **Lemma 12.** *Let $\mathcal{I} = (V_1, V_2, \chi_1, \chi_2, \mathcal{F}, \mathfrak{f})$ be an instance of multiple-colored-coset-isomorphism. Then a representation for the set $\mathrm{Iso}(\mathcal{I})$ can be computed in time*

$$\min((|V_1|!|\mathcal{F}|)^{\mathcal{O}(1)}, |\mathcal{F}|!^{\mathcal{O}(1)} 2^{\mathcal{O}((\log |V_1|)^c)}).$$

6 The isomorphism and the canonization algorithm

6.1 The isomorphism test

Before describing the main algorithm we need to state the following auxiliary lemma.

▶ **Lemma 13.** *Let $G = (D, E)$ be a graph of tree width at most k and let H be a rooted graph such that $D \subseteq V(H)$. Then, one can compute an isomorphism-invariant rooted graph H' such that*

1. *H is an induced subgraph of H',*
2. *$\mathrm{fdeg}_{H'}(w) \leq \max\{d, k+1\} + 1$ for all $w \in V(H')$ where $d = \max_{w \in V(H)} \mathrm{fdeg}_H(w)$,*
3. *$\mathrm{depth}(H') \leq \mathrm{depth}(H) + k + 2$, and*
4. *for every clique $C \subseteq D$ there is a corresponding vertex $C \in V(H')$*

in time $2^{\mathcal{O}(k)} \cdot |V(H)|^{\mathcal{O}(1)}$.

Here, isomorphism invariant means that every isomorphism $\phi \in \mathrm{Iso}(H_1, H_2)$, which naturally restricts to an isomorphism from G_1 to G_2, can be extended to an isomorphism from H_1' to H_2'.

▶ **Theorem 14.** *Let $k \in \mathbb{N}$ and let G_1, G_2 be connected graphs. There is an algorithm that either correctly concludes that $\mathrm{tw}(G_1) > k$, or computes the set of isomorphisms $\mathrm{Iso}(G_1, G_2)$ in time $2^{\mathcal{O}(k(\log k)^c)} |V(G)|^{\mathcal{O}(1)}$ for some constant c.*

Proof sketch. The first step is to decompose the given graphs. Notice that the decomposition techniques in Theorem 8 can only be applied to k-basic graphs, i.e. k-improved and clique-separator free. Therefore, we proceed as follows. First, we consider the k-improvement G_1^k and G_2^k of G_1 and G_2, respectively. We build the clique-separator decompositions of the k-improvements using Theorem 5. Secondly, we refine each (k-basic) bag of the decomposition by constructing a labeled decomposition for each bag using Theorem 8. (In fact, we need to fix a vertex in order to apply Theorem 8. For this reason we are just able to construct a family of decompositions in each k-basic bag. But it turns out, that we are also able to handle this. Also note that we use the version of Theorem 8 that runs in time $2^{\mathcal{O}(k \log k)} |V(G)|^{\mathcal{O}(1)}$ and omits the labeling cosets $\alpha(t)$.) The crucial point is that in our final decomposition the size of each bag is bounded by $c_{\mathrm{L}} \in 2^{\mathcal{O}(k \log k)}$ and more importantly each bag is assigned to a graph that restricts possible automorphisms of the corresponding graph structure. More precisely each bag $\beta(t)$ is assigned to a graph $\eta(t)$ of bounded degree such that $V(\eta(t))$ contains the vertices of $\beta(t)$, the edges of $\beta(t)$ and also the adhesion sets of t. In fact, we also need to embed the clique separators of the outer decomposition into the graph $\eta(t)$. However, this can be achieved using Lemma 13.

From now on, we start to compute isomorphisms preserving the decompositions T_1 and T_2 in a bottom up fashion. (In order to compute edge-preserving bijections, we need to consider

the edges of G_1 and G_2 rather than the "improved" edges in G_1^k and G_2^k). The decomposition of both graphs have a root bags denoted t_1 and t_2, respectively. Both roots have children $t_{11}, \dots, t_{1\ell}$ and $t_{21}, \dots, t_{2\ell}$. By T_{ji} we denote the decomposition rooted at t_{ji} and consisting of all bags that are descendants of t_{ji}. By using a dynamic programming approach we assume that the isomorphisms from T_{1i} to $T_{2i'}$ are already computed. To compute the isomorphisms from T_1 to T_2 we use our subroutine, namely coset-hypergraph-isomorphism, which is defined and algorithmically solved in Section 5. For a moment, assume that all adhesion sets of t_1 (and t_2, respectively) are distinct. We restrict the computed isomorphisms from T_{1i} to $T_{2i'}$ to their corresponding adhesions sets of t_1 and t_2, respectively. These restrictions are used to define $\mathcal{F}$ and $\mathfrak{f}$. The edge relation can also be encoded in $\mathcal{F}$ and $\mathfrak{f}$. More precisely, we add each edge $uv \in E(\beta_1(t_1))$ and $u'v' \in E(\beta_2(t_2))$ to $\mathcal{S}_1$ and $\mathcal{S}_2$, and define $\Theta_{uv}\tau_{uv,u'v'}$ as the set of bijections mapping uv to $u'v'$. The colorings χ_1 and χ_2 help to define the right instance, e.g. they distinguish the edges from the adhesion sets in $\mathcal{S}_1$ and $\mathcal{S}_2$, respectively. Finally, we solve the instance $(\beta_1(t_1), \beta_2(t_2), \mathcal{S}_1, \mathcal{S}_2, \chi_1, \chi_2, \mathcal{F}, \mathfrak{f})$ with the algorithm from Lemma 9. In case all adhesion sets are equal we simply use Lemma 12 instead. ◀

▶ Remark. The degree of the polylogarithmic term (i.e. the constant c) in the running time of the previous theorem is related to the corresponding constant in Babai's quasipolynomial time isomorphism test [1]. Since the constant that Babai's algorithm achieves is not specified in [1], we also do not specify the constant.

6.2 Canonization

We briefly describe how to adapt our techniques to obtain an algorithm which computes a canonization for a given graph of tree width of at most k. Since Babai's quasipolynomial time algorithm [1] only tests isomorphism of two given input graphs and can not be used for canonization purposes, we need to replace the methods introduced in Section 5. To achieve this we still use group theoretic techniques, but compared to isomorphism the machinery is quite lengthy and technical.

▶ **Theorem 15.** *There is a graph canonization algorithm running in time* $2^{\mathcal{O}(k^2 \log k)} \operatorname{poly}(n)$*, where* n *is the size and* k *the tree width of the input graph.*

Proof sketch. The basic approach for the canonization algorithm is very similar to the approach presented in Theorem 14. One of the main differences is how the algorithm gets its insight into the structure of the bags of the decomposition of the k-basic graphs. In the isomorphism algorithm the graph $\eta(t)$ serves as a tool to exploit the structure of each bag t. For the canonization algorithm we instead use the fact that each bag can be guarded with a labeling coset $\alpha(t)$ of bounded composition-width.

We then define the corresponding variant of the coset-hypergraph-isomorphism problem suited for canonization. For the algorithm we assume that, instead of graphs of small degree and depth, we get a labeling coset of composition width at most $k+1$. This problem can then be solved in time $n^{\mathcal{O}(k)}$ using the group theoretic techniques from [2, 12, 15] where n denotes the number of vertices (i.e. the number of vertices in a single bag in the application in the main canonization algorithm). Since the bag size is bounded by $2^{\mathcal{O}(k \log k)}$ this gives the overall running time of $2^{\mathcal{O}(k^2 \log k)} \operatorname{poly}(n)$. ◀

Abstract

We give a fully polynomial-time randomized approximation scheme (FPRAS) for the all-terminal network reliability problem, which is to determine the probability that, in a undirected graph, assuming each edge fails independently, the remaining graph is still connected. Our main contribution is to confirm a conjecture by Gorodezky and Pak (*Random Struct. Algorithms*, 2014), that the expected running time of the "cluster-popping" algorithm in bi-directed graphs is bounded by a polynomial in the size of the input.

1 Introduction

Network reliability problems are extensively studied #**P**-hard problems [5] (see also [3, 22, 18, 2]). In fact, these problems are amongst the first of those shown to be #**P**-hard, and the two-terminal version is listed in Valiant's original thirteen [24]. The general setup is that in a given (undirected or directed) graph, every edge (or arc) e has an independent probability p_e to fail, and we are interested in various kinds of connectivity notions of the remaining graph. For example, the two-terminal connectedness [24] asks for the probability that for two vertices s and t, s is connected to t in the remaining graph, and the (undirected) all-terminal network reliability asks for the probability of all vertices being connected after

[1] The work described here was supported by the EPSRC research grant EP/N004221/1 "Algorithms that Count".

edges fail. The latter can also be viewed as a specialization of the Tutte polynomial $T_G(x, y)$ with $x = 1$ and $y > 1$, yet another classic topic whose computational complexity is extensively studied [12, 25, 6, 7].

Prior to our work, the approximation complexity of network reliability problems remained elusive despite their importance. There is no known efficient approximation algorithm (for any variant), but nor is there any evidence that such an algorithm does not exist. A notable exception is Karger's fully polynomial-time randomized approximation scheme (FPRAS) for (undirected) all-terminal network *unreliability* [15] (see also [11, 16, 17] for more recent developments). Although approximating unreliability is potentially more useful in practice, it does not entail an approximation of its complement.

In this paper, we give an FPRAS for the all-terminal network reliability problem, defined below and denoted Reliability.

Name Reliability
Instance A (undirected) graph $G = (V, E)$, and failure probabilities $\mathbf{p} = (p_e)_{e \in E}$.
Output $Z_{rel}(G; \mathbf{p})$, which is the probability that if each edge e fails with probability p_e, the remaining graph is connected.

When p_e is independent of e, Reliability is an evaluation of the Tutte polynomial. The *Tutte polynomial* is a two-variable polynomial $T_G(x, y)$ associated with a graph G, which encodes much interesting information about G. As (x, y) ranges over $\mathbb{R}^2$ or $\mathbb{C}^2$ we obtain a family of graph parameters, the so-called *Tutte plane*. As already noted, the study of the computational complexity of these parameters has a long history. Reliability with a uniform failure probability $0 < p < 1$ is equivalent to evaluating the Tutte polynomial $T_G(x, y)$ on the line $x = 1$ and $y = \frac{1}{p} > 1$. Our algorithm is the first positive result on the complexity of the Tutte plane since Jerrum and Sinclair presented an FPRAS for the partition function of the ferromagnetic Ising model, which is equivalent to the Tutte polynomial on the positive branch of the hyperbola $(x - 1)(y - 1) = 2$ [14]. It also answers a well-known open problem from 1980s, when the #**P**-hardness of Reliability was established [13, 22] and the study of approximate counting initiated. This problem is explicitly proposed in, for example, [26, Conjecture 8.7.11] and [15]. We note that many conjectures by Welsh ([26, Chapter 8.7] and [27]) remain open, and we hope that our work is only a beginning to answering these questions.

Another related and important reliability measure is *reachability*, introduced and studied by Ball and Provan [3]. A directed graph $G = (V, A)$ with a distinguished root r is said to be *root-connected* if all vertices can reach r. Reachability, denoted $Z_{reach}(G, r; \mathbf{p})$ for failure probabilities $\mathbf{p} = (p_e)_{e \in A}$, is the probability that, if each arc e fails with probability p_e independently, the remaining graph is still root-connected.

We define the computational problem formally.

Name Reachability
Instance A directed graph $G = (V, A)$ with root r, and failure probabilities $\mathbf{p} = (p_e)_{e \in A}$.
Output $Z_{reach}(G, r; \mathbf{p})$.

Exact polynomial-time algorithms are known when the graph is acyclic [3] or has a small number of cycles [10]. However, in general the problem is #**P**-hard [22].

Ball [1] showed that Reliability is equivalent to Reachability in bi-directed graphs. A bi-directed[2] graph is one where every arc has an anti-parallel twin with the same failure probability. It is shown [1] that $Z_{rel}(G;\mathbf{p}) = Z_{reach}(\overrightarrow{G}, r; \mathbf{p}')$, where $\overrightarrow{G}$ and $\mathbf{p}'$ are obtained by replacing every undirected edge in G with a pair of anti-parallel arcs having the same failure probability in either direction, and r is chosen arbitrarily. See Lemma 12.

Our FPRAS for Reliability utilizes this equivalence via approximating Reachability in bi-directed graphs. The core ingredient is the "cluster-popping" algorithm introduced by Gorodezky and Pak [8]. The goal is to sample root-connected subgraphs with probability proportional to their weights, and then the reduction from counting to sampling is via a sequence of contractions. A cluster is a subset of vertices not including the root and without any out-going arc. The sampling algorithm randomizes all arcs independently, and then repeatedly resamples arcs going out from minimal clusters until no cluster is left, at which point the remaining subgraph is guaranteed to be root-connected. This approach is similar to Wilson's "cycle-popping" algorithm [28] for rooted spanning trees, and to the "sink-popping" algorithm [4] for sink-free orientations. Gorodezky and Pak [8] have noted that cluster-popping can take exponential time in general, but they conjectured that in bi-directed graphs, the algorithm runs within polynomial-time.

We confirm this conjecture. Let $p_{\max}$ be the maximum failure probability of edges (or arcs). Let m be the number of edges (or arcs) and n the number of vertices.

▶ **Theorem 1.** *There is an FPRAS for* Reliability *(or equivalently,* Reachability *in bi-directed graphs). The expected running time is* $O\left(\varepsilon^{-2} p_{\max}(1-p_{\max})^{-3} m^2 n^3\right)$ *for an* $(1 \pm \varepsilon)$*-approximation. There is also an exact sampler to draw (edge-weighted) connected subgraphs with expected running time at most* $p_{\max}(1-p_{\max})^{-1} m^2 n$.

We analyze the "cluster-popping" algorithm [8] under the *partial rejection sampling* framework [9], which is a general approach to sampling from a product distribution conditioned on avoiding a number of "bad" events. Partial rejection sampling is inspired by the Moser-Tardos algorithm for the Lovász Local Lemma [20]. It starts with randomizing all variables independently, and then gradually eliminating "bad" events. At every step, we need to find an appropriate set of variables to resample. We call an instance *extremal* [19, 23], if any two bad events are either disjoint or independent. For extremal instances, the resampling set can be simply chosen to be the set of all variables involved in occurring bad events [9], and the algorithm becomes exactly the same as the Moser-Tardos resampling algorithm [20]. In particular, all three "popping" algorithms [28, 4, 8] are special cases of partial rejection sampling for extremal instances. In case of "cluster-popping", the bad events are exactly minimal clusters.

The advantage of the partial rejection sampling treatment is that we have an explicit formula for the expected number of resampling events for any extremal instance [19, 9], which equals to the ratio between the probability of having exactly one bad event and the probability of avoiding all bad events. In order to bound this ratio, we use a combinatorial encoding idea and design a mapping from subgraphs with a unique minimal cluster to root-connected subgraphs. To make this mapping injective, we record an extra vertex and an arc so that we can recover the pre-image. This extra cost is upper-bounded by a polynomial in the size of the graph.

[2] There are other definitions of "bi-directed graphs" in the literature. Our definition is sometimes also called a symmetric directed graph.

Cluster-popping only draws root-connected subgraphs in the bi-directed setting. In order to sample connected subgraphs in the undirected setting, we provide an alternative proof of the equivalence between Reliability and Reachability in bi-directed graphs, which essentially is a coupling argument. This coupling has a new consequence that, once we have a sample of a root-connected subgraph, it is easy to generate a connected subgraph according to the correct distribution.

In Section 2 we introduce the "cluster-popping" algorithm and the partial rejection framework. In Section 3 we analyze its running time in bi-directed graphs. For completeness, in Section 4 we include the approximate counting algorithm due to Gorodezky and Pak [8]. In Section 5 we give a coupling proof of the equivalence between Reliability and Reachability in bi-directed graphs. In Section 6 we conclude by mentioning a few open problems.

2 Cluster-popping

Let $G = (V, A)$ be a directed[3] graph with root r. The graph G is called *root-connected* if there is a directed path in G from every non-root vertex to r. Let $0 < p_e < 1$ be the failure probability of arc e, and define the weight of a subgraph S to be $\mathrm{wt}(S) := \prod_{e\in S}(1-p_e)\prod_{e\notin S} p_e$. Then reachability, $Z_{reach}(G, r; \mathbf{p})$, is defined as follows,

$$Z_{reach}(G, r; \mathbf{p}) := \sum_{\substack{S\subseteq A \\ (V,S) \text{ is root-connected}}} \mathrm{wt}(S).$$

Here, $\mathbf{p} = (p_e : e \in A)$ denotes the vector of failure probabilities.

Let $\pi_G(\cdot)$ (or $\pi(\cdot)$ for short) be the distribution resulting from choosing each arc e independently with probability $1 - p_e$, and conditioning on the resulting graph being root-connected. In other words, the support of $\pi(\cdot)$ is the collection of all root-connected subgraphs, and the probability of each subgraph S is proportional to its weight $\mathrm{wt}(S)$. Then $Z_{reach}(G, r; \mathbf{p})$ is the normalizing factor of the distribution $\pi(\cdot)$. Gorodezky and Pak [8] have shown that approximating $Z_{reach}(G, r; \mathbf{p})$ can be reduced to sampling from $\pi(\cdot)$ when the graph is bi-directed.

The "cluster-popping" algorithm of Gorodezky and Pak [8], to sample root-connected subgraphs from $\pi(\cdot)$, can be viewed as a special case of partial rejection sampling [9] for extremal instances. With every arc e of G we associate a random variable that records whether that arc has failed. Bad events are characterized by the following notion of clusters.

▶ **Definition 2.** In a directed graph (V, A) with root r, a subset $C \subseteq V$ of vertices is called a *cluster* if $r \notin C$ and there is no arc $u \to v \in A$ such that $u \in C$ and $v \notin C$.

We say C is a *minimal cluster* if C is a cluster and for any proper subset $C' \subset C$, C' is not a cluster.

If (V, A) contains no cluster, then it is root-connected. For each vertex v, let $A_{\mathrm{out}}(v)$ be the set of outgoing arcs from v. We also abuse the notation to write $A_{\mathrm{out}}(S) = \bigcup_{v\in S} A_{\mathrm{out}}(v)$ for a subset $S \subset V$ of vertices. Notice that $A_{\mathrm{out}}(S)$ contains edges between vertices inside S. To "pop" a cluster C, we re-randomize all arcs in $A_{\mathrm{out}}(C)$. However, re-randomizing clusters does not yield the desired distribution. We will instead re-randomize minimal clusters.

[3] It is easy to see that in a undirected graph, reachability is the same as all-terminal reliability.

Algorithm 1 Cluster Popping.

Let S be a subset of arcs by choosing each arc e with probability $1 - p_e$ independently.
while There is a cluster in (V, S). **do**
  Let $C_1, \ldots, C_k$ be all minimal clusters in (V, S), and $C = \bigcup_{i=1}^{k} C_i$.
  Re-randomize all arcs in $A_{\text{out}}(C)$ to get a new S.
end while
return S

▶ **Claim 3.** *Any minimal cluster is strongly connected.*

Proof. Let C be a minimal cluster, and $v \in C$ be an arbitrary vertex in C. We claim that v can reach all vertices of C. If not, let C' be the set of reachable vertices of v and $C' \subsetneq C$. Since C' does not have any outgoing arcs, C' is a cluster. This contradicts to the minimality of C. ◀

▶ **Claim 4.** *If C_1 and C_2 are two distinct minimal clusters, then $C_1 \cap C_2 = \emptyset$.*

Proof. By Claim 3, C_1 and C_2 are both strongly connected components. If $C_1 \cap C_2 \neq \emptyset$, then they must be identical. ◀

For every subset $C \subseteq V$ of vertices, we define a bad event B_C, which occurs if C is a minimal cluster. Observe that B_C relies only on the status of arcs in $A_{\text{out}}(C)$. Thus, if $C_1 \cap C_2 = \emptyset$, then B_{C_1} and B_{C_2} are independent, even if some of their vertices are adjacent. By Claim 4, we know that two bad events B_{C_1} and B_{C_2} are either independent or disjoint. Thus the aforementioned extremal condition is met. Moreover, it was shown [9, Theorem 8] that if the instance is extremal, then at every step, we only need to resample variables involved in occurring bad events. This leads to the cluster-popping algorithm of Gorodezky and Pak [8], which is formally described in Algorithm 1.

The correctness of Algorithm 1 is first shown by Gorodezky and Pak [8]. It can also be easily verified using [9, Theorem 8].

▶ **Theorem 5** ([8, Theorem 2.2])**.** *The output of Algorithm 1 is drawn from π_G.*

An advantage of thinking in the partial rejection sampling framework is that we have a closed form formula for the expected running time of these algorithms on extremal instances. Let Ω_k be the collection of subgraphs with k minimal clusters, and $Z_k := \sum_{S \in \Omega_k} \text{wt}(S)$. Then $Z_0 = Z_{reach}(G, r; \mathbf{p})$, since any subgraph in Ω_0 has no cluster and is thus root-connected.

▶ **Theorem 6** ([9])**.** *Let T be the number of resampled events of the partial rejection sampling algorithm for extremal instances. Then $\mathbb{E}\, T = \frac{Z_1}{Z_0}$. In particular, for Algorithm 1, T is the number of popped clusters.*

The less-than-or-equal-to direction of Theorem 6 was shown by Kolipaka and Szegedy [19], which is the direction we will need later. The other direction is useful to show running-time lower bounds, but that is not our focus in this paper.

3 Running time of Algorithm 1 in bi-directed graphs

Gorodezky and Pak [8] have given examples of directed graphs in which Algorithm 1 requires exponential time. In the following we focus on bi-directed graphs. A graph G is called *bi-directed* if $u \to v$ is present in G, then $v \to u$ is present in G as well, and the failure

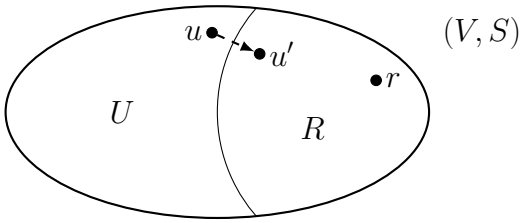

Figure 1 An illustration of R, U, and $u \to u'$.

probabilities are the same for these two arcs. We use Bi-directed Reachability to denote Reachability in bi-directed graphs. For an arc $e = u \to v$, let $\overline{e} := v \to u$ denote its reverse arc. Then in a bi-directed graph, $p_e = p_{\overline{e}}$.

▶ **Lemma 7.** *Let $G = (V, A)$ be a root-connected bi-directed graph with root r. We have that $Z_1 \le \max_{e \in A} \left\{ \frac{p_e}{1-p_e} \right\} mnZ_0$, where $n = |V|$, and $m = |A|$.*

Proof. We construct an injective mapping $\varphi : \Omega_1 \to \Omega_0 \times V \times A$. For each subgraph $S \in \Omega_1$, $\varphi(S)$ is defined by "repairing" S so that no minimal cluster is present. We choose in advance an arbitrary ordering of vertices and arcs. Let C be the unique minimal cluster in S and v be the first vertex in C. Let R denote the set of all vertices which can reach the root r in the subgraph S. Since $S \in \Omega_1$, $R \neq V$. Let $U = V \setminus R$. Since G is root-connected, there is an arc in A from U to R. Let $u \to u'$ be the first such arc, where $u \in U$ and $u' \in R$. We let

$$\varphi(S) := (S_{\text{fix}}, v, u \to u'),$$

where $S_{\text{fix}} \in \Omega_0$ is defined next. Figure 1 is an illustration of these objects.

Consider the subgraph $H = (U, S[U])$, where

$$S[U] := \{x \to y \mid x \in U,\ y \in U,\ x \to y \in S\}.$$

We consider the directed acyclic graph (DAG) of strongly connected components of H, and call it $\widehat{H}$. (We use the decoration $\widehat{\ }$ to denote arcs, vertices, etc. in $\widehat{H}$.) To be more precise, we replace each strongly connected component by a single vertex. For a vertex $w \in U$, let $[w]$ denote the strongly connected component containing w. For example, $[v]$ is the same as the minimal cluster C by Claim 3. We may also view $[w]$ as a vertex in $\widehat{H}$ and we do not distinguish the two views. The arcs in $\widehat{H}$ are naturally induced by $S[U]$. Namely, for $[x] \neq [y]$, an arc $[x] \to [y]$ is present in $\widehat{H}$ if there exists $x' \in [x]$, $y' \in [y]$ such that $x' \to y' \in S$.

We claim that $\widehat{H}$ is root-connected with root $[v]$. This is because $[v]$ must be the unique sink in $\widehat{H}$ and $\widehat{H}$ is acyclic. If there is another sink $[w]$ where $v \notin [w]$, then $[w]$ is a minimal cluster in H. This contradicts $S \in \Omega_1$.

Since $\widehat{H}$ is root-connected, there is at least one path from $[u]$ to $[v]$. Let $\widehat{W}$ denote the set of vertices of $\widehat{H}$ that can be reached from $[u]$ in $\widehat{H}$ (including $[u]$), and $W := \{x \mid [x] \in \widehat{W}\}$. Then W is a cluster and $[u]$ is the unique source in $\widehat{H}[\widehat{W}]$. As $\widehat{H}$ is root-connected, $[v] \in \widehat{W}$. Define

$$S_{\text{flip}} := \left\{x \to y \;\middle|\; [x] \neq [y],\ x, y \in W, \text{ and } x \to y \in S\right\},$$

which is the set of edges to be flipped. Notice that $S[W]$ is different from S_{flip}, namely all arcs that are inside strongly connected components are ignored in S_{flip}. Now we are ready to define S_{fix}. We reverse all arcs in S_{flip} and add the arc $u \to u'$ to fix the minimal cluster.

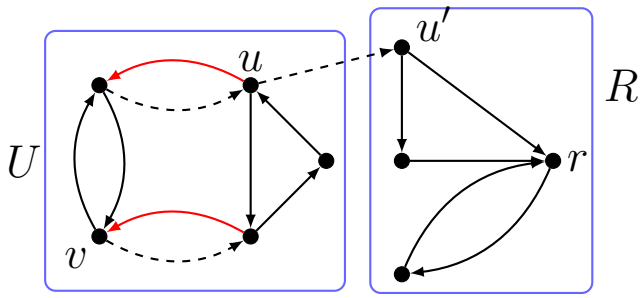

Figure 2 An example of S_{flip} (red arcs) in the subgraph (V, S). Dashed arcs are to be added to S_{fix}. The underlying graph has more arcs than are drawn here.

Formally, let

$$S_{\text{fix}} := S \cup \{u \to u'\} \cup \{y \to x \mid x \to y \in S_{\text{flip}}\} \setminus S_{\text{flip}}.$$

Figure 2 is an example of these objects we defined.

Let $\widehat{H}_{\text{fix}}$ be the graph obtained from $\widehat{H}$ by reversing all arcs induced by S_{flip}. Observe that $[u]$ becomes the unique sink in $\widehat{H}_{\text{fix}}[\widehat{W}]$ (and $[v]$ becomes the unique source).

We verify that $S_{\text{fix}} \in \Omega_0$. For any $x \in R$, x can still reach r in (V, S_{fix}) since the path from x to r in (V, S) is not changed. Since $u \to u' \in S_{\text{fix}}$, u can reach $u' \in R$ and hence r. For any $y \in W$, y can reach u as $[u]$ is the unique sink in $\widehat{H}_{\text{fix}}[\widehat{W}]$. For any $z \in U \setminus W$, z can reach $v \in W$ since the path from z to v in (V, S) is not changed.

Next we verify that φ is injective. To do so, we show that we can recover S given S_{fix}, $u \to u'$, and v. First remove $u \to u'$ from S_{fix}. The set of vertices which can reach r in $(V, S_{\text{fix}} \setminus \{u \to u'\})$ is exactly R in (V, S). Namely we can recover U and R. As a consequence, we can recover all arcs in S that are incident with R, as these arcs are not changed.

What is left to do is to recover arcs in $S[U]$. To do so, we need to find out which arcs have been flipped. We claim that $\widehat{H}_{\text{fix}}$ is acyclic. Suppose there is a cycle in $\widehat{H}_{\text{fix}}$. Since $\widehat{H}$ is acyclic, the cycle must involve flipped arcs and thus vertices in $\widehat{W}$. Let $[x] \in \widehat{W}$ be the lowest one under the topological ordering of $\widehat{H}[\widehat{W}]$. Since $\widehat{W}$ is a cluster, the outgoing arc $[x] \to [y]$ along the cycle in $\widehat{H}_{\text{fix}}$ must have been flipped, implying that $[y] \in \widehat{W}$ and $[y] \to [x]$ is in $\widehat{H}[\widehat{W}]$. This contradicts to the minimality of $[x]$.

Since $\widehat{H}_{\text{fix}}$ is acyclic, the strongly connected components of $H_{\text{fix}} := (U, S_{\text{fix}}[U])$ are identical to those of $H = (U, S[U])$. Hence contracting all strongly connected components of H_{fix} results in exactly $\widehat{H}_{\text{fix}}$. All we need to recover now is the set $\widehat{W}$. Let $\widehat{W}'$ be the set of vertices reachable from $[v]$ in $\widehat{H}_{\text{fix}}$. It is easy to see that $\widehat{W} \subseteq \widehat{W}'$. We claim that actually $\widehat{W} = \widehat{W}'$. For any $[x] \in \widehat{W}'$, there is a path from $[v]$ to $[x]$ in $\widehat{H}_{\text{fix}}$. Suppose $[x] \notin \widehat{W}$. Since $[v] \in \widehat{W}$, we may assume that $[y]$ is the first vertex along the path such that $[y] \to [z]$ where $[z] \notin \widehat{W}$. Thus $[y] \to [z]$ has not been flipped and is present in $\widehat{H}$. However, this contradicts the fact that $\widehat{W}$ is a cluster in $\widehat{H}$.

To summarize, given S_{fix}, $u \to u'$, and v, we may uniquely recover S. Hence the mapping φ is injective. Moreover, flipping arcs does not change the weight as $p_e = p_{\overline{e}}$, and only adding the arc $u \to u'$ would. We have that $\text{wt}(S_{\text{fix}}) = \frac{1-p_{u\to u'}}{p_{u\to u'}}\text{wt}(S)$. The lemma follows. ◀

We remark that an alternative way of repairing S in the proof above is to reverse all arcs in $S[W]$ without defining S_{flip}. The key point is that doing so leaves the strongly connected components intact. However this makes the argument less intuitive.

Let $p_{\max} = \max_{e \in A} p_e$. Combining Theorem 6 and Lemma 7, we have the following theorem. Notice that for each popping, we resample only a subset of arcs.

▶ **Theorem 8.** *Let T be the expected number of popped clusters in Algorithm 1. For a root-connected bi-directed graph $G = (V, A)$, $\mathbb{E}\, T \le \frac{p_{\max}}{1-p_{\max}} mn$, where $n = |V|$, and $m = |A|$. The expected running time is at most $\frac{p_{\max}}{1-p_{\max}} m^2 n$.*

4 Approximate counting

We include the approximate counting algorithm of Gorodezky and Pak [8] for completeness. Let $G = (V, A)$ be an instance of Bi-directed Reachability with root r and parameters $\mathbf{p}$. We construct a sequence of graphs $G_0, .., G_{n-1}$ where $n = |V|$ and $G_0 = G$. Given G_{i-1}, choose two arbitrary adjacent vertices u_i and v_i, remove all arcs between u_i and v_i (in either direction), and identify u_i and v_i to get $G_i = (V_i, A_i)$. Namely we contract all arcs between u_i and v_i, but parallel arcs in the resulting graph are preserved. If one of u_i and v_i is r, the new vertex is labelled r. Thus $G_{n-1} = (\{r\}, \emptyset)$. Since A_i is always a subset of A, we denote by $\mathbf{p}_i$ the parameters $\mathbf{p}$ restricted to A_i.

For $i = 1, \ldots, n-1$, define a random variable R_i as follows:

$$R_i := \begin{cases} 1 & (V_{i-1}, S_{i-1}) \text{ is root-connected in } G_{i-1}; \\ 0 & \text{otherwise,} \end{cases}$$

where $S_{i-1} \subset A_{i-1}$ is a random root-connected subgraph drawn from the distribution $\pi_{G_i}(\cdot)$, together with all arcs e between u_i and v_i added independently with probability $1 - p_e$. It is easy to see that

$$\mathbb{E}\, R_i = \frac{Z_{reach}(G_{i-1}, r; \mathbf{p}_{i-1})}{Z_{reach}(G_i, r; \mathbf{p}_i)}, \quad \text{and} \quad Z_{reach}(G, r; \mathbf{p}) = \prod_{i=1}^{n-1} \mathbb{E}\, R_i.$$

Let $p_{\max} = \max_{e \in A} p_e$ and $s = \lceil 5(1-p_{\max})^{-2}(n-1)\varepsilon^{-2} \rceil$ where s is the desired precision. We estimate $\mathbb{E}\, R_i$ by the empirical mean of s independent samples of Z_i, denoted by $\widetilde{R}_i$, and let $\widetilde{Z} = \prod_{i=1}^{n-1} \widetilde{R}_i$ and $Z = Z_{reach}(G, r; \mathbf{p})$. Gorodezky and Pak [8] showed the following.

▶ **Proposition 9** ([8, Section 9])**.** $\Pr\left(\left|Z - \widetilde{Z}\right| > \varepsilon Z\right) \le 1/4$.

In order to sample Z_i, we use Algorithm 1 to draw independent samples of root-connected subgraphs. Theorem 8 implies that each sample takes at most $\frac{p_{\max}}{1-p_{\max}} m^2 n$ time in expectation. We need $O\left(\frac{n}{\varepsilon^2 (1-p_{\max})^2}\right)$ samples for each Z_i. Putting everything together, we obtain the following theorem.

▶ **Theorem 10.** *There is an FPRAS for* Bi-directed Reachability*. The expected running time is $O\left(\varepsilon^{-2} p_{\max} (1-p_{\max})^{-3} m^2 n^3\right)$ for an $(1 \pm \varepsilon)$-approximation.*

A natural question is what if $1 - p_{\max}$ is close to 0. Intuitively, this means that some arc is very likely to fail. We note that, if $1 - p_e = O(n^{-3})$ for every arc e, then with high probability, sampling from the distribution $\pi(\cdot)$ yields a rooted spanning tree (with probability proportional to its weight). Thus, in this case, we can approximate $\pi(\cdot)$ by an efficient rooted spanning tree sampler, for example, the cycle-popping algorithm [28] (which runs in time $O(mn)$ in expectation).

5 Coupling between reliability and bi-directed reachability

In this section, we give an alternative proof of Ball's equivalence between Reliability and Bi-directed Reachability [1, Corollary 1]. Our proof constructs a coupling, between the (edge-weighted) distribution of connected subgraphs in the undirected setting, and the (edge-weighted) distribution of root-connected subgraphs in the bi-directed setting. This coupling, together with Algorithm 1, yields an efficient exact sampler for connected subgraphs.

We use $\{u, v\}$ to denote an undirected edge, and (u, v) or (v, u) to denote a directed one (namely an arc). Let $G = (V, E)$ be an undirected graph, and $\mathbf{p} = (p_e)_{e\in E}$ be a vector of failure probabilities. Let $\overrightarrow{G} = (V, A)$ be the bi-directed graph obtained by replacing every edge in G with a pair of anti-parallel arcs. Namely, $A = \{(u, v), (v, u) \mid \{u, v\} \in E\}$. Moreover, let $p_{(u,v)} = p_{(v,u)} = p_{\{u,v\}}$ and denote these failure probabilities by $\mathbf{p}'$. For $S \subseteq E$ or $S \subseteq A$, let $\mathrm{wt}(S) = \prod_{e\in S}(1 - p_e) \prod_{e\notin S} p_e$.

Consider the following coupling between the product distribution over edges of G and the one over arcs of $\overrightarrow{G}$. We reveal edges in a breadth-first search (BFS) fashion in both graphs, from the same "root" vertex r. If an edge $\{u, v\}$ is present in the subgraph of G, we couple it with the arc (u, v) or (v, u), whose direction is pointing towards r in the subgraph of $\overrightarrow{G}$. The arc in the other direction is drawn independently from everything else. The key observation is that to decide the set of vertices that can reach r, at any point, only one direction of a bi-directed edge is useful and the other is irrelevant. One can verify that in the end, the subgraph of G is connected if and only if the subgraph of $\overrightarrow{G}$ is root-connected. We will formalize this intuition next.

Fix an arbitrary ordering of V, which will be used for the exploration, and let the first vertex be a distinguished root r. Let $\mathcal{P}(S)$ denote the power set of S for a set S. Define a mapping $\Phi : \mathcal{P}(E) \to \mathcal{P}(A)$ as follows. For $S \subseteq E$, we explore all vertices that can reach r in (V, S) in a deterministic order, and add arcs to $\Phi(S)$ in the direction towards r. To be more specific, we maintain the set of explored and the set of active vertices, denoted by V_e and V_a, respectively. At the beginning, $V_e = \emptyset$ and $V_a = \{r\}$. Given V_e and V_a, let v be the first vertex (according to the predetermined ordering) in V_a. For all $u \in V \setminus V_e$, if $\{u, v\} \in S$, add (u, v) to $\Phi(S)$ and add u to V_a (u may be in V_a already). Then move v from V_a to V_e. This process ends when all vertices that can reach r in (V, S) are explored. Let σ_S be the arriving order of V_e. We will call σ_S the traversal order. We remark that if $\{u, v\} \in S$ then exactly one of the arcs (u, v) and (v, u) is in $\Phi(S)$, and otherwise neither arc is in $\Phi(S)$.

Strictly speaking, the exploration above is not a BFS (V_a may contain a newly added vertex that is lower in the predetermined ordering than all other older vertices). To perform a BFS we need to in addition maintain a layer ordering, which seems unnecessary. The key properties of the exploration are: 1) all edges incident to the current vertex are processed; 2) V_e is always connected (or root-connected for Ψ below).

Similarly, define $\Psi : \mathcal{P}(A) \to \mathcal{P}(E)$ as follows. For $S' \subseteq A$, we again maintain V_e and V_a, and initialize $V_e = \emptyset$ and $V_a = \{r\}$. Given V_e and V_a, let v be the first vertex in V_a. For all $u \in V \setminus V_e$, if $(u, v) \in S$, add $\{u, v\}$ to $\Psi(S')$ and add u to V_a. Then move v from V_a to V_e. This process ends when all vertices that can reach r in (V, S') are explored. Analogously, let $\sigma_{S'}$ be the arriving order of V_e. We remark that if $(u, v) \notin S'$, and v is visited before u, then $\{u, v\} \notin \Psi(S')$, even in case of $(v, u) \in S'$.

Let $\Omega := \{S \subseteq E \mid (V, S) \text{ is connected}\}$, and $\overrightarrow{\Omega} := \{S \subseteq A \mid (V, S) \text{ is root-connected}\}$. We have the following lemma.

▶ **Lemma 11.** *Let Φ, Ψ, Ω, and $\overrightarrow{\Omega}$ be defined as above. Then the following hold:*

1. *if $S \in \Omega$, then $\Phi(S) \in \overrightarrow{\Omega}$;*
2. *if $S' \in \overrightarrow{\Omega}$, then $\Psi(S') \in \Omega$;*
3. *if $S \in \Omega$, then $\Psi(\Phi(S)) = S$;*
4. *$\Psi(\overrightarrow{\Omega}) = \Omega$;*
5. *for any $S \in \Omega$, $\mathrm{wt}(S) = \sum_{S' \in \Psi^{-1}(S)} \mathrm{wt}(S')$.*

Proof. 1. It is easy to verify that, at any point of the construction of Φ, all vertices in V_e can reach r, in both (V, S) and $(V, \Phi(S))$. If $S \in \Omega$, then $V_e = V$ at the end of Φ. Hence $(V, \Phi(S))$ is root-connected, and $\Phi(S) \in \overrightarrow{\Omega}$.
2. This item is completely analogous to item (1).
3. If $\{u, v\} \in S$ and u is processed first during the exploration, then $(v, u) \in \Phi(S)$. The traversal orderings σ_S and $\sigma_{\Phi(S)}$ are the same. Hence, during the construction of $\Psi(\Phi(S))$, u is still processed first, and $\{v, u\} \in \Psi(\Phi(S))$. On the other hand, if $\{u, v\} \notin S$, then neither (u, v) nor (v, u) is in $\Phi(S)$ and thus $\{u, v\} \notin \Psi(\Phi(S))$.
4. This item is a straightforward consequence of items (1), (2), and (3).
5. By item (3), we have that $\Phi(S) \in \Psi^{-1}(S)$. Let

$$\Phi_c(S) := \left\{(u, v) \mid (u, v) \notin \Phi(S) \text{ and } v < u \text{ in the traversal order } \sigma_{\Phi(S)}\right\}.$$

Note that $\Phi(S) \cup \Phi_c(S)$ covers all unordered pairs of vertices as $S \in \Omega$. Moreover,

$$\prod_{e \in \Phi(S)} (1 - p_e) \prod_{e \in \Phi_c(S)} p_e = \mathrm{wt}(S). \tag{$*$}$$

Call S' consistent with $\Phi(S)$ if $\Phi(S) \subseteq S'$ and $S' \cap \Phi_c(S) = \emptyset$.
We claim that $S' \in \Psi^{-1}(S)$ if and only if S' is consistent with $\Phi(S)$. Suppose S' is not consistent with $\Phi(S)$. Consider the exploration of $\Phi(S)$ and S' in the construction of Ψ simultaneously. Since S' is not consistent with $\Phi(S)$, either $\Phi(S) \setminus S' \neq \emptyset$ or $S' \cap \Phi_c(S) \neq \emptyset$. Let v be the first vertex during the exploration so that there is an arc $(u, v) \in \Phi(S) \setminus S'$, or $(u, v) \in S' \cap \Phi_c(S)$ for some $u \notin V_e$. Since $S \in \Omega$, all vertices will be processed, and such a v must exist. (In the latter case, since $(u, v) \in \Phi_c(S)$, v is active first.) If $(u, v) \in \Phi(S) \setminus S'$, then $\{u, v\} \notin \Psi(S')$ but $\{u, v\} \in \Psi(\Phi(S))$. If $(u, v) \in S' \cap \Phi_c(S)$, $\{u, v\} \notin \Psi(\Phi(S))$ but $\{u, v\} \in \Psi(S')$. In either case, $\Psi(S') \neq \Psi(\Phi(S)) = S$ (by item (3)). On the other hand, if $\Phi(S) \subseteq S'$ and $S' \cap \Phi_c(S) = \emptyset$, then we can trace through the construction of $\Psi(\Phi(S))$ and $\Psi(S')$ to verify that $\Psi(S') = \Psi(\Phi(S)) = S$.
The claim together with $(*)$ implies that

$$\sum_{S' \in \Psi^{-1}(S)} \mathrm{wt}(S') = \sum_{S' \text{ is consistent with } \Phi(S)} \mathrm{wt}(S') = \prod_{e \in \Phi(S)} (1 - p_e) \prod_{e \in \Phi_c(S)} p_e = \mathrm{wt}(S). \qquad \blacktriangleleft$$

▶ **Lemma 12.** $Z_{rel}(G; \mathbf{p}) = Z_{reach}(\overrightarrow{G}, r; \mathbf{p}')$.

Proof. First notice that $Z_{rel}(G; \mathbf{p}) = \sum_{S \in \Omega} \mathrm{wt}(S)$ and $Z_{reach}(\overrightarrow{G}, r; \mathbf{p}') = \sum_{S \in \overrightarrow{\Omega}} \mathrm{wt}(S)$. By item (4) of Lemma 11, $\Psi(\overrightarrow{\Omega}) = \Omega$, implying that $\left(\Psi^{-1}(S)\right)_{S \in \Omega}$ is a partition of $\overrightarrow{\Omega}$. Combining this with item (5) of Lemma 11,

$$\sum_{S \in \Omega} \mathrm{wt}(S) = \sum_{S \in \Omega} \sum_{S' \in \Psi^{-1}(S)} \mathrm{wt}(S') = \sum_{S' \in \overrightarrow{\Omega}} \mathrm{wt}(S').$$

The lemma follows. $\blacktriangleleft$

Lemma 12 is first shown by Ball [1, Corollary 2] via modifying edges one by one. Instead, our proof is essentially a coupling argument and has a new consequence that Algorithm 1 can be used to sample edge-weighted connected subgraphs. Recall our notation $\pi_G(\cdot)$, and generalise it to undirected graphs. Thus, for an undirected (or directed) graph G, $\pi_G(\cdot)$ is the distribution resulting from drawing each edge (or arc) e independently with probability $1 - p_e$, and conditioning on the graph drawn being connected (or root-connected).

▶ **Lemma 13.** *If a random root-connected subgraph S' is drawn from $\pi_{\overrightarrow{G}}(\cdot)$, then $\Psi(S')$ has distribution $\pi_G(\cdot)$.*

Proof. Since $S' \in \overrightarrow{G'}$, by item (2) of Lemma 11, $\Psi(S') \in \Omega$. Moreover, for any $s \in \Omega$,

$$\Pr[\Psi(S') = s] = \sum_{s' \in \Psi^{-1}(s)} \Pr[S' = s'] = \sum_{s' \in \Psi^{-1}(s)} \frac{\mathrm{wt}(s')}{Z_{reach}(\overrightarrow{G}, r; \mathbf{p}')} = \frac{\mathrm{wt}(s)}{Z_{rel}(G; \mathbf{p})} = \pi_G(s),$$

where we used item (5) of Lemma 11 and Lemma 12 in the last line. ◀

There is also a coupling going the reversed direction of Lemma 13, by drawing a random connected subgraph S from $\pi_G(\cdot)$, mapping it to $\Phi(S)$, and excluding all arcs in $\Phi_c(S)$. All other arcs are drawn independently. The resulting S' has distribution $\pi_{\overrightarrow{G}}(\cdot)$. Its correctness is not hard to prove, given Lemma 11, but it is not the direction of use to us and we omit its proof.

Theorem 10 and Lemma 12 imply the counting part of Theorem 1. Theorem 8 and Lemma 13 imply the sampling part of Theorem 1.

6 Concluding remarks

In this paper we give an FPRAS for Reliability (or, equivalently, Bi-directed Reachability), by confirming a conjecture of Gorodezky and Pak [8]. We also give an exact sampler for edge-weighted connected subgraphs with polynomial running time in expectation. The core ingredient of our algorithms is the cluster-popping algorithm to sample root-connected subgraphs, namely Algorithm 1. We manage to analyze it using the partial rejection sampling framework.

Reliability is equivalent to counting weighted connected subgraphs, which is the evaluation of the Tutte polynomial $T_G(x, y)$ for points $x = 1$ and $y > 1$. An interesting question is about the dual of this half-line, namely for points $x > 1$ and $y = 1$, whose evaluation is to count weighted acyclic subgraphs. It is well known that for a planar graph G, $T_G(x, 1) = T_{G^*}(1, x)$ where G^* is the planar dual of G [21]. Hence, Theorem 1 implies that in planar graphs, $T_G(x, 1)$ can be efficiently approximated for $x > 1$. Can we remove the restriction of planar graphs?

Another interesting direction is to generalize Algorithm 1 beyond bi-directed graphs. What about Eulerian graphs? Is approximating Reachability **NP**-hard in general?

Abstract

We present a perfect simulation of the hard disks model via the partial rejection sampling method. Provided the density of disks is not too high, the method produces exact samples in $O(\log n)$ rounds, where n is the expected number of disks. The method extends easily to the hard spheres model in $d > 2$ dimensions. In order to apply the partial rejection method to this continuous setting, we provide an alternative perspective of its correctness and run-time analysis that is valid for general state spaces.

1 Introduction

The *hard disks model* is one of the simplest gas models in statistical physics. Its configurations are non-overlapping disks of uniform radius r in a bounded region of $\mathbb{R}^2$. For convenience, in this paper, we take this region to be the unit square $[0,1]^2$. This model was precisely the one studied by Metropolis et al. [12], in their pioneering work on the Markov chain Monte Carlo (MCMC) method. They used Los Alamos' MANIAC computer to simulate a system with 224 disks.

There are two variants of this model. To obtain the *canonical ensemble*, we fix the number (or equivalently, density) of disks and decree that all configurations are "equally likely", subject only to the disks not overlapping. In the *grand canonical ensemble*, we fix the "average" number of disks. To be more specific, centers of the disks are distributed

[1] The work described here was supported by the EPSRC research grant EP/N004221/1 "Algorithms that Count".

according to a Poisson point process of intensity $\lambda_r = \lambda/(\pi r^2)$, conditioned on the disks being non-overlapping. The hard disks model, and its higher dimensional generalization (called the *hard spheres model*) are also related to the optimal sphere packing density [4, 18, 2]. See [6, 1] and references therein for more details. See also [11] for the physics perspective.

Our main aim in this work is to describe and analyse a very simple algorithm for exactly sampling from the grand canonical ensemble, based on the partial rejection sampling paradigm introduced by Guo, Jerrum and Liu [3].

More precisely, the challenge is the following: produce a realisation $P \subset [0,1]^2$ of a Poisson point process of intensity λ_r in the unit square, conditioned on the event that no pair of points in P are closer than $2r$ in Euclidean distance. We refer to this target measure as the *hard disks distribution*. It describes an arrangement of open disks of radius r with centres in $[0,1]^2$ that are not allowed to overlap, but which otherwise do not interact. It is a special case of the Strauss process [17]. Note that, although the disks do not overlap each other, they may extend beyond the boundary of the unit square. Also, the intensity of the underlying Poisson process is normalised so that the expected number of points of P lying in a disk of radius r is λ. This normalisation gives us sensible asymptotics as the radius of the disks tends to zero (equivalently, the number of disks tends to infinity).

Classical rejection sampling applied to this problem yields the following algorithm: repeatedly sample a realisation P of the Poisson process of intensity λ in the unit square until P satisfies the condition that no two points are closer than $2r$, and return P. Unfortunately, for every $\lambda > 0$, however small, the expected number of unsuccessful trials using this approach increases exponentially in r^{-1}, as $r \to 0$. Partial rejection sampling [3] requires only a subset of P to be resampled at each iteration. Algorithm 1 below arises from a routine application of the paradigm to the problem at hand.

The original partial rejection method [3] and its analysis are tailored for the discrete case. In this paper we provide an alternative view on the correctness of the method, which is also valid in the continuous setting. In other words, as with classical rejection sampling, Algorithm 1 terminates with probability 1, producing a realisation of the exact hard disks distribution. In contrast to classical rejection sampling, the expected number of iterations (resampling steps) is now asymptotically $O(\log(r^{-1}))$ as $r \to 0$, provided λ is not too large. We prove that rapid termination occurs when $\lambda < 0.21027$. This analysis is not tight, and experiments suggests that the actual threshold for rapid termination is around $\lambda \approx 0.51$.[2] The experimental advantage of partial rejections is its simple termination rule, unlike MCMC, where it is difficult to determine how long the algorithm should run.

The method extends naturally to the *hard spheres model* in $d > 2$ dimensions. Here, the desired distribution is a Poisson point process in $[0,1]^d$ conditioned on no pair of points being closer than $2r$. The natural normalisation for the intensity of the Poisson process in d dimensions is $\lambda_{r,d} = \lambda/(v_d r^d)$, where v_d is the volume of a ball of radius 1 in $\mathbb{R}^d$. With this convention, we prove that rapid termination occurs in d dimensions provided $\lambda < 2^{-(d+\frac{1}{2})}$.

The *expected packing density* $\alpha(\lambda)$ or simply α for this model is the expected total volume of balls. (Note that, neglecting boundary effects, α is the proportion of the unit cube occupied by balls.) The quantity $\alpha(\lambda)$ grows monotonically with λ, but intuitively we expect its rate of growth to slow down dramatically as the balls pack more tightly. The connection between expected packing density α and intensity λ has recently been thoroughly explored by Jenssen, Joos and Perkins [6]. Using their results, we show that partial rejection sampling

[2] The physics prediction of phase transitions, for the *canonical ensemble* in two dimensions, is ≈ 0.7. This threshold is more related to the expected packing density $\alpha(\lambda)$ discussed below.

Algorithm 1 Partial Rejection Sampling for the hard disks model.

PRS for Hard Disks(λ, r) // r is the disk radius and $\lambda_r = \lambda/(\pi r^2)$ the intensity
Let P be a sample from the Poisson point process of intensity λ_r on the unit square
while $B \leftarrow \mathsf{BadPoints}(P) \neq \emptyset$ **do**
  $S \leftarrow B + D_{2r}(\mathbf{0})$ // Resampling set is the Minkowski sum of B with a disk of radius $2r$
  Let P_S be a sample from the Poisson point process of intensity λ_r on S
  $P \leftarrow (P \setminus B) \cup P_S$
end while
return P

can achieve expected packing density $\Omega(2^{-d})$ while retaining runtime $O(\log(r^{-1}))$. Although sphere packings of density $\Omega(d2^{-d})$ have been proved to exist, there is no polynomial-time sampler that provably achieves packing density beyond $O(2^{-d})$, as far as we are aware.

Other approaches to exact sampling include Coupling From The Past (CFTP), which was adapted to point processes by Kendall [8] and Kendall and Møller [9]. Recently, Moka, Juneja and Mandjes [13] proposed an algorithm based on rejection and importance sampling. Although this algorithm, like ours, is based on rejection sampling, it does not share our asymptotic performance guarantee. Indeed, its running time appears to grow exponentially as the number of disks goes to infinity, with the density of disks held constant. See also [6, 14] for rigorous bounds on packing densities of grand canonical ensembles.

Approximate sampling via Markov chain simulation has been studied by Kannan, Mahoney and Montenegro [7] and Hayes and Moore [5] in the context of the canonical ensemble, where the number of disks in a configuration is fixed. The best rigorous density bound to guarantee rapid mixing is below ≈ 0.154 [5]. It is should be noted that this is not directly comparable with our $\lambda < 0.21027$ due to the difference in models. To obtain canonical ensembles, we could use Algorithm 1 and further condition on the number of desired disks. However, the only rigorous guarantee of this approach, via [6], is $\alpha(0.21027) > 0.0887$.

2 The sampling algorithm

The following notation will be used throughout. If P is a finite subset of $[0,1]^2$ then

$$\mathsf{BadPairs}(P) = \big\{\{x,y\} : x,y \in P \wedge x \neq y \wedge \|x-y\| < 2r\big\},$$

where $\|\cdot\|$ denotes Euclidean norm, and

$$\mathsf{BadPoints}(P) = \bigcup \mathsf{BadPairs}(P).$$

The open disk of radius r with centre $x \in [0,1]^2$ is denoted by $D_r(x)$. The finite set $\Pi \subset [0,1]^2$ always denotes a realisation of the Poisson point process of intensity λ_r on $[0,1]^2$. For a random variable X and event $\mathcal{E}$ we use $\mathcal{D}(X)$ to denote the distribution (law) of X, and $\mathcal{D}(X \mid \mathcal{E})$ the distribution of X conditioned on $\mathcal{E}$ occurring. Thus, $\mathcal{D}(\Pi \mid \mathsf{BadPoints}(\Pi) = \emptyset)$ is the hard disks distribution that we are interested in.

Our goal is to analyse the correctness and running time of a sampling algorithm for the hard disks model (see Algorithm 1 below), specifically to determine the largest value of λ for which it terminates quickly, i.e., in $O(\log r^{-1})$ iterations. The algorithm is an example application of "Partial Rejection Sampling" [3], adapted to the continuous state space setting.

3 Correctness

Let B be any finite subset of $[0,1]^2$. We say that B is a *feasible set* of bad points if $\mathsf{BadPoints}(B) = B$; this is equivalent to saying that there is a finite subset $R \subset [0,1]^2$ with $B = \mathsf{BadPoints}(R)$. The key to establishing correctness of Algorithm 1 is the following loop invariant:

$$\mathcal{D}(P \mid \mathsf{BadPoints}(P) = B) = \mathcal{D}(\Pi \mid \mathsf{BadPoints}(\Pi) = B),$$

for every feasible set B, where P is any intermediate set of points during the execution of the algorithm, and Π is a realisation of the Poisson point process. Let us consider what the right hand side means operationally. Let $S = B + D_{2r}(\mathbf{0})$. (This is the resampling set used by the algorithm.) Let Q be a sample from the distribution $\mathcal{D}(\Pi \mid \mathsf{BadPoints}(\Pi) = B)$. The only points in Q that lie inside S are the points in B. (Any extra points would create more bad pairs than there actually are.) Thus $Q \cap S = B$. Outside of S there are no bad pairs; thus $Q \cap \overline{S}$ is a sample from the hard disks distribution on $\overline{S} = [0,1]^2 \setminus S$. Note that, setting $B = \emptyset$, we see that $\mathcal{D}(\Pi \mid \mathsf{BadPoints}(\Pi) = \emptyset)$ is just the hard disks distribution on $[0,1]^2$.

▶ **Theorem 1.** *Algorithm 1 is correct: conditional on halting, Algorithm 1 produces a sample from the hard disks distribution with intensity $\lambda_r = \lambda/(\pi r^2)$.*

Theorem 1 follows from Lemma 2 below.

Let T (a random variable) be the number of iterations of the while-loop. On each iteration, the while loop terminates with probability bounded away from 0; thus T is finite with probability 1. (Indeed, T has finite expectation.) Let P_t, for $1 \le t \le T$, be the point set P after t iterations of the loop, and P_0 be the initial value of P (which is just a realisation of the Poisson point process on $[0,1]^2$). We say that $B_0, B_1, \ldots, B_t \subset [0,1]^2$ is a *feasible sequence* of (finite) point sets if there exists a run of Algorithm 1 with $\mathsf{BadPoints}(P_0) = B_0, \ldots, \mathsf{BadPoints}(P_t) = B_t$.

▶ **Lemma 2.** *Let $B_0, B_1, \ldots, B_t \subset [0,1]^2$ be a feasible sequence. Then*

$$\begin{aligned}\mathcal{D}\big(P_t \,\big|\, \mathsf{BadPoints}(P_0) = B_0 \wedge \cdots \wedge \mathsf{BadPoints}(P_t) = B_t\big) &= \mathcal{D}(P_t \,\big|\, \mathsf{BadPoints}(P_t) = B_t) \\ &= \mathcal{D}(\Pi \,\big|\, \mathsf{BadPoints}(\Pi) = B_t).\end{aligned}$$

Proof. We prove the result by induction on t. The base case, $t = 0$, holds by construction: P_0 is just a realisation of the Poisson point process on $[0,1]^2$. Our induction hypothesis is

$$\mathcal{D}\big(P_t \,\big|\, \mathsf{BadPoints}(P_0) = B_0 \wedge \cdots \wedge \mathsf{BadPoints}(P_t) = B_t\big) = \mathcal{D}(\Pi \,\big|\, \mathsf{BadPoints}(\Pi) = B_t), \quad (1)$$

for every feasible sequence $B_0, \ldots, B_t$. Extend the feasible sequence to B_{t+1}. For the inductive step, we assume (1) and aim to derive

$$\begin{aligned}\mathcal{D}\big(P_{t+1} \,\big|\, \mathsf{BadPoints}(P_0) = B_0 \wedge \cdots \wedge \mathsf{BadPoints}(P_{t+1}) = B_{t+1}\big) \\ = \mathcal{D}(\Pi \mid \mathsf{BadPoints}(\Pi) = B_{t+1}). \quad (2)\end{aligned}$$

The resampling set on iteration $t+1$ is $S = B_t + D_{2r}(\mathbf{0})$. As a first step we argue below that

$$\mathcal{D}\big(P_{t+1} \,\big|\, \mathsf{BadPoints}(P_0) = B_0 \wedge \cdots \wedge \mathsf{BadPoints}(P_t) = B_t\big) = \mathcal{D}(\Pi \mid \mathsf{BadPairs}(\Pi) \cap \overline{S}^{(2)} = \emptyset), \quad (3)$$

where $\overline{S}^{(2)}$ denotes the set of unordered pairs of elements from $\overline{S}$. We have noted that (1) implies that, outside of the resampling set S, the point set P_t is a realisation of the

hard disks distribution. Also, the algorithm does not resample points outside of S. Thus $P_{t+1} \cap \overline{S} = P_t \cap \overline{S}$ is Poisson distributed, conditioned on there being no bad pairs. Inside S, resampling has left behind a fresh Poisson point process $P_{t+1} \cap S$. These considerations give (3).

Next, we condition on B_{t+1}:

$$\mathcal{D}\big(P_{t+1} \,\big|\, \mathsf{BadPoints}(P_0) = B_0 \wedge \cdots \wedge \mathsf{BadPoints}(P_t) = B_t \wedge \mathsf{BadPoints}(P_{t+1}) = B_{t+1}\big) \\ = \mathcal{D}\big(\Pi \,\big|\, \mathsf{BadPairs}(\Pi) \cap \overline{S}^{(2)} = \emptyset \wedge \mathsf{BadPoints}(\Pi) = B_{t+1}\big).$$

Since B_{t+1} contains no bad pairs with both endpoints in $\overline{S}$, the event $\mathsf{BadPoints}(\Pi) = B_{t+1}$ entails the event $\mathsf{BadPairs}(\Pi) \cap \overline{S}^{(2)} = \emptyset$. Thus, we have

$$\mathcal{D}\big(P_{t+1} \,\big|\, \mathsf{BadPoints}(P_0) = B_0 \wedge \cdots \wedge \mathsf{BadPoints}(P_t) = B_t \wedge \mathsf{BadPoints}(P_{t+1}) = B_{t+1}\big) \\ = \mathcal{D}(\Pi \mid \mathsf{BadPoints}(P_{t+1}) = B_{t+1}).$$

The right hand side of this equation does not involve $B_0, \ldots, B_t$, and so

$$\mathcal{D}(P_{t+1} \mid \mathsf{BadPoints}(P_{t+1}) = B_{t+1}) = \mathcal{D}(\Pi \mid \mathsf{BadPoints}(\Pi) = B_{t+1}).$$

This completes the induction step (2) and the proof. ◀

Proof of Theorem 1. As we observed earlier, T, the number of iterations of the while-loop, is finite with probability 1. By Lemma 2, noting that $B_T = \emptyset$,

$$\mathcal{D}(P_T) = \mathcal{D}(\Pi \mid \mathsf{BadPoints}(\Pi) = \emptyset).$$

In other words, at termination, Algorithm 1 produces a realisation of the hard disks distribution on $[0,1]^2$. ◀

4 Run-time analysis

We consider how the number of "bad events", i.e., the cardinality of the set $\mathsf{BadPairs}(P_t)$, evolves with time. As usual Π denotes a realisation of the Poisson point process of intensity λ_r. Also denote by Δ a realisation of the hard disks process of the same intensity. We need the following stochastic domination result.

▶ **Lemma 3.** *The hard disks distribution is stochastically dominated by the Poisson point process with the same intensity. That is, we can construct a joint sample space for* Π *and* Δ *such that* $\Delta \subseteq \Pi$.

Holley's criterion is a useful test for stochastic domination, but it is not of direct use to us in the proof of Lemma 3, because it applies only to finite state spaces. Fortunately, Preston [15, Theorem 9.1], has derived a version of Holley's criterion that fits our situation. We will mostly follow Preston's notation, except that, to save confusion, we will use P and Q, rather than x and y, to denote finite sets of points. In order to state his result, we need some notation. In our application, $\widetilde{\omega}_n$ is the distribution on $([0,1]^2)^{(n)}$ obtained by sampling n points independently and uniformly at random from $[0,1]^2$, and regarding the points as indistinguishable; furthermore, $\widetilde{\omega} = \sum_{n=0}^{\infty} \widetilde{\omega}_n / n!$. (For consistency with Preston, we have left $\widetilde{\omega}$ unnormalised. If we had made it into a probability distribution by division by e, then $\widetilde{\omega}$ could be thought of as follows: sample an integer k from the Poisson distribution with mean 1, and then pick k (unlabelled) points uniformly and independently.) Denote by Ω

the set of all finite subsets of $[0,1]^2$, and by $\mathcal{F}$ the set of non-negative measurable functions $\Omega \to \mathbb{R}$ satisfying

$$\int f \, d\widetilde{\omega} = 1, \tag{4}$$

and

$$f(P) = 0 \text{ and } P \subseteq Q \text{ implies } f(Q) = 0. \tag{5}$$

(See Preston [15, Section 9] for detailed formal definitions of the concepts here.)

▶ **Lemma 4** (Theorem 9.1 of [15]). *Let $f_1, f_2 \in \mathcal{F}$ and suppose that*

$$\frac{f_1(P+\xi)}{f_1(P)} \geq \frac{f_2(Q+\xi)}{f_2(Q)}, \quad \text{for all } Q \subseteq P \in \Omega \text{ and } \xi \in [0,1]^2 \setminus P \tag{6}$$

(where, by convention, $0/0 = 0$). Then, for all bounded, measurable, non-decreasing functions $g : \Omega \to \mathbb{R}$,

$$\int g f_1 \, d\widetilde{\omega} \geq \int g f_2 \, d\widetilde{\omega},$$

i.e., if μ_i is the probability measure having density f_i with respect to $\widetilde{\omega}$, then μ_1 stochastically dominates μ_2.

Proof of Lemma 3. We set

$$f_1(P) = C_1 \lambda_r^{|P|}$$

and

$$f_2(P) = \begin{cases} C_2 \lambda_r^{|P|}, & \text{if } \mathsf{BadPairs}(P) = \emptyset; \\ 0, & \text{otherwise.} \end{cases}$$

The normalising constants C_1 and C_2 are chosen so that both $f = f_1$ and $f = f_2$ satisfy (4). (There is an explicit expression for C_1, namely $C_1 = \exp(-\lambda_r)$, but not for C_2.) Notice that both f_1 and f_2 also satisfy (5). Notice also that the probability measures μ_1 and μ_2 of the Poisson point process and the hard disks process have densities f_1 and f_2 with respect to $\widetilde{\omega}$. The premise (6) of Lemma 4 holds, since the left-hand side is always λ_r and the right-hand side is either λ_r or 0. The conclusion is that μ_1 dominates μ_2. Strassen's Theorem [10, 16], allows us to conclude the existence of a coupling of Π and Δ as advertised in the statement of the lemma (except, possibly, on a set of measure zero). ◀

▶ **Lemma 5.** *There is a bound $\bar{\lambda} > 0$ such that the expected number of iterations of the while-loop in Algorithm 1 is $O(\log r^{-1})$ when $\lambda < \bar{\lambda}$.*

Proof. First observe that $\mathsf{BadPairs}(P)$ determines $\mathsf{BadPoints}(P)$ and vice versa. So conditioning on the set $\mathsf{BadPairs}(P)$ is equivalent to conditioning on $\mathsf{BadPoints}(P)$.

Introduce random variables $Z_t = |\mathsf{BadPairs}(P_t)|$, for $1 \leq t \leq T$. Our strategy is to show that

$$\mathbb{E}(Z_{t+1} \mid Z_0, \ldots, Z_t) \leq \alpha^{-1} Z_t, \tag{7}$$

for some $\alpha > 1$. Then $Z_0, \alpha Z_1, \alpha^2 Z_2, \alpha^3 Z_3, \ldots$ is a supermartingale (with the convention that $Z_t = 0$ for all $t > T$). Therefore, $\mathbb{E}\, Z_t \leq \alpha^{-t}\, \mathbb{E}\, Z_0 \leq \frac{1}{2}\lambda_r^2 \alpha^{-t}$. Here, we have used the fact that $|P_0|$ is a Poisson random variable with expectation λ_r, and

$$Z_0 = |\mathsf{BadPairs}(P_0)| \leq \tfrac{1}{2}|P_0|\,(|P_0| - 1),$$

and hence

$$\mathbb{E}\, Z_0 \leq \mathbb{E}\left[|P_0|\,(|P_0|-1)\right] = \tfrac{1}{2}\lambda_r^2.$$

Setting $t = O(\log r^{-1} + \log \varepsilon^{-1})$, we obtain $\mathbb{E}\, Z_t < 1/\varepsilon$, and hence $\Pr(T > t) \leq \varepsilon$. It follows that the expected number of iterations of the while-loop of Algorithm 1 is $O(\log r^{-1})$. Note that the probability of non-termination decreases exponentially with t, so the probability of large deviations above the expected value of T is low.

Crude estimates give $\bar{\lambda} = 1/(4\sqrt{2})$. The calculation goes as follows. Suppose, in (7), we condition on the random variables $\mathsf{BadPoints}(P_0), \ldots, \mathsf{BadPoints}(P_t)$, rather than simply on $Z_0, \ldots, Z_t$. This is more stringent conditioning, since the former random variables determine the latter. It is enough to establish (7) under the more stringent conditioning. So fix $\mathsf{BadPoints}(P_0) = B_0, \ldots, \mathsf{BadPoints}(P_t) = B_t$, and note that this choice also fixes the resampling sets $S_0, \ldots, S_t$. Suppose $Z_t = |\mathsf{BadPairs}(P_t)| = k$. Inside the resampling set S_t we have a Poisson point process $P_{t+1} \cap S_t$ of intensity λ_r. Outside, by Lemma 2, there is a realisation of the hard disks process. Since we are seeking an upper bound on Z_{t+1} we may, by Lemma 3, replace $P_{t+1} \cap \overline{S}_t$ by a Poisson point process of intensity λ_r.

Let $k' = \mathbb{E}(Z_{t+1} \mid Z_0, \ldots, Z_t)$. From the above considerations we have

$$k' \leq \int_{S_t} \lambda_r \int_{[0,1]^2} \lambda_r\, \mathbf{1}_{\|x-y\|\leq 2r}\, dy\, dx. \tag{8}$$

This is an overestimate, as we are double-counting overlapping disks whose centres both lie within S_t. Now, S_t is a union of at most $2k$ disks of radius $2r$. Thus

$$\begin{aligned} k' &\leq 2k\lambda_r^2 \int_{D_{2r}(\mathbf{0})} \int_{\mathbb{R}^2} \mathbf{1}_{\|x-y\|\leq 2r}\, dy\, dx \\ &= 2k\lambda_r^2 \int_{D_{2r}(\mathbf{0})} \int_{D_{2r}(x)} dy\, dx \\ &= 2k\lambda_r^2 \times 4\pi r^2 \times 4\pi r^2 \\ &= 32\lambda^2 k. \end{aligned} \tag{9}$$

There are further sources of slack here: there may be fewer than $2k$ disks, the disks comprising S_t certainly overlap, and, for points x near the boundary, some of disks $D_{2r}(x)$ will lie partly outside the unit square. (The last of these presumably has no effect asymptotically, as $r \to 0$.) Setting $\bar{\lambda} = 1/(4\sqrt{2}) = 0.17677+$, we see that $\alpha = k/k' > 1$ for any $\lambda < \bar{\lambda}$, and $(Z_t)_{t=0}^{\infty}$ is a supermartingale, as required. ◀

The constant $\bar{\lambda}$ may seem quite small. Note, however, that classical rejection sampling cannot achieve any $\bar{\lambda} > 0$. The argument goes as follows. Divide $[0,1]^2$ into $r \times r$ squares. If there are two points in the same square then they will certainly be less than distance $2r$ apart. The number of points in each square is Poisson distributed with mean λ/π. Thus for any $\lambda > 0$ the probability that a particular square has at least two points is bounded away from zero. The number of points in each square is independent of all the others. It follows that the running time of classical rejection sampling is exponential in r^{-2}.

The above derivation for $\bar{\lambda}$ is quite crude and can be improved.

▶ **Lemma 6.** *The constant $\bar{\lambda}$ in Lemma 5 can be taken to be* 0.21027.

Proof. For each of the $2k$ disks, the right-hand side of inequality (9) counts pairs of points (x, y) with x in the disk, and y anywhere within distance $2r$ of x. Since a bad event is determined by an *unordered* pair of points, this gives rise to significant double counting.

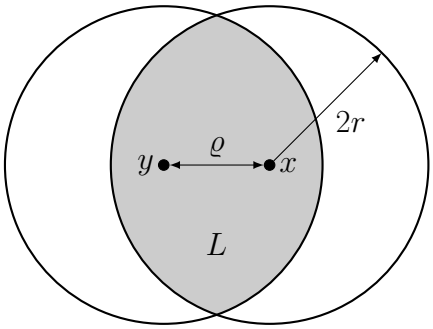

Figure 1 An illustration of double counting.

In particular, pairs (x, y) with x and y lying in the same ball are double counted. We can subtract off these pairs to obtain a better estimate.

For a single ball, the correction is

$$C = \frac{1}{2} \int_{D_{2r}(\mathbf{0})} \lambda_r \int_{D_{2r}(\mathbf{0})} \lambda_r \mathbf{1}_{\|x-y\| \le 2r} \, dy \, dx.$$

(The initial factor of one half arises because we want to count unordered pairs.) With the change of variables $x = 2rx'$ and $y = 2ry'$ this expression simplifies to

$$\begin{aligned} C &= \frac{1}{2} \times 16 r^4 \lambda_r^2 \int_{D_1(\mathbf{0})} \int_{D_1(\mathbf{0})} \mathbf{1}_{\|x'-y'\| \le 1} \, dy' \, dx' \\ &= 8\lambda_r^2 r^4 \int_{D_1(\mathbf{0})} L(\|x'\|) \, dx', \end{aligned}$$

where $L(\|x'\|)$ is the area of the "lens" $D_1(\mathbf{0}) \cap D_1(x')$. Letting ϱ denote the offset of the centres of the two disks, the area of the lens is given by

$$L(\varrho) = 2 \arccos(\varrho/2) - \tfrac{1}{2} \varrho \sqrt{4 - \varrho^2}.$$

(This is by elementary geometry: the lens is the intersection of two sectors, one from each of the disks, and its area can be computed by inclusion-exclusion.) An illustration (before shifting y to $\mathbf{0}$) is given in Figure 1. The shaded area is L.

Translating to polar coordinates (ϱ, θ),

$$\begin{aligned} C &= 8\lambda_r^2 r^4 \int_{D_1(\mathbf{0})} L(\|x'\|_2) \, dx' \\ &= 8\lambda_r^2 r^4 \int_0^{2\pi} \int_0^1 \varrho \, L(\varrho) \, d\varrho \, d\theta \\ &= \frac{8\lambda^2}{\pi^2} \times 2\pi \int_0^1 \varrho \, L(\varrho) \, d\varrho \\ &= \frac{16\lambda^2}{\pi} \left[\frac{\pi}{2} + (\varrho^2 - 1) \arccos\left(\frac{\varrho}{2}\right) - \left(\frac{\varrho}{4} + \frac{\varrho^3}{8}\right) \sqrt{4 - \varrho^2} \right]_0^1 \\ &= \left(8 - \frac{6\sqrt{3}}{\pi}\right) \lambda^2. \end{aligned}$$

(The integral was evaluated using the Maple computer algebra system.) Our revised upper bound on k' is thus

$$k' \le 2k(16\lambda^2 - C) = 2k\lambda^2 \left(8 + \frac{6\sqrt{3}}{\pi}\right), \tag{10}$$

Solving

$$\bar{\lambda}^2\left(16+\frac{12\sqrt{3}}{\pi}\right)=1$$

yields the improved bound of $\bar{\lambda}=0.21027+$. ◀

There are other factors that could in principle be used to increase $\bar{\lambda}$ further — each disk necessarily overlaps with at least one other disk, some bad events are triple or quadruple counted — but the computational difficulties rapidly increase when attempting to account for these.

5 Three or more dimensions

In higher dimensions, the hard disk model is known as the hard spheres model. Everything in Sections 3 and 4 carries across to $d>2$ dimensions with little change. For general d, the appropriate scaling for the intensity is $\lambda_{r,d}=\lambda/(v_d r^d)$, where v_d is the volume of a ball of unit radius in d dimensions. Note that in a realisation of a Poisson point process with intensity $\lambda_{r,d}$, the expected number of points in a ball of radius r is λ.

The analogue of equation (8) is

$$k' \le \int_{S_t} \lambda_{r,d} \int_{[0,1]^d} \lambda_{r,d}\, \mathbf{1}_{\|x-y\|\le 2r}\, dy\, dx,$$

which leads to

$$k' \le 2^{2d+1}\lambda^2 k.$$

So setting $\bar{\lambda}=2^{-(d+\frac{1}{2})}$ we find that $\alpha=k/k'>1$ for any $\lambda<\bar{\lambda}$. It follows that the running time of partial rejection sampling is $O(\log r)$ for any $\lambda<\bar{\lambda}$.

By a result of Jenssen, Joos and Perkins [6], we lose just a constant factor when translating from intensity λ to packing density α. (It is partly to connect with their work, we measure intensity in terms of the expected number of points in a ball of radius r.) In the proof of [6, Thm 2], the following inequality is derived:

$$\alpha \ge \inf_z \max\left\{\lambda e^{-z},\, 2^{-d}\exp[-2\cdot 3^{d/2}\lambda]\cdot z\right\}.$$

Assuming $\lambda\le\bar{\lambda}$, which holds in the range of validity of our algorithm, we have $\sqrt{2}\lambda\le 2^{-d}$ and hence

$$\begin{aligned}\alpha &\ge \inf_z \max\left\{\lambda e^{-z},\, \sqrt{2}\lambda\exp[-\sqrt{2}(3/4)^{d/2}]\cdot z\right\}\\ &= c_d\lambda,\end{aligned}$$

where

$$c_d=\inf_z \max\left\{e^{-z},\, \sqrt{2}\exp[-\sqrt{2}(3/4)^{d/2}]\cdot z\right\}.$$

Note that (c_d) is monotonically increasing, with $c_2=0.42220+$, and $\lim_{d\to\infty} c_d=0.63724+$. It follows that we can reach expected packing density $\Omega(2^{-d})$ with $O(\log r^{-1})$ expected iterations. This is currently the best that can be achieved by any provably correct sampling algorithm with polynomial (in $1/r$) runtime [7]. The asymptotically best packing density currently rigorously known is $d2^{-d}$, but achieving this would require λ to grow exponentially fast in d. This is clearly beyond the capability of partial rejection sampling, but also beyond the capability of any known efficient sampling algorithm.

Non-Preemptive Flow-Time Minimization via Rejections

Abstract

We consider the online problem of minimizing weighted flow-time on unrelated machines. Although much is known about this problem in the resource-augmentation setting, these results assume that jobs can be preempted. We give the first constant-competitive algorithm for the non-preemptive setting in the rejection model. In this rejection model, we are allowed to reject an ε-fraction of the total weight of jobs, and compare the resulting flow-time to that of the offline optimum which is required to schedule all jobs. This is arguably the weakest assumption in which such a result is known for weighted flow-time on unrelated machines. While our algorithms are simple, we need a delicate argument to bound the flow-time. Indeed, we use the dual-fitting framework, with considerable more machinery to certify that the cost of our algorithm is within a constant of the optimum while only a small fraction of the jobs are rejected.

1 Introduction

Consider the problem of scheduling jobs for weighted flow-time minimization. Given a set of m unrelated machines, jobs arrive online and have to be processed on one of these machines. Each job j is released at some time r_j, has a potentially different processing requirement (size) p_{ij} on each machine i, and a weight w_j which is a measure of its importance. The objective function is the *weighted flow time* (or *response time*): if the job j completes its processing at time C_j, the flow/response time is $(C_j - r_j)$, i.e., the time the job spends in the system. The goal is now to minimize the weighted sum $\sum_j w_j(C_j - r_j)$.

The problem of flow-time minimization has been extensively studied both from theoretical and practical perspectives. The theoretical analyses have to assume that the jobs can be pre-empted in order to prove any meaningful competitive ratio, and it is easy to see why. If we schedule a long low-weight job and a large number of short high-weight items arrive meanwhile, we cannot afford to delay the latter (else we suffer large flow-time), so the only solution would be to preempt the former (See [14] for strong lower bounds.) And even with pre-emption, the problem turns out to be difficult for multiple machines: e.g., [11] show no bounded competitive ratio is possible for the case of unrelated machines. Hence, it is natural to consider models with "resource augmentation" where the algorithm has slightly more

resources than the adversary. E.g., in the speed-augmentation setting, where the algorithm uses machines of speed $(1+\varepsilon)$-times those of the adversary, Chadha et al. [7] showed how to get a preemptive schedule with weighted flow time at most poly$(1/\varepsilon)$ times the optimal flow time.

A different model of resource augmentation was proposed by Choudhury et al. [8] in the context of load balancing and maximum weighted flow-time, where we are allowed to reject at most ε-fraction of the total weight of the incoming jobs, but we compare with the optimum off-line algorithm which is required to process all the jobs. The motivation was two-fold: (a) the model is arguably more natural, since it does not involve comparing to an imaginary optimal schedule running on a slower machine, and (b) even with speed-augmentation, there are problems, e.g. on-line load balancing, where even a constant factor speed-up does not suffice to give meaningful results. Indeed, getting a non-preemptive schedule for weighted flow-time is one of these problems. Consider for example the following input: a job of unit size and unit weight at time 0 arrives. As soon as the algorithm schedules it, the adversary releases L jobs of size $\varepsilon \ll 1/L^2$. The optimal off-line flow-time is $O(1)$, but the algorithm will incur total flow-time of $\Omega(L)$. The model of job rejection is intuitively more powerful than speed-augmentation (although no such formal connection is known): loosely, the speed-augmentation model only allows us to uniformly reject an ε-fraction of each job, whereas the rejection model allows us to "non-uniformly" reject an arbitrary subset of jobs, as long as they contribute only an ε-fraction of the total weight.

1.1 Our Results

We consider the problem of non-preemptive scheduling on unrelated machines where the objective is to minimize total weighted flow-time of jobs. Our main result is the following:

▶ **Theorem 1** (Main Theorem). *For the problem of online weighted flow-time minimization on unrelated machines, there is a deterministic algorithm that rejects at most an ε-fraction of the total weight of incoming jobs, and ensures that the total weighted flow time for the remaining jobs is at most an $O(1/\varepsilon^3)$ factor times the optimal weighted flow time without rejections.*

Note that we compare with the off-line optimum which is allowed to be preemptive (in fact, migratory), but is required to process all the jobs. Our guarantees are, in fact, stronger. Define the notion of a "departure time" D_j for the job, which is the time at which either the job completes non-preemptively (in which case $D_j = C_j$) or is the time at which the job is rejected. A different natural definition of the total weighted response time in the presence of rejections would be the following:

$$\text{total weighted response time} := \sum_j w_j(D_j - r_j).$$

Keeping this quantity small forces us to decide on jobs early, and discourages us from letting jobs linger in the system for a long time, only to reject them at some late date. (Such a behaviour would be very undesirable for a scheduling policy, and would even be considered "unprofessional" in real-world settings.)

In fact the bulk of our work is in handling the single machine case. For this case, we get a slightly stronger bound.

▶ **Theorem 2** (Single Machine). *For the problem of online weighted flow-time minimization on a single machine, there is a deterministic algorithm that rejects at most an ε-fraction of the total weight of incoming jobs, and ensures that the total weighted flow time for the remaining*

jobs is at most $O(1/\varepsilon^2)$ factor times the optimal weighted flow time without rejections even when the offline optimum is given $(1+\varepsilon)$-extra speedup.

The fact that we can compare with an optimum offline algorithm which has faster machine allows us to use known immediate-dispatch algorithms for the setting of unrelated machines in a black-box manner [7, 2].

1.2 Our Techniques

Let us first focus on the single-machine case. Our algorithm rejects jobs in two different ways: some of the jobs are rejected immediately upon arrival, and others are rejected after receiving some processing. Moreover, assume for the moment that we are running a preemptive schedule, but without speed-augmentation. The high-level idea is to reject a "random" ε-fraction of jobs that come in. At an intuitive level, this rejects only ε-fraction of the weight (although this only in expectation, whereas we want this to hold deterministically at all times), and should create the effect of ε-speed augmentation. To implement this, let α_j be the "effect" of job j on the system – i.e., the increase in the total flow-time of the jobs currently in the system (assuming no future jobs arrive). The value of α_j also naturally corresponds to settings of dual variables for a natural flow-time LP. Using this we can (more-or-less) show that (a) the α_j values of the rejected jobs give us a lower bound on OPT, whereas (b) the α_j values of the non-rejected jobs upper-bound our cost. Hence, our goal becomes: at each time cancel *at most* an ε-fraction of the total weight $\sum_j w_j$, while cancelling *at least* an ε-fraction (say) of the total "dual" value $\sum_j \alpha_j$.

A little thought shows that this abstract task is hopeless in general for any deterministic strategy (say, if the α values rise very sharply), so we have to take the structure of the α_j values into account. We do this in two steps: we break the α_j contribution into α_j^+, the effect of job j on items denser than j, and α_j^-, its effect on less-dense items. Now we put jobs into buckets based on having the same (α^+, w) or (α^-, w) values, and rejecting each $1/\varepsilon^{th}$ job in each bucket. (The actual bucketing is a little finer, see §3.) Moreover, we reject the first job in each (α^+, w) bucket. The complications arise because we are more aggresive for each such (α^+, w) bucket, and because we may not have rejected any jobs in the (α^-, w) if it had less than $1/\varepsilon$ items. In §4.3.1 we perform a delicate charging to relate our aggressive rejections for the former to the total running time of the jobs, and show that (i) this aggressive rejection does not reject too much weight, and (b) also compensates for our timid rejections in the latter bucketing.

This high-level argument was done assuming preemptions. Since we want a non-preemptive schedule, only immediate rejections do not suffice, and we also must reject some jobs which we have started processing – indeed, if a large number of high-density ("important") jobs arrive right after we start processing some long low-density job j, delaying these more important jobs would cause large flow-time. So we must reject job j. However, as long as the total weight of these new jobs is w_j/ε, we can charge the rejection to these new jobs. This rejection makes the schedule very "unstable" and hence complicates the analysis. To get around this problem, we *mark* the job j as "preemptible". We then run a version of HDF with some preemptible and other non-preemptible jobs, and show that its performance can also be related to the LP variables.

Finally, for the multiple machines case we can perform a modular reduction to the single-machines case. We first use the *immediate dispatch* algorithm of Anand et al. [2] to assign jobs to machines, assuming speed augmenation. We then show our algorithm does well even compared to a stronger benchmark (i.e., where the offline schedule – instead of the online schedule – gets the speed augmentation). This gives us the theorem for the unrelated machines.

1.3 Related Work

There has been considerable work on the problem of minimizing total flow-time in the online setting, though most of it is in the preemptive setting. Several logarithmic competitive algorithms are known for unweighted flow-time on identical machines setting [15, 3], and in the related machines setting [10, 1], but there are strong lower bounds for the case of weighted flow-time even on a single machine [5]. In the restricted assignment settings with preemption, the unweighted flow-time problem becomes considerably harder even for 3 machines [7]. The situation for non-preemptive flow-time is much harder. Kellerer et al. [14] showed that one cannot achieve $o(n)$-competitive algorithm even for a single machine.

Much stronger results are known in the speed augmentation model, where machines in the online algorithm have ε-fraction more speed than the corresponding machines in the offline setting. This model was first proposed by Kalyanasundaram and Pruhs [13] for the problem of non-clairvoyant preemptive total flow-time minimization on a single machine. They gave an $O(1/\varepsilon)$-competitive algorithm for this problem. Chadha et al. [7] gave $O(1/\varepsilon^2)$-competitive preemptive algorithm for weighted flow-time in the unrelated machines setting. This was extended to the non-clairvoyant setting by Im et al. [12]. However, the non-preemptive weighted flow-time problem has strong lower bounds in the speed augmentation model even on a single machine [16].

The rejection model was proposed by Choudhury et al. [8] in the context of load balancing and maximum weighted flow-time in the restricted assignment setting. Lucarelli et al. [16] considered the non-preemptive scheduling problem of minimizing weighted flow-time in the unrelated machines setting. They showed that one can get $O(1/\varepsilon)$-competitive algorithm if we allow both $(1+\varepsilon)$-speed augmentation and rejection of jobs of total weight ε-times the total weight. Assuming both, we can design a much simpler algorithm and use the dual fitting techniques developed for speed augmentation models to give a simple analysis of this algorithm. Independently of us, Lucarelli et al. [17] recently announced an algorithm where they can remove the speed augmentation assumption for the simpler unweighted setting.

In the *prize-collection* model, one is allowed to incur a penalty term for the rejected jobs. This model has been widely studied, see e.g. Bartal et al. [6], Eppstein et al. [9], and Bansal et al. [4], though is considerably different from our model because here one can reject a large fraction of the jobs.

2 Definitions and Preliminaries

We consider the unrelated machine scheduling problem, as defined in §1. Our schedules will be non-preemptive. For a schedule $\mathcal{S}$, let $C_j^{\mathcal{S}}$ denote the completion time of j. We use $F_j^{\mathcal{S}}$ to denote the flow-time of j, and the objective function is given by $F^{\mathcal{S}} := \sum_j w_j \cdot F_j^{\mathcal{S}}$. We may remove the superscript $\mathcal{S}$ if it is clear from the context. We use $\mathcal{O}$ to denote the optimal off-line schedule. In Section 3, when considering the special case of a single machine, we use p_j to denote the *processing time* of job j (on this machine). Define the *density* ρ_j of a job as the ratio w_j/p_j. We assume that the parameter ε satisfies $\varepsilon^2 \leq 1/2$, and that $1/\varepsilon \in \mathbb{Z}$.

Fractional weighted flow-time. Given a schedule $\mathcal{A}$, let $p_j(t)$ denote the remaining processing time of job j at time t (assuming $t \geq r_j$). The remaining weight of j at time t is defined as $w_j(t) := \rho_j \cdot p_j(t)$. The weighted flow-time of j in this schedule is defined as $w_j(C_j - r_j)$, where C_j is the completion time of j. The fractional weighted flow-time of j is defined as $\sum_{t \geq r_j} w_j(t)$. Since $w_j(t) = 0$ for $t \notin [r_j, C_j]$, and $w_j(t) \leq w_j$ for any time t, it is clear that the fractional weighted flow-time is at most the (integral) weighted flow-time of j. The following claim is easy to check.

▶ **Claim 3.** If a job j is processed without interruption during $[t, t+p_j]$, then its fractional weighted flow-time is $w_j(t-r_j) + {}^{w_j p_j}/_2$. Moreover, if a job j gets rejected at time t', its weighted fractional flow-time is at least ${}^{w_j(t'-r_j)}/_2$.

Since the integral weighted flow-time of a job as in the claim above is $w_j(t-r_j)+w_j p_j$, we see the integer and fractional flow times are within factor of 2 of each other. Thus, for jobs which do not get preempted, we can argue about weighted fractional flow-time.

3 Algorithm for Single-Machine Weighted Flow Time

In this section, we consider the single-machine setting. For ease of algorithm description, we assume that all quantities are integers so that we can schedule jobs at the level of integer time-slots. We first describe an algorithm $\mathcal{A}$ which both rejects and preempts jobs. We subsequently show how to modify this algorithm (in an online manner) to another schedule which only rejects jobs, and does no preemptions. During our algorithm, we shall say that a job j is *active* at time t if it has been released by time t, but has not finished processing until time t, and has not been rejected. Let $A(t)$ denote the set of active jobs at time t in our algorithm. A subset of these jobs, denoted by $L(t)$, will be special – these jobs are allowed to be preempted (at time t). Once a job enters the set $L(t)$ at some time t, it stays in $L(t')$ for all subsequent times $t' \geq t$ until it finishes processing.

For a job $j \in A(t)$ and time t, recall that $p_j(t)$ denotes the remaining processing time. At every point of (integer) time t, the algorithm performs the following steps (in this order):

1. If job j arrives at time t, the algorithm may choose to reject it immediately upon arrival. We will call such rejections *immediate rejections*. If the job is not rejected, it gets added to the active set $A(t)$. For the moment, this is the only way in which a job gets rejected.
2. Let j be the job getting processed just before time t (i.e., in the time-slot $[t-1, t]$). If job j was not already in the set $L(t)$, the algorithm may move it to the set $L(t)$ if "many" jobs smaller than j have arrived during its execution. We will specify the precise rule soon. Recall that once added, the job j will remain in the set $L(t)$ until it finishes.
3. If the job j getting processed in the time-slot $[t-1, t]$ did not finish at time t and it is not in $L(t)$, the algorithm will continue to process j during the next time-slot $[t, t+1]$. Otherwise, if j finishes or $j \in L(t)$, the algorithm chooses a job in $A(t)$ which has the highest density (the HDF rule) and processes it during $[t, t+1]$.

Note that if multiple jobs arrive at a time t, we consider them in arbitrary order, and carry out the first two steps above iteratively for each such job, before executing step 3. This completes the description of the algorithm, except that we have not specified the rules for the first two steps.

We first explain the rule for adding a job to $L(t)$. Suppose the algorithm processes a job j during $[t-1, t]$, and suppose $j \notin L(t-1)$. Let t' be the time when the algorithm started processing j. Since it was not allowed to preempt j, it must have processed j without interruption during $[t', t]$. If the total weight of jobs arriving during $(t', t]$ exceeds w_j/ε, we add job j to the set $L(t)$. The intuition behind this rule is simple – the final algorithm will eventually reject all jobs which get added to the set $L(t)$, for all t. We can charge the weight of the rejected job j to the weight of the jobs which arrived during $[t', t]$. Moreover, consider a job j that does not get added to $L(t)$ over its lifetime. In a preemptive setting, we may have preempted such a job j on the arrival of a new shorter job, whereas here we perform such a preemption only when enough shorter jobs arrive. Since j was not added to $L(t)$, the total weight of such shorter jobs waiting on j is at most w_j/ε, so we can pay for the additional flow-time incurred by these shorter jobs (up to an $1/\varepsilon$ factor) by the flow-time of j.

The rule for immediate rejections is more involved. We maintain two tables T^+ and T^-. Each arriving job may get assigned to either T^+ or T^-, or both. We refer to each entry of these tables as a *bucket*. At a high level, every $(1/\varepsilon)^{th}$ job arriving in each bucket in either table suffers immediate rejection, though the details differ for the two tables. Let us elaborate on this further.

With every newly arriving job j, we specify a quantity α_j, which is the increase in the total flow-time of all the jobs in the system, assuming (i) no further jobs arrive after job j, and (ii) the scheduling algorithm follows the preemptive HDF policy from r_j onwards for *all* the jobs in $A(r_j)$. As in [2], we can write an expression for α_j as follows.

$$\alpha_j := \Big(w_j \sum_{j' \in A(r_j):\ \rho_{j'} \geq \rho_j} p_{j'}(r_j)\Big) \ + \ {}^{w_j p_j}/_2 \ + \ \Big(p_j \sum_{j' \in A(r_j):\ \rho_{j'} < \rho_j} w_{j'}(r_j)\Big). \tag{1}$$

We establish the convention that $A(r_j)$ does not contain job j. Moreover, if multiple jobs are released at time r_j, we consider them in arbitrary but fixed order, and add only those jobs to $A(r_j)$ which are considered before j.

For $x \in \mathbb{R}$, let $\llbracket x \rrbracket$ denote the largest integer i such that $2^i \leq x$. For a job j, define its *density-class* as $\llbracket \rho_j \rrbracket$. We partition jobs in $A(r_j)$ depending on their density-class as follows:

$$D_j^+ := \{j' \in A(r_j) \mid \llbracket \rho_{j'} \rrbracket \geq \llbracket \rho_j \rrbracket\} \qquad \text{and} \qquad D_j^- := \{j' \in A(r_j) \mid \llbracket \rho_{j'} \rrbracket < \llbracket \rho_j \rrbracket\}. \tag{2}$$

Now let α_j^+ be the terms in the expression for α_j involving jobs in D_j^+, and define α_j^- similarly. In other words,

$$\alpha_j^+ := \Big(w_j \sum_{j' \in D_j^+ :\ \rho_{j'} \geq \rho_j} p_{j'}(r_j)\Big) + \Big(p_j \sum_{j' \in D_j^+ :\ \rho_{j'} < \rho_j} w_{j'}(r_j)\Big); \tag{3}$$

$$\alpha_j^- := \Big(p_j \sum_{j' \in D_j^- :\ \rho_{j'} < \rho_j} w_{j'}(r_j)\Big). \tag{4}$$

Clearly, $\alpha_j = \alpha_j^+ + {}^{w_j p_j}/_2 + \alpha_j^-$. We now specify the definitions of the two tables.

- Table T^+: Buckets in this table are indexed by ordered pairs of integers (κ, λ). If an arriving job j satisfies $\alpha_j^+ \geq w_j p_j/\varepsilon$, we assign it to the bucket indexed $(\llbracket {}^{\alpha_j^+}/_{w_j} \rrbracket, \llbracket w_j \rrbracket)$ in this table, and add it to the set J^+ of jobs assigned to T^+. For each bucket, we cancel the first job that is assigned to that bucket, and then every $(1/\varepsilon)^{th}$ subsequent job assigned to it.
- Table T^-: Buckets in this table are indexed by ordered triplets of integers (γ, δ, η). Each arriving job which satisfies $\alpha_j^- > w_j p_j/\varepsilon$ is assigned to the bucket indexed $(\llbracket \alpha_j^- \rrbracket, \llbracket \rho_j \rrbracket, \llbracket p_j \rrbracket)$, and added to the set J^- of jobs assigned to T^-. For each bucket, cancel every $(1/\varepsilon)^{th}$ job assigned to this bucket. Note the subtle difference with respect to T^+: here the first job to be canceled in a bucket is the $(1/\varepsilon)^{th}$ job assigned to it.

3.1 The Final Algorithm $\mathcal{B}$

The actual online algorithm $\mathcal{B}$ is almost the same as $\mathcal{A}$, except when the algorithm $\mathcal{A}$ processes a job in $L(t)$ during time-slot $[t, t+1]$, the algorithm $\mathcal{B}$ idles, leaving this slot empty. In other words, when a job being executed is added to $L(t)$, the algorithm $\mathcal{B}$ rejects the job instead of eventually finishing it, perhaps after some preemptions. (We can think of this as being a *delayed rejection*, as opposed to the *immediate rejection* that $\mathcal{A}$ performs based on the above bucketing strategy.) Clearly, we can implement $\mathcal{B}$ in an online manner.

4 Analyzing the Single-Machine Algorithm

In this section, we provide the analysis of our single-machine algorithm $\mathcal{B}$. Naturally, the two main steps are to show that (i) an $O(\varepsilon)$ fraction of jobs by weight get rejected, and (ii) the total flow time is competitive with the optimal offline algorithm.

Showing (i) is relatively straightforward: a rejected job is either immediately rejected or is later rejected in $\mathcal{B}$ due to its preemption in $\mathcal{A}$. We will show that the rejected jobs falling under each of the two categories is an $O(\varepsilon)$ fraction by weight, with a separate analysis for each category. Both of the analyses are in Section 4.1.

To show flow time competitiveness of algorithm $\mathcal{B}$, we instead focus on bounding the tota flow time of algorithm $\mathcal{A}$. By Claim 3, the total (integer) flow-time of jobs that $\mathcal{B}$ does not reject is within a factor of two of their fractional flow-time in $\mathcal{A}$, since these are precisely the jobs that $\mathcal{A}$ does not preempt. Therefore, to prove Theorem 2, it suffices to show that $\mathcal{A}$ is $O(1/\varepsilon^2)$ factor competitive with the optimal offline algorithm.

Let $J^{\texttt{immed}}$ denote the set of jobs which get rejected immediately upon arrival, and let $\mathcal{O}$ denote the optimal offline schedule and $F^{\mathcal{O}}$ its fractional weighted flow time. Roughly speaking, our goal is to establish the following chain of approximate inequalities:

$$\varepsilon F^{\mathcal{A}} \lesssim \varepsilon \sum_j \alpha_j \lesssim \sum_{j \in J^{\texttt{immed}}} \alpha_j \lesssim F^{\mathcal{O}}, \tag{5}$$

where $\lesssim$ hides additive $\sum_j {}^{w_j p_j}/_{\varepsilon^{O(1)}}$ factors. Since $F^{\mathcal{O}} \geq \sum_j w_j p_j/2$, these additive losses still provide a ${}^1/_{\varepsilon^{O(1)}}$ competitive ratio.

For the first inequality, we will bound the flow time of algorithm $\mathcal{A}$, modulo an additive $\sum_j {}^{w_j p_j}/_{\varepsilon}$ factor, by the sum of α_j over all jobs $j \notin J^{\texttt{immed}}$, which are precisely the jobs that are finished by $\mathcal{A}$. We do so by exploiting the facts that the α_j values indicate an increase in flow time to an HDF algorithm, and that $\mathcal{A}$ is "approximately" an HDF algorithm. The details are in Lemma 5.

The second inequality is the most technically involved section of the paper. Not only does the immediate rejection scheme reject an $O(\varepsilon)$ fraction of jobs, but it also rejects jobs constituting an ε fraction of the total α_j value. The analysis is in Section 4.3.

Finally, the last inequality relates the optimal offline flow time to the sum of the α_j values of immediately rejected jobs. It is restated as Lemma 6 and proved in the appendix.

4.1 Bounding Weight of Rejected Jobs

In this section, we show that the total weight of rejected jobs is only an $O(\varepsilon)$ fraction of total. Recall that jobs either suffer immediate rejection, or are added to $L(t)$ for some time t, and hence suffer delayed rejection.

Let us first bound the total weight of the set $L := \cup_t L(t)$. For a job j in $L(t)$, let s_j be the first time when it gets processed and l_j be the time at which it enters the set $L(t)$. Since j must be processed uninterrupted in this interval $(s_j, l_j]$, the intervals associated with different jobs are disjoint. Moreover job j entered $L(t)$ because the total weight of jobs released during $(s_j, l_j]$ is at least w_j/ε. Thus the total weight of jobs in L can be upper bounded by ε times the weight of all the jobs.

We now account for the weight of jobs which are rejected immediately on arrival. For job j, let $[\![w_j]\!]$ denote the *weight-class* of this job. Jobs assigned to a bucket in T^+ have the same weight-class, by construction of the buckets. Jobs assigned to a bucket in T^- have the same $[\![\rho_j]\!]$ and $[\![p_j]\!]$, which pins down their weight $w_j = \rho_j \cdot p_j$ up to a factor of 4. This gives us the following facts:

- Since we reject every $(1/\varepsilon)^{th}$ job in each bucket of T^-, the total weight of jobs in J^- which get rejected immediately is at most 4ε times the weight of all jobs in J^-.
- Let J_f^+ be the subset of jobs in J^+ which happen to be the first jobs to be assigned to their respective buckets in T^+. Then the weight of all jobs in $J^+ \setminus J_f^+$ which get rejected immediately on arrival is at most 2ε times the total weight of all the jobs in J^+.

So it remains to account for the items items in J_f^+, which are all rejected. Recall that a job in J^+ is assigned to the bucket indexed $(\llbracket \alpha_j^+/w_j \rrbracket, \llbracket w_j \rrbracket)$ in T^+. Jobs in J_f^+ are assigned to distinct buckets in T^+. Fix an integer γ, and let J^γ denote the jobs in J_f^+ which are mapped to a bucket indexed (γ, κ) for some κ. The jobs in J^γ have distinct weight-classes and so it suffices to bound the weight of the highest weight job in J^γ – let this heaviest job be j^γ. Let S denote the set of such jobs j^γ as we range over all γ. Jobs in S have distinct $\llbracket \alpha_j^+/w_j \rrbracket$ values. Let $\Gamma = \{\gamma_1 < \gamma_2 < \ldots < \gamma_k\}$ be the integers γ for which there is a job $j^\gamma \in S$, and let the corresponding jobs in S be called $j_1, j_2, \ldots, j_k$.

Now starting from the smallest index in Γ, we charge each job $j_r \in S$ to a subset of jobs of total weight at least w_{j_r}/ε. The job j_r may charge to a job fractionally – if it charges to a fraction δ of some job j, then it can only use δw_j amount of weight of j for its charging (and we say that "j_r *charges to* δp_j *size of this job* j"). Of course, we need to ensure that the total fraction charged to a job is at most 1. We inductively maintain the following invariant for all $r \in 1 \ldots k$:

- The job j_r charges to jobs of total (fractional) weight at least $w_{j_r}/8\varepsilon$.
- Jobs $j_1, \ldots, j_r$ charge to jobs of total (fractional) size at most 2^{γ_r}.

Assuming these invariants hold for $r-1$, we show that they hold for r as well. Let $\rho^\star := \llbracket \rho_{j_r} \rrbracket$ be the density class for job j_r. By j_r's choice of bucket, $\llbracket \alpha_{j_r}/w_{j_r} \rrbracket = \gamma_r$, so

$$\alpha_{j_r}^+ \geq 2^{\gamma_r} \cdot w_{j_r}. \tag{6}$$

Recall from (2) that $D_{j_r}^+$ is the set of jobs of density class $\rho^\star$ or higher which are active at the time j_r is released. Let $P_r := \sum_{j \in D_{j_r}^+} p_j$ be the total processing time of these jobs. By (3), it follows that

$$\alpha_{j_r}^+ \leq w_{j_r} P_r. \tag{7}$$

Combining (6) and (7), $P_r \geq 2^{\gamma_r}$. By the second invariant, the first r jobs $j_1, \ldots, j_{r-1}$ have only charged to jobs of total size at most $2^{\gamma_{r-1}}$, so we can find jobs in $D_{j_r}^+$ of total (fractional) size $2^{\gamma_r} - 2^{\gamma_{r-1}} \geq 2^{\gamma_r - 1}$ which have not been charged yet, and charge to them. This proves the second invariant.

To prove the first invariant, we know that $\alpha_{j_r}^+ \geq w_{j_r} p_{j_r}/\varepsilon$, else j_r would not be assigned to T^+. Moreover, $\alpha_{j_r}^+ \leq w_{j_r} 2^{\gamma_r + 1}$ by the bucketing, so $2^{\gamma_r} \geq p_{j_r}/2\varepsilon$. Consequently, we charge to jobs of total size at least $2^{\gamma_r - 1} \geq p_{j_r}/4\varepsilon$, and these jobs have density class at least $\rho^\star$. Since $2\rho^\star \geq \rho_{j_r} = w_{j_r}/p_{j_r}$, we get their total (fractional) weight is at least $w_{j_r}/8\varepsilon$. This proves the first invariant, and hence the following theorem.

▶ **Theorem 4** (Few Rejections). *The weight of jobs suffering immediate rejection, plus those in $\cup_t L(t)$, is at most an $O(\varepsilon)$ fraction of the weight of all jobs released.*

4.2 Bounding the Weighted Fractional Flow-time

Next we show that the total fractional flow-time of $\mathcal{A}$ can be bounded in terms of total α_j values. We first focus on relating $F^{\mathcal{A}}$ to the sum of the α_j values, as described in (5).

Observe that α_j denotes the increase in objective function due to the arrival of j if we had followed the preemptive HDF policy for all the jobs from time r_j onwards. However, we follow a slightly different policy – if j' denotes the job that was running on the machine at time j's release time r_j, we let j' run until it finishes, or else until j' belongs to the set $L(t')$ at some time $t' \geq r_j$. If no further jobs are released after j, the HDF policy after this time t' would be non-preemptive. Thus, we would still expect that the total fractional weighted flow-time of our algorithm to be close to $\sum_j \alpha_j$. We formalise this intuition now. For every job j, we define a job $\phi(j)$ as follows: let j' be the job which was running just before time r_j (i.e., in the slot $[r_j - 1, r_j]$). If $j' \notin L(r_j)$, we define $\phi(j)$ to be j', otherwise we leave $\phi(j)$ undefined. Our policy for adding a job to the set $L(t)$ ensures that for every job j, $w(\phi^{-1}(j))$ is at most w_j/ε. [1] Recall that $J^{\texttt{immed}}$ is the set of jobs which get rejected immediately upon arrival. The following lemma, whose proof is deferred to the full version, states that the fractional weighted flow-time of the algorithm can be charged to the α_j values of the jobs which get immediately rejected.

▶ **Lemma 5.** *The fractional weighted flow-time of $\mathcal{A}$ is at most $\sum_{j:j\notin J^{\texttt{immed}}} \alpha_j + \sum_j w_j p_j/\varepsilon$.*

Proof. Jobs in $J^{\texttt{immed}}$ get rejected immediately, so their flow-time is 0. We now consider the jobs which are not immediately rejected in the rest of the proof. Consider the jobs in order of increasing release times. Let Δ_j denote the increase in the objective function value due to arrival of j. In other words, if J_1 is the set of jobs released before j, then Δ_j equals the total fractional weighted flow-time of $\mathcal{A}$ on the input $J_2 := J_1 \cup \{j\}$ minus that on the input J_1. The total weighted flow time of $\mathcal{A}$ on the entire input would be $\sum_j \Delta_j$, the sum of these increases. We now show that

$$\Delta_j \leq \alpha_j + w_j p_{\phi(j)}. \tag{8}$$

Since $w(\phi^{-1}(j')) \leq w_{j'}/\varepsilon$, we get that $\sum_j w_j p_{\phi(j)} = \sum_{j'} w(\phi^{-1}(j'))p_{j'} \leq \sum_{j'} w_{j'} p_{j'}/\varepsilon$. Hence, summing (8) over all j which are not in $J^{\texttt{immed}}$ proves the lemma.

Now we prove (8). Since we will be dealing with two inputs, J_1 and J_2, we parameterise all quantities by J_1 or J_2 to clarify which input we refer to. For example, $A(J_k, t), k = 1, 2$ will refer to the active set $A(t)$ on input J_k. Let $F(J_k, t)$ denote the fractional weighted flow-time of jobs in $A(J_k, t)$ *beyond* time t, i.e., $F(J_k, t) := \sum_{t' \geq t} \sum_{j \in A(J_k,t')} w_j(t')$.

There are two cases when job j arrives. If $\phi(j)$ is undefined, the job j' running in slot $[r_j - 1, r_j]$ belongs to $L(r_j)$. Hence the algorithm $\mathcal{A}$ on both inputs J_1, J_2 just runs HDF starting at time r_j. The difference between the corresponding flow times is precisely α_j, by definition.

Otherwise $\phi(j)$ is well-defined. Since j is the latest arrival, the job $\phi(j)$ will not be preempted, and runs to completion. Say job $\phi(j)$ completes at time t'. During the time $[r_j, t']$ the difference in fractional weighted flow-time between the two runs is precisely $w_j \cdot (t' - r_j) \leq w_j p_{\phi(j)}$. After time t' we run HDF on the remaining jobs, and the difference in the fractional weighted flow-time of the two runs is precisely what α_j would have been had j arrived at time t' instead of time r_j. In other words, if $J' := A(J_k, r_j) \setminus \{\phi(j)\}$,

$$\begin{aligned} F(J_2, t') - F(J_1, t') &= w_j p_j/2 + \sum_{j' \in J' : \rho_{j'} \geq \rho_j} w_j p_{j'}(t') + \sum_{j' \in J' : \rho_{j'} < \rho_j} w_{j'}(t') p_j \\ &= w_j p_j/2 + \sum_{j' \in J' : \rho_{j'} \geq \rho_j} w_j p_{j'}(r_j) + \sum_{j' \in J' : \rho_{j'} < \rho_j} w_{j'}(r_j) p_j \end{aligned}$$

[1] For a set S of jobs, let $w(S)$ denote the total weight of jobs in S.

But this is a subset of the terms of α_j: indeed, we're just missing the term corresponding to job $\phi(j)$. Hence, the total difference is at most $\alpha_j + w_j p_{\phi(j)}$, proving (8). ◀

To bound our flow time against the optimum using this lemma, note that $\sum_j w_j p_j/\varepsilon \leq 2F^{\mathcal{O}}/\varepsilon$, where we recall that $\mathcal{O}$ denotes the optimal offline schedule, and $F^{\mathcal{O}}$ its fractional weighted flow time. So we just need to bound $\sum_j \alpha_j = \sum_j {}^{w_j p_j}/_2 + \sum_j \alpha_j^+ + \sum_j \alpha_j^-$. The first term is again bounded by $F^{\mathcal{O}}$, so the work is in bounding the other two terms. We first record a convenient lemma – its proof is based on LP duality arguments and construction of dual variables are similar to those in [2], and is deferred to the full version.

▶ **Lemma 6** (Duality-based Lower Bound on OPT). $\sum_{j \in J^{\texttt{immed}}} \alpha_j \leq F^{\mathcal{O}} + \sum_j {}^{w_j p_j}/_{\varepsilon}$.

4.3 Controlling the α Terms

In this section, our goal is to establish the approximate inequality $\varepsilon \sum_j \alpha_j \lesssim \sum_{j \in J^{\texttt{immed}}} \alpha_j$, introduced in (5).

▶ **Lemma 7.** $\sum_j \alpha_j^+ \leq O(1/\varepsilon) \cdot \big(\sum_j w_j p_j + \sum_{j \in J^{\texttt{immed}}} \alpha_j^+\big)$.

Proof. The definition of J^+ implies that $\sum_{j \notin J^+} \alpha_j^+ \leq \sum_{j \notin J^+} w_j p_j/\varepsilon$. It remains to bound $\sum_{j \in J^+} \alpha_j^+$. We do an accounting per bucket in T^+. Fix a bucket B indexed by a pair (κ, λ), i.e., all jobs j in this bucket have $\llbracket \alpha_j^+/w_j \rrbracket = \kappa$, and $\llbracket w_j \rrbracket = \lambda$. Hence, if j is any job in this bucket, then $2^\kappa \leq \alpha_j^+/w_j \leq 2^{\kappa+1}$, and $2^\lambda \leq w_j \leq 2^{\lambda+1}$. Multiplying, $2^{\kappa+\lambda} \leq \alpha_j^+ \leq 4 \cdot 2^{\kappa+\lambda}$, i.e., the α_j^+ values of any two jobs in this bucket differ by a factor of at most 4.

Let J_B denote the jobs in J^+ assigned to this bucket B, and n_B denote their cardinality $|J_B|$. Since we reject the first job and then every subsequent $(1/\varepsilon)^{th}$ job in J_B, we immediately reject at least $\varepsilon\, n_B$ jobs in J_B. Therefore,

$$\sum_{j \in J_B} \alpha_j^+ \leq \frac{4}{\varepsilon} \cdot \sum_{j \in J_B \cap J^{\texttt{immed}}} \alpha_j^+.$$

Summing over all buckets, the lemma follows. ◀

▶ **Lemma 8.** $\sum_j \alpha_j^- \leq O(1/\varepsilon) \cdot \big(\sum_j w_j p_j + \sum_{j \in J^{\texttt{immed}}} \alpha_j\big)$.

Proof. The argument is similar to Lemma 7 in spirit, but technically more involved. The reason is that we do not remove any jobs from a bucket of T^- until it has $1/\varepsilon$ jobs assigned to it. Hence, for a bucket B, if J_B is non-empty but $|J_B| \leq 1/\varepsilon$, we have $J_B \cap J^{\texttt{immed}} = \varnothing$. However, if J_f^- is the set of jobs in J^- which are the first jobs assigned to their corresponding buckets in T^-, then we get (as in the proof of Lemma 7) that

$$\sum_j \alpha_j^- \leq O(1/\varepsilon) \cdot \left(\sum_j w_j p_j + \sum_{j \in J^{\texttt{immed}}} \alpha_j^- + \sum_{j \in J_f^-} \alpha_j^- \right). \tag{9}$$

It remains to bound $\sum_{j \in J_f^-} \alpha_j^-$, which we accomplish via the following claim. Since the proof is more technical, we defer it to the next section.

▶ **Claim 9.** $\sum_{j \in J_f^-} \alpha_j^- \leq O(\varepsilon) \cdot \big(\sum_j w_j p_j + \sum_j \alpha_j^+\big)$.

Combining this with (9) and Lemma 7, using that $\alpha_j^+ + {}^{w_j p_j}/_2 + \alpha_j^- = \alpha_j$, the lemma follows. ◀

Combining Lemmas 7 and 8 along with Lemma 5 and Lemma 6, we get

▶ **Theorem 10.** *The fractional weighted flow-time of the non-rejected jobs in $\mathcal{A}$ is $O(F^{\mathcal{O}}/\varepsilon^2)$.*

4.3.1 Proof of Claim 9

Define $\Lambda^+ := \sum_j \alpha_j^+$. Recall that for a job j, its density class is given by $\lfloor \rho_j \rfloor = \lfloor w_j/p_j \rfloor$. For each density class $\delta \in \mathbb{Z}$, let us define some notation:

- Let $A^\delta(t) := \{j \in A(t) \mid \lfloor \rho_j \rfloor = \delta\}$ denote jobs in $A(t)$ whose density class is δ.
- Let $P^\delta(t) := \sum_{j \in A^\delta(t)} p_j(t)$ and $W^\delta(t) := \sum_{j \in A^\delta(t)} w_j(t)$ be the total processing time and residual weight of jobs in $A^\delta(t)$, respectively. Since all jobs in this set have the same density class, observe that $\frac{W^\delta(t)}{P^\delta(t)}$ also lies in the range $[2^\delta, 2^{\delta+1})$.
- Define $P^\delta := \max_t P^\delta(t)$ and $W^\delta := \max_t W^\delta(t)$.

Our proof shows that $\sum_\delta P^\delta W^\delta$ is small; then we bound $\sum_{j \in J_f^-} \alpha_j^-$ by $\sum_\delta P^\delta W^\delta$. The proof of the following technical lemma is deferred to the full version.

▶ **Lemma 11.** $\sum_\delta P^\delta W^\delta \le O(1) \cdot \left(\sum_j w_j p_j + \Lambda^+ \right)$.

▶ **Lemma 12.** $\sum_{j \in J_f^-} \alpha_j^- \le O(\varepsilon) \cdot \sum_\delta P^\delta W^\delta$.

Proof. Let us first give a general method for bounding α_j^- of any job $j \in J^-$, and then we can apply it to the jobs in $J_f^- \subseteq J^-$. Recall that the jobs which contribute to α_j^- are the ones with a strictly smaller density class than that of j. We now show that one need not look at jobs of all such classes, and a subset of these classes suffice. Fix a job $j \in J^-$ of density class δ, and define an index set $\mathbb{I}_j$ as $\{\theta < \delta \mid P^\theta(r_j) \ge (1.5)^{\delta-\theta} p_j/8\varepsilon\}$.

▶ **Claim 13.** For any job $j \in J^-$ with density class δ, $\alpha_j^- \le 4p_j \cdot \sum_{\theta \in \mathbb{I}_j} W^\theta$.

Proof. Let j' be a job in $A(r_j)$ of strictly lower density class than j. Its contribution towards α_j^- is $p_j w_{j'}(r_j)$. Therefore, α_j^- is at most

$$\sum_{\theta<\delta} p_j W^\theta(r_j) = p_j \cdot \sum_{\theta \in \mathbb{I}_j} W^\theta(r_j) + p_j \cdot \sum_{\theta \notin \mathbb{I}_j, \theta<\delta} W^\theta(r_j). \tag{10}$$

Let us bound the summation from the second expression.

$$\sum_{\theta \notin \mathbb{I}_j, \theta<\delta} W^\theta(r_j) \le \sum_{\theta \notin \mathbb{I}_j, \theta<\delta} 2^{\theta+1} P^\theta(r_j) \le \sum_{\theta<\delta} \frac{(1.5)^{\delta-\theta}}{2^{\delta-\theta}} \cdot \frac{2^\delta p_j}{4\varepsilon} \le \frac{3w_j}{4\varepsilon}. \tag{11}$$

Substituting (11) into (10), and using that $\alpha_j^- \ge w_j p_j/\varepsilon$ for all jobs $j \in J^-$, we get that $\alpha_j/4 \le p_j \sum_{\theta \in \mathbb{I}_j} W^\theta(r_j) \le p_j \sum_{\theta \in \mathbb{I}_j} W^\theta$, which proves the desired result. ◀

Recall that job $j \in J^-$ is mapped in table T^- to the bucket indexed by $(\lfloor \alpha_j^- \rfloor, \lfloor \rho_j \rfloor, \lfloor p_j \rfloor)$. For a fixed pair (δ, η), consider the jobs in J_f^- which are mapped to buckets indexed (γ, δ, η) with various values of γ, and denote these jobs by $J_{(\delta,\eta)}$. Since J_f^- only contains the first job in each bucket, the $\lfloor \alpha_j^- \rfloor$ values of the various jobs in $J_{(\delta,\eta)}$ are all distinct. It follows that if $j^\star$ is the job in $J_{(\delta,\eta)}$ with the highest α_j^- value, then $\sum_{j \in J_{(\delta,\eta)}} \alpha_j^- \le 4\alpha_{j^\star}^-$. Thus, we just need to worry about one job per $J_{(\delta,\eta)}$ – let S denote this set of jobs.

The ordered pairs $(\lfloor \rho_j \rfloor, \lfloor p_j \rfloor)$ corresponding to jobs $j \in S$ are all distinct. For density class δ, let S^δ denote the jobs in S with density class δ. Using Claim 13,

$$\sum_{j \in S^\delta} \alpha_j^- \le 4 \sum_{j \in S^\delta} p_j \sum_{\theta \in \mathbb{I}_j} W^\theta = 4 \sum_{\theta<\delta} W^\theta \sum_{j \in S^\delta : \theta \in \mathbb{I}_j} p_j. \tag{12}$$

The jobs in S^δ also have different $[\![p_j]\!]$ values, so the sum $\sum_{j\in S^\delta:\theta\in\mathbb{I}_j} p_j \le 4p_{j'}$ for the job $j' := \arg\max\{p_j \mid j \in S^\delta, \theta \in \mathbb{I}_j\}$. By definition of $\mathbb{I}_j$, $p_{j'} \le 8\varepsilon P^\theta/(1.5)^{\delta-\theta}$. Substituting into (12),

$$\sum_{j\in S^\delta} \alpha_j^- \le 16 \sum_{\theta<\delta} \frac{8\varepsilon\, W^\theta P^\theta}{(1.5)^{\delta-\theta}}. \tag{13}$$

To complete the argument, $\sum_{j\in J_f^-} \alpha_j^-$ is at most

$$4\sum_\delta \sum_{j\in S^\delta} \alpha_j^- \overset{\text{eq.(13)}}{\le} 2^9\varepsilon \sum_\delta \sum_{\theta<\delta} \frac{W^\theta P^\theta}{(1.5)^{\delta-\theta}} = 2^9\varepsilon \sum_\theta W^\theta P^\theta \cdot \sum_{\delta>\theta} \frac{1}{(1.5)^{\delta-\theta}} = O\Big(\varepsilon \sum_\theta W^\theta P^\theta\Big).$$

This completes the proof of Lemma 12. ◀

Combining Lemmas 11 and 12 completes the proof of Claim 9, and hence for Theorem 10. In the full version of the paper we show that the algorithm is competitive even against an optimal algorithm that is allowed $(1+\varepsilon)$-speed augmentation – and hence prove Theorem 2.

5 Extension to Unrelated Machines

The extension of our result on single machine to the more general scenario of unrelated machines can be done very modularly. We shall use the following result from [7, 2].

▶ **Theorem 14.** *There is an online algorithm $\mathcal{D}$ which dispatches each arriving job j immediately upon arrival to one of the m machines such that the following property holds: if $J^{(i)}$ is the set of jobs which are dispatched to machine i and $\mathcal{O}^{\varepsilon',i}$ is the optimal solution to $J^{(i)}$ when we have only one machine with speed $(1+\varepsilon')$, then $\sum_i F^{\mathcal{O}^{\varepsilon',i}}$ is at most $1/\varepsilon'$ times the optimal weighted flow-time of J.*

The algorithms in [7, 2] actually build a schedule as well and use this schedule to immediately dispatch a job. The algorithm $\mathcal{D}$ can build this schedule in the *background* and use it to dispatch jobs, but not use it for actual processing. It follows from Theorem 14 and our result showing that our algorithm is also competitive against an optimal algorithm that is allowed $(1+\varepsilon)$-speed augmentation (which we defer to the full version), that if we run our algorithm on each of the machines i (with input $J^{(i)}$ arriving on-line) independently, then the total weighted flow-time of non-rejected jobs in our algorithm is at most $O(1/\varepsilon^3)$ times the optimal value.

Abstract

Suppose a set of requests arrives online: each request gives some value v_i if accepted, but requires using some amount of each of d resources. Our cost is a convex function of the vector of total utilization of these d resources. Which requests should be accept to maximize our profit, i.e., the sum of values of the accepted demands, minus the convex cost?

We consider this problem in the random-order a.k.a. secretary model, and show an $O(d)$-competitive algorithm for the case where the convex cost function is also *supermodular*. If the set of accepted demands must also be independent in a given matroid, we give an $O(d^3\alpha)$-competitive algorithm for the supermodular case, and an improved $O(d^2\alpha)$ if the convex cost function is also separable. Here α is the competitive ratio of the best algorithm for the submodular secretary problem. These extend and improve previous results known for this problem. Our techniques are simple but use powerful ideas from convex duality, which give clean interpretations of existing work, and allow us to give the extensions and improvements.

1 Introduction

The problem we consider is a basic convex optimization problem in the online setting: n items appear one-by-one. Each item/element e has a *d-dimensional size* $s(e) \in \mathbb{R}^d_+$ and a *value* $v(e) \in \mathbb{R}_+$, which are both revealed to us when the item arrives.We must either accept

or reject an item when it arrives, before seeing the future items. If we accept a certain subset $A \subseteq [n]$ of the items, we get their total value $v(A) := \sum_{e \in A} v_e$, but incur a production cost $g(s(A)) := g(\sum_{e \in A} s(e))$, where $g : \mathbb{R}^d_+ \to \mathbb{R}_+$ is a non-decreasing *convex cost* function with $g(0) = 0$. Optionally, we may also be given a downwards-closed family of subsets $\mathscr{F} \subseteq 2^{[n]}$, and now the accepted set of elements A must lie in $\mathscr{F}$. More formally, we want to solve

$$\max_{A \in \mathscr{F}} \text{ profit } \pi(A) := \big[v(A) - g(s(A))\big]. \tag{1.1}$$

This question arises, e.g., when we are selling some service that depends on d commodities, where the value is the amount of money customer e is willing to pay for the service, and the size vector $s(e)$ is the amount of resources she will require. The cost function $g(\cdot)$ captures our operating expenses; its convexity models *diseconomies of scale* that arise when dealing with scarce commodities. In particular, it can capture d-dimensional knapsack constraints, by setting $g(z) = 0$ until the knapsack size, and ∞ afterwards. When the cost function is linear $g(z) = \langle a, z \rangle$, we want to pick a max-weight subset from $\mathscr{F}$ using item weights $v(e) - \langle a, s(e) \rangle$, which is tractable/approximable for $\mathscr{F}$ being a matroid, p-system, etc.

Blum et al. [6] defined this problem in the adversarial model, and gave posted-price algorithms for "low-degree" *separable* cost functions g, that is, of the form $g(z) = \sum_{i=1}^{d} g_i(z_i)$ for 1-dimensional functions g_i's. This result was tightened by Huang and Kim [16], still for separable functions with additonal growth control. More recently, Azar et al. [3] studied this problem for more general *supermodular* non-separable convex functions g (see also [9]). A differentiable function g is supermodular if for any vectors $x \leq x'$ we have $\nabla g(x) \leq \nabla g(x')$. Equivalently, if g is twice-differentiable, it is supermodular if $\frac{\partial^2 g}{\partial x_i \partial x_j} \geq 0$ for all $i \neq j$, i.e., increasing the consumption of a resource cannot decrease the marginal cost for another. However, to handle the worst-case ordering, Azar et al. also require the cost functions to have essentially low-degree.

Can we do better by going beyond the worst-case model? In this paper, we focus on the random-order or "secretary" setting, where the set of items is fixed by an adversary but they arrive in random order. In the single-dimensional case $d = 1$, it is easy to see that a solution that learns a "good" threshold λ and picks all further items with density $v(e)/s(e)$ at least λ essentially gives a constant approximation, much like in the secretary and knapsack secretary problems [13, 4]. The multi-dimensional case is much more challenging. This was studied by Barman et al. [5], again assuming a separable cost function $g(z) = \sum_{i=1}^{d} g_i(z_i)$. They give an $O(d)$-competitive algorithm for the unconstrained case, and an $O(d^5\alpha)$-competitive algorithm for the problem with a downward closed constraint set $\mathscr{F}$, where α is the competitive ratio for the $\mathscr{F}$-secretary problem. Their main idea is to perform a clever decomposition of the value of each item into "subvalues" $v_i(e)$ for each of the coordinate cost functions g_i's; this effectively decomposes the problem into d 1-dimension problems with values v_i's and costs g_i's. Unfortunately, since their solution explicitly relies on the decomposability of the cost function, it is unclear how to extend it to general supermodular functions. We note that when the cost function is supermodular, the profit function is a *submodular* set function (Section 2.1). However, the profit can take *negative values*, and then existing algorithms for submodular maximization break down.

Our work is then motivated by trying to better understand the multi-dimensional nature of this problem, and provide a more principled algorithmic approach.

1.1 Our Results

We use techniques from convex duality to re-interpret, simplify, and improve the existing results. First, we obtain the first approximation for non-separable supermodular cost functions. (We omit some mild regularity conditions for brevity; see Section 3 for full details.)

▶ **Theorem 1** (Unconstrained & Supermodular). *For the unconstrained problem with* supermodular *convex cost functions g, we give an $O(d)$-competitive randomized algorithm in the random-order model.*

This result generalizes the $O(d)$-approximation of Barman et al. [5] to the non-separable case. The factor d seems unavoidable, since our problem inherits the (offline) $\Omega(d^{1-\varepsilon})$ hardness of the d-dimensional knapsack, assuming $NP \neq ZPP$ [7].

Next, we consider the constrained case. For simplicity, we focus on the most interesting case where $\mathscr{F}$ is a matroid constraint; more general results can be obtained from the results and techniques in Section 5.

▶ **Theorem 2** (Constrained & Separable). *For the constrained problem with $\mathscr{F}$ being a matroid constraint, and the cost function g being* separable*, we get an $O(d^2 \log\log \mathit{rank})$-competitive randomized algorithm in the random-order model.*

This improves by a factor of d^3 the $O(d^5 \log\log \mathrm{rank})$-approximation given by [5]. Finally, we give a general reduction that takes an algorithm for *separable* functions and produces an algorithm for *supermodular* functions, both with respect to a matroid constraint, implying:

▶ **Theorem 3** (Constrained & Supermodular). *For the constrained problem with $\mathscr{F}$ being a matroid constraint, and the cost function g being* supermodular*, we get an $O(d^3 \log\log \mathit{rank})$-competitive randomized algorithm in the random-order model.*

On conceptual contributions are in bringing techniques from convex duality to obtain, in a principled way, *threshold-based* algorithms for non-linear secretary problems. Since this is a classical and heavily used algorithmic strategy for secretary problems [13, 4, 18, 2, 20] we hope that the perspectives used here will find use in other contexts.

1.2 Other Related Work

There is a vast literature on secretary problems [13]. Closest to our setting, Agrawal and Devanur study an online convex optimization problem in the random order model, and give a powerful result showing strong regret bounds in this setting [1]. They extend this result to give algorithms for online packing LPs with "large" right-hand sides. However, it is unclear how to use their algorithm to obtain results in our setting. Other algorithms solving packing LPs with large right-hand sides appear in [2, 8, 20, 17, 14, 10].

Feldman and Zenklusen [12] show how to transform any algorithm for (linear) matroid secretary into one for *submodular* matroid secretary. They give an $O(\log\log \mathrm{rank})$-algorithm for the latter, based on results of [19, 11]. All these algorithms critically assume the submodular function is non-negative everywhere, which is not the case for us, since picking too large a set may cause the profit function to go negative. Indeed, one technical contribution is a procedure for making the profit function non-negative while preserving submodularity (Section 4.1), which allows us to use these results as part of our solution.

1.3 Structure of the paper

Section 3 develops the convex duality perspective used in the paper for the offline version of the unconstrained case, hopefully in an manner accessible to non-experts. Section 4 gives the small changes required to extend this to the constrained case. Section 5 shows how transform these into online algorithms. Section 6 shows how to convert an algorithm for separable functions into one for supermodular functions, both subject to matroid constraints. To improve the presentation, we make throughout mild assumptions, which are discharged in the full version of the paper.

2 Preliminaries

Elements from a universe U of size n are presented in random order. Each element e has value $v(e) \in \mathbb{R}_+$ and size $s(e) \in \mathbb{R}^d_+$. We are given a convex cost function $g : \mathbb{R}^d_+ \to \mathbb{R}_+$. On seeing each element we must either accept or discard it. A downwards-closed collection $\mathscr{F} \subseteq 2^U$ of feasible sets is also given. When $\mathscr{F} = 2^U$, we call it the *unconstrained* problem. The goal is to pick a subset $A \in \mathscr{F}$ to maximize the *profit*

$$\pi(A) := \sum_{e \in A} v(e) - g\big(\sum_{e \in A} s(e)\big). \tag{2.2}$$

We often use vectors in $\{0,1\}^n$ to denote subsets of U; χ_A denotes the indicator vector for set A. Hence, $\mathscr{F} \subseteq \{0,1\}^n$ is a down-ideal on the Boolean lattice, and we can succinctly write our problem as

$$\max_{x \in \mathscr{F}} \quad \pi(x) := \langle v, x \rangle - g(Sx), \tag{2.3}$$

where columns of $S \in \mathbb{R}^{d \times n}$ are the item sizes. Let opt denote the optimal value. For a subset $A \subseteq U$, $v(A)$ and $s(A)$ denote $\sum_{e \in A} v(e) = \langle v, \chi_A \rangle$ and $\sum_{e \in A} s(e) = S\chi_A$ respectively.

▶ **Definition 4** (Exceptional). Item $e \in U$ is *exceptional* if $\arg\max_{\theta \in [0,1]} \{\theta\, v(e) - g(\theta\, s(e))\} \in (0,1)$.

▶ **Definition 5** (Marginal Function). Given $g : \mathbb{R}^d \to \mathbb{R}$, define the i^{th} *marginal function* $g_i : \mathbb{R} \to \mathbb{R}$ as $g_i(x) := g(x\mathbf{e}_i)$, where $\mathbf{e}_i$ is the i^{th} standard unit vector.

▶ **Definition 6** (Convex Dual). For any function $g : \mathbb{R}^d \to \mathbb{R}$, its *convex dual* is the function $g^\star : \mathbb{R}^d \to \mathbb{R}$ given by $g^\star(y) := \sup_x \big[\langle y, x \rangle - g(x)\big]$.

2.1 Supermodular Functions

While supermodular functions defined over the Boolean lattice are widely considered, one can define supermodularity for all real-valued functions.

▶ **Definition 7** (Supermodular). Let $X \subseteq \mathbb{R}^d$ be a lattice. A function $f : X \to \mathbb{R}$ is *supermodular* if for all $x, y \in X$, $f(x) + f(y) \le f(x \wedge y) + f(x \vee y)$, where $x \wedge y$ and $x \vee y$ are the component-wise minimum and maximum operations.

This corresponds to the usual definition of (discrete) supermodularity when $X = \{0,1\}^d$. For proof of the lemma below and other equivalent definitions, see, e.g., [21].

▶ **Lemma 8** (Supermodularity and Gradients). *A convex function $f : \mathbb{R}^d_+ \to \mathbb{R}$ is supermodular if and only if any of the following are true.*

- *∇f is increasing in each coordinate, if f is differentiable.*
- *$\frac{\partial^2 f(x)}{\partial x_i \partial x_j} \ge 0$ for all i, j, if f is twice-differentiable.*

▶ **Lemma 9** (Superadditivity). *If $f : \mathbb{R}^d_+ \to \mathbb{R}$ is differentiable, convex, and supermodular, then for $x, x', y \in \mathbb{R}^d_+$ such that $x' \le x$, $f(x' + y) - f(x') \le f(x + y) - f(x)$. In particular, if $f(0) = 0$, setting $x' = 0$ gives $f(x) + f(y) \le f(x + y)$.*

▶ **Corollary 10** (Subadditivity of profit). *The profit function π is subadditive.*

The next fact shows that the cost g is also supermodular when seen in a discrete way.

▶ **Fact 11** (Continuous vs. Discrete Supermodularity). *Given a convex supermodular function $g : \mathbb{R}^d \to \mathbb{R}$ and n items with sizes $s_1, \ldots, s_n \in \mathbb{R}^d_+$, define the function $h : \{0,1\}^n \to \mathbb{R}$ as $h(v) = g(\sum_i s_i v_i) = g(Sv)$. Then $h(\cdot)$ is a (discrete) supermodular function.*

3 The Offline Unconstrained Problem

We first present an offline algorithm for supermodular functions in the **unconstrained** case (where $\mathscr{F} = \{0,1\}^n$). We focus on the main techniques and defer some technicalities and all computational aspects for now. Just for this section, we assume item sizes are "infinitesimal". We make the following assumptions on the cost function g and the elements.

▶ **Assumption 12.** *We assume that cost function g is non-negative, strictly convex, closed, and differentiable. We assume $g(0) = 0$, g is supermodular, and that gradients of g go to ∞ along every positive direction. We assume elements are in general positionand that there are no exceptional items. We also assume that every individual item has profit at most $M := \mathsf{opt}/\eta d$ for $\eta \geq 10^4$ (see the full version to remove these assumptions).*

Classifiers. The offline algorithm will be based on *linear classifiers*, where a set of weights is used to aggregates the multidimensional size of an item into a scalar, and the algorithm picks all items that have high-enough value/aggregated-size ratio.

▶ **Definition 13** (Classifiers and Occupancy)**.** Given a vector $\lambda \in \mathbb{R}^d_+$ (a "classifier"), define the set of items picked by λ as $U_\lambda := \{e \in U \mid v(e) \geq \langle \lambda, s(e)\rangle\}$. Let $\mathsf{occ}_\lambda := \sum_{e:v(e)\geq\langle\lambda,s(e)\rangle} s(e)$ denote the multidimensional occupancy induced by choosing items in U_λ.

To understand the importance of classifier-based solutions it is instructive to consider the problem with single-dimensional size. A little thought shows that an optimal solution is to pick items in decreasing order of value density $v(e)/s(e)$. Adding these items causes the total occupancy – and hence the incurred cost – to increase, so we stop when the value density of the current item becomes smaller than the derivative of the cost function at the current utilization. That is, we find a density threshold λ such that $g'(\textit{total size of items having } v(e) \geq \lambda\, s(e)) \approx \lambda$, and take all these high-density items. Thus, the optimal solution is one based on the classifier λ.

To see that this holds in the multi-dimensional case, express g in terms of linearizations

$$g(z) = \max_{\lambda \in \mathbb{R}^d_+} (\langle \lambda, z\rangle - g^\star(\lambda)), \tag{3.4}$$

where $g^\star$ is its Fenchel dual. (Note we are maximizing over positive, but this is WLOG.) Then our unconstrained problem (2.2) becomes a minimax problem:

$$\max_{x\in\{0,1\}^n} \min_{\lambda\in\mathbb{R}^d_+} \left[\langle v, x\rangle - \Big(\langle \lambda, Sx\rangle - g^\star(\lambda)\Big)\right].$$

Consider an optimal pair (x^*, λ^*); i.e., a pair that is a saddle-point solution, so neither x^* nor λ^* can be improved keeping the other one fixed. This saddle-point optimality implies:

(a) Since $\lambda^* = \operatorname{argmax}_{\lambda\in\mathbb{R}^d_+} (\langle \lambda, Sx^*\rangle - g^\star(\lambda))$, it is the right linearization of g at Sx^* and thus $\lambda^* = \nabla g(Sx^*)$ (see [15, Theorem E.1.4.1] and [15, Corollary E.1.3.6]).

(b) x^* is such that $x^*_i = 1$ if $v_i > \langle \lambda^*, S^i\rangle$ and $x^*_i = 0$ if $v_i < \langle \lambda^*, S^i\rangle$, with S^i being the i^{th} column of S and the size of the i^{th} item.

From part (b) we see the optimal solution x^* is essentially the one picked by the classifier λ^* (ignoring coordinates with "0 marginal value" $v_i = \langle \lambda^*, S^i\rangle$). The converse also holds.

▶ **Claim 14.** *For a classifier $\lambda \in \mathbb{R}^d_+$, let x be the items picked by it. If we have $\lambda = \nabla g(Sx) \stackrel{def}{=} \nabla g(\mathsf{occ}_\lambda)$, then x is an optimal solution.*

Proof. For any solution x',

$$\pi(x') = \langle v, x' \rangle - g(Sx') \le \langle v, x' \rangle - \langle \lambda, Sx' \rangle + g^\star(\lambda)$$
$$\le \langle v, x \rangle - \langle \lambda, Sx \rangle + g^\star(\lambda) \overset{(\lambda = \nabla g(Sx))}{=} \langle v, x \rangle - g(Sx) = \pi(x),$$

where the second inequality holds since, by definition, x maximizes $\langle v, x \rangle - \langle \lambda, Sx \rangle$. ◀

Restricting the Set of Classifiers. The existence of such good classifiers is not enough, since we need to *find* them online. This is difficult not only because of d degrees of freedom and no control over the magnitude of the values/sizes (to be exploited in concentration inequalities), but also because picking too few or too many items could lead to low profits.

So we restrict the set of candidate classifiers to be a *monotone*[4] *1-dimensional* curve $\mathcal{C} \subseteq \mathbb{R}^d_+$, satisfying additional properties given below. The main motivation is that it imposes a total ordering on the set of items picked by the classifiers: given $\lambda \le \mu$ on such a curve $\mathcal{C}$, the sets of items picked satisfy the inclusion $U_\lambda \supseteq U_\mu$. This allows us to select a "minimally good" classifier in $\mathcal{C}$ in a robust way, avoiding classifiers that select too many items.

To design the curve $\mathcal{C}$ so it contains a classifier with profit $\approx \frac{\mathsf{opt}}{d}$, we relax the condition $\nabla g(\mathsf{occ}_\lambda) = \lambda$ from Claim 14 (too much to ask) and require the existence of $\lambda \in \mathcal{C}$ satisfying:

(P1) (don't pick too many items) $\nabla g(\mathsf{occ}_\lambda) \le \lambda$.
(P2) (partial gradient equality) There is a coordinate i^* where $(\nabla g(\mathsf{occ}_\lambda))_{i^*} = \lambda_{i^*}$.
(P3) (balanced curve) $g_i^\star(\lambda_i) = g_j^\star(\lambda_j) \quad \forall i, j \in [d]$.

Property (P1) enforces half of the equality in Claim 14, and (P2) guarantees that equality holds for *some* coordinate. Now for property (P3). Since $\lambda \ne \nabla g(\mathsf{occ}_\lambda)$ the optimality proof of Claim 14 does not go though, since $g(\mathsf{occ}_\lambda) \ne \langle \lambda, \mathsf{occ}_\lambda \rangle - g^\star(\lambda)$. As we prove later, the difference between these terms can be at most $g^\star(\lambda) \le \sum_i g_i^\star(\lambda_i)$. Property (P3) is used to control this sum, by charging it to the coordinate i^* where we know we have "the right linearization" (by property (P2)). Reinterpreting the construction of [5] in our setting, we then define $\mathcal{C}$ as any monotone curve where every $\lambda \in \mathcal{C}$ satisfies (P3).

▶ **Lemma 15.** *The curve $\mathcal{C}$ exists and contains a λ satisfying properties (P1)-(P3).*

Proof. We first show existence, that is, the set $\{\lambda \in \mathbb{R}^d_+ \mid g_i^\star(\lambda_i) = g_j^\star(\lambda_j) \ \ \forall i, j\}$ contains a monotone curve. Notice that this set is the union of the box $\{\lambda \in \mathbb{R}^d_+ \mid g_i^\star(\lambda_i) = 0 \ \ \forall i\} = \prod_i [0, g_i'(0)]$ (range of slopes where we can swivel around $g_i(0) = 0$) and a monotone curve $\{\lambda(\tau) \mid \tau > 0\}$, where $\lambda(\tau)$ is the unique vector satisfying $g_i^\star(\lambda_i(\tau)) = \tau$; uniqueness follows from the fact $g_i^\star$ stays at value zero in the interval $[0, g_i'(0)]$, but after that is strictly increasing due to its convexity, and monotonicity of this curve also follows from monotonicity of the $g_i^\star$'s. Thus, $\mathcal{C}$ is this curve plus any monotone curve extending it to the origin.

To see that $\mathcal{C}$ satisfies properties (P1) and (P2), we note that since the $g_i^\star$'s are increasing and not identically 0, $\mathcal{C}$ is unbounded in all coordinates. Thus, a sufficiently large $\lambda \in \mathcal{C}$ satisfies (P1), and we can start with such λ and move down the curve (decreasing in each coordinate) until we obtain $\lambda' \in \mathcal{C}$ with $\lambda' = \nabla g(\mathsf{occ}_{\lambda'})$, since the g has increasing gradients. (The equality in this final step uses the assumption that item sizes are infinitesimal, which we made for simplicity in this section). ◀

Making the above discussion formal, we show that $\mathcal{C}$ has a high-value classifier. Recall that U_λ is the set of items picked by λ (Definition 13).

[4] A curve $\mathcal{C}$ is *monotone* if for every pair $\lambda, \lambda' \in \mathcal{C}$, one is coordinate-wise smaller than the other.

▶ **Theorem 16.** *Given Assumption 12, let λ^* be a classifier in $\mathcal{C}$ satisfying properties (P1)-(P3). Then for all $x' \in [0,1]^n$ we have $\pi(U_{\lambda^*}) \geq \frac{1}{d+1} \cdot \pi(x')$.*

Proof. Let $x^* = \chi_{U^*_\lambda}$ be the solution picked by the classifier λ^*, and note that $\mathsf{occ}_{\lambda^*} = Sx^*$. Let $L(y,\mu) := \langle v, y\rangle - [\langle \mu, Sy\rangle - g^\star(\mu)]$ be the linearization of $\pi(y)$ at some slope μ. From (3.4) we know $g(y) \geq L(y,\mu)$ for all $\mu \geq 0$. Since x^* is optimal for the linearization $L(y,\lambda^*)$ (because $x^*_i = 1$ iff $v_i - \langle \lambda^*, S^i\rangle \geq 0$), we have

$$L(x^*,\lambda^*) \geq L(x',\lambda^*) \geq \pi(x') \qquad \text{for all } x' \in [0,1]^n. \tag{3.5}$$

Now we relate the true profit $\pi(x^*)$ to this linearized value. Observe that

$$\begin{aligned}\pi(x^*) = \langle v, x^*\rangle - g(Sx^*) &= \langle v, x^*\rangle - [\langle \nabla g(Sx^*), Sx^*\rangle - g^\star(\nabla g(Sx^*))] \\ &\geq \underbrace{\langle v, x^*\rangle - \langle \lambda^*, Sx^*\rangle}_{\geq 0} + \underbrace{g^\star(\nabla g(Sx^*))}_{\geq 0},\end{aligned} \tag{3.6}$$

where the inequality uses that $\lambda^* \geq \nabla g(Sx^*)$ by property (P1) and $Sx^* \geq 0$. The first term is non-negative because we only pick items for which $v_i - \langle \lambda, S^i\rangle \geq 0$. The second term is non-negative because $g(0) = 0$. We can now prove three lemmas that imply the theorem.

▶ **Lemma 17.** *For any $x' \in [0,1]^n$, $\pi(x^*) \geq L(x^*,\lambda^*) - g^\star(\lambda^*) \geq \pi(x') - g^\star(\lambda^*)$.*

Proof. Drop the second term from (3.6), then use the definition of $L(\cdot,\cdot)$ and (3.5). ◀

▶ **Lemma 18.** $g^\star(\lambda^*) \leq d \cdot g^\star_{i^*}(\lambda^*_{i^*})$.

Proof. Using the superadditivity of g, one can show $g^\star(\lambda^*) \leq \sum_i g^\star_i(\lambda^*_i)$. Now from property (P3) of the classifier λ^*, all the terms in the sum are equal. ◀

▶ **Lemma 19.** $\pi(x^*) \geq g^\star_{i^*}(\lambda^*_{i^*})$.

Proof. We claim that $g^\star(\nabla g(Sx^*)) \geq g^\star_{i^*}(\lambda^*_{i^*})$; plugging this into (3.6) proves the lemma. For the claim, define $\lambda' = \nabla g(Sx^*)$. By Property (P2), $\lambda'_{i^*} = \lambda^*_{i^*}$, so we want to show $g^\star(\lambda') \geq g^\star_{i^*}(\lambda'_{i^*}) = g^\star(\lambda'_{i^*}\mathbf{e}_{i^*})$. This follows because $g^\star$ is monotone. ◀

This completes the proof of Theorem 16. ◀

4 The Offline Constrained Case

Having built up tools and intuition in the unconstrained case, we turn to the case where there is a downwards-closed constraint $\mathscr{F} \subseteq \{0,1\}^n$, and the goal is to maximize the profit subject to $x \in \mathscr{F}$. We again work with Assumption 12, but do not assume anything about items sizes. We discuss computational aspects at the end of this section.

The general idea is again to use classifiers $\lambda \in \mathbb{R}^d_+$, and only consider items in U_λ, namely those with "high-enough" value $v_i \geq \langle \lambda, S^i\rangle$. However, because of the constraints $\mathscr{F}$ we may no longer be able to pick all these items. Thus, we need to consider the most profitable solution from $\mathscr{F}$ in this filtered feasible set U_λ (whose quality is less clear how to analyze).

Again we restrict to the 1-dimensional curve $\mathcal{C}$ defined in the previous section; however, it only satisfies slightly modified versions of properties (P1)-(P2), since we do not assume the item sizes to be infinitesimal anymore. To make this precise, define the "open" set $U^\circ_\lambda := \{e \in U \mid v(e) > \langle \lambda, s(e)\rangle\}$; note the strict inequality. Under the assumption of items being in general position, there is at most one "threshold" item with $v_i = \langle \lambda, S^i\rangle$, i.e., $|U_\lambda \setminus U^\circ_\lambda| \leq 1$. Now a "good" classifier is one that satisfies the following:

(P1') For all binary x with $\text{support}(x) \subseteq U^\circ_\lambda$ and $x \in \mathscr{F}$, $\nabla g(Sx) \le \lambda$.

(P2') There exists a binary x^{occ} with $\text{support}(x^{occ}) \subseteq U_\lambda$ and $x^{occ} \in \mathscr{F}$, and index i^* such that $(\nabla g(Sx^{occ}))_{i^*} \ge \lambda_{i^*}$. (Note that if $\text{support}(x^{occ}) \subseteq U^\circ_\lambda$, then by property (P1') the above inequality holds at equality; else x^{occ} contains the unique element in $U_\lambda \setminus U^\circ_\lambda$.)

(P3') This is the same as before: $g^\star_i(\lambda_i) = g^\star_j(\lambda_j) \quad \forall i, j \in [d]$.

The arguments of Lemma 15 show the following.

▶ **Lemma 20.** *Given Assumption 12, the curve $\mathcal{C}$ defined in the previous section contains a λ satisfying properties (P1')-(P3').*

Next, we show that for a good classifier $\lambda \in \mathcal{C}$, the maximum profit solution from $\mathscr{F}$ contained within U°_λ essentially gives an $O(1/d)$-approximation.

▶ **Theorem 21** (Offline Approach)**.** *Suppose Assumption 12 holds. Let λ^* be a classifier in $\mathcal{C}$ satisfying properties (P1')–(P3'). Then the better of the two solutions: (a) the maximum profit solution in $\mathscr{F}$ containing elements only from $U^\circ_{\lambda^*}$, and (b) the optimal single element in U_{λ^*}, has profit at least $\pi(x')/(2d+1)$ for any vector $x' \in \text{Conv}(\mathscr{F}) \subseteq [0,1]^n$.*

Proof. The idea is to follow the development in Theorem 16. There same solution x^* satisfied the value lower bounds of Lemmas 17 and 19; to satisfy the first lemma, we needed the solution to be optimal for the linearization of π using "slope" λ^*; to satisfy the second, we needed to satisfy (P2). Here, we construct two solutions in $\mathscr{F}$ intersect U_{λ^*} to satisfy these lemmas separately:

$x^{lin} := \text{argmax}\{\langle v, y\rangle - \langle \lambda^*, Sy\rangle \mid y \subseteq U^\circ_{\lambda^*}, y \in \mathscr{F}\}$

$x^{occ} :=$ the solution promised by property (P2').

Since property (P1') and (P3') holds for x^{lin}, Lemmas 17 and 18 hold essentially unchanged, and thus for any vector $x' \in \text{Conv}(\mathscr{F})$ we have

$$\pi(x^{lin}) \ge \pi(x') - d \cdot g^\star_{i^*}(\lambda^*_{i^*}). \tag{4.7}$$

The solution x^{occ} may not belong to the set $U^\circ_{\lambda^*}$, since it may contain the threshold item $e^\circ = \langle \lambda^*, s(e^\circ)\rangle$, if it exists (let $x^\circ = \chi_{\{e^\circ\}}$ be its characteristic vector, all 0's vector if does not exists). Let $x^{rest} = x^{occ} - x^\circ$.

▶ **Lemma 22.** *These solutions satisfy $\pi(x^{rest}) + \pi(x^\circ) \ge g^\star_{i^*}(\lambda^*_{i^*})$.*

Proof. Property (P1') gives $\nabla g(Sx^{rest}) \le \lambda^*$, and Property (P2') implies $\nabla g(S(x^{rest}+x^\circ)) = \nabla g(Sx^{occ})$ is at least λ^* at some coordinate i^*. Since g is convex and differentiable, the gradients are continuous [15, Remark D.6.2.6], so there is $\delta \in [0,1]$ where the vector $\widehat{x} := x^{rest} + \delta x^\circ$ satisfies $\nabla g(S\widehat{x}) \le \lambda^*$ and $\nabla g(S\widehat{x})_{i^*} = \lambda^*_{i^*}$ for some coordinate i^*. Due to these properties, the proof of Lemma 19 holds for $\widehat{x}$ and shows $\pi(\widehat{x}) \ge g^\star_{i^*}(\lambda^*_{i^*})$.

The assumption of no exceptional items gives $\pi(\delta x^\circ) \le \pi(x^\circ)$. From subadditivity of profit π, $g^\star_{i^*}(\lambda^*_{i^*}) \le \pi(\widehat{x}) \le \pi(x^{rest}) + \pi(\delta x^\circ) \le \pi(x^{rest}) + \pi(x^\circ)$. This concludes the proof. ◀

Combining Lemma 22 with inequality (4.7) we have $\pi(x') \le \pi(x^{lin}) + d\,\pi(x^{rest}) + d\,\pi(x^\circ)$ for any $x' \in \mathscr{F}$. Since x^{lin}, x^{rest} are feasible for (a) in the theorem statement, and x° is feasible for (b), the best of them gives a $(2d+1)$-approximation. This proves Theorem 21. ◀

Picking the most profitable singleton is trivial offline, and well-approximable online by the secretary algorithm [13]. Moreover, we need to approximately optimize the *submodular* function π (Fact 11) over $\mathscr{F}|_{U^\circ_{\lambda^*}}$ (i.e., the sets in $\mathscr{F}$ with only elements of $U^\circ_{\lambda^*}$). For several constraint structures (e.g., matroids, p-systems), there are known algorithms for approximately optimizing *non-negative* (and sometimes also monotone) submodular functions. Unfortunately, our profit function π may take negative values, so we cannot directly use these algorithms. Simply considering the truncated function $\max\{\pi(z), 0\}$ does not work because it may be non-submodular. In the next section, when g is *separable*, we introduce a way of making our profit function non-negative everywhere, while maintaining submodularity and preserving the values at the region of interest $\mathscr{F}|_{U^\circ_{\lambda^*}}$.

4.1 Making the Profit Function π Non-negative

We first show that π already satisfies the desired properties over the sets in $\mathscr{F}|_{U^\circ_{\lambda^*}}$.

▶ **Lemma 23.** *The profit function π is non-negative monotone over $\mathscr{F}|_{U^\circ_{\lambda^*}}$.*

Proof. Since $\pi(\emptyset) = 0$ it suffices to show monotonicity. Consider $x \in \mathscr{F}|_{U^\circ_{\lambda^*}}$ and let χ_e be the indicator os an item in x. Comparing the costs with and without e we have

$$g(Sx) \overset{\text{(convexity)}}{\leq} g(S(x-\chi_e)) + \langle \nabla g(Sx), S\chi_e \rangle \overset{\text{(Property (P1'))}}{\leq} g(S(x-\chi_e)) + \langle \lambda^*, s(e) \rangle.$$

Since $x \in U^\circ_{\lambda^*}$, we have $v(e) > \langle \lambda^*, s(e) \rangle$ and thus $\pi(x) > \pi(x - \chi_e)$, i.e., monotonicity. ◀

However, to run algorithms that approximately optimize π over $\mathscr{F}|_{U^\circ_{\lambda^*}}$ in a black-box fashion, non-negativity over the feasible sets $\mathscr{F}|_{U^\circ_{\lambda^*}}$ is not enough, even if the algorithm only probes π over these sets, since their *proof of correctness* may require this property outside of feasible sets. Thus, we need to modify π to ensure non-negativity outside of $\mathscr{F}|_{U^\circ_{\lambda^*}}$.

For that, the idea is to truncate the gradient of the cost g so $\nabla g(Sx)$ becomes at most λ^* for all subsets $x \subseteq U^\circ_{\lambda^*}$ (i.e., so Property (P1') holds for all subsets); this was the crucial element for the monotonicity (and hence non-negativity) proof above. Notice that since Property (P1') guarantees already $\nabla g(Sx) \leq \lambda^*$ for all $x \in \mathscr{F}|_{U^\circ_{\lambda^*}}$, this does not change the value of π over these points. The proof of the lemma is deferred to the full version.

▶ **Lemma 24.** *If g is separable, there is a submodular function π^+ satisfying the following:*

(i) *π^+ is non-negative and monotone over all subsets of $U^\circ_{\lambda^*}$, and*

(ii) *$\pi^+(x) = \pi(x)$ for every $x \in \mathscr{F}|_{U^\circ_{\lambda^*}}$.*

4.2 The Offline Algorithm: Wrap-up

Using this non-negativization procedure, we get an $O(d)$-approximation *offline* algorithm for constrained profit maximization for *separable* cost functions g; this is an offline analog of Theorem 2. For the unconstrained case, Lemma 23 implies that the profit function π it itself monotone, so we get an $O(d)$-approximation offline algorithm for the *supermodular* case. In the next section we show how to convert these algorithms into online algorithms.

One issue we have not discussed is the computational cost of finding λ^* satisfying (P1')–(P3'). In the full version of the paper, we show that for any $\varepsilon > 0$ we can efficiently find a λ^* satisfying (P1'), (P2'), and a slightly weaker condition: $|g^\star_i(\lambda^*_i) - g^\star_j(\lambda^*_j)| \leq 2\varepsilon$ for all $i, j \in [d]$. Using this condition in Theorem 21 means we get a profit of at least $\frac{\mathsf{opt}-2d\varepsilon}{2d+1} \geq [\mathsf{opt}/(2d+1)] - \varepsilon$; the running time depends on $\log \varepsilon^{-1}$ so we can make this loss negligible.

5 The Online Algorithm

In the previous sections we were working offline: in particular, in computing the "good" classifier $\lambda \in \mathcal{C}$, we assumed knowledge of the entire element set. We now present the online framework for the setting where elements come in random order. Recall the definition of the curve $\mathcal{C}$ from §3, and the fact that there is a total order among all $\lambda \in \mathcal{C}$. Recall that for simplicity we restrict the constraints $\mathscr{F}$ to be matroid constraints.

For a subset of elements $A \subseteq U$, let $\mathsf{opt}(A)$ and $\mathsf{fopt}(A)$ denote the integer and fractional optimal profit for $\mathscr{F}|_A$, the feasible solutions restricted to elements in A. Note that in the fractional case this means the best solution in the convex hull $\mathrm{Conv}(\mathscr{F}|_A)$. Clearly, $\mathsf{fopt}(A) \geq \mathsf{opt}(A)$. We use opt and fopt to denote $\mathsf{opt}(U)$ and $\mathsf{fopt}(U)$ for the entire instance U.

Again we work under Assumption 12. We will also make use of any algorithm for maximizing submodular functions over $\mathscr{F}$ in the random-order model satisfying the following.

▶ **Assumption 25.** *Algorithm SubmodMS takes a nonnegative monotone submodular function f with $f(\emptyset) = 0$, and a number N. When run on a sequence X of N elements presented in random order, it returns a (random) subset $X_{alg} \in \mathscr{F}$ with expected value $\mathbb{E}[f(X_{alg})] \geq \frac{1}{\alpha} \max_{X' \in \mathscr{F}} f(X)$. Moreover, the it only evaluates the function f on **feasible** sets.*

Our algorithm is very simple:

Algorithm 5.1 Online Algorithm for Profit Maximization

1: $L \leftarrow$ first Binomial$(n, 1/2)$ items.
2: $\mu \leftarrow$ largest vector on curve $\mathcal{C}$ s.t. $\mathsf{fopt}(L_\mu) \geq \frac{1}{12d}\,\mathsf{fopt}(L)$.
3: $R \leftarrow$ remaining instance, namely the last $n - |L|$ items.
4: $R^\circ_\mu \leftarrow \{e \in R \mid v(e) > \langle \mu, s(e) \rangle\}$ be the (strictly) "filtered" remaining instance.
5: **Un-constrained:** Select items in R°_μ not decreasing the current value of the solution.
Constrained: Run algorithm SubmodMS on R°_μ using profit function π, selecting items according to this algorithm, but do not add items that decrease the current value of the solution.

Note that L_μ denotes the set of items in the sample L picked by μ (Definition 13). In Step 2, we can use the Ellipsoid method to find fopt within negligible error. Moreover, we must do this for several sets L_μ and pick the largest one on $\mathcal{C}$ using a binary-search procedure. We defer the technical details to the full version of the paper.

5.1 Analysis

To analyze the algorithm, we need to show that the classifier μ learned in Step 2 is large enough that we do not waste space with useless items, but low enough that we admit enough useful items. For that we need the following concentration bound.

▶ **Lemma 26.** *Consider a submodular function $f : 2^{\mathcal{U}} \to \mathbb{R}$. Consider a set $Y \subseteq \mathcal{U}$ such that f is non-negative over all of its subsets, and that for some M:*

$$\text{For all } Y' \subseteq Y \text{ and element } e \in Y', \quad |f(Y') - f(Y' - e)| \leq M. \tag{5.8}$$

Let $\mathbf{Y}$ be the random subset obtained by picking each element from Y independently with some probability (possibly different for each item). Then $\Pr(|f(\mathbf{Y}) - \mathbb{E}[f(\mathbf{Y})]| \geq t) \leq \frac{2M\,\mathbb{E}[f(\mathbf{Y})]}{t^2}$.

We then also need π to satisfy (5.8) on the optimal solutions of any given sub-instance. For a vector $y \in \mathbb{R}^n$ and subset $A \subseteq U$, let y_A be the same as y on A, and zero outside A.

▶ **Claim 27.** *Consider any $U' \subseteq U$, and let y be an optimal fractional solution on $\mathscr{F}|_{U'}$ (so $\pi(y) = \mathsf{fopt}(U')$). Then for any $B \subseteq A \subseteq U'$ with $|A \setminus B| = 1$, we have $|\pi(y_A) - \pi(y_B)| \leq M$, where M is an upper bound on the profit from any single item.*

From Section 4, recall $\lambda^* \in \mathbb{R}^d_+$ is a classifier that satisfies properties (P1')–(P3').

▶ **Lemma 28.** *Given Assumption 12, the classifier μ of Line 2 of Algorithm 5.1 satisfies:*

(a) *(Not too small) $\mu \geq \lambda^*$, with probability at least $19/20$.*

(b) *(Not too big) $\mathsf{fopt}(U_\mu) \geq \frac{\mathsf{fopt}}{48d}$ with probability at least $1 - 1/20d \geq 19/20$.*

Proof sketch. For the first part, we show that the classifier λ^* satisfies the properties needed in Line 2 with probability $1 - 1/20$; since μ is the largest such vector, we get $\mu \geq \lambda^*$. Using Theorem 21 and the assumption that no item has large profit, we have $\mathsf{fopt}(U_{\lambda^*}) \geq \frac{\mathsf{fopt}}{3d}$. Moreover, the sample obtains at least half of this profit in expectation, i.e., $\mathbb{E}\,\mathsf{fopt}(L_{\lambda^*}) \geq \frac{\mathsf{fopt}}{3d}$. Then using Lemma 26 with the Lipschitz property of Claim 27 and the no-high-profit-item assumption, we have $\mathsf{fopt}(L_{\lambda^*}) \geq \frac{\mathsf{fopt}}{12d} \geq \frac{\mathsf{fopt}(L)}{12d}$ with probability at least $19/20$. Thus, with this probability λ^* satisfies the properties needed in Line 2 of the algorithm, as desired.

For the part (b) of the lemma, notice that for each scenario $\mathsf{fopt}(U_\mu) \geq \mathsf{fopt}(L_\mu)$, since feasible solutions for the sample are feasible for the whole instance. Next, by definition of μ, $\mathsf{fopt}(L_\mu) \geq \frac{\mathsf{fopt}(L)}{12d}$. Finally, if x is the fractional optimal solution on U with $\pi(x) = \mathsf{fopt}$, then $\mathbb{E}[\pi(x_L)] \geq \mathsf{fopt}/2$, since g is superadditive. Again using Lemma 26, the profit $\pi(x_L)$ is at least $\frac{\mathsf{fopt}}{4}$ with probability at least $(1 - 1/20d)$. Of course, $\mathsf{fopt}(L) \geq \pi(x_L)$. Chaining these inequalities, $\mathsf{fopt}(U_\mu) \geq \frac{\mathsf{fopt}}{48d}$ with this probability. ◀

In view of Theorem 21, we show the filtered out-of-sample instance R°_μ behaves like $U^\circ_{\lambda^*}$.

▶ **Lemma 29.** *The filtered out-of-sample instance R°_μ satisfies the following w.p. $19/20$:*

(a) *For all $e \in R^\circ_\mu$, $v(e) \geq \langle \lambda^*, s(e) \rangle$.*

(b) *For all x with support$(x) \subseteq R^\circ_\mu$ such that $x \in \mathscr{F}$, $\nabla g(Sx) \leq \lambda^*$.*

(c) $\mathsf{fopt}(R^\circ_\mu) \geq \frac{\mathsf{fopt}}{200d}$.

Proof. By Lemma 28(a), threshold $\mu \geq \lambda^*$ with probability $19/20$. When that happens, $U^\circ_\mu \subseteq U^\circ_{\lambda^*}$. Since the first two properties hold for $U^\circ_{\lambda^*}$, they also hold for U°_μ, and by downward-closedness, also for R°_μ.

For the third part, let λ^+ be the largest threshold in $\mathcal{C}$ such that $\mathsf{fopt}(U_{\lambda^+}) \geq \frac{\mathsf{fopt}}{48d}$. From Lemma 28(b), with good probability we have $\mu \leq \lambda^+$. Since μ is a smaller threshold, the instance U_{λ^+} is contained in the instance U_μ, which implies that for every scenario $\mathsf{fopt}(R_\mu) \geq \mathsf{fopt}(R_{\lambda^+})$. Next we show that that with good probability $\mathsf{fopt}(R_{\lambda^+}) \geq \frac{\mathsf{fopt}}{200d}$, and hence get the same lower bound for $\mathsf{fopt}(R_\mu)$. If y is the optimal fractional solution for U_{λ^+}, then y_R is feasible for R_{λ^+} with $\mathbb{E}[\pi(y_R)] = \frac{1}{2}\mathsf{fopt}(U_{\lambda^+}) \geq \frac{\mathsf{fopt}}{96d}$. Moreover, using the concentration bound again, we get that $\pi(y_R) \geq \frac{\mathsf{fopt}}{192d}$ with probability at least $19/20$. Finally, by the assumption of general position, there is at most one item in $R_\mu \setminus R^\circ_\mu$. Dropping this item from the solution y to get y° reduces the value by at most $M = \frac{\mathsf{fopt}}{10^4 d}$; here we use subadditivty of the profit, and that there are no exceptional items. Hence, with probability at least $19/20$: $\mathsf{fopt}(R^\circ_\mu) \geq \mathsf{fopt}(R^\circ_{\lambda^+}) \geq \pi(y^\circ_R) \geq \frac{\mathsf{fopt}}{196d} - M \geq \frac{\mathsf{fopt}}{200d}$. ◀

Finally, we are ready to prove the main theorems in the online setting.

▶ **Theorem 30** (Unconstr. Case: Supermodular Cost)**.** *Algorithm 5.1 gives an $O(d)$-approximation in expectation for the unconstrained case, if the cost function is supermodular.*

Proof. Define the event $\mathcal{E}$ that Lemmas 28 and 29 hold; $\Pr(\mathcal{E}) \geq 17/20$. Now, by Lemma 29(c), the optimal fractional solution for R°_μ has profit at least $\mathsf{fopt}/200d$. Moreover, since there are no constraints, the profit function is monotone submodular over all of $U^\circ_{\lambda^*}$ by Lemma 23. Conditioning on the good event $\mathcal{E}$, Lemma 28(a) gives that $R^\circ_\mu \subseteq U^\circ_{\lambda^*}$, so the algorithm to maximize the monotone submodular function (both integrally and fractionally) is to pick all elements. Hence, conditioned on $\mathcal{E}$, the profit we get is at least $\mathsf{fopt}/200d$. In the other case, we never pick an item that gives negative marginal value, so our solution is always non-negative. Hence our expected profit is at least $\Pr[\mathcal{E}] \cdot \mathsf{opt}(R_\mu) = \Omega(\mathsf{fopt}/d) \geq \Omega(\mathsf{opt}/d)$. ◀

The analysis of the algorithm for the constrained separable-cost case is similar, only using the constrained offline guarantees of Theorem 21, and the non-negativization Lemma 23 to argue that SubmodMS maintains its guarantees.

▶ **Theorem 31** (Constr. Case: Separable Cost)**.** *Suppose algorithm SubmodMS satisfies Assumption 25 and is α-competitive in expectation. Then Algorithm 5.1 gives a $O(\alpha d^2)$-approximation in expectation.*

6 Separability versus Supermodularity

In this section, we show that an β-approximation algorithm for the separable-cost case gives a $O(d\beta)$-approximation for a slight generalization of the supermodular-cost case. Consider the problem of picking a set A to solve

$$\pi(A) := \max_{A \in \mathscr{F}} \left(v(A) - g\Big(\sum_{e \in A} s(e)\Big) \right),$$

where $v(A)$ is a (discrete) submodular function over $\{0,1\}^n$ with $v(\emptyset) = 0$, g is a convex, (continuous) supermodular function over $\mathbb{R}^d$, and $\mathscr{F}$ is some downward-closed constraint set. We show that for the case of matroid constraints, this problem can be reduced to the setting where the cost function is separable over its d coordinates, suffering a loss of $O(d)$.

▶ **Theorem 32** (Reduction)**.** *Given an β-approximation algorithm for profit-maximization for* separable *convex cost functions under matroid constraints, we can get an $d(\beta + 2\mathrm{e}d)$-approximation algorithm for the profit-maximization problem with* supermodular costs g*,* submodular values v*, and $\mathscr{F}$ being a* matroid *constraint.*

The reduction is the following:

1. Define separable costs $\overline{g}(y) := 1/d \sum_{i=1}^d g_i(dy_i)$, where g_i are marginal functions for g.
2. W.p. $p = \frac{\beta}{\beta + 2\mathrm{e}d}$, run single-secretary algorithm to return element with maximum profit.
3. W.p. $1 - p = \frac{2\mathrm{e}d}{\beta + \mathrm{e}d}$, run algorithm for value function $v(\cdot)$ and separable cost fn. $\overline{g}(\cdot)$.

This reduction relies on the following simple but perhaps surprising observation that relates separability with supermodularity, which may find other applications.

▶ **Lemma 33.** *Given a monotone convex superadditive function g with $g(0) = 0$, let g_i be the marginal functions. Then for all $y \in \mathbb{R}^d_+$:*

1. $g(y) \geq \sum_i g_i(y_i)$
2. $g(y) \leq \frac{1}{d} \sum_i g_i(dy_i) = \overline{g}(y)$.

Proof. The first property follows from the superadditivity of g, and the second follows from Jensen's inequality. ◀

While the full proof of Theorem 32 is deferred to the full version of the paper, the main idea is clean. Given an optimal integer solution x^* for the original problem (with the original cost function), we use Lemma 33 and the Lovász (convex) extension of submodular functions to show that x^*/d is a good fractional solution for the separable cost function. Now using polyhedral properties of d-dimensional faces of the matroid polytope, and other properties of the Lovász extension, we show the existence of a good integer solution to the separable problem. Combining this reduction with Theorem 2 proves Theorem 3.

Abstract

Given an undirected unweighted graph G and a source set S of $|S| = \sigma$ sources, we want to build a data structure which can process the following query $\mathrm{Q}(s, t, e)$: find the shortest distance from s to t avoiding an edge e, where $s \in S$ and $t \in V$. When $\sigma = n$, Demetrescu, Thorup, Chowdhury and Ramachandran (SIAM Journal of Computing, 2008) designed an algorithm with $\tilde{O}(n^2)$ space[1] and $O(1)$ query time. A natural open question is to generalize this result to any number of sources. Recently, Bilò et. al. (STACS 2018) designed a data-structure of size $\tilde{O}(\sigma^{1/2}n^{3/2})$ with the query time of $O(\sqrt{n\sigma})$ for the above problem. We improve their result by designing a data-structure of size $\tilde{O}(\sigma^{1/2}n^{3/2})$ that can answer queries in $\tilde{O}(1)$ time.

In a related problem of finding fault tolerant subgraph, Parter and Peleg (ESA 2013) showed that if detours of *replacement* paths ending at a vertex t are disjoint, then the number of such paths is $O(\sqrt{n\sigma})$. This eventually gives a bound of $O(n\sqrt{n\sigma}) = O(\sigma^{1/2}n^{3/2})$ for their problem. *Disjointness of detours* is a very crucial property used in the above result. We show a similar result for a subset of replacement path which **may not** be disjoint. This result is the crux of our paper and may be of independent interest.

1 Introduction

Real life graph networks like communication network or road network are prone to link or node failure. Thus, algorithms developed for these networks must be resilient to failure. For example, the shortest path between two nodes may change drastically even if a single link fails. So, if the problem forces us to find shortest paths in the graph, then it should find the next best shortest path after a link failure. There are many ways to model this process: one of them is *fault-tolerant graph algorithm*. In this model, we have to preprocess a graph G and build a data-structure that can compute a property of the graph after any k edges/vertices

[1] $\tilde{O}(\cdot)$ hides poly $\log n$ factor.

of the graph have failed. Note the difference between this model and *dynamic graph model*. In a dynamic graph algorithm, we have to *maintain* a property of a continuously changing graph. However, in the fault tolerant model, we expect the failure to be repaired readily and restore our original graph.

In this paper, we study the shortest path problem in the fault tolerant model. Formally, we are given an undirected and unweighted graph G and a source set S of $|S| = \sigma$ sources. We want to build a data structure which can process the following query $\mathrm{Q}(s, t, e)$: find the shortest distance from s to t avoiding an edge e, where $s \in S$ and $t \in V$. Such a data-structure is also called a *distance oracle*. When there are n sources, Demetrescu et al. [9] designed an oracle that can find the shortest path between any two vertices in G after a single vertex/edge failure in $\tilde{O}(n^2)$ space and $O(1)$ query time. Recently, Bilò et. al. [5] generalized this result to any number of sources. They designed a data-structure of size $\tilde{O}(\sigma^{1/2}n^{3/2})$ with the query time of $O(\sqrt{n\sigma})$ for the above problem.

To understand our problem, we should also understand a closely related problem of finding *fault tolerant subgraph*. Here, we have to find a subgraph of G such that BFS tree from $s \in S$ is preserved in the subgraph after any edge deletion. In an unweighted graph, a BFS tree preserves the shortest path from s to all vertices in G. Parter and Peleg [17] showed that a subgraph of size $O(\sigma^{1/2}n^{3/2})$ is both necessary and sufficient to solve the above problem. The above result indicates that there should be a better fault-tolerant distance oracle for any value of σ.

Inspired by this result, we generalize the result of [9] to any number of sources – by showing that there exists a distance oracle of size $\tilde{O}(\sigma^{1/2}n^{3/2})$ which can answer queries in $\tilde{O}(1)$ time. Note that our result nearly matches the space bound achieved by Parter and Peleg[17] – up to polylog n factors. We now state the main result of this paper formally:

▶ **Theorem 1.** *There exists a data-structure of size $\tilde{O}(\sigma^{1/2}n^{3/2})$ for multiple source single fault tolerant exact distance oracle that can answer each query in $\tilde{O}(1)$ time.*

This generalization turns out to be much more complex than the result in [9]. Indeed, the techniques used by Demetrescu et al. [9] are also used by us to weed out *easy replacement* paths. To take care of other paths, we take an approach similar to Parter and Peleg[17]. They used the following trick: if the *detour* of replacement paths are *disjoint*, then the number of such paths can be bounded easily by a *counting argument*. The main challenge is then to show that paths in question are indeed disjoint – which is also easy in their problem. We use a technique similar to above – however, our paths are not disjoint, they may intersect. We believe that this technique can be of independent interest and may be used in solving closely related fault tolerant subgraph problems.

1.1 Related Work

Prior to our work, the work related to fault tolerant distance oracle was limited to two special cases, $\sigma = 1$ or $\sigma = n$. As stated previously, Demetrescu et al. [9] designed a single fault tolerant distance oracle of size $\tilde{O}(n^2)$ with a query time of $O(1)$. The time to build the data-structure is $O(mn^2)$ – which was improved to $O(mn \log n)$ by Bernstein and Karger [4]. The above result also works for a directed weighted graph. Pettie and Duan [10] were able to extend this result to two vertex faults. The size and query time of their distance oracle is $\tilde{O}(n^2)$ and $\tilde{O}(1)$ respectively. If the graph is weighted, then Demetrescu et al. [9] showed that there exists a graph in which a single vertex fault tolerant distance oracle will take $\Omega(m)$ space. Recently, Bilò et. al. [5] designed the following data-structure: for every $S, T \subseteq V$, a data-structure of size $\tilde{O}(n\sqrt{|S||T|})$ and query time $O(\sqrt{|S||T|})$, where the query asks for the shortest distance from $s \in S$ to $t \in T$ avoiding any edge. If $|S| = \sigma$ and $|T| = n$, then the size of their data-structure is $\tilde{O}(\sigma^{1/2}n^{3/2})$ and the query time is $O(\sqrt{n\sigma})$.

The next set of results are not *exact* but *approximate*, that is, they return an approximate distance (by a multiplicative *stretch* factor) between two vertices after an edge/vertex fault. Also, these oracles work for a single source only. Baswana and Khanna [14] showed that a 3-stretch single source single fault tolerant distance oracle of size $\tilde{O}(n)$ can be built in $\tilde{O}(m+n)$ time and a constant query time. Bilò et. al.[6] improved the above result: a distance oracle with stretch 2 of size $O(n)$ and $O(1)$ query time. In another result, Bilò et. al. [7] designed a k fault tolerant distance oracle of size $\tilde{O}(kn)$ with a stretch factor of $(2k+1)$ that can answer queries in $\tilde{O}(k^2)$ time. The time required to construct this data-structure is $O(kn\alpha(m,n))$, where $\alpha(m,n)$ is the inverse of the Ackermann's function. If the graph is unweighted, then Baswana and Khanna[14] showed that a $(1+\epsilon)$-stretch single source fault tolerant distance oracle of size $\tilde{O}(\frac{n}{\epsilon^3})$ can be built in $O(m\sqrt{n/\epsilon})$ time and a constant query time. Bilò et. al [6] extended this result for weighted graph by designing a distance oracle with stretch $(1+\epsilon)$ of size $O(\frac{n}{\epsilon}\log\frac{1}{\epsilon})$ and a logarithmic query time.

There is another line of work, called the *replacement path* problem. In this problem, we are given a source s and destination t and for each edge e on the shortest st path, we need to find shortest s to t path avoiding e. The problem can be generalized to finding k shortest s to t path avoiding e. The main goal of this problem is to find all shortest paths as fast as possible. Malik et al. [15] showed that in an undirected graphs, replacement paths can be computed in $O(m+n\log n)$ time. For directed, unweighted graphs, Roditty and Zwick [19] designed an algorithm that finds all replacement paths in $O(m\sqrt{n})$ time. For the k-shortest paths problem, Roditty [18] presented an algorithm with an approximation ratio 3/2, and the running time $O(k(m\sqrt{n}+n^{3/2}\log n))$. Bernstein [3] improved the above result to get an approximation factor of $(1+\epsilon)$ and running time $O(km/\epsilon)$. The same paper also gives an improved algorithm for the approximate st replacement path algorithm. See also [11, 22, 21].

As mentioned previously, a problem closely related to our problem is the fault tolerant subgraph problem. The aim of this problem is to find a subgraph of G such that BFS tree from $s \in S$ is preserved in the subgraph after any edge deletion. Parter and Peleg [17] designed an algorithm to compute single fault tolerant BFS tree with $O(n^{3/2})$ space. They also showed their result can be easily extended to multiple source with $O(\sigma^{1/2}n^{3/2})$ space. Moreover, their upper bounds were complemented by matching lower bounds for both their results. This result was later extended to dual fault BFS tree by Parter [16] with $O(n^{5/3})$ space. Gupta and Khan [12] extended the above result to multiple sources with $O(\sigma^{1/3}n^{5/3})$ space. All the above results are optimal due to a result by Parter [16] which states that a multiple source k fault tolerant BFS structure requires $\Omega(\sigma^{\frac{1}{k+1}}n^{2-\frac{1}{k+1}})$ space. Very recently, Bodwin et. al. [8] showed the existence of a k fault tolerant BFS structure of size $\tilde{O}(k\sigma^{1/2^k}n^{2-1/2^k})$.

Other related problems include fault-tolerant DFS and fault tolerant reachability. Baswana et al. [1] designed an $\tilde{O}(m)$ sized fault tolerant data structure that reports the DFS tree of an undirected graph after k faults in $\tilde{O}(nk)$ time. For single source reachability, Baswana et al. [2] designed an algorithm that finds a fault tolerant reachability subgraph for k faults using $O(2^k n)$ edges.

2 Preliminaries

We use the following notation throughout the paper:

- xy : Given two vertices x and y, let xy denote a path between x and y. Normally this path will be the shortest path from x to y in G. However, in some places in the paper, the use of xy will be clear from the context.
- $|xy|$: It denotes the number of edges in the path xy.

- $(\cdot \diamond \cdot)$: Given two paths sx and xt, $sx \diamond xt$ denotes the concatenation of paths sx and xt.
- *after or below/before or above* x : We will assume that the st path (for $s \in S$ and $t \in V$) is drawn from top to bottom. Assume that $x \in st$. The term *after or below* x on st path refers to the path xt. Similarly *before or above* x on st path refers to the path sx.
- *replacement path*: The shortest path that avoids any given edge is called a *replacement* path.

3 Our Approach

We will randomly select a set of terminals $\mathcal{T}$ by sampling each vertex with probability $\sqrt{\frac{\sigma}{n}}$. Note that the size of $\mathcal{T}$ is $\tilde{O}(\sqrt{\sigma n})$ with high probability. For a source s and $t \in V$, let t_s be the last terminal encountered on the st path. The following lemma is immediate:

▶ **Lemma 2.** *If* $|st| \geq c\sqrt{\frac{n}{\sigma}} \log n$ $(c \geq 3)$, *then* $|t_s t| = \tilde{O}(\sqrt{\frac{n}{\sigma}})$ *with a very high probability for all* $s \in S$ *and* $t \in V$.

Let G_p denote the graph where each edge is perturbed by a weight function that ensures unique shortest paths. Our st path is the shortest s to t path in G_p, let us denote its length by $|st|_p$. Note that G_p contains a unique shortest path between any two vertices, even the ones that avoid an edge – such a graph has been used before in related problems [4, 17, 13]. We can use G_p even to find all the replacement paths. However, we want our replacement paths to have other nice property, that is, *the length replacement paths(without perturbation) from* s *to* t *are different.* This property is not satisfied by replacement paths in G_p. We employ another simple strategy to find a replacement path. Following [12], we define preferred replacement paths:

▶ **Definition 3.** A path P is called a **preferred** replacement path from s to t avoiding e if (1) it diverges and merges the st path *just once* (2) it divergence point from the st path is as close to s as possible (3) it is the shortest path in G_p satisfying (1) and (2).

The replacement path has to diverge from the st path before e. Ideally, we want a replacement path that diverges from st path as close to s as possible. This is a crucial feature which will ensure that all replacement paths from s to t have different lengths. The first condition ensures that we do not diverge from st path just to get a higher point of divergence. If many shortest paths are diverging from a same vertex, the third condition is used to break ties. In the ensuing discussion, we will assume that we are always working with a preferred replacement path.

The initial st path is found out by finding the unique shortest path in G_p. Consider the query $Q(s, t, e)$. If the failed edge e does not lie on st path, then we can report $|st|$ as the shortest distance from s to t avoiding e. To this end, we should be able to check whether e lies in the shortest path from s to t. At this point, we will use the property of graph G_p. If $e(u, v)$ lies in st path, then we have to check if u and v lie on st path. To this end, we check if $|su|_p + |ut|_p = |st|_p$ and $|sv|_p + |vt|_p = |st|_p$. If both the above two equations are satisfied then the st path passes through e (as the shortest path from u to v is 1). We can also find whether u or v is closer to s on st path. Without loss of generality assume that u is closer to s than v on st path.

However, we do not have space to store all these distances. Specifically, the second term on the LHS of above two equations mandates that we store the distance of every pair of vertices in the graph. This implies that the size of our data structure is $O(n^2)$ which is not desirable.

To solve the above problem, we observe that if e lies in the $t_s t$ path, then we have just enough space to store this fact. So, given any e, we can easily find if $e \in t_s t$. If $e \in st_s$, then

we know that $|su|_p + |ut_s|_p + |t_st|_p = |st|_p$ and $|sv|_p + |vt_s|_p + |t_st|_p = |st|_p$. This equality is easier to check with the space at hand. So, we have the following two cases:

1. (Near Case) e lies on t_st.
2. (Far Case) e lies on st_s.

3.1 Handling the Near Case

For each $e(u,v) \in t_st$, let P_e be the preferred replacement path from s to t avoiding e. We put $(e, |P_e|)$ in a balanced binary search tree $\textsc{Bst}(s,t)$ with the key being e. Given any query $Q(s,t,e)$, we now need to check if e lies in $\textsc{Bst}(s,t)$. This can be done in $\tilde{O}(1)$ time and the length of the preferred replacement path can be reported.

The space required for $\textsc{Bst}(s,t)$ is directly proportional to the size of path t_st. By Lemma 2, we know that $|t_st| = \tilde{O}(\sqrt{\frac{n}{\sigma}})$. Thus, the size of $\textsc{Bst}(s,t) = \tilde{O}(\sqrt{\frac{n}{\sigma}})$. This implies that the cumulative size of all the associated binary search tree is $\cup_{t\in V} \cup_{s\in S} |t_st| = \tilde{O}(n\sigma\sqrt{\frac{n}{\sigma}}) = \tilde{O}(\sigma^{1/2}n^{3/2})$.

3.2 Handling the Far Case

We first need to check if $e \in st_s$. To this end we use the following data-structures.

- B_0: For each pair of vertices x and y where $x \in (S \cup \mathcal{T})$ and $y \in V$, the shortest path between x and y in G and G_p is stored in $B_0(x,y)$ and $B_0^p(x,y)$ respectively. The total size of B_0 is $\tilde{O}((\sigma + \sqrt{n\sigma})n) = \tilde{O}(\sigma^{1/2}n^{3/2})$.
- B_1: For each pair of vertices $s \in S$ and $t \in V$, $B_1(s,t)$ contains the vertex in $\mathcal{T}$ closest to t on st path, that is t_s. The total size of B_1 is $O(\sigma n) = \tilde{O}(\sigma^{1/2}n^{3/2})$.

To check if $e(u,v) \in st_s$, we first find $t_s \leftarrow B_1(s,t)$. Then we check if $B_0^p(s,u) + B_0^p(u,t_s) + B_0^p(t_s,t) = B_0^p(s,t)$ and $B_0^p(s,v) + B_0^p(v,t_s) + B_0^p(t_s,t) = B_0^p(s,t)$. If yes, then $e \in st_s$. We subdivide the far case into two more sub-cases:

1. The preferred replacement path avoiding e passes through t_s.
2. The preferred replacement path avoiding e avoids t_s.

The first case turns out to be a generalization of techniques used by Demetrescu et. al.[9] to solve the all pair distance oracle under single edge/vertex failure – we will use the compact version of this algorithm presented by Pettie and Duan [10]. The second case is a *new and unexplored* case. We will show that we can bound the number of preferred replacement paths in this case to $O(\sqrt{n\sigma})$ for a fixed vertex t. This would imply that the total number of such paths is $O(\sigma^{1/2}n^{3/2})$. We are able to bound the number of paths even though these paths may intersect with each other – this is a new feature of our analysis which is much different from the analysis done by Parter and Peleg [17] on a related problem.

Section 4 deals with the first case. In Section 5, we will apply our new approach to the special case when $\sigma = 1$, or there is a single source. In Section 6, we will discuss the potential problems in extending our approach to multiple sources. Section 7 and 8 extends our approach to multiple sources and in Section 9 we develop our data-structure that can answer queries in $\tilde{O}(1)$ time. To save space, we have omitted proofs in this extended abstract. The concerned reader may read the proof in the full version of the paper.

4 Preferred replacement path passes through t_s

Since this case is a generalization of the techniques developed by Demetrescu et. al. [9], concerned reader may read the full version of the paper for details – where we show that there exists a data-structure of size $\tilde{O}(\sigma^{1/2}n^{3/2})$ which takes $O(1)$ time to find a replacement path from s to t that avoids e but passes through t_s.

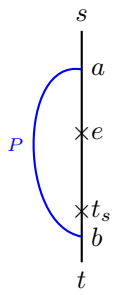

Figure 1 P does not intersect any path in $(> P)$.

Now, we move on to the harder case, that is, replacement paths avoid t_s too. For this, we will fix a vertex t. We will show that the query $Q(s, t, e(u, v))$ can be answered in $\tilde{O}(1)$ using $\tilde{O}(\sqrt{\sigma n})$ space. This immediately implies that we can answer exact queries in $\tilde{O}(1)$ time using $\tilde{O}(\sigma^{1/2} n^{3/2})$ space.

5 Preferred Replacement path avoids t_s

Handling preferred replacement paths that avoid t_s turns out to be a challenging and unexplored case. For better exposition, we will first solve the problem for the case when $\sigma = 1$, that is there is only one source. Let $\mathcal{R}$ be the set of all preferred replacement paths from s to t that do not pass through t_s. We make two important observations:

1. The size of $\mathcal{R}$ is $O(\sqrt{n})$.
2. Preferred replacement paths in $\mathcal{R}$ avoid one contiguous sub path of st.

Few remarks are in order. If the preferred replacement paths in $\mathcal{R}$ were disjoint, then bounding the size of $\mathcal{R}$ is easy. However, we are able to bound the size of $\mathcal{R}$ even if paths are intersecting. The second observation implies that we can build a balanced binary search tree containing paths in $\mathcal{R}$. Each node in this tree will contain a preferred replacement path P. The key for each node will be the start and end vertex of the sub path P avoids. We will use this BST to find an appropriate replacement path that avoids an edge e.

▶ **Definition 4.** (Detour of a replacement path) Let P be a preferred replacement path avoiding an edge e on st path. Then detour of P is defined as, $\textsc{Detour}(P) := P \setminus st$. That is, detour is a path the leaves st before e till the point it merges back to st again.

Since our replacement path P also avoids t_s, the following lemma is immediate by the definition of preferred path.

▶ **Lemma 5.** *Let P be a preferred replacement path in $\mathcal{R}$ that avoids e and t_s on st path, then (1) $\textsc{Detour}(P)$ cannot merge back to st_s path and (2) $\textsc{Detour}(P)$ is a contiguous path.*

▶ **Lemma 6.** *Let $P, P' \in \mathcal{R}$ avoid e and e' respectively on st_s path. Also assume that e is closer to s than e'. Then (1) P avoids e' (2) $\textsc{Detour}(P')$ starts after e on st_s path and (3) $|P| > |P'|$.*

The converse of the third part of the lemma is also true. Since we will be using it in future, we prove it now.

▶ **Lemma 7.** *Let P and P' be two preferred replacement paths that avoid e and e' on st path respectively. If $|P| > |P'|$, then e is closer to s than e'.*

By Lemma 6(3), we know that all preferred replacement paths in $\mathcal{R}$ have different lengths. In fact, it is the main reason we defined a preferred replacement path. We can thus arrange these paths in decreasing order of their lengths. Thus, we get the following corollary.

▶ **Corollary 8.** *Given a set $\mathcal{R}$ of preferred replacement paths from s to t (that also avoid t_s), we can arrange paths in decreasing order of their lengths.*

Given a path $P \in \mathcal{R}$, let $(< P)$ be the set of all preferred replacement paths with length less than P. Similarly, let $(> P)$ be the set of all preferred replacement paths with length greater than P. If P avoids e, then by Lemma 7, it also avoids all edges avoided by paths in $(< P)$. By Lemma 6, for any path $P' \in (< P)$, $\textsc{Detour}(P')$ starts after e on st_s path. We will now show a simple but important property of a path P in $\mathcal{R}$.

▶ **Lemma 9.** *Let $P \in \mathcal{R}$ be the shortest path from s to t avoiding e such that $|P| = |st| + \ell$ where $\ell \geq 0$, then the size of the set $(< P)$ is $\leq \ell$.*

▶ **Definition 10.** (Unique path of P) Let $\textsc{Unique}(P)$ be the prefix of $\textsc{Detour}(P)$ which does not intersect with any detours in $\cup_{P' \in (> P)} \textsc{Detour}(P')$.

We now arrange all preferred replacement paths in $\mathcal{R}$ in decreasing order of their lengths. Assume that we are processing a path P according to this ordering such that P avoids e on st path. If $|\textsc{Unique}(P)| \geq \sqrt{n}$, then we have associated $O(\sqrt{n})$ vertices on $\textsc{Unique}(P)$ to P. Else $\textsc{Unique}(P) < \sqrt{n}$ and we have the following two cases:

5.1 Detour(P) does not intersect with detour of any path in $(> P)$

Let $\textsc{Detour}(P)$ start at a and end at b – the vertex where it touches $t_s t$ path. Let ab denote the path from a to b on P. By our assumption $\textsc{Unique}(P) = ab$ and $|ab| < \sqrt{n}$. By Lemma 6, all replacement paths in $(< P)$ pass through e (as detour of these replacement paths start below e) and by Lemma 7, these replacement paths avoid edges that are closer to t than e. We can view the replacement paths as if they are starting from the vertex a. That is, consider paths $\{P \setminus sa\} \cup \{P' \setminus sa|\ P' \in (< P)\}$. These replacement paths avoid edges in at. $|P \setminus sa| = |ab| + |bt| \leq |ab| + |at| < |at| + \sqrt{n}$. Applying Lemma 9, we infer that the number of paths in $\{P' \setminus sa | P' \in (< P)\}$ is $\leq \sqrt{n}$

5.2 Detour(P) intersects with detour of a path in $(> P)$

Assume that P first intersects with $P' \in (> P)$. Let P' avoid e' and $\textsc{Detour}(P')$ start at a' and end at b' (see Figure 2). Let us assume that $\textsc{Detour}(P)$ starts at a and it intersects $\textsc{Detour}(P')$ at c. This implies that $\textsc{Unique}(P) = ac$.

Consider the path $sa' \diamond a'c \diamond ca \diamond at$. We claim that this path avoids e'. This is due to the fact that by Lemma 6, $\textsc{Detour}(P)$ starts after e' on st path. So, ca and at avoids e'. Since $P' = sa' \diamond a'c \diamond cb' \diamond b't$, length of P' must be $\leq$ length of the alternate path. Thus,

$$\begin{array}{lrcl} & |sa'| + |a'c| + |cb'| + |b't| & \leq & |sa'| + |a'c| + |ca| + |at| \\ \implies & |cb'| + |b't| & \leq & |ca| + |at| \\ \implies & |ac| + |cb'| + |b't| & \leq & 2|ca| + |at| \end{array}$$

On the left hand of the inequality, we have a path from a to t avoiding e. So, its length should be $\geq$ length of the preferred path $P \setminus sa$. Thus $|P \setminus sa| \leq 2|ca| + |at| \leq 2\sqrt{n} + |at|$. By Lemma 6, all replacement paths in $(< P)$ pass through e (as detour of these replacement paths start below e) and by Lemma 7, these replacement paths avoid edges that are closer to t than e. We can view the replacement paths as if they are starting from the vertex a. That is, consider paths $\{P \setminus sa\} \cup \{P' \setminus sa | P' \in (< P)\}$. Applying lemma 9, we infer that the number of paths in $\{P' \setminus sa | P' \in (< P)\}$ is $\leq 2\sqrt{n}$.

Our arguments above point to the following important observation: *Once we find a replacement path in $\mathcal{R}$ with unique path length $< \sqrt{n}$, then there are at most $2\sqrt{n}$ replacement paths in $\mathcal{R}$ left to process.* Since there can be at most $\sqrt{n}$ paths in $\mathcal{R}$ with unique path length $\geq \sqrt{n}$, we have proven the following lemma:

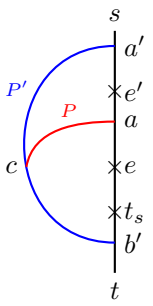

Figure 2 P intersects first with $P' \in (> P)$ at c.

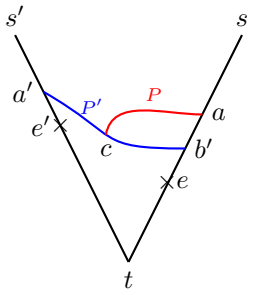

Figure 3 The bad case for us: $P' \in (> P)$ intersects with P and then passes through the edge e that P avoids

▶ **Lemma 11.** $|\mathcal{R}| = O(\sqrt{n})$.

We now build a data-structure which will exploit Lemma 11. However, we need another key but simple observation. By Lemma 6, if $|P| > |P'|$, then $\textsc{Detour}(P')$ starts below the edge avoided by P. This lemma implies that $\textsc{Detour}(P')$ starts below all edges avoided by P. Thus P avoids some contiguous path in st_s and detour of all replacement paths in $(< P)$ start below the last edge (which is closer to t_s) in this subpath. Thus, we have proved the second key lemma:

▶ **Lemma 12.** *A replacement path P avoids a contiguous subpath of st.*

Let $\textsc{First}(P)$ and $\textsc{Last}(P)$ denote the first and the last vertex of the contiguous path that P avoids. Given a vertex v, let $v.depth$ denote the depth of v in the BFS tree of s. We can store the depth of all vertices in an array (takes $O(n)$ space). Lastly, we build a balanced binary search tree $\text{BST}(t)$ in which each node represents a path P. The key used to search the node is the range: $[\textsc{First}(P).depth, \textsc{Last}(P).depth]$. By Lemma 12, all replacement paths avoid contiguous subpaths of st_s. These contiguous paths are also disjoint as there is only one preferred path avoiding an edge. Thus, the key we have chosen forms a total ordered set with respect to the relation $\{<, >\}$. The size of $\text{BST}(t)$ is $O(\sqrt{n})$ as the size of $\mathcal{R}$ is $O(\sqrt{n})$. We are now ready to process any query $\text{Q}(s, t, e(u, v))$. We just need to search for an interval in $\text{BST}(t)$ that contains $u.depth$ and $v.depth$. This can be done in $\tilde{O}(1)$ time. Thus we have proved the following theorem:

▶ **Theorem 13.** *There exists a data-structure of size $\tilde{O}(n^{3/2})$ for single source single fault tolerant exact distance oracle that can answer each query in $\tilde{O}(1)$ time.*

6 From Single Source to Multiple Sources

Unfortunately, the analysis for the single source case is not easily extendible to multiple source case. We identify the exact problem here. Consider the case described in Section 5.2. In this case, we show that if $|P'| > |P|$ and P intersects with P', then there is a path available for P (that is $ac \diamond cb' \diamond b't$). We can use this path because it also avoids e (the edge avoided by path P). First, we show that the above assertion is not true when we move to multiple source case. Consider the following example (See Figure 3). Here, P avoids e on st path and P' avoids e' on $s't$ path. Detour(P) starts at a and its intersects P' at c. Detour(P') starts at a' and it hits st path at b' and then passes through e. Note that the full path P from s to t is not shown in Figure 3. The reader can check that the path $ac \diamond cb' \diamond b't$ is not an alternate path for P as it passes through e. We say that such a path is a bad path because it breaks the easy analysis of single source case (we will formally define bad paths in Section 8.2). However, we are able to show that the total number of *good* paths (paths which are not bad) is $\geq$ the number of bad paths. Good paths exhibit properties similar to the set $\mathcal{R}$ in Section 5. This will help us in bounding them (and thus bad paths too). Once again we will fix a vertex t and show that the number of replacement paths from $s \in S$ to t that also avoids t_s is $O(\sqrt{\sigma n})$. Let BFS(t) denote the union of all shortest paths from t to $s \in S$. The reader can check that the union of these paths does not admit a cycle, so we can assume that its a tree rooted at t. Since BFS(t) has at most σ leaves, the number of vertices with degree > 2 in BFS(t) is $O(\sigma)$. We now contract all the vertices of degree 2 (except t and $s \in S$) in BFS(t) to get a tree that only contains leaves of BFS(t), the root t, all the sources and all other vertices with degree > 2 in BFS(t).

▶ **Definition 14.** (σ-BFS(t)) σ-BFS(t) is a tree obtained by contracting all the vertices with degree exactly 2 in BFS(t) except t and source $s \in S$.

▶ **Definition 15.** (Intersection vertex and segment in σ-BFS(t))
Each node σ-BFS(t) is called an intersection vertex. An edge $xy \in \sigma$-BFS(t) denotes a path between two vertices in BFS(t). We call such an edge in σ-BFS a segment. We use this term in order to differentiate between edges in BFS(t) and σ-BFS(t). Also, we will use the following convention: if xy is a segment, then y is closer to t than x.

σ-BFS(t) has at most σ vertices with degree ≤ 2. This implies that there are at most $O(\sigma)$ intersection vertices and segments in σ-BFS(t).

As in the single source case, we would like to find the preferred path for each avoided edge on the st path where $s \in S$. However, we don't have enough space to store all these paths. Also storing all paths seems wasteful. Consider two preferred replacement paths P and P' that start from s and s' respectively. These two paths meet at an intersection vertex x after which they are same, that is, they take the same detour to reach t. Storing both P and P' seems wasteful as they are essentially the same path once they hit x. To this end, we only store preferred path corresponding to each segment in σ-BFS(t). We now describe our approach in detail.

Let xy be a segment in σ-BFS(t). We divide replacement paths whose detour start in xy into two types:

$\mathcal{R}_1(xy)$: Preferred replacement paths from x to t whose detour starts in xy but the avoided edge lies in yt_x.

$\mathcal{R}_2(xy)$: Preferred replacement paths from x to t whose start of detour and avoided edge both lie strictly inside segment xy (that is, detour cannot start from x or y).

Let $\mathcal{R}_1 := \cup_{xy \in \sigma\text{-BFS}(t)} \mathcal{R}_1(xy)$ and $\mathcal{R}_2 := \cup_{xy \in \sigma\text{-BFS}(t)} \mathcal{R}_2(xy)$. The set $\mathcal{R}_1$ helps us to weed out simple preferred replacement paths. We will show that we can store preferred

replacement paths in $\mathcal{R}_1$ in $O(\sigma)$ space – one per segment in σ-BFS(t). The hardest case for us in $\mathcal{R}_2$, which contains bad paths. Let $\mathcal{B}$ denote the set of bad paths in $\mathcal{R}_2$. We will show that $|\mathcal{B}| \leq |\mathcal{R}_2 \setminus \mathcal{B}|$ (the number of bad paths is $\leq$ number of good paths in $\mathcal{R}_2$) and $|\mathcal{R}_2 \setminus \mathcal{B}| = O(\sqrt{n\sigma})$ (the number of good path is $O(\sqrt{n\sigma})$). This implies that $|\mathcal{R}_2| = O(\sqrt{n\sigma})$.

Since $\mathcal{R}_1$ and $\mathcal{R}_2$ are of size $O(\sqrt{n\sigma})$, we can make a data-structure of size $O(\sqrt{n\sigma})$. In this data-structure, we have stored a preferred path for each segment. However, we have to answer queries of type $\mathrm{Q}(s, t, e)$ where s is a source. In Section 9, we will see how to use preferred paths of segments to answer queries in $\tilde{O}(1)$ time.

7 Analysing preferred replacement paths in $\mathcal{R}_1$

We first show the following:

▶ **Lemma 16.** *For each segment $xy \in \sigma$-BFS(t), $|\mathcal{R}_1(xy)| = 1$*

The above lemma implies that $|\mathcal{R}_1| = \cup_{xy \in \sigma\text{-BFS}(t)} |\mathcal{R}_1(xy)| = O(\sigma) = O(\sqrt{n\sigma})$.

8 Analysing preferred replacement paths in $\mathcal{R}_2$

We first show that one special kind of path will never lie in $\mathcal{R}_2$. This characterization will help in analyzing bad paths in $\mathcal{R}_2$.

▶ **Lemma 17.** *Let P be a preferred path from x to t avoiding e on xt path. If P merges with any segment $x'y'$ and then diverges from $x't$ path, then $P \notin \mathcal{R}_2$.*

We will now analyze paths in $\mathcal{R}_2$. Consider two replacement paths P, P' avoiding edges e, e' (respectively) on $xy, x'y'$ segment respectively. Let a, a' be the starting vertex of $\textsc{Detour}(P), \textsc{Detour}(P')$ respectively. We say that $P \prec P'$ if $|at| < |a't|$. If $|at| = |a't|$, then the tie is broken arbitrarily.

Given a path $P \in \mathcal{R}_2$, let $(< P)$ be the set of all replacement paths in $\mathcal{R}_2$ that are $\prec P$ in the ordering. Similarly, $(> P)$ is the set of all replacement paths $P' \in \mathcal{R}_2$ for which $P \prec P'$. Define $\textsc{Unique}(P)$ according to this ordering (see definition 10). Assume that we are processing a replacement path P according to this ordering. If $|\textsc{Unique}(P)| \geq \sqrt{n/\sigma}$, then we can associate $O(\sqrt{n/\sigma})$ *unique* vertices to P. Otherwise $|\textsc{Unique}(P)| < \sqrt{n/\sigma}$ and we have the following two cases:

8.1 Detour(P) does not intersect with any other detour in $(> P)$

This case is similar to the first case in Section 5.1. We can show that once we get a replacement path $P \in \mathcal{R}_2(xy)$ with $|\textsc{Unique}(P)| < \sqrt{n/\sigma}$, then there are at most $O(\sqrt{n/\sigma})$ replacement paths in $\mathcal{R}_2(xy)$ remaining to be processed. This will bound the total number of such paths to $O(\sqrt{n\sigma})$. Please see the full version for details.

8.2 Detour(P) intersects with detour of a path in $(> P)$

We first give a formal definition of a bad path that was defined informally in Section 6.

▶ **Definition 18.** (Bad Path) A path $P \in \mathcal{R}_2$ is called a bad path if there exists another path $P' \in (> P)$ such that (1) $\textsc{Detour}(P)$ intersects with $\textsc{Detour}(P')$ and (2) $\textsc{Detour}(P')$ passes through the edge avoided by P after their intersection. We also say that P is a bad replacement path due to P' if P' satisfies the above two conditions.

A path that is not bad is called a good path. In Section 6, we saw that bad paths break the easy analysis of the single source case. So, we have two cases depending on whether the path is good or bad. Let us look at the easier case first.

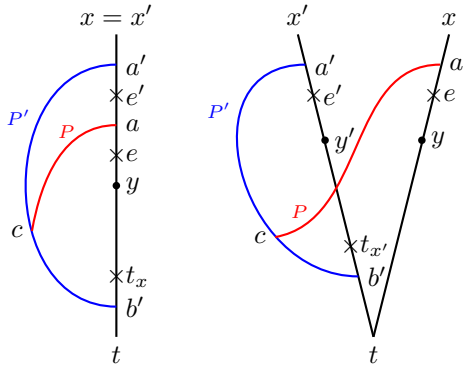

Figure 4 The figure shows two representative examples when ca and at does not pass through e'.

(1) *P is a good path.*
Assume that $P \in \mathcal{R}_2(xy)$ and it avoids an edge $e \in xy$. Assume that P intersects first with $P' \in (> P)$ and P' avoids e' on $x'y'$ segment. Note that x may be equal to x'. Let $\textsc{Detour}(P')$ start at a' and end at b'. Assume that $\textsc{Detour}(P)$ starts at a and it intersects $\textsc{Detour}(P')$ at c. Consider the path $x'a' \diamond a'c \diamond ca \diamond at$. Since $x'a' \diamond a'c$ is a part of P', it avoids e'. However, it is not clear whether $ca \diamond at$ avoids e' too. In Figure 4, we see two representative examples in which ca and at avoid e'.

In the full version of the paper, we show that ca and at cannot pass through e'. Thus, the path $x'a' \diamond a'c \diamond ca \diamond at$ is indeed a valid replacement path from x' to t avoiding e'. Since $P' = x'a' \diamond a'c \diamond cb' \diamond b't$, length of P' must be $\leq$ length of this alternate path. Thus,

$$\begin{aligned} & |x'a'| + |a'c| + |cb'| + |b't| \leq |x'a'| + |a'c| + |ca| + |at| \\ \implies & |cb'| + |b't| \leq |ca| + |at| \\ \implies & |ac| + |cb'| + |b't| \leq 2|ca| + |at| \end{aligned}$$

On the left hand of the inequality, we have a path from a to t avoiding e (since we know that P is a good path, so P' and thus $cb' \diamond b't$ does not pass through e). So, its length should be $\geq$ length of the preferred path $P \setminus xa$. Thus $|P \setminus xa| \leq 2|ca| + |at| \leq 2\sqrt{n/\sigma} + |at|$ (since $|\textsc{Unique}(P)| = |ac| < \sqrt{n/\sigma}$). Consider the following set of replacement paths $(< P)_x := \{P' \in (< P) \mid P' \text{ avoids an edge on } xy \text{ segment}\}$. By Lemma 6, all replacement paths in $(< P)_x$ pass through e (as detour of these replacement paths start below e) and by Lemma 7, these replacement paths avoid edges that are closer to y than e. Applying Lemma 9, we get that the number of replacement paths $(< P)_x$ is $\leq 2\sqrt{n/\sigma}$. Thus, once we get a replacement path $P \in \mathcal{R}_2(xy)$ with $|\textsc{Unique}(P)| < \sqrt{n/\sigma}$, then there are at most $2\sqrt{n/\sigma}$ replacement paths in $\mathcal{R}_2(xy)$ remaining to be processed. Thus, total number of paths $\in \mathcal{R}_2$ with $|\textsc{Unique}(P)| < \sqrt{n/\sigma}$ is $\sum_{xy \in \sigma\text{-BFS}(t)} 2\sqrt{n/\sigma} = O(\sqrt{n\sigma})$ (as there are $O(\sigma)$ segments in σ-BFS(t)).
(2) *P is a bad path.*
We now arrive at our hardest scenario. We will first show that the number of good paths in $\mathcal{R}_2$ is greater than the number of bad paths in $\mathcal{R}_2$. To this end, we will prove the following lemma:

▶ **Lemma 19.** *For each $P' \in \mathcal{R}_2$, there exists only one replacement path $P \in \mathcal{R}_2$ which is bad due to P'.*

The above lemma can be used to discard bad paths from $\mathcal{R}_2$. For each such discarded path, there exists at least one good path. And by the above lemma, each such good path can be used to discard at most one bad path. Thus the number of good paths in $\mathcal{R}_2$ is $\geq$

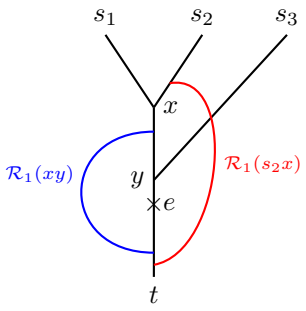

Figure 5 The shortest path from s_2 to t avoiding e can be $\mathcal{R}_1(xy)$ or $\mathcal{R}_1(s_2x)$.

number of bad paths in $\mathcal{R}_2$. We have already shown that the total number of good paths in $\mathcal{R}_2$ is $O(\sqrt{n\sigma})$. Thus the total number of paths in $\mathcal{R}_2$ is also $O(\sqrt{n\sigma})$.

9 Building the Data Structure

Let us first recognize a potential problem in using $\mathcal{R}_1(\cdot)$. Let s_1t and s_2t path meet at vertex x (See Figure 5). Another path s_3t meets s_2t path at y where y is closer to t. $\mathcal{R}_1(s_2x)$ is the shortest path from s_1 to t avoiding e and $\mathcal{R}_1(xy)$ is the shortest path from x to t avoiding $e \in yt$. This immediately leads to the following problem. Assume that the query is $\mathrm{Q}(s_2, t, e)$ and the preferred path avoiding e is in $\mathcal{R}_1$. Then there are two candidate paths that avoid e: one that goes from s_2 to the intersection vertex x and then take path $\mathcal{R}_1(xy)$ and the other $\mathcal{R}_1(s_2x)$. Thus, we need to check these two paths and return the minimum of the two. One can make a bigger example in which there are σ segments between s_2 and t and thus we have to check $O(\sigma)$ path before we can answer the query. The problem appears because we don't know from which segment the shortest path avoiding e started its detour. If this information is not there, then it seems that we have to look at all the segments between s_2 ans t. To end this dilemma, we use heavy light decomposition of σ-BFS(t) [20]. For any segment $xy \in \sigma$-BFS(t) (by our convention y is closer to t), x is a *heavy* child of y if the number of nodes in the subtree under x is $\geq 1/2$(number of nodes in the subtree under y) else it is called a *light child* (or light *segment* in our case). It follows that each intersection vertex has exactly one heavy child and each vertex is adjacent to atmost two heavy edges. A *heavy chain* is a concatenation of heavy edges. A *heavy subpath* is a subpath of a heavy chain. The following lemma notes a well known property of heavy-light decomposition.

▶ **Lemma 20.** *The path from a source s to t in σ-BFS(t) can be decomposed into $O(\log n)$ heavy subpaths and light segments .*

Given any source $s \in S$, by Lemma 20, the path from t to s may contain many heavy subpaths. Let $C(pq)$ be a heavy chain that starts at p and ends at q (where q is closer to t than p). A ts path may follow a heavy chain $C(pq)$ but may exit this chain from a vertex midway, say at r. Let $(C(pq), r)$ be a tuple associated with s such that the shortest path from t to s enters this heavy chain via q and leaves this chain at r. We keep a list $\textsc{Heavy}(s, t)$ which contains all the tuples $(C(pq), r)$ sorted according to the distance of heavy chain from t (that is distance qt). By Lemma 20, the size of $\textsc{Heavy}(s, t) = O(\log n)$. Similarly, we have one more list to store the light segments. $\textsc{Light}(s, t)$ contains all the light segments on the st path again ordered according to their distance from t in σ-BFS(t). Again by Lemma 20, the size of $\textsc{Light}(s, t) = O(\log n)$. Note that the size of these additional two data-structures is $\sum_{s\in S} O(\log n) = \tilde{O}(\sigma) = \tilde{O}(\sqrt{n\sigma})$.

Our main problem was that we have to find the minimum $\mathcal{R}_1(\cdot)$ of $O(\sigma)$ segments if there is a path of length σ between s and t. The trick we use here is that finding minimum on any heavy subpath takes $\tilde{O}(1)$ time. Since there are $O(\log n)$ heavy subpaths, the total time taken to find the minimum on heavy subpaths in $\tilde{O}(1)$. Also, since the number of light segments is also $O(\log n)$ finding the minimum among these also takes $\tilde{O}(1)$ time.

We now describe our intuition in detail. Let xy be a segment in a heavy chain $C(pq)$. We want to represent $\mathcal{R}_1(xy)$ in a balanced binary search tree $\textsc{Bst}(C)$. To this end, we will add a node with the tuple $(x.depth, |px \diamond \mathcal{R}_1(xy)|, |px|)$ in $\textsc{Bst}(C)$. The first element in this tuple is the depth of x in $\text{BFS}(t)$ – it also acts as the key in this binary search tree. The second element is the path $\mathcal{R}_1(xy)$ concatenated with px. This concatenation is done so that all paths in $\textsc{Bst}(C)$ start from p and comparing two paths in $\textsc{Bst}(C)$ is possible. The third element will be used to get the path length $\mathcal{R}_1(xy)$ (by subtracting it from the second element) when need arises. Now we can augment this tree so that the following range minimum query can be answered in $\tilde{O}(1)$ time: $\textsc{Rmq}(C(pq), [a, b])$: Find minimum of $\{|px \diamond \mathcal{R}_1(xy)| \mid xy$ is a segment in heavy chain $C(pq)$ and $x.depth \geq a.depth$ and $x.depth \leq b.depth\}$. The size of $\cup_{C \in \textsc{Heavy}(s,t)} \textsc{Bst}(C)$ is $O(\sigma) = O(\sqrt{n\sigma})$ as there are at most $O(\sigma)$ segments in σ-$\text{BFS}(t)$.

Given any edge $e(u, v)$ on st path, we can now find the shortest path in $\mathcal{R}_1$ from s to t avoiding e (Please refer to Algorithm 1 in the full version of the paper). We first find the first intersection vertex on the us path from u. Let this vertex be x. We will see that finding x is also not a trivial problem – we will say more about this problem later. Now, we will go over all possible replacement paths from u to s. Thus, we search if there exists any heavy chain in $\textsc{Heavy}(s, t)$ that contains x. To this end, we first check if x lies in some light segment (this can be checked in $\tilde{O}(1)$ time). If not, then x lies in some heavy chain. We now search each heavy chain in $\textsc{Heavy}(s, t)$ to find a node x' with the smallest depth such that $x'.depth > x.depth$. Let this node be x'. Thus we have found the segment $x'x$ where x is closer to t than x'. We can easily calculate $x.depth$ as $|st| - |sx|$ or $B_0(s, t) - B_0(s, x)$. Since there are $\tilde{O}(1)$ heavy chain in $\textsc{Heavy}(s, t)$, the time taken to find if $x'x$ exists in some heavy chain is $\tilde{O}(1)$.

Assume that we found out that $x'x \in C(pq)$, and ts path leaves the chain C at r, then we want to find the shortest replacement path from r to t avoiding e. This can be found out via the range minimum query $\textsc{Rmq}(C(p, q), [x, r])$. However, note that each replacement path in C starts from p. So, we need to remove $|pr|$ from the replacement path length returned by $\textsc{Rmq}$ query. The length pr can be found out in the node $r \in \textsc{Bst}(C)$. Finally, we add $|sr|$ to get the path from s to t.

Similarly, we can process a light segment in $O(1)$ time (please refer to Algorithm 1 in the full version). Thus, the time taken by Algorithm 1 is $\tilde{O}(1)$ as the while loop runs at most $O(\log n)$ times and each step in the while loop runs in $\tilde{O}(1)$ time.

9.1 Answering queries in $\tilde{O}(1)$ time

Given a query $Q(s, t, e(u, v))$, we process it as follows (assuming that e lies on st_s path (that is the *far case)* and v is closer to t than u)

1. Find the first intersection vertex on us path.
   In the full version of the paper, we show that we can find the first intersection vertex on us path in $\tilde{O}(1)$ time using $O(\sqrt{n\sigma})$ space.
2. Find the replacement path avoiding u if it lies in $\mathcal{R}_1$.
   To this end, we use our Algorithm 1. The first non-trivial part of this algorithm, that is, finding the first intersection vertex on the us path has already been tackled in the point

above. So we can find such a replacement path (if it exists) in $\tilde{O}(1)$ time and $\tilde{O}(\sqrt{n\sigma})$ space.

3. Find the replacement path avoiding $e(u, v)$ if it lies in $\mathcal{R}_2$.
   This part is similar to our data-structure in single source case. Let $x \leftarrow \textsc{Int}(u, t)$. Using $\textsc{Heavy}(s, t)$ and $\textsc{Light}(s, t)$, in $\tilde{O}(1)$ time, we can find the segment $xy \in \sigma\text{-BFS}(t)$ such that y is closer to t than x. In this case, we want to check if there exists any replacement path that starts in the same segment in which e resides. This replacement path first takes sx path and then takes the detour strictly inside the segment xy. All such paths are stored in $\mathcal{R}_2(xy)$ with the contiguous range of edges that they avoid on xy. We now just need to check if u and v lie in the range of some replacement path. To this end, we find $u.depth \leftarrow |st| - |su| = B_0(s, t) - B_0(s, u)$ and $v.depth \leftarrow |st| - |sv| = B_0(s, t) - B_0(s, v)$. Now we check if $u.depth$ and $v.depth$ lie in contiguous range of some replacement path in $\mathcal{R}_2(xy)$. If yes, then we return the length of that path concatenated with sx. Note that we have already stored $|sx|$ in $B_0(s, x)$. The time taken in this case is dominated by searching u and v in $\mathcal{R}_2(xy)$, that is $\tilde{O}(1)$.

Thus, the total query time of our algorithm is $\tilde{O}(1)$, and we can return the minimum of replacement paths found in Step 2 and 3 as our final answer. The reader can check that the space taken by our algorithm for a vertex t is $\tilde{O}(\sqrt{n\sigma})$. Thus the total space taken by our algorithm is $\tilde{O}(\sigma^{1/2}n^{3/2})$. Thus we have proved the main result, that is Theorem 1 of our paper.

Abstract

Interactive proofs of proximity allow a sublinear-time verifier to check that a given input is *close* to the language, using a small amount of communication with a powerful (but untrusted) prover. In this work we consider two natural *minimally interactive* variants of such proofs systems, in which the prover only sends a single message, referred to as the proof.

The first variant, known as MA-proofs of Proximity (MAP), is fully *non-interactive*, meaning that the proof is a function of the input *only*. The second variant, known as AM-proofs of Proximity (AMP), allows the proof to additionally depend on the verifier's (entire) random string. The complexity of both MAPs and AMPs is the total number of bits that the verifier observes – namely, the sum of the proof length and query complexity.

Our main result is an exponential separation between the power of MAPs and AMPs. Specifically, we exhibit an explicit and natural property Π that admits an AMP with complexity $O(\log n)$, whereas any MAP for Π has complexity $\tilde{\Omega}(n^{1/4})$, where n denotes the length of the input in bits. Our MAP lower bound also yields an alternate proof, which is more general and arguably much simpler, for a recent result of Fischer *et al.* (ITCS, 2014).

Lastly, we also consider the notion of *oblivious* proofs of proximity, in which the verifier's queries are oblivious to the proof. In this setting we show that AMPs can only be quadratically stronger than MAPs. As an application of this result, we show an exponential separation between the power of public and private coin for oblivious interactive proofs of proximity.

1 Introduction

The field of property testing [47, 23] deals with sublinear algorithms for deciding whether a given object has a predetermined property or is far from any object having this property. Such algorithms, called testers, obtain local views of the object by performing queries; that is, the object is seen as a function and the tester receives oracle access to this function. The goal of the tester is to ascertain a global property of the function based only on its local view.

In the last couple of decades, the area of property testing has attracted much attention (see surveys [44, 45, 11] and recent textbook [22]). However, while much success was found in designing testers for a myriad of natural properties, which only make a small number of queries, many other natural properties were shown to require a very large number of queries to test (often linear in the length of the input).

Proofs of proximity, first considered by Ergün, Kumar and Rubinfeld [18], are both intrinsically interesting as a natural notion of proof systems for sublinear algorithms, as well as provide means to significantly reduce the number of queries that the tester needs to make in order to verify, rather than decide. These probabilistic proof systems can be viewed as augmenting testers with a help from a powerful, yet untrusted prover. In a recent line of works [46, 33, 20, 27, 36, 25, 43, 34, 9, 14] various types of interactive [46] and non-interactive proofs of proximity [35] were studied, including arguments of proximity [36], zero-knowledge proofs of proximity [9], and proofs of proximity for distribution testing [14].

In this work we study the relation between two types of proofs of proximity that are *minimally interactive*; namely, MA and AM proofs of proximity, which can be viewed as the property testing analogue of the class MA (i.e., "randomized NP") and AM, respectively, and are described in more detail next.

Informally speaking, an MA proof of proximity (MAP) protocol consists of a tester (or rather a verifier) that receives oracle access to an input function f but also receives explicit access to a short purported proof w. Based on the proof string and a few oracle queries to f, the verifier should decide whether f has some property Π (i.e., whether $f \in \Pi$). More specifically, after reading the proof w, the verifier tosses random coins, makes queries to the oracle f, and decides whether to accept or reject. We require the following completeness and soundness conditions: if $f \in \Pi$, then there exists a proof w that the verifier accepts with high probability, and if f is "far" (in Hamming distance) from any function in Π, then the verifier rejects with high probability. Following the literature, the complexity of an MAP is the total number of bits that the verifier observes - namely, the sum of its proof length and query complexity.[3]

The reason that the foregoing model is referred to as a "Merlin-Arthur" protocol is that we think of the prover as being Merlin (the all powerful magician) and the verifier as Arthur (a mere mortal). Then in the MAP model Merlin "speaks" first (i.e., sends the proof) and Arthur "speaks" second (i.e., tosses his random coins).

It is natural to ask what happens if we switch the order - letting Arthur toss his coins first and Merlin send his proof after seeing Arthur's coin tosses. This type of protocol is typically referred to as an "Arthur-Merlin" protocol. More precisely, an AM proof of proximity (AMP) is defined similarly to an MAP, except that now the proof oracle is a function of the verifier's entire random string. We view AMPs as *minimally interactive*, since given a common random

[3] Alternatively, one could view the running time of the verifier (which serves as an upper bound on the query and communication complexities) as the main resource to be minimized. However, for simplicity (and following the property testing literature), we focus on combinatorial resources. This only makes our lower bounds stronger, whereas for all of our upper bounds the verifier is also computationally efficient.

string, the protocol consists of a single message (i.e., the proof). Analogously to MAPs, the complexity of an AMP is the sum of its proof length and query complexity. We emphasize that the prover's message can depend on all of the verifier's coin tosses. Namely, the verifier cannot toss an additional coins after receiving its message from the prover.[4]

While the difference between these two proof systems may appear minor, MA-type and AM-type proofs naturally admit very different types of strategies. In particular, note that AM proofs provide the additional power of allowing the prover and verifier to jointly restrict their attention to a random subset of the input function's domain. On the other hand, the AM model also significantly hampers the power of the verifier to detect malicious prover strategies, since the prover knows the entire randomness of the verifier, and in particular the prover knows which queries the verifier will make.

At first glance, it may seem that AMPs are extremely limited, since the prover can predict exactly what the verifier will check (knowing the verifier's *entire* random string allows the prover to deduce which queries the verifier will make). However, it turns out that a straightforward adaptation of the classical MA $\subseteq$ AM inclusion [6] implies that any MAP can be emulated by an AMP at a quadratic cost. (More precisely, an MAP with proof complexity p and query complexity q can be emulated by an AMP with proof length p and query complexity $O(p \cdot q)$.[5])

It is natural to ask the following converse question:

Can any AMP *protocol be emulated by an* MAP*, or is there a gap between the power of these two models?*

Note that any AMP can be easily emulated by an MAP with at most an exponential overhead.[6] Thus, the question that we would really like to answer is whether such an exponential overhead is inherent.

1.1 Our results

Our main result shows that it is indeed the case that AMPs can be *exponentially* stronger than MAPs and so the foregoing emulation strategy is optimal, up to polynomial factors:

▶ **Theorem 1.** *There exists a property* $\Pi \subseteq \{f : [n] \to [n]\}$ *such that:*

- Π *has an* AMP *of complexity* $O(\log(n)/\varepsilon)$*, with respect to proximity parameter* $\varepsilon > 0$*; and*
- *Every* MAP *for* Π*, with respect to proximity parameter* $\varepsilon \leq \frac{1}{10}$*, must have complexity* $\Omega(n^{\frac{1}{4}})$.

The property Π that we use to prove Theorem 1 is actually very simple and natural. Specifically, Π is the set of all permutations over $[n]$; the goal of the verifier is to check

[4] In contrast, the complexity class AM is sometimes defined as any constant-round public-coin interactive proof-system. Indeed, if one does not care about polynomial factors, then by a result of Babai and Moran [6], any public-coin constant-round interactive proof can be reduced to just 2 messages.

[5] The idea is to first reduce the soundness error of the MAP to $2^{-O(p)}$ (by repetition). Now suppose that the verifier reveals its randomness to the prover before receiving the proof-string. For soundness, observe that when f is far from the having the property, for any fixed proof-string the probability that the verifier would accept is at most $2^{-\Omega(p)}$ and so by a union bound, with high probability there simply does not exist a proof-string that will make the verifier accept.

[6] Any AMP with proof complexity p and query complexity q can be emulated by a *tester* (i.e., an MAP which does not use a proof at all) with query complexity $q \cdot 2^p$ by simply trying all possible candidate proof strings.

whether a given function $f : [n] \to [n]$ is close to being a permutation by querying the function in a few locations and with a short interaction with the prover.

The AMP protocol for deciding whether a given function $f : [n] \to [n]$ is a permutation is extremely simple. The idea is that the random string specifies some random element $y \in [n]$ and the prover should specify an inverse x of y (under f). If f is a permutation such an element must exist whereas if f is ε-far from being a permutation, then with probability ε it holds that y simply does not have an inverse. We can repeat the base protocol $O(1/\varepsilon)$ times to get constant soundness error. This protocol can actually be traced back to a result of Bellare and Yung [7] who used it resolve a gap in the [19] construction of non-interactive zero-knowledge proofs for NP based on trapdoor permutations.

Our MAP lower bound is the technically more challenging part of this work, and is actually a special case of a more general MAP lower bound that we prove. We show that any property that satisfies a relaxed notion of k-wise independence requires MAPs with complexity roughly $\sqrt{k}$. This result generalizes a recent result of Fischer, Goldhirsh and Lachish [20] which can be interpreted as an MAP lower bound of $\sqrt{k}$ for properties that are exactly k-wise independent.[7] Our proof is also (arguably) significantly simpler than that of [20] and in particular uses only elementary arguments, see further discussion in Section 1.2.

1.1.1 Oblivious Proofs of Proximity

Having established Theorem 1, we revisit the MA versus AM problem within the context of proofs of proximity *with prover-oblivious queries* (a notion first considered in [46] and further explored in [35]), or in short *oblivious proofs of proximity*. These are proofs of proximity that have the special feature that the queries that the verifier makes are independent of the proof. Viewed from a temporal perspective, in these proof systems the verifier *first* makes its queries to the input function, and only after making all of its queries does it receive the proof. One reason that makes this feature appealing is because it allows the verifier to probe the object and obtain a certificate, which can then be used later when interacting with a prover, even if the object is no longer accessible. Another reason is that many of the interactive proof systems from the literature (e.g., the sumcheck protocol of [39]) are *oblivious*.

Surprisingly, it turns out that the gap between the power of *oblivious* AMPs and MAPs is dramatically smaller than the one exhibited in Theorem 1. Loosely speaking, we show that oblivious AMPs can only be *quadratically* stronger than oblivious MAPs, and in fact, standard testers (that do not use a proof).

▶ **Theorem 2.** *For any property* Π*, if there exists an* oblivious AMP *for* Π *with proof complexity* p *and query complexity* q*, then there also exists a tester (i.e.,* MAP *with proof complexity* 0*) for* Π *with query complexity* $O(p \cdot q)$*.*

As an application, we use Theorem 2 to derive lower bounds on public-coin oblivious interactive proofs of proximity, and show an exponential separation between public-coin and private-coin protocols in this setting. See further discussion in the full version [31].

1.2 Related works

The notion of proofs of proximity was originally proposed by Ergün, Kumar and Rubinfeld. Ben Sasson *et al.* [8] and Dinur and Reingold [17] considered such proofs in the context of

[7] More precisely, [20] show that any linear code with large dual distance requires MAPs of complexity that is roughly square root of the code's blocklength.

PCPs. Rothblum, Vadhan and Wigderson [46], considered *interactive* proofs of proximity and showed that every language computable by a low-depth circuit has an interactive proof of proximity (IPP) with a sublinear time verifier. Reingold, Rothblum, and Rothblum [43] showed *constant-round* IPPs for any language computable in polynomial-time and bounded polynomial-space. Goldreich and Gur [24, 25] showed general-purpose IPP with only 3 rounds, albeit for a much smaller class.

Proofs of proximity were further studied by [27] who showed more efficient constructions for certain restricted complexity classes, such as functions accepted by small read-once branching programs and context-free languages. Gur and Rothblum proved a round hierarchy theorem for IPPs [34], showing that the power of IPPs gradually increases with the number of rounds of interaction. Several works focused on studying non-interactive (MA) proofs of proximity [35, 20, 26] (see also [30]). In addition, recent works studied (computationally sound) interactive *arguments* of proximity [36], zero-knowledge proofs of proximity [9], and proofs of proximity for distribution testing [14]. Proofs of proximity have also found applications to property testing and related models [33, 21, 34]. We remark that a concurrent work of Berman *et al.* [9], utilizes our results (specifically Theorem 1) to derive a separation between the power of MAPs and zero-knowledge IPPs.

The notion of MA and AM proofs plays a central role in the study of proofs system in various computational models, other than in the setting of polynomial-time Turing machines in which they were originally conceived [6]. For example, in quantum computation, the class QMA (quantum MA proofs) captures the most fundamental type of quantum proof systems (since quantum algorithms are inherently randomized) and it has been extensively studied in the last couple of decades (see survey [4]). Of particular relevance, Aaronson [1] considered the problem of deciding whether a function is close to a permutation to derive a quantum query complexity separation between the class QMA and the class of statistical zero knowledge SZK, showing that every QMA query complexity algorithm with a w-qubit witness and query complexity q must satisfy $q + w = \Omega(n^{1/6})$.

In addition, MA and AM proof systems received much attention in the setting of communication complexity [5, 37, 41, 38, 29, 48] and streaming algorithms [15, 16, 12, 32, 13, 49]. The former also has an interesting connection to the algebrization barrier [2] and recently found important applications to distributed PCPs and hardness of approximation [3].[8] The latter can be viewed as the property testing analogue of online annotated data streams (there, instead of oracle access to the input, the algorithm has one-pass sequential access to the input, and the goal is to minimize *space* complexity rather than *query* complexity). Indeed, part of our results concerning oblivious proofs of proximity are inspired by the techniques for online annotated data streams in [13].

Perhaps most relevant to us, the notion of MA and AM proofs for decision tree complexity (or the "query complexity model"), which can be thought of as property testing for *exact* (rather than approximate) decision problems, is closely related to proofs of proximity, though the query complexity model is much simpler to analyze than property testing. We remark that the high-level approach of our main lower bound for MAPs is inspired by the work of Raz *et al.* [42].

[8] We remark that there are several similarities between MA and AM proof systems in the setting of property testing and communication complexity. In particular, simulating MA communication complexity protocols by their AM counterparts can also be done while only incurring a quadratic blow-up in complexity, and on the other hand AM protocols can also be exponentially more powerful than MA protocols [38]. In addition, oblivious MA proofs of proximity can be viewed as analogous to *online* MA communication complexity protocols [13].

Comparison with the techniques in [20]. As we discussed above, our MAP lower bound generalizes the main result of Fischer, Goldhirsh, and Lachish [20]. The latter result can be interpreted as an MAP lower bound for any k-wise independent property. Our lower bound extends to a natural generalization of this family. We stress that this extension is *crucial* for our main result, as the permutation property (with respect to which we prove Theorem 1) is *not* k-wise independent, but does satisfy our more general notion.[9]

The proof in [20] is technically quite involved and includes several subtle and non-trivial arguments. For example, while typically property testing lower bounds are shown by exhibiting two distributions that are chosen only as a function of the property, the argument in [20] crucially relies on distributions that are functions of both the property and the description of the specific analyzed algorithm. This entails the usage of several complex mechanisms. For example, they rely on an involved treatment of adaptivity, which consists of procedures for "grafting" decision trees, and use a special type of algorithms (called "readers") that expose low-entropy portions. Perhaps the most significant complication is that their argument uses a delicate information theoretic analysis to handle MAPs that have a two-sided error.

In contrast, our proof is much shorter and consists purely of a combinatorial argument, which does not require any special treatment of adaptivity and two-sided error, and does not use information theory.

1.3 Organization

In Section 2, we introduce the notations and definitions that we use throughout this work. In Section 3, we prove our main technical contribution, which is an MAP lower bound for relaxed k-wise independent properties. Finally, in Section 4, we conclude with a discussion and raise open problems. See full version [31] for the proof of our main result: an exponential separation between MAPs and AMPs, as well as for our results regarding oblivious proofs of proximity.

2 Preliminaries

In this section we establish the definitions and notions that we will need throughout this work.

2.1 Properties and Distance

We focus on testing properties of *functions* and identify a "property" with the set of functions having that property. More accurately, for each $n \in \mathbb{N}$, let D_n and R_n be sets. Let $\mathcal{F}_n$ be the set of functions from D_n to R_n. We define a property as an ensemble $\Pi = \bigcup_n \Pi_n$, where $\Pi_n \subseteq \mathcal{F}_n$ for all n.

For an alphabet Σ, we denote the Hamming distance between two strings $x, y \in \Sigma^n$ by $\Delta(x,y) := |\{x_i \neq y_i : i \in [n]\}|$. If $\Delta(x,y) \leq \varepsilon \cdot n$, we say that x is ε-close to y, otherwise we say that x is ε-far from y. For a non-empty set $S \subseteq \Sigma^n$, we similarly define $\Delta(x,S) := \min_{y \in S} \Delta(x,y)$. Again, if $\Delta(x,S) \leq \varepsilon \cdot n$, we also say that x is ε-close to S and otherwise x is ε-far from S. We extend these definitions to functions by identifying functions with their truth tables (viewed as strings).

[9] Jumping ahead, we remark that our relaxed notion of k-wise independence refers to distributions for which the probability that any subset of k indices is equal to any given sequence of k values is upper bounded by the same probability given the uniform distribution *up to a multiplicative constant* (whereas the standard (i.e., non-relaxed) notion requires exact equality). See further details in Section 3.

Integrality. Throughout this work, for simplicity of notation, we use the convention that all (relevant) integer parameters that are stated as real numbers are implicitly rounded to the closest integer.

2.2 Proofs of Proximity

We recall the definitions of MA and AM proofs of proximity (i.e., MAPs and AMPs), following [35]. Throughout, for an algorithm V we denote by $V^f(n, \varepsilon, w)$ the output of V given oracle access to a function f and explicit access to inputs n, ε, and w; if V is a probabilistic algorithm, we write $\Pr[V^f(n, \varepsilon, w) = z]$ to represent the probability *over the internal randomness of* V that this outcome is z.

▶ **Definition 3** (MAP). A Merlin-Arthur proof of proximity (MAP) for a property $\Pi = \bigcup_n \Pi_n$ consists of a probabilistic algorithm V, called the verifier, that is given as explicit inputs an integer $n \in \mathbb{N}$, a proximity parameter $\varepsilon > 0$, and a proof string $w \in \{0,1\}^*$; in addition, it is given oracle access to a function $f \in \mathcal{F}_n$. The verifier satisfies the following conditions.

1. **Completeness:** For every $n \in \mathbb{N}$ and $f \in \Pi_n$, there exists a string w (the proof) such that for every $\varepsilon > 0$ the verifier accepts with high probability; that is,

$$\Pr\left[V^f(n, \varepsilon, w) = 1\right] \geq \frac{2}{3}.$$

2. **Soundness:** For every $n \in \mathbb{N}$, function $f \in \mathcal{F}_n$, string w, and proximity parameter $\varepsilon > 0$, if f is ε-far from Π_n, then the verifier rejects with high probability; that is,

$$\Pr\left[V^f(n, \varepsilon, w) = 0\right] \geq \frac{2}{3}.$$

A MAP is said to have query complexity $q : \mathbb{N} \times \mathbb{R}^+ \to \mathbb{N}$ if for every $n \in \mathbb{N}, \varepsilon > 0$, $f \in \mathcal{F}_n$, and string $w \in \{0,1\}^*$, the verifier reads at most $q(n, \varepsilon)$ bits in its queries to f. We say that a MAP has proof complexity $p : \mathbb{N} \to \mathbb{N}$ if for every $n \in \mathbb{N}$, there always exists a $w \in \{0,1\}^{p(n)}$ satisfying the conditions of Definition 3. We define the complexity of the MAP to be $t(n, \varepsilon) = q(n, \varepsilon) + p(n)$.

Next, we define AM proofs of proximity (AMPs) similarly to MAPs, except that here the proof is also a function of the inner randomness of the verifier (alternatively, the verifier first sends the prover its entire random string).

▶ **Definition 4** (AMP). An Arthur-Merlin proof of proximity (AMP) for a property $\Pi = \bigcup_n \Pi_n$ consists of a probabilistic algorithm V, called the verifier, that is given as explicit inputs an integer $n \in \mathbb{N}$, a proximity parameter $\varepsilon > 0$, and a proof string w that *depends on the verifier's random string* r, as well as oracle access to a function $f \in \mathcal{F}_n$. The verifier must also be deterministic given the random string r. The protocol satisfies the following conditions.

1. **Completeness:** For every $n \in \mathbb{N}$ and $f \in \Pi_n$,

$$\Pr_r\left[\exists w = w(r) \text{ such that } V^f(n, \varepsilon, w; r) = 1\right] \geq \frac{2}{3}.$$

2. **Soundness:** For every $n \in \mathbb{N}$, function $f \in \mathcal{F}_n$, and proximity parameter $\varepsilon > 0$, if f is ε-far from Π_n, then:

$$\Pr_r\left[\exists w \text{ such that } V^f(n, \varepsilon, w; r) = 1\right] \leq \frac{1}{3}.$$

Analogously to MAPs, an AMP is said to have *query complexity* $q : \mathbb{N} \times \mathbb{R}^+ \to \mathbb{N}$ if for every $n \in \mathbb{N}, \varepsilon > 0$, $f \in \mathcal{F}_n$, and string $w \in \{0,1\}^*$, the verifier reads at most $q(n,\varepsilon)$ bits in its queries to f; and *proof complexity* $p : \mathbb{N} \times \mathbb{R}^+ \to \mathbb{N}$ if for every $n \in \mathbb{N}$ and $f \in \mathcal{F}_n$, with probability at least $\frac{2}{3}$ over coin tosses in the first round, there exists a $w \in \{0,1\}^{p(n,\varepsilon)}$ satisfying the completeness condition of Theorem 4. We define the complexity of the AMP to be $t(n,\varepsilon) = q(n,\varepsilon) + p(n,\varepsilon)$.

We note that we do not include the randomness complexity of the verifier in the complexity of the protocol (although the randomness complexity in all the protocols described in this work is not large). This is a similar choice to what is done in similar contexts such as AM query and communication complexities. Moreover, we show in the full version [31] that if a property Π of functions $f : D_n \to R_n$, such that $|R_n|^{|D_n|} = O(\exp(\mathrm{poly}(n)))$, admits an AMP verifier with query complexity q and proof complexity p, then it also admits an AMP verifier with query complexity $O(q)$, proof complexity $O(p)$, and randomness complexity $O(\log n)$.[10] This transformation is similar to known results of Newman[40] in the context of communication complexity, Goldreich and Sheffet [28] in the context of property testing, and Gur and Rothblum [35] for MAPs. Its main disadvantage however is that it does not preserve the *computational* complexity of the verifier.

3 MAP Lower Bound for (Relaxed) k-wise Independence

In this section we show a general MAP lower bound for a large class of properties. More specifically, we show that any MAP for a (non-degenerate) property that is k-wise independent, must have complexity $\Omega(\sqrt{k})$. By a k-wise independent property we mean that if we sample a random element having the property, than its restriction to any k coordinates looks uniform. As mentioned in the introduction, this generalizes a result due to Fischer *et al.* [20].

We would like to apply this lower bound to the permutation property. However, the permutation property is not k-wise independent and so we cannot apply it directly.[11]. Rather, we give a relaxed notion of k-wise independence that does capture the permutation property and for which we can similarly derive an MAP lower bound.

We proceed to define our relaxed notion of k-wise independence. Recall that we use $\mathcal{F}_n$ to denote the set of all functions from D_n to R_n (see Section 2).

▶ **Definition 5** (Relaxed k-wise Independence)**.** Let $\Pi = \bigcup_{n\geq 1} \Pi_n$ be a property, where $\Pi_n \subset \mathcal{F}_n$ for every n. We say that Π is *relaxed k-wise independent*, for $k = k(n)$, if there exists a constant $C \geq 1$ such that for all positive integers n, all pairwise distinct k-tuples $(i_1, i_2, \ldots, i_k) \in (D_n)^k$ and arbitrary $(t_1, t_2, \ldots, t_k) \in (R_n)^k$, we have that

$$\Pr_{f \in \Pi_n}\left[f(i_j) = t_j \text{ for all } j \in [k]\right] \leq \frac{C}{|R_n|^k}. \tag{1}$$

Note that standard definition of a k-wise independence corresponds to the special case of Definition 5 when $C = 1$ (in which case the inequality in Eq. (1) can be replaced with an equality).

At first glance it may seem that the relaxation that we allow in Definition 5 is relatively minor and any lower bound that holds for the full-fledged definition should easily be extendable to our relaxed variant. We argue that it is not the case. For example, in a seminal

[10] For most properties, we have that both the domain and range have size that is polynomial in n. Indeed, the case that $|R_n|^{|D_n|} = \omega(\exp(\mathrm{poly}(n)))$ seems quite pathological.

[11] Indeed, it is not even pairwise independent: the chance of seeing the same element twice is *zero*.

work, Braverman [10] showed that any k-wise independent distribution (for k that is poly-logarithmic) fools AC_0 circuits. Now consider the permutation property (defined formally in the full version [31]) which as noted above is not even pairwise independent but does satisfy our relaxed variant (with $k = \sqrt{n}$). It is not too hard to see that there is a very simple AC_0 circuit for checking whether a function is a permutation: simply by checking whether there exist a pair of entries in the truth table that are identical - thus, our seemingly minor relaxation completely sidesteps Braverman's result. As a matter of fact, a similar situation occurs in the context of AMPs: Rothblum *et al.* [46] showed an AMP lower bound for exact k-wise independent distribution, whereas we show a protocol for the permutation property with logarithmic complexity.

Having defined our notion of relaxed k-wise independence, we proceed to describe a second important condition that we require: namely, that the property is *sparse*, in the sense that a random function is far from the property. Sparsity is essential for our result since there are trivial properties that are k-wise independent but are testable with very few queries (e.g., the property that consists of all functions).

▶ **Definition 6** (Sparse Property)**.** Fix the proximity parameter $\varepsilon = \frac{1}{10}$. We say that a property $\Pi_n = \bigcup_{n\in\mathbb{N}} \Pi_n$ is $t(n)$-*sparse* if:

$$\Pr_{f\in\mathcal{F}_n}[f \text{ is } \varepsilon\text{-far from } \Pi_n] \geq 1 - |R_n|^{-t(n)}.$$

We can now state our main theorem for this section.

▶ **Theorem 7.** *Let Π be a relaxed k-wise independent and k-sparse property. Then, any* MAP *for Π, with respect to proximity parameter $\varepsilon = 1/10$, with proof complexity p and query complexity q must satisfy $p \cdot q = \Omega(k)$.*

The intuition and high level approach for the proof are as follows. First, we use the duality of an MAP as a collection of partial testers [20]. More specifically, the existence of an MAP for a property Π implies that there is some large "sub-property" $\Pi' \subseteq \Pi$ and a *tester* T that distinguishes between inputs in Π' from those that are far from Π.

This simple observation reduces lower bounding MAPs for Π to lower bounding a partial tester for an arbitrary, but large, sub-property. To show such a lower bound, consider the uniform distribution on Π' vs. the uniform distribution over functions that are far from Π. We would like to argue that these two distributions look the same to T, which therefore cannot distinguish between them.

As a matter of fact, we will argue that both these distributions are "close" to being k-wise independent, which suffices as long as k is larger than the tester's query complexity. First, by the sparsity condition we have that the uniform distribution over functions that are far from Π is close to the uniform distribution over *all* functions. Clearly the latter is k-wise independent.

As for the uniform distribution over Π', we would like to argue that since Π' covers a substantial part of Π, which is relaxed k-wise independent, then also Π' is relaxed k-wise independent. The problem with this argument is that Π' only consists of a 2^{-p} fraction of Π, and so it could be quite far from being even relaxed k-wise independent (e.g., it could be that the value of functions in Π' on some fixed elements of R_n is constant over all functions in Π').

This seems like a significant difficulty and was overcome using highly elaborate techniques in [20]. In contrast, we suggest a much simpler argument. The idea is that we first reduce the soundness error of the MAP to $2^{-O(p)}$ by repetition. This increases the query complexity

of the tester to $O(p \cdot q)$ but now that the soundness error is so small, that the fact that Π' covers a 2^{-p} fraction of Π is sufficient to make the argument go through.

We proceed to the actual proof.

3.1 Proof of Theorem 7

Let C be a constant such that Π_n satisfies the constraints of Definition 5.

Let V be an MAP verifier, with respect to proximity parameter ε, for Π_n, and denote its proof complexity by p and query complexity by q. Note that any MAP with standard 2/3 completeness and soundness probability (as in Definition 3) can be amplified, via $O(p)$ repetitions, to have completeness and soundness errors $\frac{1}{10C} \cdot 2^{-p}$ at the cost of increasing the query (but not the proof) complexity by a multiplicative factor of $O(p)$, to $O(p \cdot q)$. For concreteness, let us fix a constant C' such that a $(C' \cdot p)$-fold repetition of V has completeness and soundness errors $\frac{1}{10C} \cdot 2^{-p}$ (while having proof complexity p and query complexity $C' \cdot p \cdot q$). Assume towards a contradiction that $p \cdot q \leq \frac{k}{10C'}$.

Recall that for $\Pi' \subseteq \Pi$, a (Π, Π')-partial tester (a notion due to [20]) is a tester that is required to accept functions in the subset Π' and reject functions that are ε-far from the superset Π. As pointed out by Fischer *et al.* [20] an MAP as we assumed above, implies a covering of the property by partial testers as follows. For every possible proof string $w \in \{0,1\}^p$, let

$$S_w = \left\{ f \in \Pi_n \ : \ \Pr\left[V^f(n, \varepsilon, w) = 1\right] \geq 1 - \frac{1}{10C} \cdot 2^{-p} \right\}.$$

By the completeness requirement of an MAP, these sets cover the property Π_n. That is, $\bigcup_w S_w = \Pi_n$.

Since the number of sets S_w is at most 2^p, there exists a proof w that corresponds to a large S_w. Namely, such that $|S_w| \geq |\Pi_n| \cdot 2^{-p}$. We fix such a proof w and argue that the corresponding (Π_n, S_w)-partial tester must make $\Omega(k)$ queries, which would contradict our assumption, thereby proving Theorem 7. Hence, we have reduced proving an MAP lower bound for Π_n to proving a partial testing lower bound for (Π_n, S_w).

Let $V_w^f(n, \varepsilon) \coloneqq V^f(n, \varepsilon, w)$ be the (S_w, Π_n)-partial tester that is induced by V when we fix the proof string w (and with respect to parameters n and ε). We use the notation $V_w^f(n, \varepsilon; r)$ to denote the *deterministic* output V_w^f when its random string is set to r.

Let $B_\varepsilon = \{f \in \mathcal{F}_n : f \text{ is } \varepsilon\text{-far from } \Pi_n\}$ (i.e., the no-instances). As standard in the property testing literature, we prove a lower bound on the query complexity q' of a tester by presenting a distribution over YES-instances ($f \in S_w$) and a distribution over NO-instances ($f \in B_\varepsilon$) and bounding away from 1 the distinguishing probability for every *deterministic* algorithm making q' queries. Specifically, we give distributions over S_w and B_ε such that any deterministic algorithm making q' queries to f has at most a $1 - \frac{1}{4C} \cdot 2^{-p}$ probability of distinguishing between them, which is sufficient for our purposes. In our case, we simply consider the uniform distributions over S_w and B_ε.

More formally, we first observe that

$$\begin{aligned} &\mathbb{E}_{f \in S_w}\left[\Pr_r\left[V_w^f(n, \varepsilon; r) = 1\right]\right] - \mathbb{E}_{f \in B_\varepsilon}\left[\Pr_r\left[V_w^f(n, \varepsilon; r) = 1\right]\right] \\ &= \mathbb{E}_r\left[\Pr_{f \in S_w}\left[V_w^f(n, \varepsilon; r) = 1\right] - \Pr_{f \in B_\varepsilon}\left[V_w^f(n, \varepsilon; r) = 1\right]\right], \end{aligned} \tag{2}$$

By Eq. (2), it suffices to bound the distinguishing probably for any deterministic verifier. We do this via the following lemma.

▶ **Lemma 8.** *For any deterministic verifier W with query complexity at most $\frac{k}{10}$, we have that*

$$\Pr_{f\in S_w}\left[W^f(n,\varepsilon)=1\right]-\Pr_{f\in B_\varepsilon}\left[W^f(n,\varepsilon)=1\right]\leq 1-\frac{1}{4C}\cdot 2^{-p}.$$

Proof. We first show that

$$\Pr_{f\in B_\varepsilon}\left[W^f(n,\varepsilon)=1\right]\geq\frac{1}{2C}\cdot 2^{-p}\cdot\Pr_{f\in S_w}\left[W^f(n,\varepsilon)=1\right]. \tag{3}$$

We can view the verifier W as a decision tree of depth $q'=k/10$. Each leaf of the decision tree is associated with indices $i_1,i_2,\ldots,i_{q'}\in D_n$ and values $t_1,t_2,\ldots,t_{q'}\in R_n$ such that a function $f\in\mathcal{F}_n$ is accepted at that leaf if and only if $f(i_j)=t_j$ for all $j\in[q']$. We may assume without loss of generality that the sets of indices $i_1,\ldots,i_{q'}$ for all paths in the decision tree are pairwise distinct. Fix such a sequence of indices $i_1,\ldots,i_{q'}\in D_n$ and values $t_1,\ldots,t_{q'}\in R_n$. Then,

$$\begin{aligned}\Pr_{f\in B_\varepsilon}\left[f(i_j)=t_j\text{ for all }j\in[q']\right]&\geq\frac{\left|\left\{f\in\mathcal{F}_n:f(i_j)=t_j\text{ for all }j\in[q']\right\}\right|-\left|\mathcal{F}_n\backslash B_\varepsilon\right|}{|B_\varepsilon|}\\&\geq\frac{1}{|R_n|^{q'}}-\frac{1}{|R_n|^k-1}\\&\geq\frac{1}{2|R_n|^{q'}}.\end{aligned} \tag{4}$$

Here we have used k-sparsity to note that $\frac{|\mathcal{F}_n\backslash B_\varepsilon|}{|B_\varepsilon|}\leq\frac{1}{|R_n|^k-1}$, and we used that $q'=\frac{k}{10}$. On the other hand, we also have that:

$$\Pr_{f\in S_w}\left[f(i_j)=t_j\text{ for all }j\in[q']\right]\leq\frac{\Pr_{f\in\Pi_n}\left[f(i_j)=t_j\text{ for all }j\in[q']\right]}{\Pr_{f\in\Pi_n}[f\in S_w]}\leq\frac{C\cdot 2^p}{|R_n|^{q'}} \tag{5}$$

by relaxed q'-wise independence and the lower bound on the size of S_w.

Dividing Eq. (4) by Eq. (5), we obtain that

$$\Pr_{f\in B_\varepsilon}\left[f(i_j)=t_j\text{ for all }j\in[q']\right]\geq\frac{1}{2C}\cdot 2^{-p}\cdot\Pr_{f\in S_w}\left[f(i_j)=t_j\text{ for all }j\in[q']\right].$$

Now, summing the above equation over all leaves of the decision tree corresponding to W (since these correspond to disjoint events) gives us Eq. (3).

Given Eq. (3), we now consider two cases. First, if

$$\Pr_{f\in S_w}\left[W^f(n,\varepsilon)=1\right]\leq 1-\frac{1}{2C}\cdot 2^{-p}$$

we are obviously done. Otherwise, we can assume that $\Pr_{f\in S_w}\left[W^f(n,\varepsilon)=1\right]>1-\frac{1}{2C}\cdot 2^{-p}$ and so:

$$\begin{aligned}\Pr_{f\in S_w}\left[W^f(n,\varepsilon)=1\right]-\Pr_{f\in B_\varepsilon}\left[W^f(n,\varepsilon)=1\right]&\leq 1-\frac{1}{2C}\cdot 2^{-p}\cdot\Pr_{f\in S_w}\left[W^f(n,\varepsilon)=1\right]\\&\leq 1-\frac{1}{2C}\cdot 2^{-p}\cdot\left(1-\frac{1}{2C}\cdot 2^{-p}\right)\\&\leq 1-\frac{1}{4C}\cdot 2^{-p},\end{aligned}$$

where the first inequality is by Eq. (3). The lemma follows. ◀

Now we are ready to use Lemma 8 to complete our proof of Theorem 7. Because V_w^f has completeness and soundness errors $\frac{1}{10C} \cdot 2^{-p}$, we have that

$$\mathbb{E}_{f \in S_w}\left[\Pr_r\left[V_w^f(n,\varepsilon;r)=1\right]\right] - \mathbb{E}_{f \in B_\varepsilon}\left[\Pr_r\left[V_w^f(n,\varepsilon;r)=1\right]\right] \geq 1 - \frac{1}{10C}\cdot 2^{-p} - \frac{1}{10C}\cdot 2^{-p} = 1 - \frac{1}{5C}\cdot 2^{-p}.$$

On the other hand, by Eq. (2) and Lemma 8, it holds that

$$\mathbb{E}_{f \in S_w}\left[\Pr_r\left[V_w^f(n,\varepsilon;r)=1\right]\right] - \mathbb{E}_{f \in B_\varepsilon}\left[\Pr_r\left[V_w^f(n,\varepsilon;r)=1\right]\right] \leq 1 - \frac{1}{4C}\cdot 2^{-p},$$

which is a contradiction. Therefore, we can conclude that $p \cdot q \geq \frac{k}{10C'}$, as desired.

4 Discussion and Open Problems

The complexity of the permutation property for testers, which do not use a proof, is $\tilde{\Theta}(\sqrt{n})$. In this work we showed a lower bound of $\tilde{\Omega}(n^{\frac{1}{4}})$ for MAPs for Perm. Thus, the MAP complexity of Perm is somewhere between $\tilde{\Omega}(n^{\frac{1}{4}})$ and $\tilde{O}(\sqrt{n})$ - resolving the exact complexity is an interesting open problem:

▶ **Problem 9.** *Does every* MAP *for* Permutation *have complexity* $\tilde{\Omega}(\sqrt{n})$*?*

Second, our work shows that AMPs can be exponentially more efficient than MAPs. It is natural to ask whether the converse also holds - can MAPs be much more efficient than AMPs? A partial answer to this question is known. As mentioned in Footnote 5, every MAP with complexity c can be emulated by an AMP with complexity (roughly) c^2.

Thus, MAPs can be at most *quadratically* more efficient than AMPs. However, we do not know a property for which this gap is tight. In particular, the following problem is open:

▶ **Problem 10.** *Does this exist a property* Π *that has an* MAP *with complexity* $O(\sqrt{n})$ *but every* AMP *for* Π *must have complexity* $\Omega(n)$*?*

Abstract

We present a geometric approach towards derandomizing the Isolation Lemma by Mulmuley, Vazirani, and Vazirani. In particular, our approach produces a quasi-polynomial family of weights, where each weight is an integer and quasi-polynomially bounded, that can isolate a vertex in any 0/1 polytope for which each face lies in an affine space defined by a totally unimodular matrix. This includes the polytopes given by totally unimodular constraints and generalizes the recent derandomization of the Isolation Lemma for bipartite perfect matching and matroid intersection. We prove our result by associating a lattice to each face of the polytope and showing that if there is a totally unimodular kernel matrix for this lattice, then the number of vectors of length within 3/2 of the shortest vector in it is polynomially bounded. The proof of this latter geometric fact is combinatorial and follows from a polynomial bound on the number of circuits of size within 3/2 of the shortest circuit in a regular matroid. This is the technical core of the paper and relies on a variant of Seymour's decomposition theorem for regular matroids. It generalizes an influential result by Karger on the number of minimum cuts in a graph to regular matroids.

1 Introduction

The Isolation Lemma by Mulmuley, Vazirani, and Vazirani [14] states that for any given family of subsets of a ground set E, if we assign random weights (bounded in magnitude by poly($|E|$)) to the elements of E then, with high probability, the minimum weight set in the family is unique. Such a weight assignment is called an *isolating weight assignment*. The lemma was introduced in the context of randomized parallel algorithms for the matching problem. Since

[1] The research leading to these results has received funding from the European Community's Seventh Framework Programme (FP7/2007-2013) under grant agreement number 257575 and from the Israel Science Foundation (grant number 552/16).
[2] Supported by DFG grant TH 472/4.

then it has found numerous other applications, in both algorithms and complexity: e.g., a reduction from CLIQUE to UNIQUE-CLIQUE [14], NL/poly $\subseteq \oplus$L/poly [29], NL/poly = UL/poly [17], an RNC-algorithm for linear matroid intersection [15], and an RP-algorithm for disjoint paths [3]. In all of these results, the Isolation Lemma is the only place where they need randomness. Thus, if the Isolation Lemma can be derandomized, i.e., if a polynomially bounded isolating weight assignment can be deterministically constructed, then the aforementioned results that rely on it can also be derandomized. In particular, it will give a deterministic parallel algorithm for matching.

A simple counting argument shows that a single weight assignment with polynomially bounded weights cannot be isolating for all possible families of subsets of E. We can relax the question and ask if we can construct a poly-size list of poly-bounded weight assignments such that for each family $\mathcal{B} \subseteq 2^E$, one of the weight assignments in the list is isolating. Unfortunately, even this can be shown to be impossible via arguments involving the polynomial identity testing (PIT) problem. The PIT problem asks if an implicitly given multivariate polynomial is identically zero. Derandomization of PIT is another important consequence of derandomizing the Isolation Lemma. Here, the Isolation Lemma is applied to the family of monomials present in the polynomial. In essence, if we have a small list of weight assignments that works for all families, then we will have a small hitting-set for all small degree polynomials, which is impossible (see [2]). Once we know that a deterministic isolation is not possible for all families, a natural question is to solve the isolation question for families $\mathcal{B}$, that have a succinct representation, for example, the family of perfect matchings of a graph.

For the general setting of families with succinct representations, no deterministic isolation is known, other than the trivial construction with exponentially large weights. In fact, derandomizing the isolation lemma in this setting will imply circuit lower bounds [2]. Efficient deterministic isolation is known only for very special kinds of families, for example, perfect matchings in some special classes of graphs [1, 5, 6, 9], s-t paths in directed graphs [4, 12, 28]. Recently, there has been significant progress on deterministic isolation for perfect matchings in bipartite graphs [7] and subsequently, in general graphs [25], and matroid intersection [10], which implied quasi-NC algorithms for these problems.

Motivated by these recent works, we give a generic approach towards derandomizing the Isolation Lemma. We show that the approach works for a large class of combinatorial polytopes and conjecture that it works for a significantly larger class. For a family of sets $\mathcal{B} \subseteq 2^E$, define the polytope $P(\mathcal{B}) \subseteq \mathbb{R}^E$ to be the convex hull of the indicator vectors of the sets in $\mathcal{B}$. Our main result shows that for $m := |E|$, there exists an $m^{O(\log m)}$-sized family of weight assignments on E with weights bounded by $m^{O(\log m)}$ that is isolating for any family $\mathcal{B}$ whose corresponding polytope $P(\mathcal{B})$ satisfies the following property: *the affine space spanned by any face of $P(\mathcal{B})$ is parallel to the null space of* **some** *totally unimodular (TU) matrix*; see Theorem 2.3. This is a black-box weight construction in the sense that it does not need the description of the family or the polytope.

A large variety of polytopes satisfy this property and, as a consequence, have been extensively studied in combinatorial optimization. The simplest such class is when the polytope $P(\mathcal{B})$ has a description $Ax \leq b$ with A being a TU matrix. Thus, a simple consequence of our main result is a resolution to the problem of derandomizing the isolation lemma for polytopes with TU constraints, as raised in a recent work [25]. This generalizes the isolation result for perfect matchings in a bipartite graph [7], since the perfect matching polytope of a bipartite graph can be described by the incidence matrix of the graph, which is TU. Other examples of families whose polytopes are defined by TU constraints are vertex

covers of a bipartite graph, independent sets of a bipartite graph, and, edge covers of a bipartite graph. Note that these three problems are computationally equivalent to bipartite matching and thus, already have quasi-NC algorithms due to [7]. However, the isolation results for these families are not directly implied by isolation for bipartite matchings.

Our work also generalizes the isolation result for the family of common bases of two matroids [10]. In the matroid intersection problem, the constraints of the common base polytope are a rank bound on every subset of the ground set. These constraints, in general, do not form a TUM. However, for every face of the polytope there exist two laminar families of subsets that form a basis for the tight constraints of the face. The incidence matrix for the union of two laminar families is TU (see [20, Theorem 41.11]).

Since our condition on the polytope $P(\mathcal{B})$ does not require the constraint matrix defining the polytope itself (or any of its faces) to be TU, it is quite weak and is also well studied. Schrijver [19, Theorem 5.35] shows that this condition is sufficient to prove that the polytope is *box-totally dual integral*. The second volume of Schrijver's book [20] gives an excellent overview of polytopes that satisfy the condition required in Theorem 2.3 such as

- $R - S$ bibranching polytope [20, Section 54.6]
- directed cut cover polytope [20, Section 55.2]
- submodular flow polyhedron [20, Theorem 60.1]
- lattice polyhedron [20, Theorem 60.4]
- submodular base polytope [20, Section 44.3]
- many other polytopes defined via submodular and supermodular set functions [20, Sections 46.1, 48.1, 48.23, 46.13, 46.28, 46.29, 49.3, 49.12, 49.33, 49.39, 49.53].

We would like to point out that it is not clear if our isolation results in the above settings lead to any new derandomization of algorithms. Finding such algorithmic applications of our isolation result would be quite interesting.

To derandomize the Isolation Lemma, we abstract out ideas from the bipartite matching and matroid intersection isolation [7, 10], and give a geometric approach in terms of certain *lattices* associated to polytopes. For each face F of $P(\mathcal{B})$, we consider the lattice L_F of all integer vectors parallel to F. We show that, if for each face F of $P(\mathcal{B})$, the number of near-shortest vectors in L_F is polynomially bounded then we can construct an isolating weight assignment for $\mathcal{B}$ with quasi-polynomially bounded weights; see Theorem 2.4. Our main technical contribution is to give a polynomial bound on the number of near-shortest vectors in L_F (whose ℓ_1-norm is less than $3/2$ times the smallest ℓ_1-norm of any vector in L_F), when this lattice is the set of integral vectors in the null space of a TUM; see Theorem 2.5.

The above lattice result is in contrast to general lattices where the number of such near-shortest vectors could be exponential in the dimension.

Our result on lattices can be reformulated using the language of matroid theory: the number of near-shortest circuits in a regular matroid is polynomially bounded; see Theorem 2.6. In fact, we show how Theorem 2.5 can be deduced from Theorem 2.6. One crucial ingredient in the proof of Theorem 2.6 is Seymour's remarkable decomposition theorem for regular matroids [21]. Theorem 2.6 answers a question raised by Subramanian [24] and is a generalization of (and builds on) known results in the case of graphic and cographic matroids, that is, the number of near-minimum length cycles in a graph is polynomially bounded (see [24, 26]) and the result of Karger [13] that states that the number of near-mincuts in a graph is polynomially bounded.

Thus, not only do our results make progress in derandomizing the isolation lemma for combinatorial polytopes, they make interesting connections between lattices (that are geometric objects) and combinatorial polytopes. Our structural results about the number of

near-shortest vectors in lattices and near-shortest circuits in matroids should be of independent interest and raise the question: to what extent are they generalizable?

A natural conjecture would be that for any $(0,1)$-matrix, the lattice formed by its integral null vectors has a small number of near-shortest vectors. In turn, this would give us the isolation result for any polytope which is defined by a $(0,1)$-constraint matrix. Many combinatorial polytopes have this property. One such interesting example is the perfect matchings polytope for general graphs. The recent result of [25], which showed a quasi-NC algorithm for perfect matchings, does not actually go via a bound on the number of near-shortest vectors in the associated lattice. Obtaining a polynomial bound on this number would give a proof for their quasi-NC result in our unified framework and with improved parameters. Another possible generalization is for $(0,1)$-polytopes that have this property that the integers occurring in the description of each supporting hyperplane are bounded by a polynomial in the dimension of the polytope. Such polytopes generalize almost all combinatorial polytopes and yet seem to have enough structure – they have been recently studied in the context of optimization [22, 23].

2 Our Results

2.1 Isolating a vertex in a polytope

For a set E and a weight function $w\colon E \to \mathbb{Z}$, we define the extension of w to any set $S \subseteq E$ by $w(S) := \sum_{e\in S} w(e)$. Let $\mathcal{B} \subseteq 2^E$ be a family of subsets of E. A weight function $w\colon E \to \mathbb{Z}$ is called *isolating for* $\mathcal{B}$ if the minimum weight set in $\mathcal{B}$ is unique. In other words, the set $\arg\min_{S\in\mathcal{B}} w(S)$ is unique. The Isolation Lemma of Mulmuley, Vazirani, and Vazirani [14] asserts that a uniformly random weight function is isolating with a good probability for any $\mathcal{B}$.

▶ **Lemma 2.1** (Isolation Lemma). *Let E be a set, $|E| = m$, and let $w\colon E \to \{1, 2, \ldots, 2m\}$ be a random weight function, where for each $e \in E$, the weight $w(e)$ is chosen uniformly and independently at random. Then for any family $\mathcal{B} \subseteq 2^E$, w is isolating with probability at least $1/2$.*

The task of derandomizing the Isolation Lemma requires the deterministic construction of an isolating weight function with weights polynomially bounded in $m = |E|$. Here, we view the isolation question for $\mathcal{B}$ as an isolation over a corresponding polytope $P(\mathcal{B})$, as follows. For a set $S \subseteq E$, its indicator vector $x^S := (x^S_e)_{e\in E}$ is defined as $x^S_e = 1$ if $e \in S$ and $x^S_e = 0$ otherwise. For any family of sets $\mathcal{B} \subseteq 2^E$, the polytope $P(\mathcal{B}) \subseteq \mathbb{R}^m$ is defined as the convex hull of the indicator vectors of the sets in $\mathcal{B}$, i.e., $P(\mathcal{B}) := \operatorname{conv}\left\{ x^S \mid S \in \mathcal{B} \right\}$. Note that $P(\mathcal{B})$ is contained in the m-dimensional unit hypercube.

The isolation question for a family $\mathcal{B}$ is equivalent to constructing a weight vector $w \in \mathbb{Z}^E$ such that $\langle w, x\rangle$ has a unique minimum over $P(\mathcal{B})$. The property we need for our isolation approach is in terms of total unimodularity of a matrix.

▶ **Definition 2.2** (Totally unimodular matrix). A matrix $A \in \mathbb{R}^{n\times m}$ is said to be *totally unimodular (TU)*, if every square submatrix has determinant 0 or ± 1.

Our main theorem gives an efficient quasi-polynomial isolation for a family $\mathcal{B}$ when each face of the polytope $P(\mathcal{B})$ lies in the affine space defined by a TU matrix.

▶ **Theorem 2.3** (Main Result). *Let E be a set with $|E| = m$. Consider a class $\mathcal{C}$ of families $\mathcal{B} \subseteq 2^E$ that have the following property: for any face F of the polytope $P(\mathcal{B})$, there exists*

a TU matrix $A_F \in \mathbb{R}^{n\times m}$ such that the affine space spanned by F is given by $A_F x = b_F$ for some $b_F \in \mathbb{R}^n$. We can construct a set W of $m^{O(\log m)}$ weight assignments on E with weights bounded by $m^{O(\log m)}$ such that for any family $\mathcal{B}$ in the class $\mathcal{C}$, one of the weight assignments in W is isolating.

2.2 Short vectors in lattices associated to polytopes

Our starting point towards proving Theorem 2.3 is a reformulation of the isolation approach for bipartite perfect matching and matroid intersection [7, 10]. For a set E and a family $\mathcal{B} \subseteq 2^E$, we define a lattice corresponding to each face of the polytope $P(\mathcal{B})$. The isolation approach works when this lattice has a small number of near-shortest vectors. For any face F of $P(\mathcal{B})$, consider the lattice of all integral vectors parallel to F,

$$L_F := \left\{ v \in \mathbb{Z}^E \mid v = \alpha(x_1 - x_2) \text{ for some } x_1, x_2 \in F \text{ and } \alpha \in \mathbb{R} \right\}.$$

Let $\lambda(L) := \min\{ \|v\| \mid 0 \neq v \in L \}$ denote the length of the shortest nonzero vector of a lattice L, where $\|\cdot\|$ denotes the ℓ_1-norm. We prove that if, for all faces F of $P(\mathcal{B})$ the number of near-shortest vectors in L_F is small, then we can efficiently isolate a vertex in $P(\mathcal{B})$.

▶ **Theorem 2.4** (Isolation via Lattices). *Let E be a set with $|E| = m$ and let $\mathcal{B} \subseteq 2^E$ be a family such that there exists a constant $c > 1$, such that for any face F of polytope $P(\mathcal{B})$, we have $|\{ v \in L_F \mid \|v\| < c\,\lambda(L_F) \}| \leq m^{O(1)}$. Then one can construct a set of $m^{O(\log m)}$ weight functions with weights bounded by $m^{O(\log m)}$ such that at least one of them is isolating for $\mathcal{B}$.*

The main ingredient of the proof of Theorem 2.3 is to show that the hypothesis of Theorem 2.4 is true when the lattice L_F is the set of all integral vectors in the nullspace of a TU matrix. For any $n \times m$ matrix A we define a lattice:

$$L(A) := \{ v \in \mathbb{Z}^m \mid Av = 0 \}.$$

▶ **Theorem 2.5** (Near-shortest vectors in TU lattices). *For an $n \times m$ TU matrix A, let $\lambda := \lambda(L(A))$. Then $|\{ v \in L(A) \mid \|v\| < 3/2\,\lambda \}| = O(m^5)$.*

A similar statement can also be shown with any ℓ_p-norm for $p \geq 2$, but with an appropriate multiplicative constant. Theorem 2.5 together with Theorem 2.4 implies Theorem 2.3.

Proof of Theorem 2.3. Let F be a face of the polytope $P(\mathcal{B})$ and let A_F be the TU matrix associated with F. Thus $A_F x = b_F$ defines the affine span of F. In other words, the set of vectors parallel to F is precisely the solution set of $A_F x = 0$ and the lattice L_F is given by $L(A_F)$. Theorem 2.5 implies the hypothesis of Theorem 2.4 for any $L_F = L(A_F)$, when the matrix A_F is TU. ◀

2.3 Near-shortest circuits in regular matroids

The proof of Theorem 2.5 is combinatorial and uses the language and results from matroid theory. We recall a few basic definitions from matroid theory. A matroid is said to be *represented by a matrix A*, if its ground set is the column set of A and its independent sets are the sets of linearly independent columns of A. A matroid represented by a TU matrix is said to be a *regular matroid*. A *circuit* of a matroid is a minimal dependent set. The following is one of our main results which gives a bound on the number of near-shortest circuits in a regular matroid, which, in turn, implies Theorem 2.5. Instead of the circuit size, we consider the weight of a circuit and present a more general result.

▶ **Theorem 2.6** (Near-shortest circuits in regular matroids). *Let $M = (E, \mathcal{I})$ be a regular matroid with $m = |E| \geq 2$ and let $w\colon E \to \mathbb{N}$ be a weight function. Suppose M does not have any circuit C with $w(C) < r$ for some number r. Then*

$$|\{\, C \mid C \text{ circuit in } M \text{ and } w(C) < {}^{3r}/_{2} \,\}| \;\leq\; 240\, m^5.$$

▶ Remark. An extension of this result would be to give a polynomial bound on the number of circuits of weight at most αr for any constant α. Our current proof technique does not extend to this setting.

3 Isolation via the Polytope Lattices: Proof of Theorem 2.4

This section is dedicated to a proof of Theorem 2.4. That is, we give a construction of an isolating weight assignment for a family $\mathcal{B} \subseteq 2^E$ assuming that for each face F of the corresponding polytope $P(\mathcal{B})$, the lattice L_F has small number of near-shortest vectors. First, let us see how the isolation question for a family $\mathcal{B}$ translates in the polytope setting. For any weight function $w\colon E \to \mathbb{Z}$, we view w as a vector in $\mathbb{Z}^E$ and consider the function $\langle w, x\rangle$ over the points in $P(\mathcal{B})$. Note that $\langle w, x^B\rangle = w(B)$, for any $B \subseteq E$. Thus, a weight function $w\colon E \to \mathbb{Z}$ is isolating for a family $\mathcal{B}$ if and only if $\langle w, x\rangle$ has a unique minimum over the polytope $P(\mathcal{B})$.

Observe that for any $w\colon E \to \mathbb{Z}$, the points that minimize $\langle w, x\rangle$ in $P(\mathcal{B})$ will form a face of the polytope $P(\mathcal{B})$. The idea is to build the isolating weight function in rounds. In every round, we slightly modify the current weight function to get a smaller minimizing face. Our goal is to significantly reduce the dimension of the minimizing face in every round. We stop when we reach a zero-dimensional face, i.e., we have a unique minimum weight point in $P(\mathcal{B})$.

In the following, we will denote the size of the set E by m. The following claim asserts that if we modify the current weight function on a small scale, then the new minimizing face will be a subset of the current minimizing face. See the full version [11] for a proof.

▶ **Claim 3.1.** *Let $w\colon E \to \mathbb{Z}$ be a weight function and F be the face of $P(\mathcal{B})$ that minimizes w. Let $w'\colon E \to \{0, 1, \ldots, N-1\}$ be another weight function and let F' be the face that minimizes the combined weight function $mN\, w + w'$. Then $F' \subseteq F$.*

Thus, in each round, we will add a new weight function to the current function using a smaller scale and try to get a sub-face with significantly smaller dimension. Henceforth, N will be a sufficiently large number bounded by $\mathrm{poly}(m)$. The following claim gives a way to go to a smaller face.

▶ **Claim 3.2.** *Let F be the face of $P(\mathcal{B})$ minimizing $\langle w, x\rangle$ and let $v \in L_F$. Then $\langle w, v\rangle = 0$.*

Proof. Since $v \in L_F$, we have $v = \alpha(x_1 - x_2)$, for some $x_1, x_2 \in F$ and $\alpha \in \mathbb{R}$. As $x_1, x_2 \in F$, we have $\langle w, x_1\rangle = \langle w, x_2\rangle$. The claim follows. ◀

Now, let F_0 be the face that minimizes the current weight function w_0. Let v be in L_{F_0}. Choose a new weight function $w' \in \{0, 1, \ldots, N-1\}^E$ such that $\langle w', v\rangle \neq 0$. Let $w_1 := mN\, w_0 + w'$ and let F_1 be the face that minimizes w_1. Clearly, $\langle w_1, v\rangle \neq 0$ and thus, by Claim 3.2, $v \notin L_{F_1}$. This implies that F_1 is strictly contained in F_0. To ensure that F_1 is *significantly* smaller than F_0, we choose many vectors in L_{F_0}, say $v_1, v_2, \ldots, v_k$, and construct a weight vector w' such that for all $i \in [k]$, we have $\langle w', v_i\rangle \neq 0$. The following well-known lemma actually constructs a list of weight vectors such that one of them has the desired property (see [8, Lemma 2]).

▶ **Lemma 3.3.** *Given m, k, t, let $q = mk \log t$. In time $\mathrm{poly}(q)$ one can construct a set of weight vectors $w_1, w_2, \ldots, w_q \in \{0, 1, 2, \ldots, q\}^m$ such that for any set of nonzero vectors $v_1, v_2, \ldots, v_k$ in $\{-(t-1), \ldots, 0, 1, \ldots, t-1\}^m$ there exists a $j \in [q]$ such that for all $i \in [k]$ we have $\langle w_j, v_i \rangle \neq 0$. (see the full version [11] for a proof).*

There are two things to note about this lemma: (i) It is black-box in the sense that we do not need to know the set of vectors $\{v_1, v_2, \ldots, v_k\}$. (ii) We do not know a priori which function will work in the given set of functions. So, one has to try all possibilities.

The lemma tells us that we can ensure that $\langle w', v \rangle \neq 0$ for polynomially many vectors v whose coordinates are polynomially bounded. Below, we formally present the weight construction.

To prove Theorem 2.4, let c be the constant in the assumption of the theorem. Let $N = m^{O(1)}$ be a sufficiently large number and $p = \lfloor \log_c(m+1) \rfloor$. Let $w_0 \colon E \to \mathbb{Z}$ be a weight function such that $\langle w_0, v \rangle \neq 0$ for all nonzero $v \in \mathbb{Z}^E$ with $\|v\| < c$. For $i = 1, 2, \ldots, p$, define

- F_{i-1}: the face of $P(\mathcal{B})$ minimizing w_{i-1}
- w'_i: a weight vector in $\{0, 1, \ldots, N-1\}^E$ such that $\langle w'_i, v \rangle \neq 0$ for all nonzero $v \in L_{F_{i-1}}$ with $\|v\| < c^{i+1}$.
- w_i: $mNw_{i-1} + w'_i$.

Observe that $F_i \subseteq F_{i-1}$, for each i by Claim 3.1. Hence, also for the associated lattices we have $L_{F_i} \subseteq L_{F_{i-1}}$. As we show in the next claim, the choice of w'_i together with Claim 3.2 ensures that there are no vectors in L_{F_i} with norm less than c^{i+1}.

▶ **Claim 3.4.** *For $i = 0, 1, 2, \ldots, p$, we have $\lambda(L_{F_i}) \geq c^{i+1}$.*

Proof. Consider a nonzero vector $v \in L_{F_i}$. By Claim 3.2, we have

$$\langle w_i, v \rangle = mN \langle w_{i-1}, v \rangle + \langle w'_i, v \rangle = 0. \tag{1}$$

Since v is in L_{F_i}, it is also in $L_{F_{i-1}}$ and again by Claim 3.2, we have $\langle w_{i-1}, v \rangle = 0$. Together with (1) we conclude that $\langle w'_i, v \rangle = 0$. By the definition of w'_i, this implies that $\|v\| \geq c^{i+1}$. ◀

Finally we argue that w_p is isolating.

▶ **Claim 3.5.** *The face F_p is a point.*

Proof. Let $y_1, y_2 \in F_p$ be vertices and thus belong to $\{0, 1\}^m$. Then $y_1 - y_2 \in L_{F_p}$ and $\|y_1 - y_2\| \leq m < c^{p+1}$. By Claim 3.4, we have that $y_1 - y_2$ must be zero, i.e., $y_1 = y_2$. ◀

We get a bound of $m^{O(\log m)}$ on both the number of weight vectors we need to try and the weights involved, which finishes the proof of Theorem 2.4 (see the full version [11]).

4 Number of Short Vectors in Lattices: Proof of Theorem 2.5

In this section, we show that Theorem 2.5 follows from Theorem 2.6. We define a circuit of a matrix and show that to prove Theorem 2.5, it is sufficient to upper bound the number of near-shortest circuits of a TU matrix. We argue that this, in turn, is implied by a bound on the number of near-shortest circuits of a regular matroid. Just as a circuit of a matroid is a minimal dependent set, a circuit of matrix is a minimal linear dependency among its columns. Recall that for an $n \times m$ matrix A, the lattice $L(A)$ is defined as the set of integer vectors in its kernel,

$$L(A) := \{\, v \in \mathbb{Z}^m \mid Av = 0 \,\}.$$

▶ **Definition 4.1** (Circuit). For an $n \times m$ matrix A, a vector $u \in L(A)$ is a *circuit of* A if
- there is no nonzero $v \in L(A)$ with $\text{supp}(v) \subsetneq \text{supp}(u)$, and
- $\gcd(u_1, u_2, \ldots, u_m) = 1$.

Note that if u is a circuit of A, then so is $-u$. The following property of the circuits of a TU matrix is well known (see [16, Lemma 3.18]).

▶ **Fact 4.2.** *Let A be a TU matrix. Then every circuit of A has its coordinates in $\{-1, 0, 1\}$.*

Now, we define a notion of conformality among two vectors.

▶ **Definition 4.3** (Conformal [16]). Let $u, v \in \mathbb{R}^m$. We say that u is *conformal to* v, denoted by $u \sqsubseteq v$, if $u_i v_i \geq 0$ and $|u_i| \leq |v_i|$, for each $1 \leq i \leq m$.

▶ **Observation 4.4.** *For vectors u and v with $u \sqsubseteq v$, we have $\|v - u\| = \|v\| - \|u\|$.*

The following lemma follows from [16, Lemma 3.19].

▶ **Lemma 4.5.** *Let A be a TU matrix. Then for any nonzero vector $v \in L(A)$, there is a circuit u of A that is conformal to v.*

We use the lemma to argue that any small enough vector in $L(A)$ must be a circuit.

▶ **Lemma 4.6.** *Let A be a TU matrix and let $\lambda := \lambda(L(A))$. Then any nonzero vector $v \in L(A)$ with $\|v\| < 2\lambda$ is a circuit of A.*

Proof. Suppose $v \in L(A)$ is not a circuit of A. We show that $\|v\| \geq 2\lambda$. By Lemma 4.5, there is a circuit u of A with $u \sqsubseteq v$. Since v is not a circuit, $v - u \neq 0$. Since both u and $v - u$ are nonzero vectors in $L(A)$, we have $\|u\|, \|v - u\| \geq \lambda$. By Observation 4.4, we have $\|v\| = \|v - u\| + \|u\|$ and thus, we get that $\|v\| \geq 2\lambda$. ◀

Recall that a matroid represented by a TU matrix is a regular matroid. The following lemma shows that the two definitions of circuits, 1) for TU matrices and 2) for regular matroids, coincide. See the full version [11] for a proof.

▶ **Lemma 4.7.** *Let $M = (E, \mathcal{I})$ be a regular matroid, represented by a TU matrix A. Then there is a one to one correspondence between the circuits of M and the circuits of A (up to change of sign).*

To prove Theorem 2.5, let A be TU matrix. By Lemma 4.6, it suffices to bound the number of near-shortest circuits of A. By Lemma 4.7, the circuits of A and the circuits of the regular matroid M represented by A, coincide. Moreover, the size of a circuit of M is same as the ℓ_1-norm of the corresponding circuit of A, as a circuit of A has its coordinates in $\{-1, 0, 1\}$ by Fact 4.2. Now Theorem 2.5 follows from Theorem 2.6 when we define the weight of each element being 1.

5 Proof Overview of Theorem 2.6

Here we give a proof overview of Theorem 2.6; see the full version [11] for a complete proof. Theorem 2.6 states that for a regular matroid, the number of near-shortest circuits – circuits whose size is a constant multiple of the shortest circuit size – is polynomially bounded. The starting point of the proof of this theorem is a remarkable result of Seymour [21] which showed that every regular matroid can be decomposed into a set of much simpler matroids. Each of these building blocks for regular matroids either belongs to the classes of graphic and cographic matroids – the simplest and well-known examples of regular matroids, or is a

special 10-element matroid R_{10} (see the full version [11] for the definitions). One important consequence of Seymour's result is a polynomial time algorithm, the only one known, for testing the total unimodularity of a matrix; see [18] (recall that a TU matrix represents a regular matroid). Our strategy is to leverage Seymour's decomposition theorem in order to bound the number of circuits in a regular matroid.

Seymour's Theorem and a simple inductive approach

Seymour's decomposition involves a sequence of binary operations on matroids, each of which is either a 1-sum, a 2-sum or a 3-sum. Formally, it states that for every regular matroid M, we can build a decomposition tree – which is a binary rooted tree – in which the root node is the matroid M, every node is a k-sum of its two children for $k = 1, 2$, or 3, and at the bottom we have graphic, cographic and the R_{10} matroids as the leaf nodes. Note that the tree, in general, is not necessarily balanced and can have large depth (linear in the ground set size).

This suggests that to bound the number of near-shortest circuits in a regular matroid, perhaps one can use the tree structure of its decomposition, starting from the leaf nodes and arguing, inductively, all the way up to the root. It is known that the number of near-shortest circuits in graphic and cographic matroids is polynomially bounded. This follows from the polynomial bounds on the number of near-shortest cycles of a graph [24] and on the number of near min-cuts in a graph [13]. The challenge is to show how to combine the information at an internal node.

The k-sum M of two matroids M_1 and M_2 is defined in a way such that each circuit of M can be built from a combination of two circuits, one from M_1 and another from M_2. Thus, if we have upper bounds for the number of circuits in M_1 and M_2, their product will give a naive upper bound for number of circuits in M. Since there can be many k-sum operations involved, the naive product bound can quickly explode. Hence, to keep a polynomial bound we need to take a closer look at the k-sum operations.

k-sum operations

1-sum. A 1-sum M of two matroids M_1 and M_2 is simply their direct sum. That is, the ground set of M is the disjoint union of the ground sets of M_1 and M_2, and any circuit of M is either a circuit of M_1 or a circuit of M_2.

The 2-sum and 3-sum are a bit more intricate. It is known that the set of circuits of a matroid completely characterizes the matroid. The 2-sum and 3-sum operations are defined by describing the set of circuits of the matroid obtained by the sum. To get an intuition for the 2-sum operation, we first describe it on two graphic matroids. A graphic matroid is defined with respect to a graph, where a circuit is a simple cycle in the graph.

2-sum on graphs. For two graphs G_1 and G_2, their 2-sum $G = G_1 \oplus_2 G_2$ is any graph obtained by identifying an edge (u_1, v_1) in G_1 with an edge (u_2, v_2) in G_2, that is, identifying u_1 with u_2 and v_1 with v_2 and then, deleting the edge $(u_1, v_1) = (u_2, v_2)$. It would be instructive to see how a cycle in G, i.e., a circuit of the associated graphic matroid, looks like. A cycle in G is either a cycle in G_1 or in G_2 that avoids the edge $(u_1, v_1) = (u_2, v_2)$, or it is a union of a path $u_1 \rightsquigarrow v_1$ in G_1 and a path $v_2 \rightsquigarrow u_2$ in G_2. This last possibility is equivalent to taking a symmetric difference $C_1 \triangle C_2$ of two cycles C_1 in G_1 and C_2 in G_2 such that C_1 passes through (u_1, v_1) and C_2 passes through (u_2, v_2).

2-sum on matroids. The 2-sum $M_1 \oplus_2 M_2$ of two matroids M_1 and M_2 is defined analogously. The grounds sets of M_1 and M_2, say E_1 and E_2 respectively, have an element in common, say e (this can be achieved by identifying an element from E_1 with an element from E_2). The sum $M_1 \oplus_2 M_2$ is defined on the ground set $E = E_1 \Delta E_2$, the symmetric difference of the two given ground sets. Any circuit of the sum $M_1 \oplus_2 M_2$ is either a circuit in M_1 or in M_2 that avoids the common element e, or it is the symmetric difference $C_1 \triangle C_2$ of two circuits C_1 and C_2 of M_1 and M_2, respectively, such that both C_1 and C_2 contain the common element e.

3-sum on matroids. A 3-sum is defined similarly. A matroid M is a 3-sum of two matroids M_1 and M_2 if their ground sets E_1 and E_2 have a set S of three elements in common such that S is a circuit in both the matroids and the ground set of M is the symmetric difference $E_1 \triangle E_2$. Moreover, a circuit of M is either a circuit in M_1 or in M_2 that avoids the common elements S, or it is the symmetric difference $C_1 \triangle C_2$ of two circuits C_1 and C_2 of M_1 and M_2, respectively, such that both C_1 and C_2 contain a common element e from S and no other element from S.

The inductive bound on the number of circuits

Our proof is by a strong induction on the ground set size.
Base case: For a graphic or cographic matroid with a ground set of size m, if its shortest circuit has size r then the number of its circuits of size less than αr is at most $m^{4\alpha}$. For the R_{10} matroid, we present a constant upper bound on the number of circuits.
Induction hypothesis: For any regular matroid with a ground set of size $m < m_0$, if its shortest circuit has size r, then the number of its circuits of size less than αr is bounded by $m^{c\alpha}$ for some sufficiently large constant c.
Induction step: We prove the induction hypothesis for a regular matroid M with a ground set of size m_0. Let the minimum size of a circuit in M be r. We want to show a bound of $m_0^{c\alpha}$ on the number of circuits in M of size less than αr. The main strategy here is as follows: by Seymour's Theorem, we can write M as a k-sum of two smaller regular matroids M_1 and M_2, with ground sets of size $m_1 < m_0$ and $m_2 < m_0$ respectively. As the circuits of M can be written as a symmetric differences of circuits of M_1 and M_2, we derive an upper bound on the number circuits of M from the corresponding bounds for M_1 and M_2, which we get from the induction hypothesis.

The 1-sum case. In this case, any circuit of M is either a circuit of M_1 or a circuit of M_2. Hence, the number of circuits in M of size less than αr is simply the sum of the number of circuits in M_1 and M_2 of size less than αr. Using the induction hypothesis, this sum is bounded by $m_1^{c\alpha} + m_2^{c\alpha}$, which is less than $m_0^{c\alpha}$ since $m_0 = m_1 + m_2$.

The 2-sum and 3-sum cases. Let the set of common elements in the ground sets of M_1 and M_2 be S. Note that $m_0 = m_1 + m_2 - |S|$. Recall from the definition of a k-sum that any circuit C of M is of the form $C_1 \triangle C_2$, where C_1 and C_2 are circuits in M_1 and M_2 respectively, such that either **(i)** one of them, say C_1, has no element from S and the other one C_2 is empty or **(ii)** they both contain exactly one common element from S. We will refer to C_1 and C_2 as projections of C. Note that $|C_1|, |C_2| \leq |C|$. In particular, if circuit C is of size less than αr, then so are its projections C_1 and C_2.

An obstacle. The first step would be to bound the number of circuits C_1 of M_1 and C_2 of M_2 using the induction hypothesis. However, we do not have a lower bound on the minimum size of a circuit in M_1 or M_2, which is required to use the induction hypothesis. What we do

know is that any circuit in M_1 or M_2 that does not involve elements from S is also a circuit of M, and thus, must have size at least r. However, a circuit that involves elements from S could be arbitrarily small. We give different solutions for this obstacle in case **(i)** and case **(ii)** mentioned above.

Case (i): deleting elements in S. Let us first consider the circuits C_1 of M_1 that do not involve elements from S. These circuits can be viewed as circuits of a new regular matroid $M_1 \setminus S$ obtained by deleting the elements in S from M_1. Since we know that the minimum size of a circuit in $M_1 \setminus S$ is r, we can apply the induction hypothesis to get a bound of $(m_1 - |S|)^{c\alpha}$ for the number of circuits C_1 of $M_1 \setminus S$ of size less than αr. Summing this with a corresponding bound for $M_2 \setminus S$ gives us a bound less than $m_0^{c\alpha}$ for the number of circuits of M in case **(i)**.

Case (ii): stronger induction hypothesis. The case when circuits C_1 and C_2 contain an element from S turns out to be much harder. For this case, we actually need to strengthen our induction hypothesis. Let us assume that for a regular matroid of ground set size $m < m_0$, if the minimum size of a circuit that avoids a given element $\widetilde{e}$ is r, then the number of circuits containing $\widetilde{e}$ and of size less than αr is bounded by $m^{c\alpha}$. This statement will also be proved by induction, but we will come to its proof later.

Since we know that any circuit in M_1 (or M_2) that avoids elements from S has size at least r, we can use the above stronger inductive hypothesis to get a bound of $m_1^{c\alpha}$ on the number of circuits C_1 in M_1 containing a given element from S and of size less than αr. Similarly, we get an analogous bound of $m_2^{c\alpha}$ for circuits C_2 of M_2. Since C can be a symmetric difference of any C_1 and C_2, the product of these two bounds, that is, $(m_1 m_2)^{c\alpha}$ bounds the number of circuits C of M of size less than αr. Unfortunately, this product can be much larger than $m_0^{c\alpha}$. Note that this product bound on the number of circuits C is not really tight since C_1 and C_2 both cannot have their sizes close to αr simultaneously. This is because $C = C_1 \triangle C_2$ and thus, $|C| = |C_1| + |C_2| - 1$. Hence, a better approach is to consider different cases based on the sizes of C_1 and C_2.

Number of circuits C when one of its projections is small. We first consider the case when the size of C_1 is very small, i.e., close to zero. In this case, the size of C_2 will be close to αr and we have to take the bound of $m_2^{c\alpha}$ on the number of such circuits C_2. Now, if number of circuits C_1 with small size is N then we get a bound of $N m_2^{c\alpha}$ on the number of circuits C of M of this case. Note that $N m_2^{c\alpha}$ is dominated by $m_0^{c\alpha}$ only when $N \leq 1$, as m_2 can be comparable to m. While $N \leq 1$ does not always hold, we show something weaker which is true.

Uniqueness of C_1. We can show that for any element s in the set of common elements S, there is at most one circuit C_1 of size less than $r/2$ that contains s and no other element from S. To see this, assume that there are two such circuits C_1 and C_1'. It is known that the symmetric difference of two circuits of a matroid is a disjoint union of some circuits of the matroid. Thus, $C_1 \triangle C_1'$ will be a disjoint union of circuits of M_1. Since $C_1 \triangle C_1'$ does not contain any element from S, it is also a disjoint union of circuits of M. This would lead us to a contradiction because the size of $C_1 \triangle C_1'$ is less than r and M does not have circuits of size less than r. This proves the uniqueness of C_1. Our problem is still not solved since the set S can have three elements in case of a 3-sum, and thus, there can be three possibilities for C_1 (i.e., N=3).

Assigning weights to the elements. To get around this problem, we use a new idea of considering matroids elements with weights. For each element s in S, consider the unique circuit C_1 of size at most $r/2$ that contains s. In the matroid M_2, we assign a weight of $|C_1| - 1$ to the element s. The elements outside S get weight 1. The weight of element $s \in S$ signifies that if a circuit C_2 of M_2 contains s then it has to be summed up with the unique circuit C_1 containing s, which adds a weight of $|C_1| - 1$. Essentially, the circuits of the weighted matroid M_2 that have weight γ will have a one-to-one correspondence with circuits $C = C_1 \triangle C_2$ of M that have size γ and have $|C_1| < r/2$. Hence, we can assume there are no circuits in the weighted matroid M_2 of weight less than r. Thus, we can apply the induction hypothesis on M_2, but we need to further strengthen the hypothesis to a weighted version. By this new induction hypothesis, we will get a bound of $m_2^{c\alpha}$ on the number of circuits of M_2 with weight less that αr. As mentioned above, this will bound the number of circuits $C = C_1 \triangle C_2$ of M with size less than αr and $|C_1| < r/2$. Note that the bound $m_2^{c\alpha}$ is smaller than the desired bound $m_0^{c\alpha}$.

Number of circuits C when none of its projections is small. It is relatively easier to handle the other case when C_1 has size at least $r/2$ (and less than αr). In this case, C_2 has size less than $(\alpha - 1/2)r$. The bounds we get by the induction hypothesis for the number of circuits C_1 and C_2 are $m_1^{c\alpha}$ and $m_2^{c(\alpha-1/2)}$ respectively. Their product $m_1^{c\alpha} m_2^{c(\alpha-1/2)}$ bounds the number of circuits C in this case. However, this product is not bounded by $m_0^{c\alpha}$.

Stronger version of Seymour's Theorem. To get a better bound we need another key idea. Instead of Seymour's Theorem, we work with a stronger variant given by Truemper [27]. It states that any regular matroid can be written as a k-sum of two smaller regular matroids M_1 and M_2 for $k = 1, 2$ or 3 such that one of them, say M_1, is a graphic, cographic or R_{10} matroid. The advantage of this stronger statement is that we can take a relatively smaller bound on the number of circuits of M_1, which gives us more room for the inductive argument. Formally, we know from above that when M_1 is a graphic or cographic matroid, the number of its circuits of size less than αr is at most $m_1^{4\alpha}$. One can choose the constant c in our induction hypothesis to be sufficiently large so that the product $m_1^{4\alpha} m_2^{c(\alpha-1/2)}$ is bounded by $m_0^{c\alpha}$.

A stronger induction hypothesis

To summarize, we work with an inductive hypothesis as follows: If a regular matroid (with weights) has no circuits of weight less than r that avoid a given set R of elements then the number of circuits of weight less than αr that contain the set R is bounded by $m^{c\alpha}$. As the base case, we first show this statement for the graphic and cographic case.

When we rerun the whole inductive argument with weights and with a fixed set R, we run into another issue. It turns out that in the case when the size of C_1 is very small, our arguments above do not go through if C_1 has some elements from R. To avoid such a situation we use yet another strengthened version of Seymour's Theorem. It says that any regular matroid with a given element $\widetilde{e}$ can be written as a k-sum of two smaller regular matroids M_1 and M_2, such that M_1 is a graphic, cographic or R_{10} matroid and M_2 is a regular matroid containing $\widetilde{e}$. When our R is a single element set, say $\{\widetilde{e}\}$, we use this theorem to ensure that M_1, and thus C_1, has no elements from R. This rectifies the problem when R has size 1. However, as we go deeper inside the induction, the set R can grow in size. Essentially, whenever α decreases by $1/2$ in the induction, the size of R grows by 1. Thus, we take α to be $3/2$, which means that to reach $\alpha = 1$ we need only one step of decrement, and thus, the size of R at most becomes 1. This is the reason our main theorem only deals with circuits of size less than $3/2$ times the smallest size.

Abstract

We present many new results related to reliable (interactive) communication over insertion-deletion channels. *Synchronization errors*, such as insertions and deletions, strictly generalize the usual *symbol corruption errors* and are much harder to protect against.

We show how to hide the complications of synchronization errors in many applications by introducing very general *channel simulations* which efficiently transform an insertion-deletion channel into a regular symbol corruption channel with an error rate larger by a constant factor and a slightly smaller alphabet. We utilize and generalize synchronization string based methods which were recently introduced as a tool to design essentially optimal error correcting codes for insertion-deletion channels. Our channel simulations depend on the fact that, at the cost of increasing the error rate by a constant factor, synchronization strings can be decoded in a streaming manner that preserves linearity of time. Interestingly, we provide a lower bound showing that this constant factor cannot be improved to $1+\varepsilon$, in contrast to what is achievable for error correcting codes. Our channel simulations drastically and cleanly generalize the applicability of synchronization strings.

We provide new interactive coding schemes which simulate any interactive two-party protocol over an insertion-deletion channel. Our results improve over the interactive coding schemes of Braverman et al. [TransInf '17] and Sherstov and Wu [FOCS '17] which achieve a small constant rate and require exponential time computations with respect to computational and communication complexities. We provide the first computationally efficient interactive coding schemes for synchronization errors, the first coding scheme with a rate approaching one for small noise rates, and also the first coding scheme that works over arbitrarily small alphabet sizes. We also show tight connections between synchronization strings and edit-distance tree codes which allow us to transfer results from tree codes directly to edit-distance tree codes.

Finally, using on our channel simulations, we provide an explicit low-rate binary insertion-deletion code that improves over the state-of-the-art codes by Guruswami and Wang [TransInf '17] in terms of rate-distance trade-off.

1 Introduction

Communication in the presence of *synchronization errors*, which include both insertions and deletions, is a fundamental problem of practical importance which eluded a strong theoretical foundation for decades. This remained true even while communication in the presence of *half-errors*, which consist of symbol corruptions and erasures, has been the subject of an extensive body of research with many groundbreaking results. Synchronization errors are strictly more general than half-errors, and thus synchronization errors pose additional challenges for robust communication.

In this work, we show that one-way and interactive communication in the presence of synchronization errors can be reduced to the problem of communication in the presence of half-errors. We present a series of efficient channel simulations which allow two parties to communicate over a channel afflicted by synchronization errors as though they were communicating over a half-error channel with only a slightly larger error rate. This allows us to leverage existing coding schemes for robust communication over half-error channels in order to derive strong coding schemes resilient to synchronization errors.

One of the primary tools we use are *synchronization strings*, which were recently introduced by Haeupler and Shahrasbi in order to design essentially optimal error correcting codes (ECCs) robust to synchronization errors [19]. For every $\varepsilon > 0$, synchronization strings allow a sender to index a sequence of messages with an alphabet of size $\varepsilon^{-O(1)}$ in such a way that k synchronization errors are efficiently transformed into $(1+\varepsilon)k$ half-errors for the purpose of designing ECCs. Haeupler and Shahrasbi provide a black-box construction which transforms any ECC into an equally efficient ECC robust to synchronization errors. However, channel simulations and interactive coding in the presence of synchronization errors present a host of additional challenges that cannot be solved by the application of an ECC. Before we describe our results and techniques in detail, we begin with an overview of the well-known interactive communication model.

Interactive communication. Throughout this work, we study a scenario where there are two communicating parties, whom we call Alice and Bob. The two begin with some input symbols and wish to compute a function of their input by having a conversation. Their goal is to succeed with high probability while communicating as few symbols as possible. In particular, if their conversation would consist of n symbols in the noise-free setting, then they would like to converse for at most αn symbols, for some small α, when in the presence of noise. One might hope that Alice and Bob could correspond using error-correcting codes. However, this approach would lead to poor performance because if a party incorrectly decodes a single message, then the remaining communication is rendered useless. Therefore, only a very small amount of noise could be tolerated, namely less than the amount to corrupt a single message.

There are three major aspects of coding schemes for interactive communication that have been extensively studied in the literature. The first is the coding scheme's **maximum**

tolerable error-fraction or, in other words, the largest fraction of errors for which the coding scheme can successfully simulate any given error-free protocol. Another important quality of coding schemes for interactive communication, as with one-way communication, is **communication rate**, i.e., the amount of communication overhead in terms of the error fraction. Finally, the **efficiency** of interactive coding schemes have been of concern in the previous work.

Schulman initiated the study of error-resilient interactive communication, showing how to convert an arbitrary two-party interactive protocol to one that is robust to a $\delta = 1/240$ fraction of adversarial errors with a constant communication overhead [22, 23]. Braverman and Rao increased the bound on the tolerable adversarial error rate to $\delta < 1/4$, also with a constant communication overhead [9]. Brakerski et al. [2] designed the first efficient coding scheme resilient to a constant fraction of adversarial errors with constant communication overhead. The above-mentioned schemes achieve a constant overhead no matter the level of noise. Kol and Raz were the first to study the trade-off between error fraction and communication rate [21]. Haeupler then provided a coding scheme with a communication rate of $1 - O(\sqrt{\delta \log\log(1/\delta)})$ over an adversarial channel [17]. Further prior work has studied coding for interactive communication focusing on communication efficiency and noise resilience [18, 7, 14] as well as computational efficiency [4, 3, 2, 12, 13, 14]. Other works have studied variations of the interactive communication problem [15, 11, 10, 1, 5].

The main challenge that *synchronization errors* pose is that they may cause the parties to become "out of sync." For example, suppose the adversary deletes a message from Alice and inserts a message back to her. Neither party will know that Bob is a message behind, and if this corruption remains undetected, the rest of the communication will be useless. In most state-of-the-art interactive coding schemes for symbol corruptions, the parties communicate normally for a fixed number of rounds and then send back and forth a series of checks to detect any symbol corruptions that may have occurred. One might hope that a synchronization error could be detected during these checks, but the parties may be out of sync while performing the checks, thus rendering them useless as well. Therefore, synchronization errors require us to develop new techniques.

Very little is known regarding coding for interactive communication in the presence of synchronization errors. A 2016 coding scheme by Braverman et al. [8], which can be seen as the equivalent of Schulman's seminal result, achieves a small constant communication rate while being robust against a $1/18 - \varepsilon$ fraction of errors. The coding scheme relies on edit-distance tree codes, which are a careful adaptation of Schulman's original tree codes [23] for edit distance, so the decoding operations are not efficient and require exponential time computations. A recent work by Sherstov and Wu [25] closed the gap for maximum tolerable error fraction by introducing a coding scheme that is robust against $1/6 - \varepsilon$ fraction of errors which is the highest possible fraction of insertions and deletions under which any coding scheme for interactive communication can work. Both Braverman et al. [8] and Sherstov and Wu [25] schemes are of constant communication rate, over large enough constant alphabets, and inefficient. In this work we address the next natural questions which, as arose with ordinary corruption interactive communication, are on finding interactive coding schemes that are computationally efficient or achieve super-constant communication efficiency.

Our results. We present very general channel simulations which allow two parties communicating over an insertion-deletion channel to follow any protocol designed for a regular symbol corruption channel. The fraction of errors on the simulated symbol corruption channel is only slightly larger than that on the insertion-deletion channel. Our channel simulations

are made possible by synchronization strings. Crucially, at the cost of increasing the error rate by a constant factor, synchronization strings can be decoded in a streaming manner which preserves linearity of time. Note that the similar technique is used in Haeupler and Shahrasbi [19] to transform synchronization errors into ordinary symbol corruptions as a stepping-stone to obtain insertion-deletion codes from ordinary error correcting codes in a black-box fashion. However, in the context of error correcting codes, there is no requirement for this transformation to happen in real time. In other words, in the study of insertion-deletion codes by Haeupler and Shahrasbi [19], the entire message transmission is done and then the receiving party uses the entire message to transform the synchronization errors into symbol corruptions. In the channel simulation problem, this transformation is required to happen on the fly. Interestingly, we have found out that in the harder problem of channel simulation, the factor by which the number of synchronization errors increase by being transformed into corruption errors cannot be improved to $1 + o(1)$, in contrast to what is achievable for error correcting codes. This work exhibits the widespread applicability of synchronization strings and opens up several new use cases, such as coding for interactive communication over insertion-deletion channels. Namely, using synchronization strings, we provide techniques to obtain the following simulations of corruption channels over given insertion-deletion channels with binary and large constant alphabet sizes.

▶ **Theorem 1** (Informal Statement)**.**

(a) *Suppose that n rounds of a one-way/interactive insertion-deletion channel over an alphabet Σ with a δ fraction of insertions and deletions are given. Using an ε-synchronization string over an alphabet Σ_{syn}, it is possible to simulate $n\,(1 - O_\varepsilon(\delta))$ rounds of a one-way/interactive corruption channel over Σ_{sim} with at most $O_\varepsilon\,(n\delta)$ symbols corrupted so long as $|\Sigma_{sim}| \times |\Sigma_{syn}| \leq |\Sigma|$.*

(b) *Suppose that n rounds of a binary one-way/interactive insertion-deletion channel with a δ fraction of insertions and deletions are given. It is possible to simulate $n(1 - \Theta(\sqrt{\delta \log(1/\delta)}))$ rounds of a binary one-way/interactive corruption channel with $\Theta(\sqrt{\delta \log(1/\delta)})$ fraction of corruption errors between two parties over the given channel.*

Based on the channel simulations presented above, we present novel interactive coding schemes which simulate any interactive two-party protocol over an insertion-deletion channel.

We use our large alphabet interactive channel simulation along with constant-rate efficient coding scheme of Ghaffari and Haeupler [14] for interactive communication over corruption channels to obtain a coding scheme for insertion-deletion channels that is efficient, has a constant communication rate, and tolerates up to $1/44 - \varepsilon$ fraction of errors. Note that despite the fact that this coding scheme fails to protect against the optimal $1/6 - \varepsilon$ fraction of synchronization errors as the recent work by Sherstov and Wu [25] does, it is an improvement over all previous work in terms of computational efficiency as it is the first efficient coding scheme for interactive communication over insertion-deletion channels.

▶ **Theorem 2.** *For any constant $\varepsilon > 0$ and n-round alternating protocol Π, there is an efficient randomized coding scheme simulating Π in presence of $\delta = 1/44 - \varepsilon$ fraction of edit-corruptions with constant rate (i.e., in $O(n)$ rounds) and in $O(n^5)$ time that works with probability $1 - 2^{\Theta(n)}$. This scheme requires the alphabet size to be a large enough constant $\Omega_\varepsilon(1)$.*

Next, we use our small alphabet channel simulation and the corruption channel interactive coding scheme of Haeupler [17] to introduce an interactive coding scheme for insertion-deletion channels. This scheme is not only computationally efficient, but also the first with super

constant communication rate. In other words, this is the first coding scheme for interactive communication over insertion-deletion channels whose rate approaches one as the error fraction drops to zero. Our computationally efficient interactive coding scheme achieves a near-optimal communication rate of $1 - O(\sqrt{\delta \log(1/\delta)})$ and tolerates a δ fraction of errors. Besides computational efficiency and near-optimal communication rate, this coding scheme improves over all previous work in terms of alphabet size. As opposed to coding schemes provided by the previous work[8, 25], our scheme does not require a large enough constant alphabet and works even for binary alphabets.

▶ **Theorem 3.** *For sufficiently small δ, there is an efficient interactive coding scheme for fully adversarial binary insertion-deletion channels which is robust against δ fraction of edit-corruptions, achieves a communication rate of $1 - \Theta(\sqrt{\delta \log(1/\delta)})$, and works with probability $1 - 2^{-\Theta(n\delta)}$.*

We also utilize the channel simulations in one-way settings to provide efficient binary insertion-deletion codes correcting δ-fraction of synchronization errors–for δ smaller than some constant–with a rate of $1 - \Theta(\sqrt{\delta \log(1/\delta)})$. This is an improvement in terms of rate-distance trade-off over the state-of-the-art low-rate binary insertion-deletion codes by Guruswami and Wang [16]. The codes by Guruswami and Wang [16] achieve a rate of $1 - O(\sqrt{\delta} \log(1/\delta))$.

Finally, we introduce a slightly improved definition of edit-distance tree codes, a generalization of Schulman's original tree codes defined by Braverman et al. [8]. We show that under our revised definition, edit-distance tree codes are closely related to synchronization strings. For example, edit-distance tree codes can be constructed by merging a regular tree code and a synchronization string. This transfers, for example, Braverman's sub-exponential time tree code construction [6] and the candidate construction of Schulman [24] from tree codes to edit-distance tree codes. Lastly, as a side note, we will show that with the improved definition, the coding scheme of Braverman et al. [8] can tolerate $1/10 - \varepsilon$ fraction of synchronization errors rather than $1/18 - \varepsilon$ fraction that the scheme based on their original definition did. This improved definition is independently observed by Sherstov and Wu [25].

1.1 Definitions and preliminaries

In this section, we define the channel models and communication settings considered in this work. We also provide notation and define synchronization strings.

Error model and communication channels. In this work, we study two types of channels, which we call *corruption channels* and *insertion-deletion channels*. In the corruption channel model, two parties communicate with an alphabet Σ, and if one party sends a message $c \in \Sigma$ to the other party, then the other party will receive a message $\tilde{c} \in \Sigma$, but it may not be the case that $c = \tilde{c}$.

In the one-way communication setting over an insertion-deletion channel, messages to the listening party may be inserted, and messages sent by the sending party may be deleted. The two-way channel requires a more careful setup. We emphasize that we cannot hope to protect against arbitrary insertions and deletions in the two-way setting because in the message-driven model, a single deletion could cause the protocol execution to "hang." Therefore, following the standard model of Braverman et al.'s work [8] that is employed in all other previous works on this problem [25], we restrict our attention to *edit corruptions*, which consist of a single deletion followed by a single insertion, which may be aimed at either party. Braverman et al. [8] provide a detailed discussion on their model and show that it is strong

enough to generalize other natural models one might consider, including models that utilize clock time-outs to overcome the stalling issue.

In both the one- and two-way communication settings, we study *adversarial channels* with *error rate* δ. Our coding schemes are robust in both the *fully adversarial* and the *oblivious adversary* models.

Interactive and one-way communication protocols. In an *interactive protocol* Π over a channel with an alphabet Σ, Alice and Bob begin with two inputs from Σ^* and then engage in n *rounds* of communication. In a single round, each party either listens for a message or sends a message, where this choice and the message, if one is generated, depends on the party's state, its input, and the history of the communication thus far. After the n rounds, the parties produce an output. We study *alternating protocols*, where each party sends a message every other round and listens for a message every other round. In this message-driven paradigm, a party "sleeps" until a new message comes, at which point the party performs a computation and sends a message to the other party. In the presence of noise, we say that a protocol Π' *robustly simulates* a deterministic protocol Π over a channel C if given any inputs for Π, the parties can decode the transcript of the execution of Π on those inputs over a noise-free channel from the transcript of the execution of Π' over C.

Finally, we also study *one-way communication*, where one party sends all messages and the other party listens. Coding schemes in this setting are known as *error-correcting codes*.

Synchronization Strings. In short, synchronization strings [19] allow communicating parties to protect against synchronization errors by indexing their messages without blowing up the communication rate. We describe this technique by introducing two intermediaries, C_A and C_B, that conduct the communication over the given insertion-deletion channel. C_A receives all symbols that Alice wishes to send to Bob, C_A sends the symbols to C_B, and C_B communicates the symbols to Bob. C_A and C_B handle the synchronization strings and all the extra work that is involved in keeping Alice and Bob in sync by guessing the actual index of symbols received by C_B. In this way, Alice and Bob communicate via C_A and C_B as though they were communicating over a half-error channel.

Unfortunately, trivially attaching the indices $1, 2, \ldots, n$ to each message will not allow us to maintain a near optimal communication rate. If C_A attaches an index to each of Alice's messages, it would increase the size of Σ by a factor of n and the rate would increase by a factor of $1/\log n$, which is far from optimal. Synchronization strings allow the communicating parties to index their messages using an alphabet size that is independent of the total communication length n.

Suppose that with each of Alice's n messages, C_A sends an encoding of her index using a symbol from Σ. Let S be a "synchronization string" consisting of all n encoded indices sent by C_A. Further, suppose that the adversary injects a total of $n\delta$ insertions and deletions, thus transforming the string S to the string S_τ. Let some element of S like $S[i]$ pass through the channel without being deleted by the adversary and arrive as $S_\tau[j]$. We call $S_\tau[j]$ a *successfully transmitted symbol*.

We assume that C_A and C_B know the string S *a priori*. The intermediary C_B will receive a set of transmitted indices $S_\tau[1], \ldots, S_\tau[n]$. Upon receipt of the jth transmitted index, C_B guesses the actual index of the received symbol when sent by C_A. We call the algorithm that C_B runs to determine this an *(n, δ)-indexing algorithm.* The algorithm can also return a symbol $\top$ which represents an "I don't know" response. Any successfully transmitted symbols that is decoded incorrectly is called a *misdecoding*. The number of misdecodings that

an (n, δ)-indexing algorithm might produced is used as a measure to valuate its quality. An indexing algorithm is *streaming* if its guess for a received symbol only depends on previously arrived symbols.

Haeupler and Shahrasbi [19] defined a family of synchronization strings that admit an (n, δ)-indexing algorithm with strong performance.

▶ **Definition 4** (ε-Synchronization String)**.** A string $S \in \Sigma^n$ is an ε-synchronization string if for every $1 \leq i < j < k \leq n+1$ we have that $ED\left(S[i,j), S[j,k)\right) > (1-\varepsilon)(k-i)$.

Haeupler and Shahrasbi [19, 20] prove the existence and provide several fast constructions for ε-synchronization strings and provide a streaming (n, δ)-indexing algorithm that returns a solution with $\frac{c_i}{1-\varepsilon} + \frac{c_d \varepsilon}{1-\varepsilon}$ misdecodings. The algorithm runs in time $O(n^5)$, spending $O(n^4)$ on each received symbol.

2 Channel Simulations

In this section, we show how ε-synchronization strings can be used as a powerful tool to simulate corruption channels over insertion-deletion channels. In Section 3, we use these simulations to introduce coding schemes resilient to insertion-deletion errors.

2.1 One-way channel simulation over a large alphabet

Assume that Alice and Bob have access to n rounds of communication over a one-way insertion-deletion channel where the adversary is allowed to insert or delete up to $n\delta$ symbols. In this situation, we formally define a corruption channel simulation over the given insertion-deletion channel as follows:

▶ **Definition 5** (Corruption Channel Simulation)**.** Let Alice and Bob have access to n rounds of communication over a one-way insertion-deletion channel with the alphabet Σ. The adversary may insert or delete up to $n\delta$ symbols. Intermediaries C_A and C_B *simulate* n' rounds of a corruption channel with alphabet Σ_{sim} over the given channel as follows. First, the adversary can insert a number of symbols into the insertion-deletion channel between C_A and C_B. Then for n' rounds $i = 1, \ldots, n'$, the following procedure repeats:

1. Alice gives $X_i \in \Sigma_{sim}$ to C_A.
2. Upon receiving X_i from Alice, C_A wakes up and sends a number of symbols (possibly zero) from the alphabet Σ to C_B through the given insertion-deletion channel. The adversary can delete any of these symbols or insert symbols *before*, *among*, or *after* them.
3. Upon receiving symbols from the channel, C_B wakes up and reveals a number of symbols (possibly zero) from the alphabet Σ_{sim} to Bob. We say all such symbols are *triggered* by X_i.

Throughout this procedure, the adversary can insert or delete up to $n\delta$ symbols. However, C_B is required to reveal exactly n' symbols to Bob regardless of the adversary's actions. Let $\tilde{X}_1, \cdots, \tilde{X}_{n'} \in \Sigma_{sim}$ be the symbols revealed to Bob by C_B. This procedure successfully simulates n' rounds of a corruption channel with a δ' fraction of errors if for all but $n'\delta'$ elements i of the set $\{1, \ldots, n'\}$, the following conditions hold: 1) $\tilde{X}_i = X_i$; and 2) $\tilde{X}_i$ is triggered by X_i.

When $\tilde{X}_i = X_i$ and $\tilde{X}_i$ is triggered by X_i, we call $\tilde{X}_i$ an *uncorrupted symbol*. The second condition, that $\tilde{X}_i$ is triggered by X_i, is crucial to preserving linearity of time, which is the fundamental quality that distinguishes channel simulations from channel codings. It forces C_A to communicate each symbol to Alice as soon as it arrives. Studying channel simulations

satisfying this condition is especially important in situations where Bob's messages depends on Alice's, and vice versa.

Conditions (1) and (2) also require that C_B conveys at most one uncorrupted symbol each time he wakes up. As the adversary may delete $n\delta$ symbols from the insertion-deletion channel, C_B will wake up at most $n(1-\delta)$ times. Therefore, we cannot hope for a corruption channel simulation where Bob receives more than $n(1-\delta)$ uncorrupted symbols. In the following theorem, we prove something slightly stronger: no deterministic one-way channel simulation can guarantee that Bob receives more than $n(1-4\delta/3)$ uncorrupted symbols and if the simulation is randomized, the expected number of uncorrupted transmitted symbols is at most $n(1-7\delta/6)$. This puts channel simulation in contrast to channel coding as one can recover $1-\delta-\varepsilon$ fraction of symbols there (as shown in [19]).

▶ **Theorem 6.** *Assume that n uses of a one-way insertion-deletion channel over an arbitrarily large alphabet Σ with a δ fraction of insertions and deletions are given. There is no deterministic simulation of a corruption channel over any alphabet Σ_{sim} where the simulated channel guarantees more than $n\,(1-4\delta/3)$ uncorrupted transmitted symbols. If the simulation is randomized, the expected number of uncorrupted transmitted symbols is at most $n(1-7\delta/6)$.*

We now provide a channel simulation using ε-synchronization strings. Every time C_A receives a symbol from Alice (from an alphabet Σ_{sim}), C_A appends a new symbol from a predetermined ε-synchronization string over an alphabet Σ_{syn} to Alice's symbol and sends it as one message through the channel. On the other side of channel, suppose that C_B has already revealed some number of symbols to Bob. Let $\mathtt{I}_B$ be the index of the next symbol C_B expects to receive. Upon receiving a new symbol from C_A, C_B uses the part of the message coming from the synchronization string to guess the index of the message Alice sent. We will refer to this decoded index as $\tilde{\mathtt{I}}_A$ and its actual index as $\mathtt{I}_A$. If $\widetilde{\mathtt{I}}_A < \mathtt{I}_B$, then C_B reveals nothing to Bob and ignores the message he just received. Meanwhile, if $\widetilde{\mathtt{I}}_A = \mathtt{I}_B$, then C_B reveals Alice's message to Bob. Finally, if $\widetilde{\mathtt{I}}_A > \mathtt{I}_B$, then C_B sends a dummy symbol to Bob and then sends Alice's message.Theorem 7 details the simulation guarantees.

▶ **Theorem 7.** *Assume that n uses of a one-way insertion-deletion channel over an alphabet Σ with a δ fraction of insertions and deletions are given. Using an ε-synchronization string over an alphabet Σ_{syn}, it is possible to simulate $n(1-\delta)$ rounds of a one-way corruption channel over Σ_{sim} with at most $2n\delta(2+(1-\varepsilon)^{-1})$ symbols corrupted so long as $|\Sigma_{sim}| \times |\Sigma_{syn}| \leq |\Sigma|$ and $\delta < 1/7$.*

2.2 Interactive channel simulation over a large alphabet

We now turn to channel simulations for interactive channels. As in Section 2.1, we formally define a corruption interactive channel simulation over a given insertion-deletion interactive channel. We then use synchronization strings to present one such simulation.

▶ **Definition 8** (Corruption Interactive Channel Simulation)**.** Let Alice and Bob have access to n rounds of communication over an interactive insertion-deletion channel with alphabet Σ. The adversary may insert or delete up to $n\delta$ symbols. The intermediaries C_A and C_B *simulate* n' rounds of a corruption interactive channel with alphabet Σ_{sim} over the given channel as follows. The communication starts when Alice gives a symbol from Σ_{sim} to C_A. Then Alice, Bob, C_A, and C_B continue the communication as follows:

1. Whenever C_A receives a symbol from Alice or C_B, he either reveals a symbol from Σ_{sim} to Alice or sends a symbol from Σ through the insertion-deletion channel to C_B.

2. Whenever C_B receives a symbol from Bob or C_A, he either reveals a symbol from Σ_{sim} to Bob or send a symbols from Σ through the insertion-deletion channel to C_A.
3. Whenever C_B reveals a symbol to Bob, Bob responds with a new symbol from Σ_{sim}.
4. Whenever C_A reveals a symbol to Alice, Alice responds with a symbol in Σ_{sim} except for the $\frac{n'}{2}$th time.

Throughout this procedure, the adversary can inject up to $n\delta$ edit corruptions. However, regardless of the adversary's actions, C_A and C_B have to reveal exactly $n'/2$ symbols to Alice and Bob respectively.

Let $X_1, \ldots, X_{n'}$ be the symbols Alice gives to C_A and $\tilde{X}_1, \ldots, \tilde{X}_{n'} \in \Sigma_{sim}$ be the symbols C_B reveals to Bob. Similarly, Let $Y_1, \ldots, Y_{n'}$ be the symbols Bob gives to C_B and $\tilde{Y}_1, \ldots, \tilde{Y}_{n'} \in \Sigma_{sim}$ be the symbols C_A reveals to Alice. We call each pair of tuples $(X_i, \tilde{X}_i)$ and $(Y_i, \tilde{Y}_i)$ a *round* of the simulated communication. We call a round *corrupted* if its elements are not equal. This procedure successfully simulates n' rounds of a corruption interactive channel with a δ' fraction of errors if for all but $n'\delta'$ of the rounds are corrupted.

The protocol and analysis in this large alphabet setting are similar to the harder case where the alphabet is binary. We cover interactive communication for the binary setting in the next section.

▶ **Theorem 9.** *Assume that n uses of an interactive insertion-deletion channel over an alphabet Σ with a δ fraction of insertions and deletions are given. Using an ε-synchronization string over an alphabet Σ_{syn}, it is possible to simulate $n - 2n\delta(1 + (1-\varepsilon)^{-1})$ uses of an interactive corruption channel over Σ_{sim} with at most a $\frac{2\delta(5-3\varepsilon)}{1-\varepsilon+2\varepsilon\delta-4\delta}$ fraction of symbols corrupted so long as $|\Sigma_{sim}| \times |\Sigma_{syn}| \leq |\Sigma|$ and $\delta < 1/14$.*

2.3 Binary interactive channel simulation

We now show that with the help of synchronization strings, a binary interactive insertion-deletion channel can be used to simulate a binary interactive corruption channel, inducing a $\widetilde{O}(\sqrt{\delta})$ fraction of bit-flips. In this way, the two communicating parties may interact as though they are communicating over a corruption channel. They therefore can employ corruption channel coding schemes while using the simulator as a black box means of converting the insertion-deletion channel to a corruption channel.

The key difference between this simulation and the one-way, large alphabet simulation is that Alice and Bob communicate through C_A and C_B for *blocks* of r rounds, between which C_A and C_B check if they are in sync. Due to errors, there may be times when Alice and Bob are in disagreement about which block, and what part of the block, they are in. C_A and C_B ensure that Alice and Bob are in sync most of the time.

When Alice sends C_A a message from a new block of communication, C_A holds that message and alerts C_B that a new block is beginning. C_A does this by sending C_B a header that is a string consisting of a single one followed by $s-1$ zeros (10^{s-1}). Then, C_A indicates which block Alice is about to start by sending a synchronization symbol to C_B. Meanwhile, when C_B receives a 10^{s-1} string, he listens for the synchronization symbol, makes his best guess about which block Alice is in, and then communicates with Bob and C_A accordingly. This might entail sending dummy blocks to Bob or C_A if he believes that they are in different blocks. To describe the guarantee that our simulation provides, we first define *block corruption channels*.

▶ **Definition 10** (Block Corruption Channel)**.** An n-round adversarial corruption channel is called a (δ, r)-*block corruption channel* if the adversary is restricted to corrupt $n\delta$ symbols which are covered by $n\delta/r$ blocks of r consecutively transmitted symbols.

▶ **Theorem 11.** *Suppose that n rounds of a binary interactive insertion-deletion channel with a δ fraction of insertions and deletions are given. For sufficiently small δ, it is possible to deterministically simulate $n(1-\Theta(\sqrt{\delta\log(1/\delta)}))$ rounds of a binary interactive $(\Theta(\sqrt{\delta\log(1/\delta)}), \sqrt{(1/\delta)\log(1/\delta)})$-block corruption channel between two parties, Alice and Bob, assuming that all substrings of form 10^{s-1} where $s = c\log(1/\delta)$ that Alice sends can be covered by $n\delta$ intervals of $\sqrt{(1/\delta)\log(1/\delta)}$ consecutive rounds. The simulation is performed efficiently if the synchronization string is efficient.*

Proof Sketch. Suppose Alice and Bob communicate via intermediaries C_A and C_B who act according to the algorithm described above. In total, Alice and Bob will attempt to communicate n_s bits to one another over the simulated channel, while C_A and C_B communicate a total of n bits to one another. The adversary is allowed to insert or delete up to $n\delta$ symbols and C_A sends $n/2$ bits, so C_B may receive between $n/2 - n\delta$ and $n/2 + n\delta$ symbols. To prevent C_B from stalling indefinitely, C_B only listens to the first $n(1-2\delta)/2$ bits he receives.

For $r = \sqrt{(1/\delta)\log(1/\delta)}$, we define a *chunk* to be $r_c := (s + |\Sigma_{syn}| + r/2)$ consecutive bits that are sent by C_A to C_B. In particular, a chunk corresponds to a section header and synchronization symbol followed by $r/2$ rounds of messages sent from Alice. As C_B cares about the first $n(1-2\delta)/2$ bits it receives, there are $\frac{n(1-2\delta)}{2r_c}$ chunks in total. Hence, $n_s = \frac{n(1-2\delta)}{2r_c} \cdot r$ since C_B and C_A's communication is alternating.

Note that if Alice sends a substring of form 10^{s-1} in the information part of a chunk, then Bob mistakenly detects a new block. With this in mind, we say a chunk is *good* if:

1. No errors are injected in the chunk or affecting C_B's detection of the chunk's header,
2. C_B correctly decodes the index that C_A sends during the chunk, and
3. C_A does not send a 10^{s-1} substring in the information portion of the chunk.

If a chunk is not good, we call it *bad*. If the chunk is bad because C_B does not decode C_A's index correctly even though they were in sync and no errors were injected, then we call it *decoding-bad*. If it is bad because Alice sends a 10^{s-1} substring, we call it *zero-bad* and otherwise, we call it *error-bad*. Throughout the protocol, C_B uses the variable $\mathtt{I}_B$ to denote the next index of the synchronization string C_B expects to receive and we use $\mathtt{I}_A$ to denote the index of the synchronization string C_A most recently sent. Notice that if a chunk is good and $\mathtt{I}_A = \mathtt{I}_B$, then all messages are correctly conveyed.

We now bound the maximum number of bad chunks that occur over the course of the simulation. Suppose the adversary injects errors into the i^{th} chunk, making that chunk bad. The $(i+1)^{th}$ chunk may also be bad, since Bob may not be listening for 10^{s-1} from C_A when C_A sends them, and therefore may miss the block header. However, if the adversary does not inject any errors into the $(i+1)^{th}$ and the $(i+2)^{th}$ chunk, then the $(i+2)^{th}$ chunk will be good. In effect, a single error may render at most two chunks useless. Since the adversary may inject $n\delta$ errors into the insertion-deletion channel, this means that the number of chunks that are error-bad is at most $2n\delta$. Additionally, by assumption, the number of zero-bad chunks is also at most $n\delta$.

We also must consider the fraction of rounds that are decoding-bad. In order to do this, we appeal to Theorem 6.24 from [19], which guarantees that if an ε-synchronization string of length N is sent over an insertion-deletion channel with a δ' fraction of insertions and deletions, then the receiver will decode the index of the received symbol correctly for all but $2N\delta'/(1-\varepsilon)$ symbols. In this context, N is the number of chunks, i.e. $N = n(1-2\delta)/(2r_c)$, and the fraction of chunks corrupted by errors is $\delta' = 4n\delta/N$. Therefore, the total number of bad chunks is at most $4\delta n + 2N\delta'/(1-\varepsilon) = 4\delta n(3-\varepsilon)/(1-\varepsilon)$.

In the rest of the proof, which is available in the extended version of this paper, we show that all but $12\frac{3-\varepsilon}{1-\varepsilon} \cdot \delta n$ chunks are good chunks and have $\mathtt{I}_A = \mathtt{I}_B$ upon their arrival on Bob's side and we conclude that the simulated channel is a $\left(\frac{3-\varepsilon}{1-\varepsilon}\frac{24\delta}{1-2\delta}r_c, r\right)$-block corruption channel. For the asymptotically optimal choice of $r = \sqrt{(1/\delta)\log(1/\delta)}$, we derive the simulation described in the theorem statement. ◀

The simulation stated in Theorem 11 burdens an additional condition on Alice's stream of bits by requiring it to have a limited number of substrings of form 10^{s-1}. We now introduce a high probability technique to modify a general interactive communication protocol in a way that makes all substrings of form 10^{s-1} in Alice's stream of bits fit into $n\delta$ intervals of length $r = \sqrt{(1/\delta)\log(1/\delta)}$.

▶ **Lemma 12.** *Assume that n rounds of a binary interactive insertion-deletion channel with an oblivious adversary who is allowed to inject $n\delta$ errors are given. There is a pre-coding scheme that can be utilized on top of the simulation introduced in Theorem 11. It modifies the stream of bits sent by Alice so that with probability $1 - e^{-\frac{c-3}{2}n\delta\log\frac{1}{\delta}(1+o(1))}$, all substrings of form 10^{s-1} where $s = c\log(1/\delta)$ in the stream of bits Alice sends over the simulated channel can be covered by $n\delta$ intervals of length $r = \sqrt{(1/\delta)\log(1/\delta)}$. This pre-coding scheme comes at the cost of a $\Theta(\sqrt{\delta\log(1/\delta)})$ fraction of the bits Alice sends through the simulated channel.*

Proof sketch. In the simulation process, each $r/2$ consecutive bits Alice sends forms one of the chunks C_A sends to C_B alongside some headers. The idea of this pre-coding scheme is simple. Alice uses the first $s/2$ data bits (and not the header) of each chunk to share $s/2$ randomly generated bits with Bob (instead of running the interactive protocol) and then both of them extract a string S' of $r/2$ $(s/2)$-wise independent random variables. Then, Alice XORs the rest of data bits she passes to C_A with S' and Bob XORs those bits with S' again to retrieve the original data. In the extended version, we show that this pre-coding scheme guarantees the requirements mentioned in the theorem statement. ◀

Applying this pre-coding for $c \geq 3$ on top of the simulation from Theorem 11 implies the following.

▶ **Theorem 13.** *Suppose that n rounds of a binary interactive insertion-deletion channel with a δ fraction of insertions and deletions performed by an oblivious adversary are given. For sufficiently small δ, it is possible to simulate $n(1 - \Theta(\sqrt{\delta\log(1/\delta)}))$ rounds of a binary interactive $(\Theta(\sqrt{\delta\log(1/\delta)}), \sqrt{(1/\delta)\log 1/\delta})$-block corruption channel between two parties over the given channel. The simulation works with probability $1 - \exp(-\Theta(n\delta\log(1/\delta)))$ and is efficient if the synchronization string is efficient.*

▶ **Lemma 14.** *Suppose that n rounds of a binary, interactive, fully adversarial insertion-deletion channel with a δ fraction of insertions and deletions are given. The pre-coding scheme proposed in Lemma 12 ensures that the stream of bits sent by Alice contains fewer than $n\delta$ substrings of form 10^{s-1} for $s = c\log(1/\delta)$ and $c > 5$ with probability $1 - e^{-\Theta(n\delta\log(1/\delta))}$.*

Theorem 11 and Lemma 14 allow us to conclude that one can perform the simulation stated in Theorem 11 over any interactive protocol with high probability. Note that one can trivially extend the results of Theorems 11 and 13 to one-way binary communication by ignoring the bits Bob sends.

3 Applications: New Interactive Coding Schemes

Efficient Coding Scheme Tolerating 1/44 Fraction of Errors. In this section, we will provide an efficient coding scheme for interactive communication over insertion-deletion channels by first making use of large alphabet interactive channel simulation provided in Theorem 9 to effectively transform the given channel into a simple corruption interactive channel and then use the efficient constant-rate coding scheme of Ghaffari and Haeupler [14] on top of the simulated channel. This will give an efficient constant-rate interactive communication over large enough constant alphabets as described in Theorem 2. We review the following theorem of Ghaffari and Haeupler [14] before proving Theorem 2.

▶ **Theorem 15** (Theorem 1.1 from [14]). *For any constant $\varepsilon > 0$ and n-round protocol Π there is a randomized non-adaptive coding scheme that robustly simulates Π against an adversarial error rate of $\rho \leq 1/4 - \varepsilon$ using $N = O(n)$ rounds, a near-linear $n \log^{O(1)} n$ computational complexity, and failure probability $2^{-\Theta(n)}$.*

Proof of Theorem 2. For a given insertion-deletion interactive channel over alphabet Σ suffering from δ fraction of edit-corruption errors, Theorem 9 enables us to simulate $n - 2n\delta(1 + (1-\varepsilon')^{-1})$ rounds of ordinary interactive channel with $\frac{2\delta(5-3\varepsilon')}{1-\varepsilon'+2\varepsilon'\delta-4\delta}$ fraction of symbol by designating $\log|\Sigma_{syn}|$ bits of each symbol to index simulated channel's symbols with an ε'-synchronization string over Σ_{syn}.

One can employ the scheme of Ghaffari and Haeupler [14] over the simulated channel as long as error fraction is smaller than $1/4$. Note that $\frac{2\delta(5-3\varepsilon')}{1-\varepsilon'+2\delta\varepsilon'-4\delta}\Big|_{\varepsilon'=0} = \frac{10\delta}{1-4\delta} < \frac{1}{4} \Leftrightarrow \delta < \frac{1}{44}$. Hence, as long as $\delta = 1/44 - \varepsilon$ for $\varepsilon > 0$, for small enough $\varepsilon' = O_\varepsilon(1)$, the simulated channel has an error fraction that is smaller than $1/4$. Therefore, by running the efficient coding scheme of Theorem 15 over this simulated channel one gets a constant rate coding scheme for interactive communication that is robust against $1/44 - \varepsilon$ fraction of edit-corruptions. Note that this simulation requires the alphabet size to be large enough to contain synchronization symbols (which can come from a polynomially large alphabet in terms of ε') and also meet the alphabet size requirements of Theorem 15. This requires the alphabet size to be $\Omega_\varepsilon(1)$, i.e., a large enough constant merely depending on ε. The success probability and time complexity are direct consequences of Theorem 15 and Theorem 6.24 from [19]. ◀

Efficient Coding Scheme with Near-Optimal Rate over Small Alphabets. In this section we present another insertion-deletion interactive coding scheme that achieves near-optimal communication efficiency as well as computation efficiency by employing a similar idea as in Section 3.

In order to derive a rate-efficient interactive communication coding scheme over small alphabet insertion-deletion channels, simulations described above can be used to simulate a corruption channel and then the rate-efficient interactive coding scheme for corruption channels introduced by Haeupler [17] can be used on top of the simulated channel.

▶ **Theorem 16** (Interactive Coding against Block Corruption). *By choosing an appropriate block length in the Haeupler [17] coding scheme for oblivious adversaries, one obtains a robust efficient interactive coding scheme for (δ_b, r_b)-block corruption channel with communication rate $1 - \Theta(\sqrt{\delta_b \max\{\delta_b, 1/r_b\}})$ that works with probability $1 - 2^{-\Theta(n\delta_b/r_b)}$.*

Applying the coding scheme of Theorem 16 over the simulation from Theorem 13 implies the following.

▶ **Theorem 17.** *For sufficiently small δ, there is an efficient interactive coding scheme over binary insertion-deletion channels which, is robust against δ fraction of edit-corruptions by an oblivious adversary, achieves a communication rate of $1 - \Theta(\sqrt{\delta \log(1/\delta)})$, and works with probability $1 - 2^{-\Theta(n\delta)}$.*

Moreover, in the extended version, we show that this result is extendable for the fully adversarial setup, as summarized in Theorem 3.

This insertion-deletion interactive coding scheme is, to the best of our knowledge, the first to be computationally efficient, to have communication rate approaching one, and to work over arbitrarily small alphabets.

Abstract

We study codes that are list-decodable under insertions and deletions ("insdel codes"). Specifically, we consider the setting where, given a codeword x of length n over some finite alphabet Σ of size q, $\delta \cdot n$ codeword symbols may be adversarially deleted and $\gamma \cdot n$ symbols may be adversarially inserted to yield a corrupted word w. A code is said to be list-decodable if there is an (efficient) algorithm that, given w, reports a small list of codewords that include the original codeword x. Given δ and γ we study what is the rate R for which there exists a constant q and list size L such that there exist codes of rate R correcting δ-fraction insertions and γ-fraction deletions while reporting lists of size at most L.

Using the concept of *synchronization strings*, introduced by the first two authors [Proc. STOC 2017], we show some surprising results. We show that for every $0 \leq \delta < 1$, every $0 \leq \gamma < \infty$ and every $\varepsilon > 0$ there exist codes of rate $1 - \delta - \varepsilon$ and constant alphabet (so $q = O_{\delta,\gamma,\varepsilon}(1)$) and sub-logarithmic list sizes. Furthermore, our codes are accompanied by efficient (polynomial time) decoding algorithms. We stress that the fraction of insertions can be arbitrarily large (more than 100%), and the rate is independent of this parameter. We also prove several tight bounds on the parameters of list-decodable insdel codes. In particular, we show that the alphabet size of insdel codes needs to be exponentially large in ε^{-1}, where ε is the gap to capacity above. Our result even applies to settings where the unique-decoding capacity equals the list-decoding capacity and when it does so, it shows that the alphabet size needs to be exponentially large in the gap to capacity. This is sharp contrast to the Hamming error model where alphabet size polynomial in ε^{-1} suffices for unique decoding. This lower bound also shows that the exponential dependence on the alphabet size in previous works that constructed insdel codes is actually necessary!

Our result sheds light on the remarkable asymmetry between the impact of insertions and deletions from the point of view of error-correction: Whereas deletions cost in the rate of the code, insertion costs are borne by the adversary and not the code! Our results also highlight the dominance of the model of insertions and deletions over the Hamming model: A Hamming error is equal to one insertion and one deletion (at the same location). Thus the effect of δ-fraction Hamming errors can be simulated by δ-fraction of deletions and δ-fraction of insertions — but insdel codes can deal with much more insertions without loss in rate (though at the price of higher alphabet size).

1 Introduction

We study the complexity of "insdel coding", i.e., codes designed to recover from insertion and deletion of characters, under the model of "list-decoding", i.e., when the decoding algorithm is allowed to report a (short) list of potential codewords that is guaranteed to include the transmitted word if the number of errors is small enough. Recent work by the first two authors and collaborators [12] has shown major progress leading to tight, or nearly tight, bounds on central parameters of codes (with efficient encoding and decoding algorithms as well) under the setting of *unique* decoding. However the list-decoding versions of these questions were not explored previously. Our work complements the previous studies by exploring list-decoding. In the process our results also reveal some striking features of the insdel coding problem that were not exposed by previous works. To explain some of this, we introduce our model and lay out some of the context below.

1.1 Insdel Coding and List Decoding

We use the phrase "insdel coding" to describe the study of codes that are aimed to recover from *insertions* and *deletions*. The principal question we ask is "what is the *rate* of a code that can recover from γ fraction insertions and δ fraction deletions over a sufficiently large alphabet?". Once the answer to this question is determined we ask how small an alphabet suffices to achieve this rate. We define the terms "rate", "alphabet", and "recovery" below.

An insdel *encoder* over alphabet Σ of block length n is an injective function $E : \Sigma^k \to \Sigma^n$. The associated "code" is the image of the function C. The rate of a code is the ratio k/n. We say that an insdel code C is $(\gamma, \delta, L(n))$-list-decodable if there exists a function $D : \Sigma^* \to 2^C$ such that $|D(w)| \leq L(n)$ for every $w \in \Sigma^*$ and for every codeword $x \in C$ and every word w obtained from x be $\delta \cdot n$ deletions of characters in x followed by $\gamma \cdot n$ insertions, it is the case that $x \in D(w)$. In other words the list-decoder D outputs a list of at most $L(n)$ codewords that is guaranteed to include the transmitted word x if the received word w is obtained from x by at most δ-fraction deletions and γ-fraction insertions. Our primary quest in this paper is the largest rate R for which there exists an alphabet of size $q \triangleq |\Sigma|$ and an infinite family of insdel codes of rate at least R, that are $(\gamma, \delta, L(n))$-list-decodable. Of course we are interested in results where $L(n)$ is very slowly growing with n (if at all). In all results below we get $L(n)$ which is polynomially large in terms of n. Furthermore, when a given rate is achievable we seek codes with efficient encoder and decoder (i.e., the functions E and D are polynomial time computable). Finally we also explore the dependence of the rate on the alphabet size (or vice versa).

Previous Work. Insdel coding was first studied by Levenshtein [18] and since then many bounds and constructions for such codes have been given. With respect to unique decoding, Schulman and Zuckerman [21] gave the first construction of efficient insdel codes over a constant alphabet with a (small) constant relative distance and a (small) constant rate in 1999. Guruswami and Wang [9] gave the first efficient codes over fixed alphabets to correct a

deletion fraction approaching 1, as well as efficient binary codes to correct a small constant fraction of deletions with rate approaching 1. A follow-up work gave new and improved codes with similar rate-distance tradeoffs which can be efficiently decoded from insertions and deletions [5]. Finally, [12] gave codes that can correct δ fraction of synchronization errors with a rate approaching $1-\delta-\varepsilon$ for any $\varepsilon > 0$.

A recent work by Wachter-Zeh [23] considers insdel coding with respect to list decoding and provides Johnson-like upper-bounds for insertions and deletions, i.e., bounds on the list size in terms of the minimum edit-distance of a given code. Moreover, for Varshamov-Tenengolts codes, [23] presents lower bounds on the maximum list size as well as a list-decoding algorithm against a constant number of insertions and deletions.

Several other variants of the insdel coding problem have been studied in the previous work and are summarized by the following surveys [22, 20, 19].

1.2 Our Results

We now present our results on the rate and alphabet size of insdel coding under list-decoding. Two points of contrast that we use below are corresponding bounds in (1) the Hamming error setting for list-decoding and (2) the insdel coding setting with unique-decoding.

1.2.1 Rate Under List Decoding

Our main theorem for list-decoding shows that, given $\gamma, \delta, \varepsilon \geq 0$ there is a $q = q_{\varepsilon,\gamma}$ and a slowly growing function $L = L_{\varepsilon,\gamma}(n)$ such that there are q-ary insdel codes that achieve a rate of $1-\delta-\varepsilon$ that are $(\gamma, \delta, L(n))$-list decodable. Furthermore the encoding and decoding are efficient! The formal statement of the main result is as follows.

▶ **Theorem 1.** *For every $0 < \delta, \varepsilon < 1$ and $\gamma > 0$, there exist a family of list-decodable insdel codes that can protect against δ-fraction of deletions and γ-fraction of insertions and achieves a rate of at least $1-\delta-\varepsilon$ or more over an alphabet of size $\left(\frac{\gamma+1}{\varepsilon^2}\right)^{O\left(\frac{\gamma+1}{\varepsilon^3}\right)} = O_{\gamma,\varepsilon}(1)$. These codes are list-decodable with lists of size $L_{\varepsilon,\gamma}(n) = \exp(\exp(\exp(\log^* n)))$, and have polynomial time encoding and decoding complexities.*

The rate in the theorem above is immediately seen to be optimal even for $\gamma = 0$. In particular an adversary that deletes the last $\delta \cdot n$ symbols already guarantees an upper bound on the rate of $1-\delta$.

We now contrast the theorem above with the two contrasting settings listed earlier. Under unique decoding the best possible rate that can be achieved with δ-fraction deletions and γ-fraction insertions is upper bounded by $1-(\gamma+\delta)$. Matching constructions have been achieved, only recently, by Haeupler and Shahrasbi [12]. In contrast our rate has no dependence on γ and thus dominates the above result. The only dependence on γ is in the alphabet size and list-size and we discuss the need for this dependence later below.

We now turn to the standard "Hamming error" setting: Here an adversary may change an arbitrary δ-fraction of the codeword symbols. In this setting it is well-known that given any $\varepsilon > 0$, there are constants $q = q(\varepsilon)$ and $L = L(\varepsilon)$ and an infinite family of q-ary codes of rate at least $1-\delta-\varepsilon$ that are list-decodable from δ fraction errors with list size at most L. In a breakthrough from the last decade, Guruswami and Rudra [6] showed explicit codes that achieve this with efficient algorithms. The state-of-the-art results in this field yield list size $L(n) = o(\log^{(r)} n)$ for any integer r where $\log^{(r)}$ is the rth iterated logarithm and alphabet size $2^{\tilde{O}(\varepsilon^{-2})}$ [11], which are nearly optimal.

The Hamming setting with δ-fraction errors is clearly a weaker setting than the setting with δ-fraction deletions and $\gamma \geq \delta$ fraction of insertions in that an adversary of the latter kind can simulate the former. (A Hamming error is a deletion followed by an insertion at the same location.) The insdel setting is thus stronger in two senses: it allows $\gamma > \delta$ and gives greater flexibility to the adversary in choosing locations of insertions and deletions. Yet our theorem shows that the stronger adversary can still be dealt with, without qualitative changes in the rate. The only difference is in the dependence of q and L on γ, which we discuss next.

We briefly remark at this stage that, while our result simultaneously "dominates" the results of Haeupler and Shahrasbi [12] as well as Guruswami and Rudra [6], this happens because we use their results in our work. We elaborate further on this in Section 3. Indeed our first result (see Theorem 13) shows how we can obtain Theorem 1 by using capacity achieving "list-recoverable codes" in combination with synchronization strings in a modular fashion.

We believe that using the codes from Theorem 1 in the construction of long-distance synchronization strings from [13] will give synchronization strings that allow us to reduce the decoding complexity of insdel codes of Theorem 1 and [12] to near-linear time.

1.2.2 Rate versus Alphabet Size

We now turn to understanding how large the alphabet size needs to be as a function of δ, ε and γ. We consider two extreme cases, first with only deletions (i.e., $\gamma = 0$ and then with only insertions (i.e., with $\delta = 0$).

We start first with the insertion-only setting. We note here that one cannot hope to find a constant rate family of codes that can protect n symbols out of an alphabet of size q against $(q-1)n$ many insertions or more. This is so since, with $(q-1)n$ insertions, one can turn any string $y \in [1..q]^n$ into the fixed sequence $1, 2, \cdots, q, 1, 2, \cdots, q, \cdots, 1, 2, \cdots, q$ by simply inserting $q-1$ many symbols around each symbol of y to construct a $1, \cdots, q$ there. Hence, Theorem 2 only focuses on codes that protect n rounds of communication over an alphabet of size q against γn insertions for $\gamma < q - 1$.

▶ **Theorem 2.** *Any list-decodable family of codes $\mathcal{C}$ that protects against γ fraction of insertions for some $\gamma < q-1$ and guarantee polynomially-large list size in terms of block length cannot achieve a rate R that is strictly larger than* $1 - \log_q(\gamma+1) - \gamma\left(\log_q \frac{\gamma+1}{\gamma} - \log_q \frac{q}{q-1}\right)$.

In particular, the theorem asserts that if the code has rate $R = 1 - \varepsilon$, then its alphabet size must be exponentially large in $1/\varepsilon$, namely, $q \geq (\gamma+1)^{1/\varepsilon}$.

Next, we turn to the deletion-only case. Here again we note that no constant rate q-ary code can protect against $\delta \geq \frac{q-1}{q}$ fraction of deletions since such a large fraction of deletions may remove all but the most frequent symbol of codewords. Therefore, Theorem 3 below only concerns codes that protect against $\delta \leq \frac{q-1}{q}$ fraction of deletions.

▶ **Theorem 3.** *Any list-decodable family of insdel codes that protect against δ-fraction of deletions (and no insertions) for some $0 \leq \delta < \frac{q-1}{q}$ that are list-decodable with polynomially-bounded list size has rate R upper bounded as below:*

- $R \leq f(\delta) \triangleq (1-\delta)\left(1 - \log_q \frac{1}{1-\delta}\right)$ *where $\delta = \frac{d}{q}$ for some integer d.*
- $R \leq (1 - q\delta')f\left(\frac{d}{q}\right) + q\delta' f\left(\frac{d+1}{q}\right)$ *where $\delta = \frac{d}{q} + \delta'$ for some integer d and $0 \leq \delta' < \frac{1}{q}$.*

In particular if $\delta = d/q$ for integer d and rate is $1 - \delta - \varepsilon$ then the theorem above asserts that $q \geq \left(\frac{1}{1-\delta}\right)^{\frac{1-\delta}{\varepsilon}}$, or in other words q must be exponentially large in $1/\varepsilon$. Indeed such a statement is true for all δ as asserted in the corollary below. (A detailed proof is available in the extended version.)

▶ **Corollary 4.** *There exists a function $f : (0,1) \to (0,1)$ such that any family of insdel codes that protects against δ-fraction of deletions with polynomially bounded list sizes and has rate $1 - \delta - \varepsilon$ must have alphabet size $q \geq \exp\left(\frac{f(\delta)}{\varepsilon}\right)$.*

Implications for Unique Decoding. Even though the main thrust of this paper is list-decoding, Corollary 4 also has implications for unique-decoding. (This turns out to be a consequence of the fact that the list-decoding radius for deletions-only equals the unique-decoding radius for the same fraction of deletions.) We start by recalling the main result of Haeupler and Shahrasbi [12]: Given any $\alpha, \varepsilon > 0$ there exists a code of rate $1 - \alpha - \varepsilon$ over an alphabet of size $q = \exp(1/\varepsilon)$ that *uniquely* decodes from any α-fraction synchronization errors, i.e., from γ-fraction insertions and δ-fraction deletions for any pair $0 \leq \gamma, \delta$ satisfying $\gamma + \delta \leq \alpha$. Furthermore, this is the best possible rate one can achieve for α-fraction synchronization error. (See the extended version for a more detailed description with proof.)

Till now this exponential dependence of the alphabet size on ε was unexplained. This is also in sharp contrast to the Hamming error setting, where codes are known to get ε close to unique decoding capacity (half the "Singleton bound" on the distance of code) with alphabets of size polynomial in $1/\varepsilon$. Indeed given this contrast one may be tempted to believe that the exponential growth is a weakness of the "synchronization string" approach of Haeupler and Shahrasbi [12]. But Corollary 4 actually shows that an exponential bound is necessary. We state this result for completeness even though it is immediate from the Corollary above, to stress its importance in understanding the nature of synchronization errors.

▶ **Corollary 5.** *There exists a function $f : (0,1) \to (0,1)$ such that for every $\alpha, \varepsilon > 0$ every family of insdel codes of rate $1 - \alpha - \varepsilon$ that protects against α-fraction of synchronization errors with unique decoding must have alphabet size $q \geq \exp\left(\frac{f(\delta)}{\varepsilon}\right)$.*

Corollary 5 follows immediately from Corollary 4 by setting $\delta = \alpha$ and $\gamma = 0$ (so we get to the zero insertion case) and noticing that a unique-decoding insdel code for α-fraction synchronization error is also a list-decoding insdel code for δ-fractions of deletions (and no insertions). The alphabet size lower bound for the latter is also an alphabet size lower bound for the former.

1.2.3 Analysis of Random Codes

Finally, in Section 5, we provide an analysis of random codes and compute the rates they can achieve while maintaining list-decodability against insertions and deletions. Such rates are essentially lower-bounds for the capacity of insertion and deletion channels and can be compared against the upper-bounds provided in Section 4.

Theorem 6 shows that the family of random codes over an alphabet of size q can, with high probability, protect against δ-fraction of deletions for any $\delta < 1 - 1/q$ up to a rate of $1-(1-\delta)\log_q \frac{1}{1-\delta} - \delta \log_q \frac{1}{\delta} - \delta \log_q(q-1) = 1 - H_q(\delta)$ using list decoding with super-constant list sizes in terms of their block length where H_q represents the q-ary entropy function.

▶ **Theorem 6.** *For any alphabet of size q and any $0 \leq \delta < \frac{q-1}{q}$, the family of random codes with rate $R < 1 - (1-\delta)\log_q \frac{1}{1-\delta} - \delta \log_q \frac{1}{\delta} - \delta \log_q(q-1) - \frac{1-\delta}{l+1}$ is list-decodable with list size of l from any δ fraction of deletions with high probability. Further, the family of random deletion-codes with rate $R > 1 - (1-\delta)\log_q \frac{1}{1-\delta} - \delta \log_q \frac{1}{\delta} - \delta \log_q(q-1)$ is not list-decodable with high probability.*

Further, Theorem 7 shows that the family of random block codes over an alphabet of size q can, with high probability, protect against γ fraction of insertions for any $\gamma < q - 1$ up to a rate of $1 - \log_q(\gamma + 1) - \gamma \log_q \frac{\gamma+1}{\gamma}$ using list decoding with super-constant list sizes in terms of block length.

▶ **Theorem 7.** *For any alphabet of size q and any $\gamma < q - 1$, the family of random codes with rate $R < 1 - \log_q(\gamma + 1) - \gamma \log_q \frac{\gamma+1}{\gamma} - \frac{\gamma+1}{l+1}$ is list-decodable with a list size of l from any γn insertions with high probability.*

2 Definitions and Preliminaries

2.1 Synchronization Strings

In this section, we briefly recapitulate synchronization strings, introduced by Haeupler and Shahrasbi [12] and further studied in [14, 13]. We will review important definitions and techniques from [12] that will be of use throughout this paper.

Synchronization strings are recently introduced mathematical objects that turn out to be useful tools to overcome synchronization errors, i.e., symbol insertion and symbol deletion errors. The general idea employed in [12, 14] to obtain resilience against synchronization errors in various communication setups is *indexing* each symbol of the communication with symbols of a synchronization string and then *guessing* the actual position of received symbols on the other side using indices. [12] provides a variety of different guessing strategies that guarantee a large number of correct guesses and then overcome the incorrect guesses by utilizing classic error correcting codes. As a matter of fact, synchronization strings essentially translate synchronization errors into ordinary Hamming type errors which are strictly easier to handle. We now proceed to review some of the above-mentioned definitions and techniques more formally.

Suppose that two parties are communicating over a channel that suffers from α-fraction of insertions and deletions and one of the parties sends a pre-shared string S of length n to the other one. A distorted version of S will arrive at the receiving end that we denote by S'. A symbol $S[i]$ is called to be a *successfully transmitted* symbol if it is not removed by the adversary. A *decoding algorithm* on the receiving side is an algorithm that, for any received symbol, guesses its actual position in S by either returning a number in $[1..n]$ or $\top$ which means the algorithm is not able to guess the index. For such a decoding algorithm, a successfully transmitted symbol whose index is not guessed correctly by the decoding algorithm is called a *misdecoding*.

Haeupler and Shahrasbi [12] introduce synchronization strings and find several decoding algorithms for them providing strong misdecoding guarantees and then design insertion-deletion codes based on those decoding algorithms. As details of those algorithms are not relevant to this paper we avoid further discussion of those techniques. To conclude this section we introduce ε-synchronization strings and an important property of them.

▶ **Definition 8** (ε-synchronization string)**.** String $S \in \Sigma^n$ is an ε-synchronization string if for every $1 \leq i < j < k \leq n + 1$ we have that $\text{EditDistance}\left(S[i, j), S[j, k)\right) > (1 - \varepsilon)(k - i)$ where $\text{EditDistance}(x, y)$ is the smallest number of insertions and deletions needed to convert x to y.

The key idea in the construction of insdel codes in [12] is to index an error correcting code with a synchronization string. Here we provide a formal definition of indexing operation.

▶ **Definition 9** (Indexing). The operation of indexing code $\mathcal{C}$ with block length n and String S of length n is to simply replace each codeword $w_1, w_2, \cdots, w_n$ with $(w_1, s_1), (w_2, s_2), \cdots, (w_n, s_n)$. Clearly, this operations expands the alphabet of the code.

It is shown in [12, 13] that ε-synchronization strings exist over alphabets of sizes polynomially large in terms of ε^{-1} and can be efficiently constructed. An important property of ε-synchronization strings discussed in [12] is the self matching property defined as follows.

▶ **Definition 10** (ε-self-matching property). String S satisfies ε-self-matching property if for any two sequences of indices $1 \leq a_1 < a_2 < \cdots < a_k \leq |S|$ and $1 \leq b_1 < b_2 < \cdots < b_k \leq |S|$ that satisfy $S[a_i] = S[b_i]$ and $a_i \neq b_i$, k is not larger than $\varepsilon|S|$.

In the end, we review the following theorem from [12] that shows the close connection between synchronization string property and the self-matching property.

▶ **Theorem 11** (Theorem 6.4 from [12]). *If S is an ε-synchronization string, then all substrings of S satisfy ε-self-matching property.*

2.2 List Recoverable Codes

A code $\mathcal{C}$ given by the encoding function $\mathcal{E} : \Sigma^{nr} \to \Sigma^n$ is called to be (α, l, L)-list recoverable if for any collection of n sets $S_1, S_2, \cdots, S_n \subset \Sigma$ of size l or less, there are at most L codewords for which more than αn elements appear in the list that corresponds to their position, i.e.,

$$|\{x \in \mathcal{C} \mid |\{i \in [n] \mid x_i \in S_i\}| \geq \alpha n\}| \leq L.$$

The study of list-recoverable codes was inspired by Guruswami and Sudan's list-decoder for Reed-Solomon codes [7]. Since then, list-recoverable codes have became a very useful tool in coding theory [1, 2, 3, 4] and there have been a variety of constructions provided for them by several works [6, 8, 10, 17, 16, 11, 15]. In this paper, we will make use of the following capacity-approaching polynomial-time list-recoverable codes given by Hemenway, Ron-Zewi, and Wootters [15] that is obtained by altering the approach of Guruswami and Xing [10].

▶ **Theorem 12** (Hemenway et. al. [15, Theorem A.7]). *Let q be an even power of a prime, and choose $l, \epsilon > 0$, so that $q \geq \epsilon^{-2}$. Choose $\rho \in (0, 1)$. There is an $m_{min} = O(l \log_q(l/\epsilon)/\epsilon^2)$ so that the following holds for all $m \geq m_{min}$. For infinitely many n (all n of the form $q^{e/2}(\sqrt{q} - 1)$ for any integer e), there is a deterministic polynomial-time construction of an F_q-linear code $C : \mathbb{F}_{q^m}^{\rho n} \to \mathbb{F}_{q^m}^n$ of rate ρ and relative distance $1 - \rho - O(\epsilon)$ that is $(1 - \rho - \epsilon, l, L)$-list-recoverable in time $\text{poly}(n, L)$, returning a list that is contained in a subspace over $\mathbb{F}_q$ of dimension at most $\left(\frac{l}{\epsilon}\right)^{2^{\log^*(mn)}}$.*

3 List Decoding for Insertions and Deletions

In this section, we prove Theorem 1 by constructing a list-decodable code of rate $1 - \delta - \varepsilon$ that provides resilience against $0 < \delta < 1$ fraction of deletions and γ fraction of insertions over a constant-sized alphabet. Our construction heavily relies on the following theorem that, in the same fashion as [12], uses the technique of indexing an error correcting code with a synchronization string to convert a given list-recoverable code into an insertion-deletion code.

▶ **Theorem 13.** *Let $\mathcal{C} : \Sigma^{nR} \to \Sigma^n$ be a (α, l, L)-list recoverable code with rate R, encoding complexity T_{Enc} and decoding complexity complexity T_{Dec}. For any $\varepsilon > 0$ and $\gamma \leq \frac{l\varepsilon}{2} - 1$, by indexing $\mathcal{C}$ with an $\frac{\varepsilon^2}{4(1+\gamma)}$-synchronization string, one can obtain an L-list decodable*

insertion-deletion code $\mathcal{C}' : \Sigma^{nr} \to [\Sigma \times \Gamma]^n$ *that corrects from* $\delta < 1 - \alpha - \varepsilon$ *fraction of deletions and* γ *fraction of insertions where* $|\Gamma| = \left(\varepsilon^2/(1+\gamma)\right)^{-O(1)}$. $\mathcal{C}'$ *is encodable and decodable in* $O(T_{Enc} + n)$ *and* $O(T_{Dec} + n^2(1+\gamma^2)/\varepsilon)$ *time respectively.*

We take two major steps to prove Theorem 13. In the first step (Theorem 15), we use the synchronization string indexing technique from [12] and show that by indexing the symbols that are conveyed through an insertion-deletion channel with symbols of a synchronization string, the receiver can make *lists* of candidates for any position of the sent string such that $1-\delta-\varepsilon$ fraction of lists are guaranteed to contain the actual symbol sent in the corresponding step and the length of the lists is guaranteed to be smaller than some constant $O_{\gamma,\varepsilon}(1)$.

In the second step, we use list-recoverable codes on top of the indexing scheme to obtain a list decoding using lists of candidates for each position produced by the former step.

We start by the following lemma that directly implies the first step stated in Theorem 15.

▶ **Lemma 14.** *Assume that a sequence of* n *symbols denoted by* $x_1 x_2 \cdots x_n$ *is indexed with an* ε*-synchronization string and is communicated through a channel that suffers from up to* δn *deletions for some* $0 \leq \delta < 1$ *and* γn *insertions. Then, on the receiving end, it is possible to obtain* n *lists* $A_1, \cdots, A_n$ *such that, for any desired integer* K*, for at least* $n \cdot \left(1 - \delta - \frac{1+\gamma}{K} - K \cdot \varepsilon\right)$ *of them,* $x_i \in A_i$*. All lists contain up to* K *elements and the average list size is at most* $1+\gamma$*. These lists can be computed in* $O\left(K(1+\gamma)n^2\right)$ *time.*

Proof. The decoding algorithm we propose to obtain the lists that satisfy the guarantee promised in the statement is the global algorithm introduced in Theorem 6.14 of Haeupler and Shahrasbi [12].

Let S be the ε-synchronization string used for indexing and S' be the index portion of the received string on the other end. Note that S is pre-shared between the sender and the receiver. The decoding algorithm starts by finding a longest common substring M_1 between S and S' and adding the position of any matched element from S' to the list that corresponds to its respective match from side S. Then, it removes every symbol that have been matched from S' and repeats the previous step by finding another longest common subsequence M_2 between S and the remaining elements of S'. This procedure is repeated K times to obtain $M_1, \cdots, M_K$. This way, lists A_i are formed by including every element in S' that is matched to $S[i]$ in any of $M_1, \cdots, M_K$.

A_i contains the actual element that corresponds to $S[i]$, denoted by $S'[j]$, if and only if $S[i]$ is successfully transmitted (i.e., not removed by the adversary), appears in one of M_ks, and matches to $S[i]$ in M_k. Hence, there are three scenarios under which A_i does not contain its corresponding element $S[i]$.

1. $S[i]$ gets deleted by the adversary.
2. $S[i]$ is successfully transmitted but, as $S'[j]$ on the other side, it does not appear on any of M_ks.
3. $S[i]$ is successfully transmitted and, as $S'[j]$ on the other side, it appears in some M_k although it is matched to another element of S.

The first case happens for at most δn elements as adversary is allowed to delete up to δn many elements.

To analyze the second case, note that the sizes of M_ks descend as k grows since we pick the longest common subsequence in each step. If by the end of this procedure p successfully transmitted symbols are still not matched in any of the matchings, they form a common subsequence of size p between S and the remainder of S'. This leads to the fact that

$|M_1| + \cdots + |M_K| \geq K \cdot p$. As $|M_1| + \cdots + |M_K|$ cannot exceed $|S'|$, we have $p \leq |S'|/K$. This bounds above the number of symbols falling into the second category by $|S'|/K$.

Finally, as for the third case, we draw the reader's attention to the fact that each successfully transmitted $S[i]$ which arrives at the other end as $S'[j]$ and mistakenly gets matched to another element of S like $S[k]$ in some M_t, implies that $S[i] = S[k]$. We call the pair (i, k) *a pair of similar elements in S implied by M_t*. Note that there is an actual monotone matching M' from S to S' that corresponds to adversary's actions. As M_t and M' are both monotone, the set of similar pairs in S implied by M_t is a self-matching in S. As stated in Theorem 11, the number of such pairs cannot exceed $n\varepsilon$. Therefore, there can be at most $n\varepsilon$ successfully transmitted symbols that get mistakenly matched in M_t for any t. Hence, the number of elements falling into the third category is at most $nK\varepsilon$.

Summing up all above-mentioned bounds gives that the number of bad lists can be bounded above by $n\delta + \frac{|S'|}{K} + nK\varepsilon \leq n\left(\delta + \frac{1+\gamma}{K} + K\varepsilon\right)$. This proves the list quality guarantee. As proposed decoding algorithm computes longest common substring K many times between two strings of length n and $(1+\gamma)n$ or less, it will run in $O(K(1+\gamma)\cdot n^2)$ time. ◀

▶ **Theorem 15.** *Suppose that n symbols denoted by $x_1, x_2, \cdots, x_n$ are being communicated through a channel suffering from up to δn deletions for some $0 \leq \delta < 1$ and γn insertions for some constant $\gamma \geq 0$. If one indexes these symbols with an $\varepsilon' = \frac{\varepsilon^2}{4(1+\gamma)}$-synchronization string, then, on the receiving end, it is possible to obtain n lists $A_1, \cdots, A_n$ of size $2(1+\gamma)/\varepsilon$ such that, for at least $n \cdot (1-\delta-\varepsilon)$ of them, $x_i \in A_i$. These lists can be computed in $O\left(n^2(1+\gamma)^2/\varepsilon\right)$ time.*

Proof. Using an $\varepsilon' = \frac{\varepsilon^2}{4(1+\gamma)}$-synchronization string in the statement of Lemma 14 and choosing $K = \frac{2(1+\gamma)}{\varepsilon}$ directly gives that the runtime is $O\left(n^2(1+\gamma)^2/\varepsilon\right)$ and list hit ratio is at least $n \cdot \left(1 - \delta - \frac{1+\gamma}{K} - K \cdot \varepsilon'\right) = n \cdot (1 - \delta - \varepsilon/2 - \varepsilon/2) = n \cdot (1 - \delta - \varepsilon)$ ◀

Theorem 15 facilitates the conversion of list-recoverable error correcting codes into list-decodable insertion-deletion codes as stated in Theorem 13.

Proof of Theorem 13. To prove this, we simply index code $\mathcal{C}$, entry by entry, with an $\varepsilon' = \frac{\varepsilon^2}{4(1+\gamma)}$ synchronization string. In the decoding procedure, according to Theorem 15, the receiver can use the index portion of the received symbol to maintain lists of up to $2(1+\gamma)/\varepsilon \leq l$ candidates for each position of the sent codeword of $\mathcal{C}$ so that $1 - \delta - \varepsilon > \alpha$ fraction of those contain the actual corresponding sent message. Having such lists, the receiver can use the decoding function of $\mathcal{C}$ to obtain an L-list-decoding for $\mathcal{C}'$. Finally, the alphabet size and encoding complexity follow from the fact that synchronization strings over alphabets of size ${\varepsilon'}^{-O(1)}$ can be constructed in linear time [12, 13]. ◀

One can use any list-recoverable error correcting code to obtain insertion-deletion codes according to Theorem 13. In particular, using the efficient capacity-approaching list-recoverable code introduced by Hemenway, Ron-Zewi, and Wootters [15], one obtains the insertion-deletion codes as described in Theorem 1.

Proof of Theorem 1. By setting parameters $\rho = 1 - \delta - \frac{\varepsilon}{2}$, $l = \frac{2(\gamma+1)}{\varepsilon}$, and $\epsilon = \frac{\varepsilon}{4}$ in Theorem 12, one can obtain a family of codes $\mathcal{C}$ that achieves rate $\rho = 1 - \delta - \frac{\varepsilon}{2}$ and is (α, l, L)-recoverable in polynomial time for $\alpha = 1 - \delta - \varepsilon/4$ and some $L = \exp\left(\exp\left(\exp\left(\log^* n\right)\right)\right)$ (by treating γ and ε as constants). Such family of codes can be found over an alphabet $\Sigma_{\mathcal{C}}$ of size $q = (l/\epsilon)^{O(l/\epsilon^2)} = \left(\frac{\gamma+1}{\varepsilon^2}\right)^{O\left(\frac{\gamma+1}{\varepsilon^3}\right)} = O_{\gamma,\varepsilon}(1)$ or infinitely many integer numbers larger than q.

Plugging this family of codes into the indexing scheme from Theorem 13 by choosing the parameter $\varepsilon' = \frac{\varepsilon}{4}$, one obtains a family of codes that can recover from $1-\alpha-\varepsilon' = 1-(1-\delta-\varepsilon/4)-\varepsilon/4 = \delta$ fraction of deletions and γ-fraction of insertions and achieves a rate of $\frac{1-\delta-\varepsilon/2}{1+\log|\Sigma_S|/\log|\Sigma_{\mathcal{C}}|}$ which, by taking $|\Sigma_{\mathcal{C}}|$ large enough in terms of ε, is larger than $1-\delta-\varepsilon$. As $\mathcal{C}$ is encodable and decodable in polynomial time, the encoding and decoding complexities of the indexed code will be polynomial as well. ◀

▶ Remark. We remark that by using capacity-approaching near-linear-time list-recoverable code introduced in Theorem 7.1 of Hemenway, Ron-Zewi, and Wootters [15] in the framework of Theorem 13, one can obtain similar list-decodable insertion-deletion codes as in Theorem 1 with a randomized quadratic time decoding. Further, one can use the efficient list-recoverable in the recent work of Guruswami and Xing [11] to obtain same result as in Theorem 1 except with polylogarithmic list sizes.

4 Upper Bounds on the Rate of List-Decodable Synchronization Codes

4.1 Deletion Codes (Theorem 3)

Proof of Theorem 3. To prove this claim, we propose a strategy for the adversary which can reduce the number of strings that may possibly arrive at the receiving side to a number small enough that implies the claimed upper bound for the rate.

We start by proving the theorem for the case where δq is integer. For an arbitrary code $\mathcal{C}$, upon transmission of any codeword, the adversary can remove all occurrences of δq least frequent symbols as the total number of appearances of such symbols does not exceed δn. In case there are more deletions left, adversary may choose to remove arbitrary symbols among the remaining ones. This way, the received string would be a string of $n(1-\delta)$ symbols consisted of only $q-q\delta$ many distinct symbols. Therefore, one can bound above the size of the ensemble of strings that can possibly be received by the $|\mathcal{E}| \leq \binom{q}{q(1-\delta)} [q(1-\delta)]^{n(1-\delta)}$. As the best rate that any $L = \text{poly}(n)$-list decodable code can get is at most $\frac{\log(|\mathcal{E}|\cdot L)}{n\log q} = \frac{\log|\mathcal{E}|}{n\log q} + o(1)$, the following would be an upper bound for the best rate one might hope for.

$$\frac{\log|\mathcal{E}|}{n\log q} + o(1) = \frac{\log\binom{q}{q(1-\delta)} + n(1-\delta)(\log(q(1-\delta)))}{n\log q} + o(1) = (1-\delta)\left(1-\log_q\frac{1}{1-\delta}\right) + o(1)$$

This shows that for the case where $q\delta$ is an integer number, there are no family of codes that achieve a rate that is strictly larger than $(1-\delta)\left(1-\log_q\frac{1}{1-\delta}\right)$.

We now proceed to the general case where $\delta = d/q + \delta'$ for some integer d and $0 \leq \delta' < \frac{1}{q}$. We closely follow the idea that we utilized for the former case. The adversary can partition n sent symbols into two parts of size $nq\delta'$ and $n(1-q\delta')$, and then, similar to the former case, removes the $d+1$ least frequent symbols from the first part by performing $\frac{d+1}{q}\cdot nq\delta'$ deletions and d least frequent symbols from the second one by performing $\frac{d}{q}\cdot n(1-q\delta')$ ones. This is possible because $\frac{d+1}{q}\cdot nq\delta' + \frac{d}{q}\cdot n(1-q\delta') = n\delta$. Doing so, the string received after deletions would contain up to $q-d-1$ distinct symbols in its first $nq\delta'(1-(d+1)/q)$ positions and up to $q-d$ distinct symbols in the other $n(1-q\delta')(1-d/q)$ positions. Therefore, the size of the ensemble of strings that can be received is bounded above as follows.

$$|\mathcal{E}| \leq \binom{q}{q-d-1}[q-d-1]^{nq\delta'\left(1-\frac{d+1}{q}\right)} \cdot \binom{q}{q-d}[q-d]^{n(1-q\delta')\left(1-\frac{d}{q}\right)}$$

This bounds above the rate of any family of list-decodable insdel codes by the following.

$$\begin{aligned}
&\frac{\log|\mathcal{E}|}{n\log q}\\
&= \frac{\log\binom{q}{q-d-1} + nq\delta'\left(1-\frac{d+1}{q}\right)\log(q-d-1) + \log\binom{q}{q-d} + n(1-q\delta')\left(1-\frac{d}{q}\right)\log(q-d)}{n\log q}\\
&= q\delta'\left[\left(1-\frac{d+1}{q}\right)\left(1-\log_q\frac{1}{1-(d+1)/q}\right)\right] + (1-q\delta')\left[\left(1-\frac{d}{q}\right)\left(1-\log_q\frac{1}{1-d/q}\right)\right] \blacktriangleleft
\end{aligned}$$

4.2 Insertion Codes (Theorem 2)

Before providing the proof of Theorem 2, we first point out that any $q-1$ insertions can be essentially used as a single erasure. As a matter of fact, by inserting $q-1$ symbols around the first symbol adversary can make a $1, 2, \cdots, q$ substring around first symbol and therefore, essentially, make the receiver unable to gain any information about it. In fact, with γn insertions, the adversary can repeat this procedure around any $\left\lfloor\frac{\gamma n}{q-1}\right\rfloor$ symbols he wishes. This basically gives that, with γn insertions, adversary can *erase* $\left\lfloor\frac{\gamma n}{q-1}\right\rfloor$ many symbols. Thus, one cannot hope for finding list-decodable codes with rate $1-\frac{\gamma}{q-1}$ or more protecting against γn insertions.

Proof of Theorem 2. To prove this, consider a code $\mathcal{C}$ with rate $R \geq 1-\log_q(\gamma+1) - \gamma\left(\log_q\frac{\gamma+1}{\gamma} - \log_q\frac{q}{q-1}\right)+\varepsilon$ for some $\varepsilon > 0$. We will show that there exist c_0^n many codewords in C that can be turned into one specific string $z \in [1..q]^{n(\gamma+1)}$ with γn insertions for some constant $c_0 > 1$ that merely depends on q and ε.

First, the lower bound assumed for the rate implies that

$$|C| = q^{nR} \geq q^{n\left(1-\log_q(\gamma+1)-\gamma\left(\log_q\frac{\gamma+1}{\gamma}-\log_q\frac{q}{q-1}\right)+\varepsilon\right)}. \tag{1}$$

Let Z be a random string of length $(\gamma+1)n$ over the alphabet $[1..q]$. We compute the expected number of codewords of $\mathcal{C}$ that are subsequences of Z denoted by X.

$$\begin{aligned}
\mathbb{E}[X] &= \sum_{y\in\mathcal{C}}\Pr\{y \text{ is a subsequence of } Z\}\\
&= \sum_{y\in\mathcal{C}}\sum_{1\leq a_1<a_2<\cdots<a_n\leq n(\gamma+1)}\frac{1}{q^n}\left(1-\frac{1}{q}\right)^{a_n-n} &(2)\\
&= |\mathcal{C}|\,(q-1)^{-n}\sum_{l=n}^{n(1+\gamma)}\binom{l}{n}\left(\frac{q-1}{q}\right)^l\\
&\leq |\mathcal{C}|\,(q-1)^{-n}\,n\gamma\binom{n(1+\gamma)}{n}\left(\frac{q-1}{q}\right)^{n(1+\gamma)} &(3)\\
&= n\gamma|\mathcal{C}|(q-1)^{n\gamma}q^{-n(1+\gamma)}2^{n(1+\gamma)H\left(\frac{1}{1+\gamma}\right)+o(n)}\\
&= n\gamma|\mathcal{C}|q^{n\left(\gamma\log_q(q-1)-1-\gamma+\log_q(1+\gamma)+\gamma\log_q\frac{1+\gamma}{\gamma}\right)+o(1)}\\
&= q^{n\varepsilon+o(n)} &(4)
\end{aligned}$$

Step (2) is obtained by conditioning the probability of y being a subsequence of Z over the leftmost occurrence of y in Z indicated by $a_1, a_2, \cdots, a_n$ as indices of Z where the leftmost occurrence of y is located. In that event, Z_{a_i} has to be similar to y_i and y_i cannot appear in $Z[y_{i-1}+1, y_i-1]$. Therefore, the probability of this event is $\left(\frac{1}{q}\right)^n\left(1-\frac{1}{q}\right)^{a_n-n}$. To

verify Step (3), we show that the summation in previous step takes its largest value when $l = n(1+\gamma)$ and bound the summation above by $n\gamma$ times that term. To see that $\binom{l}{n}\left(\frac{q-1}{q}\right)^l$ is maximized for $l = n(1+\gamma)$ in $n \le l \le n(1+\gamma)$ it suffices to show that the ratio of consecutive terms is larger than one for $l \le n(1+\gamma)$:

$$\frac{\binom{l}{n}\left(\frac{q-1}{q}\right)^l}{\binom{l-1}{n}\left(\frac{q-1}{q}\right)^{l-1}} = \frac{l}{l-n}\cdot\frac{q-1}{q} = \frac{1-\frac{1}{q}}{1-\frac{n}{l}} \ge 1$$

The last inequality follows from the fact that $l \le n(\gamma+1) \le nq \Rightarrow \frac{1}{q} < \frac{n}{l}$.

Finally, by (4), there exists some $z \in [1..q]^{(a+1)n}$ to which at least $q^{\varepsilon n + o(n)}$, i.e., exponentially many codewords of $\mathcal{C}$ are subsequences. Therefore, polynomial-sized list decoding for received message z is impossible and proof is complete. ◀

5 Analysis of Random Codes

5.1 Random Insertion Codes (Theorem 7)

Proof of Theorem 7. We prove the claim by considering a random insertion code $\mathcal{C}$ that maps any $x \in [1..q]^{Rn}$ to some uniformly at random chosen member of $[1..q]^n$ denoted by $E_{\mathcal{C}}(x)$ and showing that it is possible to list-decode $\mathcal{C}$ with high probability.

Note that in an insertion channel, the original message sent by Alice is a substring of the message received on Bob's side. Therefore, a random insertion code $\mathcal{C}$ is l-list decodable if for any $z \in [1..q]^{(\gamma+1)n}$, there are at most l codewords of $\mathcal{C}$ that are subsequences of z. For some fixed $z \in [1..q]^{(\gamma+1)n}$, the probability of some uniformly at random chosen $y \in [1..q]^n$ being a substring of z can be bounded above as follows.

$$\begin{aligned}\Pr_y\{y \text{ is a subsequence of } z\} &\le \binom{(\gamma+1)n}{n} q^{-n} \\ &= 2^{n(\gamma+1)H(\frac{1}{\gamma+1})+o(n)} q^{-n} \\ &= q^{n\left(\log_q(\gamma+1)+\gamma\log_q\frac{\gamma+1}{\gamma}-1+o(1)\right)}\end{aligned}$$

Therefore, for a random code $\mathcal{C}$ of rate R and any $m_1, \cdots, m_{l+1} \in [1..q]^{nR}$ and some fixed $z \in [1..q]^{n(\gamma+1)}$:

$$\Pr\{E_{\mathcal{C}}(m_1), \cdots, E_{\mathcal{C}}(m_{l+1}) \text{ are subsequences of } z\} \le q^{n(l+1)\left(\log_q(\gamma+1)+\gamma\log_q\frac{\gamma+1}{\gamma}-1+o(1)\right)}$$

Hence, using the union bound over $z \in [1..q]^{n(\gamma+1)}$, for the random code $\mathcal{C}$:

$$\begin{aligned}&\Pr_{\mathcal{C}}\left\{\exists z \in [1..q]^{n(\gamma+1)}, m_1, \cdots, m_{l+1} \in q^{nR} \text{ s.t. } E_{\mathcal{C}}(m_1), \cdots \text{ are subsequences of } z\right\} \\ \le\ & q^{n(\gamma+1)}\left(q^{Rn}\right)^{l+1} q^{n(l+1)\left(\log_q(\gamma+1)+\gamma\log_q\frac{\gamma+1}{\gamma}-1+o(1)\right)} \\ =\ & q^{n(\gamma+1)+Rn(l+1)+n(l+1)\left(\log_q(\gamma+1)+\gamma\log_q\frac{\gamma+1}{\gamma}-1+o(1)\right)} \qquad (5)\end{aligned}$$

As long as q's exponent in (5) is negative, this probability is less than one and drops exponentially to zero as n grows.

$$\begin{aligned}& n(\gamma+1) + Rn(l+1) + n(l+1)\left(\log_q(\gamma+1) + \gamma\log_q\frac{\gamma+1}{\gamma} - 1 + o(1)\right) < 0 \\ \Leftrightarrow\quad & R < 1 - \log_q(\gamma+1) - \gamma\log_q\frac{\gamma+1}{\gamma} - \frac{\gamma+1}{l+1} + o(1) \qquad (6)\end{aligned}$$

Therefore, the family of random codes with any rate R that satisfies (6) is list-decodable with a list of size l with high probability. ◀

The analysis for random deletion codes (Theorem 6) can be found in the extended version of this article.

Abstract

In the *Sparse Linear Regression* (SLR) problem, given a $d \times n$ matrix M and a d-dimensional query q, the goal is to compute a k-sparse n-dimensional vector τ such that the error $\|M\tau - q\|$ is minimized. This problem is equivalent to the following geometric problem: given a set P of n points and a query point q in d dimensions, find the closest k-dimensional subspace to q, that is spanned by a subset of k points in P. In this paper, we present data-structures/algorithms and conditional lower bounds for several variants of this problem (such as finding the closest induced k dimensional flat/simplex instead of a subspace).

In particular, we present *approximation* algorithms for the online variants of the above problems with query time $\widetilde{O}(n^{k-1})$, which are of interest in the "low sparsity regime" where k is small, e.g., 2 or 3. For $k = d$, this matches, up to polylogarithmic factors, the lower bound that relies on the *affinely degenerate conjecture* (i.e., deciding if n points in $\mathbb{R}^d$ contains $d+1$ points contained in a hyperplane takes $\Omega(n^d)$ time). Moreover, our algorithms involve formulating and solving several geometric subproblems, which we believe to be of independent interest.

1 Introduction

The goal of the *Sparse Linear Regression* (SLR) problem is to find a sparse linear model explaining a given set of observations. Formally, we are given a matrix $M \in \mathbb{R}^{d \times n}$, and a vector $q \in \mathbb{R}^d$, and the goal is to find a vector τ that is k-sparse (has at most k non-zero entries) and that minimizes $\|q - M\tau\|_2$. The problem also has a natural query/online variant

[1] [Work on this paper was partially supported by NSF AF awards CCF-1421231, and CCF-1217462.]
[2] [This work was done while this author was at MIT.]

where the matrix M is given in advance (so that it can be preprocessed) and the goal is to quickly find τ given q.

Various variants of SLR have been extensively studied, in a wide range of fields including
(i) statistics and machine learning [15, 16],
(ii) compressed sensing [6], and
(iii) computer vision [17].
The query/online variant is of particular interest in the application described by Wright *et al.* [17], where the matrix M describes a set of image examples with known labels and q is a new image that the algorithm wants to label.

If the matrix M is generated at random or satisfies certain assumptions, it is known that a natural convex relaxation of the problem finds the optimum solution in polynomial time [3, 4]. However, in general the problem is known to be NP-Hard [13, 5], and even hard to approximate up to a polynomial factor [8] (see below for a more detailed discussion). Thus, it is likely that any algorithm for this problem that guarantees "low" approximation factor must run in exponential time. A simple upper bound for the offline problem is obtained by enumerating $\binom{n}{k}$ possible supports of τ and then solving an instance of the $d \times k$ least squares problem. This results in $n^k(d+k)^{O(1)}$ running time, which (to the best of our knowledge) constitutes the fastest known algorithm for this problem. At the same time, one can test whether a given set of n points in a d-dimensional space is degenerate by reducing it to n instances of SLR with sparsity d. The former problem is conjectured to require $\Omega(n^d)$ time [7] – this is the *affinely degenerate conjecture*. This provides a natural barrier for running time improvements (we elaborate on this below in Section 1.1.1).

In this paper, we study the complexity of the problem in the case where the sparsity parameter k is constant. In addition to the formulation above, we also consider two more constrained variants of the problem. First, we consider the *Affine SLR* where the vector τ is required to satisfy $\|\tau\|_1 = 1$, and second, we consider the *Convex SLR* where additionally τ should be non-negative. We focus on the approximate version of these problems, where the algorithm is allowed to output a k-sparse vector τ' such that $\|M\tau' - q\|_2$ is within a factor of $1+\varepsilon$ of the optimum.

Geometric interpretation. The SLR problem is equivalent to the *Nearest Linear Induced Flat* problem defined as follows. Given a set P of n points in d dimensions and a d-dimensional vector q, the task is to find a k-dimensional flat spanning a subset B of k points in P and the origin, such that the (Euclidean) distance from q to the flat is minimized. The Affine and Convex variants of SLR respectively correspond to finding the *Nearest Induced Flat* and the *Nearest Induced Simplex* problems, where the goal is to find the closest $(k-1)$-dimensional flat/simplex spanned by a subset of k points in P to the query.

Motivation for the problems studied. Given a large[3] set of items (e.g., images), one would like to store them efficiently for various purposes. One option is to pick a relatively smaller subset of representative items (i.e., support vectors), and represent all items as a combination of this *supporting set*. Note, that if our data-set is diverse and is made out of several distinct groups (say, images of the sky, and images of children), then naturally, the data items would use only some of the supporting set for representation (i.e., the representation over the

[3] *Bigger than the biggest thing ever and then some. Much bigger than that in fact, really amazingly immense, a totally stunning size, "wow, that's big", time.* – The Restaurant at the End of the Universe, Douglas Adams.

Table 1 Summary of results. Here, $S(n,d,\varepsilon)$ denotes the preprocessing time and space used by a $(1+\varepsilon)$-ANN (approximate nearest-neighbor) data-structure, and $T_Q(n,d,\varepsilon)$ denotes the query time (we assume all these bounds are at least linear in the dimension d). All the data-structures, except the last one, provide $(1+\varepsilon)$-approximation. In the nearest induced segment case (i.e., this is the offline convex SLR case) the algorithm answers a single query.

supporting set is naturally sparse). As such, it is natural to ask for a sparse representation of each item over the (sparse but still relatively large) supporting set. (As a side note, surprisingly little is known about how to choose such a supporting set in theory, and the problem seems to be surprisingly hard even for points in the plane.)

Now, when a new item arrives to the system, the task is to compute its best sparse representation using the supporting set, and we would like to do this as fast as possible (which admittedly is not going to be that fast, see below for details).

1.1 Our results

Data-structures. We present data-structures to solve the online variants of the SLR, Affine SLR and Convex SLR problems, for general value of k. Our algorithms use a provided approximate nearest-neighbor (ANN) data-structure as a black box. The new results are summarized in Table 1.

For small values of k, our algorithms offer notable improvements of the query time over the aforementioned naive algorithm, albeit at a cost of preprocessing. Below in Section 1.1.1, we show how our result matches the lower bound that relies on the affinely degenerate conjecture. Moreover, our algorithms involve formulating and solving several interesting geometric subproblems, which we believe to be of independent interest.

Conditional lower bound. We show a conditional lower bound of $\Omega(n^{k/2}/(e^k \log^{\Theta(1)} n))$, for the offline variants of all three problems. Improving this lower bound further, for the case of $k=4$, would imply a nontrivial lower bound for famous Hopcroft's problem. See full version of the paper for the description. Our conditional lower bound result presented in the full version of the paper follows by a reduction from the k-sum problem which is conjectured to require $\Omega(n^{\lceil k/2\rceil}/\log^{\Theta(1)} n)$ time (see e.g., [14], Section 5). This provides further evidence that the off-line variants of the problem require $n^{\Omega(k)}$ time.

1.1.1 Detecting affine degeneracy

Given a point set P in $\mathbb{R}^d$ (here d is conceptually small), it is natural to ask if the points are in general position – that is, all subsets of $d+1$ points are affinely independent. The *affinely degenerate conjecture* states that this problem requires $\Omega(n^d)$ time to solve [7]. This can be achieved by building the arrangement of hyperplanes in the dual, and detecting

any vertex that has $d+1$ hyperplanes passing through it. This problem is also solvable using our data-structure. (We note that since the approximation of our data structure is multiplicative, and in the reduction we only need to detect distance of 0 from larger than 0, we are able to solve the exact degeneracy problem as described next). Indeed, we instantiate Theorem 11, for $k=d$, and using a low-dimensional $(1+\varepsilon)$-ANN data-structure of Arya *et al.* [1]. Such an ANN data-structure uses $S(n,d,\varepsilon)=O(n)$ space, $O(n\log n)$ preprocessing time, and $T_Q(n,d,\varepsilon)=O(\log n+1/\varepsilon^d)=O(\log n)$ query time (for a fixed constant $\varepsilon<1$). Thus, by Theorem 11, our data structure has total space usage and preprocessing time of $\tilde{O}(n^k)$ and a query time of $\tilde{O}(n^{k-1})$. Detecting affine degeneracy then reduces to solving for each point of $q\in P$, the problem of finding the closest $(d-1)$-dimensional induced flat (i.e., passing through d points) of $P\setminus\{q\}$ to q. It is easy to show that this can be solved using our data-structure with an extra log factor[4]. This means that the total runtime (including the preprocessing and the n queries) will be $\tilde{O}(n^k)=\tilde{O}(n^d)$. Thus, up to polylogarithmic factor, the data-structure of Theorem 11 provides an optimal trade-off under the affinely degenerate conjecture. We emphasize that this reduction only rules out the existence of algorithms for online variants of our problems that improve both the preprocessing time from $O(n^k)$, and query time from $O(n^{k-1})$ by much; it does not rule out for example the algorithms with large preprocessing time (in fact much larger than n^k) but small query time.

1.2 Related work

The computational complexity of the approximate sparse linear regression problem has been studied, e.g., in [13, 5, 8]. In particular, the last paper proved a strong hardness result, showing that the problem is hard even if the algorithm is allowed to output a solution with sparsity $k'=k2^{\log^{1-\delta} n}$ whose error is within a factor of $n^c m^{1-\alpha}$ from the optimum, for any constants $\delta,\alpha>0$ and $c>1$.

The query/online version of the Affine SLR problem can be reduced to the *Nearest k-flat Search Problem* studied in [11, 2, 12], where the database consists of a set of k-flats (affine subspaces) of size N and the goal is to find the closest k-flat to a given query point q. Let P be a set of n points in $\mathbb{R}^d$ that correspond to the columns of M. The reduction proceeds by creating a database of all $N=\binom{n}{k}$ possible k-flats that pass through k points of P. However, the result of [2] does not provide multiplicative approximation guarantees, although it does provide some alternative guarantees and has been validated by several experiments. The result of [11], provides provable guarantees and fast query time of $(d+\log N+1/\varepsilon)^{O(1)}$, but the space requirement is quasi-polynomial of the form $2^{(\log N)^{O(1)}}=2^{(k\log n)^{O(1)}}$. Finally the result of [12] only works for the special case of $k=2$, and yields an algorithm with space usage $O\big(n^{14}\varepsilon^{-3}S\big(n^2,d,\varepsilon\big)\big)$ and query time $O\big(T_Q\big(n^2\varepsilon^{-4},d,\varepsilon\big)\log^2 n\big)$[5]. Similar results can be achieved for the other variants.

The SLR problem has a close relationship with the *Approximate Nearest Neighbor (ANN)* problem. In this problem, we are given a collection of N points, and the goal is to build a data structure which, given any query point q, reports the data point whose distance to the query is within a $(1+\varepsilon)$ factor of the distance of the closest point to the query. There are

[4] The details are somewhat tedious – one generates $O(\log n)$ random samples of P where each point is picked with probability half. Now, we build the data-structure for each of the random samples. With high probability, for each of the query point $q\in P$, one of the samples contains, with high probability, the d points defining the closest flat, while not containing q.

[5] The exact exponent is not specified in the main theorem of [12] and it was obtained by an inspection of the proofs in that paper.

many efficient algorithms known for the latter problem. One of the state of the art results for ANN in Euclidean space answers queries in time $(d \log(N)/\varepsilon^2)^{O(1)}$ using $(dN)^{O(1/\varepsilon^2)}$ space [10, 9].

1.3 Our techniques and sketch of the algorithms

Affine SLR (nearest flat). To solve this problem, we first fix a subset $B \subseteq P$ of $k-1$ points, and search for the closest $(k-1)$-flat among those that contain B. Note, that there are at most $n-k+1$ such flats. Each such flat f, as well as the query flat Q_{flat} (containing B and the query q), has only one additional degree of freedom, which is represented by a vector v_H (v_Q, resp.) in a $d-k+1$ space. The vector v_H that is closest to v_Q corresponds to the flat that is closest to q. This can be found approximately using standard ANN data structure, resulting in an algorithm with running time $O(n^{k-1} \cdot T_Q(n,d,\varepsilon))$. Similarly, by adding the origin to the set B, we could solve the SLR problem in a similar way.

Convex SLR (nearest simplex). This case requires an intricate combination of low and high dimensional data structures, and is the most challenging part of this work. To find the closest $(k-1)$-dimensional induced *simplex*, one approach would be to fix B as before, and find the closest corresponding flat. This will work only if the projection of the query onto the closest flat falls inside of its corresponding simplex. Because of that, we need to restrict our search to the flats of *feasible simplices*, i.e., the simplices S such that the projection of the query point onto the corresponding flat falls inside S. If we manage to find this set, we can use the algorithm for affine SLR to find the closest one. Note that finding the distance of the query to the closest non-feasible simplex can easily be computed in time n^{k-1} as the closest point of such a simplex to the query lies on its boundary which is a lower dimensional object.

Let S be the unique simplex obtained from B and an additional point p. Then we can determine whether S is feasible or not only by looking at (i) the relative positioning of p with respect to B, that is, how the simplex looks like in the flat going through S, (ii) the relative positioning of q with respect to B, and (iii) the distance between the query and the flat of the simplex. Thus, if we were given a set of simplices through B such that all their flats were at a distance r from the query, we could build a single data structure for retrieving all the feasible flats. This can be done by mapping all of them in advance onto a unified $(k-1)$ dimensional space (the "parameterized space"), and then using $k-1$ dimensional orthogonal range-searching trees in that space.

However, the minimum distance r is not known in general. Fortunately, as we show the feasibility property is monotone in the distance: the farther the flat of the simplex is from the query point, the weaker constraints it needs to satisfy. Thus, given a threshold value r, our algorithm retrieves the simplices satisfying the restrictions they need to satisfy if they were at a distance r from the query. This allows us to use binary search for finding the right value of r by random sampling. The final challenge is that, since our access is to an approximate NN data structure (and not an exact one), the above procedure yields a superset of feasible simplices. The algorithm then finds the closest flat corresponding to the simplices in this superset. We show that although the reported simplex may not be feasible, its distance to the query is still approximately at most r.

For overview of the offline nearest segment, and conditional lower bound, see the full version.

2 Preliminaries

2.1 Notations

Throughout the paper, we assume $P \subseteq \mathbb{R}^d$ is the set of input points which is of size n. In this paper, for simplicity, we assume that the point-sets are non-degenerate, however this assumption is not necessary for the algorithms. We use the notation $X \subset_i B$ to denote that X is a subset of B of size i, and use $\mathbf{0}$ to denote the origin. For two points $y, u \in \mathbb{R}^d$, the segment the form is denoted by yu, and the line formed by them by $\mathrm{line}(y, u)$.

▶ **Definition 1.** For a set of points S, let $\mathsf{f}_S = \mathrm{aff}(S) = \left\{ \sum_{i=1}^{|S|} \alpha_i p_i \;\middle|\; p_i \in S, \text{ and } \sum_{i=1}^{|S|} \alpha_i = 1 \right\}$ be the $(|S|-1)$-dimensional flat (or $(|S|-1)$-*flat* for short) passing through the points in the set S (aka the *affine hull* of S). The $(|S|-1)$-dimensional simplex ($(|S|-1)$-*simplex* for short) that is formed by the convex-hull of the points of S is denoted by $\triangle_S$. We denote the *interior* of a simplex $\triangle_S$ by $\mathrm{int}(\triangle_S)$.

▶ **Definition 2** (distance and nearest-neighbor)**.** For a point $q \in \mathbb{R}^d$, and a point $p \in \mathbb{R}^d$, we use $\mathsf{d}(q, p) = \|q - p\|_2$ to denote the *distance* between q and p. For a closed set $X \subseteq \mathbb{R}^d$, we denote by $\mathsf{d}(q, X) = \min_{p \in X} \|q - p\|_2$ the *distance* between q and X. The point of X realizing the distance between q and X is the *nearest neighbor* to q in X, denoted by $\mathsf{nn}(q, X)$. We sometimes refer to $\mathsf{nn}(q, X)$ as the *projection* of q onto X.

More generally, given a finite family of such sets $\mathcal{G} = \left\{ X_i \subseteq \mathbb{R}^d \;\middle|\; i = 1, \ldots, m \right\}$, the *distance* of q from $\mathcal{G}$ is $\mathsf{d}(q, \mathcal{G}) = \min_{X \in \mathcal{G}} \mathsf{d}(q, X)$. The *nearest-neighbor* $\mathsf{nn}(q, \mathcal{G})$ is defined analogously to the above.

▶ Assumption 3. Throughout the paper, we assume we have access to a data structure that can answer $(1+\varepsilon)$-ANN queries on a set of n points in $\mathbb{R}^d$. We use $S(n, d, \varepsilon)$ to denote the space requirement of this data structure, and by $T_Q(n, d, \varepsilon)$ to denote the query time.

2.1.1 Induced stars, bouquets, books, simplices and flats

▶ **Definition 4.** Given a point b and a set P of points in $\mathbb{R}^d$, the *star* of P, with the base b, is the set of segments $\mathrm{star}(b, P) = \{ bp \mid p \in P \setminus \{b\} \}$. Similarly, given a set B of points in $\mathbb{R}^d$, with $|B| = k - 1 \leq d$, the *book* of P, with the base B, is the set of simplices $\boldsymbol{\Delta}(B, P) = \left\{ \triangle_{B \cup \{p\}} \;\middle|\; p \in P \setminus B \right\}$. Finally, the set of flats induced by these simplices, is the *bouquet* of P, denoted by $\mathrm{bqt}(B, P) = \left\{ \mathsf{f}_{B \cup \{p\}} \;\middle|\; p \in P \setminus B \right\}$.

If B is a single point, then the corresponding book is a star, and the corresponding bouquet is a set of lines all passing through the single point in B.

▶ **Definition 5.** For a set $P \subseteq \mathbb{R}^d$, let $\mathcal{L}_k(P) = \left\{ \mathsf{f}_{S \cup \{\mathbf{0}\}} \;\middle|\; S \subset_k P \right\}$ be the set of all linear k-dimensional subspaces induced by P, and $\mathcal{F}_k(P) = \{ \mathsf{f}_S \mid S \subset_k P \}$ be the set of all $(k-1)$-flats induced by P. Similarly, let $\boldsymbol{\Delta}_k(P) = \{ \triangle_S \mid S \subset_k P \}$ be the set of all $(k-1)$-simplices induced by P.

2.2 Problems

In the following, we are given a set P of n points in $\mathbb{R}^d$, a query point q and parameters k and $\varepsilon > 0$. We are interested in the following problems:

I. *SLR* (nearest induced linear subspace): Compute $\mathsf{nn}\big(q, \mathcal{L}_k(P)\big)$.
II. *ANLIF* (approximate nearest linear induced flat): Compute a k-flat $\mathsf{f} \in \mathcal{L}_k(P)$, such that $\mathsf{d}(q, \mathsf{f}) \leq (1+\varepsilon)\mathsf{d}(q, \mathcal{L}_k(P))$.

III. *Affine SLR* (nearest induced flat): Compute $\mathsf{nn}\big(q, \mathcal{F}_k(P)\big)$.
IV. *ANIF* (Approximate Nearest Induced Flat): Compute a $(k-1)$-flat $\mathsf{f} \in \mathcal{F}_k(P)$, such that $\mathsf{d}(q, \mathsf{f}) \leq (1+\varepsilon)\mathsf{d}(q, \mathcal{F}_k(P))$.
V. *Convex SLR* (Nearest Induced Simplex): Compute $\mathsf{nn}\big(q, \mathbf{\Delta}_k(P)\big)$.
VI. *ANIS* (Approximate Nearest Induced Simplex): Compute a $(k-1)$-simplex $\triangle \in \mathbf{\Delta}_k(P)$, such that $\mathsf{d}(q, \triangle) \leq (1+\varepsilon)\mathsf{d}(q, \mathbf{\Delta}_k(P))$.

Here, the parameter k corresponds to the *sparsity* of the solution.

3 Approximating the nearest induced flats and subspaces

Here, we show how to solve approximately the online variants of SLR and affine SLR problems. These are later used in Section 4. We start with the simplified case of the uniform star.

3.1 Approximating the nearest neighbor in a uniform star

Input & task. We are given a base point b, a set P of n points in $\mathbb{R}^d$, and a parameter $\varepsilon > 0$. We assume that $\|b - p\| = 1$, for all $p \in P$. The task is to build a data structure that can report quickly, for a query point q that is also at distance one from b, the $(1+\varepsilon)$-ANN segment to q in $\mathrm{star}(b, P)$.

Preprocessing. The algorithm computes the set $V = \{p - b \mid p \in P \setminus \{b\}\}$, which lies on a unit sphere in $\mathbb{R}^d$. Next, the algorithm builds a data structure $\mathcal{D}_V$ for answering $(1+\varepsilon)$-ANN queries on V.

Answering a query. For a query point q, the algorithm does the following:
(A) Compute $\tau = q - b$.
(B) Compute $(1+\varepsilon)$-ANN to τ in V, denoted by u using $\mathcal{D}_V$.
(C) Let y be the point in P corresponding to u.
(D) Return $\min\big(\mathsf{d}(q, by),\, 1\big)$.

▶ **Lemma 6.** *Consider a base point b, and a set P of n points in $\mathbb{R}^d$ all on $\mathbb{S}(b,1)$, where $\mathbb{S} = \mathbb{S}(b,1)$ is the sphere of radius 1 centered at b. Given a query point $q \in \mathbb{S}$, the above algorithm reports correctly a $(1+\varepsilon)$-ANN in $\mathrm{star}(b, P)$. The query time is dominated by the time to perform a single $(1+\varepsilon)$-ANN query. (Proof in the full version)*

3.2 Approximating the nearest flat in a bouquet

▶ **Definition 7.** For a set X and a point p in $\mathbb{R}^d$, let $p' = \mathsf{nn}(p, X)$. We use $\mathsf{dir}(X, p)$ to denote the unit vector $(p - p')/\|p - p'\|$, which is the *direction* of p in relation to X.

Input & task. We are given sets B and P of $k-1$ and n points, respectively, in $\mathbb{R}^d$, and a parameter $\varepsilon > 0$. The task is to build a data structure that can report quickly, for a query point q, a $(1+\varepsilon)$-ANN flat to q in $\mathrm{bqt}(B, P)$, see Definition 4.

Preprocessing. Let $F = \mathsf{f}_B$. The algorithm computes the set

$$V = \{\mathsf{dir}(F, p), -\mathsf{dir}(F, p) \mid p \in P \setminus B\},$$

which lies on a $d-k+2$ dimensional unit sphere in $\mathbb{R}^{d-k+1}$, and then builds a data structure $\mathcal{D}_V$ for answering (standard) ANN queries on V.

Answering a query. For a query point q, the algorithm does the following:
(A) Compute $\tau = \mathsf{dir}(F, q)$.
(B) Compute ANN to τ in V, denoted by u using the data structure $\mathcal{D}_V$.
(C) Let p be the point in P corresponding to u.
(D) Return the distance $\mathsf{d}(q, \mathsf{f}_{B\cup\{p\}})$.

▶ **Definition 8.** For sets $X, Y \subseteq \mathbb{R}^d$, let $\mathsf{proj}_X(Y) = \{\mathsf{nn}(q, X) \mid q \in Y\}$ be the *projection* of Y on X.

▶ **Lemma 9.** *Consider two affine subspaces $F \subseteq H$ with a base point $b \in F$, and the orthogonal complement affine subspace $F^\perp = \left\{b + \tau \;\middle|\; \langle \tau, u - v\rangle = 0 \text{ for all } u, v \in F, \tau \in \mathbb{R}^d\right\}$. For an arbitrary point $q \in \mathbb{R}^d$, let $q^\perp = \mathsf{proj}_{F^\perp}(q)$. We have that $\mathsf{d}(q, H) = \mathsf{d}(q^\perp, \mathsf{proj}_{F^\perp}(H))$. (Proof in the full version)*

Using the notation of Assumption 3 and Definition 4, we have the following:

▶ **Lemma 10** (ANN flat in a bouquet)**.** *Given sets B and P of $k-1$ and n points, respectively, in $\mathbb{R}^d$, and a parameter $\varepsilon > 0$, one can preprocess them, using a single ANN data structure, such that given a query point, the algorithm can compute a $(1+\varepsilon)$-ANN to the closest $(k-1)$-flat in $\mathrm{bqt}(B, P)$. The algorithm space and preprocessing time is $O(S(n, d, \varepsilon))$, and the query time is $O(T_Q(n, d, \varepsilon))$. (Proof in the full version)*

3.3 The result

Here, we show simple algorithms for the ANIF and the ANLIF problems by employing Lemma 10. We assume $\varepsilon > 0$ is a prespecified approximation parameter.

Approximating the affine SLR. As discussed earlier, the goal is to find an approximately closest $(k-1)$-dimensional flat that passes through k points of P, to the query. To this end, we enumerate all possible $k-1$ subsets of points of $B \subset_{k-1} P$, and build for each such base set B, the data structure of Lemma 10. Given a query, we compute the ANN flat in each one of these data structures, and return the closest one found.

▶ **Theorem 11.** *The aforementioned algorithm computes a $(1+\varepsilon)$-ANN to the closest $(k-1)$-flat in $\mathcal{F}_k(P)$, see Definition 5. The space and preprocessing time is $O(n^{k-1}S(n, d, \varepsilon))$, and the query time is $O(n^{k-1}T_Q(n, d, \varepsilon))$.*

Approximating the SLR. The goal here is to find an approximately closest k-dimensional flat that passes through k points of P and the origin $\mathbf{0}$, to the query. We enumerate all possible $k-1$ subsets of points of $B' \subset_{k-1} P$, and build for each base set $B = B' \cup \{\mathbf{0}\}$, the data structure of Lemma 10. Given a query, we compute the ANN flat in each one of these data structures, and return the closest one found.

▶ **Theorem 12.** *The aforementioned algorithm computes a $(1+\varepsilon)$-ANN to the closest k-flat in $\mathcal{L}_k(P)$, see Definition 5, with space and preprocessing time of $O(n^{k-1}S(n, d, \varepsilon))$, and the query time of $O(n^{k-1}T_Q(n, d, \varepsilon))$.*

4 Approximating the nearest induced simplex

In this section we consider the online variant of the ANIS problem. Here, we are given the parameter k, and the goal is to build a data structure, such that given a query point q, it can find a $(1+\varepsilon)$-ANN induced $(k-1)$-simplex.

As before, we would like to fix a set B of $k-1$ points and look for the closest simplex that contains B and an additional point from P. The plan is to filter out the simplices for which the projection of the query on to them falls outside of the interior of the simplex. Then we can use the algorithm of the previous section to find the closest flat corresponding to the feasible simplices (the ones that are not filtered out). First we define a canonical space and map all these simplices and the query point to a unique $(k+1)$-dimensional space. As it will become clear shortly, the goal of this conversion is to have a common lower dimensional space through which we can find all feasible simplices using range searching queries.

4.1 Simplices and distances

4.1.1 Canonical realization

In the following, we fix a sequence $B = (p_1, \ldots, p_{k-1})$ of $k-1$ points in $\mathbb{R}^d$. We are interested in arguing about simplices induced by $k+1$ points, i.e., B, an additional input point p_k, and a query point q. Since the ambient dimension is much higher (i.e., d), it would be useful to have a common canonical space, where we can argue about all entities.

▶ **Definition 13.** For a given set of points B, let $F = \mathsf{f}_B$. Let $p \notin F$ be a given point in $\mathbb{R}^d$, and consider the two connected components of $\mathsf{f}_{B\cup\{p\}} \setminus F$, which are *halfflats*. The halfflat containing p is the *positive halfflat*, and it is denoted by $\mathsf{f}^+(B, p)$.

Fix some arbitrary point $\boldsymbol{s}^* \in \mathbb{R}^d \setminus F$, and let $G = \mathsf{f}^+(B, \boldsymbol{s}^*)$ be a *canonical* such halfflat. Similarly, for a fixed point $\boldsymbol{s}^{**} \in \mathbb{R}^d \setminus \mathsf{f}_{B\cup\{\boldsymbol{s}^*\}}$, let $H = \mathsf{f}^+(B \cup \boldsymbol{s}^*, \boldsymbol{s}^{**})$. Conceptually, it is convenient to consider $H = \mathbb{R}^{k-2} \times \mathbb{R} \times \mathbb{R}^+$, where the first $k-2$ coordinates correspond to F, and the first $k-1$ coordinates correspond to G (this can be done by applying a translation and a rotation that maps H into this desired coordinates system). This is the *canonical parameterization* of H.

The following observation formalizes the following: Given a $(k-1)$ dimensional halfflat G passing through B, a point on G is uniquely identified by its distances from the points in B.

▶ **Observation 14.** *Given a sequence of distances $\boldsymbol{\ell} = (\ell_1, \ldots, \ell_{k-1})$, there might be only one unique point $p = p_G(\boldsymbol{\ell}) \in G$, such that $\|p - p_i\| = \ell_i$, for $i = 1, \ldots, k-1$. Such a point might not exist at all*[6].

Next, given G and H, a point q and a value $\ell < \mathsf{d}(q, F)$, we aim to define the points $q_G(\ell)$ and $q_H(\ell)$. Consider a point $q \in \mathbb{R}^d \setminus F$ (not necessarily the query point), and consider any positive $(k-1)$-halfflat g that contains B, and is in distance ℓ from q. Furthermore assume that $\ell = \mathsf{d}(q, \mathsf{g}) < \mathsf{d}(q, F)$. Let q_{g} be the projection of q to g. Observe that, by the Pythagorean theorem, we have that $d_i = \|q_{\mathsf{g}} - p_i\| = \sqrt{\|q - p_i\|^2 - \ell^2}$, for $i = 1, \ldots, k-1$. Thus, the above observation implies, that the canonical point $q_G(\ell) = p_G(d_1, \ldots, d_{k-1})$ (see Observation 14) is uniquely defined. Note that this is somewhat counterintuitive as the flat g and thus the point q_{g} are not uniquely defined. Similarly, there is a unique point $q_H(\ell) \in H$, such that:

- **(i)** the projection of $q_H(\ell)$ to G is the point $q_G(\ell)$,
- **(ii)** $\|q_H(\ell) - q_G(\ell)\| = \ell$, and these two also imply that
- **(iii)** $\|q_H(\ell) - p_i\| = \|q - p_i\|$, for $i = 1, \ldots, k-1$.

[6] *Trilateration* is the process of determining the location of $p \in G$ given $\boldsymbol{\ell}$. *Triangulation* is the process of determining the location when one knows the angles (not the distances).

Therefore, given G and H, a point q and a value $\ell < \mathsf{d}(q, F)$, the points $q_G(\ell)$ and $q_H(\ell)$ are uniquely defined. Intuitively, for a halfflat that passes through B and is at distance ℓ from the query, $q_G(\ell)$ models the position of the projection of the query onto the halfflat, and $q_H(\ell)$ models the position of the query point itself with respect to this halfflat. Next, we prove certain properties of these points.

4.1.2 Orbits

▶ **Definition 15.** For a set of points B in $\mathbb{R}^d$, define Φ_B to be the open set of all points in $\mathbb{R}^d$, such that their projection into F lies in the interior of the simplex $\triangle_B = \text{ConvexHull}(B)$. The set Φ_B is a *prism*.

Consider a query point $q \in \Phi_B$, and its projection $q_B = \mathsf{nn}(q, F)$. Let $r = \mathrm{r}_B(q) = \|q - q_B\|$ be the *radius* of q in relation to B. Using the above canonical parameterization, we have that $q_G(0) = (q_B, r)$, and $q_H(0) = (q_G(0), 0) = (q_B, r, 0)$. More generally, for $\ell \in [0, r]$, we have

$$q_G(\ell) = \left(q_B, \sqrt{r^2 - \ell^2}\right) \qquad \text{and} \qquad q_H(\ell) = \left(q_B, \sqrt{r^2 - \ell^2}, \ell\right). \tag{1}$$

The curve traced by $q_H(\ell)$, as ℓ varies from 0 to r, is the *orbit* of q – it is a quarter circle with radius r. The following lemma states a monotonicity property that is the basis for the binary search over the value of ℓ.

▶ **Lemma 16.** *(i) Define $\widehat{q}(\ell) = \left(\sqrt{r^2 - \ell^2}, \ell\right)$, and consider any point $p = (x, 0)$, where $x \geq 0$. Then, the function $d(\ell) = \|\widehat{q}(\ell) - p\|$ is monotonically increasing for $\ell \in [0, r]$.*

(ii) For any point p in the halfflat G, the function $\|q_H(\ell) - p\|$ is monotonically increasing. (Proof in the full version).

4.1.3 Distance to a simplex via distance to the flat

▶ **Definition 17.** Given a point q, and a distance ℓ, let $\triangle_G(q, \ell)$ be the unique simplex in G, having the points of B and the point $q_G(\ell)$ as its vertices. Similarly, let $\triangle_G(q) = \triangle_G(q, 0)$.

Next, we provide the necessary and sufficient conditions for a simplex to be feasible. This lemma lies at the heart of our data structure.

▶ **Lemma 18.** *(Proof in the full version) Given a query point $q \in \Phi_B$, and a point $p_k \in P \setminus B$, for a number $0 < x \leq \mathsf{d}(q, F)$ we have*

(A) $q_G(x) \in \triangle_G(p_k)$ *and* $\mathsf{d}(q, \mathsf{f}^+(B, p_k)) \leq x \implies \mathsf{d}(q, \triangle_{B \cup \{p_k\}}) \leq x$.

(B) $\mathsf{d}(q, \triangle_{B \cup \{p_k\}}) \leq x$ *and* $q \in \Phi_{B \cup \{p_k\}} \implies q_G(x) \in \triangle_G(p_k)$ *and* $\mathsf{d}(q, \mathsf{f}^+(B, p_k)) \leq x$.

4.2 Approximating the nearest page in a book

▶ **Definition 19.** Let P be a set of n points in $\mathbb{R}^d$, and let B be a sequence of $k - 1$ points. Consider the set of simplices having B and one additional point from P; that is, $\mathbf{\Delta} = \mathbf{\Delta}(B, P) = \left\{\triangle_{B \cup \{p\}} \;\middle|\; p \in P \setminus B\right\}$. The set $\mathbf{\Delta}$ is the *book* induced by (B, P), and to a single simplex in this book is (naturally) a *page*.

The task at hand, is to preprocess $\mathbf{\Delta}$ for ANN queries, as long as (i) the nearest point lies in the interior of one of these simplices and (ii) $q \in \Phi_B$. To this end, we consider the canonical representation of this set of simplices $\mathbf{\Delta}_G = \{\triangle_G(p) \mid p \in P \setminus B\}$.

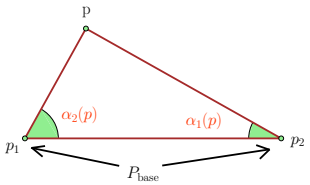

Figure 1 Example base angles when $k = 3$

Idea. The algorithm follows Lemma 18 (A). Given a query point, using standard range-searching techniques, we extract a small number of canonical sets of the points, that in the parametric space, their simplex contains the parameterized query point. This is described in Section 4.2.1. For each of these canonical sets, we use the data structure of Lemma 10 to quickly query each one of these canonical sets for their nearest positive flat (see Remark 4.2.2 below). This would give us the desired ANN.

4.2.1 Reporting all simplices containing a point

▶ **Definition 20.** Let $B = (p_1, \ldots, p_{k-1})$ be a sequence of $k-1$ points in $\mathbb{R}^d$. For a point $p \in \mathbb{R}^d$, consider the $(k-1)$-simplex $\triangle_{B\cup\{p\}}$, which is a full dimensional simplex in the flat $\mathsf{f}_{B\cup\{p\}}$ (see Definition 1). The *base angles* of p (with respect to B), is the $(k-1)$-tuple $\boldsymbol{\alpha}_B(p) = \big(\alpha_1(p), \ldots, \alpha_{k-1}(p)\big)$, where $\alpha_i(p)$ is the dihedral angle between the facet $\triangle_{B\cup\{p\}\setminus\{p_i\}}$ and the base facet $\triangle_B$. See Figure 1, where $k = 3$.

▶ **Observation 21** (Inclusion and base angles). *Let B be a set of $k-1$ points in $\mathbb{R}^{k-1}$ all with their $(k-1)$th coordinate being zero, and let p be an additional point with its $(k-1)$th coordinate being a positive number. Then, for a point $q \in \mathbb{R}^{k-1}$, we have that $q \in \triangle_{B\cup\{p\}} \iff \boldsymbol{\alpha}_B(q) \le \boldsymbol{\alpha}_B(p)$ (i.e., $(\forall i : \alpha_i(q) \le \alpha_i(p))$.*

▶ **Lemma 22.** *Given a set n of $(k-1)$-simplices $\boldsymbol{\Delta}_G$ in $\mathbb{R}^{k-1}$, that all share common $k-1$ vertices, one can build a data structure of size $O(n \log^{k-1} n)$, such that given a query point $q \in \mathbb{R}^{k-1}$, one can compute $O(\log^{k-1} n)$ disjoint canonical sets, such that the union of these sets, is the set of all simplices in $\boldsymbol{\Delta}_G$ that contain q. The query time is $O(\log^{k-1} n)$. (Proof in the full version)*

▶ **Lemma 23.** *The data structure of Lemma 22 can be used to report all simplices that contain a specific point p, and do not contain another point p', which is vertically above p (i.e., the same point with larger $(k-1)$th coordinate). This corresponds to k (possibly unbounded) box queries instead of quadrant query in the orthogonal data structure. The query time and number of canonical sets will be multiplied by at most k. The space bound remains the same. Moreover, we ensure these set of k boxes are disjoint. (Proof in the full version)*

4.2.2 Data structure and correctness

▶ Remark. For a set of points P and a base set B, consider the set of positive halfspaces (the *positive bouquet*) $\mathrm{bqt}^+(B, P) = \{\mathsf{f}^+(B, p) \mid p \in P \setminus B\}$. We can preprocess such a set for ANN queries readily, by using the data structure of Lemma 10. The only modification is that for every positive flat we assign one vector (in the positive direction), instead of two vectors in both directions which we put in the data structure of Section 3.2.

Preprocessing. The algorithm computes the set of canonical simplices $\mathbf{\Delta}_G$, see Eq. (4.2). Next, the algorithm builds the data structure of Lemma 22 for this set of simplices. For each canonical set V in this data structure, for the corresponding set of original points, we build the data structure of Remark 4.2.2 to answer ANN queries on the positive bouquet $\mathrm{bqt}^+(B, V)$. (Observe that the total size of these canonical sets is $O(n \log^{k-1} n)$.)

Answering a query. Given a query point $q \in \Phi_B$, the algorithm computes its projection $q_B = \mathsf{nn}(q, F)$, where $F = \mathsf{f}_B$. Let $r = \|q - q_B\|$ be the radius of q. The desired ANN distance is somewhere in the interval $[0, r]$, and the algorithm maintains an interval $[\alpha, \beta]$ where this distance lies, and uses binary search to keep pruning away on this interval, till reaching the desired approximation.

Observe that for every point $p \in P$, there is a critical value $\gamma(p)$, such that for $x \geq \gamma(p)$, the parameterized point $q_G(x)$ is inside the simplex $\triangle_G(p)$, and is outside if $x < \gamma(p)$. Note that this statement only holds for queries in Φ_B (otherwise it could have been false on simplices $\triangle_{B \cup \{p\}}$ with obtuse angles, see Remark 4.3 for handling the case of $q \notin \Phi_B$).

Now, by Lemma 23, we can compute a polylogarithmic number of canonical sets, such that the union of these sets, are (exactly) all the points with critical values in the range $[\alpha, \beta)$. As long as the number of critical values is at least one, we randomly pick one of these values (by sampling from the canonical sets – one can assume each canonical set is stored in an array), and let γ be this value. We have to decide if the desired ANN is smaller or larger than γ. To this end, we compute a representation, by polylogarithmic number of canonical sets, of all the points of P such that their simplex contains the parameterized point $q_G(\gamma)$, using Lemma 22. For each such canonical set, the algorithm computes the approximate closest positive halfflat, see Remark 4.2.2. Let τ be the minimum distance of such a halfflat computed. If this distance is smaller than γ, then the desired ANN is smaller than γ, and the algorithm continues the search in the interval $[\alpha, \gamma)$, otherwise, the algorithm continues the search in the interval $[\gamma, \beta)$.

After logarithmic number of steps, in expectation, we have an interval $[\alpha', \beta')$, that contains no critical value in it, and the desired ANN distance lies in this interval. We compute the ANN positive flats for all the points that their parameterized simplex contains $q_G(\beta')$, and we return this as the desired ANN distance.

For proof of correctness and query time analysis see the full version.

▶ **Lemma 24** (Approximate nearest induced page)**.** *Given a set P of n points in $\mathbb{R}^d$, a set B of $k-1$ points, and a parameter $\varepsilon > 0$, one can preprocess them, such that given a query point, the algorithm computes an $(1+\varepsilon)$-ANN to the closest page in $\mathbf{\Delta}(B, P)$, see Definition 19. This assumes that (i) the nearest point to the query lies in the interior of the nearest page, and (ii) $q \in \Phi_B$. The algorithm space and preprocessing time is $O(S(n, d, \varepsilon) \log^k n)$, and the query time is $O(T_Q(n, d, \varepsilon) \log^k n)$.*

4.3 Result: nearest induced simplex

The idea is to use brute-force to handle the distance of the query to the $\leq (k-2)$-simplices induced by the given point set which takes $O(n^{k-1})$ time. As such, the remaining task is to handle the $(k-1)$-simplices, and thus we can assume that the nearest point to the query lies in the interior of the nearest simplex, as desired by Lemma 24. To this end, we generate the $\binom{n}{k-1} = O(n^{k-1})$ choices for $B \subseteq P$, and for each one of them we build the data structure of Lemma 24, and query each one of them, returning the closet one found.

▶ Remark. Note that for a set of k points $X \subset_k P$, if the projection of the query onto the simplex $\triangle_A$ falls inside the simplex, i.e. $q \in \Phi_A$, then there exists a subset of $k-1$ points $B \subset_{k-1} X$ such that the projection of the query onto the simplex $\triangle_B$ falls inside the simplex, i.e., $q \in \Phi_B$. Therefore, either the brute-force component of the algorithm finds an ANN, or there exists a set B for which the corresponding data structure reports the correct ANN.

We thus get the following result.

▶ **Theorem 25** (Convex SLR). *Given a set P of n points in $\mathbb{R}^d$, and parameters k and $\varepsilon > 0$, one can preprocess them, such that given a query point, the algorithm can compute a $(1+\varepsilon)$-ANN to the closest $(k-1)$-simplex in $\mathbf{\Delta}_k(P)$, see Definition 5. The algorithm space and preprocessing time is $O(n^{k-1} S(n,d,\varepsilon) \log^k n)$, and the query time is $O(n^{k-1} T_Q(n,d,\varepsilon) \log^k n)$.*

Abstract

This paper presents the first polynomial time algorithm to compute geodesics in a CAT(0) cubical complex in general dimension. The algorithm is a simple iterative method to update breakpoints of a path joining two points using Miller, Owen and Provan's algorithm (Adv. in Appl. Math, 2015) as a subroutine. Our algorithm is applicable to any CAT(0) space in which geodesics between two close points can be computed, not limited to CAT(0) cubical complexes.

1 Introduction

Computing a shortest path in a polyhedral domain in Euclidean space is a fundamental and important algorithmic problem, which is intensively studied in computational geometry [16]. This problem is relatively easy to solve in the two-dimensional case; it can generally be reduced to a discrete graph searching problem where some combinatorial approaches can be applied. In three or more dimensions, however, the problem becomes much harder; it is not even discrete. In fact, it was proved by Canny and Reif [8] that the shortest path problem in a polyhedral domain is NP-hard. Mitchell and Sharir [17] have shown that the problem of finding a shortest obstacle-avoiding path is NP-hard even for the case of a region with obstacles that are disjoint axis-aligned boxes. On the other hand, there are some cases where one can obtain polynomial time complexity. For instance, it was shown by Sharir [24] that a shortest obstacle-avoiding path among k disjoint convex polyhedra having altogether n vertices, can be found in $n^{O(k)}$ time, which implies that this problem is polynomially solvable if k is a small constant.

What determines the tractability of the shortest path problem in geometric domains? One of promising answers to this challenging question is *global non-positive curvature*, or *CAT(0) property* [14]. CAT(0) spaces are metric spaces in which geodesic triangles are "not thicker" than those in the Euclidean plane, and enjoy various fascinating properties generalizing those in Euclidean and hyperbolic spaces. As Ghrist and LaValle [13] observed, no NP-hard example in [17] is a CAT(0) space. One of the significant properties of CAT(0)

spaces is the uniqueness of geodesics: Every pair of points can be joined by a unique geodesic. Computational and algorithmic theory on CAT(0) spaces is itself a challenging research field [5].

One of fundamental and familiar CAT(0) spaces is a *CAT(0) cubical complex*. A cubical complex is a polyhedral complex where each cell is isometric to a unit cube of some dimension and the intersection of any two cells is empty or a single face. Gromov [14] gave a purely combinatorial characterization of cubical complexes of non-positive curvature as cubical complexes in which the link of each vertex is a flag simplicial complex. Chepoi [9] and Roller [22] established that the 1-skeletons of CAT(0) cubical complexes are exactly *median graphs*, i.e., graphs in which any three vertices admit a unique median vertex. It is also shown by Barthélemy and Constantin [4] that median graphs are exactly the domains of event structures [18]. These nice combinatorial characterizations are one of the main reasons why CAT(0) cubical complexes frequently appear in mathematics, for instance, in geometric group theory [22, 23], metric graph theory [3], concurrency theory in computer science [18], theory of reconfigurable systems [1, 12], and phylogenetics [6].

There has been several polynomial time algorithms to find shortest paths in some CAT(0) cubical complexes. A noteworthy example is for a *tree space*, introduced by Billera, Holmes and Vogtmann [6] as a continuous space of phylogenetic trees. This space is shown to be CAT(0), and consequently provides a powerful tool for comparing two phylogenetic trees through the unique geodesic. Owen and Provan [19, 20] gave a polynomial time algorithm for finding geodesics in tree spaces, which was generalized by Miller et al. [15] to *CAT(0) orthant spaces*, i.e., complexes of Euclidean orthants that are CAT(0). Chepoi and Maftuleac [10] gave an efficient polynomial time algorithm to compute geodesics in a two dimensional CAT(0) cubical complex. These meaningful polynomiality results naturally lead to a question: What about arbitrary CAT(0) cubical complexes?

Ardila, Owen and Sullivant [2] gave a combinatorial description of CAT(0) cubical complexes, employing a poset endowed with an additional relation, called a *poset with inconsistent pairs (PIP)*. This can be viewed as a generalization of Birkhoff's theorem that gives a compact representation of distributive lattices by posets. In fact, they showed that there is a bijection between CAT(0) cubical complexes and PIPs. (Through the above-mentioned equivalence, this can be viewed as a rediscovery of the result of Barthélemy and Constantin [4], who found a bijection between PIPs and pointed median graphs.) This relationship enables us to express an input CAT(0) cubical complex as a PIP: For a poset with inconsistent pairs P, the corresponding CAT(0) cubical complex $\mathcal{K}_P$ is realized as a subcomplex of the $|P|$-dimensional cube $[0,1]^P$ in which the cells of $\mathcal{K}_P$ are specified by structures of P. Adopting this embedding as an input, they gave the first algorithm to compute geodesics in an arbitrary CAT(0) cubical complex. Their algorithm is based on an iterative method to update a sequence of cubes that may contain the geodesic, where at each iteration it solves a touring problem using second order cone programming [21]. They also showed that the touring problem for general CAT(0) cubical complexes has intrinsic algebraic complexity, and geodesics can have breakpoints whose coordinates have nonsolvable Galois group. This implies that there is no exact simple formula for the geodesic and therefore in general, one can only obtain an approximate one. Unfortunately, even if the touring problem could be solved exactly, it is not known whether or not their algorithm is a polynomial one; that is, no polynomial time algorithm has been known for the shortest path problem in a CAT(0) cubical complex in general dimension.

Main result. In this paper, we present the first polynomial time algorithm to compute geodesics in a CAT(0) cubical complex in general dimension, answering the open question suggested by these previous work; namely we show that:

> Given a CAT(0) cubical complex $\mathcal{K}$ represented by a poset with inconsistent pairs P and two points p, q in $\mathcal{K}$, one can find a path joining p and q of length at most $d(p,q)+\epsilon$ in time polynomial in $|P|$ and $\log(1/\epsilon)$.

The algorithm is quite simple, without depending on any involved techniques such as semidefinite programming. To put it briefly, our algorithm first gives a polygonal path joining p and q with a fixed number (n, say) of breakpoints, and then iteratively updates the breakpoints of the path until it becomes a desired one. To update them, we compute the midpoints of the two close breakpoints by using Miller, Owen and Provan's algorithm. The resulting number of iterations is bounded by a polynomial in n. Key tools that lead to this bound are linear algebraic techniques and the convexity of the metric of CAT(0) spaces, rather than inherent properties of cubical complexes. Due to its simplicity, our algorithm is applicable to any CAT(0) space where geodesics between two close points can be found, not limited to CAT(0) cubical complexes. We believe that our result will be an important step toward developing computational geometry in CAT(0) spaces.

Application. A *reconfigurable system* [1, 12] is a collection of states which change according to local and reversible moves that affect global positions of the system. Examples include robot motion planning, non-collision particles moving around a graph, and protein folding; see [12]. Abrams, Ghrist and Peterson [1, 12] considered a continuous space of all possible positions of a reconfigurable system, called a *state complex*. Any state complex is a cubical complex of non-positively curved [12], and it becomes CAT(0) in many situations. In the robotics literature, geodesics (in the l_2-metric) in the CAT(0) state complex corresponds to the motion planning to get the robot from one position to another one with minimal power consumption. Our algorithm enables us to find such an optimal movement of the robot in polynomial time.

2 Computing geodesics in CAT(0) spaces

In this section we devise an algorithm to compute geodesics in general CAT(0) spaces, not limited to CAT(0) cubical complexes.

2.1 CAT(0) space

Let (X,d) be a metric space. A *geodesic* joining two points $x, y \in X$ is a map $\gamma : [0,1] \to X$ such that $\gamma(0) = x, \gamma(1) = y$ and $d(\gamma(s), \gamma(t)) = d(x,y)|s-t|$ for all $s, t \in [0,1]$. The image of γ is called a *geodesic segment* joining x and y. A metric space X is called *(uniquely) geodesic* if every pair of points $x, y \in X$ is joined by a (unique) geodesic.

For any triple of points x_1, x_2, x_3 in a metric space (X,d), there exists a triple of points $\bar{x}_1, \bar{x}_2, \bar{x}_3$ in the Euclidean plane $\mathbb{E}^2$ such that $d(x_i, x_j) = d_{\mathbb{E}^2}(\bar{x}_i, \bar{x}_j)$ for $i, j \in \{1,2,3\}$. The Euclidean triangle whose vertices are $\bar{x}_1, \bar{x}_2$ and $\bar{x}_3$ is called a *comparison triangle* for x_1, x_2, x_3. (Note that such a triangle is unique up to isometry.) A geodesic metric space (X,d) is called a *CAT(0) space* if for any $x_1, x_2, x_3 \in X$ and any p belonging to a geodesic segment joining x_1 and x_2, the inequality $d(x_3, p) \leq d_{\mathbb{E}^2}(\bar{x}_3, \bar{p})$ holds, where $\bar{p}$ is the unique point in $\mathbb{E}^2$ satisfying $d(\bar{x}_i, \bar{p}) = d_{\mathbb{E}^2}(x_i, p)$ for $i = 1, 2$. See Figure 1.

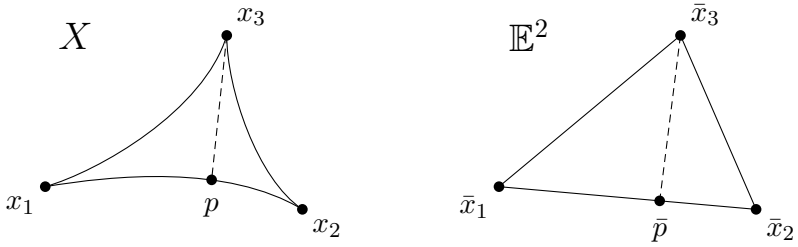

Figure 1 CAT(0) space.

This simple definition yields various significant properties of CAT(0) spaces; see [7] for details. One of the most basic properties of CAT(0) spaces is the convexity of the metric. A geodesic metric space (X, d) is said to be *Busemann convex* if for any two geodesics $\alpha, \beta : [0, 1] \to X$, the function $f : [0, 1] \to \mathbb{R}$ given by $f(t) := d(\alpha(t), \beta(t))$ is convex.

▶ **Lemma 2.1** ([7, Proposition II.2.2]). *Every CAT(0) space is Busemann convex.*

A Busemann convex space X is uniquely geodesic. Indeed, for any two geodesics $\alpha, \beta : [0, 1] \to X$ with $\alpha(0) = \beta(0)$ and $\alpha(1) = \beta(1)$, one can easily see that α and β coincide, since $d(\alpha(t), \beta(t)) \leq (1 - t)d(\alpha(0), \beta(0)) + td(\alpha(1), \beta(1)) = 0$ for all $t \in [0, 1]$. This implies that:

▶ **Theorem 2.2** ([7, Proposition II.1.4]). *Every CAT(0) space is uniquely geodesic.*

2.2 Algorithm

Let X be a CAT(0) space. We shall refer to an element x in the product space X^{n+1} as a *chain*, and write x_{i-1} to denote the i-th component of x, i.e., $x = (x_0, x_1, \ldots, x_n)$. For any chain $x \in X^{n+1}$, we define the *length* of x by $\sum_{i=0}^{n-1} d(x_i, x_{i+1})$ and denote it by $\ell(x)$. We consider the following problem:

> Given two points $p, q \in X$, a chain $x \in X^{n+1}$ with $x_0 = p$ and $x_n = q$, and a positive parameter $\epsilon > 0$, find a chain $y \in X^{n+1}$ such that $y_0 = p$, $y_n = q$ and $\ell(y) \leq d(p, q) + \epsilon$, (1)

under the situation where we are given an oracle to perform the following operation for some $D > 0$:

> Given two points $p, q \in X$ with $d(p, q) \leq D$, compute the geodesic joining p and q in arbitrary precision. (2)

To explain our algorithm to solve this problem, we need some definitions. Since X is uniquely geodesic, every pair of points $p, q \in X$ has a unique midpoint w satisfying $2d(w, p) = 2d(q, w) = d(p, q)$. For a nonnegative real number $\delta \geq 0$, a *δ-midpoint* of p and q is a point $w' \in X$ satisfying $d(w', w) \leq \delta$, where w is the midpoint of p and q.

▶ **Definition 2.3** (δ-halved chain). Let δ be a nonnegative real number. For any chain $x \in X^{n+1}$, a chain $z \in X^{n+1}$ is called a *δ-halved chain* of x if it satisfies the following:

$z_0 = x_n$, $z_n = x_0$ and z_i is a δ-midpoint of z_{i+1} and x_{n-i} for $i = 1, 2, \ldots, n - 1$.

For an integer $k \geq 0$, we say that $x^{(k)}$ is a *k-th δ-halved chain* of x if there exists a sequence $\{x^{(j)}\}_{j=0}^{k}$ of chains in X^{n+1} such that $x^{(0)} = x$ and $x^{(j)}$ is a δ-halved chain of $x^{(j-1)}$ for $j = 1, 2, \ldots, k$.

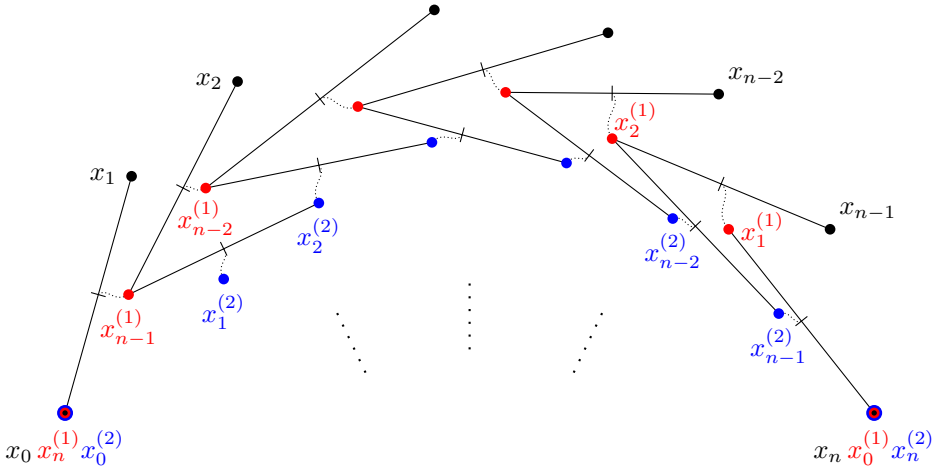

Figure 2 An illustration of Algorithm 1.

Our algorithm can be described as follows. To put it briefly, the algorithm just finds a k-th δ-halved chain of a given chain x for some large k and small δ; see Figure 2 for an illustration. In the algorithm the local optimization is done alternatively "from left to right" and "from right to left" so that the analysis will be easier.

Algorithm 1

Input. Two points $p, q \in X$, a chain $x \in X^{n+1}$ with $x_0 = p$ and $x_n = q$, and parameters $\epsilon > 0, \delta \geq 0$.

⟨**1**⟩ Set $x^{(0)} := x$.

⟨**2**⟩ For $j = 0, 1, 2, \ldots,$ do the following:

⟨**2-1**⟩ Set $z_0 := x_n^{(j)}$ and $z_n := x_0^{(j)}$.

⟨**2-2**⟩ For $i = 1, 2, \ldots, n-1$, do the following:

$$\text{Compute a } \delta\text{-midpoint } w \text{ of } z_{n-i+1} \text{ and } x_i^{(j)}, \text{ and set } z_{n-i} := w. \tag{3}$$

⟨**2-3**⟩ Set $x^{(j+1)} := (z_0, z_1, \ldots, z_n)$.

For any chain $x \in X^{n+1}$, define the *gap* of x by $\max\{d(x_0, x_1), \max_{1 \leq i \leq n-1} 2d(x_i, x_{i+1})\}$ and denote it by $\mathrm{gap}(x)$. The following theorem states that Algorithm 1 solves problem (1).

▶ **Theorem 2.4.** *Let $p, q \in X$ be given two points, $x \in X^{n+1}$ be a given chain with $x_0 = p$ and $x_n = q$, and $\epsilon > 0, 0 \leq \delta \leq \epsilon/(16n^3)$ be parameters.*

(i) *For $j \geq n^2 \log(4n \cdot \ell(x)/\epsilon)$, one has $\ell(x^{(j)}) \leq d(p, q) + \epsilon$.*

(ii) *If $\mathrm{gap}(x) \leq D/2 - \epsilon$ for some $D > 0$, then for all $j \geq 0$ and for $i = 1, 2, \ldots, n-1$, one has $d(z_{n-i+1}, x_i^{(j)}) \leq D$ in (3).*

In particular, for $\mathrm{gap}(x) \leq D/2 - \epsilon$, one can find a chain $y \in X^{n+1}$ such that $y_0 = p$, $y_n = q$ and $\ell(y) \leq d(p, q) + \epsilon$, with $O(n^3 \log(nD/\epsilon))$ calls of an oracle to perform (2).

▶ **Example 2.5.** We give an example of CAT(0) spaces to which our algorithm is applicable. A *B_2-complex* is a two dimensional piecewise Euclidean complex in which each 2-cell is isomorphic to an isosceles right triangle with short side of length one [11]. A CAT(0) B_2-complex is called a *folder complex* [9]; see Figure 3 for an example. One can show that for a

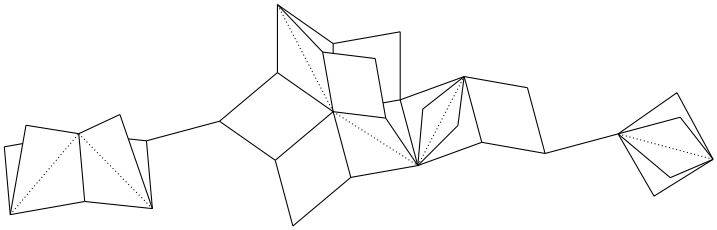

Figure 3 A folder complex.

folder complex $\mathcal{F}$, computing the geodesic between two points $p, q \in \mathcal{F}$ with $d(p,q) \leq 1$ can be reduced to an easy calculation on a subcomplex of $\mathcal{F}$ having a few cells. This implies that our algorithm enables us to find geodesics between two points in a folder complex $\mathcal{F}$ in time bounded by a polynomial in the size of $\mathcal{F}$.

2.3 Analysis

For any chain $x \in X^{n+1}$, we define the *reference chain* $\hat{x} \in X^{n+1}$ of x as follows: $\hat{x}_0 := x_0$ and $\hat{x}_i := \gamma((i+1)/(n+1))$ for $i = 1, 2, \ldots, n$, where $\gamma : [0,1] \to X$ is the geodesic with $\gamma(0) = x_0$ and $\gamma(1) = x_n$. Reference chains are designed not to be equally spaced but to have a double gap in the beginning so that the analysis of the algorithm will be easier. Note that the reference chain $\hat{x}$ of x is determined just by its end components x_0, x_n, and therefore for any chain x and any even δ-halved chain $x^{(2k)}$ of x their reference chains coincide: $\hat{x}^{(2k)} = \hat{x}$. A key observation that leads to Theorem 2.4 is that: For any chain $x \in X^{n+1}$ and any k-th δ-halved chain $x^{(k)}$ of x with k sufficiently large and δ sufficiently small, the distance between $x^{(k)}$ and its reference chain $\hat{x}^{(k)}$ is small enough for its length $\ell(x^{(k)})$ to approximate well $d(x_0, x_n)$; moreover, the value of such a k can be bounded by a polynomial in n. The next lemma states this fact.

▶ **Lemma 2.6.** *Let $x \in X^{n+1}$. Any k-th δ-halved chain $x^{(k)}$ of x satisfies*

$$d(x_i^{(k)}, \hat{x}_i^{(k)}) \leq (5/4)\ell(x)e^{-k/n^2} + 3n^2\delta$$

for $i = 1, 2, \ldots, n-1$, where e is the base of the natural logarithm.

Proof. Let $\{x^{(j)}\}_{j \geq 0}$ be a sequence of chains in X^{n+1} such that $x^{(0)} = x$ and $x^{(j)}$ is a δ-halved chain of $x^{(j-1)}$ for $j \geq 1$. Fix an integer $1 \leq i \leq n-1$ and an integer $k \geq 0$. Note that by definition $x_i^{(k+1)}$ is a δ-midpoint of $x_{i+1}^{(k+1)}$ and $x_{n-i}^{(k)}$ and that $\hat{x}_i^{(k+1)}$ is the midpoint of $\hat{x}_{i+1}^{(k+1)}$ and $\hat{x}_{n-i}^{(k)}$. Hence, by Lemma 2.1 and the triangle inequality, we have

$$2d(x_i^{(k+1)}, \hat{x}_i^{(k+1)}) \leq 2d(w, \hat{x}_i^{(k+1)}) + 2\delta \leq d(x_{i+1}^{(k+1)}, \hat{x}_{i+1}^{(k+1)}) + d(x_{n-i}^{(k)}, \hat{x}_{n-i}^{(k)}) + 2\delta, \tag{4}$$

where w is the midpoint of $x_{i+1}^{(k+1)}$ and $x_{n-i}^{(k)}$.

Let $v^{(k)}$ be a column vector of dimension $n-1$ whose i-th entry equals $d(x_i^{(k)}, \hat{x}_i^{(k)})$ for $i = 1, 2, \ldots, n-1$. Let J be a square matrix of order $n-1$ whose (i,j) entry equals 1 if $i + j = n$ and 0 otherwise. Let K be a square matrix of order $n-1$ whose (i,j) entry equals 1 if $j = i+1$ and 0 otherwise. Then, by (4) we have $2v^{(k+1)} \leq Kv^{(k+1)} + Jv^{(k)} + 2\delta\mathbf{1}$ for each $k \geq 0$, where $\mathbf{1}$ is a column vector with all entries equal to 1. Let A_{n-1} be a square matrix of order $n-1$ whose (i,j) entry equals $(1/2)^{n+1-i-j}$ if $i + j \leq n$ and 0 otherwise. Then one can easily see that $(2I - K)^{-1}J = A_{n-1}$. Hence we have

$$v^{(k+1)} \leq A_{n-1}v^{(k)} + A_{n-1}J^{-1}(2\delta\mathbf{1}) \leq A_{n-1}v^{(k)} + 2\delta\mathbf{1} \tag{5}$$

for each $k \geq 0$. We show that

$$v^{(k)} \leq ((5/4)\ell(x)e^{-k/n^2} + 3n^2\delta)\mathbf{1} \tag{6}$$

for any integer $k \geq 0$. The inequality (5) inductively yields that $v^{(k)} \leq (A_{n-1})^k v^{(0)} + 2\delta(I + A_{n-1} + \cdots + (A_{n-1})^{k-1})\mathbf{1} \leq \ell(x)(A_{n-1})^k\mathbf{1} + 2\delta(I - A_{n-1})^{-1}\mathbf{1}$. Here, the inequality $v^{(0)} \leq \ell(x)\mathbf{1}$ comes from the triangle inequality. Indeed, we have

$$\begin{aligned} d(x_i, \hat{x}_i) &\leq \min\{d(x_0, \hat{x}_i) + \textstyle\sum_{j=0}^{i-1} d(x_j, x_{j+1}),\ d(\hat{x}_i, x_n) + \sum_{j=i}^{n-1} d(x_j, x_{j+1})\} \\ &\leq (d(x_0, x_n) + \ell(x))/2 \leq \ell(x) \end{aligned}$$

for $i = 1, 2, \ldots, n-1$. In Lemma 2.7 below, we prove $(I - A_{n-1})^{-1}\mathbf{1} \leq (5(n-1)^2/4)\mathbf{1}$ (for $n-1 \geq 2$). This yields that $(I - A_{n-1})^{-1}\mathbf{1} \leq (3/2)n^2\mathbf{1}$ for $n \geq 2$. Also, we prove $(A_{n-1})^k\mathbf{1} \leq (5/4)e^{-k/(n-1)^2}\mathbf{1}$ (for $n-1 \geq 2$) in Lemma 2.7. This implies that $(A_{n-1})^k\mathbf{1} \leq (5/4)e^{-k/n^2}\mathbf{1}$ for $n \geq 2$. This proves (6) and therefore completes the proof of the lemma. ◀

Let us now prove Theorem 2.4.

Proof of Theorem 2.4. We may assume that $n \geq 2$. We first show (i). If $\delta \leq \epsilon/(16n^3)$ and $j \geq n^2 \log(4n \cdot \ell(x)/\epsilon)$, then by Lemma 2.6, any j-th δ-halved chain $x^{(j)}$ of x satisfies $d(x_i^{(j)}, \hat{x}_i^{(j)}) \leq 5\epsilon/(16n) + 3\epsilon/(16n) = \epsilon/(2n)$ for $i = 1, 2, \ldots, n-1$. Hence one has

$$\begin{aligned} d(x_i^{(j)}, x_{i+1}^{(j)}) &\leq d(x_i^{(j)}, \hat{x}_i^{(j)}) + d(\hat{x}_i^{(j)}, \hat{x}_{i+1}^{(j)}) + d(\hat{x}_{i+1}^{(j)}, x_{i+1}^{(j)}) \\ &\leq d(\hat{x}_i^{(j)}, \hat{x}_{i+1}^{(j)}) + \epsilon/n \end{aligned} \tag{7}$$

for $i = 0, 1, \ldots, n-1$. This implies that $\ell(x^{(j)}) = \sum_{i=0}^{n-1} d(x_i^{(j)}, x_{i+1}^{(j)}) \leq \sum_{i=0}^{n-1}(d(\hat{x}_i^{(j)}, \hat{x}_{i+1}^{(j)}) + \epsilon/n) = d(x_0, x_n) + \epsilon = d(p, q) + \epsilon$, and therefore completes the proof of (i).

To prove (ii), we first show

$$d(z_{n-i+1}, x_i^{(j)}) \leq \mathrm{gap}(x^{(j)}) + 2\delta \quad (i = 1, 2, \ldots, n; j \geq 0), \tag{8}$$

by induction on i. The case $i = 1$ being trivial, suppose that $i \geq 2$. Since z_{n-i+1} is a δ-midpoint of z_{n-i+2} and $x_{i-1}^{(j)}$, the triangle inequality and the induction yield $d(z_{n-i+1}, x_i^{(j)}) \leq \delta + d(z_{n-i+2}, x_{i-1}^{(j)})/2 + d(x_{i-1}^{(j)}, x_i^{(j)}) \leq \delta + (\mathrm{gap}(x^{(j)})/2 + \delta) + \mathrm{gap}(x^{(j)})/2 = \mathrm{gap}(x^{(j)}) + 2\delta$, which completes the induction.

It follows from (8) that $\mathrm{gap}(x^{(j+1)}) \leq \mathrm{gap}(x^{(j)}) + 4\delta$ for $j \geq 0$. Indeed, the case $i = n$ in (8) implies that $d(z_1, z_0) = d(z_1, x_n^{(j)}) \leq \mathrm{gap}(x^{(j)}) + 2\delta$; on the other hand, by the triangle inequality and (8), one has $d(z_{n-i+1}, z_{n-i}) \leq d(z_{n-i+1}, x_i^{(j)})/2 + \delta \leq \mathrm{gap}(x^{(j)})/2 + 2\delta$ for $i = 1, 2, \ldots, n-1$. Thus, one has $\mathrm{gap}(x^{(j+1)}) \leq \max\{\mathrm{gap}(x^{(j)}) + 2\delta, 2(\mathrm{gap}(x^{(j)})/2 + 2\delta)\} = \mathrm{gap}(x^{(j)}) + 4\delta$.

The inequality (8) implies that in order to prove (ii) it suffices to show that $\mathrm{gap}(x^{(j)}) + 2\delta \leq D$ for all $j \geq 0$. Suppose that $\delta \leq \epsilon/(16n^3)$. We consider two cases.

Case 1: $j \leq n^2 \log(4n \cdot \ell(x)/\epsilon)$. Note that $\ell(x) \leq n \cdot \mathrm{gap}(x)$ and that $\mathrm{gap}(x^{(j)}) \leq \mathrm{gap}(x) + 4j\delta$.

However roughly one estimates an upper bound of $4j\delta$, one can get

$$4j\delta \leq 4 \cdot \frac{\epsilon}{16n^3} \cdot n^2 \log \frac{4n^2 \cdot \mathrm{gap}(x)}{\epsilon} = \frac{\epsilon}{4n}\left(\log \frac{\mathrm{gap}(x)}{\epsilon} + 2\log 2n\right) \leq \frac{\mathrm{gap}(x)}{4ne} + \frac{\epsilon}{e},$$

where the last inequality comes from the fact that $\log t \leq t/e$ for any $t > 0$. It is easy to see that $\mathrm{gap}(x^{(j)}) + 2\delta \leq \mathrm{gap}(x) + \mathrm{gap}(x)/(4ne) + \epsilon/e + \epsilon/(8n^3) \leq D$, provided $\mathrm{gap}(x) \leq D/2 - \epsilon$.

Case 2: $j \geq n^2 \log(4n \cdot \ell(x)/\epsilon)$. Recall (7). Since $d(x_0, x_n)/(n+1) \leq \mathrm{gap}(x)/2$, we have

$$\mathrm{gap}(x^{(j)}) \leq \max\{\mathrm{gap}(x) + \epsilon/n, 2(\mathrm{gap}(x)/2 + \epsilon/n)\} = \mathrm{gap}(x) + 2\epsilon/n.$$

It is easy to see that $\mathrm{gap}(x^{(j)}) + 2\delta \leq \mathrm{gap}(x) + 2\epsilon/n + \epsilon/(8n^3) \leq D$, provided $\mathrm{gap}(x) \leq D/2 - \epsilon$.

From (i) and (ii), we can show the last part of the theorem. Indeed, for $k := \lceil n^2 \log(4n \cdot \ell(x)/\epsilon) \rceil$, one can find a k-th δ-halved chain $x^{(k)}$ of x with $O(nk) = O(n^3 \log(nD/\epsilon))$ oracle calls, from (ii); its length $\ell(x^{(k)})$ is at most $d(p,q) + \epsilon$, from (i). ◀

We end this section by showing the lemma used in the proof of Lemma 2.6. Let A_n be an $n \times n$ matrix whose (i,j) entry is defined by

$$(A_n)_{ij} := \begin{cases} (1/2)^{n+2-i-j} & (i+j \leq n+1), \\ 0 & (\text{otherwise}) \end{cases} \tag{9}$$

for $i, j = 1, 2, \ldots, n$. Since A_n is a nonnegative matrix, its spectral radius $\rho(A_n)$ is at most the maximum row sum of A_n, which immediately yields that $\rho(A_n) \leq 1 - (1/2)^n$. This inequality, however, is not tight unless $n = 1$. In fact, one can obtain a more useful upper bound of $\rho(A_n)$.

▶ **Lemma 2.7.** *Let $n > 1$ be an integer, and let A_n be an $n \times n$ matrix defined by (9). Then its spectral radius $\rho(A_n)$ is at most $1 - 1/n^2$. In addition, one has $(I - A_n)^{-1}\mathbf{1} \leq (5n^2/4)\mathbf{1}$ and $(A_n)^k \mathbf{1} \leq (5/4)e^{-k/n^2}\mathbf{1}$ for any integer $k \geq 0$.*

Proof. Let $A := A_n$ for simplicity. Let u be a positive column vector of dimension n whose k-th entry is defined by $u_k := k(n-k) + n^2$ for $k = 1, 2, \ldots, n$. By the Collatz–Wielandt inequality, in order to show $\rho(A) \leq 1 - 1/n^2$ it suffices to show that $Au \leq (1 - 1/n^2)u$. The k-th entry of the vector Au is

$$(Au)_k = \sum_{j=1}^{n+1-k} \frac{u_j}{2^{n+2-k-j}} = \frac{1}{2^{n+2-k}} \sum_{j=1}^{n+1-k} 2^j(-j^2 + nj + n^2).$$

Hence, using the general formulas

$$\sum_{j=1}^{m} j \cdot 2^j = 2 + 2^{m+1}(m-1) \quad \text{and} \quad \sum_{j=1}^{m} j^2 \cdot 2^j = -6 + 2^{m+1}((m-1)^2 + 2),$$

we have

$$(Au)_k = u_k - 2 - \frac{n^2 - n - 3}{2^{n+1-k}}.$$

It is easy to see that for $n \geq 2$ and $1 \leq k \leq n$ one has

$$\frac{u_k}{n^2} = 1 + \frac{k(n-k)}{n^2} \leq \frac{5}{4} \leq \left(2 - \frac{1}{2^{n+1-k}}\right) + \frac{(n-2)(n+1)}{2^{n+1-k}},$$

which implies that

$$\frac{u_k}{n^2} \leq 2 + \frac{n^2 - n - 3}{2^{n+1-k}} \quad (k = 1, 2, \ldots, n).$$

This completes the proof of the inequality $Au \leq (1 - 1/n^2)u$.

Let us show the latter part of the lemma. Note that $\mathbf{1} \leq (1/n^2)u \leq (5/4)\mathbf{1}$. Since $(1/n^2)u \leq (I-A)u$ and $(I-A)^{-1}$ is a nonnegative matrix (as $\rho(A) < 1$), we have $(I-A)^{-1}\mathbf{1} \leq (1/n^2)(I-A)^{-1}u \leq u \leq (5n^2/4)\mathbf{1}$.

Since $Au \leq (1-1/n^2)u \leq e^{-1/n^2}u$, we have $A^k u \leq e^{-k/n^2}u$ for any integer $k \geq 0$. Hence, $A^k\mathbf{1} \leq (1/n^2)A^k u \leq (1/n^2)e^{-k/n^2}u \leq (5/4)e^{-k/n^2}\mathbf{1}$. ◀

▶ Remark. In proving Theorem 2.4, we utilized only the convexity of the metric of X. Hence our algorithm works even when X is a Busemann convex space.

3 Computing geodesics in CAT(0) cubical complexes

In this section we give an algorithm to compute geodesics in CAT(0) cubical complexes, with an aid of the result of the preceding section. In Section 3.1 to 3.4, we recall CAT(0) cubical complexes, median graphs, PIPs and CAT(0) orthant spaces. Section 3.5 is devoted to proving our main theorem.

3.1 CAT(0) cubical complex

A *cubical complex* $\mathcal{K}$ is a polyhedral complex where each k-dimensional cell is isometric to the unit cube $[0,1]^k$ and the intersection of any two cells is empty or a single face. The *underlying graph* of $\mathcal{K}$ is the graph $G(\mathcal{K}) = (V(\mathcal{K}), E(\mathcal{K}))$, where $V(\mathcal{K})$ denotes the set of *vertices* (0-dimensional faces) of $\mathcal{K}$ and $E(\mathcal{K})$ denotes the set of *edges* (1-dimensional faces) of $\mathcal{K}$. A cubical complex $\mathcal{K}$ has an intrinsic metric induced by the l_2-metric on each cell. For two points $p, q \in \mathcal{K}$, a *string* in $\mathcal{K}$ from p to q is a sequence of points $p = x_0, x_1, \ldots, x_{m-1}, x_m = q$ in $\mathcal{K}$ such that for each $i = 0, 1, \ldots, m-1$ there exists a cell C_i containing x_i and x_{i+1}, and its *length* is defined to be $\sum_{i=0}^{m-1} d(x_i, x_{i+1})$, where $d(x_i, x_{i+1})$ is measured inside C_i by the l_2-metric. The distance between two points $p, q \in \mathcal{K}$ is defined to be the infimum of the lengths of strings from p to q.

Gromov [14] gave a combinatorial criterion which allows us to easily decide whether or not a cubical complex $\mathcal{K}$ is non-positively curved. The *link* of a vertex v of $\mathcal{K}$ is the abstract simplicial complex whose vertices are the edges of $\mathcal{K}$ containing v and where k edges $e_1, \ldots, e_k$ span a simplex if and only if they are contained in a common k-dimensional cell of $\mathcal{K}$. An abstract simplicial complex $\mathcal{L}$ is called *flag* if any set of vertices is a simplex of $\mathcal{L}$ whenever each pair of its vertices spans a simplex.

▶ **Theorem 3.1** (Gromov [14]). *A cubical complex $\mathcal{K}$ is CAT(0) if and only if $\mathcal{K}$ is simply connected and the link of each vertex is flag.*

3.2 Median graph

Let $G = (V, E)$ be a simple undirected graph. The distance $d_G(u, v)$ between two vertices u and v is the length of a shortest path between u and v. The *interval* $I_G(u, v)$ between u and v is the set of vertices $w \in V$ with $d_G(u, v) = d_G(u, w) + d_G(w, v)$. A vertex subset $U \subseteq V$ is said to be *convex* if $I_G(u, v)$ is contained in U for all $u, v \in U$. A graph G is called a *median graph* if for all $u, v, w \in V$ the set $I_G(u, v) \cap I_G(v, w) \cap I_G(w, u)$ contains exactly one element, called the *median* of u, v, w. Median graphs are connected and bipartite. A *median complex* is a cubical complex derived from a median graph G by replacing all cube-subgraphs of G by solid cubes. It has been shown independently by Chepoi [9] and Roller [22] that median complexes and CAT(0) cubical complexes constitute the same objects:

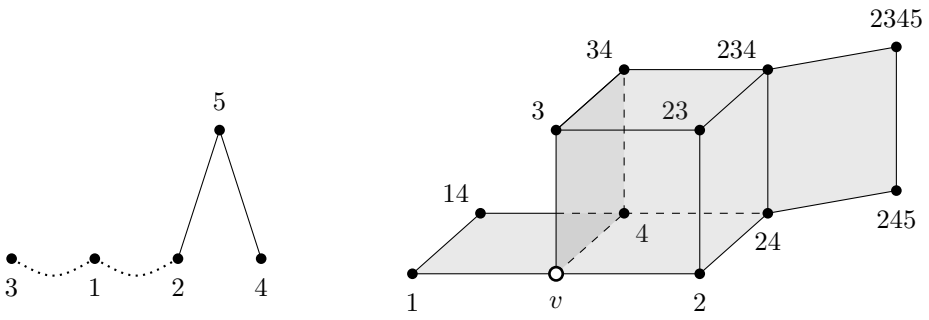

Figure 4 A poset with inconsistent pairs and the corresponding rooted CAT(0) cubical complex. Dotted line represents minimal inconsistent pairs, where an inconsistent pair $\{a, b\}$ is said to be *minimal* if there is no other inconsistent pair $\{a', b'\}$ with $a' \preceq a$ and $b' \preceq b$.

▶ **Theorem 3.2** (Chepoi [9], Roller [22]). *The underlying graph of every CAT(0) cubical complex is a median graph, and conversely, every median complex is a CAT(0) cubical complex.*

3.3 Poset with inconsistent pairs (PIP)

Barthélemy and Constantin [4] established a Birkhoff-type representation theorem for median graphs, by employing a poset with an additional relation. This structure was rediscovered by Ardila et al. [2] in the context of CAT(0) cubical complexes. An *antichain* of a poset P is a subset of P that contains no two comparable elements. A subset I of P is called an *order ideal* of P if $a \in I$ and $b \preceq a$ imply $b \in I$. A poset P is *locally finite* if every interval $[a, b] = \{c \in P \mid a \preceq c \preceq b\}$ is finite, and it has *finite width* if every antichain is finite.

▶ **Definition 3.3.** A *poset with inconsistent pairs* (or, briefly, a *PIP*) is a locally finite poset P of finite width, endowed with a symmetric binary relation $\smile$ satisfying:
1) If $a \smile b$, then a and b are incomparable.
2) If $a \smile b$, $a \preceq a'$ and $b \preceq b'$, then $a' \smile b'$.
A pair $\{a, b\}$ with $a \smile b$ is called an *inconsistent pair*. An order ideal of P is called *consistent* if it contains no inconsistent pairs.

For a CAT(0) cubical complex $\mathcal{K}$ and a vertex v of $\mathcal{K}$, the pair $(\mathcal{K}, v)$ is called a *rooted CAT(0) cubical complex*. Given a poset with inconsistent pairs P, one can construct a cubical complex $\mathcal{K}_P$ as follows: The underlying graph $G(\mathcal{K}_P)$ is a graph G_P whose vertices are consistent order ideals of P and where two consistent order ideals I, J are adjacent if and only if $|I \Delta J| = 1$; replace all cube-subgraphs (i.e., subgraphs isomorphic to cubes of some dimensions) of G_P by solid cubes. See Figure 4 for an example. In fact, the resulting cubical complex $\mathcal{K}_P$ is CAT(0), and moreover:

▶ **Theorem 3.4** (Ardila et al. [2]). *The map $P \mapsto \mathcal{K}_P$ is a bijection between posets with inconsistent pairs and rooted CAT(0) cubical complexes.*

This bijection can also be derived from Theorem 3.2 and the result of Barthélemy and Constantin [4], who found a bijection between PIPs and pointed median graphs.

Given a poset with inconsistent pairs P, one can embed $\mathcal{K}_P$ into a unit cube in the Euclidean space as follows, which we call the *standard embedding* of P [2]:

$$\mathcal{K}_P = \{(x_i)_{i \in P} \in [0,1]^P \mid i \prec j \text{ and } x_i < 1 \Rightarrow x_j = 0, \text{ and } i \smile j \Rightarrow x_i x_j = 0\}.$$

For each pair (I, M) of a consistent order ideal I of P and a subset $M \subseteq I_{\max}$, where $I_{\max}$ is the set of maximal elements of I, the subspace

$$C^I_M := \{x \in \mathcal{K}_P \mid i \in I \backslash M \Rightarrow x_i = 1, \text{ and } i \notin I \Rightarrow x_i = 0\} = \{1\}^{I \backslash M} \times [0,1]^M \times \{0\}^{P \backslash I}$$

corresponds to a unique $|M|$-dimensional cell of $\mathcal{K}_P$.

3.4 CAT(0) orthant space

Let $\mathbb{R}_+$ denote the set of nonnegative real numbers. Let $\mathcal{L}$ be an abstract simplicial complex on a finite set V. The *orthant space* $\mathcal{O}(\mathcal{L})$ for $\mathcal{L}$ is a subspace of $|V|$-dimensional orthant $\mathbb{R}^V_+$ constructed by taking a union of all subcones $\{\mathcal{O}_S \mid S \in \mathcal{L}\}$ associated with simplices of $\mathcal{L}$, where $\mathcal{O}_S$ is defined by $\mathcal{O}_S := \mathbb{R}^S_+ \times \{0\}^{V \backslash S}$ for each simplex $S \in \mathcal{L}$; namely, $\mathcal{O}(\mathcal{L}) = \bigcup_{S \in \mathcal{L}} \{x \in \mathbb{R}^V_+ \mid x_v = 0 \text{ for each } v \notin S\}$. The distance between two points $x, y \in \mathcal{O}(\mathcal{L})$ is defined in a similar way as in the case of cubical complexes. An orthant space is a special instance of cubical complexes.

▶ **Theorem 3.5** (Gromov [14]). *The orthant space $\mathcal{O}(\mathcal{L})$ for an abstract simplicial complex $\mathcal{L}$ is a CAT(0) space if and only if $\mathcal{L}$ is a flag complex.*

A typical example of CAT(0) orthant spaces is a *tree space* [6]. Owen and Provan [19, 20] gave a polynomial time algorithm to compute geodesics in tree spaces, which was generalized to CAT(0) orthant spaces by Miller et al. [15].

▶ **Theorem 3.6** ([15, 19, 20]). *Let $\mathcal{L}$ be a flag abstract simplicial complex on a finite set V and $\mathcal{O}(\mathcal{L})$ be the CAT(0) orthant space for $\mathcal{L}$. Let $x, y \in \mathcal{O}(\mathcal{L})$, and let S_1 and S_2 be the inclusion-wise minimal simplices such that $x \in \mathcal{O}_{S_1}$ and $y \in \mathcal{O}_{S_2}$. Then one can find the explicit description of the geodesic joining x and y in $O((|S_1| + |S_2|)^4)$ time.*

An interesting thing about their algorithm is that it solves as a subproblem a combinatorial optimization problem: the Maximum Weight Stable Set problem on a bipartite graph whose color classes have at most $|S_1|, |S_2|$ vertices, respectively. We should note that the above explicit descriptions of geodesics are radical expressions. Computationally, for a point p on a geodesic, one can compute a rational point $p' \in \mathcal{O}(\mathcal{L})$ such that $d(p', p) \leq \delta$ and the number of bits required for each coordinate of p' is bounded by $O(\log(|V|/\delta))$. For a real number $r > 0$, the subspace $\mathcal{O}(\mathcal{L}) \cap [0, r]^V$ of $\mathcal{O}(\mathcal{L})$, denoted by $\mathcal{O}(\mathcal{L})|_{[0,r]}$, is called a *truncated CAT(0) orthant space*. Actually, from the explicit descriptions of geodesics in $\mathcal{O}(\mathcal{L})$, one can see that $\mathcal{O}(\mathcal{L})|_{[0,r]}$ is convex in $\mathcal{O}(\mathcal{L})$, and thus:

▶ **Theorem 3.7** ([15]). *Given two points x, y in a truncated CAT(0) orthant space $\mathcal{O}(\mathcal{L})|_{[0,r]}$, one can find the explicit description of the geodesic joining x and y in $O(|V|^4)$ time.*

3.5 Main theorem

Our main result is the following theorem. It should be remarked that as stated in [2] there are no simple formulas for the breakpoints in geodesics in CAT(0) cubical complexes due to their algebraic complexity, and hence one can only compute them approximately. Also note that for the shortest path problem in a general CAT(0) cubical complex there has been no algorithm that runs in time polynomial in the size of the complex, much less the size of the compact representation PIP.

▶ **Problem 3.8.** Given a poset with inconsistent pairs P, two points p, q in the standard embedding $\mathcal{K}_P$ of P, and a positive parameter $\epsilon > 0$, find a sequence of points $p = x_0, x_1, \ldots, x_{n-1}, x_n = q$ in $\mathcal{K}_P$ with $\sum_{i=0}^{n-1} d(x_i, x_{i+1}) \leq d(p, q) + \epsilon$ and compute the geodesic joining x_i and x_{i+1} for $i = 0, 1, \ldots, n-1$.

▶ **Theorem 3.9.** *Problem 3.8 can be solved in $O(|P|^7 \log(|P|/\epsilon))$ time. Moreover, the number of bits required for each coordinate of points in $\mathcal{K}_P$ occurring throughout the algorithm can be bounded by $O(\log(|P|/\epsilon))$.*

Let us show this theorem. Let m denote the number of elements of P and let $D < 1$ be a positive constant close to 1 (e.g., set $D := 0.9$). Theorem 2.4 implies that in order to prove Theorem 3.9 it suffices to show that:

(a) Given two points $p, q \in \mathcal{K}_P$, one can find a sequence of points $p = x_0, x_1, \ldots, x_{n-1}, x_n = q$ in $\mathcal{K}_P$ such that $n = O(m)$ and $d(x_i, x_{i+1}) \leq D/4 - \epsilon$ for $i = 0, 1, \ldots, n-1$.

(b) Given two points $p, q \in \mathcal{K}_P$ with $d(p, q) \leq D$, one can compute the geodesic joining p and q in $O(m^4)$ time and find a δ-midpoint w of p and q with $O(\log(m/\delta))$ bits enough for each coordinate of w.

It is relatively easy to show (a), by considering a curve $c(p, q)$ issuing at p, going through an edge geodesic (a shortest path in the underlying graph of $\mathcal{K}_P$) between some vertices of cells containing p, q, and ending at q. (Note that one can easily find an edge geodesic between vertices u and v of $\mathcal{K}_P$. Reroot the complex $\mathcal{K}_P$ at u. In other words, construct a poset P' for which $\mathcal{K}_{P'} \cong \mathcal{K}_P$ and u is the root of $\mathcal{K}_{P'}$; this construction is implicitly stated in [2]. Then the edge geodesic in $\mathcal{K}_{P'}$ from the root $u = \emptyset$ to $v = I$, where I is a consistent order ideal of P', can be found by considering a linear extension of the elements of I.) Since such a curve $c(p, q)$ has length at most $O(m)$, dividing it into parts appropriately, one can get a desired sequence of points. To show (b), we need the following two lemmas, whose detailed proofs can be found in the full version of this work.

▶ **Lemma 3.10.** *Let $\mathcal{K}$ be a CAT(0) cubical complex and v be a vertex of $\mathcal{K}$. Then the star $\mathrm{St}(v, \mathcal{K})$ of v in $\mathcal{K}$, i.e., the subcomplex spanned by all cells containing v, is convex in $\mathcal{K}$.*

Sketch of Proof. The lemma follows from the well-known fact that the vertex set of a star in $\mathcal{K}$ is convex in the underlying graph $G(\mathcal{K})$ and the result of [10] that the subcomplex $\mathcal{K}(S)$ of $\mathcal{K}$ induced by a convex vertex subset S of $G(\mathcal{K})$ is convex in $\mathcal{K}$ in the ℓ_2-metric. ◀

▶ **Lemma 3.11.** *Let $\mathcal{K}$ be a CAT(0) cubical complex. Let p, q be two points in $\mathcal{K}$ with $d(p, q) < 1$ and R_1, R_2 be the minimal cells of $\mathcal{K}$ containing p, q, respectively. Then $R_1 \cap R_2 \neq \emptyset$.*

Sketch of Proof. One can show that there exists a vertex u_i of R_i for $i = 1, 2$, such that $d(u_1, u_2) = d(R_1, R_2) := \inf_{x \in R_1, y \in R_2} d(x, y)$. Since $d(R_1, R_2) \leq d(p, q) < 1$, one has $d(u_1, u_2) < 1$. Hence u_1 and u_2 should be the same vertex, and thus $R_1 \cap R_2 \neq \emptyset$. ◀

Using these lemmas, we show (b). Suppose that we are given two points $p, q \in \mathcal{K}_P$ with $d(p, q) \leq D$. First notice that one can find in linear time the minimal cells R_1 and R_2 of $\mathcal{K}_P$ that contain p and q, respectively, just by checking their coordinates. (Indeed, one has $R_1 = C_M^I$ for $I = \{i \in P \mid p_i > 0\}$ and $M = \{i \in P \mid 0 < p_i < 1\}$.) Since $d(p, q) \leq D < 1$, from Lemma 3.11 we know that $R_1 \cap R_2 \neq \emptyset$. Let v be a vertex of $R_1 \cap R_2$. Then p and q are contained in the star $\mathrm{St}(v, \mathcal{K}_P)$ of v. Since $\mathrm{St}(v, \mathcal{K}_P)$ is convex in $\mathcal{K}_P$ by Lemma 3.10, we only have to compute the geodesic in $\mathrm{St}(v, \mathcal{K}_P)$. Obviously, $\mathrm{St}(v, \mathcal{K}_P)$ is a truncated CAT(0) orthant space, and hence one can compute the geodesic between p and q in $\mathrm{St}(v, \mathcal{K}_P)$ in $O(m^4)$ time, by Theorem 3.7. In addition, one can find a δ-midpoint $w \in \mathrm{St}(v, \mathcal{K}_P)$ of p and q such that the number of bits required for each coordinate of w is bounded by $O(\log(m/\delta))$. This implies (b) and therefore completes the proof of Theorem 3.9.

Abstract

We introduce a weighted version of the ranking algorithm by Karp et al. (STOC 1990), and prove a competitive ratio of 0.6534 for the vertex-weighted online bipartite matching problem when online vertices arrive in random order. Our result shows that random arrivals help beating the 1-1/e barrier even in the vertex-weighted case. We build on the randomized primal-dual framework by Devanur et al. (SODA 2013) and design a two dimensional gain sharing function, which depends not only on the rank of the offline vertex, but also on the arrival time of the online vertex. To our knowledge, this is the first competitive ratio strictly larger than 1-1/e for an online bipartite matching problem achieved under the randomized primal-dual framework. Our algorithm has a natural interpretation that offline vertices offer a larger portion of their weights to the online vertices as time goes by, and each online vertex matches the neighbor with the highest offer at its arrival.

1 Introduction

With a wide range of applications, Online Bipartite Matching and its variants are a focal point in the online algorithms literature. Consider a bipartite graph $G(L \cup R, E)$ on vertices $L \cup R$, where the set L of offline vertices is known in advance and vertices in R arrive online. On the arrival of an online vertex, its incident edges are revealed and the algorithm must irrevocably either match it to one of its unmatched neighbors or leave it unmatched. In a seminal paper, Karp et al. [19] proposed the Ranking algorithm, which picks at the beginning a random permutation over the offline vertices L, and matches each online vertex to the first unmatched neighbor according to the permutation. They proved a tight competitive ratio $1 - \frac{1}{e}$ of Ranking, when online vertices arrive in an arbitrary order. The analysis has been simplified in a series of subsequent works [14, 5, 12]. Further, the Ranking algorithm has been extended to other variants of the Online Bipartite Matching problem, including the vertex-weighted case [2], the random arrival model [18, 21], and the Adwords problem [23, 7, 11].

As a natural generalization, Online Vertex-Weighted Bipartite Matching was considered by Aggarwal et al. [2]. In this problem, each offline vertex $v \in L$ has a non-negative weight w_v, and the objective is to maximize the total weight of the matched offline vertices. A weighted version of the Ranking algorithm was proposed in [2] and shown to be $(1 - \frac{1}{e})$-competitive, matching the problem hardness in the unweighted version. They fix a non-increasing perturbation function $\psi : [0, 1] \to [0, 1]$, and draw a rank $y_v \in [0, 1]$ uniformly and independently for each offline vertex $v \in L$. The offline vertices are then sorted in decreasing order of the *perturbed weight* $w_v \cdot \psi(y_v)$. Each online vertex matches the first unmatched neighbor on the list upon its arrival. It is shown that by choosing the perturbation function $\psi(y) := 1 - e^{y-1}$, the weighted Ranking algorithm achieves a tight competitive ratio $1 - \frac{1}{e}$. In a subsequent work, Devanur et al. [12] simplified the analysis under the randomized primal-dual framework and gave an alternative interpretation of the algorithm: each offline vertex v makes an offer of value $w_v \cdot (1 - g(y_v))$ as long as it is not matched, where $g(y) := e^{y-1}$, and each online vertex matches the neighbor that offers the highest.

Motivated by the practical importance of Online Bipartite Matching and its applications for online advertisements, another line of research seeks for a better theoretical bound beyond the worst-case hardness result provided by Karp et al. [19]. Online Bipartite Matching with random arrivals was considered independently by Karande et al. [18] and Mahdian et al. [21]. They both studied the performance of Ranking assuming that online vertices arrive in a uniform random order and proved competitive ratios 0.653 and 0.696 respectively. On the negative side, Karande et al. [18] explicitly constructed an instance for which Ranking performs no better than 0.727, which is later improved to 0.724 by Chan et al. [9]. In terms of problem hardness, Manshadi et al. [22] showed that no algorithm can achieve a competitive ratio larger than 0.823.

The natural next step is then to consider Online Vertex-Weighted Bipartite Matching with random arrivals. *Do random arrivals help beating* $1 - \frac{1}{e}$ *even in the vertex-weighted case?*

	Arbitrary Arrivals	Random Arrivals
Unweighted	$1 - \frac{1}{e} \approx 0.632$ [19, 5, 12, 14]	0.696 [21]
Vertex-weighted	$1 - \frac{1}{e} \approx 0.632$ [2, 12]	**0.6534 (this paper)**

1.1 Our Results and Techniques

We answer this affirmatively by showing that a generalized version of the Ranking algorithm achieves a competitive ratio 0.6534.

▶ **Theorem 1.** *There exists a* 0.6534*-competitive algorithm for the vertex-weighted Online Bipartite Matching with random arrivals.*

Interestingly, we do not obtain our result by generalizing existing works that break the $1 - \frac{1}{e}$ barrier on the unweighted case [18, 21] to the vertex-weighted case. Instead, we take a totally different path, and build our analysis on the randomized primal-dual technique introduced by Devanur et al. [12], which was used to provide a more unified analysis of the algorithms for the Online Bipartite Matching with arbitrary arrival order and its extensions.

We first briefly review the proof of Devanur et al. [12]. The randomized primal-dual technique can be viewed as a charging argument for sharing the gain of each matched edge between its two endpoints. Recall that in the algorithm of [2, 12], each unmatched offline vertex offers a value of $w_v \cdot (1 - g(y_v))$ to online vertices, and each online vertex matches the neighbor that offers the highest at its arrival. Whenever an edge (u, v) is added to the matching, where $v \in L$ is an offline vertex and $u \in R$ is an online vertex, imagine a total gain of w_v being shared between u and v such that u gets $w_v \cdot (1 - g(y_v))$ and v gets $w_v \cdot g(y_v)$. Since g is non-decreasing, the smaller the rank of v, the smaller share it gets. They showed that by fixing $g(y) = e^{y-1}$, for any edge (u, v) and any fixed ranks of offline vertices other than v, the expected gains of u and v (from all of their incident edges) combined is at least $(1 - \frac{1}{e}) \cdot w_v$ over the randomness of y_v, which implies the $1 - \frac{1}{e}$ competitive ratio.

Now we consider the problem with random arrivals.

Analogous to the offline vertices, as the online vertices arrive in random order, in the gain sharing process, it is natural to give an online vertex u a smaller share if u arrives early (as it is more likely be get matched), and a larger share when u arrives late. Thus we consider the following version of the weighted Ranking algorithm.

Let y_u be the arrival time of online vertex $u \in R$, which is chosen uniformly at random from $[0, 1]$. Analogous to the ranks of the offline vertices, we also call y_u the rank of $u \in R$. Fix a function $g : [0, 1]^2 \to [0, 1]$ that is non-decreasing in the first dimension and non-increasing in the second dimension. On the arrival of $u \in R$, each unmatched neighbor $v \in L$ of u makes an offer of value $w_v \cdot (1 - g(y_v, y_u))$, and u matches the neighbor with the highest offer. This algorithm straightforwardly leads to a gain sharing rule for dual assignments: whenever $u \in R$ matches $v \in L$, let the gain of u be $w_v \cdot (1 - g(y_v, y_u))$ and the gain of v be $w_v \cdot g(y_v, y_u)$. It suffices to show that, for an appropriate function g, the expected gain of u and v combined is at least $0.6534 \cdot w_v$ over the randomness of both y_u and y_v.

The main difficulty of the analysis is to give a good characterization of the behavior of the algorithm when we vary the ranks of both $u \in R$ and $v \in L$, while fixing the ranks of all other vertices arbitrarily. The previous analysis for the unweighted case with random arrivals [18, 21] heavily relies on a symmetry between the random ranks of offline vertices and online vertices: Properties developed for the offline vertices in previous work directly translate to their online counterparts. Unfortunately, the online and offline sides are no longer symmetric in the vertex-weighted case. In particular, for the offline vertex v, an important property is that for any given rank y_u of the online vertex u, we can define a unique marginal rank θ such that v will be matched if and only if its rank $y_v < \theta$. However, it is not possible to define such a marginal rank for the online vertex u in the vertex-weighted case: As its arrival time changes, its matching status may change back and forth. The most important technical ingredient of our analysis is an appropriate lower bound on the expected gain

which allows us to partially characterize the worst-case scenario (in the sense of minimizing the lower bound on the expected gain). Further, the worst-case scenario does admit simple marginal ranks even for the online vertex u. This allows us to design a symmetric gain sharing function g and complete the competitive analysis of 0.6534.

1.2 Other Related Works

There is a vast literature on problems related to Online Bipartite Matching. For space reasons, we only list some of the most related here.

Kesselheim et al. [20] considered the edge-weighted Online Bipartite Matching with random arrivals, and proposed a $\frac{1}{e}$-competitive algorithm. The competitive ratio is tight as it matches the lower bound on the classical secretary problem [8]. Wang and Wong [24] considered a different model of Online Bipartite Matching with both sides of vertices arriving online (in an arbitrary order): A vertex can only actively match other vertices at its arrival; if it fails to match at its arrival, it may still get matched passively by other vertices later. They showed a 0.526-competitive algorithm for a fractional version of the problem.

Recently, Cohen and Wajc [10] considered the Online Bipartite Matching (with arbitrary arrival order) on regular graphs, and provided a $(1 - O(\sqrt{\log d/d}))$-competitive algorithm, where d is the degree of vertices. Very recently, Huang et al. [16] proposed a fully online matching model, in which all vertices of the graph arrive online (in an arbitrary order). Extending the randomized primal-dual technique, they obtained competitive ratios above 0.5 for both bipartite graphs and general graphs.

Similar but different from the Online Bipartite Matching with random arrivals, in the stochastic Online Bipartite Matching, the online vertices arrive according to some known probability distribution (with repetition). Competitive ratios breaking the $1 - \frac{1}{e}$ barrier have been achieved for the unweighted case [13, 4, 6] and the vertex-weighted case [15, 17, 6].

The Online Bipartite Matching with random arrivals is closely related to the oblivious matching problem [3, 9, 1] (on bipartite graphs). It can be easily shown that Ranking has equivalent performance on the two problems. Thus competitive ratios above $1 - \frac{1}{e}$ [18, 21] directly translate to the oblivious matching problem. Generalizations of the problem to arbitrary graphs have also been considered, and competitive ratios above half are achieved for the unweighted case [3, 9] and vertex-weighted case [1].

2 Preliminaries

We consider the Online Vertex-Weighted Bipartite Matching with random arrival order. Let $G(L \cup R, E)$ be the underlying graph, where vertices in L are given in advance and vertices in R arrive online in random order. Each offline vertex $v \in L$ is associated with a non-negative weight w_v. Without loss of generality, we assume the arrival time y_u of each online vertex $u \in R$ is drawn independently and uniformly from $[0, 1]$. Mahdian and Yan [21] use another interpretation for the random arrival model. They denote the order of arrival of online vertices by a permutation π and assume that π is drawn uniformly at random from the permutation group S_n. It is easy to see the equivalence between two interpretations[4].

[4] Mapping from an arrival time vector to a permutation is immediate. Given a permutation π, we independently draw n random variables uniformly from $[0, 1]$ and assign these values to be the arrival times of all vertices according to the permutation π, from the smallest to the largest.

Weighted Ranking. Fix a function $g : [0,1]^2 \to [0,1]$ such that $\frac{\partial g(x,y)}{\partial x} \geq 0$ and $\frac{\partial g(x,y)}{\partial y} \leq 0$. Each offline vertex $v \in L$ draws independently a random rank $y_v \in [0,1]$ uniformly at random. Upon the arrival of online vertex $u \in R$, u is matched to its unmatched neighbor v with maximum $w_v \cdot (1 - g(y_v, y_u))$.

▶ Remark. In the adversarial model, Aggarwal et al.'s algorithm [2] can be interpreted as choosing $g(y_v, y_u) := e^{y_v - 1}$ in our algorithm. Our algorithm is a direct generalization of theirs to the random arrival model.

For simplicity, for each $u \in R$, we also call its arrival time y_u the rank of u. We use $\vec{y} : L \cup R \to [0,1]$ to denote the vector of all ranks.

Consider the linear program relaxation of the bipartite matching problem and its dual.

$$\begin{array}{lllllll} \max: & \sum_{(u,v)\in E} w_v \cdot x_{uv} & & & \min: & \sum_{u\in V} \alpha_u & \\ \text{s.t.} & \sum_{v:(u,v)\in E} x_{uv} \leq 1 & \forall u \in L \cup R & & \text{s.t.} & \alpha_u + \alpha_v \geq w_v & \forall (u,v) \in E \\ & x_{uv} \geq 0 & \forall (u,v) \in E & & & \alpha_u \geq 0 & \forall u \in L \cup R \end{array}$$

Randomized Primal-Dual. Our analysis builds on the randomized primal-dual technique by Devanur et al. [12]. We set the primal variables according to the matching produced by Ranking, i.e. $x_{uv} = 1$ if and only if u is matched to v by Ranking, and set the dual variables so that the dual objective equals the primal. In particular, we split the gain w_v of each matched edge (u,v) between vertices u and v; the dual variable for each vertex then equals the share it gets. Given primal feasibility and equal objectives, the usual primal-dual techniques would further seek to show approximate dual feasibility, namely, $\alpha_u + \alpha_v \geq F \cdot w_v$ for every edge (u,v), where F is the target competitive ratio. Observe that the above primal and dual assignments are themselves random variables. Devanur et al. [12] claimed that the primal-dual argument goes through given approximate dual feasibility in expectation. We formulate this insight in the following lemma and include a proof for completeness.

▶ **Lemma 2.** *Ranking is F-competitive if we can set (non-negative) dual variables such that*

- $\sum_{(u,v)\in E} x_{uv} = \sum_{u\in V} \alpha_u$*; and*
- $\mathbf{E}_{\vec{y}}[\alpha_u + \alpha_v] \geq F \cdot w_v$ *for all* $(u,v) \in E$*.*

Proof. We can set a feasible dual solution $\tilde{\alpha}_u := \mathbf{E}_{\vec{y}}[\alpha_u]/F$ for all $u \in V$. It's feasible because we have $\tilde{\alpha}_u + \tilde{\alpha}_v = \mathbf{E}_{\vec{y}}[\alpha_u + \alpha_v]/F \geq w_v$ for all $(u,v) \in E$. Then by duality we know that the dual solution is at least the optimal primal solution PRIMAL, which is also at least the optimal offline solution of the problem: $\sum_{u\in V} \tilde{\alpha}_u \geq \mathsf{PRIMAL} \geq \mathsf{OPT}$. Then by the first assumption, we have $\mathsf{OPT} \leq \sum_{u\in V} \tilde{\alpha}_u = \sum_{u\in V} \frac{\mathbf{E}_{\vec{y}}[\alpha_u]}{F} = \frac{1}{F}\mathbf{E}_{\vec{y}}\left[\sum_{u\in V} \alpha_u\right] = \frac{1}{F}\mathbf{E}_{\vec{y}}\left[\sum_{(u,v)\in E} w_v \cdot x_{uv}\right] = \frac{1}{F}\mathbf{E}[\mathsf{ALG}]$, which implies an F competitive ratio. ◀

In the rest of the paper, we set

$$g(x,y) = \frac{1}{2}\big(h(x) + 1 - h(y)\big), \qquad \forall x, y \in [0,1]$$

where $h : [0,1] \to [0,1]$ is a non-decreasing function (to be fixed later) with $h'(x) \leq h(x)$ for all $x \in [0,1]$. Observe that $\frac{\partial g(x,y)}{\partial x} = \frac{1}{2}h'(x) \geq 0$ and $\frac{\partial g(x,y)}{\partial y} = -\frac{1}{2}h'(y) \leq 0$. By definition of g, we have $g(x,y) + g(y,x) = 1$. Moreover, for any $x, y \in [0,1]$, we have the following fact that will be useful for our analysis.

▶ **Claim 2.1.** $\frac{\partial g(x,y)}{\partial y} \geq g(x,y) - 1$.

Proof. $\frac{\partial g(x,y)}{\partial y} = -\frac{1}{2}h'(y) \geq -\frac{1}{2}h(y) \geq \frac{1}{2}(h(x) + 1 - h(y)) - 1 = g(x,y) - 1$. ◀

3 A Simple Lower Bound

In this section, we prove a slightly smaller competitive ratio, $\frac{5}{4} - e^{-0.5} \approx 0.6434$, as a warm-up of the later analysis.

We reinterpret our algorithm as follows. As time t goes, each unmatched offline vertex $v \in L$ is dynamically priced at $w_v \cdot g(y_v, t)$. Since g is non-increasing in the second dimension, the prices do not increase as time goes by. Upon the arrival of $u \in R$, u can choose from its unmatched neighbors by paying the corresponding price. The utility of u derived by choosing v equals $w_v - w_v \cdot g(y_v, y_u)$. Then u chooses the one that gives the highest utility. Recall that g is non-decreasing in the first dimension. Thus, u prefers offline vertices with smaller ranks, as they offer lower prices.

This leads to the following monotonicity property as in previous works [2, 12].

▶ **Fact 3.1** (Monotonicity). *For any $\vec{y}$, if $v \in L$ is unmatched when $u \in R$ arrives, then when y_v increases, v remains unmatched when u arrives. Equivalently, if $v \in L$ is matched when $u \in R$ arrives, then when y_v decreases, v remains matched when u arrives.*

Gain Sharing. The above interpretation induces a straightforward gain sharing rule: whenever $u \in R$ is matched to $v \in L$, let $\alpha_v := w_v \cdot g(y_v, y_u)$ and $\alpha_u := w_v \cdot (1 - g(y_v, y_u)) = w_v \cdot g(y_u, y_v)$.

Note that the gain of an offline vertex is larger if it is matched earlier, i.e., being matched earlier is more beneficial for offline vertices (α_v is larger). However, the fact does not hold for online vertices. For each online vertex $u \in R$, the earlier u arrives (smaller y_u is), the more offers u sees. On the other hand, the prices of offline vertices are higher when u comes earlier. Thus, it is not guaranteed that earlier arrival time y_u induces larger α_u.

This is where our algorithm deviates from previous ones [2, 12], in which the prices of offline vertices are static (independent of time). The above observation is crucial and necessary for breaking the $1 - \frac{1}{e}$ barrier in the random arrival model.

To apply Lemma 2, we consider a pair of neighbors $v \in L$ and $u \in R$. We fix an arbitrary assignment of ranks to all vertices but u, v. Our goal is to establish a lower bound of $\frac{1}{w_v} \cdot \mathbf{E}[\alpha_u + \alpha_v]$, where the expectation is simultaneously taken over y_u and y_v.

▶ **Lemma 3.** *For each $y \in [0, 1]$, there exist thresholds $1 \geq \theta(y) \geq \beta(y) \geq 0$ such that when u arrives at time $y_u = y$,*

- *if $y_v < \beta(y)$, v is matched when u arrives;*
- *if $y_v \in (\beta(y), \theta(y))$, v is matched to u;*
- *if $y_v > \theta(y)$, v is unmatched after u's arrival.*

Moreover, $\beta(y)$ is a non-decreasing function and if $\theta(x) = 1$ for some $x \in [0, 1]$, then $\theta(x') = 1$ for all $x' \geq x$.

Proof. Consider the moment when u arrives. By Fact 3.1, there exists a threshold $\beta(y_u)$ such that v is matched when u arrives iff $y_v < \beta(y_u)$. Now suppose $y_v > \beta(y_u)$, in which case v is unmatched when u arrives. Thus v is priced at $w_v \cdot g(y_v, y_u)$ and u can get utility $w_v \cdot g(y_u, y_v)$ by choosing v.

Recall that $g(y_u, y_v)$ is non-increasing in terms of y_v. Let $\theta(y_u) \geq \beta(y_u)$ be the minimum value of y_v such that v is not chosen by u. In other words, when $\beta(y_u) < y_v < \theta(y_u)$, v is matched to u and when $y_v > \theta(y_u)$, v is unmatched after u's arrival.

Next we show that β is a non-decreasing function of y_u. By definition, if $y_v < \beta(y_u)$, then v is matched when u arrives. Straightforwardly, when y_u increases to y'_u (arrives even

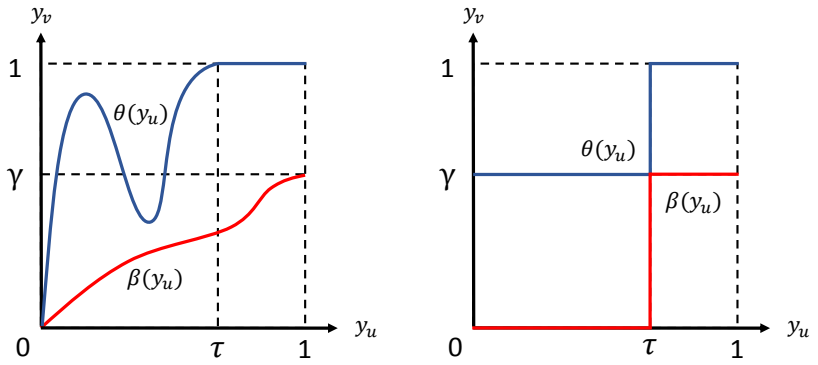

Figure 1 $\theta(y_u)$ and $\beta(y_u)$ (left hand side); truncated $\theta(y_u)$ and $\beta(y_u)$ (right hand side).

later), v would remain matched. Hence, we have $\beta(y'_u) \geq \beta(y_u)$ for all $y'_u > y_u$, i.e. β is non-decreasing (refer to Figure 1).

Finally, we show that if $\theta(x) = 1$ for some $x \in [0,1]$, then $\theta(x') = 1$ for all $x' \geq x$. Assume for the sake of contradiction that $\theta(x') < 1$ for some $x' > x$. In other words, when $y_u = x'$ and $y_v = 1$, v is unmatched when u arrives, but u chooses some vertex $z \neq v$, such that $w_z \cdot g(x', y_z) > w_v \cdot g(x', 1)$.

Now consider the case when u arrives at time $y_u = x$. Recall that we have $\theta(x) = 1$, which means that u matches v when $y_u = x$ and $y_v = 1$. By our assumption, both v and z are unmatched when u arrives at time x'. Thus when u arrives at an earlier time x, both v and z are unmatched. Moreover, choosing z induces utility

$$\begin{aligned} w_z \cdot g(x, y_z) &= w_z \cdot g(x', y_z) \cdot \frac{g(x, y_z)}{g(x', y_z)} > w_v \cdot g(x', 1) \cdot \frac{g(x, y_z)}{g(x', y_z)} \\ &= w_v \cdot g(x', 1) \cdot \frac{h(x) + 1 - h(y_z)}{h(x') + 1 - h(y_z)} \geq w_v \cdot g(x', 1) \cdot \frac{h(x) + 1 - h(1)}{h(x') + 1 - h(1)} \\ &= w_v \cdot g(x', 1) \cdot \frac{g(x, 1)}{g(x', 1)} = w_v \cdot g(x, 1), \end{aligned}$$

where the second inequality holds since h is a non-decreasing function and $x < x'$.

This gives a contradiction, since when $y_u = x$ and $y_v = 1$, u chooses v, while choosing z gives strictly higher utility. ◀

▶ Remark. Observe that the function θ is not necessarily monotone. This comes from the fact that u may prefer v to z when u arrives at time t but prefer z to v when u arrives later at time $t' > t$. Note that this happens only when the offline vertices have general weights: for the unweighted case, it is easy to show that θ must be non-decreasing.

We define $\tau, \gamma \in [0,1]$, which depend on the input instance, as follows.

If $\theta(y) < 1$ for all $y \in [0,1]$, then let $\tau = 1$; otherwise let τ be the minimum value such that $\theta(\tau) = 1$. Let $\gamma := \beta(1)$. Note that it is possible that $\gamma \in \{0,1\}$.

Since β is non-decreasing, we define $\beta^{-1}(x) := \sup\{y : \beta(y) = x\}$ for all $x \leq \gamma$.

In the following, we establish a lower bound for $\frac{1}{w_v} \cdot \mathbf{E}[\alpha_u + \alpha_v]$.

▶ **Lemma 4** (Main Lemma). *For each pair of neighbors $u \in R$ and $v \in L$, we have*

$$\frac{1}{w_v} \cdot \mathbf{E}[\alpha_u + \alpha_v] \geq \min_{0 \leq \gamma, \tau \leq 1} \left\{ (1-\tau) \cdot (1-\gamma) + \int_0^{\gamma} g(x, \tau) dx + \int_0^{\tau} g(x, \gamma) dx \right\}.$$

We prove Lemma 4 by the following three lemmas.

Observe that for any $y_u \in [0,1]$, if $y_v \in (\beta(y_u), \theta(y_u))$, u, v are matched to each other, which implies $\alpha_u + \alpha_v = w_v$. Hence we have the following lemma immediately.

▶ **Lemma 5** (Corner Gain). $\mathbf{E}\left[(\alpha_u + \alpha_v) \cdot \mathbb{1}(y_u > \tau, y_v > \gamma)\right] = w_v \cdot (1-\tau) \cdot (1-\gamma)$.

Now we give a lower bound for the gain of v when $y_v < \gamma$, i.e., $\alpha_v \cdot \mathbb{1}(y_v < \gamma)$, plus the gain of u when $y_v < \gamma$ and $y_u > \tau$, i.e., $\alpha_u \cdot \mathbb{1}(y_v < \gamma, y_u > \tau)$. The key to prove the lemma is to show that for all $y_v < \gamma$, no matter when u arrives, we always have $\alpha_v \geq w_v \cdot g(y_v, \beta^{-1}(y_v))$.

▶ **Lemma 6** (v's Gain). $\mathbf{E}\left[\alpha_v \cdot \mathbb{1}(y_v < \gamma) + \alpha_u \cdot \mathbb{1}(y_v < \gamma, y_u > \tau)\right] \geq w_v \cdot \int_0^\gamma g(x,\tau)dx$.

Proof. Fix $y_v = x < \gamma$. We first show that for all $y_u \in [0,1]$, $\alpha_v \geq w_v \cdot g(x, \beta^{-1}(x))$. By definition, we have $\beta^{-1}(x) < 1$. Hence when $y_u > \beta^{-1}(x)$, v is already matched when u arrives. Suppose v is matched to some $z \in R$, then we have $y_z \leq \beta^{-1}(x)$ and hence $\alpha_v \geq w_v \cdot g(x, \beta^{-1}(x))$. Now consider when u arrives at time $y < \beta^{-1}(x)$. If $y > y_z$, then v is still matched to z when u arrives, and $\alpha_v \geq w_v \cdot g(x, \beta^{-1}(x))$ holds. Now suppose $y < y_z$. We compare the two processes, namely when $y_u > \beta^{-1}(x)$ and when $y_u = y$.

We show that for each vertex $w \in L$, the time it is matched is not later in the second case (compared to the first case). In other words, we show that decreasing the rank of any online vertex is not harmful for all offline vertices. Suppose otherwise, let w be the first vertex in L that is matched later when $y_u = y$ than when $y_u > \beta^{-1}(x)$. I.e. among all these vertices, w's matched neighbor arrives the earliest when $y_u > \beta^{-1}(x)$.

Let u_1 be the vertex w is matched to when $y_u > \beta^{-1}(x)$ and u_2 be the vertex w is matched to when $y_u = y$. By assumption, we have $y_{u_2} > y_{u_1}$. Consider when $y_u = y$ and the moment when u_1 arrives, w remains unmatched but is not chosen by u_1. However, w is the first vertex that is matched later than it was when $y_u > \beta^{-1}(x)$, we know that at u_1's arrival, the set of unmatched neighbor of u_1 is a subset of that when $y_u > \beta^{-1}(x)$. This leads to a contradiction, since w gives the highest utility, but is not chosen by u_1.

In particular, this property holds for vertex v, i.e. v is matched earlier or at the arrival of z and hence $\alpha_v \geq w_v \cdot g(x, y_z) \geq w_v \cdot g(x, \beta^{-1}(x))$, as claimed.

Observe that for $y_v < \gamma$ and $y_u \in (\tau, \beta^{-1}(y_v))$, we have $\alpha_u + \alpha_v = w_v$. Thus for $y_v = x < \gamma$, we lower bound $\frac{1}{w_v} \cdot \mathbf{E}_{y_u}\left[\alpha_v \cdot \mathbb{1}(y_v < \gamma) + \alpha_u \cdot \mathbb{1}(y_v < \gamma, y_u > \tau)\right]$ by

$$f(x, \beta^{-1}(x)) := g(x, \beta^{-1}(x)) + \max\{0, \beta^{-1}(x) - \tau\} \cdot (1 - g(x, \beta^{-1}(x))).$$

It suffices to show that $f(x, \beta^{-1}(x)) \geq g(x, \tau)$. Consider the following two cases.

1. If $\beta^{-1}(x) < \tau$, then $f(x, \beta^{-1}(x)) = g(x, \beta^{-1}(x)) \geq g(x, \tau)$, since $\frac{\partial g(x,y)}{\partial y} \leq 0$.
2. If $\beta^{-1}(x) \geq \tau$, then $f(x, \beta^{-1}(x))$ is non-decreasing in the second dimension, since

$$\frac{\partial f(x, \beta^{-1}(x))}{\partial \beta^{-1}(x)} = \frac{\partial g(x, \beta^{-1}(x))}{\partial \beta^{-1}(x)} + 1 - g(x, \beta^{-1}(x)) - (\beta^{-1}(x) - \tau) \cdot \frac{\partial g(x, \beta^{-1}(x))}{\partial \beta^{-1}(x)} \geq 0,$$

where the inequality follows from Claim 2.1 and $\frac{\partial g(x, \beta^{-1}(x))}{\partial \beta^{-1}(x)} \leq 0$. Therefore, we have $f(x, \beta^{-1}(x)) \geq f(x, \tau) = g(x, \tau)$.

Hence for every fixed $y_v = x < \gamma$ we have $\mathbf{E}_{y_u}\left[\alpha_v \cdot \mathbb{1}(y_v < \gamma) + \alpha_u \cdot \mathbb{1}(y_v < \gamma, y_u > \tau)\right] \geq w_v \cdot g(x, \tau)$. Taking integration over $x \in (0, \gamma)$ concludes the lemma. ◀

Next we give a lower bound for the gain of u when $y_u < \tau$, i.e., $\alpha_u \cdot \mathbb{1}(y_u < \tau)$, plus the gain of v when $y_u < \tau$ and $y_v > \gamma$, i.e., $\alpha_v \cdot \mathbb{1}(y_u < \tau, y_v > \gamma)$. The following proof is in the

same spirit as in the proof of Lemma 6, although the ranks of offline vertices have different meaning from the ranks (arrival times) of online vertices.

Similar to the proof of Lemma 6, the key is to show that for all $y_u < \tau$, no matter what value y_v is, the gain of α_u is always at least $w_v \cdot g(y_u, \theta(y_u))$.

▶ **Lemma 7** (u's Gain). $\mathbf{E}\left[\alpha_u \cdot \mathbb{1}(y_u < \tau) + \alpha_v \cdot \mathbb{1}(y_u < \tau, y_v > \gamma)\right] \geq w_v \cdot \int_0^\tau g(x,\gamma)dx$.

Proof. Fix $y_u = x < \tau$. By definition we have $\theta(x) < 1$. The analysis is similar to the previous. We first show that for all $y_v \in [0,1]$, we have $\alpha_u \geq w_v \cdot g(x, \theta(x))$.

We use θ to denote the value that is arbitrarily close to, but larger than $\theta(x)$. By definition, when $y_v = \theta$, u matches some vertex other than v. Thus we have $\alpha_u \geq w_v \cdot g(x, \theta(x))$. Hence, when $y_v > \theta$, i.e. v has a higher price, u would choose the same vertex as when $y_v = \theta$, and $\alpha_u \geq w_v \cdot g(x, \theta(x))$ still holds.

Now consider the case when $y_v = y < \theta$.

As in the analysis of Lemma 6, we compare two processes, when $y_v = \theta$ and when $y_v = y < \theta$. We show that for each vertex $w \in R$ (including u) with $y_w \leq x = y_u$, the utility of w when $y_v = y$ is not worse than its utility when $y_v = \theta$. Suppose otherwise, let w be such a vertex with earliest arrival time.

Let v' be the vertex that is matched to w when $y_v = \theta$. Then we know that (when $y_v = y$) at w's arrival, w chooses a vertex that gives less utility comparing to v'. Hence, at this moment v' is already matched to some w' with $y_{w'} < y_w$. This implies that when $y_v = \theta$, v' (which is matched to w) is unmatched when w' arrives, but not chosen by w'. Therefore, w' has lower utility when $y_v = y$ compared to the case when $y_v = \theta$, which contradicts the assumption that w is the first such vertex.

Observe that when $y_v \in (\gamma, \theta(x))$, we have $\alpha_u + \alpha_v = w_v$. Thus for any fixed $y_u = x < \tau$, we lower bound $\frac{1}{w_v} \cdot \mathbf{E}_{y_v}\left[\alpha_u \cdot \mathbb{1}(y_u < \tau) + \alpha_v \cdot \mathbb{1}(y_u < \tau, y_v > \gamma)\right]$ by

$$f(x, \theta(x)) := g(x, \theta(x)) + \max\{0, \theta(x) - \gamma\} \cdot (1 - g(x, \theta(x))).$$

In the following, we show that $f(x, \theta(x)) \geq g(x, \gamma)$. Consider the following two cases.

1. If $\theta(x) \leq \gamma$, then $f(x, \theta(x)) = g(x, \theta(x)) \geq g(x, \gamma)$, since $\frac{\partial g(x,y)}{\partial y} \leq 0$.
2. If $\theta(x) > \gamma$, then

$$\frac{\partial f(x, \theta(x))}{\partial \theta(x)} = \frac{\partial g(x, \theta(x))}{\partial \theta(x)} + 1 - g(x, \theta(x)) - (\theta(x) - \gamma) \cdot \frac{\partial g(x, \theta(x))}{\partial \theta(x)} \geq 0,$$

where the inequality follows from Claim (2.1) and $\frac{\partial g(x,\theta(x))}{\partial \theta(x)} \leq 0$. Therefore, we have $f(x, \theta(x)) \geq f(x, \gamma) = g(x, \gamma)$.

Finally, take integration over $x \in (0, \tau)$ concludes the lemma. ◀

Proof of Lemma 4. Observe that $\alpha_u + \alpha_v = (\alpha_u + \alpha_v) \cdot \mathbb{1}(y_u > \tau, y_v > \gamma) + \alpha_v \cdot \mathbb{1}(y_v < \gamma) + \alpha_u \cdot \mathbb{1}(y_v < \gamma, y_u > \tau) + \alpha_u \cdot \mathbb{1}(y_u < \tau) + \alpha_v \cdot \mathbb{1}(y_u < \tau, y_v > \gamma)$. Combing Lemma 5, 6 and 7 finishes the proof immediately. ◀

▶ **Theorem 8.** *Fix $h(x) = \min\{1, e^{x-0.5}\}$. For any pair of neighbors u and v, and any fixed ranks of vertices in $L \cup R \setminus \{u, v\}$, we have $\frac{1}{w_v} \cdot \mathbf{E}_{y_u, y_v}\left[\alpha_u + \alpha_v\right] \geq \frac{5}{4} - e^{-0.5} \approx 0.6434$.*

Proof. It suffices to show that the RHS of Lemma 4 is at least $\frac{5}{4} - e^{-0.5}$. Since the expression is symmetric for τ and γ, we assume $\tau \geq \gamma$ without loss of generality.

Let $f(\tau, \gamma)$ be the term on the RHS of Lemma 4 to be minimized. By our choice of g,

$$\begin{aligned} f(\tau,\gamma) =& 1 - \tau - \gamma + \tau\cdot\gamma + \frac{1}{2}\int_0^{\gamma}\big(h(x)+1-h(\tau)\big)dx + \frac{1}{2}\int_0^{\tau}\big(h(x)+1-h(\gamma)\big)dx \\ =& 1 - \frac{\tau}{2}(1+h(\gamma)) - \frac{\gamma}{2}(1+h(\tau)) + \tau\cdot\gamma + \frac{1}{2}\int_0^{\gamma}h(x)dx + \frac{1}{2}\int_0^{\tau}h(x)dx. \end{aligned}$$

Observe that

$$\frac{\partial f(\tau,\gamma)}{\partial \tau} = \gamma - \frac{1}{2}(1+h(\gamma)) - \frac{\gamma}{2}\cdot h'(\tau) + \frac{1}{2}h(\tau).$$

It is easy to check that $\gamma - \frac{1}{2}h(\gamma) \le 0$ when $\gamma \le \frac{1}{2}$; and $\gamma - \frac{1}{2}h(\gamma) > 0$ when $\gamma > \frac{1}{2}$.

Hence when $\gamma \le \frac{1}{2}$, we have $\frac{\partial f(\tau,\gamma)}{\partial \tau} \le 0$, which means that the minimum is attained when $\tau = 1$. Note that when $\gamma \le \frac{1}{2}$, we have

$$f(1,\gamma) = \frac{1}{2}(1-h(\gamma)) + \frac{1}{2}\int_0^{\gamma}h(x)dx + \frac{1}{2}\int_0^{1}h(x)dx,$$

which attains its minimum at $\gamma = 0$ (since $h'(\gamma) = h(\gamma)$ for $\gamma \le \frac{1}{2}$):

$$f(1,0) = \frac{1}{2}(1-e^{-0.5}) + \frac{1}{2}(\frac{1}{2}+1-e^{-0.5}) = \frac{5}{4} - e^{-0.5} \approx 0.6434.$$

When $\tau \ge \gamma > \frac{1}{2}$, we have $\frac{\partial f(\tau,\gamma)}{\partial \tau} = \gamma - \frac{1}{2}h(\gamma) > 0$. Hence the minimum is attained when $\tau = \gamma$, which is $f(\gamma,\gamma) = 1 - 2\gamma + \gamma^2 + \int_0^{\gamma}h(x)dx$. Observe that

$$\frac{df(\gamma,\gamma)}{d\gamma} = -2 + 2\gamma + h(\gamma) \ge -2 + 1 + 1 = 0.$$

The minimum is attained when $\gamma = \frac{1}{2}$, which equals $f(\frac{1}{2},\frac{1}{2}) = \frac{5}{4} - e^{-0.5} \approx 0.6434$. ◀

4 Improving the Competitive Ratio

Observe that in Lemma 4, we relax the total gain of $\alpha_u + \alpha_v$ into two parts: (1) when $y_u \ge \tau$ and $y_v \ge \gamma$, $\alpha_u + \alpha_v = w_v$. (2) for other ranks y_u, y_v, we lower bound α_u and α_v by $w_v \cdot g(y_u,\gamma)$ and $w_v \cdot g(y_v,\tau)$ respectively. For the second part, the inequalities used in the proof of Lemma 6 and 7 are tight only if β, θ are two step functions (refer to Figure 1). On the other hand, given these β, θ, when $y_u \le \tau$ and $y_v \le \gamma$, we actually have $\alpha_u + \alpha_v = w_v$, which is strictly larger than our estimation $w_v \cdot (g(y_u,\gamma) + g(y_v,\tau))$.

With this observation, it is natural to expect an improved bound if we can retrieve this part of gain (even partially). In this section, we prove an improved competitive ratio 0.6534, using a refined lower bound for $\frac{1}{w_v}\cdot\mathbf{E}[\alpha_u+\alpha_v]$ (compared to Lemma 4) as follows.

▶ **Lemma 9** (Improved Bound). *For any pair of neighbors $u \in R$ and $v \in L$, we have*

$$\begin{aligned} \frac{1}{w_v}\cdot\mathbf{E}[\alpha_u+\alpha_v] \ge \min_{0\le\gamma,\tau\le 1}\Bigg\{&(1-\tau)(1-\gamma) + (1-\tau)\int_0^{\gamma}g(x,\tau)dx \\ &+ \int_0^{\tau}\min_{\theta\le\gamma}\Big\{g(x,\theta) + \int_0^{\theta}g(y,x)dy + \int_{\theta}^{\gamma}g(y,\tau)dy\Big\}dx\Bigg\}. \end{aligned}$$

Proof. Let γ and τ be defined as before, i.e., $\gamma = \beta(1)$ and $\tau = \min\{x : \theta(x) = 1\}$.

We divide $\frac{1}{w_v} \cdot \mathbf{E}\left[\alpha_u + \alpha_v\right]$ into three parts, namely (1) when $y_u > \tau$ and $y_v > \gamma$; (2) when $y_u > \tau$ and $y_v < \gamma$; and (3) when $y_u < \tau$:

$$\begin{aligned}\frac{1}{w_v} \cdot \mathbf{E}\left[\alpha_u + \alpha_v\right] = & \frac{1}{w_v} \cdot \mathbf{E}\left[(\alpha_u + \alpha_v) \cdot \mathbb{1}(y_u > \tau, y_v > \gamma)\right] \\ & + \frac{1}{w_v} \cdot \mathbf{E}\left[(\alpha_u + \alpha_v) \cdot \mathbb{1}(y_u > \tau, y_v < \gamma)\right] \\ & + \frac{1}{w_v} \cdot \mathbf{E}\left[(\alpha_u + \alpha_v) \cdot \mathbb{1}(y_u < \tau)\right].\end{aligned}$$

As shown in Lemma 5, the first term is at least $(1-\tau)\cdot(1-\gamma)$, as we have $\alpha_u + \alpha_v = w_v$ for all $y_u > \tau$ and $y_v > \gamma$. Then we consider the second term, the expected gain of $\alpha_u + \alpha_v$ when $y_v < \gamma$ and $y_u > \tau$. For any $y_v < \gamma$, as we have shown in Lemma 6, $\alpha_v \geq w_v \cdot g(y_v, \beta^{-1}(y_v))$ for all $y_u > \tau$. Moreover, when $y_u < \beta^{-1}(y_v)$, we have $\alpha_u + \alpha_v = w_v$. Hence the second term can be lower bounded by

$$\int_0^\gamma \Big((1-\tau) \cdot g(y_v, \beta^{-1}(y_v)) + \max\{0, \beta^{-1}(y_v) - \tau\} \cdot \big(1 - g(y_v, \beta^{-1}(y_v))\big)\Big) dy_v.$$

Now we consider the last term and fix a $y_u < \tau$.

As we have shown in Lemma 7, for all $y_v \in [0,1]$, $\alpha_u \geq w_v \cdot g(y_u, \theta(y_u))$.

Consider the case when $\theta(y_u) > \gamma$, then for $y_v \in (0, \gamma)$, $\alpha_v \geq w_v \cdot g(y_v, y_u)$; for $y_v \in (\gamma, \theta(y_u))$, $\alpha_u + \alpha_v = w_v$. Thus the expected gain of $\alpha_u + \alpha_v$ (taken over the randomness of y_v) can be lower bounded by

$$w_v \cdot \Big(g(y_u, \theta(y_u)) + \int_0^\gamma g(y_v, y_u) dy_v + (\theta(y_u) - \gamma) \cdot (1 - g(y_u, \theta(y_u)))\Big).$$

As we have shown in Lemma 7, the partial derivative over $\theta(y_u)$ is non-negative, thus for the purpose of lower bounding $\frac{1}{w_v} \cdot \mathbf{E}\left[\alpha_u + \alpha_v\right]$, we can assume that $\theta(y_u) \leq \gamma$ for all $y_u < \tau$.

Given that $\theta(y_u) \leq \gamma$, we have $\alpha_v \geq w_v \cdot g(y_v, y_u)$ when $y_v \in (0, , \theta(y_u))$; and $\alpha_v \geq w_v \cdot g(y_v, \beta^{-1}(y_v))$ when $y_v \in (\theta(y_u), \gamma)$.

Hence the third term can be lower bounded by

$$\int_0^\tau \Big(g(y_u, \theta(y_u)) + \int_0^{\theta(y_u)} g(y_v, y_u) dy_v + \int_{\theta(y_u)}^\gamma g(y_v, \beta^{-1}(y_v)) dy_v\Big) dy_u$$

Putting the three lower bounds together and taking the partial derivative over $\beta^{-1}(y_v)$, for those $\beta^{-1}(y_v) > \tau$, we have a non-negative derivative as follows:

$$\frac{\partial g(y_v, \beta^{-1}(y_v))}{\partial \beta^{-1}(y_v)} + 1 - g(y_v, \beta^{-1}(y_v)) - (\beta^{-1}(y_v) - \tau) \cdot \frac{\partial g(y_v, \beta^{-1}(y_v))}{\partial \beta^{-1}(y_v)} \geq 0.$$

Thus for lower bounding $\frac{1}{w_v} \cdot \mathbf{E}\left[\alpha_u + \alpha_v\right]$, we assume $\beta^{-1}(y_v) \leq \tau$ for all $y_v < \gamma$. Hence

$$\begin{aligned}\frac{1}{w_v} \cdot \mathbf{E}\left[\alpha_u + \alpha_v\right] \geq \min_{0 \leq \gamma, \tau \leq 1} \Big\{ & (1-\tau)(1-\gamma) + (1-\tau) \int_0^\gamma g(y_v, \tau) dy_v \\ & + \int_0^\tau \Big(g(y_u, \theta(y_u)) + \int_0^{\theta(y_u)} g(y_v, y_u) dy_v + \int_{\theta(y_u)}^\gamma g(y_v, \tau) dy_v\Big) dy_u \Big\}.\end{aligned}$$

Taking the minimum over $\theta(y_u)$ concludes Lemma 9. ◀

Observe that for any $\theta \le \gamma$, we have

$$g(x,\theta) + \int_0^\theta g(y,x)dy + \int_\theta^\gamma g(y,\tau)dy \ge g(x,\gamma) + \int_0^\gamma g(y,\tau)dy.$$

Thus the lower bound given by Lemma 9 is not worse than Lemma 4.

▶ **Theorem 10.** *Fix $h(x) = \min\{1, \frac{1}{2}e^x\}$. For any pair of neighbors u and v, and any fixed ranks of vertices in $L \cup R \setminus \{u, v\}$, we have $\frac{1}{w_v} \cdot \mathbf{E}_{y_u, y_v}[\alpha_u + \alpha_v] \ge 1 - \frac{\ln 2}{2} \approx 0.6534$.*

We give a proof sketch and defer the complete analysis to the full version of the paper.

Proof Sketch. For $h(x) = \min\{1, \frac{1}{2}e^x\}$, we have $h'(x) = h(x)$ when $x < \ln(2)$, and $h'(x) = 0$, $h(x) = 1$ when $x > \ln(2)$.

Let $f(\tau, \gamma)$ be the expression on the RHS to be minimized in Lemma 9. We first show that for any fixed τ and γ, the minimum (over θ) of $f(\tau, \gamma)$ is obtained when $\theta = \min\{\ln 2, \gamma\}$. Hence we can lower bound $f(\tau, \gamma)$ by

$$(1-\tau)(1-\gamma) + \frac{\gamma}{2}(1-h(\tau)) + \frac{\tau}{2}(1-h(\gamma)) + \frac{\ln 2}{2}\tau \cdot h(\tau) + \frac{1}{2}\int_0^\gamma h(y)dy + \frac{1-\ln 2}{2}\int_0^\tau h(x)dx.$$

Then we show that $f(\tau, \gamma) \ge 1 - \frac{\ln 2}{2} \approx 0.6534$ for all $\tau, \gamma \in [0, 1]$. We show that there exists $\tau^* \approx 0.3574$ (solution for $1 + h(\tau) - 2\tau = 1$) such that for $\tau \le \tau^*$, $\frac{\partial f(\tau,\gamma)}{\partial \gamma} \le 0$. Thus $f(\tau, \gamma) \ge f(\tau, 1)$. Further more, we show that $\frac{\partial f(\tau,1)}{\partial \tau} \ge 0$, which implies

$$f(\tau,\gamma) \ge f(\tau,1) \ge f(0,1) = \frac{1}{2}(1 - h(0)) + \frac{1}{2}\int_0^1 h(y)dy = 1 - \frac{\ln 2}{2} \approx 0.6534.$$

For any fixed $\tau > \tau^*$, we show that the minimum (over γ) of $f(\tau, \gamma)$ is attained when $\gamma = \ln 2$. Hence for $\tau > \tau^*$ we have $f(\tau, \gamma) \ge f(\tau, \ln 2)$. Finally, we show that $\frac{\partial f(\tau,\ln 2)}{\partial \tau} < 0$ when $\tau < \tau_0$; and $\frac{\partial f(\tau,\ln 2)}{\partial \tau} > 0$ when $\tau > \tau_0$, where $\tau_0 \approx 0.564375$, which implies

$$\begin{aligned} f(\tau,\gamma) \ge f(\tau,\ln 2) \ge f(\tau_0,\ln 2) =& (1-\tau_0)(1-\ln 2) + \frac{\ln 2}{4} \cdot (2 - e^{\tau_0} + \tau_0 \cdot e^{\tau_0}) + \frac{1}{4} \\ &+ \frac{1-\ln 2}{4}(e^{\tau_0} - 1) \approx 0.6557 > 1 - \frac{\ln 2}{2}. \end{aligned}$$

Thus for all $\tau, \gamma \in [0, 1]$, we have $f(\tau, \gamma) \ge 1 - \frac{\ln 2}{2}$, as claimed.

5 Conclusion

In this paper, we show that competitive ratios above $1 - \frac{1}{e}$ can be obtained under the randomized primal-dual framework when equipped with a two dimensional gain sharing function. The key of the analysis is to lower bound the expected combined gain of every pair of neighbors (u, v), over the randomness of the rank y_v of the offline vertex, and the arrival time y_u of the online vertex.

Referring to Figure 1, it can be shown that the competitive ratio $F \ge \int_0^1 f(y_u)dy_u$, where

$$\begin{aligned} f(y_u) :=& (1 - \theta(y_u) + \beta(y_u)) \cdot g(y_u, \theta(y_u)) + \theta(y_u) - \beta(y_u) \\ &+ \int_0^{\beta(y_u)} g(y_v, \beta^{-1}(y_v))dy_v + \int_{\theta(y_u)}^1 g(y_v, \beta^{-1}(y_v))dy_v. \end{aligned}$$

Note that here we assume $\beta^{-1}(y_v) = 1$ for all $y_v \geq \gamma$, and $g(x, 1) = 0$ for all $x \in [0, 1]$.

For every fixed g, there exist threshold functions θ and β that minimize the integration. Thus the main difficulty is to find a function g such that the integration has a large lower bound for all functions θ and β (which depend on the input instance). We have shown that there exists a choice of g such that the minimum is attained when θ and β are step functions, based on which we can give a lower bound on the competitive ratio.

It is thus an interesting open problem to know how much the competitive ratio can be improved by (fixing an appropriate function g and) giving a tighter lower bound for the integration. We believe that it is possible to give a lower bound very close to (or even better than) the 0.696 competitive ratio obtained for the unweighted case [21].

Abstract

Given n subspaces of a finite-dimensional vector space over a fixed finite field $\mathbb{F}$, we wish to find a "branch-decomposition" of these subspaces of width at most k, that is a subcubic tree T with n leaves mapped bijectively to the subspaces such that for every edge e of T, the sum of subspaces associated to the leaves in one component of $T - e$ and the sum of subspaces associated to the leaves in the other component have the intersection of dimension at most k. This problem includes the problems of computing branch-width of $\mathbb{F}$-represented matroids, rank-width of graphs, branch-width of hypergraphs, and carving-width of graphs.

We present a fixed-parameter algorithm to construct such a branch-decomposition of width at most k, if it exists, for input subspaces of a finite-dimensional vector space over $\mathbb{F}$. Our algorithm is analogous to the algorithm of Bodlaender and Kloks (1996) on tree-width of graphs. To extend their framework to branch-decompositions of vector spaces, we developed highly generic tools for branch-decompositions on vector spaces. For this problem, a fixed-parameter algorithm was known due to Hliněný and Oum (2008). But their method is highly indirect. Their algorithm uses the non-trivial fact by Geelen et al. (2003) that the number of forbidden minors is finite and uses the algorithm of Hliněný (2006) on checking monadic second-order formulas on $\mathbb{F}$-represented matroids of small branch-width. Our result does not depend on such a fact and is completely self-contained, and yet matches their asymptotic running time for each fixed k.

1 Introduction

Let $\mathbb{F}$ be a finite field and r be a positive integer. A *subspace arrangement* $\mathcal{V}$ is a (multi)set of subspaces of $\mathbb{F}^r$, which can be represented by an $r \times m$ matrix M with an ordered partition $\mathcal{I} = \{I_1, I_2, \ldots, I_n\}$ of $\{1, 2, \ldots, m\}$ such that for every $1 \leq i \leq n$, the i-th element of $\mathcal{V}$ is the column space of the submatrix of M induced by the columns in I_i.[4] Here, an *ordered partition* $\mathcal{I} = \{I_1, I_2, \ldots, I_n\}$ of $\{1, 2, \ldots, m\}$ is a partition of $\{1, 2, \ldots, m\}$ such that $x < y$ for all $x \in I_i, y \in I_j$ with $i < j$.

Robertson and Seymour [12] introduced the notion of branch-width for graphs, hypergraphs, and more generally, for connectivity functions. We are going to define the branch-width of a subspace arrangement as follows. First, a tree is *subcubic* if every node has degree at most 3. We define a *leaf* of a tree as a node of degree at most 1. A *branch-decomposition* of $\mathcal{V}$ is a pair $(T, \mathcal{L})$ of a subcubic tree T with no degree-2 nodes and a bijective function $\mathcal{L}$ from the set of all leaves of T to $\mathcal{V}$. For a node v of T and an edge e incident with v, let us write $A_v(T - e)$ to denote the set of all leaves of T in the component of $T - e$ containing v. For a branch-decomposition $(T, \mathcal{L})$ of $\mathcal{V}$ and each edge $e = uv$ of T, we define the *width* of e to be $\dim\left(\sum_{x \in A_u(T-e)} \mathcal{L}(x)\right) \cap \left(\sum_{y \in A_v(T-e)} \mathcal{L}(y)\right)$. The *width* of $(T, \mathcal{L})$ is the maximum width of all edges of T. (If T has no edges, then the width of $(T, \mathcal{L})$ is 0.) The *branch-width* of $\mathcal{V}$ is the minimum k such that there exists a branch-decomposition of $\mathcal{V}$ having width at most k.

We aim to solve the following problem, and Theorem 1.1 is our main theorem.

BRANCH-WIDTH
Parameters: A finite field $\mathbb{F}$ and an integer k.
Input: An $r \times m$ matrix M over $\mathbb{F}$ with an ordered partition $\mathcal{I} = \{I_1, I_2, \ldots, I_n\}$ of $\{1, 2, \ldots, m\}$ and an integer k.
Output: A branch-decomposition $(T, \mathcal{L})$ of width at most k of a subspace arrangement $\mathcal{V}$ consisting of the column space of the submatrix of M induced by the columns in I_i for each i or a confirmation that the branch-width of $\mathcal{V}$ is larger than k.

▶ **Theorem 1.1.** *Let $\mathbb{F}$ be a finite field, let r be a positive integer, and let k be a nonnegative integer. Let $\mathcal{V} = \{V_1, V_2, \ldots, V_n\}$ be a subspace arrangement of subspaces of $\mathbb{F}^r$ where each V_i is given by its spanning set of d_i vectors and $m = \sum_{i=1}^{n} d_i$. In time $O(rm^2 + (k+1)rmn + k^3n^3 + f(|\mathbb{F}|, k)n^2)$ for some function f, one can either find a branch-decomposition of $\mathcal{V}$ having width at most k or confirm that no such branch-decomposition exists.*

Various width parameters of discrete structures have been introduced and used for algorithmic and structural applications. One popular way of creating a width parameter of a discrete structure is to define it as the branch-width of some connectivity function defined on that discrete structure. Theorem 1.1 immediately gives rise to analogous algorithms for many of them, such as carving-width of graphs, rank-width of graphs, and branch-width of graphs, hypergraphs, and matroids. We will give a brief overview of each application.

Branch-width of matroids represented over a finite field $\mathbb{F}$. Let $\mathcal{V} = \{V_1, V_2, \ldots, V_n\}$ be a subspace arrangement of subspaces of $\mathbb{F}^r$. If each V_i is the span of a vector v_i in $\mathbb{F}^r$ for each $i = 1, 2, \ldots, n$, then $\mathcal{V}$ can be identified with the matroid M represented by the vectors v_1, v_2, …, v_n. Furthermore, branch-width and branch-decompositions of M are precisely branch-width and branch-decompositions of $\mathcal{V}$, respectively.

[4] Subspace arrangements can be regarded as representable *partitioned matroids* used in [6]. A partitioned matroid is a matroid equipped with a partition of its ground set.

Rank-width of graphs. Rank-width, introduced by Oum and Seymour [10], is a width parameter of graphs expressing how easy it is to decompose a graph into a tree-like structure, called a *rank-decomposition*, while keeping every edge cut to have a small 'complexity', called the *width* of a rank-decomposition, where the complexity is measured by the matrix rank function. Each vertex of a graph G can be associated with a subspace of dimension at most 2 so that the subspace arrangement $\mathcal{V}$ consisting of all subspaces associated with the vertices of G has branch-width $2k$ if and only if G has rank-width k (See appendix). Furthermore, a branch-decomposition of $\mathcal{V}$ of width $2k$ corresponds to a rank-decomposition of G of width k.

Branch-width of hypergraphs. Robertson and Seymour defined the notion of a branch-width [12] not only for graphs but also for hypergraphs. Let $\mathbb{F} = GF(2)$ be the binary field and let $\{v_1, v_2, \ldots, v_n\}$ be the standard basis of $\mathbb{F}^n$. For a hypergraph G with n vertices $v_1, v_2, \ldots, v_n$, we associate each edge e with the span of the vertices incident with e. Let $\mathcal{V}$ be the subspace arrangement consisting of all subspaces associated with the edges of G. Then it is not difficult to show that branch-width and branch-decomposition of G are precisely branch-width and branch-decomposition of $\mathcal{V}$, respectively.

Carving-width of graphs. Seymour and Thomas [13] introduced carving-width of graphs. Let $\mathbb{F} = GF(2)$ be the binary field and let $\{e_1, e_2, \ldots, e_m\}$ be the standard basis of $\mathbb{F}^m$. For a graph G with edges $e_1, e_2, \ldots, e_m$, we associate each vertex v with the span of the edges incident with v. If $\mathcal{V}$ is the subspace arrangement consisting of all subspaces associated with the vertices of G, then carving-width and carving of G are precisely branch-width and branch-decomposition of $\mathcal{V}$, respectively.

For the first two applications, the analogous theorems were proved earlier by Hliněný and Oum [6]. However, their approach was completely indirect; they use a non-trivial fact shown by Geelen et al. [3] that the class of matroids of branch-width at most k has finitely many forbidden minors, each having at most $O(6^k)$ elements. Then they use a monadic second-order formula to describe whether a matroid contains a fixed minor and use the dynamic programming algorithm to decide a monadic second-order formula aided by a given branch-decomposition of bounded width. So far this describes the decision algorithm of Hliněný [5] that decides whether branch-width is at most k. On top of this algorithm, Hliněný and Oum use a sophisticated reduction to modify the input and use the decision algorithm repeatedly to recover a branch-decomposition. Roughly speaking, this reduction attaches a gadget to the input matroid and this step requires extending the underlying finite field to an extension field, because this gadget is not representable if the underlying field is too small. As the list of forbidden minors is unknown, their algorithm should generate the list of minor-minimal matroids having branch-width larger than k. Thus, even for small values of k, it would be practically impossible to implement their algorithm. Contrary to the previous algorithm, our algorithm does not depend on the finiteness of obstructions and yet matches their asymptotic running time for each fixed k.

We do not know any previous analogous theorems for branch-width of hypergraphs. For branch-width of graphs, Thilikos and Bodlaender [14] posted a 50-page long technical report in 2000 proving that for every fixed k, one can check in linear time whether a graph has branch-width at most k and if so, output a branch-decomposition of minimum width. This work was presented at a conference in 1997 [2]. For carving-width of graphs, the conference paper of Thilikos, Serna, and Bodlaender [15] presented a linear-time algorithm for each fixed k that determines whether the carving-width of an input graph G is at most k, and if so, constructs a carving of G with minimum carving-width.

Our approach and technical ingredients. We develop a framework inspired by the approach of Bodlaender and Kloks [1] on their work on tree-width of graphs. (A similar framework was also given independently by Lagergren and Arnborg [9].) They created a linear-time algorithm that can find a tree-decomposition of width at most k or confirm that the tree-width of an input graph is larger than k for each fixed k. They used dynamic programming based on a given tree-decomposition of bounded width. For the dynamic programming, they designed a special encoding of all possible tree-decompositions of width at most k that can arise from certain parts of a graph.

We also use dynamic programming approach, taking advantage of having a tree-like structure from the given branch-decomposition. Then, how do we generate a branch-decomposition of small width in the first place? For this purpose, we use the technique called the iterative compression, which is initiated by Reed, Smith, and Vetta [11] and used by [4] for computing the branch-width of linear matroid. In Branch-Width Compression, we are given a branch-decomposition of width at most $2k$ of a subset of $\mathcal{V}$ and solve Branch-width. The obtained branch-decomposition of width at most k at each step is incremented by a new element of $\mathcal{V}$, which serves as a given branch-decomposition of width at most $2k$ for the next step.

To use a branch-decomposition for dynamic programming, we need a concept of a 'boundary', that plays the role of a bag in a tree-decomposition. For a branch-decomposition $(T, \mathcal{L})$ of a subspace arrangement $\mathcal{V}$ and an edge e of T, we consider the boundary B as the intersection of the sum of subspaces associated to the leaves in one component of $T - e$ and the sum of subspaces associated to the leaves of the other component of $T - e$. As the branch-width is at most k, the boundary B has dimension at most k. Furthermore, we restrict our attention to the finite field $\mathbb{F}$ and so the number of subspaces of B is finite. For the convenience of dynamic programming on branch-decompositions, we define *transcripts* of a branch-decomposition in Section 2, which is essentially a precomputed list of bases and linear transformations useful for computations with boundaries.

As usual, we need a compact encoding scheme to store partial solutions that may be extended to a branch-decomposition of width at most k, if it exists. We have two important aspects here.

First of all, we will restrict our search to a smaller set of branch-decompositions. Namely, if $(T', \mathcal{L}')$ is a given branch-decomposition of width at most $2k$ in Branch-Width Compression, then the algorithm will find a branch-decomposition of width at most k that is *totally pure with respect to* $(T', \mathcal{L}')$. In order to efficiently compress the partial solutions at each step of dynamic programming, it is crucial to ensure that some part of a partial solution can be forgotten (and can be retrieved from the unforgotten part later). A part of a partial solution can be ignored only when there is a guarantee that the said part does not need to be 'mixed' with another partial solution in the future. In other words, if there is a branch-decomposition of width at most k which is obtained via mixing, then there also exists as good a decomposition which can be obtained while mixing is avoided. This general idea lies at the core of every dynamic programming based on decomposition of small width. The first technical barrier to implement this principle for our problem is how to formalize what constitute those forgettable parts and what it means to avoid mixing. The 'forgettable part' is formalized as the notion of 'blocked' (plus some more) nodes introduced in Section 5. Intuitively, a totally pure branch-decomposition with respect to $(T', \mathcal{L}')$ is a decomposition which has successfully avoided the 'mixing' at every descendant so far. The two operations introduced in Section 3, fork and split, are technical tools developed in order to prove that it is possible to avoid mixing. Using these operations, we show that if there is a branch-decomposition of width at most k, then there is a branch-decomposition of width at

most k that is totally pure with respect to $(T', \mathcal{L}')$ in Section 3. The procedure of obtaining a compact encoding of a partial solution, introduced as *trimming* in Section 4, is essentially discarding the forgettable parts.

The second technical barrier is to devise an encoding of a (partial) branch-decomposition and all computational operations, necessary for dynamic programming, compatible with this encoding scheme. For this purpose, we will define a B-namu[5] in Section 4. Here, B is going to be the boundary for some edge in $(T', \mathcal{L}')$. A B-namu is, roughly speaking, a subcubic tree whose incidences are decorated by subspaces of B and whose edges are labeled by a nonnegative integer so that it represents the 'shadow' of a branch-decomposition of width at most k on B. We define an operation τ on B-namus that compresses a B-namu into a 'compact' B-namu and prove that there are only finitely many compact B-namus of width at most k, when B has bounded dimension and $\mathbb{F}$ is a finite field. This operation τ on B-namus consists of two steps: one is the aforementioned trimming, another is *compressing* to compress an integer sequence introduced by Bodlaender and Kloks [1] for their work on tree-decompositions. A part of B-namu processed by compressing step can be potentially mixed with another partial solution in the future, but a desired decomposition can be always retrieved if one exists. In contrast, a trimmed part is forgotten and never gets mixed in the future. Our computational operations on B-namus are designed so that the trimmed parts can be efficiently retrieved. Computational operations on B-namus for dynamic programming are defined including comparison.

Difference with our previous work. In the previous work [8], the authors found a similar algorithm for path-decompositions of a subspace arrangement. A path-decomposition of a subspace arrangement is a linearized variant of a branch-decomposition that restricts the subcubic trees to caterpillar trees. Here are the key technical differences.

First, the concept of totally pure branch-decompositions was not needed in [8]. In the previous work, two linear orderings are merged into another linear ordering and there is no need to consider the possibility of 'avoiding mixing'. In the end, compressing an integer sequence was sufficient to obtain a short encoding. For branch-decompositions, we sometimes insert a whole subtree into a branch-decomposition and this requests a new concept such as totally pure branch-decompositions. Also, 'summing' two partial solution encodings for join operation in dynamic programming is much more delicate in this work.

Second, we needed the concept of k-safeness in order to extend our algorithm for path-decompositions to the algorithm for branch-decompositions. When we sum two B-namus, some edges of trees in the B-namus are in common but some edges are not shared and will be forgotten. Although an edge in one B-namu is not in another B-namu, the width assigned to the edge can potentially increase. We hope the width of an edge not to exceed k even when this edge is 'forgotten', and thus we need to handle this carefully.

Lastly, we improve the running time of an algorithm computing transcripts. In [8], the idea of transcripts was used as well although the notion was not formally introduced. If we adapt our new method to the result of [8], we also get an $O(n^3)$-time algorithm for path-decompositions of subspace arrangements based on iterative compressions, saving a factor of $O(n)$.

Section 2, Section 3, and Section 4 give both definitions and some properties of transcripts, totally pure branch-decompositions, and B-namus, respectively. Section 5 presents the algorithm to solve the Branch-Width problem. We remark that many proofs are omitted because of the page limit. However, the detailed proofs are contained in the full version.

[5] 'Namu' is a tree in Korean.

2 Transcripts

Dynamic programming algorithms on tree-decomposition benefit from the small width by encoding solutions with respect to the bags. While the bags are explicit in a given tree-decomposition, a branch-decomposition of a subspace arrangement does not provide an easy-to-handle metric for encoding solutions to our problem. In order to make it more useful, we need some extra information.

Let $(T, \mathcal{L})$ be a branch-decomposition of a subspace arrangement $\mathcal{V}$. We will assume that T is a rooted binary tree by picking an arbitrary edge e and subdividing e to create a degree-2 root node r, and call $(T, \mathcal{L})$ a *rooted* branch-decomposition. For a node v of T, let $\mathcal{V}_v$ be the set of all elements of $\mathcal{V}$ associated with v and its descendants by $\mathcal{L}$. For a set X of vectors from a vector space over a field $\mathbb{F}$, the *span* $\langle X \rangle$ of X is the subspace consisting of all (finite) linear combinations of vectors in X, where the scalars are taken from $\mathbb{F}$. For two subspaces X and Y, we denote the subspace $\{x+y : x \in X, y \in Y\}$ by $X+Y$. For a set $\mathcal{X}$ of subspaces, let $\langle \mathcal{X} \rangle = \sum_{X \in \mathcal{X}} X$. The *boundary space* B_v at v is defined as $B_v = \langle \mathcal{V}_v \rangle \cap \langle \mathcal{V} - \mathcal{V}_v \rangle$. Later, we shall encode partial branch-decompositions with respect to the boundary spaces of a given branch-decomposition $(T, \mathcal{L})$. For this, we need to know B_v in advance.

A *transcript* of $(T, \mathcal{L})$ is a pair $\Lambda = (\{\mathfrak{B}_v\}_{v \in V(T)}, \{\mathfrak{B}'_v\}_{v \in V(T)})$ of sets of ordered bases $\mathfrak{B}_v$ and $\mathfrak{B}'_v$ of subspaces $B_v = \langle \mathfrak{B}_v \rangle$ and $B'_v = \langle \mathfrak{B}'_v \rangle$ of $\mathbb{F}^r$, respectively, such that

- the first $|\mathfrak{B}_v|$ elements of $\mathfrak{B}'_v$ are precisely $\mathfrak{B}_v$ for each node v,
- $\langle \mathfrak{B}'_v \rangle = \langle \mathfrak{B}_{w_1} \rangle + \langle \mathfrak{B}_{w_2} \rangle$ for each node v having two children w_1 and w_2,
- $\langle \mathfrak{B}'_v \rangle = \langle \mathfrak{B}_v \rangle$ for each leaf v.

If a node u of T is a parent of a node v of T, then $B_v = \langle \mathfrak{B}_v \rangle$ is a subspace of $B'_u = \langle \mathfrak{B}'_u \rangle$ and therefore there exists the unique $|\mathfrak{B}'_u| \times |\mathfrak{B}_v|$ matrix T_v over $\mathbb{F}$ such that $T_v[x]_{\mathfrak{B}_v} = [x]_{\mathfrak{B}'_u}$ for all $x \in \mathfrak{B}_v$. This matrix T_v is called the *transition matrix* of Λ at a node v. (For the root node r, let T_r be the null matrix. For a vector x in a vector space with a basis $\mathfrak{B}$ over a field $\mathbb{F}$, $[x]_{\mathfrak{B}}$ denotes the coordinate vector with respect to the basis $\mathfrak{B}$, which is a $|\mathfrak{B}| \times 1$ matrix over $\mathbb{F}$.)

We can compute the transcript of a given branch-decomposition as follows.

▶ **Theorem 2.1.** *Let $\mathcal{V}$ be a subspace arrangement of $\mathbb{F}^r$ represented by an $r \times m$ matrix M in reduced row echelon form with no zero rows such that each $V \in \mathcal{V}$ has dimension at most k. Let $n = |\mathcal{V}|$. Given branch-decomposition $(T, \mathcal{L})$ of $\mathcal{V}$, in time $O(k^3 n^2)$, one can correctly compute a basis of $\langle \mathcal{V}_v \rangle \cap \langle \mathcal{V} - \mathcal{V}_v \rangle$ for all nodes v of T or confirm that $(T, \mathcal{L})$ has width larger than k. In addition, if $(T, \mathcal{L})$ has width at most k, then we can compute the transcript $\Lambda = (\{\mathfrak{B}_v\}, \{\mathfrak{B}'_v\})$ of $(T, \mathcal{L})$ with its transition matrices in time $O(k^3 n^2)$.*

3 Pure branch-decompositions

We are going to assume that a subspace arrangement $\mathcal{V}$ and its rooted branch-decomposition $(T^b, \mathcal{L}^b)$ are given. For two nodes x, y of T^b, we say that $x \leq y$ if either $x = y$ or x is a descendant of y. We write $x < y$ if $x \leq y$ and $x \neq y$. For a node x of T^b, let $\mathcal{V}_x$ be the set of all subspaces $\mathcal{L}^b(\ell)$ where ℓ is a leaf of T^b with $\ell \leq x$ and let $B_x = \langle \mathcal{V}_x \rangle \cap \langle \mathcal{V} - \mathcal{V}_x \rangle$. Let $(T, \mathcal{L})$ be a branch-decomposition[6] of $\mathcal{V}_0 \subseteq \mathcal{V}$. Let x be a node of T^b such that $\mathcal{V}_x \subseteq \mathcal{V}_0$. We define $\mathcal{L}(T, u, v) = \{\mathcal{L}(w) : w \in A_v(T - uv)\}$ and write $\mathcal{L}_x(T, u, v) = \mathcal{L}(T, u, v) \cap \mathcal{V}_x$. (We remark that $\mathcal{L}(T, u, v)$ is a set of subspaces and $\langle \mathcal{L}(T, u, v) \rangle$ is the sum of members of $L(T, u, v)$.)

[6] One may consider $(T, \mathcal{L})$ as a (partial) solution whereas $(T^b, \mathcal{L}^b)$ is the given branch-decomposition over which dynamic programming is executed.

(a) T **(b)** T'

Figure 1 Constructing T' by forking at v by $\mathcal{V}_x$. ■ represents a leaf node mapped to an element of $\mathcal{V}_x$ by $\mathcal{L}$ and ○ represents a leaf node mapped to an element of $\mathcal{V}_0 - \mathcal{V}_x$ by $\mathcal{L}$.

We say that an edge uv of T *x-guards* its end v if $\langle \mathcal{L}_x(T,u,v)\rangle \cap B_x \subsetneq \langle \mathcal{L}_x(T,v,u)\rangle \cap B_x$. An edge uv of T is *x-degenerate* if $\langle \mathcal{L}_x(T,u,v)\rangle \cap B_x = \langle \mathcal{L}_x(T,v,u)\rangle \cap B_x$. A 2-edge path uvw of T is an *x-blocking path* if $\langle \mathcal{L}_x(T,u,v)\rangle \cap B_x = \langle \mathcal{L}_x(T,v,w)\rangle \cap B_x$, $\langle \mathcal{L}_x(T,w,v)\rangle \cap B_x = \langle \mathcal{L}_x(T,v,u)\rangle \cap B_x$, and neither uv nor vw is x-degenerate or x-guarding.

We give a general idea behind the notion of totally pure branch-decompositions. For $\mathcal{V}_x \subseteq \mathcal{V}_0$, one can consider the branch-decomposition 'induced' by $\mathcal{V}_x$ from $(T,\mathcal{L})$; such a branch-decomposition can be canonically defined by choosing a minimal subtree of T whose leaf set is mapped to $\mathcal{V}_x$ by $\mathcal{L}$ (and smoothing degree-2 nodes if necessary). Similarly, the branch-decomposition 'induced' by $\mathcal{V}_0 - \mathcal{V}_x$ can be obtained. Let $(T_x,\mathcal{L}_x)$ and $(T_{\bar{x}},\mathcal{L}_{\bar{x}})$ be the respective branch-decompositions. If uvw is an x-blocking path of T_x, then it can be shown that the connected component of $T_x - uv - vw$ containing v does not need to be mixed with another branch-decomposition in the future. Specifically, if the subtree of T homeomorphic to T_x is 'mixed' with some subtree of $T_{\bar{x}}$ in T, then one can 'untangle' the mixing: one 'lifts' the former subtree and 'plants' it on the x-blocking path uvw (so as to be rooted at a new node subdividing vw provided $\dim\langle \mathcal{L}_x(T,u,v)\rangle \cap \langle \mathcal{L}_x(T,v,u)\rangle \geq \dim\langle \mathcal{L}_x(T,v,w)\rangle \cap \langle \mathcal{L}_x(T,w,v)\rangle)$. This operation on $(T,\mathcal{L})$ is called the *forking* (see Figure 1). It can be proved that forking operations under above assumption do not increase the width. This is why we can 'forget' a subtree of T_x, namely the subtree of $T_x - uv - vw$ containing v. A similar observation can be made in regards to x-guarding edges, for which the related operation is *splitting*.

Then how do we know whether there is unwanted mixing in regards to an x-guarding edge or an x-blocking path? The following notions formalize this. An edge uv of T that x-guards v is called *improper* x-guarding if v has two neighbors v_1, v_2 in $T - uv$ such that $\mathcal{L}_x(T,v,v_1)$, $\mathcal{L}_x(T,v,v_2)$, and $\mathcal{L}(T,u,v) \cap (\mathcal{V}_0 - \mathcal{V}_x)$ are nonempty. An x-blocking path uvw of T is *improper* if v has a neighbor t in $T - u - w$ such that $\mathcal{L}_x(T,v,u)$, $\mathcal{L}_x(T,v,w)$, $\mathcal{L}_x(T,v,t)$, and $\mathcal{L}(T,v,t) \cap (\mathcal{V}_0 - \mathcal{V}_x)$ are nonempty.

When T has an x-degenerate edge e, it turns out that we can apply splitting operations at any x-degenerate edge and untangle T_x and $T_{\bar{x}}$ so that the new branch-decomposition is a disjoint union of T_x and $T_{\bar{x}}$ connected by a single edge (which will be incident with a subdividing node of the x-degenerate edge e). Hence, it is conceivable that we might be able to forget all nodes of T_x, possibly except for one node as a placeholder representing T_x. In this way, we request that any extension of T_x in the future shall be in the form of disjoint union plus one edge. However, it is possible that e is also a z-degenerate edge for some $z < x$. In this case, forcing the join of T_x and $T_{\bar{x}}$ at a subdividing node of e can violate the disjointness of T_z and $T_{\bar{z}}$. We want to prevent this, and it leads us to the definition of x-degenerate branch-decompositions.

For $\mathcal{S} \subseteq \mathcal{V}_0$, an edge uv of T is said to *cut* $\mathcal{S}$ if $\mathcal{L}(T,u,v) \cap \mathcal{S} \neq \emptyset$ and $\mathcal{L}(T,v,u) \cap \mathcal{S} \neq \emptyset$. We say that $(T,\mathcal{L})$ is *x-degenerate* if T has an x-degenerate edge uv such that uv cuts $\mathcal{V}_x$ and for all $z < x$, if $(T,\mathcal{L})$ is z-degenerate, then uv does not cut $\mathcal{V}_z$. Such an edge uv is called *improper* x-degenerate. Note that if x is a leaf of T^b, then $(T,\mathcal{L})$ is not x-degenerate because T has no edge cutting $\mathcal{V}_x$. We say that $(T,\mathcal{L})$ is *x-disjoint* if $\mathcal{V}_0 = \mathcal{V}_x$ or T has an edge uv such that $\mathcal{L}(T,u,v) = \mathcal{V}_x$ and v is incident with an improper x-degenerate edge.

We say that $(T, \mathcal{L})$ is *x-pure* if the following hold.

- If $(T, \mathcal{L})$ is x-degenerate, then $(T, \mathcal{L})$ is x-disjoint.
- If $(T, \mathcal{L})$ is not x-degenerate, then all x-blocking paths and all x-guarding edges of T are not improper.

We say that a branch-decomposition $(T, \mathcal{L})$ of $\mathcal{V}_0$ is *totally pure with respect to* $(T^b, \mathcal{L}^b)$ if $(T, \mathcal{L})$ is x-pure for all nodes x of T^b with $\mathcal{V}_x \subseteq \mathcal{V}_0$. We prove that if the branch-width of a subspace arrangement is at most k, then there exists a totally pure branch-decomposition of the subspace arrangement whose width is at most k. The proof strategy is to apply forking and splitting operations for every node x of T^b in a bottom-up manner. If $(T, \mathcal{L})$ is x-degenerate, then applying the operations will create a new branch-decomposition which is x-disjoint. If it is not x-degenerate, then the operations will resolve entanglements at the improper x-guarding edges and at the improper x-blocking paths so that no improper ones are left. For this approach to work, we need to ensure that applying these operations do not create new entanglements at nodes z of T^b where disentanglement already happened (or is happening now). That is, z-disjointness is preserved, and no new improper z-guarding edge or z-blocking path is created.

▶ **Proposition 3.1.** *Let $(T^b, \mathcal{L}^b)$ be a rooted branch-decomposition of a subspace arrangement $\mathcal{V}$ and let $\mathcal{V}_0 \subseteq \mathcal{V}$. If the branch-width of $\mathcal{V}_0$ is at most k, then $\mathcal{V}_0$ has a branch-decomposition of width at most k that is totally pure with respect to $(T^b, \mathcal{L}^b)$.*

4 Namus

Let $\mathbb{F}$ be a finite field and let B be a subspace of $\mathbb{F}^r$ of dimension θ. In this section, we introduce the data structure for encoding partial solutions and operations on this data structure required for dynamic programming. For a tree T, an *incidence* is a pair (v, e) of a node v of T and an edge e incident with v. Let $\mathcal{I}(T)$ be the union of $\{(*, \emptyset), (0, \emptyset)\}$ and the set of all incidences of T. A *B-namu* Γ is a quadruple (T, α, λ, U) of

- a subcubic tree T having at least one node,
- a function α from $\mathcal{I}(T)$ to the set of all subspaces of B,
- a function λ from the union of $\{\emptyset\}$ and the set of all edges of T to the set of integers, and
- a subspace U of B

such that

- **(i)** for every two-edge path v_0, e_1, v_1, e_2, v_2 in T, $\alpha(v_0, e_1)$ is a subspace of $\alpha(v_1, e_2)$,
- **(ii)** for all incidences (v, e) of T, $\alpha(v, e)$ is a subspace of U,
- **(iii)** $\alpha(*, \emptyset) = U$, $\alpha(0, \emptyset) = \{0\}$, and $\lambda(\emptyset) = 0$,
- **(iv)** for every edge $e = uv$ of T, $\lambda(e) \geq \dim \alpha(v, e) \cap \alpha(u, e)$.

The *width* of a B-namu $\Gamma = (T, \alpha, \lambda, U)$ is the maximum of $\lambda(e)$ over all edges $e = uv$ of T. (If T has no edges, then the width of Γ is defined to be 0.) For a B-namu $\Gamma = (T, \alpha, \lambda, U)$, we write $T(\Gamma) = T$.

Canonical B-namus. The *canonical B-namu* of a branch-decomposition $(T, \mathcal{L})$ of a subspace arrangement $\mathcal{V}$ is the B-namu (T, α, λ, U) such that

- $\alpha(v, e) = B \cap \sum_{x \in A_v(T-e)} \mathcal{L}(x)$ for each node v of T and an edge e incident with v,
- $\lambda(e) = \dim \sum_{x \in A_u(T-e)} \mathcal{L}(x) \cap \sum_{y \in A_v(T-e)} \mathcal{L}(y)$ for each edge $e = uv$ of T,
- $U = B \cap \sum_{x \in A(T)} \mathcal{L}(x)$ where $A(T)$ is the set of all leaves of a tree T.

Projections. For two subspaces B and B' with $B' \subseteq B$, we define the *projection* $\Gamma|_{B'}$ of a B-namu $\Gamma = (T, \alpha, \lambda, U)$ on B' as the B'-namu $(T, \alpha', \lambda', U')$ such that $U' = U \cap B'$, $\alpha'(v, e) = \alpha(v, e) \cap B'$ for all incidences (v, e) of T, and $\lambda'(e) = \lambda(e)$ for all edges e of T.

Compact B-namus. We have two operations, trimming and compressing, on B-namus, which will transform a B-namu into a 'compact' B-namu. Roughly speaking, *trimming* is an operation to remove irrelevant edges and *compressing* is an operation to suppress redundant edges. Irrelevant edges are those edges which can be 'untangled' by forking or splitting operations as described in Section 3. As addressed in Proposition 3.1, there exists a branch-decomposition of minimum width that is totally pure with respect to $(T^b, \mathcal{L}^b)$. Such a branch-decomposition is minimally 'mixed' at every node x of T^b in the sense that forking and splitting operations has been fully applied at every x without causing additional mixing. The idea behind trimming is that, for keeping track of totally pure branch-decompositions in the dynamic programming algorithm, those edges to be untangled by forking or splitting operations can be ignored. For a B-namu Γ, let $\mathrm{trim}(\Gamma)$ denote the B-namu obtained by trimming Γ.

For a node x of $(T^b, \mathcal{L}^b)$, can we bound the size of an arbitrary trimmed B_x-namu Γ, namely the size of $T(\Gamma)$? As $T(\Gamma)$ is a subcubic tree, bounding the size of $T(\Gamma)$ is equivalent to bounding the diameter of $T(\Gamma)$. By condition (i) in the definition of B-namu, it is not difficult to see that $T(\Gamma)$ has a large diameter if and only if $T(\Gamma)$ contains a long path in which any length-two path is x-blocking. Assuming that Γ is trimmed, such a long path induces a substructure in which every internal node has degree two and α maps every incidence to the same subspace. That is, the information on such a path dictated by Γ is almost uniform except that the values of λ changes over the edges and the values of λ can be viewed as an integer sequence. Now, the idea of compressing operation is to keep only the edges associated with local minimum and maximum values of this integer sequence and ignore all other edges. An integer sequence obtained in this way is called a *typical sequence* in the literature [1] and it is known to have length at most $2k + 1$ when the integers are in the range $\{0, \ldots, k\}$.

We say that a B-namu is *compact* if it contains no 'irrelevant' nodes or edges so that trimming or compressing does not affect to the B-namu. Let $U_k(B)$ be the set of all compact B-namus Γ of width at most k such that $V(T(\Gamma)) = \{1, 2, \ldots, n\}$ for some integer n. The previous discussion is summarized in the next statement, which ensures in Section 5 that the number of partial solutions stored at each node of $(T^b, \mathcal{L}^b)$ for the dynamic programming algorithm will be bounded.

▶ **Lemma 4.1.** *The set $U_k(B)$ contains at most $f(k, \theta, |\mathbb{F}|)$ elements and can be generated from B in $g(k, \theta, |\mathbb{F}|)$ steps for some functions f and g.*

Sum of two B-namus. For two B-namus $\Gamma_1 = (T_1, \alpha_1, \lambda_1, U_1)$ and $\Gamma_2 = (T_2, \alpha_2, \lambda_2, U_2)$, we define a *sum* $(T, \alpha, \lambda, U_1 + U_2)$ of Γ_1 and Γ_2. Roughly speaking, we first take a tree T such that a subdivision of T_1 is a subtree of T and a subdivision of T_2 is a subtree of T (see Figure 2). For each incidence (v, e) of T, if it corresponds to both an incidence (v_1, e_1) of T_1 and an incidence (v_2, e_2) of T_2, then $\alpha(v, e)$ is the sum of $\alpha_1(v_1, e_1)$ and $\alpha_2(v_2, e_2)$, and if it corresponds to only one of (v_1, e_1) and (v_2, e_2), say (v_1, e_1), then $\alpha(v, e) = \alpha_1(v_1, e_1)$. Similarly, we can define λ on every edge of T (with some correction term). The formal definition is given in the full version. Note that a sum of two B-namus is not unique because there are many choices of taking a tree T. Given B-namus Γ_1 and Γ_2, let us denote by $\Gamma_1 \oplus \Gamma_2$ the set of all sums of Γ_1 and Γ_2.

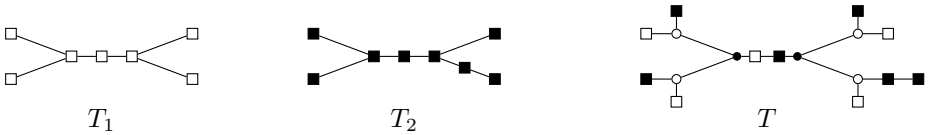

Figure 2 Obtaining a sum of two B-namus.

▶ **Lemma 4.2.** *Let Γ_1, Γ_2 be compact B-namus of width at most k. Then the set $\Gamma_1 \oplus \Gamma_2$ contains at most $2^{2^{2(2\theta k+\theta+k+3)}}$ B-namus.*

Comparing two B-namus. A B-namu $(T', \alpha', \lambda', U)$ is a *subdivision* of a B-namu $\Gamma = (T, \alpha, \lambda, U)$ if T' is a subdivision of T, $\alpha'(v', e') = \alpha(v, e)$, and $\lambda'(e') = \lambda(e)$ for every incidence (v', e') of T' and its corresponding incidence (v, e) of T.

For two B-namus $\Gamma_1 = (T_1, \alpha_1, \lambda_1, U_1)$ and $\Gamma_2 = (T_2, \alpha_2, \lambda_2, U_2)$, we say that $\Gamma_1 \leq \Gamma_2$ if $T_1 = T_2$, $\alpha_1 = \alpha_2$, $U_1 = U_2$ and $\lambda_1(e) \leq \lambda_2(e)$ for every edge e of T_1. For two B-namus Γ_1 and Γ_2, we say that $\Gamma_1 \preccurlyeq \Gamma_2$ if there exist a subdivision Γ_1' of Γ_1 and a subdivision Γ_2' of Γ_2 such that $\Gamma_1' \leq \Gamma_2'$.

▶ **Lemma 4.3.** *For two B-namus Δ and Γ, we can decide whether $\Delta \preccurlyeq \Gamma$ by executing at most $f(|V(T(\Delta))|, |V(T(\Gamma))|, \theta, |\mathbb{F}|)$ comparison operations (on integers and on subspaces of B) for some function f.*

5 The algorithm

We present an algorithm to solve the Branch-Width problem. Given a matrix M and a set Y of column indices, $M[Y]$ denotes the submatrix of M induced by columns indexed by Y.

Preprocessing. We will first describe the preprocessing steps to reduce the input size. The subspace arrangement of n subspaces is given by an $r \times m$ matrix where r and m could be arbitrary large. Our aim here is to reduce r and m or confirm that branch-width is larger than k. Eventually, we will convert the input into a smaller one. Furthermore, we will convert M into the reduced row echelon form, which is crucial for our algorithm for computing the transcript of a branch-decomposition in Theorem 2.1. In the Branch-Width problem, if a branch-decomposition of width at most k exists, then we say that $(M, \mathcal{I}, k)$ is a YES instance. Otherwise, it is a NO instance. For a matrix M, let $\mathrm{col}(M)$ be the column space of M, that is the span of all column vectors of M.

▶ **Lemma 5.1.** *Let $\mathbb{F}$ be a finite field and let k be a nonnegative integer. Let $n \geq 2$. Let M be an $r \times m$ matrix over $\mathbb{F}$ with an ordered partition $\mathcal{I} = \{I_1, I_2, \ldots, I_n\}$ of $\{1, 2, \ldots, m\}$ and let V_i be the column space of $M[I_i]$ for every i. In time $O(rm^2 + (k+1)rmn)$, we can either find $i \in \{1, 2, \ldots, n\}$ such that $\dim(V_i \cap (\sum_{j \neq i} V_i)) > k$ or find an $r' \times m'$ matrix M' over $\mathbb{F}$ with an ordered partition $\mathcal{I}' = \{I_1', I_2', \ldots, I_n'\}$ of $\{1, 2, \ldots, m'\}$ such that*

- **(i)** *$r' \leq m' \leq kn$,*
- **(ii)** *M' is of the reduced row echelon form with no zero rows,*
- **(iii)** *for each i, the column vectors of $M'[I_i']$ are linearly independent and $|I_i'| \leq k$,*
- **(iv)** *for each i, $\mathrm{col}(M'[I_i']) \subseteq \mathrm{col}(M'[\{1, 2, \ldots, m'\} - I_i'])$,*
- **(v)** *$(M, \mathcal{I}, k)$ is a YES instance with a branch-decomposition $(T, \mathcal{L})$ if and only if $(M', \mathcal{I}', k)$ is a YES instance with $(T, \mathcal{L}')$ where $\mathcal{L}'$ maps a leaf v to $\mathrm{col}(M'[I_i'])$ whenever $\mathcal{L}$ maps v to $\mathrm{col}(M[I_i])$.*

The full set. Our dynamic programming algorithm constructs a set of compact B_x-namus of width at most k at each node x of the given branch-decomposition $(T^b, \mathcal{L}^b)$ in a bottom-up manner. This set is called the *full set at x of width k with respect to* $(T^b, \mathcal{L}^b)$ and written as $\mathrm{FS}_k(x; T^b, \mathcal{L}^b)$ or $\mathrm{FS}_k(x)$ for brevity. The full set needs to be defined so that at the root node $\mathfrak{r}$ of T^b, $\mathrm{FS}_k(\mathfrak{r}) \neq \emptyset$ if and only if the branch-width of $\mathcal{V}$ is at most k. Moreover, we need to ensure that the full set at every node of T^b can be constructed from the full sets of its children.

Roughly speaking, the full set at x is an upward closed set of $(U_k(B_x), \preccurlyeq)$, where $U_k(B_x)$ and $\preccurlyeq$ are defined in the previous section. Every minimal[7] element in this upward closed set is a B-namu that can be obtained from a branch-decomposition $(T, \mathcal{L})$ of $\mathcal{V}_x$ having width at most k that is totally pure with respect to $(T^b, \mathcal{L}^b)$ by discarding some subtrees of T. This concept is captured in the notion of *reduced B-namus* below. Any discarded subtrees keep the rest of T connected. The subtrees of T that will not be mixed with another partial solution shall qualify as the disposable parts. Two types of disposable parts arise: one is a subtree consisting of x-blocked nodes (which will be defined soon), and the other type is a subtree whose entire leaf set is precisely mapped with $\mathcal{V}_z$ for some $z \leq x$ such that $(T, \mathcal{L})$ is z-degenerate. In particular, if $(T, \mathcal{L})$ is x-degenerate, then we discard all nodes except one node. Because we only consider totally pure branch-decompositions $(T, \mathcal{L})$, if $(T, \mathcal{L})$ is z-degenerate for some $z < x$, then $(T, \mathcal{L})$ is a disjoint union of $\mathcal{V}_z$ and $\mathcal{V}_x - \mathcal{V}_z$ joined via a single edge. It is intuitively easy to understand that we want to keep the subtree containing $\mathcal{V}_z$ intact from any mixing in the future and thus want to discard this part. However, implementing this idea with full technical details is quite tricky.

Moreover, not every reduced B-namu obtained in this way can be a member of a full set. A technical condition called *k-safeness* must be met by any edge that gets discarded. This condition is expressed as an inequality, indicating that when the current partial solution grows into a branch-decomposition for $\mathcal{V}$, the width at the forgotten edge is at most k.

For a B-namu $\Gamma = (T, \alpha, \lambda, U)$ and a subtree T' of T, we say that a B-namu $\Gamma' = (T', \alpha', \lambda', U)$ is *induced by T' from* Γ if $\alpha'(v, e) = \alpha(v, e)$ and $\lambda'(e) = \lambda(e)$ for every incidence (v, e) of T'. For a node x of T^b and a branch-decomposition $(T, \mathcal{L})$ of $\mathcal{V}_x$ which is totally pure with respect to $(T^b, \mathcal{L}^b)$, we obtain the *reduced B_x-namu of* $(T, \mathcal{L})$ induced by a subtree T' of T from the canonical B_x-namu of $(T, \mathcal{L})$ where T' is obtained by the following rule.

- If $(T, \mathcal{L})$ is x-degenerate, then T' is a subtree having only one node of T.
- If $(T, \mathcal{L})$ is not x-degenerate, then T' is obtained by deleting every node w if
  - **(i)** there is an x-blocking path $v_1 v v_2$ centered at $v \neq w$ such that there is a path from w to v in $T - vv_1 - vv_2$, or
  - **(ii)** some edge uv x-guards $v \neq w$ such that there is a path from w to v in $T - uv$, or
  - **(iii)** w is a node of a subtree T'' of T with a root $v \neq w$ having two children such that the leaf set of T'' is precisely mapped to $\mathcal{V}_z$ for some $z < x$ and $(T, \mathcal{L})$ is z-degenerate.

A node w satisfying (i) or (ii) is said to be *x-blocked*. A branch-decomposition $(T, \mathcal{L})$ is *k-safe with respect to x* if for every edge uv of T which is not contained in T',

$$\dim \sum_{s \in A_v(T-uv)} \mathcal{L}(s) \cap \sum_{t \in A_u(T-uv)} \mathcal{L}(t) + \dim B_x - \dim B_x \cap \sum_{t \in A_u(T-uv)} \mathcal{L}(t) \leq k.$$

Now, for each node x of T^b, *the full set at x of width k with respect to* $(T^b, \mathcal{L}^b)$ is defined

[7] Technically, a minimal element in our definition might not be a compact B_x-namu but just a trimmed B_x-namu. However, a compact B-namu of the minimal element defines the same upper set due to the transitivity of $\preccurlyeq$.

as the set of all Γ in $U_k(B_x)$ such that $\Delta \preccurlyeq \Gamma$ for the reduced B_x-namu Δ of some branch-decomposition $(T, \mathcal{L})$ of $\mathcal{V}_x$ having width at most k that is k-safe with respect to x, and totally pure with respect to $(T^b, \mathcal{L}^b)$.

Dynamic programming. For computing the full sets, we assume the following are given:

- A rooted branch-decomposition $(T^b, \mathcal{L}^b)$ of $\mathcal{V}$ of width at most θ.
- A set of transition matrices $\{T_v\}_{v \in V(T^b)}$ of some transcript Λ of $(T^b, \mathcal{L}^b)$.

A B-namu $\Gamma = (T, \alpha, \lambda, U)$ is a *k-safe extension of* $\mathrm{trim}(\Gamma)$ if for every edge uv in $E(T) - E(\mathrm{trim}(T))$, we have $\lambda(uv) + \dim U - \max(\dim \alpha(v, uv), \dim \alpha(u, uv)) \leq k$. For two sets $\mathcal{R}_1$, $\mathcal{R}_2$ of B-namus, we define $\mathcal{R}_1 \oplus \mathcal{R}_2$ as the set $\bigcup_{\Gamma_1 \in \mathcal{R}_1, \Gamma_2 \in \mathcal{R}_2} \Gamma_1 \oplus \Gamma_2$. Note that for two children x_1, x_2 of a node x in T^b, when we compute $\mathrm{FS}_k(x_1) \oplus \mathrm{FS}_k(x_2)$, we regard $\mathrm{FS}_k(x_1)$, $\mathrm{FS}_k(x_2)$ as the sets of $(B_{x_1} + B_{x_2})$-namus. Thus, $\mathrm{FS}_k(x_1) \oplus \mathrm{FS}_k(x_2)$ is well defined. If B' is a subspace of B, then we define $\mathcal{R}|_{B'}$ as the set of projections $\Gamma|_{B'}$ for all $\Gamma \in \mathcal{R}$. For a subspace B of $\mathbb{F}^r$ and a set $\mathcal{R}$ of B-namus, the set $\mathsf{up}_k(\mathcal{R}, B)$ is the collection of all B-namus $\Gamma \in U_k(B)$ with $\mathrm{trim}(\Gamma') \preccurlyeq \Gamma$ for some $\Gamma' \in \mathcal{R}$ such that Γ' is a k-safe extension of $\mathrm{trim}(\Gamma')$.

▶ **Proposition 5.2.** *Let k be a nonnegative integer. Let $(T^b, \mathcal{L}^b)$ be a rooted branch-decomposition of a subspace arrangement $\mathcal{V}$ over a finite field $\mathbb{F}$ of width at most θ.*

- *For a leaf ℓ of T^b, we have $\mathrm{FS}_k(\ell) = \{\Delta_\ell\}$ where $\Delta_\ell = (T, \alpha, \lambda, B_\ell)$ is the B_ℓ-namu such that T is a tree with $V(T) = \{1\}$.*
- *For two children x_1 and x_2 of a node x in T^b, $\mathrm{FS}_k(x) = \mathsf{up}_k((\mathrm{FS}_k(x_1) \oplus \mathrm{FS}_k(x_2))|_{B_x}, B_x)$.*
- *For the root node $\mathfrak{r}$ of T^b, $\mathrm{FS}_k(\mathfrak{r}) \neq \emptyset$ if and only if the branch-width of $\mathcal{V}$ is at most k.*

Moreover, we can compute $\mathrm{FS}_k(\mathfrak{r})$, and construct a (rooted) branch-decomposition of $\mathcal{V}$ of width at most k if $\mathrm{FS}_k(\mathfrak{r}) \neq \emptyset$, in time $f(k, \theta, |\mathbb{F}|)|\mathcal{V}|$ for some function f.

Proposition 5.2 states that when $\mathrm{FS}_k(x) \neq \emptyset$, the same B-namu or a better one can be constructed by conducting operations on B-namus in the full set at its child nodes. Therefore, when $\mathrm{FS}_k(\mathfrak{r}) \neq \emptyset$, one can identify a B-namu Γ_x at each node x of T^b which participates in the construction of the element in $\mathrm{FS}_k(\mathfrak{r})$. Additionally, we have the information including how Γ_x's are combined and how the combined B-namu is related to the B-namu at its parent. We construct a branch-decomposition of $\mathcal{V}$ having width at most k by backtracking based on such information. However, proving the correctness of this backtracking algorithm is highly nontrivial. For this, we introduce the notion of *witnesses*. Details are in the full version.

Summary. Now we are ready to present the proof of Theorem 1.1.

Proof of Theorem 1.1. We preprocess the input by applying Lemma 5.1 to $(M, \mathcal{I}, k)$ in time $O(rm^2 + (k+1)rmn)$ and obtain an equivalent instance $(M', \mathcal{I}', k)$ as described in Lemma 5.1 and otherwise, we confirm that the branch-width of $\mathcal{V}$ exceeds k. We may assume that $k > 0$ because if $I'_i = \emptyset$ for all i, then every branch-decomposition has width 0. Henceforth, we assume $M = M'$, $\mathcal{I} = \mathcal{I}'$, $V_i = \mathrm{col}(M'[I'_i])$ to simplify notations.

We may also assume that $\dim V_i \neq 0$ for all i because otherwise we delete all such V_i and later we can extend a branch-decomposition of $\mathcal{V} - \{V_i\}$ to that of $\mathcal{V}$ of the same width. After the preprocessing, if $n = 1$, then an arbitrary branch-decomposition has width 0 and so we simply output an arbitrary branch-decomposition of $\mathcal{V}$. If $n = 2$, then the branch-width is at most k because $\dim V_1, \dim V_2 \leq k$ by (iii) of Lemma 5.1. So we may assume that $n \geq 3$.

We will apply iterative compression on $\mathcal{V}_i = \{V_1, \ldots, V_i\}$ for $i = 3, \ldots, n$. We initially start with a trivial branch-decomposition $(T_2, \mathcal{L}_2)$ of $\mathcal{V}_2 = \{V_1, V_2\}$ having width at most k. We carry out a COMPRESSION STEP for each $i = 3, \ldots, n$ as follows.

(1) By adding a new leaf v to T_{i-1} and extending $\mathcal{L}_{i-1}$ to map v to V_i, we create a branch-decomposition $(T'_i, \mathcal{L}'_i)$ of $\mathcal{V}_i$. Note that the width of $(T'_i, \mathcal{L}'_i)$ is at most $2k$ because $(T_{i-1}, \mathcal{L}_{i-1})$ has width at most k and V_i has dimension at most k.

(2) We use the algorithm in Theorem 2.1 to compute transition matrices $\{T_v\}_{v \in V(T'_i)}$ of the transcript for $(T'_i, \mathcal{L}'_i)$ in time $O(k^3 n^2)$. Note that the submatrix $M[I_1 \cup I_2 \cup \cdots \cup I_i]$ is in reduced row echelon form and so we can apply Theorem 2.1 by ignoring zero rows.

(3) Given a rooted branch-decomposition $(T'_i, \mathcal{L}'_i)$ of $\mathcal{V}_i$ of width at most $2k$ and a set of the transition matrices $\{T_v\}_{v \in V(T'_i)}$, we compute the full set in time $g(k, 2k, |\mathbb{F}|)i$ for some function g by Proposition 5.2. If the full set at the root is empty, then the branch-width of $\mathcal{V}_i$ is larger than k. If so, we conclude that the branch-width of $\mathcal{V}$ is larger than k and stop. If the full set at the root is nonempty, then the algorithm in Proposition 5.2 also provides a branch-decomposition $(T_i, \mathcal{L}_i)$ of $\mathcal{V}_i$ having width at most k.

If this algorithm finds $(T_n, \mathcal{L}_n)$, then $(T_n, \mathcal{L}_n)$ is a branch-decomposition of $\mathcal{V}$ having width at most k. For each i, (1)–(3) runs in at most $O(k^3 n^2) + f(k, |\mathbb{F}|)n$ time for some function f and therefore the total running time of this step is $O(k^3 n^3) + f(k, |\mathbb{F}|)n^2$. ◀

Abstract

We give optimal sorting algorithms in the *evolving data* framework, where an algorithm's input data is changing while the algorithm is executing. In this framework, instead of producing a final output, an algorithm attempts to maintain an output close to the correct output for the current state of the data, repeatedly updating its best estimate of a correct output over time. We show that a simple repeated insertion-sort algorithm can maintain an $O(n)$ Kendall tau distance, with high probability, between a maintained list and an underlying total order of n items in an evolving data model where each comparison is followed by a swap between a random consecutive pair of items in the underlying total order. This result is asymptotically optimal, since there is an $\Omega(n)$ lower bound for Kendall tau distance for this problem. Our result closes the gap between this lower bound and the previous best algorithm for this problem, which maintains a Kendall tau distance of $O(n \log \log n)$ with high probability. It also confirms previous experimental results that suggested that insertion sort tends to perform better than quicksort in practice.

1 Introduction

In the classic version of the sorting problem, we are given a set, S, of n comparable items coming from a fixed total order and asked to compute a permutation that places the items from S into non-decreasing order, and it is well-known that this can be done using $O(n \log n)$ comparisons, which is asymptotically optimal (e.g., see [6, 8, 14]). However, there are a number of interesting applications where this classic version of the sorting problem doesn't apply.

For instance, consider the problem of maintaining a ranking of a set of sports teams based on the results of head-to-head matches. A typical approach to this sorting problem is to assume there is a fixed underlying total order for the teams, but that the outcomes of head-to-head matches (i.e., comparisons) are "noisy" in some way. In this formulation, the ranking problem becomes a one-shot optimization problem of finding the most-likely fixed total order given the outcomes of the matches (e.g., see [5, 7, 9, 10, 15]). In this paper, we study an alternative, complementary motivating scenario, however, where instead of there being a fixed total order and noisy comparisons we have a scenario where comparisons are accurate but the underlying total order is evolving. This scenario, for instance, captures the real-world phenomenon where sports teams make mid-season changes to their player rosters and/or coaching staffs that result in improved or degraded competitiveness relative to other teams. That is, we are interested in the sorting problem for *evolving data*.

1.1 Related Prior Work for Evolving Data

Anagnostopoulos *et al.* [1] introduce the *evolving data* framework, where an input data set is changing while an algorithm is processing it. In this framework, instead of an algorithm taking a single input and producing a single output, an algorithm attempts to maintain an output close to the correct output for the current state of the data, repeatedly updating its best estimate of the correct output over time. For instance, Anagnostopoulos *et al.* [1] mention the motivation of maintaining an Internet ranking website that displays an ordering of entities, such as political candidates, movies, or vacation spots, based on evolving preferences.

Researchers have subsequently studied other interesting problems in the evolving data framework, including the work of Kanade *et al.* [13] on stable matching with evolving preferences, the work of Huang *et al.* [12] on selecting top-k elements with evolving rankings, the work of Zhang and Li [18] on shortest paths in evolving graphs, the work of Anagnostopoulos *et al.* [2] on st-connectivity and minimum spanning trees in evolving graphs, and the work of Bahmani *et al.* [3] on PageRank in evolving graphs. In each case, the goal is to maintain an output close to the correct one even as the underlying data is changing at a rate commensurate to the speed of the algorithm. By way of analogy, classical algorithms are to evolving-data algorithms as throwing is to juggling.

1.2 Problem Formulation for Sorting Evolving Data

With respect to the sorting problem for evolving data, following the formulation of Anagnostopoulos *et al.* [1], we assume that we have a set, S, of n distinct items that are properly ordered according to a total order relation, "$<$". In any given time step, we are allowed to compare any pair of items, x and y, in S according to the "$<$" relation and we learn the correct outcome of this comparison. After we perform such a comparison, α pairs of items that are currently consecutive according to the "$<$" relation are chosen uniformly at random and their relative order is swapped. As in previous work [1], we focus on the case

where $\alpha = 1$, but one can also consider versions of the problem where the ratio between comparisons and random consecutive swaps is something other than one-to-one. Still, this simplified version with a one-to-one ratio already raises some interesting questions.

Since it is impossible in this scenario to maintain a list that always reflects a strict ordering according to the "$<$" relation, our goal is to maintain a list with small *Kendall tau* distance, which counts the number of inversions, relative to the correct order.[2] Anagnostopoulos *et al.* [1] show that, for $\alpha = 1$, the Kendall tau distance between the maintained list and the underlying total order is $\Omega(n)$ in both expectation and with high probability. They also show how to maintain this distance to be $O(n \log \log n)$, with high probability, by performing a multiplexed batch of quicksort algorithms on small overlapping intervals of the list. Recently, Besa Vial *et al.* [4] empirically show that repeated versions of quadratic-time algorithms such as bubble sort and insertion sort seem to maintain an asymptotically optimal distance of $O(n)$. In fact, this linear upper bound seems to hold even if we allow α, the number of random swaps at each step, to be a much larger constant.

1.3 Our Contributions

The main contribution of the present paper is to prove that repeated insertion sort maintains an asymptotically optimal Kendall tau distance, with high probability, for sorting evolving data. This algorithm repeatedly makes in-place insertion-sort passes (e.g., see [6, 8]) over the list, l_t, maintained by our algorithm at each step t. Each such pass moves the item at position j to an earlier position in the list so long as it is bigger than its predecessor in the list. With each comparison done by this repeated insertion-sort algorithm, we assume that a consecutive pair of elements in the underlying ordered list, l'_t, are chosen uniformly at random and swapped. In spite of the uncertainty involved in sorting evolving data in this way, we prove the following theorem, which is the main result of this paper.

▶ **Theorem 1.** *Running repeated insertion-sorts algorithm, for every step $t = \Omega(n^2)$, the Kendall tau distance between the maintained list, l_t, and the underlying ordered list, l'_t, is $O(n)$ with exponentially high probability.*

That is, after an initialization period of $\Theta(n^2)$ steps, the repeated insertion-sort algorithm converges to a steady state having an asymptotically optimal Kendall tau distance between the maintained list and the underlying total order, with exponentially high probability. We also show how to reduce this initialization period to be $\Theta(n \log n)$ steps, with high probability, by first performing a quicksort algorithm and then following that with the repeated insertion-sort algorithm.

Intuitively, our proof of Theorem 1 relies on two ideas: the adaptivity of insertion sort and that, as time progresses, a constant fraction of the random swaps fix inversions. Ignoring the random swaps for now, when there are k inversions, a complete execution of insertion sort performs roughly $k + n$ comparisons and fixes the k inversions (e.g., see [6, 8]). If an ϵ fraction of the random swaps fix inversions, then during insertion sort $\epsilon(k + n)$ inversions are fixed by the random swaps and $(1 - \epsilon)(k + n)$ are introduced. Naively the total change in the number of inversions is then $(1 - 2\epsilon)(k + n) - k$ and when $k > \frac{1-2\epsilon}{2\epsilon}n$, the number of inversions decreases. So the number of inversions will decrease until $k = O(n)$.

This simplistic intuition ignores two competing forces involved in the heavy interplay between the random swaps and insertion sort's runtime, however, in the evolving data model,

[2] Recall that an *inversion* is a pair of items u and v such that u comes before v in a list but $u > v$. An *inversion* in a permutation π is a pair of elements $x \neq y$ with $x < y$ and $\pi(x) > \pi(y)$.

Algorithm 1 Repeated insertion sort pseudocode

```
function REPEATED_INSERTION_SORT(l)
    while true do
        for i ← 1 to n − 1 do
            j ← i
            while j > 0 and l[j] < l[j − 1] do
                swap l[j] and l[j − 1]
                j ← j − 1
```

which necessarily complicates our proof. First, random swaps can cause an insertion-sort pass to end too early, thereby causing insertion sort to fix fewer inversions than normal. Second, as insertion sort progresses, it decreases the chance for a random swap to fix an inversion. Analyzing these two interactions comprises the majority of our proof of Theorem 1.

In Section 3, we present a complete proof of Theorem 1. The most difficult component of Theorem 1's proof is Lemma 6, which lower bounds the runtime of insertion sort in the evolving data model. The proof of Lemma 6 is presented separately in Section 4.

Due to space requirements, some proofs are left to the Arxiv version of the paper.

2 Preliminaries

The sorting algorithm we analyze in this paper for the evolving data model is the repeated insertion-sort algorithm whose pseudocode is shown in Algorithm 1.

Formally, at time t, we denote the sorting algorithms' list as l_t and we denote the underlying total order as l'_t. Together these two lists define a permutation, σ_t, of the indices, where $\sigma_t(x) = y$ if the element at index x in l_t is at position y in l'_t. We define the *simulated final state at time t* to be the state of l obtained by freezing the current underlying total order, l'_t, (i.e., no more random swaps) and simulating the rest of the current round of insertion sort (we refer to each iteration of the **while-true** loop in Algorithm 1 as a *round*). We then define a *frozen-state* permutation, $\hat{\sigma}_t$, where $\hat{\sigma}_t(x) = y$ if the element at index x in the simulated final state at time t as at index y in l'_t.

Let us denote the number of inversions at time t, in σ_t, with I_t. Throughout the paper, we may choose to drop time subscripts if our meaning is clear. The Kendall tau distance between two permutations π_1 and π_2 is the number of pairs of elements $x \neq y$ such that $\pi_1(x) < \pi_1(y)$ and $\pi_2(x) > \pi_2(y)$. That is, the Kendall tau distance between l_t and l'_t is equal to I_t, the number of inversions in σ_t. Figure 1 shows the state of l, l', I, and σ for two steps of an insertion sort (but not in the same round).
