and consider the following two circles: the circle C_1 that is centred at O_1 and has the radius $\mathtt{dist}(\mathtt{cor}(b_i), \mathtt{cor}(\mathtt{w}(b_i, r_j)))/2$, and the circle C_2 that is centred at O_2 with radius $\mathtt{dist}(\mathtt{cor}(\mathtt{w}(b_i, r_j)), \mathtt{cor}(r_j))/2$. See Figure 2(c). We draw the first part of arc (b_i, r_j) on the half circle of C_1 that lies above the diagonal starting from $\mathtt{cor}(b_i)$ and ending at $\mathtt{cor}(\mathtt{w}(b_i, r_j))$ and then the second part on the half circle of C_2 that lies below the diagonal starting from $\mathtt{cor}(\mathtt{w}(b_i, r_j))$ and ending at $\mathtt{cor}(r_j)$. (The full version of the paper shows a complete example of graph H.)

Planarity of H. Clearly, no top arc crosses a down arc (except perhaps at their endpoints). To show the planarity of H, we show that – no top arc crosses another top arc, no down arc crosses another down arc, and no mixed arc crosses a top, a down or another mixed arc.

▶ **Lemma 7.** *No two top arcs in H cross each other.*

Proof. Suppose for a contradiction that two top arcs $(a, b), (c, d) \in E'$ cross each other, and w.l.o.g. assume that $x(a) < x(c) < x(b) < x(d)$. Since (a, b) is a top arc, we must have $x(\mathtt{cor}(\mathtt{w}(a, b))) \geq x(b)$; for a similar reason, we must have $x(\mathtt{cor}(\mathtt{w}(c, d))) \geq x(d)$. We now consider two cases. (i) If $x(\mathtt{cor}(\mathtt{w}(a, b))) \leq x(\mathtt{cor}(\mathtt{w}(c, d)))$, then $\mathsf{L}(c)$ must intersect $\mathtt{w}(a, b)$, which is a contradiction because in that case we should have added (a, c) or (c, b) to E'

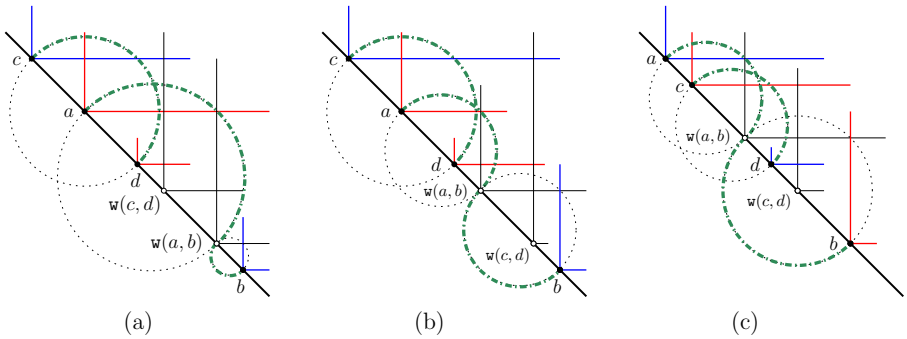

Figure 3 An illustration in supporting the proof of Lemma 9.

corresponding to $\mathsf{w}(a,b)$ instead of (a,b). (ii) If $x(\mathtt{cor}(\mathsf{w}(a,b))) > x(\mathtt{cor}(\mathsf{w}(c,d)))$, then $\mathsf{L}(b)$ must intersect $\mathsf{w}(c,d)$ – this is also a contradiction because in that case we should have added (c,b) or (b,d) to E' corresponding to $\mathsf{w}(c,d)$ instead of (c,d). ◀

▶ **Lemma 8** (∗). *No two down arcs in H cross each other.*

It remains to show that no mixed arc crosses a top arc, a down arc or another mixed arc.

▶ **Lemma 9.** *No mixed arc crosses a top arc in H.*

Proof. Suppose for a contradiction that a mixed arc (a,b) crosses a top arc (c,d) and assume w.l.o.g. that $x(a) < x(b)$ and $x(c) < x(d)$. If $x(c) < x(a)$, then we must have $x(a) < x(d) < x(\mathtt{cor}(\mathsf{w}(a,b)))$ – otherwise, the two arcs would not cross. First, we know that $x(\mathtt{cor}(\mathsf{w}(c,d))) \geq x(d)$. If $x(\mathtt{cor}(\mathsf{w}(c,d))) < x(\mathtt{cor}(\mathsf{w}(a,b)))$, then $\mathsf{L}(a)$ intersects $\mathsf{w}(c,d)$ before intersecting $\mathsf{w}(a,b)$, which is a contradiction because in that case we should have added either the top arc (c,a) or the top arc (a,d) to E' corresponding to $\mathsf{w}(c,d)$ instead of (c,d); see Figure 3(a). If $x(\mathtt{cor}(\mathsf{w}(c,d))) > x(\mathtt{cor}(\mathsf{w}(a,b)))$, then $\mathsf{L}(d)$ intersects $\mathsf{w}(a,b)$ before intersecting $\mathsf{w}(c,d)$, which is again a contradiction as we should have added either the top arc (a,d) or the mixed arc (d,b) to E' corresponding to $\mathsf{w}(a,b)$ instead of (a,b). See Figure 3(b).

Now, suppose that $x(c) > x(a)$. Then, we must have $x(a) < x(c) < x(\mathtt{cor}(\mathsf{w}(a,b))) < x(d)$ as the two arcs would not intersect otherwise. Since (c,d) is a top arc, we must have $x(\mathtt{cor}(\mathsf{w}(c,d))) \geq x(d)$ and so $\mathsf{L}(c)$ would intersect $\mathsf{w}(a,b)$ before intersecting $\mathsf{w}(c,d)$; see Figure 3(c). This is a contradiction because we should have added either the top arc (a,c) or the mixed arc (c,b) to E' corresponding to $\mathsf{w}(a,b)$ instead of (a,b). ◀

▶ **Lemma 10** (∗). *No mixed arc crosses a down arc in H.*

▶ **Lemma 11** (∗). *No two mixed arcs cross each other in H.*

By Lemma 7 – 11, it follows that H is a planar graph. The following lemma along with the planarity of H gives a PTAS for the problem on G.

▶ **Lemma 12.** *Graph $H = (\mathcal{B} \cup \mathcal{R}, E)$ satisfies the local exchange property.*

Proof. To prove the lemma, it is sufficient to show that for any vertex $u \in V$, there are $b_i \in \mathcal{B}$ and $r_j \in \mathcal{R}$ such that both $\mathsf{L}(b_i)$ and $\mathsf{L}(r_j)$ intersect $\mathsf{L}(u)$ and $(b_i, r_j) \in E'$. Take any vertex $u \in V$ and let $S \subseteq \mathcal{B} \cup \mathcal{R}$ be the set of all L-frames that intersect $\mathsf{L}(u)$. Notice that $S \cap \mathcal{B} \neq \emptyset$ and $S \cap \mathcal{R} \neq \emptyset$ because each of $\mathcal{B}$ and $\mathcal{R}$ is a feasible solution to the MDS problem

on G. Now, consider $b \in S \cap \mathcal{B}$ and $r \in S \cap \mathcal{R}$ for which $\texttt{dist}(\texttt{cor}(b), \texttt{cor}(r))$ is minimum over all such pairs (b, r). We know by definition of H that $(b, r) \in E'$, which proves the lemma. ◀

3.2 Proof of Theorem 1

We are now ready to prove Theorem 1. Here, the rectangles are anchored at the diagonal from both sides; let $G = (V, E)$ denote the corresponding graph.

Proof of Theorem 1. Let $\{X, Y\}$ be a partition of the vertices of G such that the L-frames corresponding to vertices in X (resp. Y) are anchored at D from above (resp. below). By abusing notation, we refer to these two sets of L-frames also as X and Y. For any $\epsilon > 0$, set $\epsilon' := \epsilon/2$. We apply the PTAS of Section 3.1 with parameter c/ϵ' to the L-frames in X and Y independently, and let S_X and S_Y be the solutions returned by the algorithm, respectively. We return $S := S_X \cup S_Y$ as the final solution. Let OPT, $\mathsf{OPT_X}$ and $\mathsf{OPT_Y}$ denote an optimal solution for the MDS problem on the L-frames in $X \cup Y$ (i.e., graph G), X and Y, respectively.

Consider the solution OPT. Let $S \subseteq \mathsf{OPT}$ be a minimum size set of L-frames that dominates all the L-frames in X. If there is an L-frame $P \in S$ that is in Y, then P can only dominate those L-frames in X that are anchored at the diagonal at the same point as P, in which case we can replace P by one of those L-frames from X. As such, there exists a set $S' \subseteq X$ of size at most $|S| \leq |\mathsf{OPT}|$ that dominates the L-frames of X. It follows that $|\mathsf{OPT_X}| \leq |\mathsf{OPT}|$. Similarly, one can show that $|\mathsf{OPT_Y}| \leq |\mathsf{OPT}|$. Now, by using the result from Section 3.1, we have $|S_X| \leq (1+\epsilon')|\mathsf{OPT_X}|$ and $|S_Y| \leq (1+\epsilon')|\mathsf{OPT_Y}|$. Then,

$$|S| \leq |S_X| + |S_Y| \leq (1+\epsilon')|\mathsf{OPT_X}| + (1+\epsilon')|\mathsf{OPT_Y}| \leq 2(1+\epsilon')|\mathsf{OPT}| = (2+\epsilon)|\mathsf{OPT}|,$$

which completes the proof of the theorem. ◀

3.3 Proof of Theorem 2

Recall that Theorem 2 claims APX-hardness of the problem on L-frames in the diagonal-intersecting case. We show a gap-preserving reduction from the MDS problem on *circle graphs*, which is known to be APX-hard [10]. Recall that a graph is called a circle graph, if it is the intersection graph of chords of a circle. Take any circle graph $G = (V, E)$ with n vertices, and consider a geometric representation of G. By a closer look at the APX-hardness proof [10], we can assume that no two chords share an endpoint; that is, there are exactly $2n$ distinct points on the circle determining the endpoints of the chords. Cut the circle at an arbitrary point p and consider the ordering $M := \langle p_1, p_2, \ldots, p_{2n} \rangle$ of the endpoints of chords visited in counter-clockwise along the circle starting at p. Now, let D be the diagonal line $y = (2n+1) - x$. Consider each endpoint p_i (where $1 \leq i \leq 2n$) in the order given by M. Then, we map each point p_i to the point $((2n+1) - i, i)$ on D. Let $e := (p_j, p_k)$ be a chord of G. Then, the L-frame corresponding to e is the unique L-frame that lies below D and connects the two points mapped on D corresponding to p_j and p_k; see Figure 4 for an example. Let $G' = (V', E')$ be the graph corresponding to the constructed L-frames. Clearly, D has slope -1 and the construction can be done in polynomial time. Moreover, since the $2n$ endpoints of chords of the input representation are pairwise distinct, the points mapped to the line D are in general position; that is, no two such points have the same x- or the same y-coordinates. The following lemma completes the proof of Theorem 2.

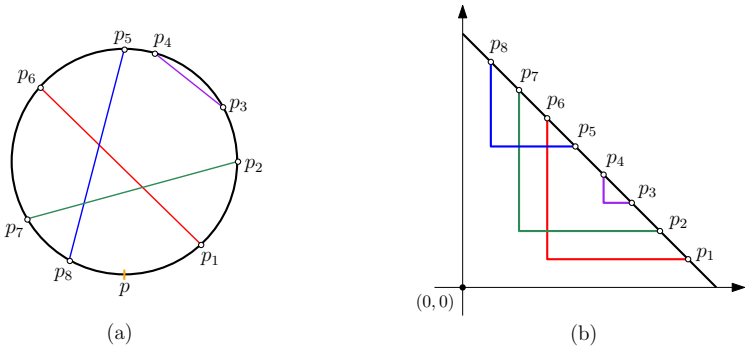

Figure 4 An illustration supporting the proof of Theorem 2.

▶ **Lemma 13.** *G has a dominating set of size k if and only if G' has a dominating set of size k.*

Proof. First, we show that there is a one-to-one correspondence between the vertices of G and those of G' such that $(i,j) \in E$ if and only if $(i,j) \in E'$. The one-to-one correspondence between the vertices of these two graphs is clear from the construction. Now, suppose that $(i,j) \in E$. This means that the endpoints of vertices i and j appear in M as either $\langle p_i, p_j, p_{i'}, p_{j'} \rangle$ or $\langle p_j, p_i, p_{j'}, p_{i'} \rangle$, where p_i and $p_{i'}$ with $i < i'$ (resp., p_j and $p_{j'}$ with $j < j'$) correspond to the endpoints of i (resp., j). By the mapping used in the construction, this ordering is preserved on D (when going from $(2n+1, 0)$ to $(0, 2n+1)$ along D) and so the L-frames $\mathsf{L}(i)$ and $\mathsf{L}(j)$ intersect each other below D; that is, $(i,j) \in E'$. Conversely, if $(i,j) \notin E$, then their endpoints appear in M as either $\langle p_i, p_j, p_{j'}, p_{i'} \rangle$ or $\langle p_j, p_i, p_{i'}, p_{j'} \rangle$, where p_i and $p_{i'}$ with $i < i'$ (resp., p_j and $p_{j'}$ with $j < j'$) correspond to the endpoints of i (resp., j). Consequently, this ordering is preserved on D by the mapping (when going from $(2n+1, 0)$ to $(0, 2n+1)$ along D) and so $\mathsf{L}(i)$ and $\mathsf{L}(j)$ do not intersect each other inside D; that is, $(i,j) \notin E'$. It is now straightforward to see that G has a dominating set of size k if and only if G' has a dominating set of size k, which is clearly a gap-preserving reduction. ◀

Remark. Using a similar reduction in the other direction one can show that, for every intersection graph G of a set of diagonal-intersecting L-frames that intersect each other only below the diagonal, one can find a circle graph G' such that G has a dominating set of size k if and only if G' has a dominating set of size k. As one can obtain a $2+\epsilon$-approximation for MDS on *circle graphs* [11], MDS can be approximated within a factor of $2+\epsilon$ in this special case of diagonal-intersecting L-frames. Note that this is the version which we have just proved to be APX-hard.

4 Vertical-intersecting L-frames

In this section, we prove Theorems 3 and 4. To prove Theorem 3, we first show that the MDS problem is APX-hard even when each L-frame intersects a vertical line. The proof is essentially the same as that of Theorem 2, but by a slight modification of replacing the diagonal D with a quarter of a circle and then extending the horizontal segment of each L-frame until it hits a vertical line that is placed far to the right. See the full version of the paper for the complete proof.

To complete the proof of Theorem 3, we show that the MDS problem is NP-hard on L-frames even if the horizontal and vertical segments of every L-frame have the same length. The reduction is from a variant of the 3SAT problem. For any 3SAT instance, one can define

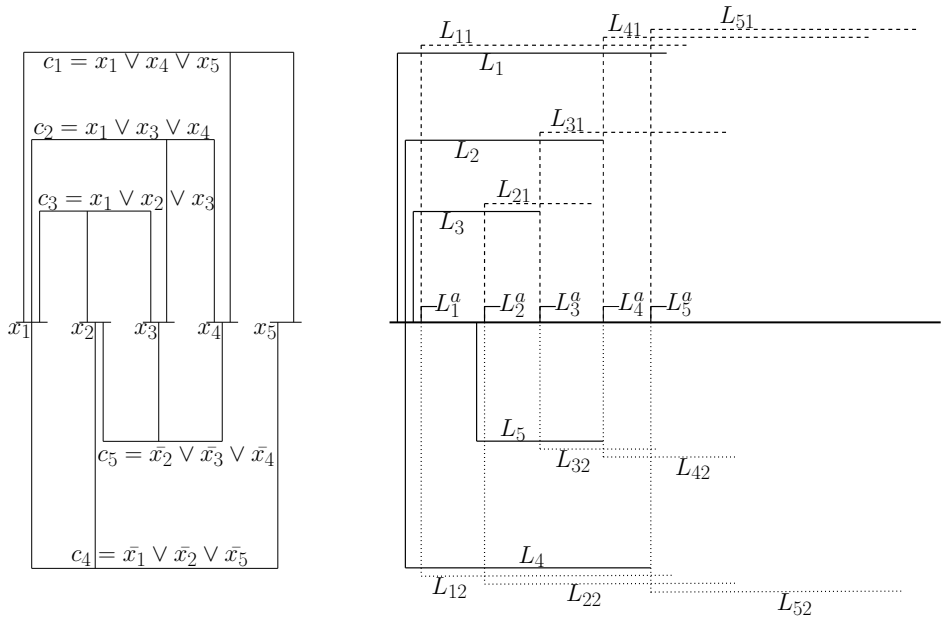

Figure 5 A drawing of an instance of Planar Monotone Rectilinear 3SAT (left) and the corresponding instance of the MDS problem before rotation (right). The variable L-frames above (resp. below) the x-axis are shown in dashed (resp. dotted) style. The clause L-frames and the auxilliary L-frames are shown in normal style.

a bipartite graph on the clauses and the variables which we refer to as the incidence graph. For any clause c_j, if c_j contains a literal corresponding to a variable v_i, the edge (v_i, c_j) is added to the graph. A drawing of a planar incidence graph is called *planar rectilinear* if it has the following properties. Each variable vertex is drawn as a horizontal segment on the x-axis and the clause vertices are drawn as horizontal segments above and below the x-axis. For each edge (v_i, c_j), the horizontal segment corresponding to c_j has a vertical connection to the horizontal segment corresponding to v_i. Moreover, this vertical connection does not intersect any other horizontal segments. See the left figure of Figure 5 for an example. An instance of the 3SAT problem is called *monotone* if, for every clause in the instance, the literals of the clause are either all positive (called a *positive* clause) or all negative (called a *negative* clause). A planar rectilinear drawing of an incidence graph is called *monotone* if it corresponds to a monotone 3SAT instance such that all the positive (resp., negative) clauses are drawn above (resp., below) the x-axis. In the Planar Monotone Rectilinear 3SAT problem the incidence graph of any instance has a planar rectilinear and monotone drawing. The problem is known to be NP-hard even when the drawing is given [13]. Given an instance of the Planar Monotone Rectilinear 3SAT, we construct a set of L-frames such that the horizontal and vertical segments of each L-frame have the same length and they all intersect a vertical line.

Let n be the number of variables. Due to the hierarchical structure of the clauses lying above and below the x-axis, respectively in the given drawing, one can modify the drawing in a way such that for each clause, the length of the horizontal segment corresponding to it is the same as the length of the vertical segments corresponding to it (see the left figure of Figure 5). Let T be the new drawing. We construct the instance I of MDS from T in the following way. For each clause c_j, removing all the vertical connections except the leftmost one creates an L-frame. We add this L-frame (denoted by L_j) to our instance. For each

variable x_i, we add two L-frames: one (denoted by L_{i1}) above and the other (denoted by L_{i2}) below the x-axis. The vertical segments of these two L-frames are the maximum length vertical connections corresponding to x_i lying above and below x-axis, respectively. For the variable L-frames, their horizontal segments lie on the right of their vertical segment. Moreover, for any variable L-frame above (resp., below) the x-axis, the corner is the topmost (resp., bottommost) point of the vertical segment. The two L-frames corresponding to each variable are shifted accordingly so that they intersect at a point on the x-axis (see Figure 5). Also, for each variable x_i, we add an auxiliary L-frame L_i^a that intersects only the two L-frames corresponding to it as shown in Figure 5. Note that in the constructed instance, one endpoint of each L-frame lies on the x-axis. Now it could be the case that, for some i, j and $k \in \{1, 2\}$, an L_{ik} intersects L_j though c_j does not contain any literal of x_i. To get rid of these intersections, we extend each L_{ik} vertically and then horizontally (to maintain the symmetry) so that it does not intersect any L_j such that c_j does not contain x_i. Note that, as we do not modify the L_j's, if c_j contains the literal x_i (resp. $\bar{x_i}$), L_{i1} (resp. L_{i2}) still intersects L_j. Finally, we rotate the created instance clockwise by 90° with respect to the origin. Hence all the L-frames in the constructed instance now intersect the vertical line $x = 0$ or the y-axis, and thus together they form an instance of the problem with vertical-intersecting L-frames. Lemma 15 below completes the proof of the second part of Theorem 3. We first need the following observation whose proof is immediate from the construction.

▶ **Observation 14.** *For all i, j, L_{i1} (resp., L_{i2}) intersects L_j if and only if the clause c_j contains the literal x_i (resp., $\bar{x_i}$).*

▶ **Lemma 15.** *The instance I has a dominating set of size n if and only if the 3SAT instance is satisfiable.*

Proof. Suppose I has a dominating set D of size n. We construct a satisfiable assignment in the following way. Consider any variable x_i. As L_i^a intersects only L_{i1} and L_{i2}, one of these three L-frames must be in the dominating set. The size of D being n, only one of the above mentioned three L-frames can be in D and no clause L-frame can be in D. If L_{i1} is in D, we set x_i to be true. Otherwise, we set x_i to be false. Now consider any clause c_j. Let x_i be a variable such that a L-frame corresponding to x_i is in D that intersects L_j. Note that there exists such an x_i. Now if L_{i1} is the chosen L-frame that dominates L_j, then L_{i1} is in D and by Observation 14 c_j must be a positive clause. It follows that, we have set x_i to be true and thus c_j is satisfied. Similarly, one can show that if L_{i2} is the chosen L-frame that dominates L_j, then also c_j is satisfied.

Now, suppose that we are given a satisfiable assignment of the 3SAT instance. We construct a dominating set in the following way. For any variable x_i, if x_i is set to be true, then we select L_{i1}. If x_i is set to be false, then we select L_{i2}. We claim that the selected L-frames form a dominating set. It is easy to see that the selected L-frames dominate the variable and auxiliary L-frames. Now, consider any clause L-frame L_j. There must be a variable x_i that satisfies c_j. If c_j is positive, the literal x_i must be set to true and we select L_{i1}. By Observation 14, L_{i1} intersects L_j, and thus L_j is being dominated. If c_j is negative, one can similarly show that L_j is also being dominated. ◀

We now prove Theorem 4. To this end, we show that the intersection graph of L-frames that inersect a vertical and a horizontal line is a permutation graph and so MDS is linear-time solvable on such a graph [7]. Geometrically, a graph G is a permutation graph if there are two embeddings of its vertices on two parallel lines such that, when connecting a vertex from

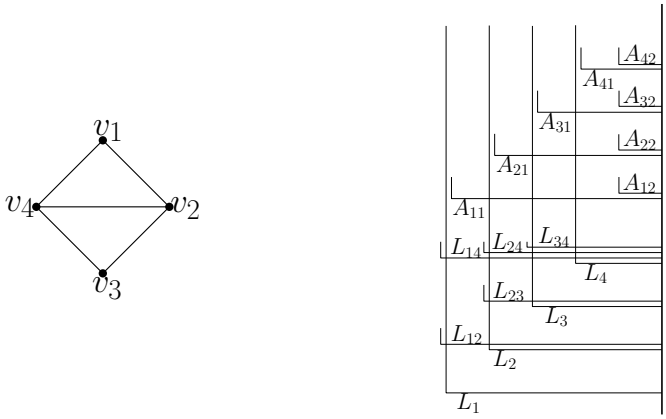

Figure 6 An example graph with 4 vertices (left) and its corresponding instance of the MDS problem (right).

the first line to the same vertex on the other line using a line segment, the edge set of the graph is realized exactly by the intersections of those segments. That is, two vertices appear in different order on the parallel lines (and, so their line segments intersect) whenever they are adjacent in the graph. By taking the two orderings in which the endpoints of the L-frames in the input graph intersect the two lines, we can construct the geometric representation of a permutation graph having the same edges. Hence, Theorem 4 follows.

5 Edge Intersection Model

In this section, we show our results for the edge intersection model [18].

Proof of Theorem 5. We show a reduction from the Vertex Cover problem. In Vertex Cover, we are given a graph $G = (V, E)$ with n vertices and the goal is to find a subset $V' \subseteq V$ such that for any edge $(v_i, v_j) \in E$, $V' \cap \{v_i, v_j\} \neq \emptyset$. Let $VC(G)$ be the size of any minimum size vertex cover of G. As noted in [2], from the work of Dinur and Safra [14] the following theorem can be derived.

▶ **Theorem 16** (Dinur and Safra [14]). *Let $1/3 < p < p_{max} = (3 - \sqrt{5})/2$ and $q = 4p^3 - 3p^4$. For any constant $\epsilon > 0$, given any unweighted graph $G = (V, E)$ with bounded degrees, it is NP-hard to distinguish between "Yes": $VC(G) < (1 - p + \epsilon)|V|$, and "No": $VC(G) > (1 - q - \epsilon)|V|$.*

Given the vertex cover graph $G = (V, E)$, we construct an instance I of MDS. In the instance I, all the L-frames lie on the left of the line $x = 0$ and intersect the line, and thus each has the ⌞ shape. The construction is as follows. For each vertex v_i, we have an L-frame L_i that intersects $x = 0$ at the point $(0, 2i)$ as shown in Figure 6. Note that these L-frames do not intersect each other. For each edge (v_i, v_j) with $i < j$, we have an L-frame L_{ij} that intersects $x = 0$ at $(0, 2j)$, and thus intersects (i.e., has a common horizontal grid edge) with v_j. It also intersects (has a common vertical grid edge) with v_i (see Figure 6). Also, for each vertex v_i, we have two auxiliary L-frames A_{i1} and A_{i2} that intersect $x = 0$ at $(0, 2n + i)$, and A_{i1} shares a vertical grid edge with L_i. Note that the only L-frame A_{i2} intersects is A_{i1}. Also, all the L-frames intersect the vertical line $x = 0$. We first need the following observations.

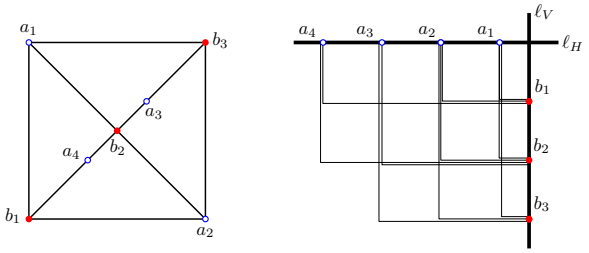

Figure 7 A bipartite graph on 7 vertices (left) and its corresponding representation in the edge intersection model (right).

▶ **Observation 17.** *For $1 \leq i < j \leq n$, the only* L*-frames that L_{ij} intersects are L_i, L_j and L_{tj}, where $(v_t, v_j) \in E$ with $t < j$.*

▶ **Observation 18.** *The only* L*-frames that get dominated by the* L*-frames in $\{A_{i1} : 1 \leq i \leq n\}$ are L_i and A_{i2} for $1 \leq i \leq n$.*

▶ **Observation 19.** *Any dominating set contains at least one of A_{i1} and A_{i2} for each $1 \leq i \leq n$. Also for any dominating set of size k, there is a dominating set D of size at most k such that D contains A_{i1} for all $1 \leq i \leq n$ and does not contain any A_{i2} for $1 \leq i \leq n$.*

▶ **Lemma 20.** *G has a vertex cover of size k if and only if I has a dominating set of size $k + n$.*

Proof. Suppose G has a vertex cover of size k. We construct a dominating set D of size $k + n$ in the following way. At first add all the L-frames $\{A_{i1} : 1 \leq i \leq n\}$ to D. Then for each v_i in the vertex cover, add L_i to D. Clearly $|D| = k + n$. By Observation 18, D dominates any L_i and A_{i2} for $1 \leq i \leq n$. Now consider any L_{ij}. Note that we have added at least one of L_i and L_j to D, and hence D dominates L_{ij} as well.

Now, suppose we have a dominating set D' of size $k + n$. By Observation 19, we can assume that D' contains A_{i1} for all i and does not contain any A_{i2}. Thus D' contains k L-frames corresponding to the vertices and the edges. Now suppose D' contains an edge L-frame L_{ij}. By Observation 17 and 18, the only L-frames that cannot get dominated by D' by the removal of L_{ij} from D' are L_{tj}, where $(v_t, v_j) \in E$ with $t < j$. Thus if we replace L_{ij} by L_j in D', D' still remains a dominating set. Thus, we can assume w.l.o.g. that D' does not contain any L_{ij}. Now we construct a subset $V' \subseteq V$ by selecting vertices corresponding to the vertex L-frames contained in D'. Clearly $|V'| = k$. We claim that V' is a vertex cover. Consider any edge (v_i, v_j). Then by Observation 18, at least one of L_i and L_j must be in D'. It follows that at least one of v_i and v_j is present in V' which finishes the proof. ◀

By Theorem 16 and Lemma 20, we have the following lemma.

▶ **Lemma 21.** *Let $1/3 < p < p_{max} = (3 - \sqrt{5})/2$ and $q = 4p^3 - 3p^4$. For any constant $\epsilon > 0$, given an input graph (in the edge intersection model) H with $O(n)$ vertices, it is* NP*-hard to distinguish between "Yes": H has a dominating set of size $< (2 - p + \epsilon)n$, and "No": The size of any dominating set of H is $> (2 - q - \epsilon)n$.*

Therefore, the gap between the sizes of the minimum dominating set in the "yes" and the "no" cases approaches $(2 - 4p^3 + 3p^4)/(2 - p) \approx 1.1377$ for $p = p_{max}$. Hence, Theorem 5 follows.

NP-hardness. We show a reduction from the *Edge Dominating Set* problem that is known to be NP-hard, even on planar bipartite graphs [21]. Recall that the objective of the Edge Dominating Set problem on a graph is to choose a minimum-cardinality set S of edges of the graph such that every edge not in S shares at least one endpoint with one edge in S. Given a planar bipartite graph $G = (A \cup B, E)$, we construct an intersection graph G' of L-frames in polynomial time such that G has an edge dominating set of size k if and only if G' has a dominating set of size k (in the edge intersection model). To this end, let $A = \{a_1, \ldots, a_r\}$ and $B = \{b_1, \ldots, b_s\}$, and for each vertex $a_i \in A$ (resp., vertex $b_j \in B$), consider the point $(-i, 0)$ (resp., point $(0, -j)$) of the Cartesian coordinate system in the plane. Then, for each edge $(a_i, b_j) \in E(G)$, add to $V(G')$ the unique L-frame that connects $(-i, 0)$ to $(0, -j)$ and has the point $(-i, -j)$ as its corner. See Figure 7. Let G' be the resulting graph. Clearly, every L-frame in G' intersects a vertical and a horizontal line and it can be constructed in polynomial time. Moreover, notice the one-to-one correspondence between the edges of G and the L-frames in G'. It is now easy to see that G has an edge dominating set of size k if and only if G' has a dominating set of size k (in the edge intersection model).

6 Conclusion

In this paper, we considered the MDS problem on the intersection graphs of rectangles and L-frames. Among several other approximation and hardness results, we gave a $(2+\epsilon)$-approximation algorithm for the problem on diagonal-anchored rectangles, which was based on a PTAS for when the rectangles are anchored from one side. However, the complexity of the latter problem remains open. The problem is NP-hard when the rectangles are anchored from both sides; is the problem APX-hard? Or, does the problem admit a PTAS? Even, finding an algorithm with approximation factor better than $(2+\epsilon)$ remains open.

Abstract

The constraint satisfaction problems k-SAT and Quantum k-SAT (k-QSAT) are canonical NP-complete and QMA_1-complete problems (for $k \geq 3$), respectively, where QMA_1 is a quantum generalization of NP with one-sided error. Whereas k-SAT has been well-studied for special tractable cases, as well as from a parameterized complexity perspective, much less is known in similar settings for k-QSAT. Here, we study the open problem of computing satisfying assignments to k-QSAT instances which have a "matching" or "dimer covering"; this is an NP problem whose decision variant is trivial, but whose search complexity remains open.

Our results fall into three directions, all of which relate to the "matching" setting: (1) We give a polynomial-time classical algorithm for k-QSAT when all qubits occur in at most two clauses. (2) We give a parameterized algorithm for k-QSAT instances from a certain non-trivial class, which allows us to obtain exponential speedups over brute force methods in some cases by reducing the problem to solving for a single root of a single univariate polynomial. (3) We conduct a structural graph theoretic study of 3-QSAT interaction graphs which have a "matching". We remark that the results of (2), in particular, introduce a number of new tools to the study of Quantum SAT, including graph theoretic concepts such as transfer filtrations and blow-ups from algebraic geometry; we hope these prove useful elsewhere.

1 Introduction

Constraint satisfaction problems (CSPs) are cornerstones of both classical and quantum complexity theory. Indeed, CSPs such as 3-SAT and MAX-2-SAT are complete for NP [13], and their analogues Quantum 3-SAT (3-QSAT) and the 2-local Hamiltonian problem are QMA_1- and QMA-complete, respectively [3, 10, 16, 15]. (QMA is Quantum Merlin-Arthur, a quantum generalization of Merlin-Arthur, and QMA_1 is QMA with perfect completeness.) As such CSPs are intractable in the worst case, approaches such as approximation algorithms, heuristics, and exact algorithms are employed. In this paper, we focus on the latter technique, and ask: Which special cases of k-QSAT can be solved efficiently on a classical computer?

Unfortunately, this problem appears to be markedly more difficult than in the classical setting. For example, classically, if each clause c of a k-SAT instance can be matched with a unique variable v_c, then clearly the k-SAT instance is satisfiable, and finding a solution is trivial: Set variable v_c to satisfy clause c. (Note that the matching can be found efficiently via, e.g., the Ford-Fulkerson algorithm [11].) In the quantum setting, it has been known [17] since 2010 that k-QSAT instances with such "matchings" (also called a "dimer covering" in physics [17]) are also satisfiable, and moreover the satisfying assignment can be represented succinctly as a tensor product state. Yet, *finding* the satisfying assignment efficiently has proven elusive (indeed, the proof of [17] is *non-constructive*). In other words, we have a trivial NP *decision* problem whose analogous *search* version is not known to be efficiently solvable (see, e.g., [2] regarding the longstanding open question of decision versus search complexity for NP problems). This is the starting point of the present work.

Results and techniques. Our results fall under three directions, all of which are related to k-QSAT with matchings. For this, we first define Quantum k-SAT (k-QSAT) [3] and the notion of a system of distinct representatives (SDR). For k-QSAT, the input is a two-tuple $\Pi = (\{\Pi_i = |\psi_i\rangle\langle\psi_i|\}_i, \alpha)$ of rank 1 projectors or *clauses* $\Pi_i \in \mathcal{L}(\mathbb{C}^2)^{\otimes k}$, each acting non-trivially on a set of k (out of n) qubits, and non-negative real number $\alpha > 1/p(n)$ for some fixed polynomial p. The output is to decide whether there exists a satisfying assignment on n qubits $|\psi\rangle \in (\mathbb{C}^2)^{\otimes n}$, i.e. to distinguish between the cases $\Pi_i|\psi\rangle = 0$ for all i (YES case), or whether $\langle\psi| \sum_i \Pi_i |\psi\rangle \geq \alpha$ (NO case). Note that k-QSAT generalizes k-SAT. As for a *system of distinct representatives (SDR)* (see, e.g., [12]), given a set system such as a hypergraph $G = (V, E)$, an SDR is a set of vertices $V' \subseteq V$ such that each edge in $e \in E$ is paired with a distinct vertex $v_e \in V'$ such that $v_e \in e$. In previous work on QSAT, an SDR has been referred to as a "dimer covering" [17].

1. Quantum k-SAT with bounded occurrence of variables. Our first result concerns the natural restriction of limiting the number of times a variable can appear in a clause. For example, 3-SAT with at most 3 occurrences per variable is NP-hard. We complement this as follows.

▶ **Theorem 1.** *There exists a polynomial time classical algorithm which, given an instance* Π *of k-QSAT in which each variable occurs in at most two clauses, outputs a satisfying product state if* Π *is satisfiable, and otherwise rejects. Moreover, the algorithm works for clauses ranging from* 1*-local to k-local in size.*

To show this, our idea is to "partially reduce" the k-QSAT instance to a 2-QSAT instance. We then use the transfer matrix techniques of [3, 18, 4] (particularly the notion of *chain reactions* from [4]), along with a new notion of "fusing" chain reactions, to deal with the remaining clauses of locality at least 3 in the instance.

Although this setting seems unrelated to the open question of computing solutions to k-QSAT instances with SDRs, we show the following. Denote the *interaction hypergraph* $G = (V, E)$ of a k-QSAT instance as a k-uniform hypergraph (i.e. all edges have size precisely k), in which the vertices correspond to qubits, and each clause c acting on a set of k qubits S_c, is represented by a hyperedge of size k containing the vertices corresponding to S_c.

▶ **Theorem 2.** *Let $G = (V, E)$ be a hypergraph with all hyperedges of size at least 2, and such that each vertex has degree at most 2. Then, G has an SDR.*

Thus, Theorem 1 resolves the open question of [17] for k-QSAT instances with SDRs in which (1) each variable occurs in at most two clauses and (2) there are no 1-local clauses. ((2) is necessary, as allowing edges of size 1 easily makes Theorem 2 false in general.)

2. On parameterized complexity for Quantum k-SAT. Our next result, and the main contribution of this paper, gives a parameterized algorithm[3] for explicitly computing (product state) solutions for a non-trivial class of k-QSAT instances. As discussed in Section 3, this algorithm in some cases provides an *exponential* speedup over brute force diagonalization.

At the core of the algorithm is a new graph theoretic notion of *transfer filtration of type b* for a k-uniform hypergraph $G = (V, E)$, for fixed $b > 0$. Intuitively, one should think of b as denoting the size of a set of b qubits which form the hard "foundation"' of any k-QSAT instance on G. With the notion of transfer filtration in hand, our framework for attacking k-QSAT can be sketched at a high level as follows.

1. First, given a k-QSAT instance Π on G with transfer filtration of type b, we "blow-up" Π to a larger, *decoupled* instance Π^+ (Decoupling Lemma, Lemma 9). The decoupled nature of Π^+ makes it "easier" to solve (Transfer Lemma, Lemma 17), in that any assignment to the b "foundation" qubits can be *extended* to a solution to all of Π^+. This raises the question – how does one map the solution of Π^+ back to a solution of Π?
2. We next give a set of "qualifier" constraints $\{h_s\}$ (Qualifier Lemma, Lemma 19) acting on *only the b foundation qubits*, with the following strong property: If a (product state) assignment $\mathbf{v}$ to the b foundation qubits satisfies the constraints $\{h_s\}$, then not only can we extend $\mathbf{v}$ via the Transfer Lemma to a full solution for Π^+ as in Step 1 above, but we can also map this extended solution back to one for the *original* k-QSAT instance Π.

Once the framework above is developed, we show that it applies to the non-trivial family of k-QSAT instances whose k-uniform hypergraph $G = (V, E)$ has a transfer filtration of type $b = |V| - |E| + 1$. This family includes, e.g., the semi-cycle, tiling of the torus, and "fir tree" (full version). Our main result (Theorem 23) says the following: For any k-QSAT instance Π on such a G and whose constraints are generic (see Section 3), computing a (product state) solution to Π reduces to solving for a root of a *single univariate* (see Remark 25) polynomial P – *any* such root (which always exists if the field $\mathbb{K}$ is algebraically closed) can then be extended back to a full solution for Π.

The key advantage of this approach, and what makes it a parameterized algorithm, is the following – the *degree* of P, and hence the runtime of the algorithm, scale exponentially only in b and a "radius" parameter r of the transfer filtration. Thus, given a transfer filtration

[3] Roughly, parameterized complexity characterizes the complexity of computational problems with respect to specific *parameters* of interest other than just the input size (e.g. the treewidth of the input graph).

where b and r are at most logarithmic, finding a (product state) solution to k-QSAT reduces to solving for a single root over $\mathbb{C}$ for a single univariate polynomial h_1 of polynomial degree, which can be done in polynomial time [25, 24]. Indeed, in Section 3 we give a non-trivial family of k-uniform hypergraphs, denoted Crash, for which our algorithm runs in polynomial time, whereas brute force diagonalization would require exponential time.

Conveniently, even when the foundation b and radius r are superlogarithmic, our algorithm still gives a *constructive* proof that all k-QSAT instances satisfying the preconditions of Theorem 23 have a (product state) solution. In particular, in Corollary 27, we observe that such hypergraphs must have SDRs, and so we constructively reproduce the result of [17] that any 3-QSAT instance with an SDR is satisfiable (by a product state) (again, assuming the additional conditions of Theorem 23 are met).

Finally, although this result stems primarily from tools of projective algebraic geometry (AG), the presentation herein avoids any explicit mention of AG terminology (with the exception of defining the term "generic" in Section 3.3) to be accessible to readers without an AG background. A brief overview of the ideas in AG terms is given in the full version.

3. A study of 3*-uniform hypergraphs with SDRs.* Our final contribution, which we hope guides future studies on the topic, is to take steps towards understanding the structure of all 3-QSAT instances with SDRs, particularly when $|E| = |V|$. Unfortunately, this seems a difficult task (if not potentially impossible, see "finite characterization" comments below). We first give various characterizations involving intersecting families (each pair of edges has non-empty intersection). We then study *linear* hypergraphs (each pair of edges intersects in at most one vertex), which are generally more complex. (For example, the set of edge-intersection graphs of 3-uniform linear hypergraphs is known not to have a "finite" characterization in terms of a finite list of forbidden induced subgraphs [19].) We study "extreme cases" of linear hypergraphs with SDRs, such as the Fano plane and "tiling of the torus", and in contrast to these two examples, demonstrate a (somewhat involved) linear hypergraph we call the iCycle which also satisfies the *Helly property* (which generalizes the notion of "triangle-free"). A main conclusion of this study is that even with multiple additional restrictions in place (e.g. linear, Helly), the set of 3-uniform hypergraphs with SDRs remains non-trivial. To complement these results, we show how to fairly systematically construct large linear hypergraphs with $|E| = |V|$ without SDRs. We hope this work highlights the potential complexity involved in dealing with even the "simple" case of 3-QSAT with SDRs.

Discussion, previous work and open questions. Regarding our parameterized algorithm, our notions of transfer filtrations and blow-ups apply to *any* instance of k-QSAT (and thus also[4] k-SAT), including QMA_1-complete instances. (For example, every k-uniform hypergraph has a trivial foundation obtained by iteratively removing vertices until the resulting set contains no edges. A key question is how *small* the foundation and radius of the filtration can be chosen for a given hypergraph, as our algorithm's runtime scales exponentially in these parameters.) More precisely, our techniques in Section 3, up to and including the Qualifier Lemma, apply to arbitrary k-QSAT instances. The main question is when *local* solutions to the qualifier constraints (which act only on b out of n qubits) can

[4] For the special case of k-SAT, note that it is not *a priori* clear that having a transfer filtration with a small foundation suffices to solve the system trivially. This is because the genericity assumption on constraints, which k-SAT constraints do not satisfy, is required to ensure that any assignment to the foundation propagates to all bits in the instance. Thus, the brute force approach of iterating through all 2^b assignments to the foundation does not obviously succeed.

be extended to *global* solutions to the entire k-QSAT instance. We answer this question affirmatively for the non-trivial class of k-QSAT instances which satisfy the preconditions of Theorem 23 (e.g. the semi-cycle, fir tree, crash, and any k-uniform hypergraph with $b = |V| - |E| + 1$), obtaining polynomial to exponential speedups over brute force in Section 3.

Moving to previous work, Quantum k-SAT was introduced by Bravyi [3], who gave an efficient (quartic time) algorithm for 2-QSAT, and showed that 4-QSAT is QMA_1-complete. Subsequently, Gosset and Nagaj [10] showed that Quantum 3-SAT is also QMA_1-complete, and independently and concurrently, Arad, Santha, Sundaram, Zhang [1] and de Beaudrap, Gharibian [4] gave linear time algorithms for 2-QSAT. The original inspiration for this paper was the work of Laumann, Läuchli, Moessner, Scardicchio and Sondhi [17], which showed *existence* of a product state solution for any k-QSAT instance with an SDR. Thus, the decision version of k-QSAT with SDRs is in NP and trivially efficiently solvable. However, whether the search version (i.e. compute an explicit satisfying assignment) is also in P remains open. The question of whether the decision and search complexities of NP problems are the same is a longstanding open problem in complexity theory; conditional results separating the two are known (see e.g. Bellare and Goldwasser [2]).

Regarding *classical* k-SAT, as mentioned above, in contrast to k-QSAT, solutions to k-SAT instances with an SDR can be trivially computed. As for parameterized complexity, classically it is a well-established field of study (see, e.g., [5] for an overview). The parameterized complexity of SAT and #SAT, in particular, has been studied by a number of works, such as [26, 6, 23, 7, 22, 21, 8], which consider parameterizations including based on tree-width, modular tree-width, branch-width, clique-width, rank-width, and incidence graphs which are interval bipartite graphs. Regarding parameterized complexity of *Quantum* SAT, as far as we are aware, our work is the first to initiate a "formal" study of the subject; however, we should be clear that existing works in Quantum Hamiltonian Complexity [20, 9] have long implicitly used "parameterized" ideas (e.g. in tensor network contraction, the bond dimension can be viewed as a parameter constraining the complexity of the contraction).

We close with open questions. Which ideas from classical parameterized complexity be generalized to the quantum setting? We develop a number of tools for studying Quantum SAT – can these be applied in more general settings, for example beyond the families of k-QSAT instances considered in Theorem 23? The "parameter" in our results of Section 3 involves the radius of a transfer filtration – whether a transfer filtration (of a fixed type b) of *minimum* radius can be computed efficiently, however, is left open for future work. Similarly, it is not clear that given $b \in \mathbb{N}$, the problem of deciding whether a given hypergraph G has a transfer filtration of type at most b is in P. We conjecture this latter problem is NP-complete. Finally, the question of whether solutions to arbitrary instances of k-QSAT with SDRs can be computed efficiently (recall they are guaranteed to exist [17]) remains open.

Organization. Section 2 gives an efficient algorithm for 3-QSAT with bounded occurrence of variables, and introduces the notion of transfer matrices (which are generalized via transfer functions in Section 3). Our main result is given in Section 3, and concerns a new parameterized complexity-type approach for solving k-QSAT. Our structural graph theoretic study of hypergraphs with SDRs, and any omitted proofs, are deferred to the full version.

Notation and basic definitions. For complex Euclidean space $\mathcal{X}$, $\mathcal{L}(\mathcal{X})$ denotes the set of linear operators mapping $\mathcal{X}$ to itself. For unit vector $|\psi\rangle \in \mathbb{C}^2$, the unique orthogonal unit vector (up to phase) is denoted $|\psi^\perp\rangle$, i.e. $\langle\psi|\psi^\perp\rangle = 0$.

▶ **Definition 3** (Hypergraph)**.** A *hypergraph* is a pair $G = (V, E)$ of a set V (vertices), and a family E (edges) of subsets of V. If each vertex has degree d, we say G is d-regular. When convenient we use $V(G)$ and $E(G)$ to denote the vertex and edge sets of G, respectively. We say G is k-uniform if all edges have size k.

▶ **Definition 4** (Cycle, Semicycle, Chain [14])**.** A k-uniform hypergraph $G = (V, E)$ is a *cycle* if there exists a sequence $S = (v_1, v_2, ..., v_l) \in V^l$ for $l \geq n$ such that (1) $v \in S$ for all $v \in V$, (2) for all $1 \leq i \leq l$, $e_i = \{v_i, v_{i+1}, ..., v_{i+k-1}\}$ are distinct edges in E, where indices are understood modularly. The length of the cycle G is $m = l$. If instead $1 \leq i \leq l - k + 1$ and $v_1 = v_l$ ($v_1 \neq v_l$), we obtain a *semicycle* (*chain*) of length $m = l - k + 1$.

2 Quantum SAT with bounded occurrence of variables

Transfer matrices, chain reactions, and cycle matrices. To study 3-QSAT with each qubit occurring in at most two constraints, we first recall transfer matrix tools from the study of 2-QSAT [3, 18, 4]. For any rank-1 constraint $\Pi_i = |\psi\rangle\langle\psi| \in \mathcal{L}((\mathbb{C}^2)^{\otimes k})$, consider Schmidt decomposition $|\psi\rangle = \alpha|a_0\rangle|b_0\rangle + \beta|a_1\rangle|b_1\rangle$, where $|a_i\rangle \in (\mathbb{C}^2)^{\otimes(k-1)}$ lives in the Hilbert space of the first $k-1$ qubits and $|b_i\rangle \in \mathbb{C}^2$ the last qubit. Then, the *transfer* matrix $T_\psi : (\mathbb{C}^2)^{\otimes k-1} \mapsto \mathbb{C}^2$ is given by $T_\psi = \beta|b_0\rangle\langle a_1| - \alpha|b_1\rangle\langle a_0|$. In words, given any assignment $|\phi\rangle$ to the first $k-1$ qubits, if $T_\psi|\phi\rangle \in \mathbb{C}^2$ is non-zero, then it is the *unique* assignment to qubit k (given $|\phi\rangle$ on qubits 1 to $k-1$) which satisfies Π_i.

In the special case of $k = 2$, transfer matrices are particularly useful. Consider first a 2-QSAT interaction graph (which is a 2-uniform hypergraph, or just a graph) $G = (V, E)$ which is a path, i.e. a sequence of edges $e_1 = (v_1, v_2), e_2 = (v_2, v_3), \ldots, e_m = (v_{m-1}, v_m)$ for distinct $v_i \in V$, and where edge e_i corresponds to constraint $|\psi_i\rangle$. Then, any assignment $|\phi\rangle \in \mathbb{C}^2$ to qubit 1 *induces a chain reaction (CR)* in G, meaning qubit 2 is assigned $T_{\psi_1}|\phi\rangle$, qubit 3 is assigned $T_{\psi_2}T_{\psi_1}|\phi\rangle$, and so forth. If this CR terminates before all qubits labelled by V receive an assignment, which occurs if $T_{\psi_i}|\phi'\rangle = 0$ for some i, this means that constraint i (acting on qubits i and $i+1$) is satisfied by the assignment $|\phi'\rangle$ to qubit i alone, and no residual constraint is imposed on qubit $i+1$. Thus, the graph G is reduced to a path $e_{i+1}, \ldots, e_m$. In this case, we say the CR is *broken*. Note that if G is a path, then it is a satisfiable 2-QSAT instance with a product state solution.

Finally, consider a 2-QSAT instance whose interaction graph G is a cycle $C = (v_1, \ldots, v_{m+1})$ with m. Then, a CR induced on vertex v_1 with any assignment $|\psi\rangle \in \mathbb{C}^2$ will in general propagate around the cycle and impose a consistency constraint on v_1. Formally, denote $T_C = T_{\psi_m} \cdots T_{\psi_1} \in \mathcal{L}(\mathbb{C}^2)$ as the *cycle matrix* of C. Then, if the cycle matrix is not the zero matrix, it be shown that the satisfying assignments for the cycle are precisely the eigenvectors of T_C. (If $T_C = 0$, any assignment on v_1 will only propagate partially around the cycle, thus decoupling the cycle into two paths.) Thus, if G is a cycle, it has a product state solution.

Here, when we refer to "solving the path or cycle", we mean applying the transfer matrix techniques above to efficiently compute a product state solution to the path or cycle.

***k*-QSAT with bounded occurence of variables.** We now prove Theorem 1.

Proof of Theorem 1. We begin by setting terminology. Let Π be an instance of k-QSAT with k-uniform interaction graph $G = (V, E)$. For any clause c, let Q_c denote the set of qubits acted on c, i.e. Q_c is the edge in G representing c. We say c is *stacked* if Q_c is contained in another clause $Q_{c'}$, i.e. if $\exists c' \neq c$ such that $Q_c \subseteq Q_{c'}$. For a qubit v, we use shorthand $|v\rangle$ to

denote the current assignment from $\mathbb{C}^2$ to v. For a clause c, $|c\rangle$ denotes the bad subspace of c, i.e. clause c is given by rank-1 projector $I - |c\rangle\langle c|$. The set of clauses vertex v appears in is denoted C_v. For any assignment $|v\rangle$, let $S_{|v\rangle} = \{\langle v|c\rangle \mid c \in C_v\} \subseteq \bigcup_{i=0}^{k-1} \mathbb{C}^{2^i}$, where recall c can be a clause on $1, \ldots, k$ qubits, and we assume $\langle v|$ acts as the identity on the qubits of c which are not v. Thus, $S_{|v\rangle}$ is the set of constraints we obtain by taking the clauses in C_v, and projecting down qubit v in each clause onto assignment $|v\rangle$ (i.e. clauses in $S_{|v\rangle}$ do not act on v). Our algorithm will satisfy that the only possible element of $\mathbb{C}$ in $S_{|v\rangle}$ is 0, obtained by projecting a constraint $|c\rangle \in \mathbb{C}^2$ onto its orthogonal complement to satisfy it; thus, assume without loss of generality that $S_{|v\rangle} \subseteq \bigcup_{i=1}^{k-1} \mathbb{C}^{2^i}$. Finally, two 1-local clauses $|c\rangle, |c'\rangle \in \mathbb{C}^2$ *conflict* if $|c\rangle$ and $|c'\rangle$ are linearly independent.

Algorithm A. Let Π satisfy the conditions of our claim. We repeatedly "partially reduce" Π to a 2-QSAT instance, and use the transfer matrix techniques outlined above to solve this subproblem. Combining this with a new notion of fusing CRs, the technique can be applied iteratively to reduce k-local constraints to 2-local ones until the entire instance is solved. Note: If a CR on a path is broken by a transfer matrix T_ψ on edge (u, v), i.e. $T_\psi|u\rangle = 0$, we implicitly continue by choosing assignment $|0\rangle$ on v to induce a new CR on the path.

1. While there exists a 1-local constraint c acting on some qubit v:
   - **a.** If c conflicts with another 1-local clause on v, reject. Else, set $|v\rangle = |c^\perp\rangle \in \mathbb{C}^2$. Set[5] $C_v = S_{|v\rangle}$, and remove v from Π.
2. While there exists a qubit v appearing only in clauses of size at least $k' \geq 3$:
   - **a.** Set $|v\rangle = |0\rangle$ and $C_v = S_{|v\rangle}$. Remove v from Π.
3. While there exists a 2-local clause:
   - **a.** If there exists a stacked 2-local clause c, i.e. $c' \neq c$ such that $Q_c \subseteq Q_{c'}$:
     - **i.** If $Q_c = Q_{c'}$, remove the qubits c acts on, and set their values to satisfy c and c'.
     - **ii.** Else, $Q_c \subset Q_{c'}$. Thus, c' is k'-local for $3 \leq k' \leq k$. Set the values of the qubits in Q_c so as to satisfy c. This collapses c' to a $(k'-2)$-local constraint on $Q_{c'} \setminus Q_c$.
       - **A.** If $k' - 2 = 1$, then c' has been collapsed to a 1-local constraint on some vertex $v \in Q_{c'} \setminus Q_c$, creating a path rooted at v. Set v so as to satisfy c', and use a CR to solve the resulting path until either the path ends, or a k''-local constraint is hit for $3 \leq k'' \leq k'$. In the latter case (Figure 1, Left), the k''-local constraint is reduced to a $(k''-1)$-local constraint and we return to the beginning of Step 3.
   - **b.** Else, pick an arbitrary 2-local clause c acting on variables v_1 and v_2. Then, v_1 (v_2) is the start of a path h_1 (h_2) (e.g., Figure 1, Middle).
     - **i.** If the path forms a cycle from v_1 to v_2, use the cycle matrix to solve the cycle. Remove the corresponding qubits and clauses from Π.
     - **ii.** Else, set v_1 and v_2 so as to satisfy c. Solve the resulting paths h_1 (h_2) until a k'-local (k''-local) constraint l_1 (l_2) is hit for $3 \leq k' \leq k$ ($3 \leq k'' \leq k$). If both l_1 and l_2 are found:
       - **A.** If $l_1 = l_2$ (i.e. $k' = k''$) and $k' - 2 = 1$, then fuse the paths h_1 and h_2 into a new path beginning at the qubit in l_1 which is not in h_1 or h_2 (Figure 1, Right). Iteratively solve the resulting path until a k'-local constraint is hit for $3 \leq k' \leq k$.
4. If any qubits are unassigned, set their values to $|0\rangle$.

In the full version, we prove correctness, run algorithm A on a sample input, and discuss its general applicability to an entire family of non-trivial 3-QSAT instances. ◀

[5] Note there is one "global copy" of each clause c that is "shared" by all C_v.

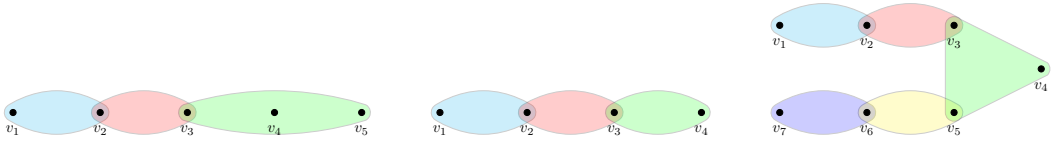

Figure 1 (Left) Solving the path rooted at v_1 via CR satisfies clauses (v_1, v_2) and (v_2, v_3), and projects clause (v_3, v_4, v_5) onto a 2-local residual clause on (v_4, v_5). The CR then stops. (Middle) Letting c denote the clause on (v_2, v_3), v_2 is the start of path $(v_2, v_1, \ldots)$, and v_3 is the start of path $(v_3, v_4, \ldots)$. (Right) Inducing CRs on v_1 and v_7, we assign values to v_3 and v_5. This collapses 3-local clause (v_3, v_4, v_5) into a 1-local clause on v_4 with a unique satisfying assignment, which induces a new CR starting at v_4. Thus, two CR's are "fused" into one CR.

3 Quantum SAT and parameterized algorithms

We next develop a parameterized algorithm for computing an explicit (product state) solution to a non-trivial class of k-QSAT instances (Theorem 23). Although the inspiration stems from algebraic geometry (AG), we generally avoid AG terminology to increase accessibility (see the full version for an overview in AG terms).

3.1 The transfer type of a hypergraph

▶ **Definition 5.** A hypergraph $G = (V, E)$ is of *transfer type* b if there exists a chain of subhypergraphs (denoted a *transfer filtration of type* b) $G_0 \subseteq G_1 \subseteq \cdots \subseteq G_m = G$ and an ordering of the edges $E(G) = \{E_1, \ldots, E_m\}$ such that

1. $E(G_i) = \{E_1, \ldots, E_i\}$ for each $i \in \{0, \ldots, m\}$,
2. $|V(G_i)| \leq |V(G_{i-1})| + 1$ for each $i \in \{1, \ldots, m\}$,
3. if $|V(G_i)| = |V(G_{i-1})| + 1$, then $V(G_i) \setminus V(G_{i-1}) \subseteq E_i$,
4. $|V(G_0)| = b$, where we call $V(G_0)$ the *foundation*,
5. and each edge of G has at least one vertex not in $V(G_0)$.

In other words, a transfer filtration of type b builds up G iteratively by choosing b vertices as a "foundation", and in each iteration adding precisely one new edge E_i and *at most* one new vertex. If a new vertex is added in iteration i, condition (3) says it must be in edge E_i added in iteration i.

▶ **Example 6** (Running example)**.** We introduce a hypergraph G to serve as a running example in this section. Let $V(G) = \{1, 2, 3, 4\}$ with edges $E_1 = \{1, 2, 3\}$, $E_2 = \{1, 2, 4\}$, $E_3 = \{1, 3, 4\}$ and $E_4 = \{2, 3, 4\}$. By Definition 4, G is a 3-uniform cycle. Consider hypergraphs G_0, G_1, G_2, G_3 such that $V(G_0) = \{1, 2\}$, $V(G_1) = \{1, 2, 3\}$, $V(G_2) = V(G_3) = V(G_4) = V(G)$, $E(G_0) = \emptyset$ and $E(G_j) = \{E_1, \ldots, E_j\}$ for $j = 1, 2, 3$. Then $G_0 \subseteq G_1 \subseteq G_2 \subseteq G_3 \subseteq G_4 = G$ is a transfer filtration of type 2, G_2 is a chain, and G_3 is a semicycle.

▶ Remark 7. Let G be a hypergraph with transfer filtration $G_0 \subseteq G_1 \subseteq \cdots \subseteq G_m = G$ of type b. Order the edges of G so that $E(G_i) = \{E_1, \ldots, E_i\}$ $\forall i \in \{1, \ldots, m\}$. Since by construction each edge contains at least one vertex not in $V(G_0)$, there exists a function $r : \{1, \ldots, m\} \to \{0, \ldots, m-1\}$ such that $r(i) < i$ and $|E_i \setminus V(G_{r(i)})| = 1$ for all $i \in \{1, \ldots, m\}$.

▶ **Example 8** (Running example)**.** Let G be the 3-uniform cycle of Example 6. Then one can choose $r : \{1, 2, 3, 4\} \to \{0, 1, 2, 3\}$ with $r(1) = r(2) = 0$, $r(3) = 1$ and $r(4) = 1$.

As the first step in our construction, we show how to map any k-uniform hypergraph G of transfer type b to a new k-uniform hypergraph G' of transfer type b whose transfer filtration

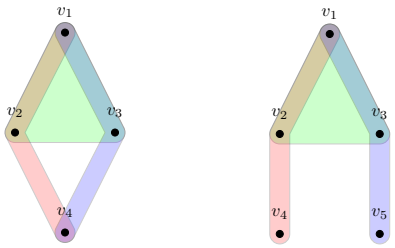

Figure 2 For the hypergraph on the left, consider the transfer filtration with foundation $G_0 = \{v_1, v_2\}$, and we iteratively add edges $\{v_1, v_2, v_3\}$, $\{v_1, v_2, v_4\}$, and $\{v_1, v_3, v_4\}$. The Decoupling Lemma maps this hypergraph to the one on the right, decoupling the intersection on vertex v_4. The surjective function p "undoes" the decoupling by mapping v_1, v_2, v_3 to themselves, and v_4, v_5 to v_4.

must add a vertex in each step (this follows directly from the relationship between $|V(G)|$ and $|E(G)|$ below). This has two effects worth noting: First, G' is guaranteed to have an SDR. Second, it *decouples* certain intersections in the hypergraph, as illustrated in Figure 2. For clarity, in the lemma below, for a function p acting on vertices, we implicitly extend its action to edges in the natural way, i.e. if $e = (v_1, v_2, v_3)$ then $p(e) = (p(v_1), p(v_2), p(v_3))$.

▶ **Lemma 9** (Decoupling lemma). *Given a k-uniform hypergraph G of transfer type b, there exists a k-uniform hypergraph $\widetilde{G}$ of transfer type b with $|E(G)| + b$ vertices and a surjective function $p : V(\widetilde{G}) \to V(G)$ such $p(\widetilde{E}) \in E(G)$ for every $\widetilde{E} \in E(\widetilde{G})$.*

Proof. (Sketch) Let $G_0 \subseteq G_1 \subseteq \cdots \subseteq G_m = G$ be a transfer filtration such that $V(G_0) = \{1, \ldots, b\}$, $E(G_i) = \{E_1, \ldots, E_i\}$ for every $i \geq 1$ and let $r : \{1, \ldots, m\} \to \{0, \ldots, m-1\}$ as in Remark 7. By Remark 7, there is a surjection $p : \{1, \ldots, m+b\} \to \{1, \ldots, n\}$ such that $p(i) = i$ for all $i \in \{1, \ldots, b\}$ and $\{p(i)\} = E_{i-b} \setminus V(G_{r(i-b)})$ for all $i \in \{b+1, \ldots, b+m\}$. For each $j \in \{1, \ldots, m+b\}$, let $\underline{j} = \min(p^{-1}(p(j)))$ and $\widetilde{E}_i = \{i+b\} \cup \{\underline{j} \mid j \in p^{-1}(E_i \setminus p(i+b))\}$ for each $i \in \{1, \ldots, m\}$. Setting $V(\widetilde{G}_i) = \{1, \ldots, b\}$ and $E(\widetilde{G}_i) = \{\widetilde{E}_1, \ldots, \widetilde{E}_i\}$ for each $i = \{0, \ldots, m\}$ we obtain a transfer filtration $\widetilde{G}_0 \subseteq \widetilde{G}_1 \subseteq \cdots \subseteq \widetilde{G}_m = \widetilde{G}$ of type b satisfying the requirements of the claim. ◀

▶ **Example 10** (Running example). Let G be the 3-uniform cycle of Example 6. The proof of Lemma 9 (full version) produces a 3-uniform hypergraph $\widetilde{G}$ with vertices $\{1, 2, 3, 4, 5, 6\}$ and edges $\widetilde{E}_1 = \{1, 2, 3\}$, $\widetilde{E}_2 = \{1, 2, 4\}$, $\widetilde{E}_3 = \{1, 3, 5\}$, $\widetilde{E}_4 = \{2, 3, 6\}$, and surjective function $p : \{1, 2, 3, 4, 5, 6\} \to \{1, 2, 3, 4\}$ defined by $p(1) = 1$, $p(2) = 2$, $p(3) = 3$, $p(4) = p(5) = p(6) = 4$. This choice is not unique: setting $\widetilde{E}_4 = \{2, 4, 6\}$ and $p(6) = 3$ also satisfies Lemma 9.

One of the "parameters" in our parameterized approach will be the *radius* of a transfer filtration, defined next. The concept is reminiscent of radii of graphs, and roughly measures "how far" an edge is from the foundation of b vertices with respect to the filtration.

▶ **Definition 11** (Radius of transfer filtration). Let G be a hypergraph admitting a transfer filtration $G_0 \subseteq \cdots \subseteq G_m = G$ of type b. Consider the function (whose existence is guaranteed by Remark 7) $r : \{0, \ldots, m\} \to \{0, \ldots, m-1\}$ such that $r(0) = 0$ and $r(i)$ is the smallest integer such that $|E_i \setminus V(G_{r(i)})| = 1$ $\forall i \in \{1, \ldots, m\}$. The *radius of the transfer filtration $G_0 \subseteq \cdots \subseteq G_m = G$ of type b* is the smallest integer β such that $r^\beta(i) = 0$ for all $i \in \{1, \ldots, m\}$ (r^β denotes composition of r with itself β times). The *type b radius of G* is the minimum value $\rho(G, b)$ of β over the set of all possible transfer filtrations of type b on G.

▶ **Example 12** (Running example). For G the 4-cycle from Example 6, since function r described in Example 8 is non-constant and $r(r(i)) = 0$ for all $i \in \{1, 2, 3, 4\}$, the transfer filtration of Example 6 has radius $\beta = 2$.

3.2 The main construction

Let W be a two dimensional vector space over a field $\mathbb{K}$. To discuss k-local constraints and product state solutions to k-QSAT instances, we now set up somewhat more general terminology than is standard in the literature. While this level of generality is natural given the geometric nature of our construction, for simplicity one may set $\mathbb{K} = \mathbb{C}$ and identify W with $\mathbb{C}^2$ if desired.

▶ **Definition 13.** A function $H_i : W^n \to \mathbb{K}$ is *k-local* if there exists a subset $E_i = \{i_1, \ldots, i_k\} \subseteq \{1, \ldots, n\}$ and a nonzero functional $H_i^* : W^{\otimes k} \to \mathbb{K}$ such that $H_i(v_1, \ldots, v_n) = H_i^*(v_{i_1} \otimes \cdots \otimes v_{i_k})$ for all $v_1, \ldots, v_n \in W$, i.e. H_i acts non-trivially only on a subset of k indices. A collection $H = (H_1, \ldots, H_m)$ of k-local functions $H_1, \ldots, H_n : W^n \to \mathbb{K}$ is *k-local*. The corresponding subsets E_i (i.e. on which H_i acts non-trivially) are the edges of a hypergraph G_H with vertices $\{1, \ldots, n\}$, the *interaction graph of H*. The *product satisfiability set* of k-local collection H is the set $\mathcal{S}_H$ of all $(v_1, \ldots, v_n) \in W^n$ such that $v_i \neq 0$ for all $i \in \{1, \ldots, n\}$ and $H_j(v_1, \ldots, v_n) = 0$ for all $j \in \{1, \ldots, m\}$.

▶ Remark 14. Consider an isomorphism $\sharp$ between W and its dual $W^\vee$ that to each $v \in W$ assigns a functional $v^\sharp \in W^\vee$ such that $v^\sharp(v) = 0$. For instance, if a basis $\{w_1, w_2\}$ for W is chosen then we may define $\sharp$ by setting $((a_1w_1 + a_2w_2)^\sharp)(b_1w_1 + b_2w_2) = a_1b_2 - a_2b_1$ for all $a_1, a_2, b_1, b_2 \in \mathbb{K}$. Given any $v_1, v_2 \in W$, $v_1^\sharp(v_2) = 0$ if and only if $\exists \lambda \in \mathbb{K}$ such that $\lambda v_2 = v_1$.

▶ **Definition 15.** For $N \in \mathbb{Z}^+$, the *Fibonacci numbers of order N* are the entries of the sequence $(F_r^{(N)})$ such that $F_r^{(N)} = F_{r-1}^{(N)} + \ldots + F_{r-N}^{(N)}$ for all $r \geq N$, $F_{N-1}^{(N)} = 1$ and $F_r^{(N)} = 0$ for all $r \leq N - 2$. Note that there exists [27] a monotonically increasing sequence (ψ_N) with values in the real interval $[1, 2)$ such that, for each $N \geq 1$, $F_r^{(N)} \sim \psi_N^r$ as $r \to +\infty$.

▶ **Definition 16.** A function f on W^l with values in a $\mathbb{K}$-vector space has *degree* $(d_1, \ldots, d_l)$ if $f(\lambda_1 v_1, \ldots, \lambda_l v_l) = \lambda_1^{d_1} \cdots \lambda_l^{d_l} f(v_1, \ldots, v_l)$ for every $\lambda_1, \ldots, \lambda_l \in \mathbb{K}$ and every $v_1, \ldots, v_l \in W$.

Applying the Decoupling Lemma to an input k-uniform hypergraph G with transfer type b, we obtain a k-uniform hypergraph $\widetilde{G}$ of type b with $m = n - b$, for m and n the number of edges and vertices, respectively. The next lemma shows that $\widetilde{G}$ is "easier to solve", in that any global (product) solution to the k-QSAT system can be derived from a set of assignments to the b foundation vertices, and conversely, any (product) assignment to the latter can be extended to a global (product) solution.

▶ **Lemma 17** (Transfer Lemma). *Let $H = (H_1, \ldots, H_{n-b})$ be a k-local collection of functions $H_i : W^n \to \mathbb{K}$ whose interaction graph is a k-uniform hypergraph of transfer type b. There exist non-zero (non-constant) functions, "transfer functions" $g_1, \ldots, g_n : W^b \to W$, s.t.:*

1. *(Global to local assignments) If $(v_1, \ldots, v_n) \in \mathcal{S}_H$ (recall $v_i \neq 0$ by definition of $\mathcal{S}_H$) there exist nonzero $\lambda_1, \ldots, \lambda_n \in \mathbb{K}$ such that, $\forall i \in \{1, \ldots, n\}$, $\lambda_i v_i = g_i(v_1, \ldots, v_b)$.*
2. *(Local to global assignments) For any nonzero $v_1, \ldots, v_b \in W$ there exist $v_{b+1}, \ldots, v_n \in W$ such that $(v_1, \ldots, v_n) \in \mathcal{S}_H$ and $v_i = g_i(v_1, \ldots, v_b)$ for every i such that $g_i(v_1, \ldots, v_b) \neq 0$.*
3. *(Degree bounds) g_i has degree $(d_{i1}, \ldots, d_{ib})$ such that $d_{ij} \leq F_i^{(b)}$ for all $j \in \{1, \ldots, b\}$.*

Proof. (Sketch) We sketch the proof in the case $b = 2$ and $k = 3$. Define $g_1(v_1, v_2) = v_1$ and $g_2(v_1, v_2) = v_2$. Assume $G_0 \subseteq G_1 \subseteq \cdots \subseteq G_{n-2} = G_H$ is a transfer filtration of type b, $V(G_i) = \{1, \ldots, i + 2\}$ for all $i \in \{1, \ldots, n - 2\}$. Assume $E(G_i) = \{E_1, \ldots, E_i\}$ with

$E_i = \{i, i_1, i_2\}$ for some $i_1, i_2 < i$. We construct transfer functions inductively as follows. First define $(g_i^\sharp(v_1, v_2))(v) = H^*_{i-2}(g_{i_1}(v_1, v_2) \otimes g_{i_2}(v_1, v_2) \otimes v)$ for all $v_1, v_2, v \in W$. Then, given an isomorphism $\sharp$ between W and $W^\vee$ as in Remark 14, define $g_i : W^2 \to W$ such that $(g_i(v_1, v_2))^\sharp = g_i^\sharp(v_1, v_b)$ for all $v_1, v_2 \in W$. The properties of transfer functions stated in the lemma are proved by straightforward induction. We leave the details to the reader. ◀

▶ **Example 18** (Running example). Let $H = (H_1, H_2, H_3, H_4)$ be a 3-local collection of functions $H_i : W^6 \to \mathbb{K}$ whose interaction graph is the 3-uniform chain $\widetilde{G}$ described in Example 10 (obtained by plugging the 4-cycle G of Example 6 into the Decoupling Lemma). For clarity, H_i is defined on hyperedge $\widetilde{E}_i$, where the order of vertices in each edge is fixed by the transfer filtration chosen; in particular, use ordering $\widetilde{E}_1 = (1, 2, 3)$, $\widetilde{E}_2 = (1, 2, 4)$, $\widetilde{E}_3 = (1, 3, 5)$, $\widetilde{E}_4 = (2, 4, 6)$ with foundation $\{1, 2\}$. The proof of Lemma 17 constructs transfer functions $g_1, \ldots, g_6 : W^2 \to W$ which give assignments to qubits 1 through 6, respectively, as follows. Fixing a basis $\{w_1, w_2\}$ of W: $g_1(v_1, v_2) = v_1, g_2(v_1, v_2) = v_2, g_3(v_1, v_2) = H_1^*(v_1 \otimes v_2 \otimes w_2)w_1 - H_1^*(v_1 \otimes v_2 \otimes w_1)w_2, g_4(v_1, v_2) = H_2^*(v_1 \otimes v_2 \otimes w_2)w_1 - H_2^*(v_1 \otimes v_2 \otimes w_1)w_2, g_5(v_1, v_2) = H_3^*(v_1 \otimes g_3(v_1, v_2) \otimes w_2)w_1 - H_3^*(v_1 \otimes g_3(v_1, v_2) \otimes w_1)w_2, g_6(v_1, v_2) = H_4^*(v_2 \otimes g_4(v_1, v_2) \otimes w_2)w_1 - H_4^*(v_2 \otimes g_4(v_1, v_2) \otimes w_1)w_2$.

Thus far, we have seen how combining the Decoupling and Transfer Lemmas "blows up" an input k-QSAT system Π to a larger "decoupled" system Π^+ which is easier to solve due to its decoupled property. Now we wish to relate the solutions of Π^+ *back* to Π. This is accomplished by the next lemma, which introduces a set of "qualifier" constraints $\{h_s\}$ with the key property: Any solution to $\{h_s\}$ can be extended to one for Π^+, and then *mapped back* to a solution for Π. Importantly, the qualifier constraints *act only* on the b foundation vertices, as opposed to all n vertices!

▶ **Lemma 19** (Qualifier Lemma). *Let $H = (H_1, \ldots, H_m)$ be a k-local collection of functions $H_i : W^n \to \mathbb{K}$ whose interaction graph is a k-uniform hypergraph of transfer type b such that $m > n - b$. Then there exist non-zero (non-constant) functions, called* qualifiers, *$h_1, \ldots, h_{m-n+b} : W^b \to \mathbb{K}$ and $\pi : W^n \to W^b$ such that*

1. *$h_s(\pi(\mathcal{S}_H)) = 0$ for all $s \in \{1, \ldots, m - n + b\}$;*
2. *h_s has degree $(d_{s1}, \ldots, d_{sb})$ with $d_{sr} \leq 2F^{(b)}_{\rho(G,b)+b+1}$ $\forall s \in [m + b]$ and $\forall r \in [b]$.*

Proof. (Sketch) We sketch the proof in the case $b = 2$. Given a transfer filtration $G_0 \subseteq \cdots \subseteq G_m = G_H$ of type 2 and radius $\rho(G_H, 2)$, the Decoupling Lemma yields a hypergraph $\widetilde{G_H}$ and a surjection p. Note that $\widetilde{G_H}$ is the interaction graph of a k-local collection $\widetilde{H} = (\widetilde{H}_1, \ldots, \widetilde{H}_m)$ of functions $\widetilde{H}_i : W^{m+2} \to \mathbb{K}$ such that $\widetilde{H}_i^* = H_i^*$ for each $i \in \{1, \ldots, m\}$. Let $\Delta : W^n \to W^{m+2}$ be such that $\Delta(v_1, \ldots, v_n) = (\widetilde{v}_1, \ldots, \widetilde{v}_{m+2})$, where $\widetilde{v}_i = v_{p(i)}$ for all $i \in \{1, \ldots, m + 2\}$. In particular $(v_1, \ldots, v_n) \in \mathcal{S}_H$ if and only if $\Delta(v_1, \ldots, v_n) \in \mathcal{S}_{\widetilde{H}}$. Applying the Transfer Lemma to $\widetilde{G_H}$ yields transfer functions $g_1, \ldots, g_{m+2} : W^2 \to W$. Borrowing notation from the proof of Lemma 9, let $\{i_1, \ldots, i_{m-n+2}\}$ be the subset of all $i \in \{1, \ldots, m+2\}$ such that $\underline{i} < i$. For each $s \in \{1, \ldots, m-n+2\}$, define qualifier $h_s : W^2 \to \mathbb{K}$ such that $h_s(v_1, v_2) = (g_{i_s}^\sharp(v_1, v_2))(g_{\underline{i_s}}(v_1, v_2))$ for all $v_1, v_2 \in W$. If $(v_1, \ldots, v_n) \in \mathcal{S}_H$, then for every $s \in \{1, \ldots, m - n + 2\}$ there exists $\lambda_{i_s}, \lambda_{\underline{i_s}} \in \mathbb{K}$ such that $\lambda_{i_s} v_{p(i_s)} = g_{i_s}(v_1, v_2)$ and $\lambda_{\underline{i_s}} v_{p(i_s)} = g_{\underline{i_s}}(v_1, v_2)$. Therefore $h_s(v_1, v_2) = \lambda_{i_s}\lambda_{\underline{i_s}} v^\sharp_{p(i_s)}(v_{p(i_s)}) = 0$ for every $s \in \{1, \ldots, m - n + 2\}$. Upon defining π as the composition of Δ with the projection onto the first two entries, this proves the first statement of the lemma. The second statement follows from the Transfer Lemma. ◀

▶ Remark 20. To recap, the construction in the proof of Lemma 19 implies that to solve the k-QSAT instance Π, we: (1) Apply the Decoupling Lemma to blow up Π to decoupled instance Π^+. (2) Apply the transfer functions from the Transfer Lemma to $v_1, \ldots, v_b$ to

obtain a solution on all $m+b$ vertices for Π^+. Crucially, the qualifier constraints ensure that all decoupled copies of a vertex v receive the *same* assignment. (3) Map this solution back to one on n vertices for Π by "merging" decoupled copies of vertices.

▶ **Example 21** (Running example)**.** Let $H = (H_1, H_2, H_3, H_4)$ be a 3-local collection of functions $H_i : W^4 \to \mathbb{K}$ whose interaction graph is the 3-uniform cycle of transfer type 2 from Example 6. If p is chosen as in Example 10, then the two qualifier functions are $h_1(v_1, v_2) = (g_5^\sharp(v_1, v_2))(g_4(v_1, v_2))$ of degree $(3, 2)$ and $h_2(v_1, v_2) = (g_6^\sharp(v_1, v_2))(g_3(v_1, v_2))$ of degree $(2, 3)$, where g_3, g_4, g_5, g_6 so that $d_{sr} \leq 3 \leq 10 = 2F_5^{(2)}$ for each $s, r \in \{1, 2\}$.

3.3 Generic constraints

Remark 20 outlined the high-level strategy for computing a (product-state) solution to an input k-QSAT system Π. For this strategy to work, however, we require an assignment to the foundation of the transfer filtration which (1) satisfies the qualifier functions from the Qualifier Lemma, and (2) causes the transfer functions g_i from the Transfer Lemma to output non-zero vectors. When are (1) and (2) possible? We now answer this question affirmatively for a non-trivial class of k-QSAT instances, assuming constraints are chosen generically.

▶ Remark 22 (Generic constraints). The set of k-local constraints H on k-uniform interaction hypergraph G is canonically identified with the projective variety $\mathcal{X}_G(\mathbb{K}) = (\mathbb{P}^{2^k-1}(\mathbb{K}))^m$. (See also [17].) We say a property holds for the *generic constraint with interaction graph* G if it holds for every k-local constraint on a Zariski open set of $\mathcal{X}_G(\mathbb{K})$. In the important case $\mathbb{K} = \mathbb{C}$, this implies in particular that such a property holds for almost all choices of constraints (with respect to the natural measure on $\mathcal{X}_G(\mathcal{C})$ induced by the Fubini-Study metric).

We now show the main theorem of this section (whose proof requires a few other definitions and a Surjectivity Lemma; see full version). The theorem applies to k-uniform hypergraphs of transfer type $b = n - m + 1$, which includes non-trivial instances such as the semi-cycle and the "fir tree" (full version). In words, the theorem says that for any k-uniform hypergraph of transfer type $b = n - m + 1$ (i.e. there is one qualifier function h_1), if the constraints are chosen generically, then any zero of h_1 is the image under the map π (defined in Qualifier Lemma) of a satisfying assignment to the corresponding k-QSAT instance. The key advantage to this approach is simple: To solve the k-QSAT instance, instead of solving a system of equations, we are reduced to solving for the roots of just one polynomial – h_1. Moreover, if both the foundation size b and the radius of the transfer filtration of G are at most logarithmic in m and n, then h_1 has polynomial degree in m and n.

▶ **Theorem 23.** *Let $\mathbb{K}$ be algebraically closed, and let $\mathcal{F}$ denote the set of k-uniform hypergraphs with n vertices, m edges, and transfer type $b = n - m + 1$. If H is a generic k-local constraint with interaction graph $G \in \mathcal{F}$ and h_1 and π are as in the Qualifier Lemma (Lemma 19), then $(h_1 \circ \pi)^{-1}(0) \cap \mathcal{S}_H$ is nonempty.*

▶ **Example 24** (Running example)**.** We illustrate the proof of Theorem 23 by specializing the construction to the 3-uniform semicycle G_3 from Example 6. Then $\widetilde{G}_3$ is the hypergraph with vertices $\{1, 2, 3, 4, 5\}$ and edges $\widetilde{E}_1 = \{1, 2, 3\}$, $\widetilde{E}_2 = \{1, 2, 4\}$, $\widetilde{E}_3 = \{1, 3, 5\}$. Moreover, the transfer functions $g_1, \ldots, g_5 : W^2 \to W$ can be chosen as in Example 18. Let h_1 be as in Example 21 and suppose $v_1, v_2 \in W$ are such that $h_1(v_1, v_2) = 0$. If none of the $g_i(v_1, v_2)$ are zero, then a solution of the form (v_1, v_2, v_3, v_4) can be found by Remark 20. Else, suppose (say) $g_3(v_1, v_2) = 0$ (generically, only one $g_i(v_1, v_2)$ will be zero in this case) so that v_3 is not constrained by v_1 and v_2. With respect to a fixed basis $\{w', w''\}$ of W, we need to show that v_3

can be chosen in such a way that (v_1, v_2, v_3, v_4), where (according the Transfer Lemma) $v_4 = H_2^*(v_1 \otimes v_2 \otimes w'')w' - H_2^*(v_1 \otimes v_2 \otimes w')w''$, is a solution. The idea is to modify $\widetilde{G_3}$ by removing the edge $\widetilde{E_1}$ and adding the vertex labeled by 3 to the foundation. With this modification, the Transfer Lemma yields $g_5(v_1, v_2, v_3) = H_3^*(v_1 \otimes v_3 \otimes w'')w' - H_3^*(v_1 \otimes v_3 \otimes w')w''$. By the Qualifier Lemma, we conclude that $g_5(v_1, v_2, v_3)$ is a non-zero multiple of v_4 if and only if $H_3^*(v_1 \otimes v_3 \otimes w')H_2^*(v_1 \otimes v_2 \otimes w'') - H_3^*(v_1 \otimes v_3 \otimes w'')H_2^*(v_1 \otimes v_2 \otimes w') = 0$. Introducing a coordinate $v_3 = w' + xw''$, this last condition is equivalent to the vanishing of a polynomial in x. While this particular example the polynomial is linear, it is in general of high degree and the assumption that $\mathbb{K}$ is algebraically closed is required in order to guarantee the existence of a root.

▶ Remark 25 (Reduction to univariate polynomials). Theorem 23 reduces us to solving a single polynomial equation, $h_1(v_1, \ldots, v_b) = 0$, which is multi-variate. In this case, we can reduce it further to a univariate polynomial by fixing arbitrary vectors $w_1, \ldots, w_b \in W$ and $w_b' \in W$ linearly independent from w_b. Then $P(x) = h_1(w_1, \ldots, w_b + xw_b')$ is a *univariate* polynomial in $\mathbb{K}[x]$, which has a root $x \in \mathbb{K}$ since $\mathbb{K}$ is algebraically closed.

▶ Remark 26 (Runtimes, and complexity of solving for roots). By Theorem 23 and Remark 25, solving k-QSAT instances on hypergraphs in $\mathcal{F}$ with generic constraints reduces to solving for the roots of a single univariate polynomial, $P(x) \in \mathbb{K}[x]$. This can be accomplished by combining Theorem 2.7 of [25] and the algorithm of Schönhage [24] (Section 3.4 therein), which yields numerical approximations to all the roots of P within additive inverse exponential error in time exponential only in r and b. More specifically, in the full version, we give an explicit statement of the algorithm and a formal runtime analysis. We find k-QSAT instances with generic constraints and $b = n - m + 1$ require total time at most (for radius r, foundation size b, degree $d \leq 2^{r+b+2}$, m the number of constraints, n the number of qubits, $k \in \Theta(1)$ the locality of the constraints, and p a fixed polynomial which determines the additive accuracy $2^{-p(n)}$ to which we solve for roots of polynomials)

$$O(mn) + O\left(2^{2kb(r+b)}\right) + O\left(d^3 \log d + d^2 \log\left(9^d 2^{p(n)d}\right)\right) + O((r+b)2^{b(r+b+2)}). \qquad (1)$$

Thus, the algorithm is polynomial in m, n, and p, and exponential in k (the locality of the constraints), r (the radius), and b (foundation size).

Before discussing exponential speedups, we tie Theorem 23 back to SDRs:

▶ **Corollary 27.** *If G is a k-uniform hypergraph of transfer type $b = |V(G)| - |E(G)| + 1$, then G has an SDR.*

Thus, Theorem 23 constructively recovers the result of [17] (that any k-QSAT instance with an SDR has a (product-state) solution) in the case when the additional conditions of Theorem 23 are met (recall [17] works on all graphs with an SDR, but is not constructive). More generally, we can prove

▶ **Theorem 28.** *If G is a k-uniform hypergraph of transfer type $b \leq |V(G)| - |E(G)| + k - 1$, then G has an SDR.*

On exponential speedups via Theorem 23. Recall Theorem 23 applies to k-uniform hypergraphs of transfer type $b = n - m + 1$, such as the semicycle. From a parameterized complexity perspective, however, most interesting are hypergraphs for which the foundation size b and filtration radius r satisfy $b, r \in o(n + m)$, for which we might obtain an asymptotic speedup over brute force diagonalization of the Quantum SAT system (note the semicycle has $b \in \Theta(k), r \in \Theta(n)$). In the full version, we discuss the triangular tiling of the torus and

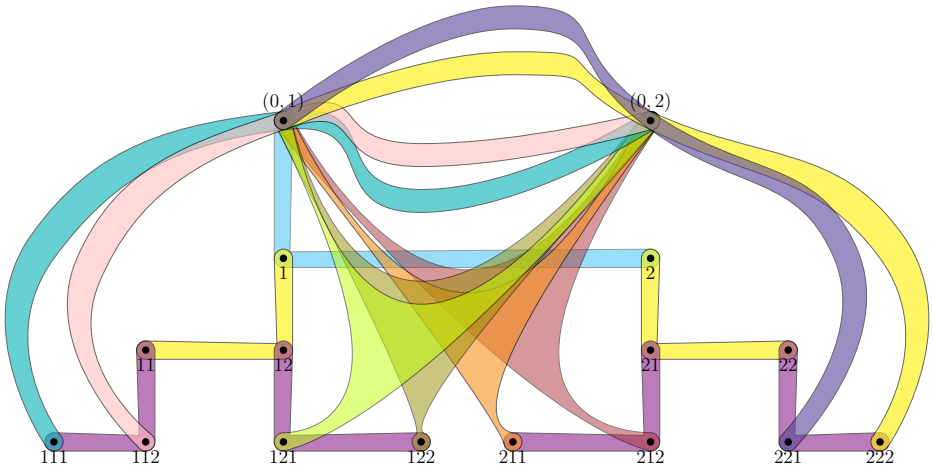

Figure 3 Depiction of 3-uniform crash hypergraph $C_{3,3}$. Generally, $C_{t,k}$ has an exponential separation between the filtration radius and foundation size versus number of vertices and edges.

the fir tree as examples with a quadratic separation $b, r \in \Theta(\sqrt{n} + \sqrt{m})$. (Note that for the runtime of Equation (1), however, a quadratic separation is unfortunately not enough for an asymptotic speedup.) Here, however, we give a hypergraph with a stronger, *exponential*, separation. Namely, we introduce the hypergraph *Crash* (Figure 3), with $r \in \Theta(t)$ and $b \in O(k)$, but $n, m \in \Theta((k-1)^t)$ for $k \geq 3$. On such hypergraphs, our parameterized algorithm hence runs in polynomial time, whereas brute force diagonalization would require time exponential in m and n.

We define k-uniform hypergraph family *Crash*, denoted $C_{t,k}$, as follows. For $k \geq 2$, let $\Sigma = \{1, 2, \ldots, k-1\}$. For $t \geq 1$, $C_{t,k}$ has vertices $V(C_{t,k}) = \bigcup_{j=0}^{t} V_j$ where $V_0 = \{(0, x) \,|\, x \in \Sigma\}$ and $V_j = \Sigma^{t-j+1}$ for all $1 \leq j \leq s$. The edge set of $C_{t,k}$ is the union of all edges of the following three forms:

1. For every $x \in V_1$, $E_x = \{x\} \cup V_0$;
2. for every $2 \leq j \leq t$ and every $x \in V_j$, $E_x = \{x\} \cup \{xa \,|, a \in \Sigma\}$;
3. $E_0 = \{(0, 1)\} \cup V_t$.

Then $C_{t,k}$ has a transfer filtration with foundation V_0 obtained by first adding all the edges E_x with $x \in V_1$, then adding all the edges E_x with $x \in V_2$, etc, with E_0 added last. This transfer filtration has radius t and type $k - 1 = |V(C_{n,k})| - |E(C_{n,k})| + 1$, whereas $|V(C_{n,k})|, |E(C_{n,k})| \in \Theta((k-1)^t)$ (full version).

Abstract

We consider a partitioning problem for grid graphs with special constraints: a (square) grid graph as well as a number of colors is given, a solution is a coloring approximatively assigning the same number of vertices to each color and such that the induced subgraph for each color is connected. In a "rooted" variant, a vertex to be included in the coloring for each color is specified as well. This problem has a concrete motivation in multimedia streaming applications.

We show that the general problem is NP-complete. On the other hand, we define a reasonable easy subclass of grid graphs for which solutions always exist and can be computed by a greedy algorithm.

1 Introduction

We study a particular partitioning problem of (square) grid graphs. Consider a finite grid (a rectangle) and a subset of squares present (shown in black on the second leftmost image of Figure 1). The present squares are vertices of a graph where the edges are implicit by the neighboring relation (leftmost image).

The problem we study is to color/partition such a graph with a given number of colors so that the induced subgraph for each color is connected and that the partition is balanced, i.e. the number of vertices for each color is (almost) the same. In the example of Figure 1, we choose to color with three colors. The third image shows a coloring satisfying both constraints. In the "rooted variant", we additionally specify for each color a root node that has to take that color (fourth image). For this choice, the third image is not a solution, but the fifth image is. Of course, the fifth image is also a solution of the unrooted problem.

The practical motivation for this particular problem concerns (broadcast) streaming in physical networks in multimedia applications (where each square is a screen tile and there may be holes and irregular borders), but also routing problems in NoC [10] (network on a chip) with horizontal and vertical communication links and dead vertices (due to manufacturing

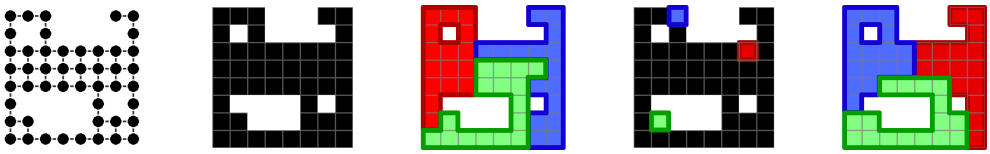

Figure 1 Grid graph and balanced connected coloring.

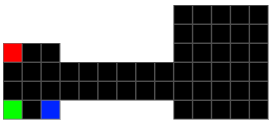

Figure 2 A rooted problem with 3 colors stuck in a corridor of width 2.

issues). For these systems, the limited bandwidth of links can be compensated by partitioning and injecting the data into the network from several "roots". Each root is thus responsible for a subset of vertices and the broadcast messages from distinct roots do not cross.

For the general case, we show that finding a balanced connected partition is NP-complete for both the rooted and the unrooted case (Theorems 1, 2). We achieve the NP-hardness result by a reduction from the Hamiltonian circuit problem on hexagonal graphs [7].

Intuitively, the connectivity of each colored zone is subject to conflicts when there are fewer connections than colors that need to pass. In our reduction, we exploit this by binary conflicts on connections that can only be used by a single color. Beyond binary conflicts, taking the point of view of our grid as a maze, several parallel and adjacent lines of vertices form a corridor of a limited capacity for colors to pass. For instance, in the example of Figure 2, the three roots are connected by a corridor of width 2, hence only two colors can connect to the big zone and obviously, no balanced connected partition exists. In order to define "easy" subclasses of graphs called *q-square connected graphs*, we formalize the idea of a maze with all corridors, whether straight or "diagonal" (zigzaging), large enough to let all colors pass. The condition of q-square connectedness can be verified on bounded windows of the graph and thus decided in linear time. It guarantees that a solution exists. Indeed, we give a greedy polynomial time algorithm for the unrooted case that always finds a solution on such topologies (Theorem 6). We also claim that this simple greedy algorithm can be extended to the rooted case and improved to compute solutions in linear time (for any fixed q).

The definition, intuitively similar but not equivalent to the classical definition of k-connectedness of graphs, is not trivial and is the result of fine-tuning the conditions in order to obtain a correctness proof. However, it is intuitive and may have an interest in itself. We have implemented the algorithm for simulation where it proves to be well behaved (it produces partitions that are "compact" and not unnecessarily intertwined).

Related work. To the best of our knowledge, the hardness of the precise problem studied here, as well as the easy subclass and the greedy algorithm, are unknown.

The much studied Balanced Connected q-Partition Problem (BCP_q), related to our work, is the problem of partitioning a weighted graph $G = (V, E)$ into q connected subgraphs of similar size/weight. In this work, we study this problem for unweighted grid graphs.

The unweighted BCP_q is shown NP-Hard in [4] for bipartite graphs for $q \geq 2$, but the result does not cover grid graphs. It has been proven in [1] that the BCP_q is NP-Hard in $G_{m\times n}$ grid graphs for any $n >= 3$, but this result requires weights on the vertices. That work also gives approximation algorithms considering the relative error under some hypothesis. In

[3] it is shown that finding a solution with an absolute error less than $|V|^{1-\epsilon}$ is NP-Hard even for the unweighted variant of the BCP_q, but on general graphs only. Our NP-hardness proof requires novel ideas and a different construction from previous works.

In [8, 9], polynomial algorithms for BCP_q are given for unweighted q-connected graphs. However grid graphs are 2-connected only. There exist also polynomial approximation results under certain restrictions. In [3] a 4/3-approximation algorithm is shown to exist for BCP_2 without other assumptions. More recently, [11] shows a polynomial time 7/6 approximation algorithm for BCP_2 in grid graphs. In [2], it is shown that there is no approximation algorithm with ratio smaller than 6/5 for arbitrary graphs. The same article also shows that BCP_q is strongly NP-Hard even on q-connected graphs with weights, as well as an inapproximability result for (BCP_2).

With motivations from VLSI design, a lot of work focuses on minimizing the number of transversal edges between parts, not necessarily keeping them connected, e.g. [5], [6].

Outline. The remainder of this article is structured as follows: Section 2 formalizes the model and the problem statement. In Section 3, we recall the Hamiltonian circuit problem for hexagonal graphs and develop the reduction from this problem to show NP-hardness for the general case. Essentially the same reduction can be used for the unrooted and for the rooted case. NP-completeness follows trivially as it is straightforward to verify a solution by a linear algorithm. In Section 4, we define the subclasses of q-square connected graphs by two alternative definitions (one intuitive, the other for algorithmic purposes) and show their equivalence. Then we define a rule based greedy algorithm for the unrooted case for coloring a graph one color after the other. We prove termination and correctness of the algorithm. Then we discuss how this algorithm can be extended to deal with the rooted case. In Section 5, we conclude and give an outlook on future work.

2 Model

We now formalize the notions of square grid graph and the partitioning problem. We simplify the presentation by assuming all square grid graphs embedded in the plane of pairs of integers.

For any finite set of pairs $V \subset \mathbb{Z}^2$ and the induced set of neighboring edges $E = \{((x_1, y_1), (x_2, y_2)) \in V \times V \mid |x_2 - x_1| + |y_2 - y_1| = 1\}$, we call $G_V = (V, E)$ a *square grid graph*. By $|G_V| := |V|$ we denote the *size* of a square grid graph

For simplicity, by grid graphs we will mean square grid graphs in the following (as opposed to hexagonal grid graphs, for instance).

For a subset of vertices $V' \subset V$ of a (grid) graph $G_V = (V, E)$, the graph (V', E') with $E' = E \cap (V' \times V')$ is the induced subgraph of G_V restricted to vertex set V'. Obviously, for a grid graph $G_V = (V, E)$ and a subset of vertices V', the induced subgraph (V', E') equals the grid graph $G_{V'}$.

A graph (V, E) is *connected* if for each pair $u, v \in V$ there exists a sequence $u = v_0, v_1, \ldots, v_l = v$ for some $l \geq 0$ and $(v_i, v_{i+1}) \in E$ for all $0 \leq i < l$.

We will represent grid graphs and induced subgraphs by colored 2D matrices, see Figure 1. An obvious data structure to represent grid graphs is a list of vertices. Alternatively, the *containing rectangle* of a grid graph G_V is defined as $R(V) = \{(x, y) \mid \exists (x_1, y_1), (x_2, y_2), (x_3, y_3), (x_4, y_4) \in V : x_1 - 1 \leq x \leq x_2 + 1 \text{ and } y_3 - 1 \leq y \leq y_4 + 1\}$, a full matrix containing V and an external border without vertices. The containing rectangle allows for matrix representations of grid graphs d.

A *connected part* $G_{V'}$ of a grid graph G_V is an induced subgraph of G_V that is connected. A *q-partition* $\mathcal{P}$ of a grid graph G_V is a set of q parts G_{V_i} with $1 \leq i \leq q$ such that : $V = \bigcup_{G_{V'} \in \mathcal{P}} V'$ and for any $G_{V_i}, G_{V_j} \in \mathcal{P}$ we have that $i \neq j$ implies $V_i \cap V_j = \emptyset$. We call a partition *connected* if all parts are connected.

For a subset of vertices $R = \{r_1, \ldots, r_q\} \subseteq V$ of a grid graph V_G called *roots*, an *R-rooted* partition of G_V is a partition $\{G_{V_i} \mid r_i \in V_i\}$.

A partition $\mathcal{P}$ of a grid graph G is *perfectly balanced* if and only if for all $G_{V_i} \in \mathcal{P}, |V_i| = \frac{|V|}{|\mathcal{P}|}$. Additionnaly, considering a partition $\mathcal{P}$ of a grid graph G, we say a part $G_{V_i} \in \mathcal{P}$ is *perfectly saturated* if it fits the requirement for P to be perfectly balanced, *i.e.* $|V_i| = \frac{|V|}{|\mathcal{P}|}$. If $|V_i|$ is below/above the *saturation threshold* $\frac{|V|}{|\mathcal{P}|}$, we respectively say that the part is *under/over-saturated*.

Perfect balance may often be an undesirably restrictive condition when it comes to balancing load in networks. In order to relax it, we may specify an error tolerance ratio $0 \leq r \leq 1$ with perfect balance corresponding to $r = 0$. For $0 \leq r \leq 1$ we say that a q-partition $\mathcal{P}$ of a grid graph G_V is *r-balanced* if and only if for each part $G_{V_i} \in \mathcal{P}$ we have $\frac{|G_V|}{q} \cdot (1-r) \leq |G_{V_i}| \leq \frac{|G_V|}{q} \cdot (1+r)$. The same way, we say that a part G_{V_i} of a q-partition $\mathcal{P}$ of a grid graph G_V is *r-saturated* if and only if $\frac{|G_V|}{q} \cdot (1-r) \leq |G_{V_i}| \leq \frac{|G_V|}{q} \cdot (1+r)$. If $|V_i|$ sits outside of the *saturation interval* $\left[\frac{|G_V|}{q} \cdot (1-r), \frac{|G_V|}{q} \cdot (1+r)\right]$, we respectively say that the part is *under/over-r-saturated*. When the ratio r is clear from the context, we will simply say that an area is balanced instead of r-balanced, and that a part is (under/over)saturated instead of (under/over)r-saturated.

The *r-balanced connected partitioning problem* (rBCP) is the problem of finding, for any grid graph G_V and number q, an r-balanced connected partition with q parts.

The *rooted r-balanced connected partitioning problem* (RrBCP) is the problem of finding, for any grid graph G_V and set of roots $R \subseteq V$, an R-rooted r-balanced connected partition.

3 NP-Hardness

In this section we present a polynomial time reduction from the Hamiltonian cycle problem (HCP) on hexagonal grid graphs to the rooted r-balanced connected partitioning problem (rRBCP) on square grid graphs, for $r \leq \frac{1}{7}$. We then argue that the reduction also applies to r-balanced connected partitioning problem (rBCP).

For any finite set $V \subset \mathbb{Z}^2$ of vertices, we construct the *hexagonal grid graph* $H_V = (V, E)$ with the induced set of edges $E = \{((x_1, y_1), (x_2, y_2)) \in V \times V \mid (|x_2 - x_1| = 1 \text{ and } |y_2 - y_1| = 0) \text{ or } (x_2 - x_1 = 0 \text{ and } y_2 - y_1 = 1 \text{ and } x_1 + y_1 \mod 2 \equiv 0)\}$. By $|H_V| := |V|$ we denote the *size* of the hexagonal grid graph. An example is shown on Figure 5 (left).

The *Hamiltonian cycle problem* (HCP) is the following decision problem: given a graph G, does there exist a cycle containing exactly once each vertex of G? This problem has been proven to be NP-complete when restricted to hexagonal grid graphs [7].

Given a hexagonal grid graph for the HCP, we will construct a square grid graph and set of roots for rRBCP. The section is split in four parts. In the first part we give intuitions on some simple rRBCP instances. Then we describe the reduction and concepts at stake. Finally, we demonstrate the correctness of the reduction. The last part explains how to apply the same idea for a reduction to rBCP.

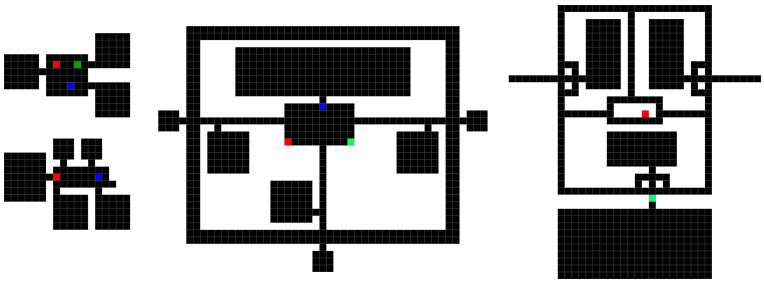

Figure 3 Intuition on the construction: tanks and roots/colors interaction.

3.1 Intuitions on the construction

Let us introduce step by step some straightforward "tricks" used in the reduction.

Consider a large connected region of a square grid graph, uncolored and accessible only via a single vertex or a single path, then this region will own a single color. This is exemplified on Figure 3 (left top): any partitioning must assign the same color to each of the three large outer regions (possibly three different colors, but a single color for each). We call such a region a "tank". In contrast, lines of vertices of width 1 are called "*paths*".

The basis of the construction will be to connect tanks via paths, and choose sizes of tanks such that the total number of vertices used in paths is negligible compared to a single tank.

If the tolerance ratio and the size of tanks are tightly chosen, then coloring a given tank may result in saturating the part corresponding to that color, i.e. a color tied to a tank may not color other tanks without oversaturating. For example, on Figure 3 (left bottom), the red root must color the large tank on the left in any partitioning, nearly saturating that color. Hence, red cannot own any of the two bottom tanks without oversaturating.

Some instances can "trap" parts/colors inside a restricted area. On Figure 3 (middle), blue is tied to a very large tank and must color it nearly saturating that color (for some suitable ratio r). But blue cannot reach the outer ring, because otherwise it would have to cover at least one of the three remaining *inner tanks* and oversaturate.

A color can prevent another color from creating a fork. In Figure 3 at right, the upper rectangle of paths has three access points (left, right, bottom). Green has to color the lower tank, and we suppose that adding any of the three inner tanks would lead to oversaturation. On the other hand, red requires the three inner tanks to saturate. Suppose that green was connected to the two exit points left and right by paths. Whichever the choice of paths taken, red could no longer reach all three inner tanks. In other words, this construction forces a decision for green between the left and the right exit point. This "gadget" will be used as a *macrocell* representing a vertex of the hexagonal grid, and the green color can only connect two of the three exits of any macrocell in order for the partition to be balanced, forcing green on a Hamiltonian path.

3.2 Reduction construction up to calculations

For a given hexagonal grid graph (instance of HCP), we build a square grid graph and set of roots (instance of rRBCP). This instance will admit a solution if and only if the HCP instance admits a solution: the square grid graph mimics the structure of the hexagonal grid, and the part of a specific color will be forced to correspond to a Hamiltonian cycle of the hexagonal grid graph (if one exists, otherwise no r-balanced partioning exists). Our construction will exclusively be composed of tanks and paths.

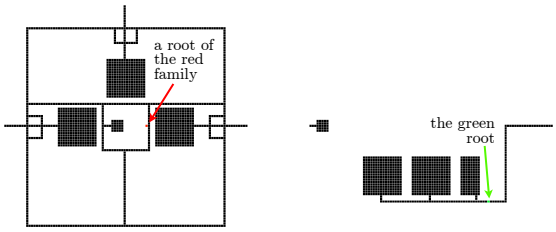

Figure 4 Macrocells with their root vertices for red (left) and green (right) parts.

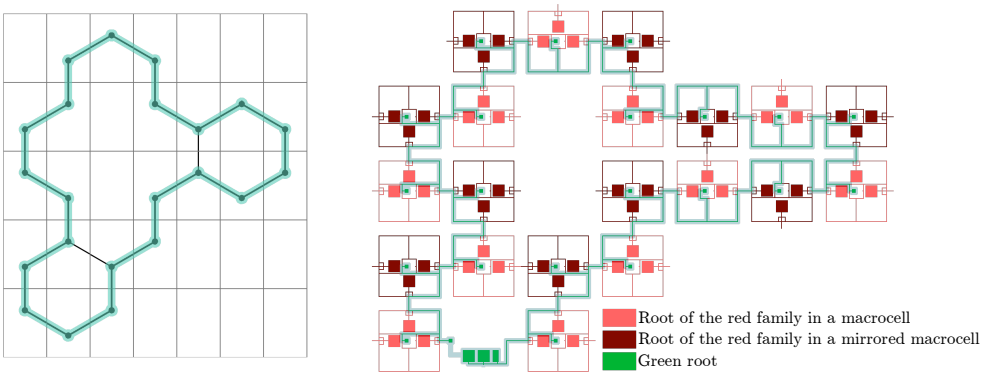

Figure 5 An hexagonal grid graph (left), and the corresponding grid graph construction (right).

Consider a macrocell as Figure 4 (left), which recalls the construction in Figure 3 (right) with an additional tank in the center. As the sizes of the tanks will depend on the hexagonal grid size and on the tolerance ratio r, it is crucial that we can scale up macrocells. Let $T \times T$ be the size of a containing rectangle of such macrocells (such that the three entry paths lie on the center of three sides), let t_i, t_c be the respective sizes of the three inner tanks and of the center tank, and let p be the total number of path vertices (not tank) in one macrocell. It is straightforward to scale up a macrocell so that the number of paths vertices becomes negligible: p grows linearly with T, whereas t_i, t_c grow quadratically.

Let us distinguish a vertex of degree two of the hexagonal grid graph, which we call *primary root* (there always exists one). By using copies of this macrocell or its mirror for each vertex distinct from the primary root, we can mimic the layout of the hexagonal grid graph, as shown on Figure 5 (right). Let m be the number of vertices in the hexagonal grid graph, and let us call *red family* the set of m colors used for roots in these macrocells.

For the primary root vertex (of degree two in the hexagonal grid graph), we replace it with a special macrocell containing (see Figure 4 (right)): on one entry path a tank of size $t_g \approx 3 \cdot \frac{5}{6} t_i$ called *green tank* with a *green* root tied to it, and on the other entry path a tank of size $t_c \approx \frac{t_i}{6m}$. The main idea here is that the green root misses approximately $3 \cdot \frac{1}{6} t_i$ vertices to be balanced (compared to the family of red colors each taking three tanks of size t_i), and will have to take the *central tanks* of size t_c in all macrocells (m times t_c) in order to enter the saturation interval and be r-balanced, hence creating a Hamiltonian path.

A complete construction is shown on Figure 5 (right).

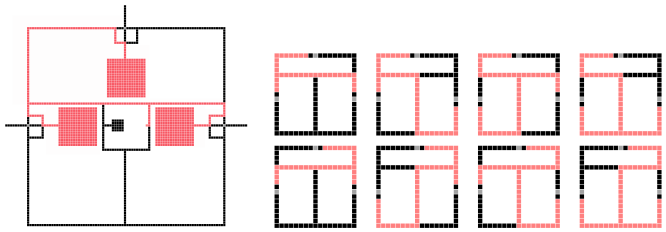

Figure 6 If another color goes across a macrocell, then the red color enforces it to take exactly two out of the three entry paths. In any case red takes the three inner tanks. Detailed schematic of the first possibility on the left, simplified schematics on the right for the eight possibilities.

3.3 Reduction correctness and calculations

Let us recall that $r < \frac{1}{7}$. We now argue about the correctness of a series of facts, leading to the correctness of the reduction.

Figure 6 shows a full case disjunction regarding the fact that macrocells owned by colors in the red family prevent green from creating forks (corresponding to degree three vertices).

▶ **Fact 1.** *If green goes across a macrocell, then it must take exactly two entry paths.*

In other words, green part is constrained by the adversary family of red colors to follow a Hamiltonian cycle.

Now, let us see how to calculate the sizes of tanks and macrocells such that the number of path vertices is negligible compared to the size of any single tank, and that green must take exactly all central tanks of size t_c in each macrocell (and therefore runs across each one).

We introduce variables to specify the construction precisely:

- m: total number of vertices in the hexagonal grid graph,
- n: total number of vertices in the square grid graph,
- k: scaling factor of macrocells,
- t_i: size of each of the three inner tank in each macrocell,
- t_c: size of the central tank in each macrocell (plus one in the primary root macrocell),
- t_g: size of the tank tied to the green root in the primary root macrocell,
- p: number of path vertices (not tank) in one macrocell,
- $s = \frac{n}{m}$: perfect saturation threshold.

By definition, we have the saturation interval ratio $I_s = [s(1-r), s(1+r)]$. We have two kinds of roots (the red family and the green), and four kinds of vertices (path and tanks t_i, t_c, t_g). This gives three groups of inequations to consider. Recall that $t_g \approx 3 \cdot \frac{5}{6} t_i$ and $t_c \approx \frac{t_i}{6m}$.

Path vertices. The *unitary macrocell* shown in Figure 4 (left) permits tanks of maximum size c_t with a minimum of c_p path vertices. By multiplying the dimensions of the unitary macrocell by an integer factor k (except for path wideness), we get a *k-scaled macrocell* permitting tanks of maximum size $k^2 \times c_t$ with less than $k \times c_p$ path vertices (the needed path length to link tanks together grows linearly with k whereas maximum possible tank size grows quadraticaly) :

$$\exists k \in \mathbb{N} : \quad p \geq k \times c_p \quad \text{and} \quad t_i, t_c \leq k^2 \times c_t \quad \text{with } c_p = 639 \text{ and } c_t = 256 \tag{1}$$

We want paths to be negligible and dominated by tanks for balance, meaning that modifying the number of path vertices without modifying the number of tanks in a part has no impact on its saturation. The total number of path vertices is mp.

Red family and inner tanks. We want that each root of the red family reaches the saturation interval with exactly the three inner tanks of its macrocell, *i.e.*

$$2t_i + mp < s(1-r) < 3t_i \quad \text{and} \quad 3t_i + mp < s(1+r) < 4t_i. \tag{2}$$

Red family and green tank. In any partitioning, roots of the red family cannot take the green tank.

Green and all tanks. Green always owns the green tank, and we want the green root to reach the saturation interval with exactly the green tank plus all m central tanks, *i.e.*

$$t_g + (m-1)t_c + mp < s(1-r) \leq t_g + mt_c \text{ and } t_g + mt_c + mp < s(1+r) < t_g + t_i. \tag{3}$$

Red family and central tanks. As we constrained green to take all central tanks, Reds can't take any central tank.

▶ **Fact 2.** *For any rational ratio $r = \frac{a}{b} < \frac{1}{7}$ and any $m > 3 \in \mathbb{N}$, if*

$$t_g = \tfrac{5}{6}s \qquad t_c = \tfrac{s(\frac{1}{6}-\frac{a}{b})}{m} \qquad t_i = ms - (t_g + m(t_c+p)) = \tfrac{(-1+12m^2+12m(-1+\frac{a}{b})+6\frac{a}{b})s}{36(m-1)m}$$
$$p = \tfrac{t_c}{2m} = \tfrac{s(\frac{1}{6}-\frac{a}{b})}{2m^2} \qquad s = 36 \cdot 71 \cdot 10^6 \cdot b \cdot (m-1) \cdot m^3 \qquad k = \tfrac{p}{c_p} = s\tfrac{\frac{1}{6}-\frac{a}{b}}{2 \cdot 639 \cdot m^2}$$

then in any r-balanced connected partitioning green must take exactly all m central tanks (one in each macrocell plus one in the primary root macrocell).

Proof. The statement satisfies Relations (1-3), implying the result (see Appendix A.1). ◀

From Fact 2 in any r-balanced partitioning the green root must go across every macrocell, and from Fact 1 it can do so only via a connected "macropath" of degree two among all m macrocells, which corresponds exactly to a Hamiltonian cycle in the HCP instance. Conversely, a Hamiltonian cycle gives a solution for the green root to do so. In both cases each root of the red family will own the three inner tanks of its macrocell.

This reduction can straightforwardly be done in polynomial time (choose a vertex of degree 2, compute the equations given in Fact 2, and map each vertex of the hexagonal grid graph to its corresponding macrocell) which gives the result.

▶ **Theorem 1.** *rRBCP is NP-hard for any rational ratio $r < \frac{1}{7}$.*

3.4 r-balanced connected partitioning problem (rBCP)

The previously described construction also applies to rBCP (without fixed roots). Indeed, it is enough to notice that when roots are removed, then there are no other solutions to the rBCP instance than those of the rRBCP instance. This is rather straightforward.

The part owning the green tank (previously green, let us now call it *yellow*) must behave the same as green and take all central tanks (it verifies Fact 2). Then, given that yellow must not own any inner tank (Relation (3), these inner tanks must be owned by other parts (previously the red family, let us now call them the *orange family*). It is now enough to notice that each orange part must own three inner tanks belonging to a single macrocell: as green runs across each macrocell to take all central tanks, there is only one remaining entry path in each macrocell, therefore the inner tanks of a macrocell cannot be shared between two parts of the orange family without letting at least one of them under-saturated (Relations (2)). As a consequence Fact 1 also holds and the result follows.

▶ **Theorem 2.** *rBCP is NP-hard for any rational ratio $r < \frac{1}{7}$.*

4 Partitionning q-square Connected Grids

Intuitively, the difficulty of the balanced connected partitioning problem is a consequence of conflicts: if large areas are acessible from a very limited number of paths, you will have to carefully choose which part will cover which area to avoid a part blocking a crucial access.

One might consider as solution to remove these conflicts by assuring that there is always a distinct path for any part to access any area, but the usual graph theoretic notion of k-connectivity is not well suited for square grids where the degree of vertices is limited to 4 in general and which always include vertices with degree less than 2 (e.g. in the corner). Moreover, k-connectivity is a global property of a graph and difficult to verify locally. Hence the need for a new definition.

In the following, we define for each q a subclass of grid graphs called *q-square connected*, which is easy to verify and for which connected balanced q-partitions always exist and which can be efficiently computed. The idea is to make corridors (Figure 2) sufficiently large for all colors to pass. Then a greedy algorithm can expand a connected part (from a root) until it is saturated (reaches $\frac{|G_V|}{q}$ vertices), in such a way that the remaining uncolored graph remains $(q-1)$-square connected. However, while "width" seems obvious for straight "corridors", it is less evident for angles, branching, etc.

4.1 Two definitions of q-square connected graphs

We represent a "square" of a given side length by its lower left corner: for $(x,y) \in \mathbb{Z}^2$, $q > 0$, let $sq(x,y,q) = \{(x+i, y+j) \mid 0 \leq i,j < q\}$ denote *the q-square at (x,y)*. A grid graph G_V is said to *contain* $sq(x,y,q)$ iff $sq(x,y,q) \subseteq V$. A grid graph G_V is *covered by q-squares* if for each $(x,y) \in V$ there exist x', y' such that $sq(x',y',q)$ is contained in G_V and $(x,y) \in sq(x',y',q)$.

Two q-squares $sq(x,y,q), sq(x',y',q)$ are *adjacent* iff $|x-x'| + |y-y'| = 1$. For a set $V \subseteq \mathbb{Z}^2$, let $Sq(V,q) = (V', E')$ such that V' the set of q-squares in V, E' the set of adjacent pairs of q-squares in V, denote the *induced graph of q-squares*. The *distance of two q-squares $sq(x,y,q), sq(x',y',q)$ in $Sq(V,q)$* is denoted by $dist((x,y),(x',y'),V,q)$.

A grid graph G_V covered by q-squares is *q-connected* if for $sq(x,y,q), sq(x',y',q)$ in $Sq(V,q)$ with $\max\{|x-x'|, |y-y'|\} \leq q$ and $\min\{|x-x'|, |y-y'|\} < q$ we have $dist((x,y),(x',y'),V,q) = dist((x,y),(x',y'),\mathbb{Z}^2,q) = |x-x'| + |y-y'|$.

The condition for q-connectedness considers square that are overlapping (their intersection is non-empty) or touching (at least one vertex in one square is adjacent to a vertex in the other square). For such squares, we require the existence of a path of squares that somehow zigzags from one square to the other without changing the direction on either axis.

▶ **Lemma 3.** *Let a connected grid graph G_V be covered by q-squares and q-connected with $q > 1$. Then G_V is also $(q-1)$-connected.*

The proof is given in the appendix. Now we consider an alternative definition that is equivalent, less intuitive, but better suited for the description of the algorithm.

A grid graph G_V is *q-wide* iff for all $v = (x,y) \in V$ there exist x', y' such that $0 \leq x - x' < q$, $0 \leq y - y' < q$ and for all $0 \leq i < q$ we have $(x'+i, y), (x, y'+i) \in V$, i.e. every vertex is part of a horizontal and a vertical segment of q vertices.

A grid graph G_V satisfies the *q-completion property* iff for every $(x,y) \in V$ and $a, b \in \{-1, 1\}$ and $c \in \{0, 1\}$ such that $(x + i \times a, y + j \times b) \in V$ with $i = 1$ and $1 \leq j \leq q$ or $j = 1$ and $1 \leq i \leq q$ as well as $(x + c \times a, y + (1-c)b) \in V$ also $(x, y+j) \in V$ for all $1 \leq j \leq q$ or $(x+i, y) \in V$ for all $1 \leq i \leq q$.

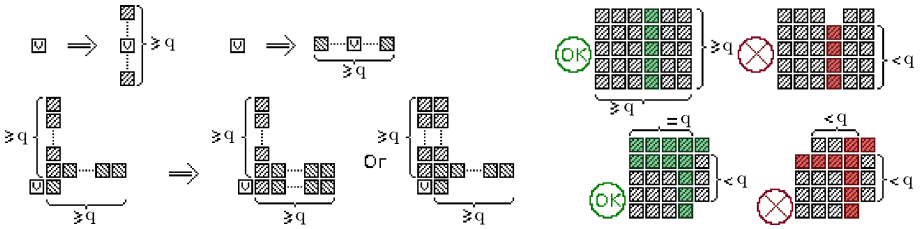

Figure 7 q-width (top) and q-completion (bottom) constraints, and examples.

The q-width and q-completion properties are depicted in Figure 7 at left ($a = b = c = 1$).

▶ **Lemma 4.** *For a connected grid graph G_V, the following two conditions are equivalent:*

1. *G_V is q-square covered and q-connected.*
2. *G_V is q-wide and satisfies the q-completion property.*

Holes in q-square connected grid graphs require a subtle definition of connectedness : two vertices $u, v \notin V$ are *close* iff their distance in $\mathbb{Z}^2$ is at most 2. For instance, two vertices on diagonal positions are close. A subset $H \subseteq \mathbb{Z}^2 \backslash V$ is *close-closed* iff for a vertex $v \in H$ and a vertex $v' \in \mathbb{Z}^2 \backslash V$ which is close to v, also $v' \in H$. The unique maximal close-closed subset $H \subseteq \mathbb{Z}^2 \backslash V$ that is infinite is called *the outside of* G_V, a finite H is called a *hole* of G_V. Note, that holes or the outside are not connected in the neighboring sense as is the grid graph. A grid graph G_V for which there exist no non-empty holes is *solid*.

A *segment* is a straight line of vertices: for $(x, y) \in \mathbb{Z}^2$, $a \in \{0, 1\}$ and $k > 0$ the *segment* $S((x, y), a, k)$ denotes the set of vertices $S((x, y), a, k) = \{(x + ai, y + (1 - a)i) \mid 0 \leq i < k\}$.

4.2 An algorithm for the unrooted problem

We now describe an algorithm for the unrooted balanced connected partitioning problem on q-square connected grid graphs. The algorithm recursively colors a connected zone of $\frac{m}{q}$ vertices leaving $\frac{m(q-1)}{q}$ vertices forming a $(q-1)$-square connected subgraph. Then we pass to the next color and repeat the process leaving a $(q-2)$-square uncolored remainder and so forth. This process can intuitively be compared to coloring the edges of a graph with q-wide corridors leaving $(q-1)$-wide corridors and thus preserving sufficiently large access for $(q-1)$ colors.

For a given q, the coloring phase of the algorithm preserves a complex invariant, *q-compliance*: a *q-compliant coloring* of G_V is a subset $C \subset V$ such that G_C is connected and $G_{V \backslash C}$ is $(q-1)$-covered and $(q-1)$-connected and that there exists a vertex v outside G_V with a neighbor in C.

The algorithm is easier to understand on solid grid graphs, as holes introduce an additional problem. We therefore invite the reader to first try to understand the algorithm in ignoring holes and then read the text again with regard to the way we treat holes: we *cut* them.

A hole H of a grid graph G_V is *cut by coloring* C if there exists a vertex $v \in H$ with a neighbor in C. The vertices of a cut hole are considered outside of G_V with respect to C.

The coloring phase starts by coloring an external corner (a vertex $v \in V$ with two neighbors outside G_V), and then augments q-compliant colorings by three operations:

1. Add a vertex v to C, such that $v \in V \backslash C$ and v has a neighbor in C.
2. Add a segment $S = S((x, y), a, k) \subseteq V \backslash C$ such that $k < q$, (x, y) has a neighbor in C and
   a. either all vertices in $(x + ai, y + (1 - a)i)$ have a neighbor in C or outside V_G and in particular S is terminated by $(x + ak, y + (1 - a)k) \notin V \backslash C$,
   b. or $k = q - 1$, and $(x + ak, y + (1 - a)k) \in H$ for some uncut hole H.

Algorithm 1 Simplified partitioning algorithm.

```
input int q, vertexSet V, such that G_V is q-square connected
int part= |V|/q;
// compute the set of all vertices in uncut holes
vertexSet holeVertices = computeUncutHoles(V)
while(q>0){
   vertexSet C={v} where v is an external corner of V
   while(|C| < part){
      // CLAIM 1, the following extension is always possible :
      C=C∪S for some simple extension S with C∪S q-compliant
      // remove vertices of holes that are cut
      holeVertices = updateUncutHoles(holeVertices,S)
   }
   output part C
   V=V\C , q=q-1
}
```

We call an extension S satisfying one of these three conditions a *simple extension*. Our algoritm below incrementally computes such colorings for determinig a part. An illustrating execution trace is given in the appendix.

▶ **Lemma 5** (Extension lemma). *In Algorithm 1, CLAIM 1 is always true, i.e. for a q-compliant coloring C of a graph G_V such that $|C| < \frac{|V|}{q}$ there exists simple extension S such that $C \cup S$ is q-compliant.*

▶ **Theorem 6.** *For a q-square connected grid graph G_V, Algorithm 1 terminates and computes an (up to $q-2$ vertices per part) balanced connected q-partition in time*[1] *$O(|R||V|q^2)$, where R is the smallest rectangle containing V, or in time $O(|V|^3q^2)$.*

Proof. The Extension lemma (proof: appendix) states that the line of CLAIM 1 is always possible. The invariant ensures that each iteration of the outer loop works on a q-compliant coloring. The termination condition of the inner loop guarantees that after the loop $\frac{|V|}{q} \leq |C| < \frac{m}{q} + q - 1$, the maximal deviation of a part. The algorithm is simplified and can, under bad circumstances, produce a final partition that lacks $(q-1)^2$ vertices, but it is easy to improve this to $q-1$ by balancing the limit between iterations of the outer loop. Moreover, a simple improvement of the algorithm could distributed the last segment attributed to a part in the inner loop between the current part and the next part, limiting the deviation from $\frac{|V|}{q}$ to at most 1 and in fact to 0, perfect balance, in the case of $|V|$ a multiple of q.

For the complexity considerations, we suppose a matrix representation of the input V as a subset of a rectangle R. This rectangle can of course be computed in $O(|R|)$ and $|R| \leq |V|^2$ since V is connected. For practical purposes, the problem can be stated such that $|R|$ itself is a measure of the input size, but for the question of Algorithm 1 being polynomial or not, this detail is of no consequence.

The functions `computeUncutHoles` and `updateUncutHoles` compute reachable sets, e.g. by depth first search, in linear time. Moreover, since `updateUncutHoles` removes vertices from the set of uncut holes and removes each vertex at most once, the total computation time for `updateUncutHoles` is linear in $|R|$.

[1] We neglect non-constant access time to the matrix R, which is of no practical consequence.

Since each iteration of the inner loop increments C and each iteration of the outer loop reduces V by C, the total number of iterations of the inner loop is limited by $|V|$. In each iteration of the inner loop, in principle, all vertices of $V \backslash C$ have to be examined for a possible simple extension. The examination of whether the extension violates the q-compliance however is local around the extension point and can be done[2] in $O(q^2)$. Note also that there is no need to test econnectedness of the uncolored part after an extension: indeed, each path leading through the extension can be replaced by a path avoiding it: width constraints imply this for extensions of type (1) and (2a), whereas an uncut hole is surrounded by a cyclic path that also allows to circumvent the cutting segment. ◀

5 Perspectives and future work

Algorithm optimization. Above, we stated the complexity of Algorithm 1 as $O(|R||V|q^2)$ or $O(|R|^2q^2)$. The complexity is quadratic in $|R|$ because of blindly sweeping R at each iteration in search of the next extension. Several options for improvement exist, for instance, tracking in parallel C and a doubly linked list of actually possible simple extensions in connection with R, we can always pick the first extension of the list and update the list in each iteration in essentially $O(q^3)$ since the impact to other extensions is local. Cutting holes may temporarily require slower updates, but their global impact remains linear in $|R|$. On the other hand, prioritizing simple extensions may allow to bound the set of extensions at any point of the algorithm execution, potentially bringing the complexity to $O(|R|q^2)$.

Towards an algorithm for the rooted problem. We conjecture that Algorithm 1 can be modified to solve the rooted variant of the BCP as follows: In the rooted variant, we start with a grid graph G an a set of q vertices that are already colored with distinct colors: $\forall 1 < i \leq n, C_i = \{v_i\}$, where the C_i designate parts we are building. Here, we cannot greadily extend colors one after the other and keep the q-connection of the remaining uncolored subgraph $G \backslash \bigcup C_i$. Indeed, while a part C_i is not saturated, this part must keep at least a single access to the uncolored part of the graph, i.e $\exists (u, v), u \in C_i, v \in G \backslash \bigcup C_i$. This greatly restricts the possibilities for extensions if we consider a single color at any step.

Instead of extending a single color until the corresponding part is saturated, we can search possible extensions of any color that keeps unsaturated part connected to the uncolored graph, i.e, we search for a set S of maximum $q-1$ vertices $v_1 ... v_q$ that we will add to a colored part C_i, such that $G \backslash \cup C_i$ is $q-1$-connected and $\forall 0 < i < q, \exists (u, v), u \in C_i, v \in G \backslash \cup C_i$. When a colored part C_i becomes saturated, we can remove it and recursively consider the smaller problem on the subgraph $G \backslash C_i$, with the remaining $q-1$ unsaturated parts still connected to the uncolored subgraph which is $(q-2)$-connected.

An important difficulty introduced in the rooted problem is the possible emergence of access conflicts that will exclude a completion of the partition. If these conflicts are not avoided, the greedy algorithm can get stuck. As an example of a simple conflict, consider two unsaturated parts C_i and C_j which both access the uncolored part of the graph by same single vertex. Obviously, such a coloring cannot be completed (c.f. Figure 8 at left for green and red). More general cases can involve up to q parts when all the k parts get their unique

[2] Whereas extensions by a single vertex can produce a violation of q-width or the q-completion property, the extensions by a segment S can only produce a violation of the q-width property.

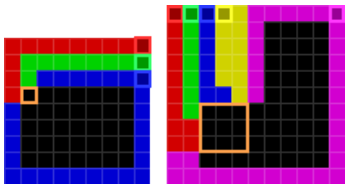

Figure 8 Binary (red and green, at left), and 4-nary (red, green, blue, yellow, at right) conflicts.

access to the uncolored subgraph into the same square of size $(k-1) \times (k-1)$: In Figure 8 (right), extending either red, green, blue, or yellow will recursively create a $(q-1)$-ary conflict between the remaining colors.

We conjecture that the Extension lemma can be modified to take into account such q-ary conflicts and avoid them, at the price of a limited imbalance when approching the saturation of all colors. In the future, we will try to extend Algorithm 1 with this reasoning.

A Appendix

A.1 Idea behind the solution given in Fact 2

In Fact 2, we gave a set of dimensions for macrocells to build a square grid instance that satisfies Relations (1) to (3) for given values of tolerance ratio r and number of macrocells m. Let us present the reasoning behind these values.

As the cumulated surface of three inner tanks will be chosen close to the saturation threshold s, we first choose the size of the green tank $t_g = \frac{5}{6}s$, so green will be unable to take inner tanks (Relation (3) right).

Then we choose the size of central tanks so that green exactly enters the saturation interval by covering the green tank and all the central tanks: $t_g + mt_c = s(1-r)$ (Relation (3) left). Now we choose total path length in such a way that it is neglectible in front of tanks: $mp = \frac{t_c}{2}$, so collecting all the path vertices in the topology accounts for less that collecting a single central tank (mp in Relations (2) and (3)). The inner tanks get all the remaining vertices: $mt_i = ms - t_g - m(t_c + p)$ (Relation (2)).

Finally, the last dimension to set is the saturation threshold s. As all previously set dimensions must be integers and are multiples of s, we choose s to be a multiple of all denominators. Finally we also take s sufficiently large so that there exists $k = \frac{p}{c_p}$ such as $p \geq k \times c_p$, *i.e.* there is enough path vertices to wire all the tanks (Relation (1)).

A.2 Proofs of Lemma 3 and Lemma 4

In order to prove these properties, we first prove auxiliary observations:

▶ **Lemma 7.** *Let a connected grid graph G_V be covered by q-squares and q-connected. Then the induced graph $Sq(V, q)$ is also connected.*

Proof. We show that for any two squares $sq(x_1, y_1, q)$ and $sq(x_2, y_2, q)$ in G_V there exists a path in $Sq(V, q)$. The proof uses induction on the least distance d of pairs of vertices $(x'_1, y'_1) \in sq(x_1, y_1, q)$ and $(x'_2, y'_2) \in sq(x_2, y_2, q)$: if this distance is 0 then the squares are intersecting and the q-connected property implies that there is a path between the two squares. Otherwise, there is a first vertex (x'_3, y'_3) on the shortest path from (x'_1, y'_1) to (x'_2, y'_2) that is not in $sq(x_1, y_1, q)$. Since G_V is q-square covered, there exists $sq(x_3, y_3, q)$ in V_G with $(x'_3, y'_3) \in sq(x_3, y_3, q)$. Moreover, because of q-connectedness, there exists a path from $sq(x_1, y_1, q)$ to (x_3, y_3, q) in $Sq(V, q)$. On the other hand, the distance of (x'_3, y'_3) and (x'_2, y'_2) is less than d, hence by induction, there exists a path from $sq(x_3, y_3, q)$ to $sq(x_2, y_2, q)$ in $Sq(V, q)$ and the two paths joint connect $sq(x_1, y_1, q)$ and $sq(x_2, y_2, q)$ as desired. ◀

▶ **Lemma 8.** *Let a connected grid graph G_V be covered by q-squares and q-connected with $q > 1$. Then each $(q-1)$-square in G_V is contained in a q-square of G_V.*

Proof. Sketch: let $sq(x, y, q-1)$ be a $(q-1)$-square. In order to show the existence of a q-square in G_V containing it, we first show that there exists a q-square containing one or several lines from one side of the $(q-1)$-square and from there by induction we show that there exists a q-square containing all the $(q-1)$ lines from that side. The proof necessarily makes use of the q-connected property. ◀

Proof of Lemma 3. Suppose that two $(q-1)$-squares are touching or intersecting. Any two q-squares containing them also touch or intersect. We consider two q-squares containing them of minimal distance and consider a path between the two. A path consists of steps

"up", "left", "right" or "down" and it never contains both "up" and "down" on the one hand or "left" and "right" on the other. A $(q-1)$-square can imitate the same directions and always be included in the q-square of a path, however, it may end up on the "wrong" among the 4 $(q-1)$-squares in the final q-square and require correction. However, it is easy to see that this correction can either be achieved by skipping a step of the q-square path (thus relatively moving in the opposite direction) or by adding a step in the final q-square and we thus end up with a path of the desired distance. ◀

Proof of Lemma 4. (1) implies (2): q-width trivially follows from q-square covering. Suppose a constellation (x, y) and a, b, c concerning the q-completion property. Without loss of generality we suppose $a = b = c = 1$, other cases are very similar. Supposing the property fails to hold for this instance of parameters, then there exist vertices $(x+i, y), (x, y+j) \notin V$ with $1 \leq i, j \leq q$. We suppose i, j minimal, i.e. for all $1 \leq i' < i$ we have $(x+i', y) \in V$ and $(x, y+j') \in V$. We show the existence of q-squares in G_V that touch or overlap, yet violate the q-connected property because of the obstacles represented by $(x+i, y), (x, y+j)$. First assume $j = 1$, then the only q-square containing $(x+1, y+1)$ can be $sq(x+1, y+1, q)$. This q-square touches the q-square containing $(x+1, y)$ yet a direct path to the letter q-square starting at $sq(x+1, y+1, q)$ would have to start either down or left, but there are no edges in that direction, a contradiction. So $j > 1$. Now consider the q-squares containing vertices $(x+i', y+1)$ with $0 \leq i' <\leq i$, all of which belong to G_V. Some of them (e.g. $(x, y+1)$) must be below $y + j' - q + 1$, others above $y + 1$ and hence there must exist an i' such that $(x+i', y+1)$ is in a q-square below $y + j' - q + 1$ and $(x+i'+1, y+1)$ in a q-square above $y+1$ and these q-squares touch or intersect, yet there is no direct path between them because of the two obstacle vertices. Another contradiction. Hence, we cannot at the same time have both $(x+i, y), (x, y+j) \notin V$, hence the constellation satisfies the q-completion property.

(2) implies (1):

First we show that the grid graph is q-square covered. We do this by a construction of coloring a part of the vertices of the graph incrementally in such a way, that the colored zone is invariantly a union of q-squares. We show that this process can be continued until all vertices are colored. The construction starts by choosing a vertex (x, y) with x minimal. Since the graph is q-wide this gives us q vertices $(x, y_1)...(x, y_q)$ with $y = y_i$, all with x minimal. Again because of q-width, it follows that $sq(x, y_1, q) \subseteq V$ and this is the first square we color. Now suppose that there are uncolored vertices left. Since the graph is connected, at least one such vertex is adjacent to a colored square. Without loss of generality, let us suppose $sq(x, y+1, q)$ fully colored and $(x+i, y)$ with $0 \leq i < q$ not yet colored. Because of q-width, there exists x' such that $x' + k = x + i$ with $0 \leq k < q$ and for all $0 \leq l < q$ we have $(x'+l, y) \in V$. We suppose furthermore x, y, i, x' chosen with these conditions such that $|x - x'|$ is minimal. Then either $x = x'$, but then $sq(x, y, q) \subseteq$ and we can color $(x, y)...(x+q-1, y)$ and continue. Or $x! = x'$ and let us suppose that $x' < x$. Then the preconditions for q-completion are satisfied for $(x-1, y)$ and $a = b = c = 1$ and either completion contradicts the assumption of having chosen x, y, i, x' such that $|x - x'|$ is minimal.

Now we want to show that G_V is q-connected. Supposing it is not, then there are two q-squares $sq(x, y, q), sq(x', y', q)$ such that $\max\{|x-x'|, |y-y'|\} \leq q$ and $\min\{|x-x'|, |y-y'|\} < q$ but their distance in $Sq(V, q)$ is greater than $|x - x'| + |y - y'|$. Assume $|x - x'| + |y - y'|$ minimal for such a pair of q-squares. Obviously, $\min\{|x - x'|, |y - y'|\} > 0$ otherwise a straight path between the two q-squares obviously exists contradicting assumptions. The non-trivially overlapping or touching squares give rise to a constellation of the q-completion property which in turn yields a third square at distance 1 from one of the two squares and 1

unit closer to the other square. Since we assumed $|x - x'| + |y - y'|$ minimal, this results in an intermediate q-square on a path of length $|x - x'| + |y - y'|$ between the original q-squares, contradicting assumptions. ◀

A.3 Proof of the Extension Lemma

The proof of the Extension lemma is based on a (constructive) recursive analysis of a q-compliant coloring: it is based on the identification of potential extension points, and if the latter induces a conflict to q-compliance, there is a way to subdivide the area of extension points until necessarily we reach an area too small to contain a conflict.

In order to formalize the search area, we introduce the notion of *coloring border* as the edge between the outside and the colored part of V_G on the one hand and the uncolored part of V_G on the other hand: Visually, this border is between vertices and we formalize it as couples: let (u, v) be a pair of neighboring vertices such that $v \in V \backslash C$ and $u \in C$ or $u \in H$ for some cut hole of V_G or such that u is outside of V_G *coloring border candidate*. If $u \in C$ we call it a *colored edge*, in the case of $u \in H$ we call it an *uncolored edge*. Coloring border candidates $(u, v), (u', v')$ are *connected* iff u is a neighbor of u' and v is a neighbor of v' or $u = u'$ and $v = (x, y), v' = (x', y')$ satisfy $|x - x'| + |y - y'| = 2$, i.e. they are on diagonal positions, or conversely $v = v'$ and u, u' are on diagonal positions. Graphically, connected coloring border candidates can be drawn without lifting the pen and share a common point. An extension point is a coloring border candidate (u, v) with $u \in C$ and v the first vertex of a simple extension S. A *coloring border* is a connected set of coloring border candidates.

A coloring border B is *promising* if

- it contains colored segments;
- for any simple extension $S(x, y, a, k)$ with (x, y) having a colored neighbor on the border its addition to C either preserves q-compliance or it causes a conflict with an uncut hole or with a colored edge that is either on the coloring border or directly connected to it;
- one of the following cases holds :
  1. It contains uncolored segments $S(x, y, a, q - 1)$ such that all vertices are connected to coloring border candidates and such that $(x - a, y - (1 - a)), (x + a(q - 1), y + (1 - a)(q - 1)) \notin V \backslash C$.
  2. It does not satisfy (1), there exists a vertex $v \in V \backslash C$ having one neighbor $v_1 \in C$ and another neighbor $v_2 \in \mathbb{Z}^2 \backslash V$ (a corner with one side colored, the other outside V), with (v, v_1) in the coloring border.
  3. It does not satisfy (1) or (2), but it contains edges (v, v') with $v' \in \mathbb{Z}^2 \backslash V$.
  4. It does not satisfy (1) or (2) or (3), but it contains two "colored corners", i.e. pairs of edges (v_i, v_i') and (v_i, v_i'')such that $v_i \in V \backslash C$ and $v_i', v_i'' \in C$ (concave corners with color on both sides), and such that no convex corner (with color on both sides) exists between them (such pairs of concave corners naturally contain a segment all along the edges between the two corners).

Proof of Lemma 5 (Extension lemma). By induction, we claim that a promising coloring border contains an extension that is q-compliant. Then, since the complete border of the partially colored graph is trivially promising, the result follows.

Now let B be a promising coloring border. We examine the cases and show that for each case either a q-compliant simple extension can be identified, or that a smaller promising coloring border can be identified. Case (1) allows immediate coloring, as such a segment cannot break $(q - 1)$-completion and the only way it could break the $(q - 1)$-width would be if $|V \backslash C| = (q - 1)^2$, which contradicts the assumptions $|C| < \frac{|V|}{q}$.

Suppose case (2): adding a single vertex in the corner cannot break $(q-1)$-width, because this contradicts that (1) is not satisfied. Without loss of generality, let us assume $v = (x, y)$ such that $(x-1, y) \in C$ and $(x, y-1) \notin V$ (other cases are symmetric). In order to generate a conflict to $(q-1)$-completion, we must have $(x+q-1, y), (x+q-2, y)...(x+q-2, y+q-1) \in V \backslash C$ but that $(x', y') \notin V \backslash C$ for an $(x', y') \in \{(x+q-1, y+1), ..., (x+q-1, y+q-1)\}$. Since V_G is q-square connected, it is not difficult to see that $\{(x+q-1, y+1), ..., (x+q-1, y+q-1)\} \subseteq V$ hence $(x', y') \in C$. With $(x'-1, y') \in V \backslash C$ it forms a coloring border candidate and since the coloring border is promising, it is connected to the corner. Considering the shortest path between the corner and the conflicting edge, then by removing the edge linking the corner to the colored vertex, we obtain a new coloring border. We claim that it is promising : it contains concave corners because of the orientation of the edges at the two vertices, and moreover, if an extension of any of the types (1)-(4) on this sub-border have conflicts, they must occur within the sub-border.

For the case (3), let us suppose (other cases are symmetric) that $v = (x, y), (x+1, y) \in V \backslash C$ and moreover $(x, y-1) \in C$ and $(x+1, y-1) \notin V$. If adding v produces a conflict to q-compliance, it is either a conflict to $(q-1)$-width or to $(q-1)$-completion.

Let us first consider the case of an $(q-1)$-width conflict. Such a conflict can concern $(x, y+q-2)$, $(x-k, y)$ or $(x+k, y)$ for some $1 < k < q-1$. In the first case, since G_V is q-square connected, it is easy to see that $(x, y+q-2) \in V$, and consequently, it is in C. By removing the edges $(x, y), (x, y-1)$ and $((x, y+q-2), (x, y+q-3))$ from the border coloring and by keeping a path between these two edges connecting them and containing colored edges, we obtain a coloring border of reduced size, which we claim to be promising : for example, the two removed edges are parallel and the connecting path necessarily contains concave corners (otherwise, we end up with a contradiction to the assumption that (1) does not hold), and finally, given that the remaining coloring border is "almost closed", a conflict with respect to some extension point cannot be situated beyond the two removed edges. In the second case, we consider the simple extension $(x-k+1, y)$. It cannot have an $(q-1)$-width conflict (otherwise we would have (1), but we assume that we did not) and because of $(x+1, y-1) \notin V$ we find that a conflicting vertex with respect to $(q-1)$-completion must be $(x-k+q-1, y+q-2) \in C$ we apply a similar reasoning as above in order to identify a sub coloring border. Finally, In the third case (and excluding the second case), the segment $\{(x, y), ..., (x+k-1, y)\}$ is a simple extension that cannot introduce a conflict to $(q-1)$-width and as before, if there is a conflict to $(q-1)$-completion, this conflict is between the edge below (x, y) and some colored edge and again, we apply a reduction of the coloring border. In any case, either the extension preserves q-compliance, or the reduced coloring border is promising and contains by induction an extension preserving q-compliance, that extends obviously to the complete bordering color.

For the case (4), we suppose (up to symmetry) corners $(x, y), (x+k, y)$ with $(x-1, y), (x+k+1, y) \in C$ and $(x, y-1), ..., (x+k, y-1) \in C$. If adding (x, y) to C causes a conflict, it is either due to a colored vertex and we proceed by induction as above. If, on the other hand, there exists a conflicting vertex $v' \notin V$ then this vertex cannot be on the coloring border (assumption of case (4)), hence it must be part of an uncut hole at position $(x+q-1, y+q-1)$. We claim that in this case, the simple extension $S = \{(x+q-1, y), ..., (x+q-1, y+q-2)\}$ preserves q-compliance. First, it cannot introduce a conflict with $(q-1)$-completion, but also, it cannot introduce a conflict with $(q-1)$-width. Also observe that the uncut hole is surrounded by some closed path in $V \backslash C$, cutting it cannot cause $V \backslash (C \cup S)$ to become disconnected. ◀

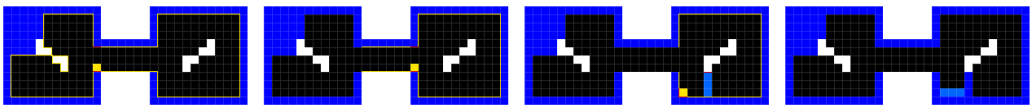

Figure 9 Promising coloring border and extension search.

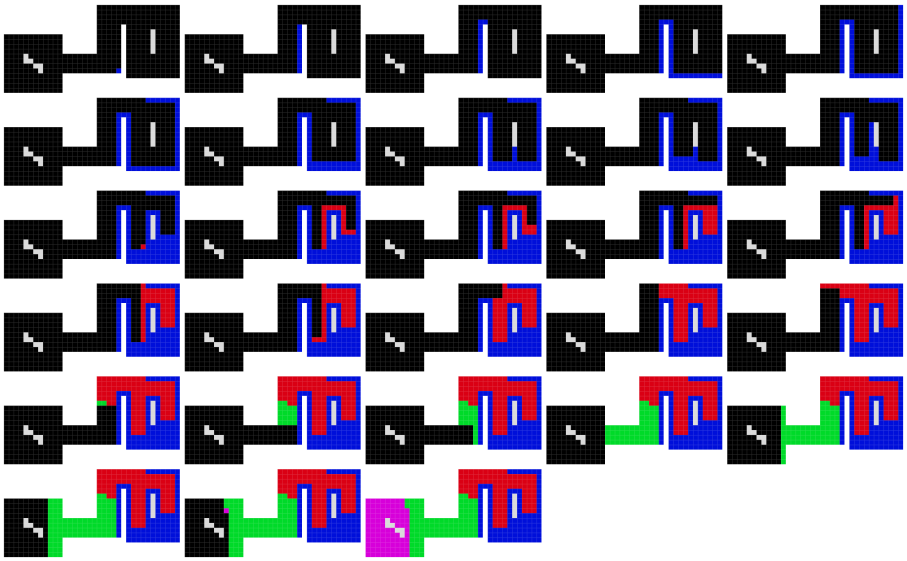
The recursive reasoning of the proof is illustrated in Figure 9 for the case $q = 4$, from left to right: (a) A partial coloring and a promising coloring border (initially the inner contour) is given and a possible simple extension (Case 3) is shown in yellow, but it induces a conflict concerning $(q-1)$-width, the edges cut are marked red, we keep the path connecting these edges at right. A second attempt of Case 3 is shown in the second picture. In the third picture, there are no more uncolored edges (Case 4) in the coloring border so we try a concave corner, but there is a conflict with an uncut hole, so we cut it instead, which conclude the search for the extension. The last picture shows an application of Case 1.

A.4 Example computation of our coloring algorithm

Below, we show a trace of the partitioning by Algorithm 1 for illustration.



Concurrent Games and Semi-Random Determinacy

Abstract

Consider concurrent, infinite duration, two-player win/lose games played on graphs. If the winning condition satisfies some simple requirement, the existence of Player 1 winning (finite-memory) strategies is equivalent to the existence of winning (finite-memory) strategies in finitely many derived one-player games. Several classical winning conditions satisfy this simple requirement.

Under an additional requirement on the winning condition, the non-existence of Player 1 winning strategies from all vertices is equivalent to the existence of Player 2 stochastic strategies almost-sure winning from all vertices. Only few classical winning conditions satisfy this additional requirement, but a fairness variant of omega-regular languages does.

1 Introduction

Computer science models systems interacting concurrently with their environment via infinite duration two-player win/lose games played on graphs: a play starts at a *state* of the graph, where the players *concurrently* choose one *action* each and thus induce the next state, and so on for infinitely many rounds. The *winning condition* is a given subset W of the infinite sequences of states, and Player 1 wins the play iff the sequence of visited states belongs to W. A *strategy* of a player prescribes one action depending on what has been played so far, and a *winning strategy* is a strategy ensuring victory regardless of the opponent strategy.

There are games where neither of the players has a winning strategy, but Borel determinacy [25] guarantees the existence of a winning strategy in games where the players play alternately and the winning condition is a Borel set. Under Borel condition again, Blackwell determinacy [26] guarantees a weaker conclusion when the players play concurrently: there exists a value $v \in [0, 1]$ such that for all $\epsilon > 0$ the players have stochastic strategies guaranteeing victory with probability $v - \epsilon$ and $1 - v - \epsilon$, respectively.

In the special case of concurrent games played on finite graphs with ω-regular winning conditions, [11] designed algorithms to decide the existence of (stochastic) strategies that are winning, winning with probability one, and winning with probability $1 - \epsilon$ for all $\epsilon > 0$. [11] also mentions a three-state game where only the latter exist, which exemplifies the complexity of the concurrent ω-regular games on finite graphs. Then [6] studied concurrent

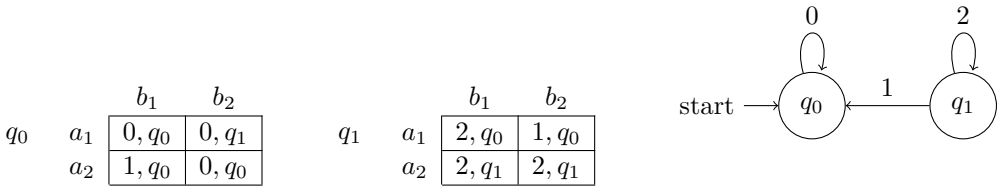

Figure 1 To the left, a concurrent game with states q_0, q_1, colors $0, 1, 2$, and two actions per player. To the right, a one-player game derived by using the delayed response $[(0, q_0)(0, q_0)]; [(1, q_0)(2, q_1)]$.

prefix independent winning conditions, which is strictly more general than the ω-regular conditions, and [13] further improved upon some results. Some of these results were extended recently to multi-player multi-outcome games, see e.g. [3], [15].

The new games. This article studies slightly different games: when the players concurrently choose one action each, it also produces a *color*; the winning condition is now a given subset W of the infinite sequences of colors; and Player 1 wins the play iff the produced sequence of colors belongs to W. There are two differences between the classical games and the new games. First, the winning condition does not involve the visited states but the transitions instead; second it does so indirectly, via colors labeling the transitions. E.g. in the game on the left-hand side of Figure 1, starting at q_0, the action sequence $(a_1, b_1)(a_1, b_2)(a_1, b_1)$ yields the state sequence $q_0q_0q_1q_0$ and the color sequence 002.

There are several reasons why these new games are interesting.

- The classical games can be encoded easily into the new ones by using state names as colors. Variants such as the games with colored states, or the colorless games with winning condition on the transitions can also be encoded easily into the new games.
- The converse encoding may increase the state space (to infinity for games with infinitely many actions). Note that the transition-versus-state issue was already studied in the turned-based setting in [10]. Likewise, colorless games are encoded easily in games with colors without size increase, and colors usually lead to more succinct winning conditions.
- Colors are widely used in turn-based games, and for all games they help to study the winning conditions independently from the game structure, and thus to approximate or even characterize nice winning conditions for classes of games (usually simple to check) rather than for single games (usually more accurate but harder to check). This is exemplified by the difference between Theorems 5 and 7 in [27].
- Whereas classical one-state games are trivial, the new one-state games are fairly complex and constitute a nice intermediate object towards the understanding of the more complex general games. Likewise, some one-state (aka stateless) objects from the literature are interesting in their own right: [1] studied one-state multi-objective Markov decision processes; vector addition systems (VAS, [17]) are still studied despite the vector addition systems with states (VASS, [16]); the Minkowski games [24] defined with finite sets are a special case of the one-state games from this article.

The main results.

- If W is closed under *interleaving* and *prefix removal*, and if states and colors are finitely many, the existence of a Player 1 winning (finite-memory) strategy is equivalent to the existence of winning (finite-memory) strategies in finitely many derived one-player games.

- If, in addition, W is *factor-prefix complete* and there are finitely many actions, either Player 1 has a winning strategy from one state, or every Player 2 constant (stronger than positional!), positive, stochastic strategy is almost-sure winning from all vertices. This is *semi-random determinacy*.
- One-state games enjoy a stronger conclusion than in the previous item under somewhat weaker assumptions: if the winning condition is *factor-set complete* and closed under interleaving, if Player 2 has finitely many actions, either Player 1 has a winning strategy, or every Player 2 constant, positive stochastic strategy is almost-sure winning.

The finitary flavor of the above characterizations yields decidability and memory sufficiency, in the rough range of double exponentials in the number of states times the number of colors.

In the context of semi-random determinacy, a neutral, random Player 2 is therefore as bad for Player 1 as a hostile environment. Also, the victory is clear-cut in the above results: no need for approximate optimal strategies, no need for the notion of value, etc. This is due to the assumptions, and it is legitimate to wonder how restrictive they are.

Several classical winning conditions from computer science are closed under interleaving, see Section 5. The Muller condition is not, but the parity condition is, so the first characterization result extends to the concurrent Muller games via the Last Appearance Record (LAR), as done in [28]. So, closedness under interleaving is not as restrictive as it may seem.

Fewer classical winning conditions are factor-prefix complete (defined in Section 3.2), but the boundedness condition from [24] and a variant of the ω-regular languages are both closed under interleaving and factor-prefix complete. The variant is as follows: each produced color requests some combinations of colors to occur in the future. In winning plays, the number of currently unsatisfied requests should be uniformly bounded over time. It may be relevant even as a business model: at every time unit the system can pay penalties for every currently unsatisfied request, which may be covered by greater, albeit bounded, instantaneous income.

The above variant relates to the notion of *fairness*, which requires that co-finitely many requests are eventually satisfied. The *finitary fairness* [2] additionally requires uniformly bounded response time. This idea was used in [12] to study temporal logic, and in [9] to study finitary parity games. Requiring uniformly bounded response time (or variants thereof) to study games has been further used later, e.g. in [5]. However, these notions of fairness do not enjoy closedness under interleaving and factor-prefix completeness. (Details in Section 5.)

Related works. The semi-random determinacy implies the *bounded limit-one property* from [11] for the new games: if one state has positive value, one state has value one.

Corollary 4 generalizes the nice Theorem 4 from [18]. Note that the convexity of winning conditions defined in [18] is a essentially the same as the interleaving closedness defined here.

This article also shares similarities with [14]: both use abstract winning conditions, and both characterize the existence of winning strategies in two-player games by the existence of winning strategies in finitely many derived one-player games. Several articles adopted a similar approach: [19] and [20] reduce multi-player multi-outcome Borel games to simpler two-player win/lose Borel games, and characterize the preferences and structures that guarantee the existence of Nash equilibrium in infinite tree-games; [21] does the same to characterize the preferences that guarantee the existence of subgame perfect equilibrium (at low levels of the Borel hierarchy); [23] and [27] do the same to almost characterize the existence of finite-memory Nash equilibrium in games on finite graphs; [22] reduces one-shot concurrent two-player multi-outcome games to simpler one-shot concurrent two-player win/lose games, with applications to generalized Muller games and generalized "parity" games.

One of the benefits of abstraction is that it leads to more general results: e.g. [23] noted that the lexicographic product of mean-payoff and reachability objectives cannot be encoded into real-valued payoffs, and [27] proved it.

Structure of the article. Section 2 gives basic definitions. Section 3 presents the main results and additional definitions. Section 4 discusses the key elements of the proofs. Section 5 presents applications.

2 Definitions

The folklore Observation 1 below will be used extensively to lift properties from finite words to infinite words. It will be first explicitly invoked, and then only implicitly used.

▶ **Observation 1.** *Let $f : S^* \to T^*$ be such that $u \sqsubseteq v \Rightarrow f(u) \sqsubseteq f(v)$, where $\sqsubseteq$ is the prefix relation. Then f can be uniquely extended to $S^* \cup S^\omega \to T^* \cup T^\omega$ such that $f(\rho_{\leq n}) \sqsubseteq f(\rho)$ for all $n \in \mathbb{N}$ and $\rho \in S^\omega$.*

Games. A *game (with colors and states)* is a tuple $\langle A_1, A_2, Q, q_0, \delta, C, \mathrm{col}, W\rangle$ such that
- A_1 and A_2 are non-empty sets (of actions for Player 1 and Player 2),
- Q is a non-empty set (of states),
- $q_0 \in Q$ (is the initial state),
- $\delta : Q \times A_1 \times A_2 \to Q$ (is the state update function).
- C is a non-empty set (of colors),
- $\mathrm{col} : Q \times A_1 \times A_2 \to C$ (is a color trace),
- $W \subseteq C^\omega$ (is the winning condition for Player 1)

Histories. The *full histories* (*full runs*) of such a game are the finite (infinite) words over $A_1 \times A_2$, the Player 2 *histories* (Player 2 *runs*) are the finite (infinite) words over A_2, and the Player 1 *histories* (Player 1 *runs*) are the finite (infinite) words over A_1.

Strategies. A Player 1 strategy is a function from A_2^* to A_1. Informally, it requires Player 1 to remember exactly how Player 2 has played so far, and it tells Player 1 how to play.

Induced histories. The function h is defined inductively below. As arguments it expects a strategy and a Player 2 history in A_2^*, and it returns a full history: the very full history that, morally, should happen if Player 1 followed the given strategy while Player 2 played the given Player 2 history. Namely, $h(s, \epsilon) := \epsilon$ and $h(s, \beta \cdot b) := h(s, \beta) \cdot (s(\beta), b)$.

By Observation 1 the function h is extended to expect opponents runs in A_2^ω and return full runs: $h(s, \boldsymbol{\beta})$ is the only action run whose prefixes are the $h(s, \boldsymbol{\beta}_{\leq n})$ for $n \in \mathbb{N}$.

Extending the update and trace functions. The state update function δ is extended to $\Delta : (A_1 \times A_2)^* \to Q$ inductively: $\Delta(\epsilon) := q_0$ and $\Delta(\rho \cdot (a, b)) := \delta(\Delta(\rho), a, b)$. Using Δ, the trace function col is naturally lifted to full histories by induction: $\mathrm{col}(\epsilon) := \epsilon$ and $\mathrm{col}(\rho \cdot (a, b)) := \mathrm{col}(\rho) \cdot \mathrm{col}(\Delta(\rho), a, b)$. The trace function is further extended to full runs by Observation 1. When considering several games, indices may be added to the corresponding Δ and col.

Winning strategies. A Player 1 strategy s is winning if $\mathrm{col} \circ h(s, \boldsymbol{\beta}) \in W$ for all $\boldsymbol{\beta} \in A_2^\omega$. If there is a Player 1 winning strategy in a game, one says that Player 1 wins the game.

Memory. A Player 1 strategy s is said be implementable with memory M, or memory size $\log_2 |M|$, if there exist a set M and $m_0 \in M$, and two functions $\sigma : Q \times M \to A_1$ and $\mu : Q \times M \times A_2 \to M$ such that $s(\beta) = \sigma(\Delta \circ h(s, \beta), m(\beta))$, where m is defined inductively by $m(\epsilon) := m_0$ and $m(\beta b) := \mu(\Delta \circ h(s, \beta), m(\beta), b)$. If M is finite, s is called a finite-memory strategy. Note that every Player 1 strategy is implementable with memory A_2^ω.

One-player games. Intuitively, a *one-player game (with colors and states)* amounts to a game where Player 2 has only one strategy available, i.e. $|A_2| = 1$. Formally, it is a tuple $\langle A_1, Q, q_0, \delta, C, \mathrm{col}, W\rangle$ such that A_1, Q, and C are non-empty sets, $q_0 \in Q$, $\delta : Q \times A_1 \to Q$, $\mathrm{col} : Q \times A_1 \to C$, and $W \subseteq C^\omega$. In this context, the *full histories* (*full runs*) of such a game are the finite (infinite) words over A_1, and the Player 2 *histories* of Player 1 are the natural numbers (telling how many rounds have been played). There is only one Player 2 *run*, namely ω. Then, a Player 1 strategy is a function from $\mathbb{N}$ to A_1, and the notation for the induced full histories is overloaded: $h(s, 0) := \epsilon$ and $h(s, n + 1) := h(s, n) \cdot s(n)$. By Observation 1 the function h is (again) extended: $h(s, \omega)$ is the only action run whose prefixes are the $h(s, n)$ for $n \in \mathbb{N}$. A Player 1 strategy s is winning if $\mathrm{col} \circ h(s, \omega) \in W$.

Prefix removal. A set of infinite sequences is closed under prefix removal if the tails of the sequences from the set are again in the set. Formally, $W \subseteq C^\omega$ is closed under prefix removal if the following holds: $\forall(\gamma, \boldsymbol{\gamma}) \in C^* \times C^\omega$, $\gamma \cdot \boldsymbol{\gamma} \in W \Rightarrow \boldsymbol{\gamma} \in W$. Note that closedness under prefix removal is weaker than the prefix independence assumed in [6], [13], and [18].

Interleaving. Interleaving two infinite sequences consists in enumerating sequentially (prefixes of) the two sequences to produce a new infinite sequence. For example, interleaving $(2n)_{n\in\mathbb{N}}$ and $(2n + 1)_{n\in\mathbb{N}}$ can produce the sequences $(n)_{n\in\mathbb{N}}$ (perfect alternation), $1 \cdot 0 \cdot 3 \cdot 5 \cdot 2 \cdot 7 \cdot 4 \cdot 6 \cdot (n + 8)_{n\in\mathbb{N}}$, and $(2n)_{n\in\mathbb{N}}$ (by enumerating the first sequence only), but not the sequences $(4n)_{n\in\mathbb{N}}$ or $0 \cdot 1 \cdot 4 \cdot 3 \ldots$.

Delayed response. Consider a game $g = \langle A_1, A_2, Q, q_0, \delta, C, \mathrm{col}, W\rangle$ with finite Q and C. For every $q \in Q$ let $E_1^q, \ldots, E_{k_q}^q$ be the elements of $\{(\mathrm{col}, \delta)(q, a, A_2) \mid a \in A_1\}$, where $(\mathrm{col}, \delta)(q, a, A_2) := \{(\mathrm{col}(q, a, b), \delta(q, a, b)) \mid b \in A_2\}$ for all $a \in A_1$. The elements of $\otimes_{q\in Q, i\leq k_q} E_i^q$ are called the Player 2 *delayed responses*. Intuitively, a Player 2 delayed response amounts to a Player 2 positional strategy in (and only in) a sequentialized version of the game. In every round of this version, Player 1 chooses an action first, then Player 2 chooses an action (or more precisely some color and state among the pairs he could induce by choosing an action). E.g. $[(0, q_0)(0, q_0)]; [(1, q_0)(2, q_1)]$ is a delayed response for Figure 1. It means that at state q_0, Player 2 selects $(0, q_0)$ for both actions of Player 1, and at state q_1 it selects $(1, q_0)$ if Player 1 chooses action a_1. Note that delayed responses are not Player 2 (positional) strategies in the concurrent game, e.g. as $[(0, q_0)(0, q_0)]$ is not achievable in any column.

Derived one-player games. Let t be a Player 2 delayed response. The one-player game $g(t) := \langle A_1, Q, q_0, \delta_t, C, \mathrm{col}_t, W\rangle$ is defined by $(\mathrm{col}_t, \delta_t)(q, a) := t_{q,(\mathrm{col},\delta)(q,a,A_2)}$, the projection of t on the (q, E_i^q)-component such that $E_i^q = (\mathrm{col}, \delta)(q, a, A_2)$. Intuitively, $g(t)$ is the game obtained by letting Player 2 fix his strategy (to realize) t in the sequentialized version of g. For example, the game on the left-hand side of Figure 1 applied to the delayed response $[(0, q_0)(0, q_0)]; [(1, q_0)(2, q_1)]$ yields the game on the right-hand side of Figure 1.

3 Main results

Section 3.1 characterizes the existence of Player 1 winning strategies and gives a complexity result. Section 3.2 defines additional concepts and uses the above characterization to characterize the existence of Player 2 everywhere-winning stochastic strategies. Section 3.3 studies the special case of one-state games and presents the semi-random determinacy.

3.1 Existence of Player 1 winning strategies

Theorem 2 below characterizes the existence of Player 1 winning strategies in a game via the existence of winning strategies in finitely many derived one-player games. Theorem 3 afterwards drops the assumption on closedness under prefix removal from Theorem 2, but at the cost of a universal quantification over the starting state of the game. In Theorems 2 and 3, the finiteness and the closedness assumptions are used only to prove the $2 \Rightarrow 1$ implications.

▶ **Theorem 2.** *Consider a game $g = \langle A_1, A_2, Q, q_0, \delta, C, \mathrm{col}, W\rangle$. If Q and C are finite, and W is closed under interleaving and prefix removal, the following are equivalent.*

1. Player 1 *wins g.*
2. Player 1 *wins $g(t)$ for all delayed responses t.*

If A_1 is finite and Player 1 *wins, she can do it with memory size $O(f(|A_1|,|Q|,|C|)\cdot(|C\times Q|)^{|Q|2^{|C\times Q|}})$, where $f(|A_1|,|Q|,|C|)$ is a sufficient memory size to win the one-player games using A_1, Q and C.*

▶ **Theorem 3.** *Consider games $g_q = \langle A_1, A_2, Q, q, \delta, C, \mathrm{col}, W\rangle$ parametrized by $q \in Q$. If A_1, A_2, and Q are finite, if W is factor-prefix complete and closed under interleaving and prefix removal, the following are equivalent.*

1. Player 1 *wins g_q for all $q \in Q$.*
2. Player 1 *wins $g_q(t)$ for all $q \in Q$ and delayed responses t.*

If the above holds, Player 1 *wins every g_q with memory size as in Theorem 2.*

In games that are (or encode) turn-based games, the delayed responses are Player 2 positional strategies. So, restricting Theorems 2 and 3 to turn-based games yields Corollaries 4 and 5, respectively. Note that Corollary 4 generalizes Theorem 4 from [18] by only assuming closedness under prefix removal instead of prefix independence. This is significant since the safety condition is closed under interleaving and prefix removal, but is not prefix independent.

▶ **Corollary 4.** *Consider a game $g = \langle A_1, A_2, Q, q_0, \delta, C, \mathrm{col}, W\rangle$ encoding a turn-based game. If Q and C are finite, and W is closed under interleaving and prefix removal, either* Player 1 *has a winning strategy or* Player 2 *has a positional winning strategy.*

▶ **Corollary 5.** *Consider games $g_q = \langle A_1, A_2, Q, q, \delta, C, \mathrm{col}, W\rangle$ parametrized by $q \in Q$ and encoding a turn-based games. If Q and C are finite, and W is closed under interleaving, either* Player 1 *wins all g_q, or* Player 2 *has a positional winning strategy for some g_q.*

The characterizations from Theorems 2 and 3 yields decidability results and rough algorithmic complexity estimates in Corollary 6 below. Note that checking all the possible strategies using memory size given by Theorems 2 and 3 would be slower than Corollary 6.

▶ **Corollary 6.** *Let $\mathcal{C} \neq \emptyset$, let $W \subseteq \mathcal{C}^\omega$ be closed under interleaving and prefix removal (resp. by interleaving), and let $f : \mathbb{N}^3 \to \mathbb{N}$ be such that for all finite $C \subseteq \mathcal{C}$ and all one-player games $\langle A_1, Q, q_0, \delta, C, \mathrm{col}, W\rangle$, it takes at most $f(|A_1|,|Q|,|C|)$ computation steps to decide*

the existence of a (finite-memory) winning strategy in the game. Then for all finite games $g_{q_0} = \langle A_1, A_2, Q, q_0, \delta, C, \mathrm{col}, W\rangle$ *it takes at most*

$$f(|A_1|, |Q|, |C|) \cdot (|C \times Q|)^{|Q|2^{|C\times Q|}} + |Q||A_1||A_2|$$

computation steps to decide whether Player 1 *wins* g_{q_0} *(with finite memory).*

(resp. $|Q| \cdot f(|A_1|, |Q|, |C|) \cdot (|C \times Q|)^{|Q|2^{|C\times Q|}} + |Q||A_1||A_2|$ *computation steps to decide whether* Player 1 *wins* g_q *(with finite memory) for all* $q \in Q$*.)*

3.2 Existence of Player 2 almost-sure winning random strategies

Consider a game $\langle A_1, A_2, Q, q_0, \delta, C, \mathrm{col}, W\rangle$.

Probability distribution. A probability distribution on a finite set E is a function $f : E \to [0, 1]$ such that $\sum_{e\in E} f(e) = 1$. Let us call $D(E)$ the set of the probability distributions on E.

Stochastic strategies. A Player 1 (Player 2) stochastic strategy is a function $\sigma : (A_1 \times A_2)^* \to D(A_1)$ ($\tau : (A_1 \times A_2)^* \to D(A_2)$).

Induced stochastic histories. The function H is defined inductively below. As arguments it expects stochastic strategies σ and τ for Player 1 and a Player 2, respectively, and it returns a function from $(A_1 \times A_2)^*$ to $\mathbb{R}$. Namely, $H(\sigma, \tau)(\epsilon) := 1$, and $H(\sigma, \tau)(\rho \cdot (a, b)) := H(\sigma, \tau)(\rho) \cdot \sigma(\rho)(a) \cdot \tau(\rho)(b)$. It is easy to check that $H(\sigma, \tau)(\rho) \geq 0$ for all $\rho \in (A_1 \times A_2)^*$, and that $\sum_{|\rho|=n} H(\sigma, \tau)(\rho) = 1$ for all $n \in \mathbb{N}$.

Induced probability measure. For every pair $(\sigma, \tau) \in D(A_1)^{(A_1\times A_2)^*} \times D(A_2)^{(A_1\times A_2)^*}$ one defines a probability measure $\lambda(\sigma, \tau)$ on $(A_1 \times A_2)^\omega$ by setting $\lambda(\sigma, \tau)(\rho \cdot (A_1 \times A_2)^\omega) := H(\sigma, \tau)(\rho)$ for all $\rho \in (A_1 \times A_2)^*$. (It is then extended uniquely to measurable sets.)

Almost-sure winning stochastic strategies. A Player 2 stochastic strategy τ is said to be almost-sure winning if $\lambda(\sigma, \tau)(\mathrm{col}^{-1}[W]) = 0$ for all $\sigma \in D(A_1)^{(A_1\times A_2)^*}$. (Recall that $\mathrm{col} : (A_1 \times A_2)^\omega \to C^\omega$ is an extension of $\mathrm{col} : Q \times A_1 \times A_2 \to C$ with notation overload.)

Factor-prefix completeness. Informally, W is factor-prefix complete if the following holds: if the prefixes of an infinite sequence occur as factors arbitrarily far in the tail of a second sequence in W, the first sequence is also in W. (A factor, aka substring, is a subsequence of consecutive elements.) Formally, $W \subseteq C^\omega$ is factor-prefix complete if the following holds: $\forall \boldsymbol{\gamma} \in C^\omega, (\exists \boldsymbol{\gamma}' \in W, \forall n, m \in \mathbb{N}, \exists k \in \mathbb{N}, \boldsymbol{\gamma}_{\leq n} = \boldsymbol{\gamma}'_{m+k} \cdots \boldsymbol{\gamma}'_{m+k+n}) \Rightarrow \boldsymbol{\gamma} \in W$.

In Theorem 7 below, a distribution is said to be positive if it assigns only positive masses. A (stochastic) strategy is said to be constant if it is a constant function, i.e. it returns always the same distribution, which is stronger than being Markovian (aka memoryless, positional).

▶ **Theorem 7** (semi-random determinacy). *Consider games* $g_q = \langle A_1, A_2, Q, q, \delta, C, \mathrm{col}, W\rangle$ *parametrized by* $q \in Q$*. If* A_1 *and* A_2 *are finite, if* W *is factor-prefix complete and closed under interleaving and prefix removal, the following are equivalent.*

1. *for all* $q \in Q$, Player 1 *has no winning strategies in* g_q*.*
2. *for all* $q \in Q$, Player 2 *has a constant, positive, stochastic strategy almost-sure winning* g_q*.*
3. *for all* $q \in Q$ *every* Player 2 *stochastic strategy involving probabilities bounded away from* 0 *(i.e. with positive infimum) almost-sure wins* g_q*.*

So in the setting of Theorem 7, either Player 1 has a winning strategy for some g_q, or every constant, positive strategy is almost-sure winning, hence the determinacy. Also note that semi-random determinacy implies the *bounded limit-one property* from [11] for the new games: if one state has positive value, one state has value one.

3.3 The special case of stateless (i.e. one-state) games

Stateless games. Intuitively, a *stateless game (with colors)* amounts to a game with only one state, i.e. $|Q| = 1$. Formally, it is a tuple $\langle A_1, A_2, C, \mathrm{col}, W\rangle$ such that A_1, A_2, and C are non-empty sets, $\mathrm{col} : A_1 \times A_2 \to C$ (as opposed to $\mathrm{col} : Q \times A_1 \times A_2 \to C$ in the general case), and $W \subseteq C^\omega$. Histories, runs, strategies, and induced histories are defined as in the general case . It is easier to extend the trace function in this context: $\mathrm{col}(\epsilon) := \epsilon$ and $\mathrm{col}(\rho \cdot (a, b)) = \mathrm{col}(\rho) \cdot \mathrm{col}(a, b)$.

Restricting Theorem 3 to stateless games yields a simpler Corollary 8 below. (Note that restricting Theorem 2 would yield a weaker variant of Corollary 8, i.e. additionally assuming closedness under prefix removal.) Memory size and algorithmic complexity estimates could be obtained essentially by replacing $|Q|$ with 1 in Theorem 3 and Corollary 6.

▶ **Corollary 8.** *Consider a game $\langle A_1, A_2, C, \mathrm{col}, W\rangle$ with finite C and interleaving-closed W. Let $C_1, \ldots, C_k$ be the elements of $\{\mathrm{col}(a, A_2) \mid a \in A_1\}$. The following are equivalent.*

1. Player 1 *has a winning strategy (resp. finite-memory winning strategy).*
2. $\forall (c_1, \ldots, c_k) \in C_1 \times \cdots \times C_k$, $W \cap \{c_1, \ldots, c_k\}^\omega \neq \emptyset$ *(resp. $W \cap \{c_1, \ldots, c_k\}^\omega \cap \mathrm{reg}_C \neq \emptyset$), where reg_C are the regular infinite sequences over C.*

Restricting Theorem 7 to stateless games cancels the universal quantification over states, but an even stronger version can be obtained: finiteness of A_1 and prefix removal closedness are dropped, and the assumption on factor-prefix completeness is weakened to factor-set completeness, as below.

Factor-set completeness. A language of infinite sequences is called *factor-set complete* if the following holds: if a sequence in the language has factors of unbounded length over some C_0, the language has a sequence over C_0. This is formally defined by contraposition: $W \subseteq C^\omega$ is factor-set complete if for all $C_0 \subseteq C$ and for all $\rho \in W$, we have $W \cap C_0^\omega = \emptyset \Rightarrow \forall \rho \in W, \exists m \in \mathbb{N}, \forall n \in \mathbb{N}, \exists i \in \mathbb{N}, i < m \wedge \rho_{n+i} \notin C_0$.

▶ **Observation 9.** *Factor-prefix completeness implies factor-set completeness (finite alphabets).*

▶ **Theorem 10** (Stateless semi-random determinacy)**.** *Consider a stateless game $\langle A_1, A_2, C, \mathrm{col}, W\rangle$ with finite C and A_2. Let us assume that W is interleaving-closed and factor-set complete. Then either* Player 1 *has a winning strategy, or every* Player 2 *constant, positive, stochastic strategy is almost-sure winning.*

4 The proofs

Theorems 2 and 3 characterize a concurrent game by finitely many one-player games. A natural idea would be to split their proof into two parts: first, reduce the problem to turn-based games via the well-known observation that a player has a winning strategy in a concurrent game iff she has one in the sequential version of the game where she plays first; second, use similar techniques as in [18]. For this to work, the sequential versions of the

	b_1	b_2
a_1	$1,1$	$2,1$
a_2	$1,-1$	$0,-1$
a_3	$-1,0$	$-2,0$

$1,1$	$1,1$	$1,1$	$1,1$	$2,1$
$1,-1$	$1,-1$	$0,-1$	$0,-1$	$1,-1$
$-1,0$	$-2,0$	$-1,0$	$-2,0$	$-1,0$

Figure 2 A concurrent Minkowski game and its derived games.

concurrent games must allow for colorless transitions, or a fresh color should be used for the transitions where Player 1 plays. This raises three issues: first, true colors should occur infinitely often in every run in these turn-based games, which would require a more complex notion of turn-based game (and considering only games with strict player alternation does not help, as this property is lost during the induction); second, the winning condition should be rephrased to take the fresh color into account, and so should its closedness properties; third, it would be much more difficult to obtain stronger results for the one-state concurrent games, since the one-state property may be hard to track through the translation into turn-based games. Instead, this article overcomes the concurrency directly thanks to Lemma 11.

▶ **Lemma 11.** *Let $(X_i)_{i\in I}$ be a family of sets. Then*
$\forall f : \prod_{i\in I} X_i \to I, \exists i \in I, \forall x \in X_i, \exists y \in \prod_{i\in I} X_i, y_i = x \wedge f(y) = i.$

Proof. Towards a contradiction, let us assume the negation of the claim, i.e. $\exists f : \prod_{i\in I} X_i \to I, \forall i \in I, \exists x \in X_i, \forall y \in \prod_{i\in I} X_i, y_i \neq x \vee f(y) \neq i$. By collecting one witness $x =: z_i$ for each i, one constructs $z \in \prod_{i\in I} X_i$ such that $\forall y \in \prod_{i\in I} X_i, y_i \neq z_i \vee f(y) \neq i$. In particular, taking $y := z$ yields $z_i \neq z_i \vee f(z) \neq i$ for all i, which contradicts the type of f. ◀

Consider the one-state game g in Figure 2 (to the left), where each cell encloses one vector of the real plane. Player 1's objective is that the sum of the outcome vectors remains bounded, which is closed under interleaving and prefix removal, so g is a concurrent version of the Minkowski games [24]. There are $2^3 = 8$ delayed responses, and five of the corresponding one-player games $g_0, \dots g_7$ are displayed to the right in Figure 2. Player 1 wins $g_0, \dots, g_7$, since for each $i \leq 7$ the vector $(0, 0)$ is in the convex hull of the three vectors defining g_j. The idea is to let Player 1 play g as if she were playing $g_0, \dots, g_7$ in parallel, more specifically in an interleaved way. Then, summing up the eight bounded trajectories yields a bounded trajectory for g.

The main difficulty to play the $g_0, \dots, g_7$ in an interleaved way is that at every stage, Player 1 should pick an action such that whichever action Player 2 chooses, the resulting vector is exactly the expected one by the (fixed) winning strategy for *some* g_j. Let $f : \{1, 2\}^3 \to \{a_1, \dots, a_3\}$ be the function that tells which action should be played currently in each of the $2^3 = 8$ one-player games. By Lemma 11 there exists an action a_i such that the following holds: if Player 2 chooses b_1, there exists g_j expecting the vector in the cell (a_i, b_1), and likewise if Player 2 chooses b_2, there exists g_k expecting the vector in the cell (a_i, b_2).

Let us now quickly mention semi-random determinacy. The proof of Theorem 7 below uses similar techniques as, e.g., a proof in [24].

Proof of 1 ⇒ 3 from Theorem 7. Let $p \in]0, \frac{1}{|A_2|}]$ and let τ be a Player 2 stochastic strategy that always assigns probability at least p to every action.

For all $q \in Q$, by contraposition of Theorem 2 let t_q be a delayed response (in g_q) such that Player 1 loses the one-player game $g_q(t_q)$. For all $n \in \mathbb{N}$, anytime a play reaches the

state q, the probability that from then on Player 2 follows t_q for n rounds in a row, as if second-guessing Player 1, is greater than or equal to p^n.

Consider a play where Player 2 follows τ. Let q be a state that is visited infinitely often. (Such a state exists since Q is finite.) Thanks to the argument above, for all $n \in \mathbb{N}$, the probability that, at some point, Player 2 follows t_q for n rounds in a row from q on is one. Since the countable intersection of measure-one sets has also measure one, the probability that, for all $n \in \mathbb{N}$, at some point Player 2 follows t_q for n rounds in a row from q on is one.

Let $(\rho^n)_{n\in\mathbb{N}}$ be the corresponding full histories. Since A_1 and A_2 are finite, the tree induced by prefix closure of the $(\rho^n)_{n\in\mathbb{N}}$ is finitely branching, so by Koenig's Lemma it has an infinite path $\boldsymbol{\rho}$, which corresponds to Player 2 following t_q infinitely many rounds in a row. So $\mathrm{col}(\boldsymbol{\rho}) \notin W$. By factor-prefix closedness the original play is also losing for Player 1, i.e. winning for Player 2. ◀

5 Applications

Abstract assumptions need not only be general, they also need to be practical. Section 5.1 shows that the closedness and completeness axioms enjoy nice algebraic properties: individually, w.r.t. Boolean combination, as well as collectively via the derived closure or completion operators. Section 5.2 mentions several classical or recent winning conditions from computer science and tells which of them satisfy the closedness and completeness axioms. Section 5.3 introduces the notion of bounded residual load as an alternative to the finitary fairness [2], and uses it to define a finitary variant of the ω-regular languages that satisfies the closedness and completeness axioms.

5.1 Algebraic properties of the closedness and completeness axioms

Lemma 12 below shows how the axioms behave w.r.t. Boolean combination.

▶ **Lemma 12.**

1. *The set of the factor-set complete languages is closed under union.*
2. *The set of the interleaving-closed languages is closed under intersection.*
3. *The set of the factor-prefix complete languages is closed under intersection and union.*

The set of the interleaving-closed languages is not closed under union: $\{0^\omega\}$ and $\{1^\omega\}$ are closed under interleaving (and by prefix removal), but $\{0^\omega, 1^\omega\}$ is not. The set of the interleaving-closed languages is not closed under complementation: the interleaving of two infinite sequences that are not eventually constant is not eventually constant, but interleaving the eventually constant sequences 0^ω and 1^ω may yield $(01)^\omega$. The set of the factor-set complete languages is not closed under intersection: indeed, both two-element sets $\{0(12)0(12)^20(12)^30\ldots, (12)^\omega\}$ and $\{0(12)0(12)^20\ldots, (112)^\omega\}$ are factor-set complete, but their intersection $\{0(12)0(12)^20\ldots\}$ is not. The set of the factor-set (-prefix) complete languages is not closed under complementation: $\{1^\omega\}$ is factor-set (-prefix) complete, but $\{0,1\}^\omega \setminus \{1^\omega\}$ is not.

The closedness under interleaving and prefix removal, and the factor-prefix completeness induce closure operators. If a relevant winning condition fails to satisfy an equaly relevant axiom, such an operator conveniently constructs a (more generous, axiom satisfying) variant of the winning condition. The closure by prefix removal of a set consists in adding the tails of the sequences from the set; the closure by interleaving consists in adding sequences obtained by interleaving the sequences from the set; and the factor-prefix completion consists in adding

the sequences whose prefixes occur arbitrarily far in a sequence from the set. Note that factor-set completeness does not induce a canonical closure operator due to the existential quantifier in its definition.

Lemma 13 below shows that the operators behave as expected. This is not for granted in general, as one may need to perform the addition operation an ordinal number of times. Here, one step suffices, which is convenient if computation is of concern.

▶ **Lemma 13.**

1. *Closure by prefix removal yields sets that are closed under prefix removal.*
2. *Closure by interleaving yields sets that are closed under interleaving*
3. *Factor-prefix completion yields sets that are factor-prefix complete.*

Lemma 14 shows that the operators preserve the existing properties. (Lemma 13 is invoked as a proof technique.)

▶ **Lemma 14.**

1. *Closure by prefix removal preserves closedness under interleaving.*
2. *Closure by prefix removal preserves factor-set and factor-prefix completeness.*
3. *Closure by interleaving preserves closedness under prefix removal.*
4. *Closure by interleaving preserves factor-set and factor-prefix completeness.*
5. *Factor-prefix completion preserves closedness under prefix removal.*

5.2 Concrete winning conditions

The non-comprehensive list below displays classical or recent winning conditions from computer science. It especially shows that new winning conditions obtained by conjunction of older winning conditions have been recently studied, e.g. in [7] and [4].

Parity $C := \{0, 1, \dots n\}$ for some $n \in \mathbb{N}$. A sequence is winning iff the least number occurring infinitely many times in the sequence is even.

Muller $C := \{0, 1, \dots n\}$ for some $n \in \mathbb{N}$. Let $M \subseteq \mathcal{P}(C)$ be a set of subsets of C. A sequence is winning iff the numbers occurring infinitely many times in the sequence constitute a set in M.

Mean-payoff $C = \mathbb{R}$, and a sequence is winning iff the limit superior of the partial sums is non-negative: $(u_n)_{n\in\mathbb{N}} \in \mathbb{R}^{\mathbb{N}}$ is winning iff $\limsup_{n\to\infty} \frac{1}{n} \sum_{i=0}^{n} u_n \geq 0$. (Variants exist with limit inferior or positivity instead of non-negativity.)

Energy $C = \mathbb{R}$, and a sequence is winning iff its partial sums are non-negative: $(u_n)_{n\in\mathbb{N}} \in \mathbb{R}^{\mathbb{N}}$ is winning iff $\forall n \in \mathbb{N}, \sum_{i=0}^{n} u_n \geq 0$.

Boundedness [24] $C = \mathbb{R}^d$, and a sequence is winning iff its partial sums are uniformly bounded: $(u_n)_{n\in\mathbb{N}} \in (\mathbb{R}^d)^{\mathbb{N}}$ is winning iff $\exists b \forall n \in \mathbb{N}, \| \sum_{i=0}^{n} u_n \| \leq b$.

Discounted sum C is a bounded subset of $\mathbb{R}$. Let $0 < \alpha < 1$ and $t \in \mathbb{R}$. A sequence $(u_n)_{n\in\mathbb{N}} \in C^{\mathbb{N}}$ is winning iff $\sum_{n=0}^{+\infty} \alpha^n u_n \geq t$.

Energy-parity [7] $C := \mathbb{R} \times \{0, 1, \dots n\}$ for some $n \in \mathbb{N}$. The winning condition is the conjunction of the energy (first component) and the parity (second component) conditions.

Average energy [4] $C = \mathbb{R}$. The objective is to maintain a non-negative energy while keeping the average level of energy below a threshold $t \in \mathbb{R}$: a sequence $(u_n)_{n\in\mathbb{N}} \in \mathbb{R}^{\mathbb{N}}$ is winning iff $(\forall n \in \mathbb{N}, \sum_{i=0}^{n} u_n \geq 0) \wedge \limsup_{n\to+\infty} \frac{1}{n} \sum_{i=0}^{n} \sum_{j=0}^{i} u_j \leq t$.

▶ **Observation 15.**

1. *The parity, mean-payoff, energy, boundedness, energy-parity, and average energy conditions are all closed under interleaving. (It uses Lemma 12.2 to deal with energy-parity and average energy.)*

2. *The Muller and discounted sum conditions are not closed under interleaving.*
3. *The boundedness condition is factor-prefix complete; the others are not.*
4. *The energy condition (thus also energy-parity and average energy) and the discounted sum condition are not closed under prefix removal; the others are.*

▶ **Corollary 16.** *The turn-based safety-mean-payoff-parity games are half-positionally determined. (By Corollary 4 and Section 5.1.)*

It may be disappointing that the Muller condition is not even closed under interleaving, but Proposition 17 below extends Theorem 2 to the concurrent Muller games. Using results from [11] is likely to yield a better algorithmic complexity, though, but the point here is mainly that Theorem 2 can be extended.

▶ **Proposition 17.** *[Similar to [11]] Consider the finite games $\langle A_1, A_2, Q, q_0, \delta, C, \mathrm{col}, W\rangle$ where W is a Muller condition. Deciding the existence of a* Player 1 *winning (finite-memory) strategy can be done in big O of*

$$(|A_1||A_2||C||C|!)^2 \cdot (|Q||C|^2|C|!)^{|Q||C||C|!\left(2^{|Q||C|^2|C|!}\right)}$$

computation steps.

5.3 Bounded residual load

Unlike Theorems 2 and 3, Theorems 7 and 10 are not likely to be extended to include ω-regular languages. Before defining a variant of the ω-regular languages that satisfies the closedness and completeness properties from this article, let us consider notions of fairness that can be defined via a predicate S on $\mathbb{N} \times \mathbb{N} \times C^\omega$. Intuitively $S(n, d, \boldsymbol{\gamma})$ is supposed to mean that the sequence $\boldsymbol{\gamma}$ has satisfied, with delay at most d, a request that was formulated in $\boldsymbol{\gamma}$ at time n.

There are several reasonable ways to express the good behavior of an infinite sequence using the $S(n, d, \boldsymbol{\gamma})$. The classical definition of *fairness* requires that all problems be eventually solved (see F below), or cofinitely many problems (see FCI below), for a usual weakening that ensures prefix independence of the condition. Arguing that this kind of fairness gives no guarantee about response time, [11] strengthened fairness into *finitary fairness*, which requires the existence of a uniform bound on the waiting time (see FF below).

Yet another variant, *bounded residual load* (BRL), is introduced below. It says that $\boldsymbol{\gamma} \in C^\omega$ satisfies S wrt bounded residual load, if the number of problems that have currently not yet been solved is uniformly bounded over time.

1. $F(\boldsymbol{\gamma}) := \forall n \in \mathbb{N}, \exists d \in \mathbb{N},\ S(n, d, \boldsymbol{\gamma})$
2. $FCI(\boldsymbol{\gamma}) := |\{n \in \mathbb{N} \mid \forall d \in \mathbb{N},\ \neg S(n, d, \boldsymbol{\gamma})\}| < \infty$
3. $FF(\boldsymbol{\gamma}) := \exists d \in \mathbb{N}, \forall n \in \mathbb{N},\ S(n, d, \boldsymbol{\gamma})$
4. $BRL(\boldsymbol{\gamma}) := \exists b \in \mathbb{N}, \forall n \in \mathbb{N},\ b \geq |\{k \in \mathbb{N} \mid k \leq n \wedge \neg S(k, n-k, \boldsymbol{\gamma})\}|$

▶ **Observation 18.**

1. $FF(\gamma) \Rightarrow F(\gamma) \quad \wedge \quad F(\gamma) \Rightarrow FCI(\gamma)$
2. $FF(\gamma) \Rightarrow BRL(\boldsymbol{\gamma}) \quad \wedge \quad BRL(\boldsymbol{\gamma}) \Rightarrow FCI(\gamma)$
3. *F and BRL are incomparable in general.*

The finitary fairness and the like may be too strict for some applications: gladly accepting to wait b time units, but categorically refusing to wait $b+1$ time units sounds unusual indeed. Instead, the system (which is responsible for solving the problems) could pay a penalty for

each problem spending each time unit unsolved. Thanks to the bounded residual load, one has then the guarantee that the amount of money to be paid per time unit is bounded.

It is possible to combine the two ideas, though: by setting an acceptable response time and an acceptable uniform bound on the number of missed deadlines. This however, turns out to be equivalent to the simple BRL, which argues for the robustness of the concept.

▶ **Observation 19.** *Let* $BRLD(\boldsymbol{\gamma}) := \exists b, d \in \mathbb{N}, \forall n \in \mathbb{N},\ b \geq |\{k \in \mathbb{N} \mid k \leq n - d \wedge \neg S(k, n-k, \boldsymbol{\gamma})\}|$*, then* $BRLD(\boldsymbol{\gamma}) \Leftrightarrow BRL(\boldsymbol{\gamma})$*.*

A second justification for the BRL is that it has nice properties that the other notions of fairness lack when $S(n, d, \boldsymbol{\gamma})$ is defined to minic ω-regular languages, as shown below. Consider a non-empty set C of colors and a function $\mathcal{C} : C \to \mathcal{P}(C^*)$. A sequence $\boldsymbol{\gamma} \in C^\omega$ is said to satisfy $\mathcal{C}$ from position n after delay d, denoted $S_{\mathcal{C}}(n, d, \boldsymbol{\gamma})$, if the following holds.

$$\exists u \in \mathcal{C}(\boldsymbol{\gamma}_n), \exists (k_1, \dots, k_{|u|}) \in \mathbb{N}^{|u|},\ n < k_1 < \cdots < k_{|u|} \leq n + d \wedge \forall i \leq |u|,\ u_i = \boldsymbol{\gamma}_{k_i}$$

Intuitively, each color is a problem or a request, and the problem may be solved in several ways, each way consisting in enumerating suitable colors quickly. (This might very well correspond to the positive fragment of some bounded-time temporal logic.) To simulate the parity condition, one can set $C := \mathbb{N}$ and $\mathcal{C}(2n) := \{\{k\} \mid k \in \mathbb{N}\}$ and $\mathcal{C}(2n+1) := \{\{2k\} \mid k \in \mathbb{N} \wedge k \leq n\}$ for all $n \in \mathbb{N}$. The corresponding $BRL_{\mathcal{C}}$ is the parity condition with bounded residual load.

Lemma 20 below says that however $\mathcal{C}$ may be instantiated, all Theorems 2, 3, 7, and 10 can be applied with the $BRL_{\mathcal{C}}$ winning condition.

▶ **Lemma 20.** *For every non-empty set* C *of colors and every function* $\mathcal{C} : C \to \mathcal{P}(\mathbb{N}^C)$*, the winning condition* $BRL_{\mathcal{C}}$ *is closed under prefix removal and interleaving, and factor-prefix complete.*

Even when $\mathcal{C}$ simulates the parity condition as above, none of the corresponding $F_{\mathcal{C}}$, $FCI_{\mathcal{C}}$, or $FF_{\mathcal{C}}$ is both closed under interleaving and factor-set complete. $FF_{\mathcal{C}}$ is not closed under interleaving: $FF_{\mathcal{C}}((01)^\omega)$ and $FF_{\mathcal{C}}((23)^\omega)$, but $\neg FF_{\mathcal{C}}(\boldsymbol{\gamma})$, where $\boldsymbol{\gamma} := (23)01(23)^2 01 \dots 01(23)^n 01 \dots$ can be obtained by interleaving $(01)^\omega$ and $(23)^\omega$. $FCI_{\mathcal{C}}$ is not factor set-complete: $FCI_{\mathcal{C}}(\boldsymbol{\gamma})$, where $\boldsymbol{\gamma} := 101^2 01^3 \dots 01^n 0 \dots$, but $\neg FCI_{\mathcal{C}}(1^\omega)$ altough factors of 1's occur with arbitrary length in $\boldsymbol{\gamma}$. $F_{\mathcal{C}}$ is neither: first, $F_{\mathcal{C}}((10)^\omega)$ and $F_{\mathcal{C}}(2^\omega)$, but $\neg F_{\mathcal{C}}(1 \cdot 2^\omega)$, altough $1 \cdot 2^\omega$ can be obtained by interleaving $(10)^\omega$ and 2^ω; second, as above for $FCI_{\mathcal{C}}$. Note that the window-parity condition [8],[5] is not closed under interleaving either, as again exemplified by $(01)^\omega$ and $(23)^\omega$.

Abstract

Low rank approximation of matrices is an important tool in machine learning. Given a data matrix, low rank approximation helps to find factors, patterns, and provides concise representations for the data. Research on low rank approximation usually focuses on real matrices. However, in many applications data are binary (categorical) rather than continuous. This leads to the problem of low rank approximation of binary matrices. Here we are given a $d \times n$ binary matrix $\mathbf{A}$ and a small integer $k < d$. The goal is to find two binary matrices $\mathbf{U}$ and $\mathbf{V}$ of sizes $d \times k$ and $k \times n$ respectively, so that the Frobenius norm of $\mathbf{A} - \mathbf{UV}$ is minimized. There are two models of this problem, depending on the definition of the dot product of binary vectors: The GF(2) model and the Boolean semiring model. Unlike low rank approximation of a real matrix which can be efficiently solved by Singular Value Decomposition, we show that approximation of a binary matrix is NP-hard, even for $k = 1$.

In this paper, our main concern is the problem of Column Subset Selection (CSS), in which the low rank matrix $\mathbf{U}$ must be formed by k columns of the data matrix, and we are interested in the approximation ratio achievable by CSS for binary matrices. For the GF(2) model, we show that CSS has approximation ratio bounded by $\frac{k}{2} + 1 + \frac{k}{2(2^k-1)}$ and this is asymptotically tight. For the Boolean model, it turns out that CSS is no longer sufficient to obtain a bound. We then develop a Generalized CSS (GCSS) procedure in which the columns of $\mathbf{U}$ are generated from Boolean formulas operating bitwise on selected columns of the data matrix. We show that the approximation ratio achieved by GCSS is bounded by $2^{k-1} + 1$, and argue that an exponential dependency on k is seems inherent.

1 Introduction

Low rank approximation of matrices is a classical problem. Given a matrix $\mathbf{A}$ of size $d \times n$, the goal is to find two low rank matrices $\mathbf{U}$ and $\mathbf{V}$, such that $\mathbf{UV}$ approximates $\mathbf{A}$. Formally, the problem is to solve the equation $\min_{\mathbf{U},\mathbf{V}} \|\mathbf{A} - \mathbf{UV}\|_F^2$, where the minimum is over all matrices $\mathbf{U}, \mathbf{V}$ of sizes $d \times k$ and $k \times n$ respectively. The parameter k, typically a small integer, is the desired rank. The error is measured in terms of the Frobenius norm $\|\cdot\|_F$.

In many applications, $\mathbf{A}$ is a *data matrix*: Each column of $\mathbf{A}$ is a d-dimensional data vector, and each row of $\mathbf{A}$ corresponds to an attribute. In the literature, low rank approximation of $\mathbf{A}$ is often called factor analysis or dimensionality reduction: the k columns of the matrix $\mathbf{U}$ are the *factors* or *basis vectors* of the low dimensional space, and each column of $\mathbf{V}$ contains the combination coefficients.

If $\mathbf{A}$, $\mathbf{U}$, $\mathbf{V}$ are real matrices, low rank approximation can be efficiently solved by Singular Value Decomposition (SVD). This problem has been studied for more than a century, and is known as Principal Component Analysis (PCA) [28], Karhunen-Loève Transform [30], to name a few.

In this paper we consider low rank approximation of binary matrices. The motivation is that in many applications data are binary (categorical) rather than continuous. Indeed, nearly half of the data sets in the UCI repository contains categorical features. In the binary case, we require that the data matrix $\mathbf{A}$ *as well as* the rank-k matrices $\mathbf{U}, \mathbf{V}$ are binary. There are two natural formulations of the binary low rank approximation problem, depending on the definition of vector dot product. One formulation will be referred to as the GF(2) model, in which the dot product of two binary vectors $\mathbf{u}, \mathbf{v}$ is defined as $\mathbf{u}^T\mathbf{v} := \oplus_i u_i v_i$. The other formulation will be referred to as the *Boolean* model, in which the dot product is defined as $\mathbf{u}^T\mathbf{v} := \bigvee_i (u_i \wedge v_i)$.

The Boolean model is usually called Boolean Factor Analysis (BFA). It has found numerous applications in machine learning and data mining including latent variable analysis, topic models, association rule mining, clustering, and database tiling [3, 33, 38, 40, 44]. The GF(2) model, while being less studied, has been applied to Independent Component Analysis (ICA) over string data, attracting attention from the signal processing community [25, 35, 48].

Despite of various applications and heuristic algorithms [19, 21, 31, 33], little is known from a theoretical point of view about the binary low rank approximation problem. In fact, previously the only known result is that for the very special case of $k = 1$ (where the GF(2) and the Boolean model are equivalent) there are 2-approximation algorithms (see Section 1.1).

In this paper, we provide the *first* theoretical results for the general binary low rank approximation problem, which is formally stated as follows. Given $\mathbf{A} \in \{0,1\}^{d\times n}$, solve

$$\min_{\mathbf{U}\in\{0,1\}^{d\times k},\mathbf{V}\in\{0,1\}^{k\times n}} \|\mathbf{A}-\mathbf{UV}\|_F^2. \tag{1}$$

where the matrix product $\mathbf{UV}$ is over GF(2) or the Boolean semiring respectively.

Before stating the results, let us first consider the differences between low rank approximation of real matrices and our GF(2) and Boolean models. First, the linear space over GF(2) has a very different structure from the Euclidean space. The dot product over GF(2) is not an inner product and does not induce a norm: there exists $\mathbf{a} \neq \mathbf{0}$ such that $\mathbf{a}^T\mathbf{a} = 0$ over GF(2). An immediate consequence is that for binary matrices of the GF(2) model, there is no Singular Value Decomposition (SVD), which is the basis for low rank approximation of real matrices. The Boolean model is even more different: As it is a semiring rather than a field, we do not even have a linear space (see below for details).

Thus the methodologies from the setting of real matrices do not carry over to the setting of binary matrices. In fact, we will show that finding the exact solution of (1) is NP-hard even for $k = 1$ (see Section 4). This result was obtained independently by Gillis and Vavasis [22].

Another well-studied approach for low rank approximation of matrices is Column Subset Selection (CSS) [20, 32]. The goal of CSS is to find a subset of k columns of $\mathbf{A}$ and form the low rank basis matrix so that the residual is as small as possible. An advantage of CSS is that the result is more interpretable than that of SVD. CSS has been extensively studied for low rank approximation of real matrices [1, 5, 6, 10, 11, 13–16, 24, 36, 43, 46, 47]. Below is a formal definition of CSS over real matrices.

▶ **Definition 1** (CSS for real matrices)**.** Given a matrix $\mathbf{A} \in \mathbb{R}^{d\times n}$ and a positive integer k, pick k columns of $\mathbf{A}$ forming a matrix $\mathbf{P}_A \in \mathbb{R}^{d\times k}$ such that the residual

$$\|\mathbf{A}-\mathbf{P}_A\mathbf{Q}\|_\xi$$

is minimized over all possible $\binom{n}{k}$ choices for the matrix $\mathbf{P}_A$. Here $\mathbf{Q}$ denotes the optimal matrix of size $k \times n$ given $\mathbf{P}_A$, which can be obtained by solving a least squares problem, and $\xi = 2$ or F denotes the spectral norm or Frobenius norm.

The central problem in CSS is to determine the best function $\phi(n, k)$ of n, k satisfying

$$\|\mathbf{A}-\mathbf{P}_A\mathbf{Q}\|_\xi^2 \leq \phi(k,n)\|\mathbf{A}-\mathbf{A}_k\|_\xi^2 \ , \tag{2}$$

where $\mathbf{A}_k$ denotes the best rank-k approximation to the matrix $\mathbf{A}$ as computed with SVD. Two classical results [14, 24] shows that for real matrices we have

$$\|\mathbf{A}-\mathbf{P}_A\mathbf{Q}\|_2^2 \leq (k(n-k)+1)\|\mathbf{A}-\mathbf{A}_k\|_2^2 \ , \tag{3}$$

$$\|\mathbf{A}-\mathbf{P}_A\mathbf{Q}\|_F^2 \leq (k+1)\|\mathbf{A}-\mathbf{A}_k\|_F^2 \ . \tag{4}$$

There is extensive work on developing efficient algorithms for CSS with approximation ratio close to the above bounds, possibly using more than k columns of $\mathbf{A}$. These include methods such as rank revealing QR [36], adaptive sampling [15], subspace sampling (leverage scores) [6, 16], efficient volume sampling [13], projection-cost preserving sketches [11] and greedy CSS [1].

In this work, we study the CSS problem for binary matrices over GF(2) and Boolean semiring respectively. We consider the central problem expressed by Eq. (2) and aiming to determine the best $\phi(k, n)$. We only consider the Frobenius norm, since the spectral norm does not exist in the GF(2) and Boolean models.

The difficulty of the CSS problem for GF(2) and Boolean semiring model is that all methods developed for CSS over real matrices rely on at least one of the following concepts which are intrinsic to the Euclidean space: SVD, volume of a simplex, Euclidean distance, orthogonal projection, and QR decomposition. However, none of these concept exists in the GF(2) or Boolean models.

In this paper, we develop new methods for the CSS problem for GF(2) and Boolean model respectively. For GF(2) model, we show that by picking the best k columns of $\mathbf{A}$ to form $\mathbf{P}_A$, we achieve the bound

$$\|\mathbf{A} - \mathbf{P}_A\mathbf{Q}\|_F^2 \leq \left(\frac{k}{2} + 1 + \frac{k}{2(2^k - 1)}\right) \|\mathbf{A} - \mathbf{A}_k\|_F^2,$$

where $\mathbf{A}_k = \mathbf{UV}$ is the optimal solution of (1). Moreover, we show that the ratio is asymptotically tight.

For Boolean model, it turns out that basic CSS is no longer sufficient for obtaining a bound, simply because the Boolean semiring is not a field. We instead propose a Generalized CSS (GCSS) procedure. In this GCSS framework, we select a larger number of columns of $\mathbf{A}$ and potential basis matrices $\mathbf{P}_A$ are generated from these using carefully designed Boolean formulas operating bitwise on the chosen columns of $\mathbf{A}$. We show that GCSS based on $(2^k - 1)$ columns of $\mathbf{A}$ achieves approximation ratio $(2^{k-1} + 1)$ relative to $\|\mathbf{A} - \mathbf{A}_k\|_F^2$. Moreover, we argue that the exponential dependence in k seems inherent with the Boolean model (see Section 3 for details).

Our work is a first step towards a good understanding of low rank approximation of matrices over GF(2) and the Boolean semiring. While our work gives approximation algorithms for low rank approximation for both the GF(2) and the Boolean model, our work is should mainly by viewed as existence results for (Generalized) CSS for binary matrices, parallel to the classical existence theorems [14, 24] for CSS of real matrices stated in Eq. (3) and (4). Moreover, as SVD does not apply to the GF(2) or Boolean model, CSS is so far the only method that obtains a low rank approximation for binary matrices with theoretical guarantees and deserves an in-depth study. Finally, it is an important future direction to develop efficient algorithms to achieve or approximately achieve the ratios obtained in this paper. We believe this requires new techniques futher exploiting the algebraic structure of GF(2) and the Boolean semiring.

The rest of this paper is organized as follows. In Section 1.1 we discuss existing results on low rank approximation of binary matrices. In Section 2 we present the information-theoretically optimal upper bound for the approximation ratio of CSS over GF(2). In Section 3 we propose the GCSS procedure and give the upper bound for the Boolean semiring model. In Section 4 we show that finding the exaction solution of the low rank binary matrix approximation problem is NP-hard even for $k = 1$. Finally we give our conclusion in Section 5.

1.1 Other Related Works

To the best of our knowledge, all known theoretical results on the low rank approximation problem are about the special case of rank-one, i.e., $k = 1$. In the rank-one case, one looks for binary vectors $\mathbf{u}$, $\mathbf{v}$ such that $\|\mathbf{A} - \mathbf{uv}^T\|_F$ is minimized, and the GF(2) and Boolean models are therefore equivalent.

Shen et al. [39] formulate the rank-one problem as an integer linear program and showed that solving its linear programming relaxation yields a 2-approximation algorithm. They also improved the efficiency by reducing the linear program to a max-flow problem using

a technique developed in [26]. Jiang et al. [29] observed that for the rank-one case, simply choosing the best column from $\mathbf{A}$ yields a 2-approximation algorithm.

In the GF(2) model, low rank approximation is related to the concept of matrix rigidity introduced by Valiant [45], as a method of proving lower bounds for linear circuits. For a matrix $\mathbf{A}$ over GF(2), the rigidity $R_{\mathbf{A}}(k)$ is the smallest number of entries of $\mathbf{A}$ that must be changed in order to bring its rank down to k. Thus for a $d \times n$ matrix $\mathbf{A}$, $R_{\mathbf{A}}(k)$ is *precisely* the minimum approximation error possible by a product of a $d \times k$ matrix $\mathbf{U}$ and a $k \times n$ matrix $\mathbf{V}$. By the results of Valiant, an $n \times n$ matrix $\mathbf{A}$ for which $R_{\mathbf{A}}(k) \geq n^{1+\varepsilon}$, for $k = O(n/\log\log n)$ and for some constant $\varepsilon > 0$ cannot be computed by a linear circuit of size $O(n)$ and depth $O(\log n)$. Such rigid matrices exists in abundance – the challenge is to come up with an explicit construction of a family of rigid matrices. For the low rank approximation problem we are however interested in the setting of $k \ll n$ and we are interested in algorithms rather than explicit matrices.

2 Column Subset Selection for Binary Matrices Over GF(2)

In this section we characterize the best possible approximation ratio of CSS in the GF(2) model. As mentioned in Section 1, the best approximation ratio of CSS for real matrices is $k+1$ under the Frobenius norm. This result is proved by the so-called volume sampling method [14]. Concretely, the volume sampling method randomly samples a set of k columns of $\mathbf{A}$ with probability proportional to the volume of the k-dimensional simplex formed by the k-columns along with the origin. Volume sampling generates an (expected) $k+1$ approximation ratio.

However, the GF(2) model does not have a notion of volume, since the dot product over GF(2) is not an inner product. Nevertheless, we develop a new approach and show the following bound.

▶ **Theorem 2.** *For any binary matrix* $\mathbf{A} \in \{0,1\}^{d\times n}$*, there exist* $\mathbf{P}_A \in \{0,1\}^{d\times k}$ *and* $\mathbf{Q} \in \{0,1\}^{k\times n}$*, where the columns of* $\mathbf{P}_A$ *are chosen from the columns of* $\mathbf{A}$*, such that*

$$\|\mathbf{A} - \mathbf{P}_A\mathbf{Q}\|_F^2 \leq \left(\frac{k}{2} + 1 + \frac{k}{2(2^k-1)}\right) \cdot \mathrm{OPT}_k,$$

where $\mathrm{OPT}_k := \|\mathbf{A} - \mathbf{A}_k\|_F^2$*, and* $\mathbf{A}_k = \mathbf{UV}$ *is the optimal solution of (1). Here all matrix operations are over* GF(2)*.*

Moreover, we show that the approximation ratio $\left(\frac{k}{2} + 1 + \frac{k}{2(2^k-1)}\right)$ is asymptotically tight.

▶ **Theorem 3.** *In the* GF(2) *model, for every* $k \geq 1$ *and every* $\epsilon > 0$*, there exists* $\mathbf{A}$ *such that*

$$\|\mathbf{A} - \mathbf{P}_A\mathbf{Q}\|_F^2 > \left(\frac{k}{2} + 1 + \frac{k}{2(2^k-1)} - \epsilon\right) \cdot \mathrm{OPT}_k,$$

for all $\mathbf{P}_A, \mathbf{Q}$*, where* $\mathbf{P}_A$ *are formed by* k *columns of* $\mathbf{A}$*.*

Below, we give a high level description of the proof of the theorems. Our method uses the structure of GF(2) and is different to the techniques developed for CSS of real matrices.

Consider the problem given by Eq. (1). Throughout this paper, we will call the matrix $\mathbf{U}$ the *basis matrix*, since its column vectors are the basis of the low dimensional space. Likewise we call the right matrix $\mathbf{V}$ the *coefficient matrix*, since its columns contain the linear combination coefficients. Let $\mathbf{U}$ and $\mathbf{V}$ be an optimal solution of Eq. (1), and let $\mathbf{u_1}, \ldots, \mathbf{u_k}$

be the k columns of $\mathbf{U}$. For each column $\mathbf{u}_i$ of the optimal basis matrix $\mathbf{U}$, consider its nearest neighbor among all the columns of $\mathbf{A}$. Let $\mathbf{a}_1, \ldots, \mathbf{a}_n$ be the n columns of $\mathbf{A}$, and denote by $\mathbf{a}_{(\mathbf{u}_i)}$ the nearest neighbor column of $\mathbf{u}_i$ in $\mathbf{A}$. Given an optimal basis matrix $\mathbf{U}$, we thus have a matrix $\mathbf{A}_{(\mathbf{U})} := (\mathbf{a}_{(\mathbf{u}_1)}, \ldots, \mathbf{a}_{(\mathbf{u}_k)})$, consisting of columns of $\mathbf{A}$. Note that the optimal solution of Eq.(1) is not unique. In fact, fixing an optimal basis matrix $\mathbf{U}$, for every matrix $\mathbf{B} = (\mathbf{b}_1, \ldots, \mathbf{b}_k)$, $\mathbf{b}_i \in \{0,1\}^k$, if the rank[3] of $\mathbf{B}$ is k over GF(2), then $(\mathbf{UB}, \mathbf{B}^{-1}\mathbf{V})$ must also be an optimal solution. Each optimal basis matrix $\mathbf{UB}$ induces a nearest neighbor matrix $\mathbf{A}_{(\mathbf{UB})}$. We will show that there must exist a rank k matrix $\mathbf{B}$ such that the induced nearest neighbor matrix $\mathbf{A}_{(\mathbf{UB})}$, which when used as basis matrix, achieves an approximation error at most $(\frac{k}{2} + 1 + \frac{k}{2(2^k-1)})$ times that of the optimal solution $(\mathbf{UB}, \mathbf{B}^{-1}\mathbf{V})$. Let $\mathrm{Err}(\mathbf{b}_1, \ldots, \mathbf{b}_k)$ be the approximation error associated with the basis matrix $\mathbf{A}_{(\mathbf{UB})}$ for $\mathbf{B} = (\mathbf{b}_1, \ldots, \mathbf{b}_k)$. Our goal is to bound the quantity

$$\min_{\mathbf{b}_1,\ldots,\mathbf{b}_k} \mathrm{Err}(\mathbf{b}_1, \ldots, \mathbf{b}_k) \ , \tag{5}$$

where $\mathbf{b}_i \in \{0,1\}^k$ for all $i \in [k]$.

Directly bounding Eq.(5) is prohibitive. The approach we take is to consider a sequence of $k+1$ error minimization problems. For the r-th ($0 \le r \le k$) minimization, we only optimize r vectors among $\mathbf{b}_1, \ldots, \mathbf{b}_k$ and keep the other $k-r$ vectors fixed. Given $\mathbf{b}_1, \ldots, \mathbf{b}_k$, let

$$\mathrm{Err}^{(0)}(\mathbf{b}_1, \ldots, \mathbf{b}_k) := \mathrm{Err}(\mathbf{b}_1, \ldots, \mathbf{b}_k), \tag{6}$$

$$\mathrm{Err}^{(r)}(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r}) := \min_{\mathbf{b}\in\{0,1\}^k} \mathrm{Err}^{(r-1)}(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r}, \mathbf{b}). \tag{7}$$

Note that $\mathrm{Err}^{(k)}()$ is exactly the quantity of Eq.(5).

Although the final goal is to bound the *ratio* between $\mathrm{Err}^{(k)}()$ and the error of the optimal solution of Eq.(1), we instead prove *additive* bounds for $\mathrm{Err}^{(r)}(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r})$ for all $0 \le r \le k$. To be more precise, letting OPT_k be the error of the optimal solution of Eq.(1), we will show that $\mathrm{Err}^{(r)}(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r})$ is bounded by OPT_k plus a term depending on r and $\mathbf{b}_1, \ldots, \mathbf{b}_{k-r}$ (Theorem 5). Then when $r = k$, this additive bound becomes a multiplicative bound with respect to OPT_k and gives the desired ratio. The reason for introducing $\mathrm{Err}^{(0)}, \ldots, \mathrm{Err}^{(k-1)}$ is that we make use of the relation between $\mathrm{Err}^{(r)}$ and $\mathrm{Err}^{(r-1)}$ to prove the bound. More precisely, is the additive bound proved by induction in r.

Although the relation of $\mathrm{Err}^{(r)}$ and $\mathrm{Err}^{(r-1)}$ is

$$\mathrm{Err}^{(r)}(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r}) = \min_{\mathbf{b}} \mathrm{Err}^{(r-1)}(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r}, \mathbf{b}),$$

directly optimizing $\mathbf{b}$ seems very difficult. Our approach is to use *weighted averaging*. Since for each $\mathbf{b} \in \{0,1\}^k$ it holds that,

$$\mathrm{Err}^{(r)}(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r}) \le \mathrm{Err}^{(r-1)}(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r}, \mathbf{b}),$$

we have that for any set of weights $w_{\mathbf{b}}$ such that $w_{\mathbf{b}} \ge 0$ and $\sum_{\mathbf{b}} w_{\mathbf{b}} = 1$,

$$\mathrm{Err}^{(r)}(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r}) \le \sum_{\mathbf{b}} w_{\mathbf{b}} \mathrm{Err}^{(r-1)}(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r}, \mathbf{b}).$$

We carefully choose the weights $w_{\mathbf{b}}$ to get a small upper bound. We perform weighted averaging in two layers. Consider the quotient space $\mathrm{GF}(2)^k/\mathrm{span}(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r})$ and the coset $[\mathbf{b}] := \mathbf{b} + \mathrm{span}(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r})$. In the first layer, we perform weighted averaging within

[3] Throughout this section, matrix inverse and matrix rank are all over GF(2).

each coset $[\mathbf{b}]$, and obtain a bound for $\mathrm{Err}^{(r)}$ depending on the coset. In the second layer we average over all cosets using another set of weights. We need different rules to set the weights in the two layers. Within a coset $[\mathbf{b}]$, we choose the weights as follows. Let $\mathbf{U}, \mathbf{V}$ be the already fixed optimal solution of Eq.(1). For each $\mathbf{c} \in [\mathbf{b}]$, let $n_{\mathbf{c}}$ denote the number of columns of $\mathbf{V}$ that are equal to $\mathbf{c}$. The weight we assign to $\mathbf{c}$ is proportional to $n_{\mathbf{c}}$. For the second layer, let

$$n_{[\mathbf{b}]} := \sum_{\mathbf{c} \in [\mathbf{b}]} n_{\mathbf{c}}$$

be the total number of columns of $\mathbf{V}$ that belong to the coset $[\mathbf{b}]$. We assign the weight to a coset $[\mathbf{b}]$ as follows. If

$$[\mathbf{b}] = \mathrm{span}(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r}),$$

then the weight is set to be zero. Otherwise, we assign the weight to $[\mathbf{b}]$ proportional to

$$\frac{n_{[\mathbf{b}]}}{\sum_{[\mathbf{b}]} n_{[\mathbf{b}]} - \lambda n_{[\mathbf{b}]}},$$

where λ is a constant depending on r. Combining the two layers of averaging we obtain the additive bound and that implies the desired approximation ratio. This finishes the description of the proof of Theorem 2.

The lower bound in Theorem 3 is proved by explicit construction. We construct a matrix which is approximately low rank in the sense that it is the product of two rank-k matrix plus a very sparse matrix. The key ingredient of the proof is the construction of the two rank-k matrices, which have special structures so that the approximation ratio of column subset selection cannot be smaller than $\frac{k}{2} + 1 + \frac{k}{2(2^k-1)}$ significantly.

The additive bounds are stated in Theorem 5, which is technical. Below we first describe the notions that will appear in Theorem 5. These notions will also be frequently used in the proof as well. For clarity, we list the notions in two tables.

▶ **Definition 4.** For $1 \le r \le k$ and linear independent vectors $\mathbf{b}_1, \ldots, \mathbf{b}_r$ in $\{0,1\}^k$:

Table 1 Definitions for vector spans.

Definition	Explanation
$\mathrm{span}^c(\mathbf{b}_1, \ldots, \mathbf{b}_r) := \{0,1\}^k \setminus \mathrm{span}(\mathbf{b}_1, \ldots, \mathbf{b}_r)$	Complement of $\mathrm{span}(\mathbf{b}_1, \ldots, \mathbf{b}_r)$.
$\mathrm{span}^{\setminus i}(\mathbf{b}_1, \ldots, \mathbf{b}_r) := \mathrm{span}(\mathbf{b}_1, \ldots, \mathbf{b}_{i-1}, \mathbf{b}_{i+1}, \ldots, \mathbf{b}_r)$	Span of all vectors except the ith.

Let $\mathbf{A}$ be the matrix to be approximated and $(\mathbf{U}, \mathbf{V})$ be a fixed optimal solution of the problem in Eq.(1). For $\mathbf{u} \in \{0,1\}^d$, $\mathbf{c} \in \{0,1\}^k$, and $\mathcal{X} \subset \{0,1\}^k$:

Table 2 Definitions for errors and nearest neighbors.

Definition	Explanation
$\mathbf{a}_{(\mathbf{u})}$	The nearest neighbor of $\mathbf{u}$ among the columns of $\mathbf{A}$ (If more than one nearest neighbor, choose one arbitrarily.)
$\mathcal{J}_{\mathbf{c}} := \{j \in [n] : \mathbf{V}_j = \mathbf{c}\}$	The set of columns of $\mathbf{V}$ that are equal to vector $\mathbf{c}$.
$n_{\mathbf{c}} := \lvert\mathcal{J}_{\mathbf{c}}\rvert$	The number of columns of $\mathbf{V}$ that are equal to $\mathbf{c}$.
$L_{\mathbf{c}} := \sum_{j \in \mathcal{J}_{\mathbf{c}}} \lvert\mathbf{a}_j - \mathbf{U}\mathbf{c}\rvert$	The total approximation error of those columns in $\mathcal{J}_{\mathbf{c}}$.
$N_{\mathcal{X}} := \sum_{\mathbf{c} \in \mathcal{X}} n_{\mathbf{c}}$	The total number of columns of $\mathbf{V}$ that belong to set $\mathcal{X}$.
$M_{\mathbf{c}} = \begin{cases} \frac{L_{\mathbf{c}}}{n_{\mathbf{c}}} & n_{\mathbf{c}} > 0 \\ d & n_{\mathbf{c}} = 0 \end{cases}$	Upper bound of the average error of the columns in $\mathcal{J}_{\mathbf{c}}$.

Now we can state the additive bounds.

▶ **Theorem 5.** *Let* $\mathbf{b}_1, \ldots, \mathbf{b}_k$ *be* k *linear independent vectors in* $\{0,1\}^k$*. Then for each* $0 \leq r \leq k$*,*

$$\mathrm{Err}^r(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r}) \leq \mathrm{OPT}_k + \lambda_r \cdot \sum_{\mathbf{c} \in \mathrm{span}^c(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r})} L_{\mathbf{c}} + \sum_{i=1}^{k-r} f_i(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r}) M_{\mathbf{b}_i}, \quad (8)$$

where $M_{\mathbf{b}_i}$ *has been defined in Definition 4, and*

$$\lambda_r = \begin{cases} 0 & r = 0 \\ \frac{r}{2}\left(1 + \frac{1}{2^r - 1}\right), & 1 \leq r \leq k \end{cases}$$

and

$$f_i(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r}) = N_{\mathcal{X}} + \frac{1}{2} N_{\mathcal{Y}}, \quad (9)$$

here $\mathcal{X} = \mathbf{b}_i + \mathrm{span}^{\setminus i}(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r})$*, and* $\mathcal{Y} = \mathrm{span}^c(\mathbf{b}_1, \ldots, \mathbf{b}_{k-r})$*.*

The formal proof of Theorem 5 is lengthy and can be found in the full version of the paper [12]. Theorem 2 follows from Theorem 5 immediately.

Proof of Theorem 2. Let $r = k$ in Theorem 5. Then the last term in the RHS of Eq.(8) vanishes. The second term in the RHS of Eq.(8) becomes $\lambda_k \cdot \sum_{\mathbf{c} \in \{0,1\}^k} L_{\mathbf{c}}$. Observe that

$$\sum_{\mathbf{c} \in \{0,1\}^k} L_{\mathbf{c}} = \mathrm{OPT}_k,$$

and

$$1 + \lambda_k = \frac{k}{2} + 1 + \frac{k}{2(2^k - 1)},$$

the theorem follows. ◀

3 Generalized CSS Over Boolean Semiring

It is not difficult to see that the method developed for GF(2) model in the previous section does not apply to the Boolean model, simply because the Boolean semiring does not have a field structure. It turns out that, somewhat surprisingly, CSS is not sufficient to yield a bound relative to the optimal low rank solution in the Boolean model.

Here, we propose a Generalized CSS (GCSS) procedure. In GCSS, instead of using the columns of $\mathbf{A}$ directly to form $\mathbf{P}_A$, we apply carefully designed Boolean formulas (bitwise) to a predefined number of columns of $\mathbf{A}$ to form $\mathbf{P}_A$.

To illustrate the ideas, we first give an informal high level description of GCSS. We can capture our GCSS by the following framework, which we denote as an *oblivious basis generation scheme with advice*. Let $f(k)$ and $g(k)$ be functions of k. An oblivious basis generation scheme with *advice size* $f(k)$ and *column dependence size* $g(k)$ operates as follows. Given as input an advice string $\mathbf{o} \in \{0,1\}^{f(k)}$ the scheme outputs k Boolean formulas $\Phi_1, \ldots, \Phi_k$ each of $g(k)$ bits. Given $g(k)$ columns $\mathbf{a}_{i_1}, \ldots, \mathbf{a}_{i_{g(k)}}$ of the matrix $\mathbf{A}$, the k basis vectors $\mathbf{u}_1, \ldots, \mathbf{u}_k$ of $\mathbf{P}_A$ are constructed as

$$\mathbf{u}_j = \Phi_j(\mathbf{a}_{i_1}, \ldots, \mathbf{a}_{i_{g(k)}}),$$

where the Boolean function Φ_j is applied *entry-wise*. From such a basis generation scheme we immediately obtain an approximation result by iterating over all possible selections of $g(k)$ columns of $\mathbf{A}$ as well as all possible advice strings $\mathbf{o} \in \{0,1\}^{f(k)}$. We stress that the amount of information about $\mathbf{A}$ that can be supplied to the algorithm using the advice string is *independent* of the actual size of $\mathbf{A}$. Our construction of GCSS will have column dependence size $2^k - 1$ and advice size $O(k2^k)$ in which we encode an *ordering* of the given $2^k - 1$ columns. This results in an approximation ratio of $2^{k-1} + 1$.

To give a precise description of GCSS, it is more convenient to use sets instead of vectors as the representation. For a column $\mathbf{a}_i$ of $\mathbf{A}$, let

$$\mathcal{A}_i := \{j \in [d] : (\mathbf{a}_i)_j = 1\},$$

i.e., $\mathbf{a}_i$ is the characteristic vector of $\mathcal{A}_i$. Similarly, for an optimal solution $(\mathbf{U}, \mathbf{V})$ of the Boolean low rank approximation problem, let

$$\mathcal{U}_i := \{j \in [d] : (\mathbf{u}_i)_j = 1\},$$

and

$$\mathcal{V}_i := \{j \in [k] : v_{ij} = 1\}.$$

Thus in this section we will always think of a column of $\mathbf{A}$, $\mathbf{U}$ or $\mathbf{V}$ as a set. Given a set $\mathcal{S} \subset [k]$, let

$$\mathcal{J}_\mathcal{S} := \{j \in [n] : \mathcal{V}_j = \mathcal{S}\},$$

and $n_\mathcal{S} := |\mathcal{J}_\mathcal{S}|$. Using these notions, the Boolean product of $\mathbf{U}$ and a vector which is the characteristic vector of $\mathcal{S}$ will be denoted by $\mathcal{U}_\mathcal{S} := \bigcup_{i\in\mathcal{S}} \mathcal{U}_i$. Abusing the notion slightly, we shall still use $\mathcal{U}_i$ instead of $\mathcal{U}_{\{i\}}$ from now on. Like in the previous section, the nearest neighbor column of $\mathcal{U}_\mathcal{S}$ in $\mathbf{A}$ is defined by $\mathbf{a}_{(\mathcal{U}_\mathcal{S})}$. As we use set representation in this section, for notational simplicity we let $\mathcal{D}_\mathcal{S} \subset [d]$ be the set corresponding to this nearest neighbor column $\mathbf{a}_{(\mathcal{U}_\mathcal{S})}$, i.e.,

$$\mathcal{D}_\mathcal{S} := \{i \in [d] : \mathbf{a}_{(\mathcal{U}_\mathcal{S})_i} = 1\}$$

We are going to construct a rank-k solution $\mathcal{B}_1, \ldots, \mathcal{B}_k$, where $\mathcal{B}_i \subset [d]$ is the set representation of the column of the basis matrix. Once the basis matrix is obtained, the coefficient matrix can be calculated in the same way as in the previous section. The concrete GCSS procedure is described in Algorithm 1.

Now we can state the main result of this section.

▶ **Theorem 6.** *GCSS (as described above) has approximation ratio 2^k relative to the optimal solution of (1) over Boolean semiring.*

We now give the very high level idea of the proof. Fix a bijection π that satisfies $n_{S_1} \leq \cdots \leq n_{S_{2^k-1}}$. By construction the set $\mathcal{D}_{S_\ell}$ is the best approximation to $\mathcal{U}_{\mathcal{S}_\ell}$ given by a column of $\mathbf{A}$. Ideally the sets $\mathcal{B}_1, \ldots, \mathcal{B}_k$ should be such that $\bigcup_{i\in S_\ell} \mathcal{B}_i$ is a comparable substitute for all ℓ. What we instead will be able to achieve is that for all $\ell \in [2^k - 1]$

$$\mathcal{U}_{\mathcal{S}_\ell} \triangle \left(\bigcup_{i\in S_\ell} \mathcal{B}_i \right) \subseteq \left(\bigcup_{\ell' \geq \ell} (\mathcal{U}_{\mathcal{S}_{\ell'}} \triangle \mathcal{D}_{\mathcal{S}_{\ell'}}) \right) \tag{10}$$

where as seen from the algorithm the sets $\mathcal{B}_i$ are Boolean combinations of the sets $\mathcal{D}_{\mathcal{S}_\ell}$. Intuitively, we give more importance to approximating the columns of $\mathbf{A}$ from $\mathcal{J}_{\mathcal{S}_\ell}$ as ℓ increases. As the sizes $n_{\mathcal{S}_\ell}$ of these sets of columns also increase this means that we can account for the extra cost of possible poor approximation of the sets $\mathcal{U}_{\mathcal{S}_\ell}$ for smaller ℓ in terms of the approximation error of the sets $\mathcal{D}_{\mathcal{S}_{\ell'}}$ to $\mathcal{U}_{\mathcal{S}_{\ell'}}$ for larger $\ell' \geq \ell$.

Intuitively we should attempt to approximate all the sets $\mathcal{D}_{\mathcal{S}_\ell}$ simultaneously by $\bigcup_{i\in\mathcal{S}_\ell} \mathcal{B}_i$. But since we work over a semiring we will have to work with under-approximations. So for every ℓ we instead approximate the under-approximation $\bigcup_{i\in\mathcal{S}_\ell} \mathcal{E}_i^\ell$ of $\mathcal{D}_{\mathcal{S}_\ell}$. We do this by initially letting $\mathcal{B}_i = \mathcal{E}_i^1$ and then for each $\ell \in [2^k - 1]$ adding $\left(\bigcup_{i\in\mathcal{S}_\ell} \mathcal{E}_i^\ell\right) \setminus \left(\bigcup_{i\in\mathcal{S}_\ell} \mathcal{E}_i^1\right)$ to $\bigcup_{i\in S_\ell} \mathcal{B}_i$. This last step has to be done carefully piece by piece using the ordering of the sets $\mathcal{S}_1, \ldots, \mathcal{S}_{2^k-1}$. In the algorithm this is done using the sets $\mathcal{F}_i^{\ell_1,\ell_2}$.

The approximation ratio of GCSS over the Boolean semiring is $O(2^k)$, and thus much larger than that of GF(2). However we shall argue that this exponential dependency on k is not an artifact of proof technique, it seems inherent to the model.

Let k be even and let $n = 2^{k/2}$. We define the $n \times n$ matrix $\mathbf{A} = (a_{\alpha,\beta})$ indexed by strings $\alpha, \beta \in \{0,1\}^{k/2}$ by $a_{\alpha,\beta} = 1$ if and only if $\alpha \neq \beta$. Thus $\mathbf{A}$ is just the negation of the $n \times n$ identity matrix. It is well-known that the Boolean rank of $\mathbf{A}$ is equal to k. In particular, we can write $\mathbf{A}$ as the Boolean product of $\mathbf{U}$ and $\mathbf{V}$, where the columns of $\mathbf{U}$ and the rows of $\mathbf{V}$ are indexed by pairs (i, b) where $i \in [k/2]$ and $b \in \{0, 1\}$ and entry $(\alpha, (i, b))$ of $\mathbf{U}$ is 1 if and only if $\alpha_i = b$ and entry $((i, b), \beta)$ of $\mathbf{V}$ is 1 if and only if $\beta_i \neq b$. We note that the columns of $\mathbf{U}$ can be written as Boolean formulas applied entry-wise to (all of) the columns of $\mathbf{A}$. Since we consider approximation algorithms with *multiplicative error*, when supplied with input A and k our algorithm is required to compute an *exact factorization* of $\mathbf{A}$ into $n \times k$ and $k \times n$ matrices $\mathbf{U}$ and $\mathbf{V}$. If the underlying basis generation algorithm receives, say, only half of the columns of $\mathbf{A}$ it does not seem possible to compute such a factorization. It therefore seems that column dependence size at least $2^{k/2-1}$ is necessary, which is about the square-root of the column dependence size of our algorithm.

▶ Remark. Using the technique of weighted averaging developed for the GF(2) model, we can actually improve the approximation ratio to $2^{k-1} + 1$. We omit the details of the proof.

The proof of Theorem 6 can be found in the full version of the paper [12].

4 Hardness of Low Rank Approximation of Binary Matrices

Prior to our work, the computational complexity of the low rank approximation problem was not fully understood. For the rank-1 case, Tan showed that the equivalent problem Maximum Edge Weight Biclique for $\{-1, 1\}$-matrices is NP-hard under *randomized* reductions [42]. In the case when the rank k is unrestricted (i.e. part of the input) deciding whether there exist $\mathbf{U}$ and $\mathbf{V}$ such that $\mathbf{A} = \mathbf{UV}$ in the Boolean semiring model is precisely the NP-complete Minimal Set Basis problem [41], and that immediately implies that the approximation problem is NP-hard to approximate within *any* factor, as noted by Miettinen et al. [34]. On the other hand, this does not imply hardness when $k \ll d, n$. Indeed, the Minimal Set Basis problem is fixed-parameter tractable with parameter k, by a simple kernelization algorithm [17]. Note also that in the GF(2) model, deciding the existence of $\mathbf{U}$ and $\mathbf{V}$ such that $\mathbf{A} = \mathbf{UV}$ is efficiently solvable using Gaussian elimination, regardless of the rank k being unrestricted.

In this section we show the rank-1 Binary Matrix Approximation problem is NP-hard under normal polynomial time reduction. We first define two related problems. Let H be a *complete* bipartite graph with edge weight, and let $\mathbf{W} = (w_{ij})$ be the $d \times n$ matrix consisting

of these edge weights. The Maximum Edge Weight Biclique problem is to find a biclique subgraph of H with maximizing total edge weight. As an optimization problem: maximize $\mathbf{x}^\mathsf{T}\mathbf{W}\mathbf{y}$, where $\mathbf{x} \in \{0,1\}^d$ and $\mathbf{y} \in \{0,1\}^n$. The Bipartite Max-Cut problem is to find a cut of the vertices of H maximum the total weight of the edges cut. As an optimization problem: maximize $\mathbf{x}^\mathsf{T}\mathbf{W}\mathbf{y}$, where $\mathbf{x} \in \{-1,1\}^d$ and $\mathbf{y} \in \{-1,1\}^n$. Note that these two problems differ only in the domain from which $\mathbf{x}$ and $\mathbf{y}$ are chosen.

Shen, Ji, and Ye [39] observed that the rank-1 Binary Matrix Approximation problem is equivalent to Maximum Edge Weight Biclique when all edge weights are chosen from $\{-1,1\}$. Namely, if $\mathbf{A}$ is a $d \times n$ Boolean matrix, $\mathbf{u} \in \{0,1\}^d$, and $\mathbf{v} \in \{0,1\}^n$, and let $\mathbf{J}_{d,n}$

denote the $d \times n$ all-1 matrix, we have

$$\begin{aligned}\|\mathbf{A} - \mathbf{u}\mathbf{v}^\mathsf{T}\|_F^2 &= \|\mathbf{A}\|_F^2 - 2\mathbf{u}^\mathsf{T}\mathbf{A}\mathbf{v} + \|\mathbf{u}\mathbf{v}^\mathsf{T}\|_F^2 \\ &= \|\mathbf{A}\|_F^2 - \mathbf{u}^\mathsf{T}(2\mathbf{A} - \mathbf{J}_{d,n})\mathbf{v}.\end{aligned}$$

Therefore, minimizing $\|\mathbf{A}-\mathbf{u}\mathbf{v}^\mathsf{T}\|_F^2$ is equivalent of maximizing $\mathbf{u}^\mathsf{T}(2\mathbf{A}-\mathbf{J}_{d,n})\mathbf{v}$. Also note that $(2\mathbf{A} - \mathbf{J}_{d,n})$ is a $\{-1,1\}$-matrix. Thus NP-hardness of Maximum Edge Weight Biclique with $\{-1,1\}$ edge weights implies NP-hardness of rank-1 Binary Matrix Approximation. To show the NP-hardness of Maximum Edge Weight Biclique, we consider reduction from the Bipartite Max-Cut problem.

Roth and Viswanathan showed that Bipartite Max-Cut is NP-hard even when all weights are chosen from the set $\{-1,1\}$ [37]. This is done by first showing NP-hardness when the weights are chosen from $\{-1,0,1\}$ and then reducing to the case of weights from $\{-1,1\}$.

Tan showed that Maximum Edge Weight Biclique is NP-hard [42] when weights are chosen from $\{-1,0,1\}$, and shows NP-hardness under randomized reductions when weights are chosen from $\{-1,1\}$. He leaves it as an open problem to obtain NP-hardness under normal polynomial time reductions. The complexity of this problem was also stated as an open problem by Amit [2]

The reduction from weights chosen from $\{-1,0,1\}$ to $\{-1,1\}$ by Roth and Viswanathan and by Tan is similar. The idea is to transform the $n \times n$ $\{-1,0,1\}$-weight matrix $\mathbf{W}$ into a new $nm \times nm$ $\{-1,1\}$-weight matrix $\mathbf{W}'$, where $\mathbf{W}'$ consists of $m \times m$ blocks corresponding to each entry of $\mathbf{W}$. A (-1)-entry is transformed into the all-(-1) $m \times m$ matrix, and similarly is a 1-entry transformed into the all 1 $m \times m$ matrix. But where Tan transforms a 0-entry to a *random* $m \times m$ $\{-1,1\}$-matrix, Roth and Viswanathan instead transforms a 0-entry into a $m \times m$ *Hadamard* matrix. We will show that this transformation into *Hadamard* matrix also work in the setting of the Maximum Edge Weight Biclique problem, thereby properly establishing its NP-hardness.

▶ **Theorem 7.** *The rank-*1 Binary Matrix Approximation *problem is* NP*-hard.*

We give a polynomial time many-one reduction from Maximum Edge Weight Biclique with weights from $\{-1,0,1\}$ to Maximum Edge Weight Biclique with weights from $\{0,1\}$, thereby showing the theorem. The proof is based on the following three lemmas.

The lemma below is an adaptation of [37, Lemma 4.2] from the $\{-1,1\}$ case to the $\{0,1\}$ case.

▶ **Lemma 8.** *Let* $\mathbf{W}$ *be an* $n \times n$ *matrix and let* $m \geq 1$*, and define* $\mathbf{W}' = \mathbf{W} \otimes \mathbf{J}_m$*, where* $\mathbf{J}_m := \mathbf{J}_{m,m}$*. Then*

$$\max_{\mathbf{u},\mathbf{v}} \mathbf{u}^\mathsf{T}\mathbf{W}'\mathbf{v} = m^2 \cdot \max_{\mathbf{x},\mathbf{y}} \mathbf{x}^\mathsf{T}\mathbf{W}\mathbf{y} \ ,$$

where $\mathbf{u},\mathbf{v} \in \{0,1\}^{mn}$ *and* $\mathbf{x},\mathbf{y} \in \{0,1\}^n$*, respectively. Furthermore, if* $\mathbf{x}$ *and* $\mathbf{y}$ *maximize* $\mathbf{x}^\mathsf{T}\mathbf{W}\mathbf{y}$*, then* $\mathbf{u} = \mathbf{x} \otimes \mathbf{1}_m$ *and* $\mathbf{v} = \mathbf{y} \otimes \mathbf{1}_m$ *maximize* $\mathbf{u}^\mathsf{T}\mathbf{W}'\mathbf{v}$*.*

Proof. Consider first $\mathbf{u} = \mathbf{x} \otimes \mathbf{1}_d$ and $\mathbf{v} = \mathbf{y} \otimes \mathbf{1}_m$. Then

$$\begin{aligned}\mathbf{u}^\mathsf{T}(\mathbf{W} \otimes \mathbf{J}_m)\mathbf{v} &= (\mathbf{x} \otimes \mathbf{1}_m)^\mathsf{T}(\mathbf{W} \otimes \mathbf{J}_m)(\mathbf{y} \otimes \mathbf{1}_m) \\ &= (\mathbf{x}^\mathsf{T}\mathbf{W}\mathbf{y}) \otimes (\mathbf{1}_m^\mathsf{T}\mathbf{J}_m\mathbf{1}_m) = m^2 \cdot (\mathbf{x}^\mathsf{T}\mathbf{W}\mathbf{y}) \ .\end{aligned}$$

Next, take $\mathbf{u}$ and $\mathbf{v}$ maximizing $\mathbf{u}^\mathsf{T}\mathbf{W}'\mathbf{v}$. We show that $\mathbf{u}$ and $\mathbf{v}$ can be brought to the form $\mathbf{u} = \mathbf{x} \otimes \mathbf{1}_m$ and $\mathbf{v} = \mathbf{y} \otimes \mathbf{1}_m$ without decreasing the value of $\mathbf{u}^\mathsf{T}\mathbf{W}'\mathbf{v}$. We first fix $\mathbf{v}$ and bring $\mathbf{u}$ to the desired form, and then similarly bring $\mathbf{v}$ to the desired form.

So fix $\mathbf{v}$, and let $\mathbf{z} = \mathbf{W}'\mathbf{v}$. Note that $\mathbf{u}$ maximizing $\mathbf{u}^\mathsf{T}\mathbf{z}$ must satisfy $\mathbf{u}_i = 1$ when $\mathbf{z}_i > 0$ and $\mathbf{u}_i = 0$ when $\mathbf{z}_i < 0$. Since $\mathbf{W}' = \mathbf{W} \otimes \mathbf{J}_m$ we have that $\mathbf{z}_{jm+1} = \mathbf{z}_{jm+2} = \cdots = \mathbf{z}_{(j+1)m}$ for all $j = 0, 1, \ldots, n-1$. Hence we can choose a maximizing $\mathbf{u}$ satisfying $\mathbf{u}_{jm+1} = \mathbf{u}_{jm+2} = \cdots = \mathbf{u}_{(j+1)m}$ for all $j = 0, 1, \ldots, n-1$ as well, meaning $\mathbf{u} = \mathbf{x} \otimes \mathbf{1}_m$ for suitable $\mathbf{x} \in \{0,1\}^n$. We can now fix $\mathbf{u}$ and in a similar way bring $\mathbf{v}$ to the form $\mathbf{v} = \mathbf{y} \otimes \mathbf{1}_m$ for suitable $\mathbf{y} \in \{0,1\}^n$. ◀

The following lemma, which is the $\{0,1\}$ analogue of [37, Lemma 4.3], is a direct consequence of Lindsey's Lemma. We state the proof for completeness.

▶ **Lemma 9.** *Let $\mathbf{H}$ be a $m \times m$ Hadamard matrix. For every $\mathbf{x}, \mathbf{y} \in \{0,1\}^m$, $|\mathbf{x}^\mathsf{T}\mathbf{H}\mathbf{y}| \leq m^{3/2}$.*

Proof. First note

$$\|\mathbf{H}\mathbf{y}\|^2 = \mathbf{y}^\mathsf{T}(\mathbf{H}^\mathsf{T}\mathbf{H})\mathbf{y} = \mathbf{y}^\mathsf{T}(m\mathbf{I})\mathbf{y} = m \cdot \|\mathbf{y}\|^2 \ .$$

We can then complete the proof by the Cauchy-Schwartz inequality,

$$|\mathbf{x}^\mathsf{T}\mathbf{H}\mathbf{y}| \leq \|\mathbf{x}^\mathsf{T}\| \cdot \|\mathbf{H}\mathbf{y}\| = \sqrt{m} \cdot \|\mathbf{x}\| \cdot \|\mathbf{y}\| \leq m^{3/2} \ . \qquad ◀$$

▶ **Lemma 10.** *Let $\mathbf{W} = (w_{ij})$ be a $n \times n$ $\{-1,0,1\}$-matrix and let $\mathbf{H}$ be a $m \times m$ Hadamard matrix. Define the $(mn) \times (mn)$ $\{-1,1\}$-block matrix $\widetilde{\mathbf{W}} = (\widetilde{\mathbf{W}}_{ij})$, where block $\widetilde{\mathbf{W}}_{ij}$ is given by*

$$\widetilde{\mathbf{W}}_{ij} = \begin{cases} w_{ij}\mathbf{J}_m & \text{if } w_{ij} \neq 0 \\ \mathbf{H} & \text{if } w_{ij} = 0 \end{cases} \ .$$

Let $\mathbf{W}' = \mathbf{W} \otimes \mathbf{J}_m$. Then for all $\mathbf{u}, \mathbf{v} \in \{0,1\}^{mn}$, $\left|\mathbf{u}^\mathsf{T}\widetilde{\mathbf{W}}\mathbf{v} - \mathbf{u}^\mathsf{T}\mathbf{W}'\mathbf{v}\right| \leq n^2 \cdot m^{3/2}$.

Proof. This is by simple estimation.

$$\begin{aligned} \left|\mathbf{u}^\mathsf{T}\widetilde{\mathbf{W}}\mathbf{v} - \mathbf{u}^\mathsf{T}\mathbf{W}'\mathbf{v}\right| &= \left|\mathbf{u}^\mathsf{T}(\widetilde{\mathbf{W}} - \mathbf{W}')\mathbf{v}\right| \\ &\leq n^2 \cdot \max_{\mathbf{x},\mathbf{y} \in \{0,1\}^m} \left|\mathbf{x}^\mathsf{T}\mathbf{H}\mathbf{y}\right| \\ &\leq n^2 \cdot m^{3/2} \ , \end{aligned}$$

where the last inequality follows from Lemma 9. ◀

Proof. of Theorem 7 Suppose now that $\mathbf{W}$ is an $n \times n$ $\{-1,0,1\}$-matrix. Let $m = 2^\ell$ be the smallest power of 2 that is greater than $4n^4$, and let $\mathbf{H}$ be the $m \times m$ Sylvester Hadamard matrix. We then define $\widetilde{\mathbf{W}}$ and $\mathbf{W}'$ as in Lemma 10. Then

$$\begin{aligned} &\left| \max_{\mathbf{u},\mathbf{v} \in \{0,1\}^{mn}} \mathbf{u}^\mathsf{T}\widetilde{\mathbf{W}}\mathbf{v} - m^2 \cdot \max_{\mathbf{x},\mathbf{y} \in \{0,1\}^n} \mathbf{x}^\mathsf{T}\mathbf{W}\mathbf{y} \right| \\ =& \left| \max_{\mathbf{u},\mathbf{v} \in \{0,1\}^{mn}} \mathbf{u}^\mathsf{T}\widetilde{\mathbf{W}}\mathbf{v} - \max_{\mathbf{u},\mathbf{v} \in \{0,1\}^{mn}} \mathbf{u}^\mathsf{T}\mathbf{W}'\mathbf{v} \right| \\ \leq& n^2 \cdot m^{3/2} \leq \frac{m^{1/2}}{2} \cdot m^{3/2} = \frac{m^2}{2} \ , \end{aligned}$$

where the first equality is by Lemma 8 and the first inequality is by Lemma 10.
Since the expression $m^2 \cdot \max_{\mathbf{x},\mathbf{y} \in \{0,1\}^n} \mathbf{x}^\mathsf{T}\mathbf{W}\mathbf{y}$ is an integer multiple of m^2, the value $\max_{\mathbf{u},\mathbf{v} \in \{0,1\}^{mn}} \mathbf{u}^\mathsf{T}\widetilde{\mathbf{W}}\mathbf{v}$ uniquely determines the value $\max_{\mathbf{x},\mathbf{y} \in \{0,1\}^n} \mathbf{x}^\mathsf{T}\mathbf{W}\mathbf{y}$. This then gives the desired reduction. ◀

5 Conclusion

We have studied Column Subset Section (CSS) for low rank binary matrix approximation. CSS is often used as an alternative approach of SVD for low rank approximation of real matrices, where the advantage of CSS is the interpretability of its results. For binary matrices, CSS is so far the only approach yielding theoretical guarantees, as solving the low rank problem exactly is NP-hard. We provide an upper bound on the approximation ratio of CSS for the GF(2) model and show the bound is tight. This is a complete characterization from an information-theoretic point of view. For the Boolean semiring model, we propose a Generalized CSS (GCSS) method, since CSS is not strong enough to yield a bound in this scenario. We also show an upper bound for GCSS.

CSS has been actively studied for nearly three decades and the first work can at least date back to [23], where it was called rank revealing QR in the numerical linear algebra community. The progress on CSS exhibits an interesting trajectory. Early results either gave bounds exponential in k or the running time of the algorithm is $O(n^k)$ [4, 7–9, 18, 27]. After efforts of many researches, there are now polynomial time algorithms that have polynomial bounds for the approximation ratio.

Our understanding of CSS for binary matrices is at the very beginning stage. It is an important problem for future work to develop efficient CSS algorithms that achieves or approximately achieves the bounds of this paper.

Abstract

An algorithm for computing optimal strategies in pushdown reachability games was given by Cachat. We show that the information tracked by this algorithm is too coarse and the strategies constructed are not necessarily optimal. We then show that the algorithm can be refined to recover optimality. Through a further non-trivial argument the refined algorithm can be run in 2EXPTIME by bounding the play-lengths tracked to those that are at most doubly exponential. This is optimal in the sense that there exists a game for which the optimal strategy requires a doubly exponential number of moves to reach a target configuration.

1 Introduction

Pushdown systems are popular models for program verification. They are equipped with an unbounded stack that can model the call stack of a procedural program. That is, the control flow of first-order recursive programs (such as C and Java programs) can be accurately modelled [10].

In a pushdown game, configurations of a pushdown system belong to one of two players (Elvis and the Anarchist). The player who owns a configuration chooses which configuration the game moves to next. In a reachability game, Elvis wins if he is able to force the play into a target configuration, while the Anarchist must prevent this from happening.

One may consider a reachability game to be a competition between a program (Elvis) and its environment (the Anarchist). The program is required to reach a good terminating configuration under all conditions presented by the (uncontrollable) environment. In this situation it is interesting to be able to determine the configurations from which Elvis is able to always win the game, and, moreover, the strategy he should employ. That is, how should

[1] Supported by the French National Research Agency (ANR), through the excellence program Bézout (ANR-10-LABX-58).
[2] Supported by EPSRC [EP/K009907/1].

the program behave in order to respond to the given inputs to ensure a correct execution. The problem of constructing a winning strategy for Elvis corresponds to synthesising a complete, correct program from a given program skeleton.

It is known that the players have *positional* winning strategies in a pushdown reachability game. That is a winning strategy needs only to have access to the current state of the game (as opposed to the entire history of play) [16]. A variety of methods are known for constructing winning strategies in pushdown reachability games [15, 4, 14, 12, 11, 8, 5]. One such method introduced by Cachat computes the *optimal* strategy [3]. That is, the strategy that will reach a target configuration in the fewest number of steps. Such a strategy has obvious applications in the synthesis of efficient programs.

Cachat's algorithm is based on the saturation technique. Saturation is a technique that, beginning from a finite automaton representing a set of configurations, repeatedly adds new transitions to the automaton. The goal is to expand the representation to include all configurations either reachable from, or that can reach, the initial set.

It was shown by Büchi that the set of configurations reachable from the initial configuration of a pushdown system form a regular language and hence can be represented by a finite state automaton [2]. While Büchi's procedure is exponential, Caucal showed that this problem can be solved in polynomial time [6]. The improved algorithm is a saturation process where transitions are incrementally added to a finite automaton. This technique was simplified and adapted to the model-checking setting by Bouajjani *et al.* in [1] and independently by Finkel *et al.* in [7]. In particular, it was shown that the set of predecessors of a regular set of target configurations is also regular. In the same work, the saturation method was shown to work for pushdown reachability games, though the complexity increases to EXPTIME, for which the problem is complete. Cachat builds on this algorithm by annotating each transition added to the finite automaton with a corresponding move in the pushdown game, as well as a weight indicating its "distance" from the target set.

Unfortunately, Cachat's algorithm contains a non-trivial error. In short, by keeping only a single weight per transition, Cachat loses important information about the cost of the different paths of execution through which the Anarchist may force play. This leads to the algorithm computing non-optimal weights for some choices of Elvis, meaning the recommended moves may no longer be optimal. In this work we present the following contributions:

- A counter-example showing how Cachat's algorithm may compute non-optimal strategies.
- A corrected saturation-based algorithm using weights that are fine-grained enough to compute optimal strategies precisely.

  Termination of this algorithm relies on well-quasi orders and we do not have an elementary bound on its runtime.
- A non-trivial proof that the above algorithm can be restricted to only include weights that are doubly exponential in size (whilst still computing optimal strategies). With such a restriction optimal strategies can be computed in 2EXPTIME.
- A matching lower bound giving a game in which Elvis's optimal strategy requires a doubly exponential number of moves to reach a target configuration.

We give preliminaries in Section 2 and the basic saturation algorithm in Section 3. Cachat's algorithm for optimal strategies appears in Section 4 along with our counter-example. We correct the algorithm in Section 5 with the complexity results in Section 6.

2 Preliminaries

2.1 Alternating Finite Automata

To analyse two player games we will make use of alternating finite automata to represent sets of configurations of a pushdown system. For convenience, we will often refer to alternating finite automata simply as automata.

▶ **Definition 2.1** (Alternating Automata). An *alternating automaton* is a tuple $\mathcal{A} = (\mathbb{S}, \Sigma, \mathcal{F}, \delta)$ where $\mathbb{S}$ is a finite set of states, Σ is a finite alphabet, $\mathcal{F} \subseteq \mathbb{S}$ is the set of accepting states, and $\delta \subseteq \mathbb{S} \times \Sigma \times 2^{\mathbb{S}}$ is a transition relation.

We write $s \xrightarrow{A} S$ for a transition (s, A, S) in δ. To simplify the presentation, we will assume that S is always non-empty. A run of an alternating automaton over $w = A_1 \dots A_\ell \in \Gamma^*$ is an unordered unranked tree of depth ℓ with nodes labelled by states in $\mathbb{S}$ and edges labelled by transitions in δ such that for each node η at depth $0 \leq i \leq \ell - 1$ labelled s there is a transition $\tau = s \xrightarrow{A_{i+1}} \{s_1, \dots, s_m\}$ and η has children $\eta_1, \dots, \eta_m$ labelled $s_1, \dots, s_m$ respectively and each edge (η, η_j) for all $1 \leq j \leq m$ is labelled by τ.

If the root of the run is labelled by s and the set of states appearing at the leaves of the run is S, we say that the run starts with s and ends in S. The run is accepting if $S \subseteq \mathcal{F}$. For a state s, the set $\mathcal{L}_s(\mathcal{A})$ contains all words over which there is an accepting run of $\mathcal{A}$ from s.

A branch in a run is a sequence of nodes $\eta_0 \cdots \eta_\ell$ with η_0 the root of the run, η_ℓ a leaf and for each $1 \leq i \leq \ell$, we have η_i is a child of η_{i-1}.

For a word $w \in \Sigma^*$, a state s and a set of states S, we write $\left[s \overset{w}{\underset{\mathcal{A}}{\Rightarrow}} S \right]$ for the set of all runs of $\mathcal{A}$ starting from s and ending precisely with S and $s \overset{w}{\underset{\mathcal{A}}{\Rightarrow}} S$ to denote the existence of a run of $\mathcal{A}$ over w starting from s and ending precisely in S.

2.2 Pushdown Reachability Games

A pushdown reachability game is played between two players on the configuration graph of a pushdown system. The owner of a configuration is indicated by its state and the set of target configurations is accepted by an alternating finite automaton.

▶ **Definition 2.2** (Pushdown Reachability Games). A two-player pushdown reachability game is a tuple $G = (\mathcal{Q}, \Gamma, \Delta, \mathcal{A})$ such that $\mathcal{Q}$ is a finite set of control states partitioned $\mathcal{Q} = \mathcal{Q}_E \uplus \mathcal{Q}_A$ into Elvis and the Anarchist states respectively, Γ is the finite stack alphabet, $\Delta \subseteq (\mathcal{Q} \times \Gamma) \times \left(\mathcal{Q} \times \Gamma^{\leq 2}\right)$ is the set of transitions, and $\mathcal{A}$ is an alternating finite automaton $(\mathbb{S}, \Gamma, \mathcal{F}, \delta)$ with $\mathcal{Q} \subseteq \mathbb{S}$.

We write $(q, A) \to (p, w)$ for the transition $((q, A), (p, w))$ in Δ. A configuration is a tuple (q, w) where q is a state in $\mathcal{Q}$ and w is a stack content in Γ^*. Let $\mathcal{C}_G$ be the set of configurations of G. In the configuration (q, Aw), it is possible to apply a transition $(q, A) \to (p, u)$ to go to the configuration (p, uw). A configuration (q, w) is final if the stack content w is accepted by $\mathcal{A}$ from the state q (*i.e.* $w \in \mathcal{L}_q(\mathcal{A})$).

A play of a pushdown game is a (possibly infinite) sequence $(q_0, w_0), (q_1, w_1), \dots$ where (q_0, w_0) is some starting configuration and (q_{i+1}, w_{i+1}) (if defined) is obtained from (q_i, w_i) via some transition $(q_i, A) \to (q_{i+1}, w) \in \Delta$. In the case where $q_i \in \mathcal{Q}_E$, it is Elvis who chooses the transition to apply, otherwise the Anarchist chooses the transition.

Elvis wins the game if there is some i such that (q_i, w_i) is final or if q_i belongs to the Anarchist and (q_i, w_i) does not have any successors. Otherwise, the Anarchist wins the play.

A strategy for Elvis is a partial function $\sigma : \mathcal{C}_G^* \to \Delta$ which may assign to each play $(q_0, w_0), \ldots, (q_\ell, w_\ell)$ with $q_\ell \in \mathcal{Q}_E$ a transition in Δ applicable to the configuration (q_ℓ, w_ℓ). A given play $(q_0, w_0), (q_1, w_1), \ldots$ is played according to σ if for all i such that $q_i \in \mathcal{Q}_E$ and (q_i, w_i) has a successor in the play, we have $\sigma((q_0, w_0), \ldots, (q_i, w_i)) = r$ and $(q_i, w_i) \to (q_{i+1}, w_{i+1})$ via transition r. A strategy is winning for Elvis from a configuration (q_0, w_0) if all maximal plays starting from (q_0, w_0) and according to σ are winning for Elvis. A strategy is called positional if its value only depends on the last configuration of the play. Hence a positional strategy is fully described by a mapping from the set of configurations belonging to Elvis to Δ. Winning strategies for the Anarchist are defined analogously.

The winning region W of a pushdown reachability game is the set of all configurations from which Elvis has a winning strategy.

It is well-known (see [9]) that $W = \mathrm{Pre}_G^*(\mathcal{A})$ defined as $\mathrm{Pre}_G^*(\mathcal{A}) = \bigcup_{i<\omega} \mathrm{Pre}_G^i(\mathcal{A})$ where

$$\begin{array}{rcl} \mathrm{Pre}_G^0(\mathcal{A}) & = & \{(q,w) \mid w \in \mathcal{L}_q(\mathcal{A})\} \\ \mathrm{Pre}_G^{i+1}(\mathcal{A}) & = & \mathrm{Pre}_G^i(\mathcal{A}) \cup \\ & & \{(q,w) \mid q \in \mathcal{Q}_E \wedge \exists\, (q,w) \to (q',w') \,.\, (q',w') \in \mathrm{Pre}_G^i(\mathcal{A})\} \cup \\ & & \{(q,w) \mid q \in \mathcal{Q}_A \wedge \forall\, (q,w) \to (q',w') \,.\, (q',w') \in \mathrm{Pre}_G^i(\mathcal{A})\} \,. \end{array}$$

The rank $\mathrm{rank}(p,w)$ of a configuration (p,w) in W is the smallest i such that $(p,w) \in \mathrm{Pre}_G^i(\mathcal{A})$. Intuitively the rank captures the distance for Elvis to a final configuration.

▶ **Definition 2.3** (Optimal Strategies)**.** A strategy for Elvis is optimal if, for plays ending in (p,w) in the winning region of Elvis, with $p \in \mathcal{Q}_E$, it prescribes a move to (p',w') that minimises $\mathrm{rank}(p',w')$ amongst all possible moves.

Optimal strategies are positional and winning from all configurations in W.

3 The Saturation Algorithm

In [1], Bouajjani et al. present an algorithm that given a pushdown reachability game $(\mathcal{Q}, \Gamma, \Delta, \mathcal{A})$ with an automaton $\mathcal{A} = (\mathbb{S}, \Gamma, \mathcal{F}, \delta)$, constructs a new automaton $\mathcal{B}$ accepting $\mathrm{Pre}_G^*(\mathcal{A})$. The requirements[3] on $\mathcal{A}$ are that no transition in δ goes back to a state in $\mathcal{Q}$. This is required to ensure that the invariants maintained by the algorithm hold initially.

The algorithm proceeds by adding transitions to $\mathcal{A}$ until no new transition can be added. The resulting automaton $\mathcal{B}$ accepts $\mathrm{Pre}_G^*(\mathcal{A})$. That is $w \in \mathcal{L}_q(\mathcal{B})$ iff $(q,w) \in \mathrm{Pre}_G^*(\mathcal{A})$.

The intuition of the algorithm can be seen as follows. Suppose q is a state of Elvis, there is a rule $(q,A) \to (p,w) \in \Delta$, and the configuration (p, ww') is accepted by the automaton by a run beginning with $p \overset{w}{\Rightarrow} S$. The configuration (q, Aw') should also be accepted since an application of the rule reaches (p, ww') from which a target configuration can be reached. Thus, a transition $q \xrightarrow{A} S$ is added, meaning (q, Aw') can now be accepted using the run we know exists over w' from S. For a move of the Anarchist we use alternation to gather together runs from all possible next configurations.

The algorithm constructs a finite sequence $(\mathcal{A}_i)_{i \in [0,N]}$ of automata. The automaton $\mathcal{A}_0$ is $\mathcal{A}$. Each $\mathcal{A}_i$ is of the form $(\mathbb{S}, \mathcal{F}, \delta_i)$, meaning that they only differ by their set of transitions. The construction guarantees that for all $i \in [0, N-1]$ we have $\delta_i \subseteq \delta_{i+1}$. It terminates when $\delta_{i+1} = \delta_i$. This occurs since the set of possible transitions is finite.

The set δ_{i+1} is obtained from δ_i as the smallest set of transitions such that

[3] This requirement is easily met by adding a copy of each state in $\mathcal{Q}$ if necessary.

1. $\delta_i \subseteq \delta_{i+1}$, and
2. for each $q \in \mathcal{Q}_E$, if $(q, A) \to (p, w) \in \Delta$ and $p \overset{w}{\underset{\mathcal{A}_i}{\Rightarrow}} S$, then $q \xrightarrow{A} S \in \delta_{i+1}$, and
3. for each $q \in \mathcal{Q}_A$ and $A \in \Gamma$ let

$$(q, A) \to (p_1, u_1), \ldots, (q, A) \to (p_n, u_n)$$

be all rules from (q, A) in Δ. For all sets $S_1, \ldots, S_n$ of states such that:

$$p_1 \overset{u_1}{\underset{\mathcal{A}_i}{\Rightarrow}} S_1, \ldots, p_n \overset{u_n}{\underset{\mathcal{A}_i}{\Rightarrow}} S_n \quad \text{we have} \quad q \xrightarrow{A} \bigcup_j S_j \in \delta_{i+1} \ .$$

One can prove that $(p, w) \in \mathrm{Pre}^*_G(\mathcal{A})$ iff $w \in \mathcal{L}_p(\mathcal{B})$ to obtain regularity of the winning region. Since an alternating automaton has at most exponentially many transitions in the number of states (and we do not add any new states), we have that $\mathcal{B}$ is constructible in EXPTIME.

4 Cachat's Algorithm

In Section 4.1, we describe Cachat's min-rank algorithm [3, 4]. This algorithm constructs a weighted alternating automaton which is used to associate to every accepted configuration a weight. We will see in Section 4.2 that this weight is an upper-bound on the rank of the configuration. In Section 4.3, we will show that contrary to Cachat's claim, it is not equal to the rank of the configuration and hence the associated strategy is not an optimal strategy.

4.1 Saturation Algorithm with Weights

Cachat's algorithm proceeds by annotating new transitions of the saturated automaton with two pieces of information: a weight in $\mathbb{N}$ and a rule of the pushdown system. Intuitively if a transition $q \xrightarrow{A} S$ is introduced by the saturation algorithm this means that, for every configuration (q, Aw), Elvis has a strategy to win without ever popping the A or to ensure that the A is popped and that the resulting state belongs to S. The weight of the transition is meant to capture the length of the longest play under an optimal strategy for Elvis. We will see that it is only an upper-bound on this length. The rule in the annotation is the one responsible for the introduction of the transition in the saturation algorithm.

Before presenting the algorithm, we need to define the weight of a run and of a set of runs when the transitions of the automaton are given weights by a function $\mathcal{W}$. The weight of a run ρ, denoted by $\mathcal{W}^*(\rho)$ is the maximum weight of a branch in the run where the weight of a branch is simply the sum of the weights of the transitions appearing in this branch. By convention, a run of depth 0 has weight 0.

For a word $w \in \Sigma^*$, a state s and a set of states S such that $s \overset{w}{\underset{\mathcal{A}}{\Rightarrow}} S$, we take:

$$\mathcal{W}^*(s \overset{w}{\underset{\mathcal{A}}{\Rightarrow}} S) = \min \left\{ \mathcal{W}^*(\rho) \mid \rho \in \left[s \overset{w}{\underset{\mathcal{A}}{\Rightarrow}} S \right] \right\}$$

The saturation function is updated to assign weights to new transitions based on the maximum weights of the runs it is based on. Formally a function α is defined which associates to each transition of the saturated automaton a tuple consisting of a weight and a rule of the pushdown system. For convenience, we use $\#$ to indicate the absence of an associated rule (for transitions of the initial automaton and moves of the Anarchist). Moreover, we denote by $\mathcal{W}$ the projection of α on the weight component.

Given some initial reachability target set represented by an automaton $\mathcal{A}_0 = \mathcal{A} = (\mathbb{S}, \Gamma, \delta_0, \mathcal{F})$, we initially define $\alpha(\tau) = (0, \#)$ for all $\tau \in \delta_0$.

The annotation function α is updated as new transitions are added. At each iteration, we define $\mathcal{A}_{i+1} = (\mathbb{S}, \Gamma, \delta_{i+1}, \mathcal{F})$ where δ_{i+1} is the smallest set of transitions such that

1. $\delta_i \subseteq \delta_{i+1}$, and
2. for each $q \in \mathcal{Q}_E$, if $r = (q, A) \to (p, w) \in \Delta$ and $p \overset{w}{\underset{\mathcal{A}_i}{\Longrightarrow}} S$ then $\tau = q \xrightarrow{A} S \in \delta_{i+1}$ and furthermore, we assign

$$\alpha(\tau) = \left(1 + \mathcal{W}^*\left(p \overset{w}{\underset{\mathcal{A}_i}{\Longrightarrow}} S\right), r\right) .$$

3. for each $q \in \mathcal{Q}_A$ and $A \in \Gamma$ let $(q, A) \to (p_1, u_1), \ldots, (q, A) \to (p_m, u_m)$ be all rules from (q, A) in Δ. For each set of runs $p_1 \overset{u_1}{\underset{\mathcal{A}_i}{\Longrightarrow}} S_1, \ldots, p_n \overset{u_m}{\underset{\mathcal{A}_i}{\Longrightarrow}} S_m$ we have $\tau = q \xrightarrow{A} \bigcup_j S_j \in \delta_{i+1}$ and furthermore, we assign

$$\alpha(\tau) = \left(1 + \max_{1 \leq j \leq m}\left(\mathcal{W}^*\left(p_j \overset{u_j}{\underset{\mathcal{A}_i}{\Longrightarrow}} S_j\right)\right), \#\right)$$

Cachat writes that the algorithm terminates when "no new transitions can be added". The formulation of the algorithm seems to indicate that the weights are final and that the algorithm terminates when all transitions have been added. It is possible to construct an example in which the weight of a transition would decrease from its initial value. It would be easy to adapt the algorithm to allow the weight of the transitions to decrease after their initial introduction but this would not fix the deeper problem pointed out in Section 4.3. In the case where there is only one player (*i.e.* all states belong to Elvis), it is possible to ensure the weight of transitions are final by adding transitions one by one: at each round the transition with the smallest possible weight is created [13, p. 63]. In the following, we will consider that the algorithms stops when the transition structure is stable (*i.e.* $\delta_{i+1} = \delta_i$) and that a transition τ is added to δ_{i+1} only if does not belong to δ_i.

4.2 Min-Rank Strategy

We now assume that $\mathcal{B}$ is the saturated automaton produced by the previous algorithm and that α is the corresponding annotation function. Recall $\mathcal{W}$ is the projection of α on the weight component.

First we remark that as the saturated automaton $\mathcal{B}$ is identical to the one obtained in the original saturation algorithm, $\mathcal{B}$ accepts the winning region of Elvis. Hence the weight of a configuration (q, w) in the winning region can be defined as the minimal weight for an accepting run for this configuration:

$$\mathcal{W}^*(q, w) = \min\left(\mathcal{W}^*\left(q \overset{w}{\underset{\mathcal{B}}{\Longrightarrow}} S\right) \mid S \subseteq \mathcal{F} \text{ and } q \overset{w}{\underset{\mathcal{B}}{\Longrightarrow}} S\right) .$$

Cachat defines what he calls the min-rank positional strategy for Elvis. In this strategy Elvis plays, at a configuration $(q, w) \in W$ (which he owns), the move corresponding to the rule annotating the first transition in any accepting run of $\mathcal{B}$ on w starting with p of minimal weight $\mathcal{W}^*(q, w)$. If the rule annotating the top-most transition is undefined then the configuration is final and no moves needs to be played.

As stated by Cachat, the move outputted by the strategy can be computed in time linear in the length of the input configuration and exponential in the size of the pushdown game (with an exponential precomputation in the size of the game). The algorithm consists in reading w from right to left while maintaining for each state q the weight of the minimal run

accepting the stack content from q. This information can be updated in $O(|\mathcal{B}|)$ upon reading a new stack symbol.

From the definition of the algorithm, it can be shown that for all configurations $(q, w) \in W$:

- if (q, w) is owned by the Anarchist, then for all configurations (q', w') with $(q, w) \to (q', w')$, we have $\mathcal{W}^*(q, w) > \mathcal{W}^*(q', w')$.
- if (q, w) is owned by Elvis, then for a configuration (q', w') prescribed by the min-rank positional strategy (if it exists) then $\mathcal{W}^*(q, w) > \mathcal{W}^*(q', w')$.

These properties allow the following properties of the min-rank strategy to be proved.

▶ **Theorem 4.1** ([3]). *The min-rank strategy is positional and winning from all configurations in Elvis's winning region.*

In [3], Cachat in addition claims that the min-rank strategy is optimal, which is not the case. The mistake lies in [3, Proposition 6] where Cachat's claims in that the weight of a configuration $(q, w) \in W$ is equal to the rank of this configuration. However, this turns out not to be true as we will see in the next section. Cachat's proof [4, p. 34] in fact shows that $\mathcal{W}^*(p, w)$ is an upper bound on $\text{rank}(p, w)$, but not the converse inequality.

▶ **Proposition 4.2** ([3]). *For any configuration $(q, w) \in \text{Pre}^*_G(\mathcal{A})$ we have $\text{rank}(q, w) \leq \mathcal{W}^*(q, w)$.*

From this, we can obtain the following corollary which we will need in the sequel.

▶ **Corollary 4.3** (Upper Bound). *Take a pushdown game $G = (\mathcal{Q}, \Gamma, \Delta, \mathcal{A})$ with an alternating automaton $\mathcal{A} = (\mathbb{S}, \Gamma, \mathcal{F}, \delta)$ and let $\mathcal{B}$ be the result of Cachat's saturation algorithm. For $C = 2^{|\mathcal{Q}|\cdot|\Gamma|\cdot 2^{|\mathbb{S}|}}$, we have:*

- *for all transitions $q \xrightarrow{A} S$ in $\mathcal{B}$, its weight is bounded by C, and*
- *for any configuration $(p, w) \in \text{Pre}^*_G(\mathcal{A})$ we have $\text{rank}(p, w) \leq C \cdot |w|$.*

Proof. At each iteration of the saturation, the weight of a new transition is at most $1 + 2k$ where k is the maximum weight appearing on a transition in the previous iteration. A direct induction shows that for all $i \geq 0$, the maximum weight of a transition in δ_i is at most $2^i - 1$. As there are at most as many iterations as there are possible transitions of the saturated automaton, after at most $|\mathcal{Q}| \cdot |\Gamma| \cdot 2^{|\mathbb{S}|}$ iterations, no new transitions will be added. It follows that the weight of a transition in the saturated automaton is at most $2^{|\mathcal{Q}|\cdot|\Gamma|\cdot 2^{|\mathbb{S}|}}$ which is the announced constant.

Now consider a configuration $(q, w) \in \text{Pre}^*_G(\mathcal{A})$. From Proposition 4.2, we know that $\text{rank}(q, w)$ is bounded by the weight of any accepting run of $\mathcal{B}$ on w starting from q. The cost of such a run is a most $C \cdot |w|$ which concludes. ◀

4.3 Non-optimality of the Min-Rank Strategy

We give a counter-example in which the weight of configurations are strictly greater than their rank. Then we adapt this counter-example into a game where the min-rank strategy is not optimal. The goal of our counter example is to introduce a transition $q \xrightarrow{A} \{r, s\}$ corresponding to a situation in the game where

- the cost of a play to r is low, but the play from r to a target configuration is long, and
- the cost of a play to s is high, but the play from s to a target configuration is short.

Our game has one control state p belonging to the Anarchist and all other states q, q', r, r', s, and f belong to Elvis. The goal is to reach a configuration $(f, \bot)$. We give the moves below,

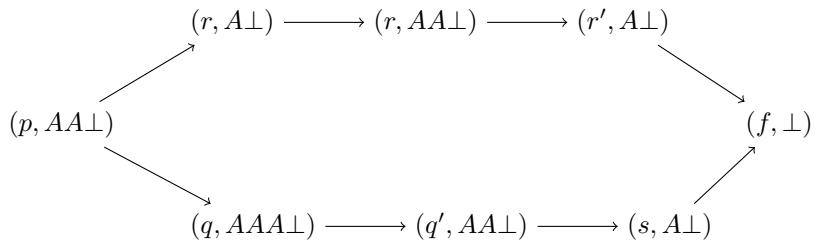

Figure 1 A game showing a counter example to the algorithm of Cachat.

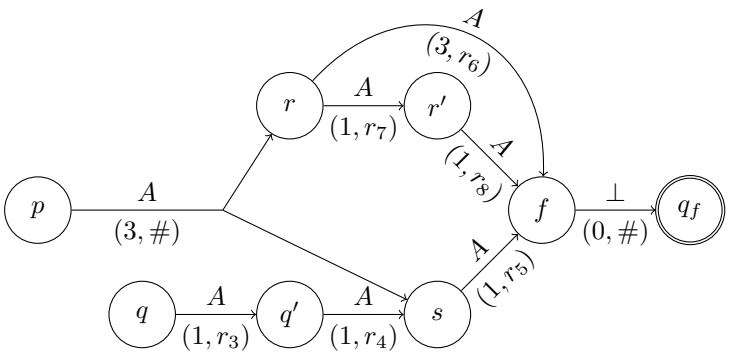

Figure 2 The saturated automaton.

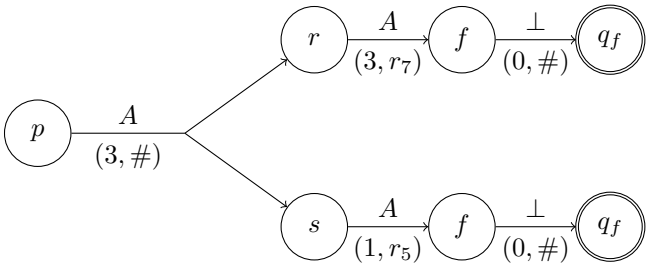

Figure 3 The accepting run of $(p, aa\bot)$.

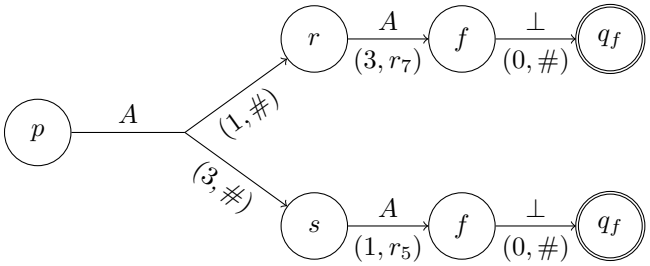

Figure 4 A run of $(p, aa\bot)$ with fine-grained weights.

and show in Figure 1 the game graph from $(p, AA\bot)$. No matter how the Anarchist plays, it will take four steps to reach $(f, \bot)$.

The moves available to the Anarchist are

$$r_1 = (p, A) \to (r, \varepsilon) \qquad \text{and} \qquad r_2 = (p, A) \to (q, AA)$$

and the remaining moves are available to Elvis and consist of

$$\begin{array}{lll} r_3 = (q, A) \to (q', \varepsilon) & r_4 = (q', A) \to (s, \varepsilon) & r_5 = (s, A) \to (f, \varepsilon) \\ r_6 = (r, A) \to (r, AA) & r_7 = (r, A) \to (r', \varepsilon) & r_8 = (r', A) \to (f, \varepsilon) \ . \end{array}$$

We start with $\mathcal{A}_0$ containing only the transition $f \xrightarrow[(0,\#)]{\bot} q_f$ where q_f is the only accepting state, and $(0, \#)$ is the annotation.

We then begin saturation. The pop rules r_3, r_4, r_5, r_7, and r_8 from states belonging to Elvis immediately lead to the introduction of new transitions. These can be seen in Figure 2 where the annotations show which rule lead to each new transition. The transitions from p and r are described below.

First, we can deal with the push at control state r using r_6. This leads to the introduction of a transition $r \xrightarrow[(3,r_6)]{A} f$ because of the run $r \xrightarrow[(1,r_7)]{A} r' \xrightarrow[(1,r_8)]{A} f$. Next, both rules from p need to be considered simultaneously. That is we introduce a transition $p \xrightarrow[(3,\#)]{A} \{r, s\}$ because of the rule r_1 which is a pop rule from p to r and r_2 and the run $q \xrightarrow[(1,r_3)]{A} q' \xrightarrow[(1,r_4)]{A} s$. No more transitions can be added. The result is shown in Figure 2. The alternating transition is shown with a split arrow.

Given this automaton, we consider the accepting run of $(p, AA\bot)$ shown in Figure 3. Note that the weight of this run is 6, but the longest run that the Anarchist can enforce is 4.

One can extend this to a full counter example to the optimality of Cachat's algorithm as follows. From an initial configuration $(p_0, AAA\bot)$ we give Elvis the choice of moving to $(p, AA\bot)$ via a pop, or to another configuration $(p_1, AA\bot)$ from which 5 steps are required to reach $(f, \bot)$. Since the rank of $(p, AA\bot)$ is estimated to be 6 rather than 4, the strategy will choose to move to $(p_1, AA\bot)$ rather than $(p, AA\bot)$, leading to a play that is not optimal.

To be more explicit, in the full counter example, the game has one control state p belonging to the Anarchist and all other states q, q', r, r', s, and f as well as p_0, p_1, p_2, p_3, p_4, and p_5 belong to Elvis. The goal is to reach a configuration $(f, \bot)$. The moves available to the Anarchist are as before

$$r_1 = (p, A) \to (r, \varepsilon) \qquad \text{and} \qquad r_2 = (p, A) \to (q, AA)$$

and the remaining moves are available to Elvis and consist of the previous rules

$$\begin{array}{lll} r_3 = (q, A) \to (q', \varepsilon) & r_4 = (q', A) \to (s, \varepsilon) & r_5 = (s, A) \to (f, \varepsilon) \\ r_6 = (r, A) \to (r, AA) & r_7 = (r, A) \to (r', \varepsilon) & r_8 = (r', A) \to (f, \varepsilon) \ . \end{array}$$

as well as

$$\begin{array}{lll} r_9 = (p_0, A) \to (p, \varepsilon) & r_{10} = (p_0, A) \to (p_1, \varepsilon) & r_{11} = (p_1, A) \to (p_2, A) \\ r_{12} = (p_2, A) \to (p_3, A) & r_{13} = (p_3, A) \to (p_4, A) & r_{14} = (p_4, A) \to (p_5, \varepsilon) \\ r_{15} = (p_5, A) \to (f, \varepsilon) \ . & & \end{array}$$

At $(p_0, AAA\bot)$ Elvis has two possible moves. The first is to $(p, AA\bot)$ which, as shown above, has a calculated rank of 6. The second is to $(p_1, AA\bot)$ which one can easily verify has a rank of 5. Thus, Cachat's strategy is to move to $(p_1, AA\bot)$ which is not optimal.

This overapproximation occurs because the information stored on the transition from p is too coarse. The weight of 3 comes from the weight of the run to s. The weight of the run to r is 1. Thus, if we were to store a weight for each control state we would obtain two weights on the transition from p. This would allow us to identify that the true cost of the run is 4. This can be seen in Figure 4 and is the basis of our corrected algorithm.

5 Computing Optimal Strategies

We refine Cachat's algorithm to compute optimal strategies in pushdown reachability games. The key idea is to replace simple annotations $\alpha\left(s \xrightarrow{A} S\right) = (d, r)$ with a more fine-grained version, which assigns a separate weight to each state in S. For this, we include annotations in the definition of a transition. That is, a transition is a tuple (s, A, S, D, r) where s is a state in $\mathbb{S}$, A is a character in Γ, $S \subseteq \mathbb{S}$, $D : S \mapsto \mathbb{N}$ is a weight function, and r is a rule of G. We write such transitions as $s \xrightarrow[D,r]{A} S$. As before, we calculate the weights of runs.

5.1 Profile of a run

In an automaton run ρ with annotated transitions, we define the weight of a branch inductively

$$\mathcal{W}^*(\eta_0) = 0 \quad \text{and} \quad \mathcal{W}^*(\eta_0 \cdots \eta_\ell) = D(s_1) + \mathcal{W}^*(\eta_1 \cdots \eta_\ell)$$

where D is the weight function the transition labeling (η_0, η_1) and s_1 is the state labeling η_1. We define a run profile.

▶ **Definition 5.1** (Profiles). Given a run ρ over a word w, the *profile* of ρ is given by $\mathbb{P}(\rho) = (S, D)$ where S is the set of states in $\mathbb{S}$ labelling leaves of ρ and $D : S \to \mathbb{N}$ is the function such that, for all $s \in S$, we have that $D(s)$ is the maximum weight of a branch from the root node to a leaf labelled s. Moreover, we define

$$(1 + D)(s) = 1 + D(s) \quad \text{and} \quad \max(D_1, \ldots, D_m)(s) = \max_{1 \le j \le m} (D_j(s)) \ .$$

Finally, given (S, D) and (S, D'), we write $D \le D'$ when for all $s \in S$ we have $D(s) \le D(s')$. By Dickson's Lemma, $\le$ is a well-quasi-ordering on the weights.

5.2 Saturation

We use the saturation algorithm with run profiles rather than Cachat's annotations. At each iteration, we set $\mathcal{A}_{i+1} = (\mathbb{S}, \Gamma, \delta_{i+1}, \mathcal{F})$ where δ_{i+1} is the smallest set of transitions with

1. $\delta_i \subseteq \delta_{i+1}$, and
2. for each $q \in \mathcal{Q}_E$, if $r = (q, A) \to (p, w) \in \Delta$ and ρ is a run of $\mathcal{A}_i$ over w from p with profile $\mathbb{P}(\rho) = (S, D)$ then

$$\tau = q \xrightarrow[1+D,r]{A} S \in \delta_{i+1} \ .$$

3. for each $q \in \mathcal{Q}_A$ and $A \in \Gamma$ let $(q, A) \to (p_1, u_1), \ldots, (q, A) \to (p_m, u_m)$ be all rules from (q, A) in Δ. For each set $\rho_1, \ldots, \rho_m$ of runs of $\mathcal{A}_i$ such that for each $1 \le j \le m$ the run ρ_j is a run over u_j with root note labelled s_j and profile (S_j, D_j), we have

$$\tau = q \xrightarrow[D',\#]{A} \bigcup_j S_j \in \delta_{i+1}$$

where $D' = 1 + \max(D_1, \ldots, D_m)$.

The algorithm terminates at the first i such that for all $s \xrightarrow[D,r]{A} S \in \delta_{i+1}$ there exists $s \xrightarrow[D',r']{A} S \in \delta_i$ with $D' \leq D$. Equivalently, the algorithm terminates when the set of transitions with a minimal weights stabilizes.

▶ **Lemma 5.2.** *The saturation algorithm terminates and computes* $\mathrm{Pre}^*_G(\mathcal{A})$.

Proof. We have $\mathrm{Pre}^*_G(\mathcal{A})$ from saturation without weights. We terminate as the set of possible transitions (without weight) is finite and $\leq$ is a well-quasi-ordering on the weights. ◀

5.3 Defined Strategy

We define our optimal strategy σ_O as follows. Let $\mathcal{A}'$ be the saturated automaton and let $\mathrm{AccRuns}(q,w)$ be the set of accepting runs of $\mathcal{A}'$ over w from q. We define

$$\mathcal{W}^*(q,w) = \min_{\rho \in \mathrm{AccRuns}(q,w)} \left(\max_{\substack{\mathbb{P}(\rho)=(S,D),\\ s\in S}} (D(s)) \right).$$

From each configuration (q,w) in the winning region of Elvis, if it is the move of Elvis, he plays the move which leads to the configuration (q',w') that minimises the value of $\mathcal{W}^*(q',w')$. In particular, let $q \xrightarrow[D,r]{A} S'$ be the first transition on a run with weight $\mathcal{W}^*(q,w)$. If it is Elvis's move, he should play the rule r. If $r = \#$, then either Elvis has already reached a target configuration or it is the Anarchist's move. Note, this strategy is non-deterministic since there may be multiple choices of minimal run. In order to define a strategy that is a function, we can fix an ordering on the moves of the game, and always choose the smallest. Note, moreover, that σ_O is positional.

▶ **Lemma 5.3.** *The strategy* σ_O *is an optimal winning strategy.*

6 Optimal Computation of Optimal Strategies

We show how to reduce the complexity to 2EXPTIME as well as give a lower bound example showing that a doubly exponential number of moves is optimal. For this we will first show that we can bound the value of the weights appearing in *minimal* transitions by a constant K which is doubly exponential in the size of the pushdown game. Then we will restrict the saturation to only consider transitions with weights at most K. Finally we will give a lower bound showing that the constant K needs to be doubly exponential.

6.1 Bounding Play Lengths

We show that there exists a constant K such that any point-wise minimal transitions has all its weights below K. For this we need a stronger result below.

▶ **Lemma 6.1.** *Let* $K = 2^{|\mathcal{Q}|\cdot|\mathbb{S}|\cdot|\Gamma|\cdot 2^{|\mathbb{S}|}+|\mathbb{S}|}$. *For all transitions* $q \xrightarrow[D,r]{A} S$ *such that for some* $s \in S$ *we have* $D(s) > K$ *then there exists a transition* $q \xrightarrow[D',r']{A} S$ *such that* $D' \leq D$ *and* $D'(s) \leq K$ *for all* $s \in S$.

The proof of Lemma 6.1 is non-trivial. To give the idea of the proof, we consider the case of a pushdown game whose target is the empty stack. Intuitively we proceed as follows.

Let C be the bound obtained in Corollary 4.3. Fix a transition $q \xrightarrow[D,r]{A} S$ of the saturated automaton. We consider the *reduced game*, which broadly corresponds to the game starting with (q, A) and where Elvis aims to empty the stack whilst reaching one of the control states in S. Let σ be a strategy for Elvis associated with the transition in the sense that it ensures that any play following σ and ending in $s \in S$ has length at most $D(s)$.

The simplest case is when $D(s) \geq C$ for all $s \in S$. Then we can find a transition by Cachat that improves on all points. Otherwise, there is at least one $D(s) < C$. We make a new strategy which plays according to σ for $D(s)$ moves. If we have not reached s in this time, we know that playing by σ will never reach s. In particular, there exists a strategy to reach $S \setminus \{s\}$. Moreover, we have increased the stack height by at most C. Thus, we know from Cachat that we can empty the stack and reach any state in $S \setminus \{s\}$ in $C \cdot C$ moves (that is at most C moves per stack character that needs to be removed). We repeat the above argument but this time remove some state s' with $D(s') < C^2$. We play until we are sure not to reach s', increasing the stack height by at most C^2. This means we can reach $S \setminus \{s, s'\}$ in $C \cdot (C + C^2)$ moves and so on. The existence of the strategy in turns implies the existence of a transition in the saturated automaton. In this way, we obtain the bound $K = 2^{|\mathbb{S}|} \cdot C^{|\mathbb{S}|}$.

▶ Remark. We know from Corollary 4.3 (Upper Bound) that there is a doubly exponential bound C on the weight of individual transitions. It is therefore tempting to consider this bound as a proof of the sufficiency of the saturation algorithm with shortcuts described in Section 6.2. However, the bound obtained from Cachat does not guarantee *a priori* that for every transition outside of the bound, there is a transition within the bound that is a pointwise improvement. For example, it is conceivable that Elvis may have two strategies for reaching either the state q_1 or q_2 from q whilst removing A from the stack. The first, corresponding to Cachat's bound, may give a play length of 2 whether the Anarchist forces play to q_1 or q_2. The second, which may violate Cachat's bound, may give a play length of 1 if the Anarchist forces play to q_1, but an extremely large play length (violating Cachat's bound) if the Anarchist forces play to q_2. Let's say this large play length is 100.

Now, consider a configuration (q, Aw). Suppose (q_1, w) requires 100 steps to reach a target configuration, and (q_2, w) is a target configuration. The strategy corresponding to the within-bounds transition has rank 102, whilst the strategy corresponding to the out-of-bounds transition has rank 101. Thus, we have not dismissed the need for out-of-bounds transitions.

6.2 Shortcutting Saturation

We adjust the saturation algorithm by insisting that a transition $s \xrightarrow[D,r]{A} S$ only appears in δ_{i+1} if for all $s \in S$ we have $D(s) \leq K$. Lemma 6.1 guarantees that the set of point-wise minimal transitions is not affected by this restriction.

With this restriction, the worst case running time of saturation becomes doubly exponential. The number of possible weight functions is $K^{|\mathbb{S}|}$ and hence the number of possible transitions is doubly exponential. Since at least one transition must be added during each step of the saturation, the algorithm must terminate in 2EXPTIME.

Like Cachat using a backward algorithm, the move for this strategy on (q, w) can be computed in time linear in the length of w and doubly exponential in the size of the pushdown game (assuming that the saturated automaton has been computed). We read w from right to left maintaining for each state s the value $\mathcal{W}^*(s, u)$ (if it exists) where u is the word read so far. This information can be updated in $\mathcal{O}(|\mathcal{B}|)$ upon reading a new letter and allows the first transition of an accepting run of minimal weight to be found.

6.3 Lower Bound

We give an example game where the shortest run to the target set is doubly exponential, hence showing that the bound K needs to be doubly exponential. The intuition is simple. First, suppose we wanted to force an exponential-length run. In this case we could store a binary number of n digits on the stack, with the least significant bit at the top. E.g. the number 3 would be encoded in a configuration $(q_0, 11000)$ when $n = 5$. To increment the number, we pop 1 characters from the stack until we find the first 0. We record in the control state how many pops are needed. In this case we need two pops and reach $(q_2, 000)$. Then, we replace the topmost 0 with a 1 and push 0s onto the stack until the height is n again. In our example, we reach $(q_0, 00100)$. The goal is to reach a stack with only 1 character, from a stack with only 0. This requires 2^n steps and can be done even in a single-player game.

To generate a doubly exponential run, we follow the same outline, but require the binary encoding to be exponentially long. We cannot use only the control states to enforce this length since it would require an exponential number of them. However, when rebuilding the stack during the increment, we can build a game which forces Elvis to construct a stack of at least exponential height. To do this, after changing the first 0 to 1 Elvis must push any number of 0 characters. Once he is done the Anarchist may accept that the stack is large enough, or challenge the height. To challenge the height we use the fact that the least common divisor of the first n prime numbers is exponential in n. Hence, the Anarchist can pick any of the first n primes, say p, and start a subgame with control states $q_0, \ldots, q_{p-1}$. From each of these control states q_i the only move is a pop to $q_{(i+1 \bmod p)}$. This sub-game is won only if q_0 is reached when the bottom of the stack is reached. Consequently, Elvis must have built the stack up to a multiple of the least common divisor of the first n primes. Note, Elvis may build a stack that is taller than the least common divisor, but this only makes reaching the target state harder.

7 Conclusion

We have studied optimal strategy construction for pushdown reachability games. Initial results due to Cachat [3] unfortunately were too coarse in their analysis and the claimed optimality is in fact an over-approximation. We showed that a refinement of Cachat's algorithm can be made to compute the optimal strategy accurately; however, the additional information required makes it difficult to obtain good complexity results. We gave a non-trivial argument that the algorithm can be refined further to obtain a 2EXPTIME algorithm. Moreover, the doubly exponential weights computed by the algorithm are optimal as demonstrated by a game where the winning strategy requires a doubly exponential number of moves to reach a target configuration.

Why are CSPs Based on Partition Schemes Computationally Hard?

Abstract

Many computational problems arising in, for instance, artificial intelligence can be realized as infinite-domain constraint satisfaction problems (CSPs) based on *partition schemes*: a set of pairwise disjoint binary relations (containing the equality relation) whose union spans the underlying domain and which is closed under converse. We first consider partition schemes that contain a strict partial order and where the constraint language contains all unions of the basic relations; such CSPs are frequently occurring in e.g. temporal and spatial reasoning. We identify three properties of such orders which, when combined, are sufficient to establish NP-hardness of the CSP. This result explains, in a uniform way, many existing hardness results from the literature. More importantly, this result enables us to prove that CSPs of this kind are not solvable in subexponential time unless the exponential-time hypothesis (ETH) fails. We continue by studying constraint languages based on partition schemes but where relations are built using disjunctions instead of unions; such CSPs appear naturally when analysing first-order definable constraint languages. We prove that such CSPs are NP-hard even in very restricted settings and that they are not solvable in subexponential time under the randomised ETH. In certain cases, we can additionally show that they cannot be solved in $O(c^n)$ time for any $c \geq 0$.

1 Introduction

The *constraint satisfaction problem* over a constraint language Γ (CSP(Γ)) is the decision problem of verifying whether a set of constraints based on the relations in Γ admits a satisfying assignment. For finite domains the complexity of CSP(Γ) is well understood due to the recent dichotomy theorem separating tractable from NP-complete problems [6, 30], but for infinite domains the situation differs markedly. This class of problems includes both undecidable problems and NP-intermediate problems, and it is therefore common to impose

additional assumptions on the allowed constraints. The predominant method has been to fix a constraint language Γ, usually satisfying certain model-theoretic properties, and analyse the complexity of CSPs over first-order reducts of Γ. Traditionally, this has also been the case for CSPs arising from artificial intelligence, e.g. temporal and spatial reasoning problems, albeit usually with weaker closure conditions.

Motivated by problems of this form, we study the complexity of infinite-domain CSPs over *partition schemes*. A partition scheme [20] is a set of pairwise disjoint binary relations $\mathcal{B}$ over a domain D such that $\bigcup_{R\in\mathcal{B}} R = D^2$ and which for every relation contains its converse. Partition schemes are the de facto standard for CSPs in the artificial intelligence community [8], due to their capability of modelling many different kinds of reasoning problems. Given a partition scheme, the predominant way of forming new relations is to allow unions of the relations in $\mathcal{B}$, and we let $\mathcal{B}^{\vee=}$ denote this set. We will also study languages where each relation can be defined as a disjunction of constraints from $\mathcal{B}$ of arity at most $k \geq 1$, and let $\mathcal{B}^{\vee k}$ denote this set. Note that $\mathcal{B}^{\vee=} \subseteq \mathcal{B}^{\vee k}$ for sufficiently large k but that $\mathcal{B}^{\vee k} \subseteq \mathcal{B}^{\vee=}$ does not necessarily hold for any $k > 1$. Languages of the form $\mathcal{B}^{\vee k}$ occur naturally in theoretical CSP research since such classification projects typically aim to understand the complexity of all first-order reducts of a base set $\mathcal{B}$ of relations.

Famous AI examples of formalisms based on partition schemes include *Allen's interval algebra*, the *region connection calculus*, and the *rectangle algebra*. For more examples, see e.g. the survey by Dylla et al. [9]. $\mathrm{CSP}(\mathcal{B}^{\vee=})$ problems have been proven to be NP-hard for many choices of $\mathcal{B}$. The proofs have utilised various reductions from various problems, but there has not been a clear explanation why the majority of them are NP-hard. We will try to obtain such an explanation in the sequel. Our first step (in Section 3) is to note that the majority of practically relevant partition schemes contain strict partial orders satisfying certain properties, which we in this paper refer to as *infinite height*, *in-forks*, and *out-forks*. In Section 4 we prove that these properties are sufficient to guarantee that $\mathrm{CSP}(\mathcal{B}^{\vee=})$ is NP-hard. It might be interesting to observe that we do not need any strong model-theoretic properties, e.g. ω-categoricity, which is otherwise common for infinite-domain CSPs. This result is also interesting to compare to the procedure by Renz and Li [25] which takes a partition scheme as input and tries to prove NP-hardness. One important distinction is that our result provides a concrete source of NP-hardness while the algorithm in Renz and Li gives no such insight. Moreover, this procedure is not complete, and is due to computational constraints not applicable to e.g. the rectangle algebra, while it is a straightforward task to prove that this algebra falls within the scope of our result. Hence, our study offers a more theoretical explanation of why so many naturally occurring CSPs over partition schemes are computationally hard.

Having identified a natural class of NP-hard CSPs based on partition schemes, we turn, in Section 4.2 and Section 5, to the problem of showing lower bounds for problems of this form. Traditionally, it is fair to say that such investigations have largely been neglected by both the artificial intelligence community and the CSP community. There are a few reasons for this. First, significant efforts have been made to solve hard reasoning problems with efficient heuristics [24], which are typically difficult to analyse rigorously even if they work well for certain real-world instances. Second, existing lower bounds are typically based on size-preserving reductions from SAT-like problems where one needs the ability to express disjunctive clauses, which is difficult to express with partition schemes. In fact, to the best of our knowledge, the only concrete lower bounds for a CSP over a partition scheme is the bound by Jonsson and Lagerkvist [16] which relates the complexity of Allen's interval algebra to the complexity of the Chromatic Number problem. We show that a

size-preserving reduction from a SAT-like problem, perhaps contrary to intuition, is possible for certain CSPs over partition schemes, using ideas from Opatrny [23]. More precisely we prove that $\mathrm{CSP}(\mathcal{B}^{\vee=})$ cannot be solved in subexponential time unless the *exponential-time hypothesis* is false. One way of interpreting this result is that $\mathrm{CSP}(\mathcal{B}^{\vee=})$ is far from being polynomial-time solvable: there is a constant $c > 1$ such that the problem cannot be solved in $O(c^n)$ time. An immediate consquence of lower bounds of this form is that we can immediately rule out certain kinds of algorithms for $\mathrm{CSP}(\mathcal{B}^{\vee=})$, e.g. algorithms based on graph-decomposition and k-consistency, which typically run in subexponential or polynomial time. It is of course tempting to strengthen our lower bound even further since the current best known algorithm for $\mathrm{CSP}(\mathcal{B}^{\vee=})$ for an arbitrary partition scheme $\mathcal{B}$ runs in $2^{O(n^2)}$ time, if $\mathrm{CSP}(\mathcal{B})$ is polynomial-time solvable [16, 27]. While we do not succeed in doing this, we can provide stronger lower bounds for $\mathrm{CSP}(\mathcal{B}^{\vee k})$: we prove that $\mathrm{CSP}(\{\prec\}^{\vee 4})$, where $\prec$ is a strict partial order of infinite height, is not solvable in $O(c^n)$ time for any $c \geq 0$ assuming the complexity theoretical assumption known as the *randomised exponential-time hypothesis* (r-ETH). We also show that $\mathrm{CSP}(\mathcal{B}^{\vee 2})$ cannot be solved in subexponential time if we assume the r-ETH and that a non-empty relation $R \subseteq \{(x, y, z) \in D^3 \mid x \neq y, x \neq z, y \neq z\}$ can be defined in $\mathcal{B}^{\vee 2}$. Note that we do not require $\mathcal{B}$ to contain any partial orders in this case. We conclude the paper with some discussion in Section 6, where we point out some future research directions concerning both lower and upper bounds.

2 Preliminaries

In this section we introduce the necessary prerequisites concerning constraint satisfaction problem, disjunctive relations, and partition schemes. We begin by defining the CSP problem when it is parameterized by a set of relations.

▶ **Definition 1.** Let Γ be a set of finitary relations over some set D of values. The *constraint satisfaction problem* over Γ ($\mathrm{CSP}(\Gamma)$) is defined as follows:

Instance: A set V of variables and a set C of *constraints* of the form $R(v_1, \ldots, v_k)$, where k is the arity of R, $v_1, \ldots, v_k \in V$ and $R \in \Gamma$.
Question: Is there a function $f : V \to D$ such that $(f(v_1), \ldots, f(v_k)) \in R$ for every $R(v_1, \ldots, v_k) \in C$?

The set Γ is called a *constraint language*. Given an instance I of $\mathrm{CSP}(\Gamma)$ we write $||I||$ for the number of bits required to represent I. We will occasionally encounter *bounded-degree* CSP instances. Let (V, C) denote an instance of $\mathrm{CSP}(\Gamma)$. If a variable x occurs in B constraints in C, then we say that the degree of x is B. We let $\mathrm{CSP}(\Gamma)$-B denote the $\mathrm{CSP}(\Gamma)$ problem where each variable in the input is restricted to have degree at most B. Note that if (V, C) is a $\mathrm{CSP}(\Gamma)$-B instance, then $|C| \leq B \cdot |V|$, implying that the number of constraints is linearly bounded with respect to the number of variables.

We continue by describing how to use disjunctions for combining relations.

▶ **Definition 2.** Let D be a set of values and let $\mathcal{B} = \{B_1, \ldots, B_m\}$ denote a finite set of relations over D, i.e. $B_i \subseteq D^j$ for some $j \geq 1$.

1. A *disjunctive formula* over $\mathcal{B}$ is of the form $B_1(\mathbf{x}_1) \vee \cdots \vee B_t(\mathbf{x}_t)$ where $\mathbf{x}_1, \ldots, \mathbf{x}_t$ are sequences of variables from $\{x_1, \ldots, x_p\}$ such that the length of $\mathbf{x}_j$ equals the arity of B_j, and $B_1, \ldots, B_t \in \mathcal{B}$. The arity of a disjunctive formula $B_1(\mathbf{x}_1) \vee \cdots \vee B_t(\mathbf{x}_t)$ is t.
2. $\mathcal{B}^{\vee k} = \{R \mid R \text{ is definable by a disjunctive formula over } \mathcal{B} \text{ of arity } l \leq k\}$.

For simplicity we represent relations in $\mathcal{B}^{\vee k}$ by their defining disjunctive formulas. Two syntactially distinct disjunctive formulas may now denote the same relation, implying that

Table 1 The thirteen basic relations in Allen's interval algebra. The endpoint relations $x^s < x^e$ and $y^s < y^e$ that are valid for all relations have been omitted.

Basic relation		Example	Endpoints
x precedes y	p	xxx yyy	$I^+ < J^-$
y preceded by x	p^{-1}		
x meets y	m	xxxx yyyy	$I^+ = J^-$
y met-by x	m^{-1}		
x overlaps y	o	xxxx yyyy	$I^- < J^- < I^+$, $I^+ < J^+$
y overl.-by x	o^{-1}		
x during y	d	xxx yyyyyyy	$I^- > J^-$, $I^+ < J^+$
y includes x	d^{-1}		
x starts y	s	xxx yyyyyyy	$I^- = J^-$, $I^+ < J^+$
y started by x	s^{-1}		
x finishes y	f	xxx yyyyyyy	$I^+ = J^+$, $I^- > J^-$
y finished by x	f^-1		
x equals y	$\equiv$	xxxx yyyy	$I^- = J^-$, $I^+ = J^+$

this representation is not unique. To avoid tedious technicalities we ignore this issue and whenever convenient view constraint languages as multisets.

We are now ready to introduce *partition schemes* [20]. Let $\mathcal{B} = \{B_1, \ldots, B_m\}$ be a set of binary relations over a domain D. We say that $\mathcal{B}$ is *jointly exhaustive* if $\bigcup \mathcal{B} = D^2$ and that $\mathcal{B}$ is *pairwise disjoint* if $B_i \cap B_j = \emptyset$ whenever $i \neq j$. We say that $\mathcal{B}$ is a *partition scheme* if (1) $\mathcal{B}$ is jointy exhaustive and pairwise disjoint, (2) $\mathsf{eq}_D = \{(x, x) \mid x \in D\} \in \mathcal{B}$, and (3) for every $B_i \in \mathcal{B}$, the converse relation $B_i^\smile$ (i.e. $B_i^\smile = \{(y, x) \mid (x, y) \in B_i\}$) is in $\mathcal{B}$. We define $\mathcal{B}^{\vee=}$ to be the set of all unions of relations from $\mathcal{B}$. Equivalently, each relation in $\mathcal{B}^{\vee=}$ can be viewed as a disjunction $B_1(x, y) \vee B_2(x, y) \vee \cdots \vee B_k(x, y)$ for some $\{B_1, \ldots, B_k\} \subseteq \mathcal{B}$. We sometimes abuse notation and write $(B_1, \ldots, B_k)$ to denote the relation $B_1 \cup \cdots \cup B_k$. The set $\mathcal{B}^{\vee=}$ and the problem $\mathrm{CSP}(\Gamma)$ where $\Gamma \subseteq \mathcal{B}^{\vee=}$ are typical objects that are studied in artificial intelligence literature. For example, it has been common to use a *relation algebra* $\mathcal{A}$ as a starting point and then define a *network satisfaction problem* over $\mathcal{A}$, which in our notation is nothing else than the CSP over a set of binary relations. Note that if $\mathrm{CSP}(\mathcal{B})$ is polynomial-time solvable, then both $\mathrm{CSP}(\mathcal{B}^{\vee k})$ and $\mathrm{CSP}(\mathcal{B}^{\vee=})$ are members of NP.

▶ **Example 3.** *Allen's interval algebra* [2] is a well-known formalism for temporal reasoning where one considers relations between intervals of the form $I = [I^+, I^-]$, where $I^+, I^- \in \mathbb{R}$ is the start and end point, respectively. In Allen's algebra one can for instance describe that one interval begins before another interval, and one express such relations in terms of a partition scheme consisting of 13 basic relations (see Table 1), and then form more complicated relations by taking the union of the basic relations. If we let $\mathcal{A}$ denote the set of 13 basic relations in Allen's algebra, then $\mathrm{CSP}(\mathcal{A}^{\vee=})$ is an alternative formulation of the network consistency problem over Allen's algebra.

An extension of the interval algebra is the so-called *rectangle algebra* [13, 22]. Here, one considers relations between rectangles in the plane by extending the basic relations in the interval algebra to the projections of a rectangle onto the x- and y-axis, respectively. In other words, given $r, s \in \mathcal{A}$ and two rectangles represented by the intervals I_x, I_y, J_x, J_y we may define the relation $r \oplus s$ in the rectangle algebra holding if $I_x(r)J_x$ and $I_y(s)J_y$.

3 Partial Orders

CSPs based on partition schemes are very often used for *qualitative reasoning*. We acknowledge that it is not obvious how to define "qualitative reasoning" rigorously, but the concept seems to have an informal meaning that is generally accepted. Renz and Nebel [27, p. 161] write

> Qualitative reasoning is an approach for dealing with commonsense knowledge without using numerical computation. Instead, one tries to represent knowledge using a limited vocabulary such as qualitative relationships between entities or qualitative categories of numerical values, ...

Abstraction is the defining feature of qualitative reasoning: qualitative reasoning is about disregarding unnecessary and uninteresting details. With this in mind, it is clear that an important kind of qualitative relationships between objects are "part-of" relations. One may argue that such relations are strict partial orders that satisfy certain additional properties. We will now define three properties of strict partial orders, *infinite height*, *in-fork*, and *out-fork*, that appear to be relevant in the pursuit of classifying the complexity of $\mathrm{CSP}(\mathcal{B}^{\vee=})$. A typical example of such a relation is the NTPP relation in RCC-8 – this can be viewed as an archetypical example of a "part-of" relation. Many other relations that are not "part-of" relations satisfy these properties, too: one example is the precedes relation p in Allen's algebra. In fact, relations of this kind appear very frequently in CSPs for qualitative reasoning.

Let $\prec \subseteq D^2$ denote a binary relation let $\succ$ denote its converse $\prec^{\smile}$. We say that $\prec$ is a *strict partial order* if there is no $d \in D$ such that $d \prec d$ (irreflexivity) and for arbitrary $d, d', d'' \in D$: $d \prec d'$ and $d' \prec d''$ imply $d \prec d''$ (transitivity). Note that these two properties also ensure that $\prec$ is antisymmetric, i.e. if $d \prec d'$, then $d' \prec d$ does not hold.

We will now define three additional properties of strict partial orders. First define $\sqcap = D^2 \setminus \bigcup\{\prec, \succ, \mathsf{eq}_D\}$, and note that $x \sqcap y$ holds if and only if x and y are incomparable with respect to $\prec$.

▶ **Definition 4.** Let $\prec \subseteq D^2$ be a strict partial order over a domain D. We define the following properties.

C1. (infinite height) for every $k \geq 1$, there exists a sequence of elements $d_1, d_2, \ldots, d_k$ in D such that $d_1 \prec d_2 \prec \cdots \prec d_k$,

C2. (in-fork) if $a, b, c \in D$ and $a \prec b \prec c$, then there exists $d_1 \in D$ such that $d_1 \sqcap a$, $d_1 \sqcap b$, and $d_1 \prec c$, and

C3. (out-fork) if $a, b, c \in D$ and $a \prec b \prec c$, then there exists $d_2 \in D$ such that $d_2 \succ a$, $d_2 \sqcap b$, and $d_2 \sqcap c$.

Partial orders satisfying these three properties are abundant in the artificial intelligence literature, but has to the best of our knowledge not been explicitly formalized before. The conditions in-fork and out-fork are illustrated in Figure 1. Given a binary relation $\prec$ it is typically easy to check if it is a strict partial order of infinite height, but checking if it also satisfies in-fork and out-fork may need additional work. Consider Allen's algebra and the relation p, i.e. the relation stating that one interval appears strictly before another interval. In this case, $\sqcap$ is the relation that holds if and only if two distinct intervals have at least one point in common. Pick three intervals $I_j = [I_j^-, I_j^+]$, $1 \leq j \leq 3$, such that $I_1(\mathsf{p})I_2(\mathsf{p})I_3$. For in-fork, we choose $I_4 = [I_1^-, I_2^+]$ so that $I_4 \sqcap I_1$, $I_4 \sqcap I_2$, and $I_4 \prec I_3$. For out-fork, one may choose $I_5 = [I_2^-, I_3^+]$.

Let us consider another example where the domain contains the closed disks in $\mathbb{R}^2$ and the relation $\prec$ is the strict subset relation. Pick three disks $d_1, d_2, d_3 \in D$ such that $d_1 \prec d_2 \prec d_3$. How to choose suitable disks for verifying in-fork and out-fork is illustrated in Figure 2. This

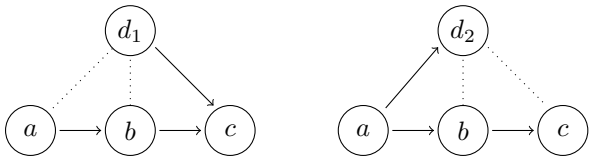

Figure 1 Illustration of in-fork (left) and out-fork (right). Arrows denote the $\prec$ relation and dotted lines the $\sqcap$ relation.

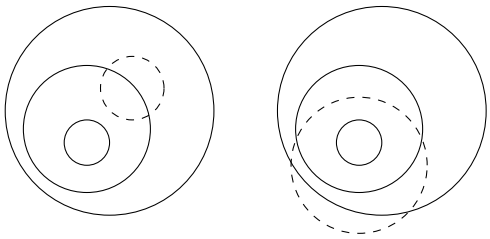

Figure 2 The dashed circles show possible choices of disks for in-fork (left) and out-fork (right).

example can easily be adapted to relations such as (PP) in RCC-5 and (NTPP) in RCC-8, and the relation $\mathsf{d} \oplus \mathsf{d}$ in the rectangle algebra. Many additional examples can be found in the survey by Dylla et al. [9], e.g. Goyal & Egenhofer's Cardinal Direction Calculus and Ragni & Scivos' Dependency Calculus. Last, let us remark that there are examples of strict partial orders that do not have in- or out-forks. Well-known examples are the less-than relation $<$ in the (1-dimensional) point algebra and in the branching time algebra. Interestingly, $\mathrm{CSP}(\mathcal{B}^{\vee=})$ is polynomial-time solvable in these two cases and we will come back to this observation at the end of Section 4.1.

4 Lower Bounds for $\mathrm{CSP}(\mathcal{B}^{\vee=})$

We will now study the computational complexity of $\mathrm{CSP}(\mathcal{B}^{\vee=})$ when $\mathcal{B}$ contains a strict partial order of infinite height with in- and out-forks. In Section 4.1, we prove that $\mathrm{CSP}(\mathcal{B}^{\vee=})$ is NP-hard and we use this result in Section 4.2 for proving that $\mathrm{CSP}(\mathcal{B}^{\vee=})$ cannot be solved in subexponential time (given that the ETH holds).

4.1 NP-hardness

NP-hardness of $\mathrm{CSP}(\mathcal{B}^{\vee=})$ for specific partition schemes $\mathcal{B}$ containing a strict partial order of infinite height with in- and out-forks has been proven many times in the literature. Examples where this connection is quite pronounced can be found in, for instance, Grigni et al. [12], Renz and Nebel [26], Moratz et al. [21], and Krokhin et al. [18] The basis for our reduction is the NP-complete problem Betweenness.

Instance: A finite set A and a collection T of ordered triples (a, b, c) of distinct elements from A.
Question: Is there a total ordering $<$ on A such that for each $(a, b, c) \in T$, we have either $a < b < c$ or $c < b < a$?

Our hardness result requires two steps that are presented in Lemma 5 and Theorem 6.

▶ **Lemma 5.** *Let $\mathcal{B}$ be a set of binary relations over a domain D containing a strict partial order $\prec$ of infinite height. Let $G(a, b, c, x_1, \ldots, x_m)$ be an instance (V, C) of CSP$(\mathcal{B}^{\vee=})$, where $V = \{a, b, c, x_1, \ldots, x_k\}$, and having the following properties.*

G1. *For arbitrary elements* $d_a, d_b, d_c \in D$ *such that* $d_a \prec d_b$ *and* $d_b \prec d_c$*, there exist elements* $d_1, \ldots, d_m \in D$ *such that the function* $s : V \to \{d_a, d_b, d_c, d_1, \ldots, d_m\}$ *defined by* $s(a) = d_a$*,* $s(b) = d_b$*,* $s(c) = d_c$*, and* $s(x_i) = d_i$*,* $1 \leq i \leq m$*, is a solution to the instance* $(V, C \cup \{a \prec b, b \prec c\})$*.*

G2. *For arbitrary elements* $d_a, d_b, d_c \in D$ *such that* $d_c \prec d_b$ *and* $d_b \prec d_a$*, there exist elements* $d_1, \ldots, d_m \in D$ *such that the function* $s : V \to \{d_a, d_b, d_c, d_1, \ldots, d_m\}$ *defined by* $s(a) = d_c$*,* $s(b) = d_b$*,* $s(c) = d_a$*, and* $s(x_i) = d_i$*,* $1 \leq i \leq m$*, is a solution to the instance* $(V, C \cup \{c \prec b, b \prec a\})$*.*

G3. $(V, C \cup \{b \prec a, b \prec c, a(\prec, \succ)c\})$ *is not satisfiable.*

G4. $(V, C \cup \{a \prec b, c \prec b, a(\prec, \succ)c\})$ *is not satisfiable.*

Let Γ *be the set of relations that appear in* G*. Then, CSP*$(\Gamma \cup \{\prec, \succ\})$ *is NP-hard.*

Proof. Let $\Gamma' = \Gamma \cup \{(\prec, \succ)\}$. We present a polynomial-time reduction from Betweenness to CSP(Γ'). Arbitrarily choose an instance (A, T) of Betweenness and construct an instance I of CSP(Γ') as follows:

1. for each pair of distinct elements $a, b \in A$, add the constraint $a(\prec, \succ)b$ to I, and
2. for each triple $(a, b, c) \in T$, introduce m fresh variables $x_1, \ldots, x_m$ and add $G(a, b, c, x_1, \ldots, x_m)$ to I.

We refer to the variables in I that correspond to the set A as basic variables and the other variables as auxiliary variables. We first assume that s is a solution to I. Let $S = \{s(a) \mid a \in A\}$. The constraints introduced in step (1) implies that the $|S| = |A|$ and the relation $\prec$ induces a total order on the set S. Assume to the contrary that there, for example, exists a triple $(a, b, c) \in T$ such that $s(b) \prec s(a) \prec s(c)$. Then, the instance $(V, C \cup \{b(\prec)a, b(\prec)c, a(\prec, \succ)c\})$ introduced in step (2) is satisfiable and this contradicts our assumptions. Analogously, we can rule out all orderings except $s(a) \prec s(b) \prec s(c)$ and $s(c) \prec s(b) \prec s(a)$. We conclude that there is a solution to the instance (A, T): for all $a, b \in A$, set $a < b$ if and only if $s(a) \prec s(b)$.

Assume now that there exists a solution $<$ to (A, T). We show how to construct a solution to the instance I. We rename the members of A such that $A = \{a_1, \ldots, a_n\}$ and $a_1 < a_2 < \cdots < a_n$. Arbitrarily choose elements $d_1, \ldots, d_n \in D$ such that $d_1 \prec d_2 \prec \cdots \prec d_n$. Such elements exist since $\prec$ is a strict partial order of infinite height. Let $s(a_i) = d_i$, $1 \leq i \leq n$, and note that s satisfies all constraints introduced in step 1.

Arbitrarily choose a triple $(a, b, c) \in T$ and consider the gadget $G(a, b, c, x_1, \ldots, x_k)$ that is introduced in step 2. If $a < b < c$, then $s(a) \prec s(b) \prec s(c)$ and $x_1, \ldots, x_k$ can be assigned values that satisfy the gadget by condition (1). If $c < b < a$, then $s(c) \prec s(b) \prec s(a)$ and $x_1, \ldots, x_k$ can be assigned values that satisfy the gadget by condition (2). Thus, for every triple $(a, b, c) \in T$, we can find values for the auxiliary variables that satisfy all G-gadgets. Note that two distinct G-gadgets do not have any auxiliary variables in common. We conclude that I is satisfiable. ◀

▶ **Theorem 6.** *Let* $\mathcal{B}$ *be a partition scheme with domain* D *containing a strict partial order* $\prec$ *of infinite height with in- and out-forks. Then CSP*$(\mathcal{B}^{\vee=})$ *is NP-hard.*

Proof. First observe that the relation $\sqcap = D^2 \setminus \bigcup\{\prec, \succ, \mathsf{eq}_D\}$ is a member of $\mathcal{B}^{\vee=}$ since $\mathcal{B}$ is a partition scheme. We will now define the following gadget: $G(a, b, c, x_1, x_2) = (\{a, b, c, x_1, x_2\}, \{x_1 \sqcap a, x_1 \sqcap b, x_1(\prec, \succ)c, x_2(\prec, \succ)a, x_2 \sqcap b, x_2 \sqcap c\})$. We demonstrate that G satisfies the preconditions of Lemma 5. We first consider the following condition:

C4. if $a \prec b \prec c$, then there does not exist $d_3 \in D$ such that $d_3 \sqcap a$, $d_3(\prec, \succ)b$, and $d_3 \sqcap c$.

We verify that C4 always holds under the assumptions stated in the theorem. Assume to the contrary that $a \prec b \prec c$ and $d_3 \in D$ satisfies $d_3 \sqcap a$, $d_3(\prec, \succ)b$, and $d_3 \sqcap c$. The relation $\prec$ is a strict partial order so it is transitive. If $d_3 \prec b$, then $d_3 \prec c$ and $d_3 \sqcap c$ cannot hold since the relations $\prec$ and $\sqcap$ are disjoint. Similarly, if $d_3 \succ b$, then $a \prec d_3$ and $d_3 \sqcap a$ cannot hold.

Next, we consider conditions G1 and G2 and show that they are satisfied: we see that proper assignments to variables x_1 and x_2 exist due to in-fork and out-fork. Assume to the contrary that G3 does not hold, i.e. $\{x_1 \sqcap a, x_1 \sqcap b, x_1(\prec, \succ)c, x_2(\prec, \succ)a, x_2 \sqcap b, x_2 \sqcap c\} \cup \{b(\prec)a, b(\prec)c, a(\prec, \succ)c\}$ is satisfiable. Under these constraints, two orderings of a, b, c are possible: $b \prec a \prec c$ and $b \prec c \prec a$. We consider the case $b \prec a \prec c$; the other case is analogous. Note now that $x_2 \sqcap b$, $x_2(\prec, \succ)a$, and $x_2 \sqcap c$. These constraints do not have a solution due to C4, and we conclude that G3 holds. That G4 holds can be shown analogously. The result then follows from Lemma 5. ◀

Hence, the properties in Definition 4 are sufficient for establishing NP-hardness of $\mathrm{CSP}(\mathcal{B}^{\vee=})$, and it is thus natural to ask to which extent they are also necessary. Although a complete answer seems difficult to obtain, we may at least observe that if $\prec \in \mathcal{B}$ is a strict partial order of finite height, then $\mathrm{CSP}(\mathcal{B}^{\vee=})$ is NP-hard, regardless of whether $\prec$ have in- and out-forks or not. This can be seen via a polynomial-time reduction from k-Colourability to $\mathrm{CSP}(\mathcal{B}^{\vee=})$ for some constant $k \geq 1$. Let (V, E) be an arbitrary undirected graph. Introduce variables $c_1, \ldots, c_k$ for each colour, and constrain them as $c_1(\prec)c_2(\prec)\ldots(\prec)c_k$. For each vertex $v \in V$, introduce a variable w and the constraints $w(\prec, \succ, \mathsf{eq}_D)c_i$, $1 \leq i \leq k$, and observe that $\succ, \mathsf{eq}_D \in \mathcal{B}$ since $\mathcal{B}$ is a partition scheme. Note that these constraints imply that w equals exactly one colour variable in any satisfying assignment. Finally, introduce the constraint $w(\prec, \succ)w'$ for each edge (v, v') in E. It is easy to verify that the resulting $\mathrm{CSP}(\mathcal{B}^{\vee=})$ instance has a solution if and only if (V, E) is k-colourable. It is also easy to verify that the reduction can be computed in polynomial time since k is a constant that only depends on the choice of $\mathcal{B}$. Since k-Colourability is NP-hard whenever $k \geq 3$, NP-hardness of $\mathrm{CSP}(\mathcal{B}^{\vee=})$ follows.

Similarly, it is natural to ask what happens if $\prec$ is a strict partial order of infinite height which does not have in- and/or out-forks. We have seen that this sometimes leads to tractability, as in the case of e.g. the point algebra and the branching time algebra, but this is not always the case. For a simple counter example, let $D = \{(0, i), (1, i), (2, i) \mid i \in \mathbb{N}\}$ and define $\prec \subseteq D^2$ such that $(a, b) \prec (c, d)$ if and only if $a = c$ and $b < d$. It is easy to verify that $\prec$ is a strict partial order of infinite height and that it does not have in- or out-forks. Let $\mathcal{B} = \{\prec, \succ, \sqcap, \mathsf{eq}_D\}$ where $\sqcap = D^2 \setminus \bigcup\{\prec, \succ, \mathsf{eq}_D\}$, and observe that $\mathcal{B}$ is a partition scheme. We show that $\mathrm{CSP}(\mathcal{B}^{\vee=})$ is an NP-hard problem via a polynomial-time reduction from 3-Colourability. Let (V, E) be an arbitrary undirected graph. For each vertex $v \in V$, introduce a variable w, and for each edge $(w, w') \in E$, introduce the constraint $w \sqcap w'$. Note that $((a, b), (c, d)) \in \sqcap$ if and only if $a \neq c$ and that a and c are restricted to the three-element set $\{0, 1, 2\}$. Given this, it is easy to verify that the resulting $\mathrm{CSP}(\mathcal{B}^{\vee=})$ instance has a solution if and only if (V, E) is 3-colourable.

4.2 ETH-based Lower Bound

Based on the results presented in the previous section, we will now show that $\mathrm{CSP}(\mathcal{B}^{\vee=})$ cannot be solved in subexponential time if $\mathcal{B}$ contains a strict partial order of infinite height with in- and out-forks, unless the exponential-time hypothesis (ETH) does not hold. If $\mathrm{CSP}(\Gamma)$ is solvable in $O(c^n)$ time by a deterministic algorithm for every $c > 1$ (where n denotes the number of variables) then $\mathrm{CSP}(\Gamma)$ is said to be *subexponential*. The exponential-time hypothesis is the conjecture that 3-SAT is not solvable in subexponential time [15].

The NP-hardness proof of BETWEENNESS by Opatrny [23] is based on a reduction from the RANK-3 HYPERGRAPH 2-COLOURABILITY problem. A *hypergraph* is a pair $H = (V, \mathcal{E})$ such that V is a non-empty finite set and $\mathcal{E}$ is a non-empty finite set of subsets of V. The elements of V are called the *nodes* of H and the elements of $\mathcal{E}$ are the *edges* of H. The *rank* of H is $\max\{|e| \mid e \in \mathcal{E}\}$, and the RANK-$k$ HYPERGRAPH 2-COLOURABILITY problem is defined as follows.

Instance: A rank-k hypergraph $H = (V, \mathcal{E})$.
Question: Do there exist sets $V_0, V_1 \subseteq V$ such that $V_0 \cap V_1 = \emptyset$ and $V_0 \cap e \neq \emptyset$, $V_1 \cap e \neq \emptyset$ for every $e \in \mathcal{E}$?

Define relations $R_1 = \{(0,1),(1,0)\}$ and $R_2 = \{0,1\}^3 \setminus \{(0,0,0),(1,1,1)\}$ and note that $\mathrm{CSP}(\{R_1, R_2\})$ is an obvious reformulation of the RANK-3 HYPERGRAPH 2-COLOURABILITY problem. Lemma 2 in Opatrny [23] immediately implies the following result.

▶ **Lemma 7.** *Let $I = (V, C)$ denote an arbitrary instance of CSP$(\{R_1, R_2\})$. It is possible to construct an instance (A, T) of the* BETWEENNESS *problem in polynomial time with the following properties.*

1. *I has a solution if and only if (A, T) has a solution,*
2. *$|A| \leq |V| + 1 + |C|$, and*
3. *$|T| \leq 2|C|$.*

▶ **Theorem 8.** *Assume the ETH holds. If $\mathcal{B}$ is a partition scheme such that $\prec \in \mathcal{B}$ and $\prec$ is a strict partial order of infinite height with in- and out-forks, then CSP$(\mathcal{B}^{\vee=})$ is not solvable in subexponential time.*

Proof. Results by Jonsson et al. [17] imply that $\mathrm{CSP}(\{R_1, R_2\})$-$B$ cannot be solved in subexponential time for some $B \geq 1$. Let $I = (V, C)$ denote an arbitrary instance of $\mathrm{CSP}(\{R_1, R_2\})$-$B$. Recall that $|C| \leq B \cdot |V|$ since each variable can occur in at most B constraints. Lemma 7 shows that we can (in polynomial time) construct an instance (A, T) of BETWEENNESS such that

1. I has a solution if and only if (A, T) has a solution,
2. $|A| \leq K \cdot |V|$, and
3. $|T| \leq L \cdot |C| \leq L \cdot B \cdot |V|$.

for some universal constants K, L. Lemma 5 combined with the standard gadget shows that we can (in polynomial time) construct an instance $I' = (V', C')$ of $\mathrm{CSP}(\mathcal{B}^{\vee=})$ such that

1. I' has a solution if and only if (A, T) has a solution and
2. $|V'| \leq |A| + 2|T|$.

Note that $|V'| \leq |A| + 2|T| \leq K|V| + 2L|C| \leq K|V| + 2LB|V| = (K + 2LB)|V|$. If $\mathrm{CSP}(\mathcal{B}^{\vee=})$ is solvable in subexponential time, then $\mathrm{CSP}(\{R_1, R_2\})$-$B$ is solvable in subexponential time, too, and this leads to a contradiction. ◀

In summary, we may rule out subexponential time algorithms for $\mathrm{CSP}(\mathcal{B}^{\vee=})$ for partition schemes $\mathcal{B}$ containing a strict partial order of infinite height with in- and out-forks. However, the best general algorithm for $\mathrm{CSP}(\mathcal{B}^{\vee=})$ runs in $O(2^{O(n^2)})$ time (if $\mathrm{CSP}(\mathcal{B})$ is tractable) [16, 27]. Hence, there is a large discrepancy between the upper and lower bound for this problem, suggesting that (at least) one of these bounds can be strengthened.

5 Lower Bounds for CSP($\mathcal{B}^{\vee k}$)

In this section, we will make use of the randomised version of ETH, and need a few additional definitions. First, let $\Gamma_{d,k}$, $d, k \geq 1$, denote the set of relations with arity at most k over the domain $\{1, \ldots, d\}$. A CSP algorithm A is said to be a $2^{c \cdot n}$-randomised algorithm if its running time is bounded by $2^{c \cdot n} \cdot poly(||I||)$ (where n is the number of variables) and its error probability is at most $1/3$. Let $c_{d,k} = \inf\{c \mid \exists\ 2^{c \cdot n}\text{-randomised algorithm for CSP}(\Gamma_{d,k})\}$. The variant of the ETH that we will use in the forthcoming lower bound states that $c_{2,3} > 0$, i.e., 3-SAT cannot be solved in subexponential time even if we are allowed to use randomised algorithms. We let r-ETH denote this hypothesis. Traxler [29] has shown the following result.

▶ **Theorem 9.** *If r-ETH holds, then there exists a universal constant $\alpha > 0$ such that for all $d \geq 3$, $\alpha \cdot \log(d) \leq c_{d,2}$.*

We begin by proving a result for $\mathcal{B}^{\vee 2}$ that is analogous to Theorems 6 and 8. Let $\mathcal{B}$ be a partition scheme over a domain D. Assume that $\mathcal{B}$ admits a gadget that forces three variables to be assigned distinct values, i.e., it is possible to define a non-empty ternary relation R such that $R \subseteq \{(x, y, z) \in D^3 \mid x \neq y, x \neq z, y \neq z\}$. This gadget can be defined for all examples considered in this paper, and in particular it can be defined by any strict partial order relating at least three elements (via $R(x, y, z) \equiv x \prec y \prec z$). Let $S(x, y, z) \equiv \mathsf{eq}_D(x, y) \vee \mathsf{eq}_D(x, z)$. Note that the relation S is a member of $\mathcal{B}^{\vee 2}$ since $\mathcal{B}$ is a partition scheme.

▶ **Theorem 10.** *Assume that $\mathcal{B}$ is a partition scheme admitting a gadget as described above. Then, CSP($\mathcal{B}^{\vee 2}$) is NP-hard, and if the r-ETH holds, there is no $2^{\frac{c_{3,2}}{5} \cdot n}$-randomised algorithm for CSP($\mathcal{B}^{\vee 2}$).*

Proof. We present a polynomial-time reduction from CSP($\Gamma_{3,2}$) to CSP($\mathcal{B}^{\vee 2}$). If the given CSP($\Gamma_{3,2}$) instance contains n variables, then the CSP($\mathcal{B}^{\vee 2}$) instance will contain at most $5n + K$ variables where K is a constant. By Theorem 9, CSP($\Gamma_{3,2}$) cannot be solved in $2^{c_{3,2} n}$ time, so CSP($\mathcal{B}^{\vee 2}$) cannot be solved in $2^{\frac{c_{3,2}}{5} n}$ time.

Let (V, C) be an arbitrary instance of CSP($\Gamma_{3,2}$) where $V = \{x_1, \ldots, x_n\}$. To construct our CSP($\mathcal{B}^{\vee 2}$) instance, we perform the following steps.

1. Introduce three variables d_1, d_2, d_3 and the gadget that makes them distinct. These variables will be used to denote the three domain elements.
2. For each variable x_i, $1 \leq i \leq n$, we introduce the variable x'_i.
3. For each variable x_i, $1 \leq i \leq n$, introduce the variable y_i together with the constraints $S(y_i, d_2, d_3)$ and $S(x_i, d_1, y_i)$. These constraints imply that x_i is equal to d_1, d_2, or d_3.
4. For each variable x_i, $1 \leq i \leq n$, introduce variables $x_i^{\neq 1}, x_i^{\neq 2}, x_i^{\neq 3}$ together with the constraints $S(x_i^{\neq 1}, d_2, d_3)$, $S(x_i^{\neq 2}, d_1, d_3)$, and $S(x_i^{\neq 3}, d_1, d_2)$. These variables are used for "simulating" inequalities in step 5.
5. For each constraint $R(x_i, x_j) \in C$ and each tuple $(a, b) \in \{1, 2, 3\}^2$ that is not in R, introduce the constraint $\mathsf{eq}_D(x_i, x_i^{\neq a}) \vee \mathsf{eq}_D(x_j, x_j^{\neq b})$.

The resulting CSP($\mathcal{B}^{\vee 2}$) instance (V', C') can obviously be constructed in polynomial time. It contains $5n$ variables plus the constant number of variables needed for the gadget. We claim that (V', C') has a solution if and only if (V, C) has a solution. Assume that $f : V \to \{1, 2, 3\}$ is a solution to (V, C). Let $c_1, c_2, c_3 \in D$ be three distinct values that are permitted by the gadget. Let U denote the set of other values used by the gadget. Define $f' : V' \to U \cup \{c_1, c_2, c_3\}$ as follows.

- f' assigns suitable values from U to the gadget,
- $f'(d_i) = c_i$, $1 \leq i \leq 3$,
- $f'(y_i) = c_2$ if $f(x_i) = 2$ and $f'(y_i) = c_3$ otherwise,
- $f'(x'_i) = c_{f(x_i)}$
- $f'(x_i^{\neq 1}) = c_{f(x_i)}$ if $f(x_i) \neq 1$ and $f'(x_i^{\neq 1}) = c_2$, otherwise,
- $f'(x_i^{\neq 2}) = c_{f(x_i)}$ if $f(x_i) \neq 2$ and $f'(x_i^{\neq 2}) = c_1$, otherwise,
- $f'(x_i^{\neq 3}) = c_{f(x_i)}$ if $f(x_i) \neq 3$ and $f'(x_i^{\neq 3}) = c_2$, otherwise.

The function f' can easily be seen to satisfy the constraints introduced in steps 1, 3 and 4. We consider the constraints introduced in step 5. Pick a constraint $R(x_i, x_j) \in C$ and a tuple $(a, b) \in \{1, 2, 3\}^2$ that is not in R. We assume without loss of generality that $a = 1$ and $b = 2$. The corresponding constraint in C' is now $\mathsf{eq}_D(x'_i, x_i^{\neq 1}) \vee \mathsf{eq}_D(x'_j, x_j^{\neq 2})$. We know that $f(x_i) \neq 1$ or $f(x_j) \neq 2$. Assume, for example, that $f(x_i) = 2$ and $f(x_j) = 2$. We see that $f'(x_i^{\neq 1}) = c_2$ and $f'(x_j^{\neq 2}) = c_2$ so f' satisfies this constraint. The other cases can be verified analogously.

Assume that $f' : V' \to U \cup \{c_1, c_2, c_3\}$ is a solution to (V', C') where c_i, $1 \leq i \leq 3$, is the value assigned to variable d_i. Define $f : V \to \{1, 2, 3\}$ such that $f(x_i) = p$ when $f(x'_i) = c_p$. Arbitrarily choose a constraint $R(x_i, x_j) \in C$ and assume to the contrary that $(f(x_i), f(x_j)) = (a, b) \notin R$. This implies that f' satisfies the constraint $\mathsf{eq}_D(x'_i, x_i^{\neq a}) \vee \mathsf{eq}(x'_j, x_j^{\neq b})$ that was introduced in step 5. In order to do so, either $f'(x'_i) = f'(x_i^{\neq a})$ and $f'(x'_i) \neq c_a$ or $f'(x'_j) = f'(x_j^{\neq b})$ and $f'(x'_j) \neq c_b$. In both cases, $(f(x_i), f(x_j)) \neq (a, b)$ and this leads to a contradiction. ◀

If we consider $\mathcal{B}^{\vee k}$ with larger k and require that certain relations are members of $\mathcal{B}$, then stronger lower bounds can be obtained.

▶ **Theorem 11.** *Let $\prec \subseteq D^2$ be a strict partial order of infinite height over a domain D. If the r-ETH holds, then there is no $2^{c \cdot n}$-randomised algorithm for CSP($\{\prec\}^{\vee 4}$) for any $c \geq 0$.*

Proof. Assume there exists a $2^{c \cdot n}$-randomised algorithm for CSP($\{\prec\}^{\vee 4}$). Arbitrarily choose $d \geq 3$ such that $c_{d,2} > c$. We show how to polynomial-time reduce CSP($\Gamma_{d,2}$) to CSP($\{\prec\}^{\vee 4}$) in a way such that only a constant number of new variables are introduced. This implies that CSP($\Gamma_{d,2}$) can be solved by a $2^{c \cdot n}$-randomised algorithm where $c < c_{d,2}$ which contradicts the r-ETH due to Traxler's result.

Let $I = (V, C)$ be an arbitrary instance of CSP($\Gamma_{d,2}$). We assume (without loss of generality) that the variable domain is $\{1, \ldots, d\}$. Introduce $d + 1$ fresh variables $V_1 = \{a_1, \ldots, a_{d+1}\}$ and define $C_1 = \{a_1(\prec)a_2, a_2(\prec)a_3, \ldots, a_d(\prec)a_{d+1}\}$. Since $\prec$ is a strict partial order of infinite height, we know that $I_1 = (V_1, C_1)$ is satisfiable. In every solution s, it holds that $s(a_i) \prec s(a_j)$ when $1 \leq i < j \leq d + 1$ by the transitivity of $\prec$. We then constrain each $x \in V$ as follows: $a_1(\prec)x$, $x(\prec)a_i \vee a_i(\prec)x$ for $2 \leq i \leq d$, and $x(\prec)a_{d+1}$. Let C_2 denote the corresponding set of constraints and let $I_2 = (V \cup V_1, C_1 \cup C_2)$. It is easy to verify that in every solution s to I_2, each variable $x \in V$ satisfies $s(a_i) \prec s(x) \prec s(a_{i+1})$ for exactly one $1 \leq i \leq d$. For each constraint $S(x, y)$ in C, we finally introduce the following set of constraints $\{x(\prec)a_e \vee a_{e+1}(\prec)x \vee y(\prec)a_{e'} \vee a_{e'+1}(\prec)y \mid (e, e') \notin S\}$.

Let C_3 denote the resulting set of constraints and let $I_3 = (V \cup V_1, C_1 \cup C_2 \cup C_3)$. We claim that I_3 is satisfiable if and only if I is satisfiable. Assume that I_3 has the solution s_3. We know that every variable v in V satisfies $s(a_i) \prec s(v) \prec s(a_{i+1})$ for exactly one $1 \leq i \leq d$. The constraints in C_3 assure that s_3 assigns values to the variables in V that are consistent with the constraints in (V, C). Thus, the function $s : V \to D$ defined by $s(v) = i$ where $v \in V$ and $s_3(a_i) \prec s_3(v) \prec s_3(a_{i+1})$ is a solution to I.

Assume that I has the solution s. We construct a solution s_3 to I_3 as follows. Arbitrarily choose $e_1, \ldots, e_{d+1}, e'_1, \ldots, e'_d$ in D such that $e_i \prec e'_i \prec e_{i+1}$, $1 \leq i \leq d$; such elements exists since $\prec$ has infinite height. Let $s_3(a_i) = e_i$, $1 \leq i \leq d+1$. This choice satisfies all constraints in C_1. Let $s_3(v) = e'_i$, $v \in V$, when $s(v) = i$. It follows from the choice of $e_1, \ldots, e_{d+1}, e'_1, \ldots, e'_d$ that all constraints in C_2 are satisfied. Finally, s_3 satisfies the constraints in C_3: this is an immediate consequence of s being a solution to the instance I combined with the restrictions imposed by the constraints in $C_1 \cup C_2$.

Last, we verify that I_3 can be computed in polynomial time. The constraints in C_1 and C_2 can be computed in constant time since d is fixed, and each constraint in C gives rise to at most d^2 new constraints in C_3, so this set can trivially be computed in polynomial time. ◀

The bound in Theorem 11 is substantially stronger than the bounds that we have been able to prove for CSP($\mathcal{B}^{\vee=}$). We may also observe that CSP($\{\prec\}^{\vee k}$), $k \geq 1$, is solvable in $O(|V|! \cdot \mathrm{poly}(||I||)) = 2^{O(|V| \log |V|)} \cdot \mathrm{poly}(||I||)$ time, implying that the lower bound in Theorem 11 does not admit large improvements (unless r-ETH fails).

▶ **Theorem 12.** *Let $\prec \subseteq D^2$ be a strict partial order of infinite height over a domain D, and let $k \geq 1$. Then CSP($\{\prec\}^{\vee k}$) is solvable in $O(|V|! \cdot \mathrm{poly}(||I||))$ time.*

Proof. Let (V, C) be an instance of CSP($\{\prec\}^{\vee k}$). For each total order $\sqsubset$ over V, we answer yes if there for every disjunctive clause in C exists a disjunct $x \prec y$ such that $x \sqsubset y$. The time complexity of this algorithm is clear, and we now turn to correctness. Assume first that f is a satisfying assignment to (V, C). Let C' denote the set of all disjuncts satisfied by f. This set induces a strict partial order which can be extended into a total order by topological sorting. For the other direction, assume that $\sqsubset$ satisfies at least one disjunct in every clause. Let $i_1, \ldots, i_{|V|} \subseteq \{1, \ldots, |V|\}$ be indices such that $x_{i_1} \sqsubset \ldots \sqsubset x_{i_{|V|}}$ and $|\{i_1, \ldots, i_{|V|}\}| = |V|$. Since $\prec$ is of infinite height there then exists $d_1, \ldots, d_{|V|} \in D$ such that $d_1 \prec \ldots \prec d_{|V|}$, and we can form a satisfying assignment f by letting $f(x_{i_j}) = d_j$ for every $i_j \in \{i_1, \ldots, i_{|V|}\}$. ◀

6 Discussion

Our main focus has been to study the complexity of CSPs over partition schemes $\mathcal{B}$, with a particular emphasis on CSP($\mathcal{B}^{\vee=}$) when $\mathcal{B}$ contains a strict partial order. We have identified three properties resulting in NP-hardness, which explains the NP-hardness for many different CSP problems. Towards a better understanding of the time complexity of these problems we have also proven lower bounds under complexity-theoretic assumptions. We have studied lower bounds for CSP($\mathcal{B}^{\vee k}$), too, and obtained general bounds for this kind of problems. At this stage it is worth to yet again point out that none of our results require model-theoretic assumptions such as ω-categoricity, i.e., that the first-order theory of $\mathcal{B}$ admits only one model up to isomorphism. A large amount of research on infinite-domain CSPs has concentrated on ω-categorical constraint languages. However, there are interesting problems that are not amenable using this approach.

▶ **Example 13.** Bodirsky and Jonsson [5, Sec. 4.2] present a partition scheme $\mathcal{B}$ with domain $\mathbb{R}^3$ that demonstrate how to integrate arithmetics into partition schemes. They show that $\mathcal{B}$ is not ω-categorical and there does not exist any ω-categorical constraint language Γ such that CSP(Γ) and CSP($\mathcal{B}$) is the same computational problem. We will not define $\mathcal{B}$ explicitly, but remark that the relation $\mathrm{Less} = \{((a,b,p),(c,d,q)) \subseteq (\mathbb{R}^3)^2 \mid a < c \wedge p \neq q\}$ is a member of $\mathcal{B}^{\vee=}$. Obviously, the constraints $\mathrm{Less}(d_1, d_2)$ and $\mathrm{Less}(d_2, d_3)$ force d_1, d_2, d_3

to be assigned distinct values. By definition, there exists relations $B_1, \ldots, B_k \in \mathcal{B}$ such that Less $= B_1 \cup \cdots \cup B_k$ so there exist (not necessarily distinct) $1 \leq i, j \leq k$ such that the constraints $B_1(d_1, d_2)$ and $B_2(d_2, d_3)$ force d_1, d_2, d_3 to be assigned distinct values, too. We know that $\mathsf{eq}_D \in \mathcal{B}$ since $\mathcal{B}$ is a partition scheme. We conclude (by Theorem 10) that CSP($\mathcal{B}^{\vee 2}$) cannot be solved in $O(2^{\frac{c_{3,2}}{5}n})$ time.

One important consequence of lower bound results is that they can be used to rule out certain types of algorithms. First of all, k-consistency algorithms are not applicable since they run in polynomial time for arbitrary fixed k. The powerful generalisation of k-consistency, the *Datalog* framework [11, 4], is not applicable either since every Datalog program runs in polynomial time, too. Another example is provided by graph-decomposition algorithms for CSPs (for instance, algorithms that exploit treewidth). Such algorithms have been highly influential in the CSP context [1, 3, 7], but they typically result in polynomial-time or subexponential algorithms and are therefore unlikely to be usable for CSP($\mathcal{B}^{\vee=}$) problems. Even more can be said if we take a detour via degree-bounded problems.

▶ **Lemma 14.** *Let $\mathcal{B}$ be a constraint language such that CSP($\mathcal{B}$) is solvable in polynomial time. For arbitrary constants B and k, CSP($\mathcal{B}^{\vee k}$)-B can be solved in $2^{B \cdot \log k \cdot |V|} \cdot poly(||I||)$ time and CSP($\mathcal{B}^{\vee=}$)-B can be solved in $2^{B \cdot \log(|\mathcal{B}|-1) \cdot |V|} \cdot poly(||I||)$ time.*

Proof. Let $I = (V, C)$ be an arbitrary instance of CSP($\mathcal{B}^{\vee k}$)-B. Pick one disjunct out of each constraint in C, put the disjuncts into the set S, and check whether S is satisfiable or not. This check can be performed in polynomial time. There are at most $k^{B \cdot |V|}$ different sets S since each constraint contains at most k disjuncts and there are at most $B \cdot |V|$ constraints in C. Furthermore, (V, C) is satisfiable if and only if at least one of them is satisfiable. We conclude that (V, C) can be solved in $k^{B \cdot |V|} \cdot poly(||I||)$ time. The proof for CSP($\mathcal{B}^{\vee=}$)-B is essentially identical, with the difference that we never need to consider a relation containing all relations in $\mathcal{B}$, explaining $|\mathcal{B}| - 1$ in the exponent. ◀

Thus, both CSP($\mathcal{B}^{\vee k}$)-B and CSP($\mathcal{B}^{\vee=}$)-B can be solved in $2^{O(n)}$ time. We know (from Theorem 11) that there is no 2^{cn}-randomised algorithm for the CSP($\{\prec\}^{\vee 4}$) problem. This shows that techniques used for transforming CSP instances into sparse instances, e.g. *linear kernelisations* [19], are unlikely to be applicable to CSP($\mathcal{B}^{\vee k}$). We cannot rule out linear kernelisations for CSP($\mathcal{B}^{\vee=}$), though, since we do not have a sufficiently strong lower bound in this case.

Naturally, there are approaches that are not directly ruled out by our lower bounds. Jonsson and Lagerkvist [16] have presented general results for obtaining algorithms based on enumeration of domain values. These algorithms are sometimes much faster than the branching algorithms that are typically used for infinite-domain CSPs: the branching algorithm for CSP($\mathcal{A}^{\vee=}$) runs in $2^{O(n^2)}$ time while the enumeration-based algorithm runs in $2^{O(n \log n)}$ time. The range of applicability for enumeration-based algorithms is unfortunately not well understood, and more work is needed to clarify this. Another viable approach is to use methods that have been successful in solving finite-domain CSPs. Einarson [10] demonstrates how the finite-domain version of the PPSZ algorithm [14] can be applied to infinite-domain CSPs. His results are inconclusive: the algorithm is faster than previously known algorithms for certain CSP($\mathcal{B}^{\vee k}$) problems but it is, for instance, not competetive for Allen's interval algebra CSP($\mathcal{A}^{\vee=}$).

These examples suggest that it may be worthwhile to strengthen the subexponential lower bound for CSP($\mathcal{B}^{\vee=}$) even further – if possible. One possible way of doing this is to exploit the *strong exponential-time hypothesis*, i.e. the conjecture that SAT is not solvable in $O^*(c^n)$

time for any $c < 2$, The challenge here is that the SETH intrinsically requires reductions where one can "simulate" clauses of arbitrary high arity with a very small overhead. This seems difficult for $\mathrm{CSP}(\mathcal{B}^{\vee=})$ and in Theorem 8 we could only produce a reduction from a SAT problem with a linear number of constraints. This assumption cannot be made for SAT since sparsification, the process of reducing an instance to a subexponential number of instances with a linear number of constraints, is not possible for SAT [28]. Another possibility is to use bounds based on the Chromatic Number problem: Jonsson and Lagerkvist [16, Th. 21] have related the time complexity of Allen's interval algebra with the time complexity of the Chromatic Number problem and obtained concrete lower bounds of the form $O^*(c^n)$ for a constant $c > 1$ depending on the complexity of Chromatic Number. Thus, we ask the following: should stronger lower bounds for $\mathrm{CSP}(\mathcal{B}^{\vee=})$ be pursued in the setting of CNF-SAT and the SETH, or are problems of this kind fundamentally closer to e.g. colouring problems?

Abstract

Graph minors are a primary tool in understanding the structure of undirected graphs, with many conceptual and algorithmic implications. We propose new variants of *directed graph minors* and *directed graph embeddings*, by modifying familiar definitions. For the class of 2-terminal directed acyclic graphs (TDAGs) our two definitions coincide, and the class is closed under both operations. The usefulness of our directed minor operations is demonstrated by characterizing all TDAGs with serial-parallel width at most k; a class of networks known to guarantee bounded negative externality in nonatomic routing games. Our characterization implies that a TDAG has serial-parallel width of 1 if and only if it is a directed series-parallel graph. We also study the computational complexity of finding a directed minor and computing the serial-parallel width.

1 Introduction

Graph theory has been one of the fundamental tools in computer science since its inception and in many computational problems the inputs are in a form of a graph, e.g., analysis of electric circuits and communication networks, and training of neural nets. More important still, numerous problems from various domains are often solved by reducing them to some algorithmic problem on a graph. Some prominent examples include search and path-finding [31]; planning graphs [3]; constraint satisfaction [26]; AND-OR graph [4]; and inference in Bayesian networks [7].

The *structure* of these graphs is often crucial to the modeling of the problem. For instance, the last two examples above use *directed acyclic graphs* (DAGs), which are also used to represent belief structures, influence relations and decision diagrams [15]. Restrictions on the degree, maximum length, or other properties of the underlying graph, can be exploited: problems that are not guaranteed to have a solution in general may behave better on some classes of graphs, and many algorithms are guaranteed to have a lower runtime subject to structural assumptions.

Graph minors

When considering *undirected graphs*, some of the primary tools of structural analysis use *graph embeddings* and *graph minors*. These are substructures whose exclusion from a graph indicates certain "simplicity" properties. Some famous results are the characterization of planar graphs [23], and of graphs with bounded treewidth [32] by excluded minors. In fact, for undirected graphs there is by now a sound theory of graph minors with many applications; see, e.g., [25] for a survey, and [8] for algorithmic implications. The culmination of this theory is the Graph Minor Theorem [40, 33], which states that *any* class of undirected graphs that is closed under the minor operation, can be characterized by a finite set of excluded minors.

Perhaps the most important application of graph minor theory to computer science is its use for developing efficient algorithms on graphs with bounded treewidth and/or other properties [13, 6, 34]. Graph minors were also recently used to characterize classes of graphs induced by planning problems to identify potential effects of time-inconsistent planning [21, 38].

Although the graphs encountered in many theoretical and realistic problems are *directed*, there is no single theory of directed graph minors, and results are far more scarce than in the undirected case. Several papers suggested various definitions of directed minors, embeddings, and subdivisions, and provided various characterization results [17, 20, 14, 18, 19, 22]. However, each such definition uses different graph operations, some of which we explain in detail later on. Certain notions of directed minors are only applicable for subclasses of directed graphs. For example, the definitions in [22] apply only to minors with a certain structure called "crown".

In this paper, we will be interested mainly in directed graphs that are acyclic (DAG), or 2-terminal, or both (TDAG). 2-terminal graphs occur in routing [1], circuit analysis [36] and in many planning problems [21]. Thus understanding the structure of graphs in these classes is an important challenge.

Paper structure and contribution. In the first part of the paper (Section 3) we define new notions of graph embedding and graph minor for general directed graphs.[1] We show that for the class of 2-terminal directed acyclic graphs (TDAGs) these two operations exactly reverse one another. Thus, a TDAG G' is a directed minor of G if and only if it is embedded in G. Also, the class of TDAG is closed under directed minor and directed embedding operations. We thus argue that our definitions provide a sound basis for a theory of directed graph minors, at least for the class of TDAGs.

To demonstrate the usefulness of our directed minor theory, we apply it in Section 4 to characterize TDAGs with bounded *parallel width* and *serial-parallel width*. The parallel width of a graph corresponds to the maximal cut separating the source from the target. Serial-parallel width of a graph is a parameter recently introduced in the context of routing games [28], and it is useful for bounding negative externalities. We describe a finite set of graphs (generalized variants of the Braess/Wheatstone network) whose exclusion as directed minors of a TDAG G is necessary and sufficient to determine that G has serial-parallel width lower than k, for any k.

In Section 5 we settle several computational questions arising from our definitions. Some proofs are omitted due to space constraints and are available in the full version of this paper which is attached at the end of the file.

[1] To avoid confusion, we should note that the term *graph embedding* is used in the machine learning literature to describe embedding of graphs in various topological or metric spaces (e.g., [41]), which is a very different problem.

2 Preliminaries

For convenience, we will use the letter H for undirected graphs, and the letter G for directed graphs. We denote a path in graph $\langle V, E\rangle$ by $(v_1, v_2, \ldots, v_m)$, where for every $i \leq m-1$, $(v_i, v_{i+1}) \in E$. We use dash to abbreviate the path, e.g. $a - b - c$ is an abbreviation to a path $(a, \ldots, b, \ldots, c)$; if more than one such path exists, we refer to one of them arbitrarily, unless stated otherwise.

If nodes x, y are on some path p, then p_{xy} denotes the *open* subpath of p between nodes x and y, and $[p_{xy}] = x - p_{xy} - y$ the *closed* subpath that includes the extreme vertices.

▶ **Definition 1** (2-terminal graph [29, 14])**.** A *2-terminal [directed] graph* $G = \langle V, E, s, t\rangle$ is a [directed] multigraph with no self-loops and two distinguished vertices $s, t \in V$, such that every vertex and edge belong to at least one [directed] simple $s - t$ path.

A *forward-subtree* of a directed 2-terminal graph G is a subset of edges that form a directed tree with a single source. Similarly, a *backward-subtree* of G is a subset of edges that form a directed tree with a single target.

A directed 2-terminal graph with no cycles is referred to as *TDAG* (2-Terminal Directed Acyclic Graph). The vertices of a TDAG can always be sorted in increasing order, called *topological order*, so that all edges, and thus all directed paths, are from v_i to v_j for some $j > i$. In particular, s and t are the first and last vertices, respectively.

▶ **Lemma 2.** *A DAG is a TDAG if and only if it has a unique source and a unique sink.*

3 Directed Graph Minors and Embeddings

In undirected graphs, a graph H' is called a *minor* of H if H' can be obtained from H by a sequence of edge deletions and contractions. As an example of a simple characterization via exclusion of minors, observe that any graph H (not a multigraph) is acyclic if and only if it excludes a triangle as a minor.

3.1 Directed minors.

There are several extensions of the notion of a minor to directed graphs. One that is closest to our needs is the *butterfly minor* [17], see Def. 3 without the underlined part. However, neither the class of 2-terminal graphs nor the class of TDAGs is closed under the butterfly minor operation, since, for example, it may leave an isolated node. We thus modify it by restricting which edges may be deleted (underlined).

▶ **Definition 3** (Directed minor)**.** A graph G' is a *directed minor* (or simply *a d-minor*) of a directed graph G, if G' can be obtained from G by a sequence of the following local operations:

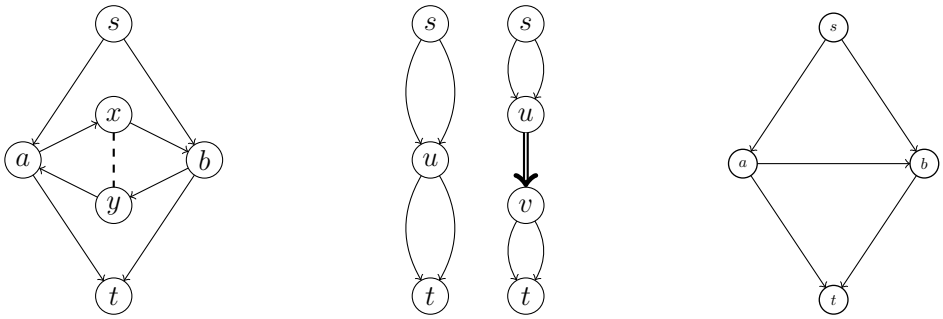
Deletion. Deleting an edge (a, b) where a has outdegree at least 2, and b has indegree at least 2.

Backward contraction. Contracting an edge (a, b) where b has indegree 1.

Forward contraction. Contracting an edge (a, b) where a has outdegree 1.

For example, the edge (a, b) in Fig. 1c may not be contracted, but can be backward-contracted after the edge (s, b) is deleted.

▶ **Lemma 4.** *The class of directed acyclic graphs is closed under d-minor operations.*



(a) **(b)** **(c)** The Braess graph.

Figure 1 The graph in Fig. 1a is a directed 2-terminal graph (solid edges only). Adding the dashed edge (x, y), regardless of its direction, results in a non-2-terminal graph. Fig. 1b: The graph G' on the left is d-embedded in G on the right, as we can forward-split u into (u, v) (u retains all incoming edges, and v retains at least one outgoing edge). However, there is no edge we can add or subdivide to get G from G' so G' is not h-embedded in G. The Braess graph G_B is on Fig. 1c. Examples.

3.2 Graph Embeddings

There are various definitions of graph embeddings and subdivisions [12, 29, 14], which can be summarised together as follows.

▶ **Definition 5** (Homeomorphic embedding)**.** A [directed] graph G' is *h-embedded* in (or a topological minor of) G, if G (or a graph isomorphic to G) can be derived from G' by a sequence of the following operations:

Addition. The addition of a new edge joining two existing vertices.

Subdivision. Replacement of an edge (a, b) by two edges (a, x) and (x, b).

Terminal extension. (only for 2-terminal graphs) Addition of a new edge e joining s or t with a new vertex, which becomes the new source or target.

For an undirected graph H', every h-embedding operation maintains various properties like being a 2-terminal graph. However, for a 2-terminal directed graph G', an h-embedding operation may not maintain this property (see Fig. 1a). Also, this set of operations is not rich enough for our needs. Thus, we propose a new definition for directed embeddings.

▶ **Definition 6** (Directed embedding)**.** A directed graph G' is *d-embedded* in a directed graph G if G' is isomorphic to G or to a graph derived from G by a sequence of the following operations:

Addition. Addition of a new edge (a, b), such that there is no path $b - a$.

Forward split. Replacement of node $a \neq t$ with outdegree greater than zero, by two nodes a_1 and a_2 and an edge (a_1, a_2), where a_1 retains all incoming edges, and a_2 retains at least one outgoing edge.

Backward split. Replacement of node $a \neq s$ with indegree greater than zero, by two nodes a_1 and a_2 and an edge (a_1, a_2), where a_2 retains all outgoing edges, and a_1 retains at least one incoming edge.

It is not hard to see that a subdivision of an edge (directed or undirected) can be replicated by splitting one of its end nodes, and a terminal extension can be replicated by splitting the terminal (backward split of s or forward split of t). We thus allow the operations of **edge subdivision** and **terminal extension** as valid d-embedding operations as well.

▶ **Lemma 7.** *The classes of 2-terminal directed graphs and directed acyclic graphs are closed under d-embedding.*

In particular, if G' is a TDAG and G' is d-embedded in G, then G is a TDAG.

For a 2-terminal directed graph G, the graph G' is a *valid subgraph* of G if it is a subgraph of G and is also 2-terminal. While the next lemma may seem trivial, note that it does not hold for general 2-terminal directed graphs, since a single edge is not d-embedded in any cyclic graph.

▶ **Lemma 8.** *Let G be a TDAG. If G' is a valid subgraph of G, then G' is d-embedded in G.*

We will need the following lemma later on, but it is useful to know regardless. An immediate corollary is that embedding steps only add paths and increase the connectivity of a graph.

▶ **Lemma 9.** *If G, G' differ by a single split step of vertex a into (a, b), then there is a one to one mapping between paths in G' and paths in G.*

3.3 Relations among graph operations

The way we defined them, d-minors are more restrictive than butterfly minors, whereas d-embeddings are more permissive than h-embeddings when restricting attention to acyclic graphs; see Fig. 1b. However, d-embeddings are not infinitely richer than h-embeddings. A vertex is called a *hub* if it has both an indegree and an outdegree larger than one.

▶ **Proposition 10.** *Let $G' = \langle V', E' \rangle$ and let $J \subseteq V'$ be the hubs of G'. There is a set $\mathcal{G}$ of at most $2^{|J| \times |V'|^2}$ graphs, such that for any $G = \langle V, E \rangle$, graph G' is d-embedded in G if and only if some graph in $\mathcal{G}$ is h-embedded in G. Each such graph has at most $|V|(1 + |J|)$ vertices.*

For the class of TDAGs, the concepts of directed-minor and directed-embedding turn out to be equivalent.

▶ **Theorem 11.** *Let G and G' be TDAGs. G' is d-embedded in G if and only if G' is a d-minor of G.*

Intuitively, addition and deletion operations cancel one another, as do split and contraction operations. This equivalence does not hold for general directed graphs, as added edges may not qualify for deletion (e.g. if we add an edge (a, b) where a has only incoming edges), and vice versa (if we remove an edge that is part of a cycle).

Proof. By induction, it is sufficient to show this for G', G that differ by a single d-embedding or d-minor operation. "⇒" There are 3 cases, depending on the embedding operation:

1. The addition of edge (a, b) to G' can be reversed by deleting the same edge from G. Note that $b \neq s$ as otherwise there is a path in G' from $b = s$ to a, and similarly $a \neq t$. Thus, a has outdegree at least 1 in G' and at least 2 in G. Similarly, b has indegree at least 2 in G, and thus deleting the edge (a, b) is a valid d-minor step.
2. Suppose that a vertex a in G' is split to $\{a, b\}$ with a forward split. Then, since a retains all incoming edges, b has a single incoming edge (a, b) in G. Thus, we can contract the edge (a, b) in G using backward contraction.
3. Similarly, a backward split can be reversed with a forward contraction.

"⇐" There are 3 cases, depending on the d-minor operation:

1. If the edge (a, b) is deleted from G, then since G is acyclic there is no path $b - a$. Thus adding (a, b) to G' is a valid d-embedding step.

2. Suppose that the edge (a, b) in G is backward-contracted to some vertex x in G'. This means that b has a single incoming edge. Thus all edges incoming to the pair $\{a, b\}$ are leading to a. Let $R(a)$ and $R(b)$ be the out-neighbors of a and b in G, respectively. Then by forward-splitting node x in G' and split the outgoing edges of x according to $R(a)$ and $R(b)$, we get the graph G^i.
3. Similarly, forward contraction can be reversed with backward split. ◀

4 Serial-Parallel Width

A *cut* in a 2-terminal graph $G = \langle V, E, s, t\rangle$ is a set of edges $C \subseteq E$ such that there is no $s - t$ path in $E \setminus C$. C is *minimal* if there is no cut $C' \subsetneq C$.

A set of edges $S \subseteq E$ is *parallel* if there is some $C \subseteq E$ s.t. $S \subseteq C$, and C is a minimal cut;S is *serial* if there is a simple directed $s - t$ path p that contains S.

▶ **Definition 12** (Parallel Width)**.** The *parallel width* of a directed 2-terminal graph, $PW(G)$, is the size of the largest parallel set $S \subseteq E$.

▶ **Definition 13** (Serial-Parallel Width [28])**.** The *serial-parallel width* of a directed 2-terminal graph, $SPW(G)$, is the size of the largest set $S \subseteq E$ that is both serial and parallel.

Intuitively, the parallel width is the size of a maximum $s-t$ cut. For example, the width of an electric circuit coincides with the parallel width of its underlying TDAG [5]. A serial-parallel width of k means that there are at least k source-target paths, and some additional path that edge-intersects all of them. It was shown in [28] that in nonatomic routing games with diverse players, the negative externality is bounded by the serial-parallel width of the underlying network.

▶ **Example 14.** Consider the Braess graph in Fig. 1c. The minimal $s - t$ cuts are: $\{sa, sb\}, \{at, bt\}$, $\{sa, bt\}$, and $\{sb, ab, at\}$. The set $\{sa, bt\}$ is both parallel and serial, which means $SPW(G_B) \geq 2$. The set $\{sa, at\}$ is serial but not parallel; and $\{sa, sb, ab\}$ is neither. In fact, the *only* parallel set of size greater than 2 is $\{sb, ab, at\}$, which is not serial, thus $SPW(G_B) < 3$. We conclude that the serial-parallel width of the Braess graph is 2.

In contrast, both graphs in Fig. 1b have $PW(G) = 2$ and $SPW(G) = 1$.

For any 2-terminal graph G, we have $1 \leq SPW(G) \leq |V| - 1$. The lower bound is since any single edge is both parallel and serial, and the upper bound since there is no simple path of length $|V|$ or more.

▶ **Definition 15.** For any $k \geq 2$, we define the *k-serial-parallel graph* $G_{SP(k)}$ as follows. $G = \langle V, E, s, t\rangle$, where $V = \{s, t, a_2, \ldots, a_k, b_1, \ldots, b_{k-1}\}$, and $E = \bigcup_{i=2}^{k-1}\{(s, a_i), (a_i, b_i), (b_i, t), (b_i, a_{i+1})\} \cup \{(s, b_1), (a_k, t)\}$ (see Fig.2). Furthermore, $G_{P(k)}$ is a TDAG that contains k internally disjoint $s - t$ paths.

▶ **Definition 16.** A graph G is a *variant of* $G_{SP(k)}$ if we replace the edges $\{(s, a_i)\}_{i=2}^{k}$ with an arbitrary forward-subtree that respects the lexicographic order $s, a_2, \ldots, a_k$, and replace the edges $\{(b_i, t)\}_{i=1}^{k-1}$ with an arbitrary backward-subtree that respects the lexicographic order $b_1, \ldots, b_{k-1}, t$.

The serial-parallel width of $G_{SP(k)}$ is exactly k, where
$\{(s, b_1), (a_2, b_2), \ldots, (a_{k-1}, b_{k-1}), (a_k, t)\}$ are the serial-parallel edges.

The graph $G_{SP(k)}$ was used under different names in [2, 30, 28], usually to derive examples of games with high equilibrium costs.

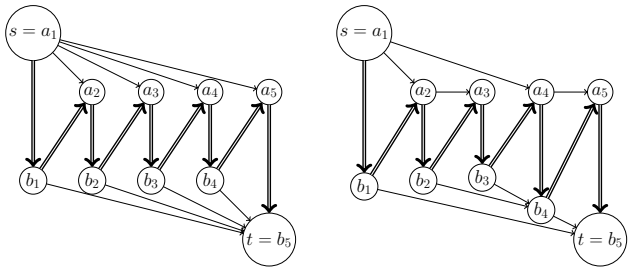


Figure 2 The left figure is the graph $G_{SP(5)}$, and the right figure is a variant of it. For convenience, the long path in each graph appears in double lines, and the forward- and backward-trees in thin lines.

▶ **Lemma 17.** *If S is a set of parallel [serial] edges in a 2-terminal graph G', then after any sequence of d-embedding steps on G', the set S is still parallel [resp., serial]. In particular, if G' is d-embedded in G then $PW(G) \geq PW(G')$ and $SPW(G) \geq SPW(G')$.*

Proof sketch. For serial sets the statement is obvious.

Consider a sequence of J d-embedding operations on $G^0 = G'$ that ends in $G^J = G$. Suppose that S is parallel. Let C^0 be a minimal cut in $G^0 = G'$ containing S. We show by induction that after every step $j \leq J$ there is a minimal cut C^j in G^j, such that $C^{j-1} \subseteq C^j$.

Assume by induction that C^{j-1} is a minimal cut in G^{j-1}. The graph G^j differs from G^{j-1} either by a single added edge, or by a single split vertex. By Lemma 9 split steps do not change the set of paths, and thus $C^j = C^{j-1}$ is still a minimal cut. Thus suppose G^j differs by an addition step of an edge $e = (a, b)$. Either C^{j-1} is still a cut in G^j, or e connects a node a reachable from s to a node b with a path to t. In the latter case, $C^j = C^{j-1} \cup \{e\}$ is a cut. To see that C^j is minimal suppose we remove an edge $e' \neq e$. If $C' = C^j \setminus \{e'\}$ is a cut in G^j, then $C' \setminus \{e\} = C^{j-1} \setminus \{e'\}$ is a cut in G^{j-1}, in contradiction to the induction hypothesis that C^{j-1} is minimal. In either case, S is still contained in a minimal cut C^j after every operation, and in particular contained in a minimal cut C^J of $G^J = G$. ◀

4.1 Characterization of graphs with bounded serial-parallel width

Before we get to our main theorem we start with a characterization of parallel sets.

▶ **Proposition 18** (Parallel sets characterization)**.** *Let $G = \langle V, E, s, t\rangle$ be a TDAG, and a set of k edges $S \subseteq E$, where for each $e_i \in S$, $e_i = (a_i, b_i)$. The following conditions are equivalent: (1) S is parallel; (2) there is a forward-subtree T_s in G with root s and leafs $\{a_i\}_{i\leq k}$, and a backward-subtree T_t in G with leaf t and roots $\{b_i\}_{i\leq k}$; (3) there is a sequence of d-minor operations that deletes or contracts all edges except S.*

Proof. "1 ⇒ 2": Suppose that S is parallel, then it is contained in a minimal cut C. Let G_C be graph G without the edges of C. Let T_s be all vertices reachable from s in G_C, and T_t all vertices from which t is reachable and let $G(X)$ be the subgraph of G induced by $X \subseteq V$. $T_s \cap T_t = \emptyset$ as otherwise there is a path from s to t in G_C. Also, $a_i \in T_s$ for all i, as otherwise the edge e_i can be removed from C and $C \setminus \{e_i\}$ is still a cut. Likewise for $b_i \in T_t$. Since G is a TDAG, and $G(T_s)$ contains a path from s to every a_i, then $G(T_s)$ is w.l.o.g. a forward-tree. Similarly for T_t.

"2 ⇒ 3": The union of $G(T_s), G(S)$, and $G(T_t)$ is a valid subgraph G' of G of which S is a minimal cut: for any e_i there is a path $s - a_i - b_i - t$. Since G' is a valid subgraph of G, then by Lemma 8 it is d-embedded and thus a d-minor of G. Then, since all nodes in T_s

have indegree at most 1, we can backward-contract all of T_s to a single node s. Similarly, we forward-contract all of T_t to the node t, and we are left with a graph that has two nodes whose only edges are S.

"$3 \Rightarrow 1$": By Theorem 11 we can consider the reverse sequence of d-embedding operations from $G^0 = G_{P(k)}$ to $G^J = G$. By Lemma 17, the set S is still parallel after every operation and in particular in G. ◀

We get a characterization of graphs with bounded parallel width as a simple corollary.

▶ **Theorem 19.** *For any TDAG G and $k \geq 2$, $PW(G) \geq k$ if and only if $G_{P(k)}$ is a d-minor of G.*

Proof. "$\Rightarrow$": Consider some parallel set S of size k. By Prop. 18 there is a sequence of d-minor operations that ends with a graph whose only edges are S. This graph is $G_{P(k)}$. "$\Leftarrow$": Follows directly from Lemma 17 and Thm. 11, since $PW(G_{P(k)}) = k$. ◀

▶ **Theorem 20** (Main Theorem)**.** *For any TDAG G and $k \geq 2$, $SPW(G) \geq k$ if and only if some variant of $G_{SP(k)}$ is a d-minor of G.*

Proof. "$\Rightarrow$": Consider the graph G. Suppose that $SPW(G) \geq k$, then there is a set $S = \{e_1, \ldots, e_k\}$ that is part of a minimal cut C between s and t. Denote $e_i = (a_i, b_i)$.

By Prop. 18, G has a forward-subtree T_s with root s and leafs $\{a_i\}_{i \leq k}$, and a backward-subtree T_t in G with leaf t and roots $\{b_i\}_{i \leq k}$. Also, by definition of the parallel width, there is a *simple* $s - t$ path p' containing S, w.l.o.g. in lexicographic order.

We now describe a series of d-minor steps on G that will result in a variant of $G_{SP(k)}$. Delete all edges and vertices that are not part of p', T_s or T_t. This leaves us with a graph G' that is a valid subgraph of G and thus, by Lemma 8 and Thm. 11, is also a d-minor of G.

p' is composed of a sequence of subpaths between vertices $s, y_1, x_2, y_2 \ldots, x_{k-1}, y_{k-1}, x_k, t$, where each x_i is the first intersection of $[p'_{b_{i-1}a_i}]$ with T_s. Thus x_i is an ancestor of (or coincides with)a_i in T_s. Similarly, $\{y_i\}_{i=1}^{k-1}$ are on the backward-subtree T_t, where y_i is the last intersection of $[p'_{b_i a_{i+1}}]$ and T_t. Denote by $A_i \subseteq \{a_2, \ldots, a_k\}$ all leafs of the subtree of T_s rooted at x_i, and by $B_i \subseteq \{b_1, \ldots, b_{k-1}\}$ all roots of the subtree of T_t whose leaf is y_i. In particular, $a_i \in A_i$, and $a_j \notin A_i$ for $j < i$, as otherwise there is a cycle $x_i - a_j - b_j - y_j - x_i$. Likewise, $b_i \in B_i$ and $b_j \notin B_i$ for $j > i$.

Note that the indegree of all nodes in T_s is 1, except for $\{x_i\}_{i=2}^{k}$ whose indegree is 2 (one edge from the parent in T_s, and one from the predecessor node on p'), and s whose indegree is 0. We thus backward-contract all edges in T_s that do not point to some x_i. We get a forward-subtree $\hat{T}_s$:

- The root of $\hat{T}_s$ is $s = x_1$, and its nodes are $\{x_i\}_{i=2}^{k}$;
- Each path $x_i - a_i$ in G' becomes a single node $x_i = a_i$ in $\hat{G}$;
- The subtree rooted by x_i in T_s becomes a subtree in $\hat{T}_s$ over nodes A_i maintaining their order, i.e., children have higher index than their parent. For example, in Fig. 2 on the right, $A_4 = \{a_4, a_5\}$ and a_4 is a parent of a_5.

We similarly contract T_t to $\hat{T}_t$ on nodes $\{y_i\}$.

The last step is to contract every subpath $[p'_{y_i x_{i+1}}]$ to a single edge (y_i, x_{i+1}). Denote the union of these edges by $\hat{F}$, so that $S \cup \hat{F}$ is the path we get after contracting p'.

We get that the contracted graph $\hat{G}' = S \cup \hat{F} \cup \hat{T}_s \cup \hat{T}_t$ is isomorphic to a variant of $G_{SP(k)}$. More specifically, s and t are mapped to themselves, each x_i for $i = 2, \ldots, k$ in $\hat{G}$ is mapped to a_i in $G_{SP(k)}$, and each y_i for $i = 1, \ldots, k-1$ in $\hat{G}'$ is mapped to b_i in $G_{SP(k)}$. For each $i = 2, \ldots, k$, let j be the maximal index such that x_j is an ancestor of x_i in T_s. If such

j exists, then the parent of a_i in $\hat{G}'$ is a_j, and otherwise its parent is $s = a_1$. The parent of a_i in $G_{SP(k)}$ is the closest ancestor x_j of the node x_i in T_s (and similarly for the child of b_i).

"⇐": Follows directly from Lemma 17 and Thm. 11, since SPW for any variant of $G_{SP(k)}$ is k. ◀

Since $G_{SP(k)}$ has $2k$ vertices, we get that $SPW(G) \leq \frac{|V|}{2}$. Another corollary of Theorem 20 is a generalization of the lower bounds on negative externality from [2, 28]. These papers show how instances with high externality (depending on k) can be constructed from any variant of $G_{SP(k)}$. By Theorem 20 this is true for *any graph* G with $SPW(G) \geq k$.

4.2 Series-parallel graphs

Series-parallel 2-terminal graphs have been long studied in contexts such as electric circuits [9], complexity of graph algorithms [37], and also routing games [29, 11].

▶ **Definition 21** (Series-parallel graph [10, 16]). *[directed] series-parallel graph* is a 2-terminal graph $\langle V, E, s, t\rangle$, and is either a single edge (s, t), or is composed recursively by one of the two following steps:

Serial composition. Combine two [directed] 2-terminal graphs $\langle V_1, E_1, s_1, t_1\rangle, \langle V_2, E_2, s_2, t_2\rangle$ serially by merging t_1 with s_2.

Parallel composition. Combine two [directed] 2-terminal graphs $\langle V_1, E_1, s_1, t_1\rangle$, $\langle V_2, E_2, s_2, t_2\rangle$ in parallel by merging s_1 with s_2, and t_1 with t_2.

Our last result in this section is showing that directed series-parallel graphs (DSP) characterize exactly the 2-terminal graphs with serial-parallel width of 1.

▶ **Proposition 22** ([14]). *Let G be a 2-terminal directed graph. Then G is a DSP if and only if the directed Braess graph G_B is not h-embedded in G.*

Proposition 22 and the relation between h-embeddings and d-embeddings yield the following.

▶ **Theorem 23.** *Let G be a TDAG, and let $k \geq 2$. The following conditions coincide. (1) G is a directed series-parallel graph. (2) The directed Braess graph G_B is not d-embedded in G. (3) $SPW(G) = 1$.*

Proof. Note that G_B has no hubs, as all vertices have at most 3 neighbors. Thus by Prop. 10, G_B is d-embedded in G if and only if it is h-embedded (as $|J| = 0$, $\mathcal{G}$ contains only G_B itself). Thus we get (1) $\iff$ (2).

(2) $\iff$ (3) follows as a special case from Thm. 20. ◀

5 Computational Problems

We first ask whether we can efficiently decide when a directed graph is 2-terminal.

▶ **Proposition 24.** *It is $\mathcal{NP}$-complete to decide if a directed graph is 2-terminal, but in $\mathcal{P}$ if the graph is acyclic.*

The next two natural computational questions accept as input 2-terminal graphs G and G'.

IsDMinor: Is G' a d-minor of G?

IsDEmbedded: Is G' d-embedded in G?

The complexity may depend on whether the graphs are TDAGs (in which case the questions coincide), and also on whether G' is a fixed graph of size k. We write down some of our results explicitly, and summarize all of them in Table 1.

Table 1 The computational complexity of problems we study. Results without references either follow from other results in the table or from known results.
* - IsDEmbedded is easy if the minor G' is acyclic.

5.1 Testing properties of edge sets

We are interested in the following questions on a given 2-terminal graph $G = \langle V, E, s, t\rangle$ and a set $S = \{(a_i, b_i)\}_{i\leq k}$ of k edges:
IsSerial: Is there an $s - t$ path containing S?
IsParallel: Is S parallel?
IsSerialParallel: Is S both serial and parallel?
Note that since all of these properties are phrased in terms of existence, containment in $\mathcal{NP}$ is trivial.

Our main tool in many of the results, both positive and negative, will be the m-VertexDisjointPaths problem: given a directed graph $G = \langle V, E\rangle$ and m pairs of vertices $\{(x_i, y_i)\}_{i\leq m}$, find whether there are vertex-disjoint paths $x_i - y_i$ in G for all $i \leq m$. This problem is equivalent to that of checking if a graph G' is h-embedded in G [12], yet using it for our problems requires some modifications. The problem is $\mathcal{NP}$-complete even when G is a DAG [39], and $\mathcal{NP}$-complete for $m = 2$ in general directed graphs [12]. In contrast, it is in $\mathcal{P}$ when G is a DAG *and* m is fixed [12].

▶ **Proposition 25.** IsSerial *and* IsSerialParallel *are $\mathcal{NP}$-complete even for $k = 3$.*

For $k = 1$ every instance is a 'yes' instance, as any single edge is part of a simple path and part of a minimal cut.

The most tricky part is the complexity of identifying a parallel set. Using some of the structural results obtained in the previous sections, we can show the following.

▶ **Proposition 26.** IsParallel *is in $\mathcal{P}$ for TDAGs and fixed k.*

Proof. Denote $e_i = (a_i, b_i)$ for any $e_i \in S$. Denote $A = \{a_1, \ldots, a_k\}$ and $B = \{b_1, \ldots, b_k\}$. By Prop. 18, it suffices to decide if G contains a forward-subtree T_s to all of A, and a backward-subtree T_t from all of B to t. Note that T_s contains at most $k - 1$ "junctions", i.e., nodes with outdegree greater than one (including s). Suppose first that we guess what these vertices are and what is their hierarchy, and denote them by $X = \{s = x_1, \ldots, x_{k'}\}$ and relations T_X. We similarly guess a set Y of junctions in T_t and the relations among them T_Y. Our algorithm works as follows:

- For every x_j with degree d_j in T_X, split x_j into $d_j + 1$ nodes such that one of them x_j^0 retains all incoming edges (entry port), and each of the other $x_j^{v_j}$ (exit port) retains all outgoing edges. v_j is the first node from $X \cup A$ downward from x_j on T_s.

- Connect x_j^0 to all of $x_j^{v_j}$.
- Similarly split each $y_j \in Y$ to multiple entry ports and a single exit port.
- Find vertex-disjoint paths from each exit port to the entry port of one child in T_X or T_Y, respectively. E.g. from $x_j^{v_j}$ to a_i if $v_j = a_i$ for some $i \leq k$, or to $x_{j'}^0$ if $v_j = x_{j'}$ for some $j' \leq k'$.

Consider the algorithm above. The total number of edges in each tree T_X, T_Y is at most $2k$, so the total number of paths we seek in each iteration is less than $4k$. Such paths, if exist, can be found in time $|V|^{O(k^2)}$ due to the result of [12].

If such vertex-disjoint paths exist, then merging back all copies of each junction will provide us with a disjoint forward-subtree T_s and backward-tree T_t. In the other direction, if such trees exist and use junctions X and Y respectively, then the paths between every two junctions are vertex-disjoint except in the junctions themselves. Since we split each junction, these paths will be fully vertex disjoint. Thus the algorithm will always find trees T_s, T_t using junctions X, Y, if such exist.

The total number of iterations is the number of ways to select $2k$ vertices out of $|V|$, times the number of trees we can try on each set of size $2k$ (less than $(2k)^{(2k)}$ by Cayley's formula), so in total no more than $|V|^{O(k^2)}$ iterations.

The total runtime is $|V|^{O(k^2)}$ which is polynomial for fixed k.

In the full version of the paper we have shown a polynomial time algorithm to determine if S is serial(even polynomial in k for TDAGs). Hence, we can check whether S is serial-parallel by checking each property separately. ◀

5.2 Testing width properties of graphs

Given 2-terminal graph G and an integer k we study:
MaxSerial: Is there a serial set S of size $\geq k$?
MaxParallel: Is $PW(G) \geq k$?
MaxSerialParallel: Is $SPW(G) \geq k$?

▶ **Proposition 27.** MaxParallel *is $\mathcal{NP}$-complete even on TDAGs.*

Proof. MaxParallel problem is in $\mathcal{NP}$. Given any 2-terminal directed graph $G = \langle V, E\rangle$ and a set S of edges in E we can easily check whether S is an $s-t$ cut; if S is indeed an $s-t$ cut, then by deleting the edges in S there is no directed path from s to t and this can be easily verified via Dijkstra algorithm .

To show completeness we reduce from MaxDiCut on DAGs [24]. In an instance of MaxDiCut problem we are given a directed acyclic graph $G = \langle V, E\rangle$ and an integer k, and we are asked if there is a partition of V into two sets V_1 and V_2 so that the cardinality of the edge set $C = \{(u, v) \in E | u \in V_1, v \in V_2\}$ is at least k. We construct a 2-terminal DAG G' as follows. We add the vertex s and we connect it with every vertex $v \in V$ via an edge directed from s to v. Furthermore, we add the vertex t and we connect it with every vertex $v \in V$ via an edge directed from v to t. Clearly, G' is a 2-terminal graph. Furthermore, it is not hard to see that no directed cycles were created. Thus, G' is a 2-terminal DAG. We will prove that there exists a directed cut of size k in G if and only if there exists an $s-t$ directed cut of size $|V| + k$ in G'.

Firstly, assume that in G there exists a partition of V into V_1 and V_2 such that the size of C, i.e., the number of directed edges from V_1 to V_2, is k. Then, the set S that contains C, the edges from the vertices of V_1 to t and the edges from s to vertices of V_2, is a minimal $s-t$ cut. Observe, $|S| = |C| + |V_1| + |V_2| = k + |V|$. To see why S is an $s-t$ cut, observe

that there is no path of the form $s - v - t$ with $v \in V$, because one of the edges (s, v) and (v, t) is missing. The only other way to reach t from s is to go from s to some vertex of V_1, move to V_2, and then reach t. But every edge from V_1 to V_2 is in C, hence there is no such $s - t$ path. Furthermore, S is minimal since for any edge (u, v) in C there is clearly a path $s - u - v - t$ in G' that does not contain any other edge in S, and for any other edge in $S \setminus C$ there is an $s - t$ path of length three that does not use any other in S.

For the other direction now, consider a minimal $s - t$ cut S in G' of size $|V| + k$. Denote by A all the vertices accessible from s in $E \setminus S$, and by B all other vertices of G. The cut S contains every edge from A to B, every edge from s to B, and every edge from A to t, so in particular we get that the size of the cut defined by the partition of V to A and B in G is exactly $|S| - (|A| + |B|) = |V| + k - |V| = k$. Finally, observe that the partition defined by A and B is a directed cut for G, because otherwise there would be a directed $s - t$ path and thus S would not be an $s - t$ cut. ◀

As an immediate corollary we get that IsDMinor and IsDEmbedded are $\mathcal{NP}$-complete even on a TDAG. When $G' = \langle V', E' \rangle$ is fixed, both problems are in $\mathcal{P}$: we use the algorithm of [12] for h-embedding as a subroutine on at most $2^{|V'|^3}$ graphs due to Proposition 10.

Since by Theorems 19 and 20 finding the parallel (or serial-parallel) width is equivalent to check for excluded minors whose size is a function of k, we get the following.

▶ **Corollary 28.** MaxParallel *and* MaxSerialParallel *are in* $\mathcal{P}$ *for TDAGs and fixed* k.

6 Discussion

Many different variations of operations can be used to obtain "simple" graphs that capture the essential forbidden properties of large classes of graphs: minors, embeddings, subdivisions, etc. These operations should be rich enough to allow for a small set of forbidden graphs, but restricted enough to only capture the intended class.

We believe that d-embeddings and d-minors will turn out to be useful, beyond the applications demonstrated in the paper. For example, in [21] bad graphs for planning are identified by *undirected minors*, which mislabels many graphs due to ignoring edge directions. A tighter characterization could be obtained by d-minors.

It is interesting whether d-embeddings or d-minors can be used to characterize other classes of directed graphs, such as graphs with bounded triangular width [27] or D-width [35]. Finally, there is the question of whether a directed graph version of the Graph Minor Theorem holds for d-minors or d-embeddings [19].

Abstract

Temporal graphs are graphs with time-stamped edges. We study the problem of finding a small vertex set (the separator) with respect to two designated terminal vertices such that the removal of the set eliminates all temporal paths connecting one terminal to the other. Herein, we consider two models of temporal paths: paths that pass through arbitrarily many edges per time step (non-strict) and paths that pass through at most one edge per time step (strict). Regarding the number of time steps of a temporal graph, we show a complexity dichotomy (NP-hardness versus polynomial-time solvability) for both problem variants. Moreover we prove both problem variants to be NP-complete even on temporal graphs whose underlying graph is planar. We further show that, on temporal graphs with planar underlying graph, if additionally the number of time steps is constant, then the problem variant for strict paths is solvable in quasi-linear time. Finally, we introduce and motivate the notion of a temporal core (vertices whose incident edges change over time). We prove that the non-strict variant is fixed-parameter tractable when parameterized by the size of the temporal core, while the strict variant remains NP-complete, even for constant-size temporal cores.

(a) A temporal graph $\boldsymbol{G}$. **(b)** Layers of $\boldsymbol{G}$.

Figure 1 Subfigure (a) shows a temporal graph $\boldsymbol{G}$ and subfigure (b) shows its four layers $G_1, \ldots, G_4$. The gray squared vertex forms a strict temporal (s, z)-separator, but no temporal (s, z)-separator. The two squared vertices form a temporal (s, z)-separator.

1 Introduction

In complex network analysis, it is nowadays very common to have access to and process graph data where the interactions among the vertices are time-stamped. When using static graphs as a mathematical model, the dynamics of interactions are not reflected and important information of the data might not be captured. *Temporal graphs* address this issue. A temporal graph is, informally speaking, a graph where the edge set may change over a discrete time interval, while the vertex set remains unchanged. Having the dynamics of interactions represented in the model, it is essential to adapt definitions such as connectivity and paths to respect temporal features. This directly affects the notion of *separators* in the temporal setting. Vertex separators are a fundamental primitive in static network analysis and it is well-known that they can be computed in polynomial time (see, e.g., proof of [1, Theorem 6.8]). In contrast to the static case, Kempe et al. [25] showed that in temporal graphs it is NP-hard to compute minimum separators.

Temporal graphs are well-established in the literature and are also referred to as time-varying [27] and evolving [15] graphs, temporal networks [24, 25, 30], multidimensional networks [8], link streams [26, 36], and edge-scheduled networks [7]. In this work, we use the well-established model in which each edge has a time stamp [8, 24, 3, 22, 25, 30]. Assuming discrete time steps, this is equivalent to a sequence of static graphs over a fixed set of vertices [31]. Formally, we define a temporal graph as follows.

▶ **Definition 1.1** (Temporal Graph)**.** An (undirected) *temporal graph* $\boldsymbol{G} = (V, \boldsymbol{E}, \tau)$ is an ordered triple consisting of a set V of vertices, a set $\boldsymbol{E} \subseteq \binom{V}{2} \times \{1, \ldots, \tau\}$ of *time-edges*, and a maximal time label $\tau \in \mathbb{N}$.

See Figure 1 for an example with $\tau = 4$, that is, a temporal graph with four time steps, also referred to as *layers*. The static graph obtained from a temporal graph $\boldsymbol{G}$ by removing the time stamps from all time-edges we call the *underlying graph* of $\boldsymbol{G}$.

Many real-world applications have temporal graphs as underlying mathematical model. For instance, it is natural to model connections in public transportation networks with temporal graphs. Other examples include information spreading in social networks, communication in social networks, biological pathways, or spread of diseases [24].

A fundamental question in temporal graphs, addressing issues such as connectivity [5, 30], survivability [27], and robustness [34], is whether there is a "time-respecting" path from a

distinguished start vertex s to a distinguished target vertex z.[3] We provide a thorough study of the computational complexity of separating s from z in a given temporal graph.

Moreover, we study two natural restrictions of temporal graphs:

(i) planar temporal graphs and

(ii) temporal graphs with a bounded number of vertices incident to edges that are not permanently existing – these vertices form the so-called *temporal core*.

Both restrictions are naturally motivated by settings e.g. occurring in (hierarchical) traffic networks. We also consider two very similar but still significantly differing temporal path models (both used in the literature), leading to two corresponding models of temporal separation.

Two path models. We start with the introduction of the "non-strict" path model [25]. Given a temporal graph $\boldsymbol{G} = (V, \boldsymbol{E}, \tau)$ with two distinct vertices $s, z \in V$, a *temporal (s,z)-path* of length ℓ in $\boldsymbol{G}$ is a sequence $P = ((\{s = v_0, v_1\}, t_1), (\{v_1, v_2\}, t_2), \ldots, (\{v_{\ell-1}, v_\ell = z\}, t_\ell))$ of time-edges in $\boldsymbol{E}$, where $v_i \neq v_j$ for all $i, j \in \{0, \ldots, \ell\}$ with $i \neq j$ and $t_i \leq t_{i+1}$ for all $i \in \{1, \ldots, \ell - 1\}$. A vertex set S with $S \cap \{s, z\} = \emptyset$ is a *temporal (s,z)-separator* if there is no temporal (s,z)-path in $\boldsymbol{G} - S := (V \setminus S, \{(\{v, w\}, t) \in \boldsymbol{E} \mid v, w \in V \setminus S\}, \tau)$. We are ready to state the central problem of our paper.

Temporal (s,z)-Separation
Input: A temporal graph $\boldsymbol{G} = (V, \boldsymbol{E}, \tau)$, two distinct vertices $s, z \in V$, and $k \in \mathbb{N}$.
Question: Does $\boldsymbol{G}$ admit a temporal (s,z)-separator of size at most k?

Our second path model is the "strict" variant. A temporal (s,z)-path P is called *strict* if $t_i < t_{i+1}$ for all $i \in \{1, \ldots, \ell - 1\}$. In the literature, strict temporal paths are also known as journeys [3, 2, 31, 30].[4] A vertex set S is a *strict temporal (s,z)-separator* if there is no strict temporal (s,z)-path in $\boldsymbol{G} - S$. Thus, our second main problem, Strict Temporal (s,z)-Separation, is defined in complete analogy to Temporal (s,z)-Separation, just replacing (non-strict) temporal separators by strict ones.

While the strict version of temporal separation immediately appears as natural, the non-strict variant can be viewed as a more conservative version of the problem. For instance, in a disease-spreading scenario the spreading speed might be unclear. To ensure containment of the spreading by separating patient zero (s) from a certain target (z), a temporal (s,z)-separator might be the safer choice.

Main results. Table 1 provides an overview on our results.[5]

A central contribution is to prove that both Temporal (s,z)-Separation and Strict Temporal (s,z)-Separation are NP-complete for all $\tau \geq 2$ and $\tau \geq 5$, respectively, strengthening a result by Kempe et al. [25] (they show NP-hardness of both variants for all $\tau \geq 12$). For Temporal (s,z)-Separation, our hardness result is already tight.[6] For the strict variant, we identify a dichotomy in the computational complexity by proving

[3] In the literature the sink is usually denoted by t. To be consistent with Michail [31] we use z instead as we reserve t to refer to points in time.

[4] We also refer to Himmel [21] for a thorough discussion and comparison of temporal path concepts.

[5] Due to the space constraints, several details and proofs (marked with $\star$) are deferred to a long version of this paper, see e.g. `https://arxiv.org/abs/1711.00963`.

[6] Temporal (s,z)-Separation with $\tau = 1$ is equivalent to (s,z)-Separation on static graphs.

Table 1 Overview on our results. Herein, NP-c. abbreviates NP-complete, n and $\boldsymbol{m}$ denote the number of vertices and time-edges, respectively, $G_{\downarrow}$ refers to the underlying graph of an input temporal graph. [a] (Thm. 3.1; W[1]-hard wrt. k) [b] (Thm. 3.2) [c] (Cor. 4.3) [d] (Prop. 4.4) [e] (Thm. 5.2)

	General (Section 3)		Planar $G_{\downarrow}$ (Section 4)		Temporal core (Section 5)
(s,z)-Separation	$2 \leq \tau \leq 4$	$5 \leq \tau$	τ unbounded	τ constant	constant size
Temporal	NP-complete[a]		NP-c.[c]	*open*	$n^{O(1)} + O(\boldsymbol{m} \log \boldsymbol{m})$ [e]
Strict Temporal	$\mathcal{O}(k \cdot \boldsymbol{m})$ [b]	NP-c.[a]	NP-c.[c]	$\mathcal{O}(\boldsymbol{m} \log \boldsymbol{m})$ [d]	NP-complete[a]

polynomial-time solvability of Strict Temporal (s,z)-Separation for $\tau \leq 4$. Moreover, we prove that both problems remain NP-complete on temporal graphs that have an underlying graph that is planar.

We introduce the notion of temporal cores in temporal graphs. Informally, the temporal core of a temporal graph is the set of vertices whose edge-incidences change over time. We prove that Temporal (s,z)-Separation is fixed-parameter tractable (FPT) when parameterized by the size of the temporal core, while Strict Temporal (s,z)-Separation remains NP-complete even if the temporal core is empty.

A particular aspect of our results is that they demonstrate that the choice of the model (strict versus non-strict) for a problem can have a crucial impact on the computational complexity of said problem. This contrasts with wide parts of the literature where both models were used without discussing the subtle but crucial differences in computational complexity.

Technical contributions. To show the polynomial-time solvability of Strict Temporal (s,z)-Separation for $\tau \leq 4$, we prove that a classic separator result of Lovász et al. [28] translates to the strict temporal setting. This is surprising since many other results about separators in the static case do not apply in the temporal case. In this context, we also develop a linear-time algorithm for Single-Source Shortest Strict Temporal Paths, improving the running time of the best known algorithm due to Wu et al. [37] by a logarithmic factor.

We settle the complexity of Length-Bounded (s,z)-Separation on planar graphs by showing its NP-hardness, which was left unanswered by Fluschnik et al. [17] and promises to be a valuable intermediate problem for proving hardness results. In the hardness reduction for Length-Bounded (s,z)-Separation we introduce a grid-like, planarity-preserving vertex gadget that is generally useful to replace "twin" vertices which in many cases are not planarity-preserving and which are often used to model weights.

While showing that Temporal (s,z)-Separation is fixed-parameter tractable when parameterized by the size of the temporal core, we employ a case distinction on the size of the temporal core, and show that in the non-trivial case we can reduce the problem to Node Multiway Cut. We identify an "above lower bound parameter" for Node Multiway Cut that is suitable to lower-bound the size of the temporal core, thereby making it possible to exploit a fixed-parameter tractability result due to Cygan et al. [12].

Related work. Our most important reference is the work of Kempe et al. [25] who proved that Temporal (s,z)-Separation is NP-hard. In contrast, Berman [7] proved that computing temporal (s,z)-cuts (edge deletion instead of vertex deletion) is polynomial-time

solvable. In the context of survivability of temporal graphs, Liang and Modiano [27] studied cuts where an edge deletion only lasts for δ consecutive time stamps. Moreover, they studied a temporal maximum flow defined as the maximum number of sets of journeys where each two journeys in a set do not use a temporal edge within some δ time steps. A different notion of temporal flows on temporal graphs was introduced by Akrida et al. [2]. They showed how to compute in polynomial time the maximum amount of flow passing from a source vertex s to a sink vertex z until a given point in time.

The vertex-variant of Menger's Theorem [29] states that the maximum number of vertex-disjoint paths from s to z equals the size of a minimum-cardinality (s, z)-separator. In static graphs, Menger's Theorem allows for finding a minimum-cardinality (s, z)-separator via maximum flow computations. However, Berman [7] proved that the vertex-variant of an analogue to Menger's Theorem for temporal graphs, asking for the maximum number of (strict) temporal paths instead, does not hold. Kempe et al. [25] proved that the vertex-variant of the former analogue to Menger's Theorem holds true if the underlying graph excludes a fixed minor. Mertzios et al. [30] proved another analogue of Menger's Theorem: the maximum number of strict temporal (s, z)-path which never leave the same vertex at the same time equals the minimum number of node departure times needed to separate s from z, where a node departure time (v, t) is the vertex v at time point t.

Michail and Spirakis [32] introduced the time-analogue of the famous Traveling Salesperson problem and studied the problem on temporal graphs of dynamic diameter $d \in \mathbb{N}$, that is, informally speaking, on temporal graphs where every two vertices can reach each other in at most d time steps at any time. Erlebach et al. [14] studied the same problem on temporal graphs where the underlying graph has bounded degree, bounded treewidth, or is planar. Additionally, they introduced a class of temporal graphs with regularly present edges, that is, temporal graphs where each edge is associated with two integers upper- and lower-bounding consecutive time steps of edge absence. Axiotis and Fotakis [5] studied the problem of finding the smallest temporal subgraph of a temporal graph such that single-source temporal connectivity is preserved on temporal graphs where the underlying graph has bounded treewidth. In companion work, we recently studied the computational complexity of (non-strict) temporal separation on several other restricted temporal graphs [18].

2 Preliminaries

Let $\mathbb{N}$ denote the natural numbers without zero. For $n \in \mathbb{N}$, we use $[n] := [1, n] = \{1, \ldots, n\}$.

Static graphs. We use basic notations from (static) graph theory [13]. Let $G = (V, E)$ be an *undirected, simple graph*. We use $V(G)$ and $E(G)$ to denote the set of vertices and set of edges of G, respectively. We denote by $G - V' := (V \setminus V', \{\{v, w\} \in E \mid v, w \in V \setminus V'\})$ the graph G without the vertices in $V' \subseteq V$. For $V' \subseteq V$, $G[V'] := G - (V \setminus V')$ denotes the *induced subgraph* of G by V'. A *path* of length ℓ is sequence of edges $P = (\{v_1, v_2\}, \{v_2, v_3\}, \ldots, \{v_\ell, v_{\ell+1}\})$ where $v_i \neq v_j$ for all $i, j \in [\ell + 1]$ with $i \neq j$. We set $V(P) = \{v_1, v_2, \ldots, v_{\ell+1}\}$. Path P is an (s, z)-*path* if $s = v_1$ and $z = v_{\ell+1}$. A set $S \subseteq V \setminus \{s, z\}$ of vertices is an (s, z)-*separator* if there is no (s, z)-path in $G - S$.

Temporal graphs. Let $\boldsymbol{G} = (V, \boldsymbol{E}, \tau)$ be a temporal graph. The graph $G_i(\boldsymbol{G}) = (V, E_i(\boldsymbol{G}))$ is called *layer* i of the temporal graph $\boldsymbol{G} = (V, \boldsymbol{E}, \tau)$ where $\{v, w\} \in E_i(\boldsymbol{G}) \Leftrightarrow (\{v, w\}, i) \in \boldsymbol{E}$. The *underlying graph* $G_\downarrow(\boldsymbol{G})$ of a temporal graph $\boldsymbol{G} = (V, \boldsymbol{E}, \tau)$ is defined as $G_\downarrow(\boldsymbol{G}) := (V, E_\downarrow(\boldsymbol{G}))$, where $E_\downarrow(\boldsymbol{G}) = \{e \mid (e, t) \in \boldsymbol{E}\}$. (We write G_i, E_i, $G_\downarrow$, and $E_\downarrow$ for short

if $\boldsymbol{G}$ is clear from the context.) For $X \subseteq V$ we define the *induced temporal subgraph* of X by $\boldsymbol{G}[X] := (X, \{(\{v, w\}, t) \in \boldsymbol{E} \mid v, w \in X\}, \tau)$. We say that $\boldsymbol{G}$ is *connected* if its underlying graph $G_{\downarrow}$ is connected. For surveys concerning temporal graphs we refer to [9, 31, 24, 26, 23].

Strict and non-strict temporal separators. Throughout the paper we assume that the underlying graph of the temporal input graph $\boldsymbol{G}$ is connected and that there is no time-edge between s and z. Furthermore, in accordance with Wu et al. [37] we assume that the time-edge set $\boldsymbol{E}$ is ordered by ascending time stamps. Moreover, we can assume that the number of layers is at most the number of time-edges:

▶ **Lemma 2.1 (⋆).** *Let $\mathcal{I} = (\boldsymbol{G} = (V, \boldsymbol{E}, \tau), s, z, k)$ be an instance of* (Strict) Temporal (s, z)-Separation. *There is an algorithm which computes in $\mathcal{O}(|\boldsymbol{E}|)$ time an instance $\mathcal{I}' = (\boldsymbol{G}' = (V, \boldsymbol{E}', \tau'), s, z, k)$ of* (Strict) Temporal (s, z)-Separation *which is equivalent to $\mathcal{I}$, where $\tau' \leq |\boldsymbol{E}'|$.*

Regarding our two models, we have the following connection:

▶ **Lemma 2.2 (⋆).** *There is a linear-time computable many-one reduction from* Strict Temporal (s, z)-Separation *to* Temporal (s, z)-Separation *that maps any instance $(\boldsymbol{G} = (V, \boldsymbol{E}, \tau), s, z, k)$ to an instance $(\boldsymbol{G}' = (V', \boldsymbol{E}', \tau'), s, z, k')$ with $k' = k$ and $\tau' = 2 \cdot \tau$.*

3 Hardness Dichotomy Regarding the Number of Layers

In this section we settle the complexity dichotomy of both Temporal (s, z)-Separation and Strict Temporal (s, z)-Separation regarding the number τ of time steps. We observe that both problems are strongly related to the following NP-complete [10, 35] problem:

Length-Bounded (s, z)-Separation (LBS)
Input: An undirected graph $G = (V, E)$, distinct vertices $s, z \in V$, and $k, \ell \in \mathbb{N}$.
Question: Is there a subset $S \subseteq V \setminus \{s, z\}$ such that $|S| \leq k$ and there is no (s, z)-path in $G - S$ of length at most ℓ?

Length-Bounded (s, z)-Separation is NP-complete even if the lower bound ℓ for the path length is five [6] and W[1]-hard with respect to the postulated separator size [20]. We obtain the following, improving a result by Kempe et al. [25] who showed NP-completeness of Temporal (s, z)-Separation and Strict Temporal (s, z)-Separation for all $\tau \geq 12$.

▶ **Theorem 3.1 (⋆).** Temporal (s, z)-Separation *is* NP*-complete for every maximum label $\tau \geq 2$ and* Strict Temporal (s, z)-Separation *is* NP*-complete for every $\tau \geq 5$. Moreover, both problems are* W[1]*-hard when parameterized by the solution size k.*

We only present the construction of the NP-hardness reduction for Temporal (s, z)-Separation, which is inspired by Baier et al. [6], and postpone the rest to the long version.

Proof (Construction). To show NP-completeness of Temporal (s, z)-Separation for $\tau = 2$ we present a reduction from the Vertex Cover problem where, given a graph $G = (V, E)$ and an integer k, the task is to determine whether there exists a set $V' \subseteq V$ of size at most k such that $G - V'$ does not contain any edge. Let $(G = (V, E), k)$ be an instance of Vertex Cover. We say that $V' \subseteq V$ is a *vertex cover* in G of size k if $|V'| = k$ and V' is a solution to $(G = (V, E), k)$. We refine the gadget of Baier et al. [6, Theorem 3.9] and reduce from Vertex Cover to Temporal (s, z)-Separation. Let $\mathcal{I} := (G = (V, E), k)$ be a Vertex Cover instance and $n := |V|$. We construct a Temporal (s, z)-Separation

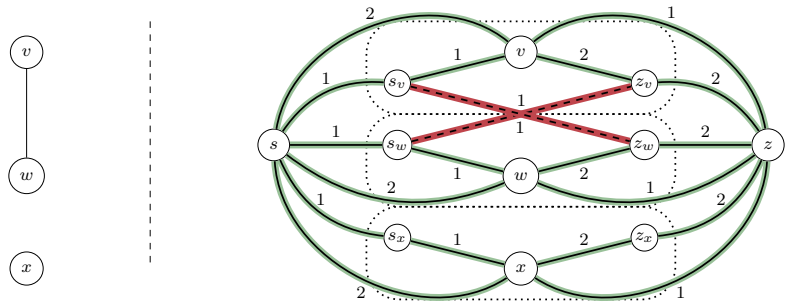

Figure 2 The Vertex Cover instance $(G, 1)$ (left) and the corresponding Temporal (s, z)-Separation instance from the reduction of Theorem 3.1 (right). The edge-edges are dashed (red), the vertex-edges are solid (green), and the vertex gadgets are in dotted boxes.

instance $\mathcal{I}' := (\boldsymbol{G}' = (V', \boldsymbol{E}', 2), s, z, n + k)$, where $V' := V \cup \{s_v, t_v \mid v \in V\} \cup \{s, z\}$ are the vertices and the time-edges are defined as

$$\boldsymbol{E}' := \overbrace{\{(\{s, s_v\}, 1), (\{s_v, v\}, 1), (\{v, z_v\}, 2), (\{z_v, z\}, 2), (\{s, v\}, 2), (\{v, z\}, 1) \mid v \in V\}}^{\text{vertex-edges}} \cup \underbrace{\{(\{s_v, z_w\}, 1), (\{s_w, z_v\}, 1) \mid \{v, w\} \in E\}}_{\text{edge-edges}}.$$

Note that $|V'| = 3 \cdot n + 2$, $|\boldsymbol{E}'| = 6 \cdot |V'| + 2 \cdot |E|$, and $\mathcal{I}'$ can be computed in polynomial time. For each vertex $v \in V$ there is a *vertex gadget* which consists of three vertices s_v, v, z_v and six vertex-edges. In addition, for each edge $\{v, w\} \in E$ there is an *edge gadget* which consists of two edge-edges $\{s_v, z_w\}$ and $\{z_v, s_w\}$. See Figure 2 for an example. ◀

In the remainder of this section we prove that the bound on τ is tight in the strict case (for the non-strict case the tightness is obvious). This is the first case where we can observe a significant difference between the strict and the non-strict variant of our separation problem.

▶ **Theorem 3.2.** Strict Temporal (s, z)-Separation *for maximum label $\tau \leq 4$ can be solved in $\mathcal{O}(k \cdot |\boldsymbol{E}|)$ time, where k is the solution size.*

As a subroutine hidden in several of our algorithms, we need to solve the Single-Source Shortest Strict Temporal Paths problem on temporal graphs: find shortest strict paths from a source vertex s to all other vertices in the temporal graph. Herein, we say that a strict temporal (s, z)-path is *shortest* if there is no strict temporal (s, z)-path of length $\ell' < \ell$. Indeed, we provide a linear-time algorithm for this. We believe this to be of independent interest; it improves (with few adaptations to the model; for details we refer to the long version) previous results by Wu et al. [37], but in contrast to the algorithm of Wu et al. [37] our subroutine cannot be adjusted to the non-strict case.

▶ **Proposition 3.3** ($\star$). Single-Source Shortest Strict Temporal Paths *is solvable in $\Theta(|\boldsymbol{E}|)$ time.*

Our algorithm behind Theorem 3.2 executes the following steps:

1. As a preprocessing step, remove unnecessary time-edges and vertices from the graph.
2. Compute an auxiliary graph called *directed path cover graph* of the temporal graph.
3. Compute a separator for the directed path cover graph.

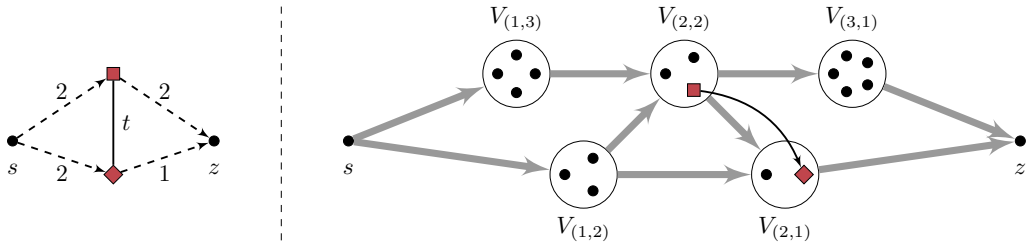

Figure 3 The left side depicts an excerpt of a reduced temporal graph with maximum time-edge label $\tau = 4$. Dashed arcs labeled with a number x indicate a shortest strict temporal path of length x. The right side depicts the directed path cover graph D from s to z of the reduced temporal graph. A gray arc from vertex set $V_{(i,j)}$ to vertex set $V_{(i',j')}$ denotes that for two vertices $v \in V_{(i,j)}$ and $w \in V_{(i',j')}$ there can be an arc from v to w in D. Take as an example the square-shaped vertex in $V_{(2,2)}$ and the diamond-shaped vertex in $V_{(2,1)}$.

In the following, we explain each of the steps in more detail.

The preprocessing *reduces* the temporal graph such that it has the following properties. A temporal graph $\boldsymbol{G} = (V, \boldsymbol{E}, \tau)$ with two distinct vertices $s, z \in V$ is *reduced* if

(i) the underlying graph $\boldsymbol{G}_{\downarrow}$ is connected,
(ii) for each time-edge $e \in \boldsymbol{E}$ there is a strict temporal (s, z)-path which contains e, and
(iii) there is no strict temporal (s, z)-path of length at most two in $\boldsymbol{G}$.

This preprocessing step can be performed in polynomial time:

▶ **Lemma 3.4** (⋆). *Let $\mathcal{I} = (\boldsymbol{G} = (V, \boldsymbol{E}, \tau), s, z, k)$ be an instance of* Strict Temporal (s, z)-Separation. *In $\mathcal{O}(k \cdot |\boldsymbol{E}|)$ time, one can either decide $\mathcal{I}$ or construct an instance $\mathcal{I}' = (\boldsymbol{G}' = (V', \boldsymbol{E}', \tau), s, z, k')$ of* Strict Temporal (s, z)-Separation *such that $\mathcal{I}'$ is equivalent to $\mathcal{I}$, $\boldsymbol{G}'$ is reduced, $|V'| \leq |V|$, $|\boldsymbol{E}'| \leq |\boldsymbol{E}|$, and $k' \leq k$.*

Lovász et al. [28] showed that the minimum size of an (s, z)-separator for paths of length at most four in a graph is equal to the number of vertex-disjoint (s, z)-paths of length at most four in a graph. We adjust their idea to strict temporal paths on temporal graphs. The proof of Lovász et al. [28] implicitly relies on the transitivity of connectivity in static graphs. This does not hold for temporal graphs; hence, we have to extend their result to the temporal case. To this end, we define a directed auxiliary graph.

▶ **Definition 3.5** (Directed Path Cover Graph). Let $\boldsymbol{G} = (V, \boldsymbol{E}, \tau = 4)$ be a reduced temporal graph with $s, z \in V$. The *directed path cover graph* from s to z of $\boldsymbol{G}$ is a directed graph $D = (V, \vec{E})$ such that $(v, w) \in \vec{E}$ if and only if

(i) $v, w \in V$,
(ii) $(\{v, w\}, t) \in \boldsymbol{E}$ for some $t \in [\tau]$, and
(iii) $v \in V_{(i,j)}$ and $w \in V_{(i',j')}$ such that $i < i'$, $v \in V_{(2,2)}$ and $w \in V_{(2,1)}$, $v = s$ and $w \in V_{(1,j)}$, or $w = z$ and $v \in V_{(i,1)}$ for some $i, j \in \{2, 3\}$.

Herein, a vertex $x \in V$ is in the set $V_{(i,j)}$ if the shortest strict temporal (s, x)-path is of length i and the shortest strict temporal (x, z)-path is of length j.

Figure 3 depicts a generic directed path cover graph of a reduced temporal graph with $\tau = 4$. Note that due to the definition of reduced temporal graphs, one can prove that the set $V_{(1,1)}$ is always empty, and hence not depicted in Figure 3. This is a crucial property that allows us to prove the following.

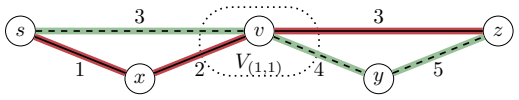

Figure 4 A reduced temporal graph with maximum label $\tau = 5$ where the vertex set $V_{(1,1)}$ of the directed path cover graph is not empty. The solid (red) and dashed (green) edges are strict temporal paths and show that edges $(\{s, v\}, 3)$ and $(\{v, z\}, 3)$ are not removed when the graph is reduced. Furthermore, v is not removed since $((\{s, v\}, 3), (\{v, z\}, 3))$ is not a strict temporal path.

▶ **Lemma 3.6** ($\star$). *Let $\boldsymbol{G} = (V, \boldsymbol{E}, \tau = 4)$ be a reduced temporal graph with $s, z \in V$. Then the directed path cover graph D from s to z of $\boldsymbol{G}$ can be computed in $\mathcal{O}(|\boldsymbol{E}|)$ time and $S \subseteq V \setminus \{s, z\}$ is a strict temporal (s, z)-separator in $\boldsymbol{G}$ if and only if S is an (s, z)-separator in D.*

Figure 4 shows that if $\tau = 5$, then we can construct a reduced temporal graph where the set $V_{(1,1)}$ is not empty. This indicates why our algorithm fails for $\tau = 5$.

Finally, with Lemmata 3.4 and 3.6 we can prove Theorem 3.2.

Proof of Theorem 3.2. Let $\mathcal{I} := (\boldsymbol{G} = (V, \boldsymbol{E}, \tau = 4), s, z, k)$ be an instance of Strict Temporal (s, z)-Separation. First, apply Lemma 3.4 in $\mathcal{O}(k \cdot |\boldsymbol{E}|)$ time to either decide $\mathcal{I}$ or to obtain an instance $\mathcal{I}' = (\boldsymbol{G}' = (V', \boldsymbol{E}', \tau), s, z, k')$ of Strict Temporal (s, z)-Separation. In the second case, compute the directed path cover graph D of $\boldsymbol{G}'$ from s to z in $\mathcal{O}(|\boldsymbol{E}'|)$ time (by Lemma 3.6). Next, check whether D has an (s, z)-separator of size at most k' in $\mathcal{O}(k' \cdot |\boldsymbol{E}'|)$ time by a folklore result [19]. By Lemma 3.6, D has an (s, z)-separator of size k' if and only if $\boldsymbol{G}'$ has a strict temporal (s, z)-separator of size k'. Since by Lemma 3.4 we have that $\boldsymbol{G}'$ is reduced, $|V'| \leq |V|$, $|\boldsymbol{E}'| \leq |\boldsymbol{E}|$, and $k' \leq k$, the overall running time is $\mathcal{O}(k \cdot |\boldsymbol{E}|)$. ◀

4 On Temporal Graphs with Planar Underlying Graph

In this section, we study our problems on *planar temporal graphs*, that is, temporal graphs that have a planar underlying graph. We show that both Temporal (s, z)-Separation and Strict Temporal (s, z)-Separation remain NP-complete on planar temporal graphs. On the positive side, we show that on planar temporal graphs with a constant number of layers, Strict Temporal (s, z)-Separation can be solved in $\mathcal{O}(|\boldsymbol{E}| \cdot \log |\boldsymbol{E}|)$ time.

In order to prove our hardness results, we first prove NP-hardness for Length-Bounded (s, z)-Separation on planar graphs – a result which we consider to be of independent interest; note that NP-completeness on planar graphs was only known for the edge-deletion variant of Length-Bounded (s, z)-Separation on undirected graphs [17] and weighted directed graphs [33].

▶ **Theorem 4.1.** Length-Bounded (s, z)-Separation *on planar graphs is* NP*-hard.*

Proof. We give a many-one reduction from the NP-complete [17] edge-weighted variant of Length-Bounded (s, z)-Cut, referred to as Planar Length-Bounded (s, z)-Cut, where the input graph $G = (V, E)$ is planar, has edge costs $c : E \to \{1, k + 1\}$, has maximum degree $\Delta = 6$, the degree of s and z is three, and s and z are incident to the outer face. Since the maximum degree is constant, one can replace a vertex with a planar grid-like gadget.

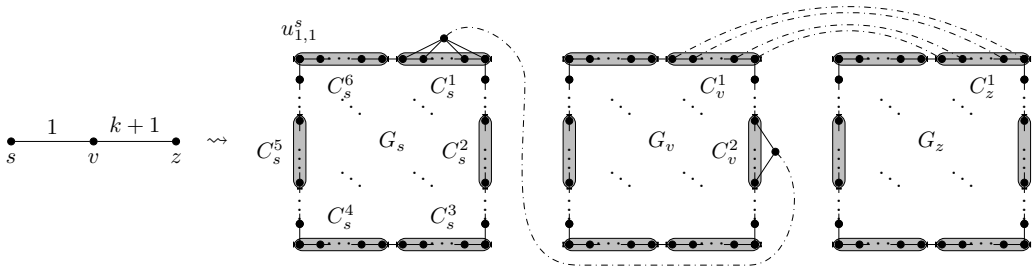

Figure 5 A simple planar graph G (left) with edge costs (above edges) and the obtained graph G' in the reduction from Theorem 4.1. The connector sets are highlighted in gray. The edge-gadgets are indicated by dash-dotted lines.

Let $\mathcal{I} := (G = (V, E, c), s, z, \ell, k)$ be an instance of Planar Length-Bounded (s, z)-Cut, and we assume k to be even[7]. We construct an instance $\mathcal{I}' := (G', s', z', \ell', k)$ of Length-Bounded (s, z)-Separation as follows (refer to Figure 5 for an illustration).

Construction. For each vertex $v \in V$, we introduce a *vertex-gadget* G_v which is a grid of size $(2k + 2) \times (2k + 2)$, that is, a graph with vertex set $\{u^v_{i,j} \mid i, j \in [2k + 2]\}$ and edge set $\{\{u^v_{i,j}, u^v_{i',j'}\} \mid |i - i'| + |j - j'| = 1\}$. There are six pairwise disjoint subsets $C^1_v, \ldots, C^6_v \subseteq V(G_v)$ of size $k + 1$ that we refer to as *connector sets*. As we fix an orientation of G_v such that $u^v_{1,1}$ is in the top-left, there are two connector sets on the top of G_v, two on the bottom of G_v, one on the left of G_v, and one on the right of G_v. Formally, $C^1_v = \{u^v_{1,k+2}, \ldots, u^v_{1,2k+2}\}$, $C^2_v = \{u^v_{k/2,2k+2}, \ldots, u^v_{3k/2,2k+2}\}$, $C^3_v = \{u^v_{2k+2,k+2}, \ldots, u^v_{2k+2,2k+2}\}$, $C^4_v = \{u^v_{2k+2,1}, \ldots, u^v_{2k+2,k+1}\}$, $C^5_v = \{u^v_{k/2,1}, \ldots, u^v_{3k/2,1}\}$, and $C^6_v = \{u^v_{1,1}, \ldots, u^v_{1,k+1}\}$.

Note that all (x, y)-paths are of length at most $k' := (2k + 2)^2 - 1$, for all $x, y \in V(G_v)$, because there are only $(2k + 2)^2$ vertices in $V(G_v)$.

Let $\phi(G)$ be a plane embedding of G. We say that an edge e incident with vertex $v \in V$ is *at position i on v* if e is the ith edge incident with v when counted clockwise with respect to $\phi(G)$.

For each edge $e = \{v, w\}$, we introduce an *edge-gadget* G_e that differs on the weight of e, as follows. Let e be at position $i \in \{1, \ldots, 6\}$ on v and at position $j \in \{1, \ldots, 6\}$ on w.

If $c(e) = 1$, then G_e is constructed as follows. Add a path consisting of $(\ell + 1) \cdot k' - 1$ vertices and connect one endpoint with each vertex in C^i_v by an edge and connect the other endpoint with each vertex in C^j_w by an edge.

If $c(e) = k + 1$, then G_e is constructed as follows. We introduce a planar matching between the vertices in C^i_v and C^j_w. That is, for instance, we connect vertex $u^v_{1,k+2+p}$ with vertex $u^w_{1,2k+2-p}$ for each $p \in \{0, \ldots, k\}$, if $i = j = 1$, or we connect vertex $u^v_{1,1+p}$ with vertex $u^w_{2k+2,3k/2-p}$ for each $p \in \{0, \ldots, k\}$, if $i = 6$ and $j = 2$ (we omit the remaining cases). Then, replace each edge by a path of length at least $(\ell + 1) \cdot k' + 1$ where its endpoints are identified with the endpoints of the replaced edge. Hence, a path between two vertex-gadgets has length at least $(\ell + 1) \cdot k' + 1$.

Next, we choose connector sets $C^{i'}_s$ and $C^{j'}_z$ such that no vertex $v \in C^{i'}_s \cup C^{j'}_z$ is adjacent to a vertex from an edge-gadget. Such i' and j' always exist because the degrees of s and z are both three. Now, we add two special vertices s' and z' and edges between s' and each vertex in $C^{i'}_s$, as well as between z' and each vertex in $C^{j'}_z$.

[7] If k is odd, since s and z are incident to the outer face, then we can add a path of length $\ell - 1$ with endpoints s and z and set the budget for edge deletions to $k + 1$.

Finally, we set $\ell' := 2 + (\ell+1) \cdot k' + \ell\,((\ell+1) \cdot k' + 1)$. Note that G' can be computed in polynomial time. Moreover, one can observe that G' is planar by obtaining an embedding from ϕ. This concludes the description of the construction.

Correctness. We claim that $\mathcal{I}$ is a yes-instance if and only if $\mathcal{I}'$ is a yes-instance.

$\Rightarrow$: Let $\mathcal{I}$ be a yes-instance. Thus, there is a solution $C \subset E$ with $c(C) \leq k$ such that there is no (s,z)-path of length at most ℓ in $G - C$. We construct a set $S \subset V(G')$ of size at most k by taking for each $\{v,w\} \in C$ one arbitrary vertex from the edge-gadget $G_{\{v,w\}}$ into S. Note that since $c(C) \leq k$, each edge in C is of cost one.

Assume towards a contradiction that there is a shortest (s',z')-path P' of length at most ℓ' in $G' - S$. Since a path between two vertex-gadgets has length at least $(\ell+1) \cdot k' + 1$, we know that P' goes through at most ℓ edge-gadgets. Otherwise P' would be of length at least $2 + (\ell+1) \cdot [(\ell+1) \cdot k' + 1] = 2 + (\ell+1) \cdot k' + \ell \cdot [(\ell+1) \cdot k' + 1] + 1 = \ell' + 1$. Now, we reconstruct an (s,z)-path P in G corresponding to P' by taking an edge $e \in E$ into P if P' goes through the edge-gadget G_e. Hence, the length of P is at most ℓ. This contradicts that there is no (s,z)-path of length at most ℓ in $G - C$. Consequently, there is no (s',z')-path of length at most ℓ' in $G' - S$ and $\mathcal{I}'$ is a yes-instance.

$\Leftarrow$: Let $\mathcal{I}'$ be a yes-instance. Thus, there is a solution $S \subseteq V(G')$ of minimum size (at most k) such that there is no (s',z')-path of length at most ℓ' in $G' - S$. Since S is of minimum size, it follows from the following claim that $V(G_v) \cap S = \emptyset$ for all $v \in V$.

▶ **Claim 4.2.** *Let G_v be a vertex-gadget and $i,j \in \{1,\ldots,6\}$ with $i \neq j$. Then, for each vertex set $S \subseteq V(G_v)$ of size at most k it holds that there are $v_1 \in C_v^i \setminus S$ and $v_2 \in C_v^j \setminus S$ such that there is a (v_1,v_2)-path of length at most k' in $G_v - S$.*

Proof of Claim 4.2. Let C_v^i, C_v^j two connector sets of a vertex-gadget G_v, where $i,j \in \{1,\ldots,6\}$ and $i \neq j$. We add vertices a and b and edges $\{a,a'\}$ and $\{b,b'\}$ to G_v, where $a' \in C_v^i$ and $b' \in C_v^j$. There are $\binom{6}{2}$ different cases in which $i \neq j$. It is not difficult to see that in each case there are $k+1$ vertex-disjoint (a,b)-paths. The claim then follows by Menger's Theorem [29]. ◀

Note that by minimality of S, it holds that $V(G_e) \cap S = \emptyset$ for all $e \in E$ with $c(e) = k+1$. We construct an edge set $C \subseteq E$ of cost at most k by taking $\{v,w\} \in E$ into C if there is a $y \in V(G_{\{v,w\}}) \cap S$.

Assume towards a contradiction that there is a shortest (s,z)-path P of length at most ℓ in $G - C$. We reconstruct an (s',z')-path P' in G' which corresponds to P as follows. First, we take an edge $\{s',v\} \in E(G')$ such that $v \in C_s^{i'} \setminus S$. Such a v always exists, because $|C_s^{i'}| = k+1$ and $|S| \leq k$. Let $\{s,w\} \in E$ be the first edge of P and at position i on w. Then we add a (v,v')-path P_s in $G_s - S$, such that $v' \in C_s^i \setminus S$. Due to Claim 4.2, such a (v,v')-path P_s always exists in $G_s - S$ and is of length at most k'.

We take an edge-gadget G_e into P' if e is in P. Recall, that an edge-gadget is a path of length $(\ell+1) \cdot k' + 1$. Due to Claim 4.2, we can connect the edge-gadgets $G_{\{v_1,v_2\}}, G_{\{v_2,v_3\}}$ of two consecutive edges $\{v_1,v_2\},\{v_2,v_3\}$ in P by a path of length at most k' in G_{v_2}. Let $\{v_p,z\}$ be the last edge in P, be at position j on z, $v \in C_z^j$, and $v' \in C_z^{j'}$. We add a (v,v')-path of length k' in $G_z - S$ (Claim 4.2). Note that P' visits at most $\ell+1$ vertex-gadgets and ℓ edge-gadgets. The length of P' is at most $2 + (\ell+1) \cdot k' + \ell\,[(\ell+1) \cdot k' + 1] = \ell$. This contradicts that S forms a solution for $\mathcal{I}'$.

It follows that there is no (s,z)-path of length at most ℓ in $G - C$ and $\mathcal{I}$ is a yes-instance. ◀

From the proofs of Theorem 3.1 and Lemma 2.2 (planarity-preserving reductions for the underlying graph), together with Theorem 4.1 we get the following:

▶ **Corollary 4.3.** *Both* Temporal (s,z)-Separation *and* Strict Temporal (s,z)-Separation *on planar temporal graphs are* NP*-complete.*

In contrast to the case of general temporal graphs, Strict Temporal (s,z)-Separation on planar temporal graphs is efficiently solvable if the maximum label τ is any constant. To this end, we employ the optimization variant of Courcelle's Theorem [4, 11].

▶ **Proposition 4.4** ($\star$)**.** Strict Temporal (s,z)-Separation *on planar temporal graphs can be solved in* $\mathcal{O}(|\boldsymbol{E}| \cdot \log |\boldsymbol{E}|)$ *time, if the maximum label* τ *is constant.*

Due to space constrains, we only sketch how one can develop MSO formulas over temporal graphs and postpone the full proof to the long version.

Proof (Sketch). Let $\mathcal{I} = (\boldsymbol{G} = (V, \boldsymbol{E}, \tau), s, z, k)$ be an instance of Strict Temporal (s,z)-Separation, where the underlying graph $G_{\downarrow}$ of $\boldsymbol{G}$ is planar. We define the edge-labeled graph $L(\boldsymbol{G})$ to be $G_{\downarrow}$ with the edge-labeling $\omega : E(G_{\downarrow}) \to [2^{\tau}-1]$ with $\omega(\{v,w\}) = \sum_{i=1}^{\tau} \mathbb{1}_{\{v,w\}\in E_i} \cdot 2^{i-1}$, where $\mathbb{1}_{\{v,w\}\in E_i} = 1$ if and only if $(\{v,w\}, i) \in \boldsymbol{E}$, and 0 otherwise. Observe that in binary representation, the i-th bit of $\omega(\{v,w\})$ is 1 if and only if $\{v,w\}$ exists at time point i.

We define the optimization variant of Strict Temporal (s,z)-Separation in MSO on $L(\boldsymbol{G})$. First, the MSO formula $\mathrm{layer}(e,t) := \bigvee_{i=1}^{\tau} \bigvee_{j\in\sigma(i,2^{\tau}-1)} \big(t = i \ \wedge \omega(e) = j\big)$ checks whether an edge e is present in the layer t, where $\sigma(i,j) := \{x \in [j] \mid i\text{-th bit of } x \text{ is } 1\}$. Second, we can write an MSO formula $\mathrm{tempadj}(v,w,t) := \exists_{e\in E}\big(\mathrm{inc}(e,v) \wedge \mathrm{inc}(e,w) \wedge \mathrm{layer}(e,t)\big)$ to determine whether two vertices v and w are adjacent at time point t. Third, there is an MSO formula

$$\mathrm{path}(S) := \exists_{x_1,\ldots,x_{\tau+1}\in V\setminus S}\Big(x_1 = s \wedge x_{\tau+1} = z \wedge \bigwedge_{i=1}^{\tau}\big(x_i = x_{i+1} \vee \mathrm{tempadj}(x_i, x_{i+1}, i)\big)\Big)$$

to check whether there is a strict temporal (s,z)-path which does not visit any vertex in S. Note that the length of $\mathrm{layer}(e,t)$, and hence the length of $\mathrm{path}(S)$, is upper-bounded by some function in $2^{\mathcal{O}(\tau)}$. The facts that the length of a strict temporal (s,z)-path is at most τ and the treewidth of a planar graph can be bounded in its diameter (see Flum and Grohe [16]), together with an application of Courcelle's Theorem (optimization variant, see long version) on the MSO formula $\phi(S) := S \subseteq (V \setminus \{s,z\}) \wedge \neg\mathrm{path}(S)$ complete the proof. ◀

5 On Temporal Graphs with Small Temporal Cores

In this section, we investigate the complexity of deciding (Strict) Temporal (s,z)-Separation on temporal graphs where the number of vertices whose incident edges change over time is small. We call the set of such vertices the *temporal core* of the temporal graph.

▶ **Definition 5.1** (Temporal core)**.** For a temporal graph $\boldsymbol{G} = (V, \boldsymbol{E}, \tau)$, the vertex set $W = \{v \in V \mid \exists\{v,w\} \in (\bigcup_{i=1}^{\tau} E_i) \setminus (\bigcap_{i=1}^{\tau} E_i)\} \subseteq V$ is called the *temporal core*.

A temporal graph is often composed of a public transport system and an ordinary street network. Here, the temporal core consists of vertices involved in the public transport system.

For Strict Temporal (s,z)-Separation, we can observe that the hardness reduction described in the proof of Theorem 3.1 produces an instance with an empty temporal core. In stark contrast, we show that Temporal (s,z)-Separation is fixed-parameter tractable when parameterized by the size of the temporal core[8]. We reduce an instance to Node

[8] Note that we can compute the temporal core in $\mathcal{O}(|\boldsymbol{E}| \log |\boldsymbol{E}|)$ time.

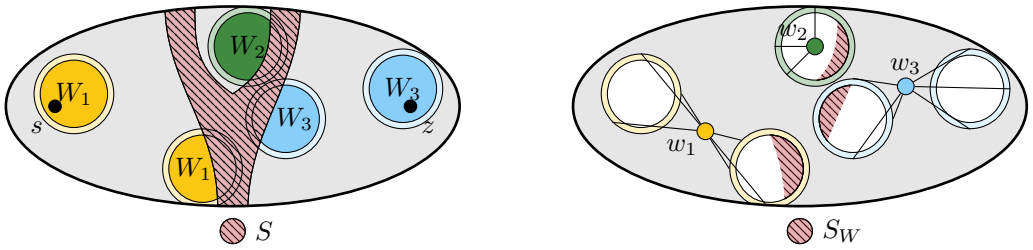

Figure 6 Illustration of the idea behind the proof of Theorem 5.2. *Left-hand side*: Sketch of a temporal graph $\boldsymbol{G}$ (enclosed by the ellipse) with temporal (s, z) separator S (red hatched) and induced partition $\{S_W, W_1, W_2, W_3\}$ of the temporal core W, where $S_W = W \cap S$. The outer rings of W_1, W_2, W_3 contain the open neighborhood of the sets. *Right-hand side*: Sketch of the constructed graph G' (enclosed by the ellipse). The partition $\{S_W, W_1, W_2, W_3\}$ is guessed in steps (1) and (2). The vertices w_1, w_2, w_3 with edges to the neighborhood of W_1, W_2, W_3, respectively, are created in step (3).

Multiway Cut (NWC) in such a way that we can use an above lower bound FPT-algorithm due to Cygan et al. [12] for NWC as a subprocedure in our algorithm for Temporal (s, z)-Separation. Note that the above lower bound parameterization is crucial to obtain the desired FPT-running time bound. Recall the definition of NWC:

Node Multiway Cut (NWC)
Input: An undirected graph $G = (V, E)$, a set of terminals $T \subseteq V$, and an integer k.
Question: Is there a set $S \subseteq (V \setminus T)$ of size at most k such there is no (t_1, t_2)-path for every distinct $t_1, t_2 \in T$?

We remark that Cygan et al.'s algorithm can be modified to obtain a solution S. Formally, we show the following.

▶ **Theorem 5.2.** Temporal (s, z)-Separation *can be solved in* $2^{|W|\cdot(\log|W|+2)} \cdot |V|^{\mathcal{O}(1)} + \mathcal{O}(|\boldsymbol{E}| \log |\boldsymbol{E}|)$ *time, where* W *denotes the temporal core of the input graph.*

Proof. Let instance $\mathcal{I} = (\boldsymbol{G} = (V, \boldsymbol{E}, \tau), s, z, k)$ of Temporal (s, z)-Separation with temporal core $W \subseteq V$ be given. Without loss of generality, we can assume that $s, z \in W$, as otherwise we add two vertices one being incident only with s and the other being incident only with z, both only in layer one. Furthermore, we need the notion of a *maximal static subgraph* $\widehat{G}$ of a temporal graph $\boldsymbol{G} = (V, \boldsymbol{E})$: It contains all edges that appear in every layer, more specifically $\widehat{G} = (V, \widehat{E})$ with $\widehat{E} = \bigcap_{i \in [\tau]} E_i$. Our algorithm works as follows.

(1) Guess a set $S_W \subseteq (W \setminus \{s, z\})$ of size at most k.
(2) Guess a number r and a partition $\{W_1, \ldots, W_r\}$ of $W \setminus S_W$ such that s and z are not in the same W_i, for some $i \in [r]$.
(3) Construct the graph G' by copying $\widehat{G} - W$ and adding a vertex w_i for each part W_i. Add edge sets $\{\{v, w_i\} \mid v \in N_{\widehat{G}}(W_i) \setminus W\}$ for all $i \in [r]$ and for all $i, j \in [r]$ add an edge $\{w_i, w_j\}$ if $N_{\widehat{G}}(W_i) \cap W_j \neq \emptyset$.
(4) Solve the NWC instance $\mathcal{I}' = (G', \{w_1, \ldots, w_r\}, k - |S_W|)$.
(5) If a solution S' is found for $\mathcal{I}'$ and $S' \cup S_W$ is a solution for $\mathcal{I}$, then output yes.
(6) If all possible guesses in (1) and (2) are considered without finding a solution for $\mathcal{I}$, then output no.

See Figure 6 for a visualization of the constructed graph G'. Since we do a sanity check in step (5) it suffices to show that if $\boldsymbol{G}$ has a temporal (s, z)-separator of size at most k, then there is a partition $\{S_W, W_1, \ldots, W_r\}$ of W where s and z are in different parts such that

(i) the NWC instance $\mathcal{I}'$ has a solution of size at most $k - |S_W|$, and
(ii) if S' is a solution to $\mathcal{I}'$, then $S_W \cup S'$ is a temporal (s,z)-separator in $\boldsymbol{G}$.

Let S be a temporal (s,z)-separator of size at most k in $\boldsymbol{G}$. First, we set $S_W = S \cap W$. Let $C_1, \ldots, C_r$ be the connected components of $\widehat{G} - S$ with $C_i \cap W \neq \emptyset$ for all $i \in [r]$. Now we construct a partition $\{S_W, W_1, \ldots, W_r\}$ of W such that $W_i = W \cap C_i$ for all $i \in [r]$. It is easy to see that s and z are in different parts of this partition. Observe that for $i, j \in [r]$ with $i \neq j$ the vertices $v \in W_i$ and $u \in W_j$ are in different connected components of $\widehat{G} - S$. Hence, $w_1, \ldots, w_r$ are in different connected components of $G' - (S \setminus S_W)$. Thus $S \setminus S_W$ is a solution of size at most $k - |S_W|$ of the NWC instance $\mathcal{I}' = (G', \{w_1, \ldots, w_r\}, k - |S_W|)$, proving (i).

For the correctness, it remains to prove (ii). Let S' be a solution of size at most $k - |S_W|$ of the NWC instance $\mathcal{I}'$. We need to prove that $S' \cup S_W$ forms a temporal (s,z)-separator in $\boldsymbol{G}$. Clearly, if $S' = S \setminus S_W$, we are done by the arguments before. Thus, assume $S' \neq S \setminus S_W$. Since S' is a solution to $\mathcal{I}'$, we know that $w_1, \ldots, w_r$ are in different connected components of $G' - S'$. Hence, for $i, j \in [r]$ with $i \neq j$ the vertices $v \in W_i$, $u \in W_j$ are in different connected components of $\widehat{G} - (S' \cup S_W)$.

Now assume towards a contradiction that there is a temporal (s,z)-path P in $\boldsymbol{G} - (S' \cup S_W)$. Observe that $\{s,z\} \subseteq V(P) \cap W$. Hence, we have two different vertices $u_1, u_2 \in V(P) \cap W$ such that there is no temporal (u_1,u_2)-path in $\boldsymbol{G} - S$ and all vertices that are visited by P between u_1 and u_2 are contained in $V \setminus W$: Take the furthest vertex in P that is also contained in W and is reachable by a temporal path from s in $\boldsymbol{G} - S$ as u_1, and take the next vertex (after u_1) in P that is also contained in W as u_2. Note that u_1 and u_2 are disconnected in $\widehat{G} - S$, and hence there are $i, j \in [r]$ with $i \neq j$ such that $u_1 \in W_i$ and $u_2 \in W_j$. Since P does not visit any vertices in $(S' \cup S_W)$ we can conclude that u_1 and u_2 are connected in $\widehat{G} - (S' \cup S_W)$, and hence w_i and w_j are connected in $G' - S'$. This contradicts the fact that S' is a solution for $\mathcal{I}'$.

Running time: It remains to show that the our algorithm runs in the proposed time. For the guess in step (1) there are at most $2^{|W|}$ many possibilities. For the guess in step (2) there are at most $B_{|W|} \leq 2^{|W| \cdot \log(|W|)}$ many possibilities, where B_n is the n-th Bell number. Step (3) and the sanity check in step (5) can clearly be done in polynomial time.

Let L be a minimum (s,z)-separator in $\widehat{G} - (W \setminus \{s,z\})$. If $k \geq |W \setminus \{s,z\}| + |L|$, then $(W \setminus \{s,z\}) \cup L$ is a temporal (s,z)-separator of size at most k for $\boldsymbol{G}$. Otherwise, we have that $k - |L| < |W|$. Cygan et al. [12] showed that NWC can be solved in $2^{k-b} \cdot |V|^{\mathcal{O}(1)}$ time , where $b := \max_{x \in T} \min\{|S| \mid S \subseteq V \text{ is an } (x, T \setminus \{x\})\text{-separator}\}$. Since s and z are not in the same W_i for any $i \in [r]$, we know that $|L| \leq b$. Hence, $k - b \leq k - |L| < |W|$ and step (4) can be done in $2^{|W|} \cdot |V|^{\mathcal{O}(1)}$ time. Thus we have an overall running time of $2^{|W| \cdot (\log |W| + 2)} \cdot |V|^{\mathcal{O}(1)} + \mathcal{O}(|\boldsymbol{E}| \log |\boldsymbol{E}|)$. ◀

We conclude that the strict and the non-strict variant of Temporal (s,z)-Separation behave very differently on temporal graphs with a constant-size temporal core. While the strict version stays NP-complete, the non-strict version becomes polynomial-time solvable.

6 Conclusion

The temporal path model strongly matters when assessing the computational complexity of finding small separators in temporal graphs. This phenomenon has so far been neglected in the literature. We settled the complexity dichotomy of Temporal (s,z)-Separation and Strict Temporal (s,z)-Separation by proving NP-hardness on temporal graphs

with $\tau \geq 2$ and $\tau \geq 5$, respectively, and polynomial-time solvability if the number of layers is below the respective constant. The mentioned hardness results also imply that both problem variants are W[1]-hard when parameterized by the solution size k. When considering the parameter combination $k + \tau$, it is easy to see that Strict Temporal (s, z)-Separation is fixed-parameter tractable [38]: There is a straightforward search-tree algorithm that branches on all vertices of a strict temporal (s, z)-path which has length at most τ. Whether the non-strict variant is fixed-parameter tractable regarding the same parameter combination remains open.

We showed that (Strict) Temporal (s, z)-Separation on temporal graphs with planar underlying graphs remains NP-complete. However, for the planar case we proved that if additionally the number τ of layers is a constant, then Strict Temporal (s, z)-Separation is solvable in $\mathcal{O}(|\boldsymbol{E}| \cdot \log |\boldsymbol{E}|)$ time. We leave open whether Temporal (s, z)-Separation admits a similar result. Finally, we introduced the notion of a temporal core as a temporal graph parameter. We proved that on temporal graphs with constant-size temporal core, while Strict Temporal (s, z)-Separation remains NP-hard, Temporal (s, z)-Separation is solvable in polynomial time.

Abstract

The transducer synthesis problem on finite words asks, given a specification $S \subseteq I \times O$, where I and O are sets of finite words, whether there exists an implementation $f : I \to O$ which (1) fulfils the specification, i.e., $(i, f(i)) \in S$ for all $i \in I$, and (2) can be defined by some input-deterministic (aka sequential) transducer $\mathcal{T}_f$. If such an implementation f exists, the procedure should also output $\mathcal{T}_f$. The realisability problem is the corresponding decision problem.

For specifications given by synchronous transducers (which read and write alternately one symbol), this is the finite variant of the classical synthesis problem on ω-words, solved by Büchi and Landweber in 1969, and the realisability problem is known to be ExpTime-c in both finite and ω-word settings. For specifications given by asynchronous transducers (which can write a batch of symbols, or none, in a single step), the realisability problem is known to be undecidable.

We consider here the class of multi-sequential specifications, defined as finite unions of sequential transducers over possibly incomparable domains. We provide optimal decision procedures for the realisability problem in both the synchronous and asynchronous setting, showing that it is PSpace-c. Moreover, whenever the specification is realisable, we expose the construction of a sequential transducer that realises it and has a size that is doubly exponential, which we prove to be optimal.

1 Introduction

The realisability and synthesis problem. In general, the realisability problem is given by some input and output data domains $D_{\mathtt{i}}, D_{\mathtt{o}}$, a *specification* $S \subseteq D_{\mathtt{i}} \times D_{\mathtt{o}}$ defining for every $d \in D_{\mathtt{i}}$ the set of allowed outputs $\{d' \in D_{\mathtt{o}} \mid (d, d') \in S\}$ (assumed to be non-empty) and a class of target *implementations* $\mathcal{I}$ consisting of (total) functions $D_{\mathtt{i}} \to D_{\mathtt{o}}$. It asks whether there exists $f \in \mathcal{I}$ such that for all $d \in D_{\mathtt{i}}$, $(d, f(d)) \in S$, i.e., the implementation f satisfies the specification. The synthesis problem asks to generate (a representation of) f. So, instead of designing f and verifying its correctness *a posteriori*, a synthesis algorithm automatically generates f from it, making it *correct by construction*. The underlying idea behind synthesis is that the specification may be written in a high-level language, e.g. a logic, and an implementation is a low-level computational model e.g. an automaton. It is based on the assumption that it is less error-prone to design a specification, i.e. to describe *what* a system has to do, than designing the system itself, i.e. describing *how* it must do it.

Synchronous transducer synthesis. In the original setting defined by Church [7, 29], $D_{\mathtt{i}}, D_{\mathtt{o}}$ are sets of ω-words over two alphabets $\Sigma_{\mathtt{i}}, \Sigma_{\mathtt{o}}$ respectively, and the specification S is given by an ω-language $L \subseteq (\Sigma_{\mathtt{i}} \times \Sigma_{\mathtt{o}})^\omega$ as follows: $S = \{(\pi_1(w), \pi_2(w)) \mid w \in L\}$, where π_i is the projection on the ith component. The language L is represented by an MSO-sentence or, equivalently, an automaton. Such automata are also called (non-deterministic) *synchronous transducers*, as they can be seen as machines alternately reading one input symbol and synchronously producing one output symbol. In Church's setting, the target implementations are synchronous *sequential* transducers (also called *input-deterministic*): they alternately read one input symbol and deterministically produce a symbol to output. Determinism is required because implementations are required to use only finite-memory. The Church's instance of the realisability problem is decidable if the specification is given in MSO and ExpTime-c if it is given by a synchronous transducer [21]. For LTL specifications, it is 2ExpTime-c [27]. Motivated by reactive systems, the synthesis problem from LTL specifications has been revisited recently with efficient symbolic methods [20, 28, 14, 10, 18]. The synthesis problem in general has also motivated an active research on infinite games [1, 9, 5].

Asynchronous transducer synthesis. In the asynchronous setting, specifications may not strictly alternate between input and output symbols, hence they can no longer be seen as languages over $\Sigma_{\mathtt{i}} \times \Sigma_{\mathtt{o}}$. Similarly, the target implementations may not be synchronous: the system can delay its production of outputs, or produce several symbols at once. Transducers, in contrast to synchronous transducers, are by definition asynchronous: their transitions are labelled by pairs (i, w) where $i \in \Sigma_{\mathtt{i}}$ is a symbol and $w \in \Sigma_{\mathtt{o}}^*$ a word, possibly empty. Since they are generally non-deterministic, to a single input word may correspond several output words, and thus transducers define subsets of $\Sigma_{\mathtt{i}}^* \times \Sigma_{\mathtt{o}}^*$. Therefore, they are well-suited to represent (asynchronous) specifications, and in their sequential version, asynchronous implementations. Any asynchronous specification is realisable by some unambiguous (functional) asynchronous transducer [24, 11, 3]. However, evaluating unambiguous transducers on arbitrarily long or even infinite input words may require arbitrarily large memory. Therefore, just as in Church's setting, a sequentiality requirement can be put on implementations for efficient memory usage. However, the realisability of asynchronous specifications by (asynchronous) sequential transducers, which is called the *sequential uniformisation problem* in transducer-theoretic terms, is undecidable for finite words [4, 12]. If the specification is finite-valued (i.e. any input word has a constant number of output words), the problem is in 3ExpTime [12]. The

proof of [12] is based on Ramsey's theorem and word combinatorics arguments, and it is not clear how to reduce the complexity. This raises the question of whether there are natural and non-trivial subclasses of asynchronous specifications with better complexity.

Multi-sequential specifications. In this paper, we consider a class of specifications S on finite words, i.e. $S \subseteq \Sigma_{\mathtt{i}}^* \times \Sigma_{\mathtt{o}}^*$, which strictly restricts the class of finite-valued specifications to so-called multi-sequential specifications. Such class is obtained by closure under finite unions of graphs of sequential functions. Precisely, $S = \bigcup_{i=1}^{n} S_i$ where S_i is the graph of a (partial) function $f_i : \Sigma_{\mathtt{i}}^* \to \Sigma_{\mathtt{o}}^*$ defined by a sequential transducer. Likewise, a transducer is multi-sequential if it is a union of state-disjoint sequential transducers. For instance, consider the specification S consisting of the pairs (w, w') such that w' is a subword of w of fixed length k. This specification is multi-sequential: $S = \bigcup_{w' \in \Sigma_{\mathtt{i}}^k} S_{w'}$ where $S_{w'} = \{(w, w') \mid w' \text{ subword of } w\}$. Clearly, $S_{w'}$ can be represented by a sequential transducer, because w' is fixed: once the first symbol of w' is met in w, output it, and proceed to the second symbol of w', etc., until the last symbol of w' is produced, reject otherwise. The notion of multi-sequentiality has been introduced for functions in [6] and studied for relations in [19]. An important property of the class of multi-sequential specifications is its decidability in PTime: Given a transducer, it is decidable in PTime whether it defines a multi-sequential specification [19]. This fact and their natural definition as closure of sequential functions under union make multi-sequential specifications a good candidate for a class of specifications with better complexity than the known results of the literature.

Contributions. We investigate the complexity of sequential transducer synthesis from specifications defined by multi-sequential transducers on finite words. We show that both in the synchronous and asynchronous settings, the realisability problem is PSpace-complete. To the best of our knowledge, it is the first non-trivial class of specifications which admits a realisability test below ExpTime. If the specification is realisable, we show how to extract an implementation as a winning strategy in a two-player game called the *synthesis game*. It is parameterised by a value $k \in \mathbb{N}$ which bounds the maximal number of output symbols which can be queued before being outputted, allowing for an incremental synthesis algorithm. To keep track of such output symbols, we use the notion of *delay* [2].

Difficulties and examples. Let us briefly explain what are the main difficulties to overcome. Consider $S = \bigcup_i S_i$ a multi-sequential specification. If all of the S_i have disjoint domains, then S is a function, which is realisable by a sequential transducer iff it is sequential. The latter can be tested in PTime [2]. The problem becomes more interesting and challenging when the S_i have domains which are not necessarily disjoint. Consider for example the 2-sequential transducer $\mathcal{D}_1 \cup \mathcal{D}_2$ of Fig. 1. The transducer $\mathcal{D}_1$ accepts the words containing at least two a's, and replaces b's with a's, and $\mathcal{D}_2$ accepts the words containing at least one b, and replaces a's with b's. This specification can be realised by a sequential transducer which waits two steps before outputting something, since it then knows whether the input contains at least one b or two a's. It then behaves as $\mathcal{D}_1$ in the first case, and as $\mathcal{D}_2$ in the second.

This example shows that a sequential realiser may have to wait before reacting, keeping in memory what remains to be output in the future. Take on the contrary the 2-sequential transducer $\mathcal{D}'_1 \cup \mathcal{D}'_2$ of Fig. 1, which is the same as $\mathcal{D}_1 \cup \mathcal{D}_2$ except that it can additionally read and copy c's at any moment. In that case, a sequential realiser would have to store arbitrary long sequences of c's before outputting them, for instance when processing words in $ac^*\{a, b, c\}^*$. In particular, this specification is not sequentially realisable.

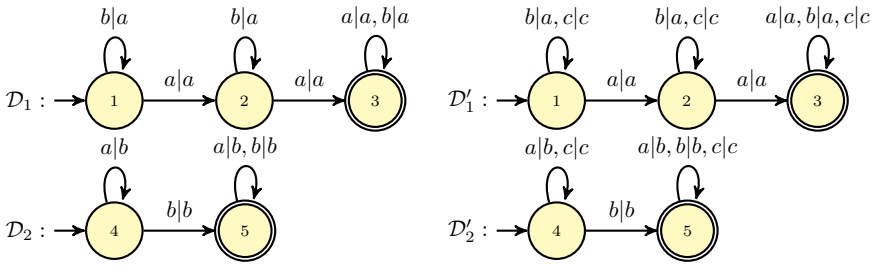

Figure 1 Four synchronous sequential transducers.

Structure of the paper. After a formal definition of transducer synthesis (Section 2), we solve the synchronous case and provide a characterisation of realisable synchronous multi-sequential specifications, decidable in PSpace (Section 3). Then, we present the notion of synthesis game (Section 4), which is a useful tool for the proofs and also to get a synthesis procedure. For the asynchronous setting, we define a recursive characterisation of realisable multi-sequential specifications and show that it can be decided in PSpace (Section 5).

Related work. Games with delays have been used in [4, 15]. Perhaps the closest formulation to ours is that of [4]. However, it is tailored to automatic relation. Our game structure is more general, as it is defined for uniformising any transducer (defining a rational relation). In particular, our game structure is exponentially larger that the one of [4].

We would also like to mention an interesting related line of works on ω-words, where the specification is synchronous, but the implementation may be asynchronous [15, 17, 22, 23, 30, 31, 32]. Unlike the setting where the specification and implementations are both asynchronous, the realisability problem is decidable here, for ω-regular specifications (i.e., regular ω-languages over $\Sigma_{\mathtt{i}} \times \Sigma_{\mathtt{o}}$), and ExpTime-c if the specification is given by a parity automaton [22]. In this setting, the authors often consider a notion of delay games. In these games, the delay is a quantitative notion, corresponding to the waiting time before outputting a symbol, while for us, a delay is a word that still remains to be output (this is a standard terminology in transducer theory). It is known in particular that constant "waiting time" (depending on the specification) is always sufficient to win, for ω-regular specifications. This is different to our setting: for instance, the function f mapping any word of the form $a^n\sigma$, for $n > 0$ and $\sigma \in \{a, b\}$, to σ is realisable by a sequential transducer, but the production of a and b might have to be delayed for an unbounded amount of time.

2 Transducer synthesis problem

Words. For an alphabet Σ, we denote by Σ^* the set of finite words over it, and by ϵ the empty word. The length $|w|$ of a word w is its number of symbols. For $k \in \mathbb{N}$, we denote by Σ^k (resp. $\Sigma^{\leq k}$) the set of words of length k (resp. at most k). For $u, v \in \Sigma^*$, we write $u \preceq v$ if u is a prefix of v, and denote by $u^{-1}v$ the word such that $u(u^{-1}v) = v$. For $L \subseteq \Sigma^*$, the residual language $u^{-1}L$ is $u^{-1}L = \{u' \mid uu' \in L\}$. Given $S \subseteq \Sigma^* \times \Gamma^*$, and $(u, v) \in \Sigma^* \times \Gamma^*$, the residual relation $(u, v)^{-1}S$ is defined by $(u, v)^{-1}S = \{(u', v') \mid (uu', vv') \in S\}$.

Automata. In this paper, finite (non-deterministic) automata over an alphabet Σ are denoted as tuples $\mathcal{A} = (\Sigma, Q, I, F, \Delta)$ where Σ is the alphabet, Q the set of states, among which I (resp. F) denotes the initial (resp. final or accepting) states, and $\Delta \subseteq Q \times \Sigma \times Q$ is the transition relation. $\mathcal{A}$ is deterministic if there is only one initial state and for all $(q, \sigma) \in Q \times \Sigma$, there exists at most one $q' \in Q$ such that $(q, \sigma, q') \in \Delta$.

A *run* of $\mathcal{A}$ on a word $w = \sigma_1 \dots \sigma_n$ consists in either a single state $q \in Q$ if $n = 0$, or a sequence $r \in \Delta^*$ of n transitions $t_1 \dots t_n$ such that the target state of t_i equals the source state of t_{i+1} for all $1 \leq i < n$. It is said to be initial if the source state of t_1 is initial, and accepting if the target state of t_n is accepting. If p is the source state of t_1 and q the target state of t_n, we may write $p \xrightarrow{w}_{\mathcal{A}} q$ to mean that there exists a run from p to q on w. The language accepted by an automaton $\mathcal{A}$, denoted $L(\mathcal{A})$, is the set of words admitting an accepting run. A state $q \in Q$ is reachable (resp. co-reachable) if there is a run from an initial state (resp. to a final state) for some $u \in \Sigma^*$. A state is said to be *useful* if it is both reachable and co-reachable, and $\mathcal{A}$ is said to be *trim* if all its states are useful. It is well-known that any automaton can be transformed into an equivalent trim automaton in PTime. Given two automata $\mathcal{A}_1 = (\Sigma, Q_1, I_1, F_1, \Delta_1)$ and $\mathcal{A}_2 = (\Sigma, Q_2, I_2, F_2, \Delta_2)$, their disjoint union $\mathcal{A}_1 \uplus \mathcal{A}_2$ is the automaton $(\Sigma, Q_1 \uplus Q_2, I_1 \uplus I_2, F_1 \uplus F_2, \Delta_1 \uplus \Delta_2)$.

Transducers. A *transducer*[4] over two alphabets Σ, Γ is a tuple $\mathcal{T} = (\mathcal{A}, \rho, \tau)$ such that $\mathcal{A} = (\Sigma, Q, I, F, \Delta)$ is an automaton over Σ, called the *input automaton*, $\rho : \Delta \to \Gamma^*$ is a mapping, called the output function, associating with every transition an output word, and $\tau : F \to \Gamma^*$ is a terminal function associating with every accepting state an output word. Given a run r of $\mathcal{A}$ on a word w, its output $\text{out}(r) \in \Gamma^*$ is defined by ϵ if $w = \epsilon$, and by $\rho(t_1) \dots \rho(t_n)$ if $r = t_1 \dots t_n$ for some $n \geq 1$. We write $p \xrightarrow{u|v}_{\mathcal{T}} q$ whenever there exists a run r of $\mathcal{A}$ on u from p to q, such that $v = \text{out}(r)$, and say that r *produces* v. The *relation* defined by $\mathcal{T}$ is the set $[\![\mathcal{T}]\!]$ of pairs $(u, v\tau(q)) \in \Sigma^* \times \Gamma^*$ such that $p \xrightarrow{u|v}_{\mathcal{T}} q$ for $p \in I$ and $q \in F$. We define $\text{dom}(\mathcal{T})$ by $\text{dom}(\mathcal{T}) = \text{dom}([\![\mathcal{T}]\!]) = L(\mathcal{A})$.

A transducer is *trim* if its input automaton is trim. It is called *sequential* if its input automaton is deterministic, and *functional* if $[\![\mathcal{T}]\!]$ is a function, i.e. for all $u \in \text{dom}(\mathcal{T})$, there exists at most one pair $(u, v) \in [\![\mathcal{T}]\!]$. In that case we let $\mathcal{T}(u) = v$. Note that any sequential transducer is functional. A transducer $\mathcal{T} = (\mathcal{A}, \rho, \tau)$ is called *synchronous* (or sometimes *letter-to-letter* in the literature) if, whenever it reads an input symbol, it produces exactly one output symbol, i.e. for all transition t, $|\rho(t)| = 1$, and $\tau(q) = \epsilon$ for all accepting state q. For example, consider the transducer $\mathcal{D}_1$ on Fig. 1 (the terminal function is assumed to output ϵ and is not depicted). It is sequential and synchronous. Its domain is $L = b^*ab^*a(a + b)^*$.

Two transducers are said to be *equivalent* if they define the same relation. Finally, the disjoint union of transducers is naturally defined as the disjoint union of their input automata and the disjoint union of their output functions (seen as graphs). For all transducers $\mathcal{T}_1, \mathcal{T}_2$, we have $[\![\mathcal{T}_1 \uplus \mathcal{T}_2]\!] = [\![\mathcal{T}_1]\!] \cup [\![\mathcal{T}_2]\!]$.

Transducer Synthesis Problem. Let $\Sigma_{\mathtt{i}}, \Sigma_{\mathtt{o}}$ be two alphabets of input and output symbols respectively. They may not necessarily be disjoint. A *specification* is a subset of $\Sigma_{\mathtt{i}}^* \times \Sigma_{\mathtt{o}}^*$, and an *implementation* is a function, possibly partial, from $\Sigma_{\mathtt{i}}^*$ to $\Sigma_{\mathtt{o}}^*$. The transducer *realisability* problem asks, given a specification S defined by a transducer $\mathcal{T}$, i.e. $S = [\![\mathcal{T}]\!]$, whether there exists a sequential transducer $\mathcal{I}$ such that (1) $\text{dom}(\mathcal{I}) = \text{dom}(\mathcal{T})$ and (2) for all $u \in \text{dom}(\mathcal{T})$, $(u, \mathcal{I}(u)) \in [\![\mathcal{T}]\!]$. In that case, we say that $\mathcal{I}$ realises S (or $\mathcal{T}$), and that S is realisable by a sequential transducer, or sequentially realisable. We also say that $\mathcal{I}$ is a *realiser* of S. The synthesis problem asks to output $\mathcal{I}$. The realisability problem is undecidable in general [4, 12], but decidable, in 3ExpTime, if $\mathcal{T}$ is finite-valued, i.e. there exists $k \in \mathbb{N}$ such that for all $u \in \text{dom}(\mathcal{T})$, $|\{v \mid (u, v) \in [\![\mathcal{T}]\!]\}| \leq k$ [12].

[4] Our definition is sometimes called *real-time* transducer in the literature, in contrast to transducers with ϵ-input transitions. For the purpose of this paper, this does not make a difference.

Multi-sequential specifications. A transducer $\mathcal{T}$ is called *k-sequential* if it is the disjoint union of k sequential transducers. It is called *multi-sequential* if it is k-sequential for some k. Observe that when the k sequential transducers have pairwise disjoint domains, then $\mathcal{T}$ is functional, but it may not be the case in general. Deciding whether given a transducer $\mathcal{T}$, there exists an equivalent multi-sequential transducer $\mathcal{T}'$, can be done in PTime; however, $\mathcal{T}'$ may be exponentially larger than $\mathcal{T}$ [19]. Minimising the number of sequential transducers of the disjoint union is also doable: deciding whether $\mathcal{T}$ is equivalent to some k-sequential transducer for k given in unary is decidable in PSpace [8]. In this paper, we consider *multi-sequential specification*, i.e. relations $S \subseteq \Sigma_{\mathtt{i}}^* \times \Sigma_{\mathtt{o}}^*$ defined by multi-sequential transducers.

PSpace-hardness. In both the synchronous and asynchronous case, the realisability problem of multi-sequential specifications by (a)synchronous sequential transducers is PSpace-hard.

We build a reduction from the emptiness problem of the intersection of n DFA $\mathcal{A}_1, \dots, \mathcal{A}_n$ on some alphabet Σ, proven PSpace-c in [25]. We define a specification S over $\Sigma \cup \{\#, a, b\}$ by $S = \bigcup_{i=1}^{n}(S_i \cup N_i)$ where $S_i = \{(w\#^m\sigma, w\sigma\#^m) \mid \sigma \in \{a,b\}, m \geq 0, w \in L(\mathcal{A}_i)\}$ and $N_i = \{(w\#^m\sigma, w\#^m\sigma) \mid \sigma \in \{a,b\}, m \geq 0, w \notin L(\mathcal{A}_i)\}$. If there exists $w \in \bigcap_{i=1}^{n} L(\mathcal{A}_i)$, then on the domain $w\#^*\{a,b\}$, the specification is a function which is not definable by any sequential transducer, thus not sequentially realisable, since it would imply counting the #s (in the synchronous setting, it suffices to take $m = 1$ since a synchronous transducer would be forced to guess the future). Conversely, if $\bigcap_{i=1}^{n} L(\mathcal{A}_i) = \varnothing$, then the identity function (trivially definable by a synchronous sequential transducer) realises the specification.

It is readily seen that each S_i (resp. N_i) is definable by a 2-(resp. 1-)sequential transducer, hence S is multi-sequential, concluding the proof.

3 The synchronous setting

In this section, we consider first the synchronous setting, where the specification is given as a disjoint union of synchronous sequential transducers, and the target implementations are synchronous sequential transducers. Not only is this setting interesting in itself, but it helps to understand the asynchronous setting. First, we characterise the realisable specifications through a property called the *residual property*, then we show it is decidable in PSpace.

Residual property. Let $\mathcal{T} = \biguplus_{i=1}^{n} \mathcal{D}_i$ be an n-sequential transducer on $\Sigma_{\mathtt{i}}, \Sigma_{\mathtt{o}}$. Intuitively, the residual property says that if on some input prefix u, two sequential transducers of the union disagree on their outputs, i.e. produce different outputs, then a synchronous realiser of $[\![\mathcal{T}]\!]$ must "drop" one of the two transducers. However, it must do so while preserving the residual domain $u^{-1}\mathrm{dom}(\mathcal{T})$, i.e., the realiser must still accept any word of $u^{-1}\mathrm{dom}(\mathcal{T})$. For example, consider again Fig. 1 and the specification defined by $\mathcal{D}_1 \uplus \mathcal{D}_2$. On input a, the two transducers disagree, hence, since we want a synchronous realiser, a choice has to be made and therefore one of the two transducers must be dropped. However, by doing so, the residual domain will not be fully covered by the remaining transducer. For example, if a realiser chooses to output a when reading a, the residual language b^* is not covered anymore. As a matter of fact, $\mathcal{D}_1 \uplus \mathcal{D}_2$ is not realisable by any sequential and synchronous transducer.

Formally, let $u \in \Sigma_{\mathtt{i}}^*$ and let r_i, r_j be runs of some $\mathcal{D}_i, \mathcal{D}_j$ respectively, on u. We say that r_i and r_j agree on their output if $\mathrm{out}(r_i) = \mathrm{out}(r_j)$. Now, u is called *smooth* if every $\mathcal{D}_i$ admits an initial run on input u, and all these runs agree on the corresponding output. The word u is called *critical* if it is not smooth.

We say that $\mathcal{T}$ satisfies the *residual property* if for every critical prefix $u \in \Sigma_{\mathtt{i}}^*$ of a word of $\mathrm{dom}(\mathcal{T})$, there exists a subset $P \subsetneq \{1, \dots, n\}$ satisfying:

1. All the transducers $\mathcal{D}_i$, $i \in P$, produce the same output $\phi(u)$ on u;
2. $u^{-1}\mathrm{dom}(\mathcal{T}) = \bigcup_{i \in P} u^{-1}\mathrm{dom}(\mathcal{D}_i)$;
3. $\biguplus_{i \in P}(u, \phi(u))^{-1}[\![\mathcal{D}_i]\!]$ is realisable by a synchronous and sequential transducer.

▶ **Theorem 1.** *A specification S defined by a synchronous multi-sequential transducer $\mathcal{T}$ is realisable by a synchronous sequential transducer iff $\mathcal{T}$ satisfies the residual property.*

Sketch. If $[\![\mathcal{T}]\!]$ is realised by a synchronous sequential transducer $\mathcal{U}$, for every critical prefix u, let P be the set of i such that $\mathcal{D}_i$ and $\mathcal{U}$ map the same output to u. Property 1 is satisfied by definition, and the other two follow from the fact that $\mathcal{U}$ is sequential and realises $[\![\mathcal{T}]\!]$.

Conversely, if the residual property is satisfied, we can construct a synchronous and sequential realiser. The idea is to make a synchronised product of all the transducers $\mathcal{D}_i$, and, whenever on some input symbol σ at least two of them disagree on the output, we know by the residual property that there exists a subset P of them having the good properties $1, 2, 3$. Then, the realiser just goes on simulating all the transducers $\mathcal{D}_i$ corresponding to P in parallel.

It also shows that if the property is satisfied, then we can synthesise a realiser, which might however be exponentially larger than $\mathcal{T}$. ◀

▶ **Theorem 2.** *The realisability problem of synchronous multi-sequential specifications by synchronous sequential transducers is PSpace-complete.*

Sketch. The PSpace-hardness is obtained by reducing the problem from the emptiness problem of the intersection of n DFAs (*cf* Section 2 p. 6).

To show membership to PSpace, given a transducer $\mathcal{T} = \biguplus_{i=1}^{n} \mathcal{D}_i$, we show that the residual property can be tested by a non-deterministic algorithm running in polynomial space. First, we bound the size of witnesses of the negation of the property: roughly, if there is such witness, namely a critical prefix u, then there exists a critical prefix v of exponential length (in $\mathcal{T}$) such that for any subset $P \subsetneq \{1, \dots, n\}$, one of the conditions $1, 2, 3$ is falsified. Then, the algorithm guesses the prefix v on the fly, simulating all transducers $\mathcal{D}_i$ in parallel and keeping their states in memory (it also needs a counter for the length of v). As soon as the transducers disagree on an output symbol, for each subset $P \subsetneq \{1, \dots, n\}$ (they can obviously be enumerated using only polynomial space), the algorithm checks whether property 1, 2 or 3 is falsified. Checking property 1 is easy: it suffices to look at the symbols produced when reading the last input symbol. Checking property 2 can be done using the current set of states reached by the transducers on input v, and by using any PSpace algorithm for automata inclusion. Finally, to check property 3, it suffices to recursively apply the PSpace algorithm described so far on a smaller set of transducers. The stack of recursive calls is linear in n, hence the memory used by the whole procedure remains polynomial. ◀

4 The synthesis game

We now define a 2-player safety game from a transducer $\mathcal{T}$ such that if Eve wins the game then $\mathcal{T}$ is realisable by a sequential transducer. This game notion will prove useful to show the correctness of the characterisation of Theorem 5, and may also be used as a practical way to synthesise implementations, as winning strategies of this game. In the asynchronous setting, two different runs of a transducer on the same input word may not only produce different outputs, but also the same output at different rates (i.e. one run is ahead, output-wise, of the other for some time). This leads us to the notion of delays, a classical tool to compare outputs in transducer theory. Let us define this notion formally.

Delays. Given two words $u_1, u_2 \in \Sigma^*$, their longest common prefix ℓ is denoted by $u_1 \wedge u_2$. The *delay* between u_1 and u_2 is an element of $\Sigma^* \times \Sigma^*$ defined by $\mathrm{del}(u_1, u_2) = (\ell^{-1}u_1, \ell^{-1}u_2)$. Intuitively, if a transducer produces u_1 and another one produces u_2, then $u_1 \wedge u_2$ is what can safely be output by the two transducers and $\mathrm{del}(u_1, u_2)$ what remains to be produced by each of them respectively. This notion is naturally extended to tuples of words: $\mathrm{del}(u_1, \ldots, u_n) = (\ell^{-1}u_1, \ldots, \ell^{-1}u_n)$ where $\ell = \bigwedge_{i=1}^{n} u_i$.

We now introduce notations that are useful when comparing the outputs of different runs on the same input of a transducer $\mathcal{T} = (\mathcal{A}, \rho, \tau)$ over $\Sigma_{\mathtt{i}}, \Sigma_{\mathtt{o}}$ with $\mathcal{A} = (\Sigma_{\mathtt{i}}, Q, I, F, \Delta)$. Given a pair $(q, w) \in Q \times \Sigma_{\mathtt{o}}^*$, where w is intended to be some delay associated with state q, given a transition $t = (q, \sigma, q') \in \Delta$ and some output word u prefix of $w\rho(t)$, we denote by $\mathit{next}((q, w), t, u)$ the "next" pair (state,delay), assuming that u is output, i.e. $\mathit{next}((q, w), t, u) = (q', u^{-1}w\rho(t))$. More generally, given a (total) function $D : Q \to 2^{\Sigma_{\mathtt{o}}^*}$ associating each state with a set of delays, we let $\mathit{live}(D) = \{q \in Q \mid D(q) \neq \varnothing\}$. For $\sigma \in \Sigma_{\mathtt{i}}$, $\mathit{next}(D, \sigma)$ maps every state which can be reached from $\mathrm{dom}(D)$ by reading σ to the corresponding delays obtained by outputting the longest common prefix of the words that can be formed from the previous delays and the output on these transitions. Formally, we call *safe output of D for σ* the word $\ell = \bigwedge\{w\rho(t) \mid q \in \mathit{live}(D), w \in D(q), t = (q, \sigma, q') \in \Delta\}$. Then $\mathit{next}(D, \sigma) = \{\mathit{next}((q, w), t, \ell) \mid q \in \mathit{live}(D), w \in D(q), t = (q, \sigma, q') \in \Delta\}$.

The synthesis game. In the synchronous setting, synthesis problems are classically solved by reduction to two-player games in which the players alternately choose one input symbol (the adversary, whom we call Adam) and one output symbol (the protagonist, called Eve). Their interaction induces a pair of input and output words by concatenating their respective symbols, and the protagonist wins if such pair satisfies the specification, or if the input word is out of the domain. Then, a finite-memory winning strategy in the game corresponds to an implementation of the specification.

In the asynchronous setting, the protagonist may choose arbitrary output words at each round instead of a single symbol, and one needs to introduce output delays in the game in order to define the winning condition in a regular manner. The game we now present follows this idea. Given a transducer $\mathcal{T} = (\mathcal{A}, \rho, \tau)$ with $\mathcal{A} = (\Sigma_{\mathtt{i}}, Q, I, F, \Delta)$, $\rho : \Delta \to \Sigma_{\mathtt{o}}^*$ and $\tau : F \to \Sigma_{\mathtt{o}}^*$, we build a two-player safety game $G_{\mathcal{T}} = (V_\forall, V_\exists, A_\forall, A_\exists, T_\forall, T_\exists, \mathsf{Safe})$, called the *synthesis game*, whose vertices keep track of the runs in $\mathcal{T}$ and the associated delays. More precisely, it consists of two disjoint sets of vertices $V_\forall = 2^Q \times (Q \to 2^{\Sigma_{\mathtt{o}}^*})$ and $V_\exists = V_\forall \times \Sigma_{\mathtt{i}}$, respectively controlled by Adam and Eve. The initial vertex is $v_0 = (I, D_0) \in V_\forall$ where $D_0(q) = \varnothing$ if $q \notin I$, and $D_0(q) = \{\epsilon\}$ otherwise.

Eve's vertices are Adam's vertices extended with the last input symbol picked by Adam. Suppose now that the game has been played for some rounds and is currently in some vertex (C, D) of Adam. Along these rounds, Adam has chosen a sequence u of input symbols, and Eve has chosen a set of runs over u from the initial states. C is the set of states in which these runs end. Each run induces some delays compared to the longest common prefix of all the outputs they can produce. D maps each state to the delays of the runs ending in it. Eve's actions consist in selecting some of these runs to prevent some delays to grow too high, i.e., she can drop from any set $D(q)$ some of its elements. By restricting the set of possible runs, Eve can be in a situation where some state q of C is accepting while none of the states of $\mathit{live}(D)$ is, in which case she loses, as none of the runs she has selected accepts the input word chosen by Adam. Such vertices constitute the set of *unsafe* vertices she needs to avoid.

More precisely, the set of Adam's *transitions* $T_\forall$ and Eve's transitions $T_\exists$ are defined as follows. From any game position (C, D), Adam can pick a symbol $\sigma \in \Sigma_{\mathtt{i}}$ and the game evolves to the position (C, D, σ). From (C, D, σ), Eve's actions is a subset $\alpha \subseteq \mathit{next}(D, \sigma)$

(she can "drop" some pairs of $next(D, \sigma)$), and the game evolves to (C', D_α) where C' is the set of states reached from C by reading σ, and D_α maps any $q \in Q$ to the set $\{w \mid (q, w) \in \alpha\}$.

Given $K \in \mathbb{N}$, we define the *K-synthesis game* as the restriction of $G_{\mathcal{T}}$ to delays of length at most K: $G_{\mathcal{T},K} = (V_\forall^K, V_\exists^K, v_0^K, A_\forall^K, A_\exists^K, T_\forall^K, T_\exists^K, \mathsf{Safe}^K)$, where $V_\forall^K = 2^Q \times (Q \to 2^{\Sigma_\mathfrak{o}^{\leq K}})$, $A_\exists \subseteq Q \times \Sigma_\mathfrak{o}^{\leq K}$, etc. There is no deadlock in $G_{\mathcal{T},K}$ because Eve can always play $\varnothing$, at the risk of going to an unsafe position.

Example. First, note that by definition of the game, any reachable vertex (C, D) or (C, D, σ) satisfies $live(D) \subseteq C$. Figure 2 represents the 1-synthesis game for $\mathcal{D}_1 \cup \mathcal{D}_2$ (*cf* Figure 1). The states depicted in a vertex correspond to C, together with their values by D (thanks to the previous remark, there is no need to represent the values D assigns for the states outside C). The circle vertices are Eve's positions, whose labels are not depicted, as they are just the label of their predecessor vertex extended with Adam's action. Bold nodes correspond to the unsafe states. Let us now explain how the game proceeds in more detail. First, since both $\mathcal{D}_1$ and $\mathcal{D}_2$ are complete and sequential, for each state (C, D) of Adam, C contains exactly one state of $\mathcal{D}_1$ and one state of $\mathcal{D}_2$. Eve's actions in the synthesis game, which consist in dropping a subset of pairs (state,delay), actually correspond here to "dropping" one of the two sequential transducers: at any moment, she can choose to drop $\mathcal{D}_2$, which leads her into the red part of the game, or to drop $\mathcal{D}_1$, which leads her into the blue part of the game. Note that once she has dropped one of the transducers, she is stuck in the corresponding part.

The initial vertex, owned by Adam, corresponds to being in the initial states of both $\mathcal{D}_1$ and $\mathcal{D}_2$, with no delays. If Adam chooses to play a as the first input letter, Eve has four choices. Either she keeps both transducers, with a delay of length 1, or she drops one of them, or both (not depicted). If Eve chooses to drop $\mathcal{D}_2$, respectively $\mathcal{D}_1$, Adam can then play a b, respectively an a, which leads her into an unsafe state. Note that this proves that Eve cannot win the 0-synthesis game corresponding to $\mathcal{D}_1 \cup \mathcal{D}_2$. If Eve keeps both, she has to drop one of them once Adam plays a second letter, since otherwise the delay would grow larger than 1. However, in both cases she has a move which ensures her a win: if Adam plays a second a, Eve can safely drop $\mathcal{D}_2$ since the accepting state of $\mathcal{D}_1$ has been reached, and if Adam plays b, Eve can safely drop $\mathcal{D}_1$ since the accepting state of $\mathcal{D}_2$ has been reached. If Adam chooses to play a b in the first place, Eve can immediately drop $\mathcal{D}_1$ and win. Hence, Eve wins the 1-synthesis game associated to $\mathcal{D}_1 \cup \mathcal{D}_2$. The described strategy then directly induces a sequential transducer realising the specification.

▶ **Proposition 3.** *Let S be a specification defined by some transducer $\mathcal{T}$. If Eve wins the K-synthesis game $G_{\mathcal{T},K}$ for some K, then S is realisable by a sequential transducer.*

Sketch. If Eve wins the K-synthesis game, then, since it is a safety game, she can win with a *positional* strategy. Thus, her actions only depend on the last visited vertex. This allows to reconstruct a realiser for S, whose states are the possible vertices of Adam visited by the strategy. Then, when Adam chooses an input symbol σ in a vertex (C, D) and Eve decides to go to some vertex (E, F) from (C, D, σ), then in the realiser, we add a transition from (C, D) to (E, F) on σ, outputting the safe output of D for σ. ◀

Synthesis algorithm. It is worth noting that the synthesis game allows for a synthesis procedure: for ascending values of K, test whether Eve wins the K-synthesis game (this can be done in PTime in the size of the game). If it is the case, then by Proposition 3 the specification is realisable, and we can even extract an implementation corresponding to a winning strategy of Eve. If it is not the case, then increment K and try again, until K

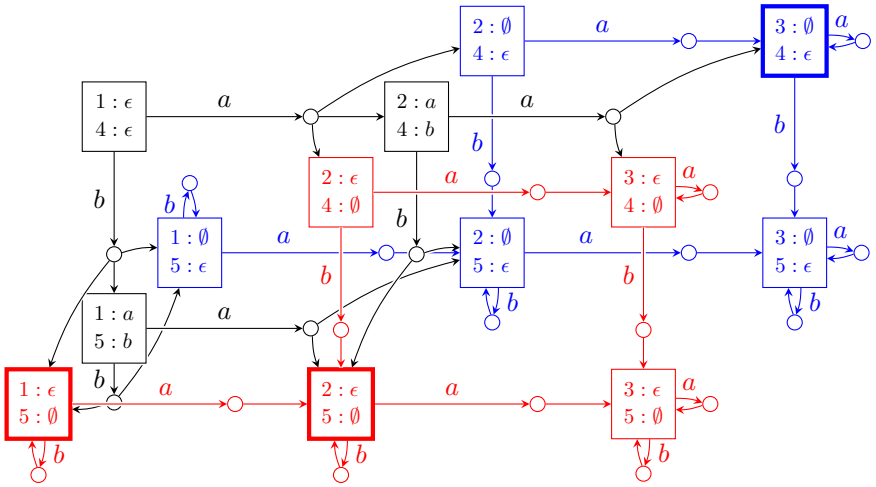

Figure 2 The 1-synthesis game corresponding to the union of $\mathcal{D}_1$ and $\mathcal{D}_2$ (*cf* Figure 1).

reaches some given upper bound B. The K-synthesis game is exponentially large in general (in the transducer defining the specification, and in K). Solving this game efficiently, using for instance symbolic methods, as done for LTL synthesis in the synchronous case [10, 13], is beyond the scope of this paper, but is an interesting research direction.

This algorithm is not complete in general: it is shown for instance in [12] that some specifications defined by transducers are realisable by sequential transducers while Eve has no winning strategy in $G_{\mathcal{T},K}$ for any K. Still, the converse of Proposition 3 holds for some subclasses of specifications $[\![\mathcal{T}]\!]$. For example, in the synchronous setting, where we want to synthesise a synchronous sequential transducer, it suffices to take $K = 0$. This gives an ExpTime procedure to check the realisability of $[\![\mathcal{T}]\!]$ by a synchronous sequential transducer. If $\mathcal{T}$ is *finite-valued*, then by taking K large enough (triply exponential in $\mathcal{T}$), we get completeness [12]. Finally, if $\mathcal{T}$ is functional, then Eve wins $G_{\mathcal{T},K}$ for some K iff $\mathcal{T}$ is equivalent to a sequential transducer, and a polynomial K (in $\mathcal{T}$) suffices [2].

In this paper, we obtain completeness for multi-sequential specifications by taking K exponential in $\mathcal{T}$ (Proposition 6). While this allows us to decide realisability using the game approach, the time complexity will not be optimal (2ExpTime). We indeed devise, in Section 5, a PSpace realisability-checking procedure based on an effective characterisation of realisable multi-sequential specifications. If the PSpace procedure concludes that the specification is realisable, one can run the former game-solving procedure to synthesise a realiser, for ascending values of K. This way, one may hope to synthesise a "small" realiser.

5 The asynchronous setting

We first characterise recursively the multi-sequential specifications which are sequentially realisable (Theorem 5). Then, we provide an equivalent characterisation, non-recursive and easier to check algorithmically, but more technical.

Similarly to the synchronous case, we define a notion of critical situation to which a realiser must react. In the synchronous case, it was just a prefix on which at least two sequential transducers were producing different outputs. In the asynchronous case, two sequential transducers may produce different outputs on the same prefix, but this may not be problematic in the case where one is ahead of the other, i.e., the output of one run is

a prefix of the output of the other. A critical situation is rather a prefix where the delays between all the outputs of the sequential transducers are too large. Since no bound is known a priori to define "too large", we formalise a critical situation as a prefix of the form uv, such that at least two sequential transducers loop on v, and have a different delay before and after the loop. By iterating this loop, i.e. by taking a prefix uv^n, the delay between these two transducers will grow unboundedly when n increases. For such loops, the situation will get critical if a realiser does not react.

▶ **Definition 4** (critical loop). Let $\mathcal{T} = \biguplus_{i=1}^{n} \mathcal{D}_i$ be an n-sequential transducer. A *critical loop* for $\mathcal{T}$ is a triple $(u, v, \mathcal{X}) \in \Sigma_{\mathtt{i}}^* \times \Sigma_{\mathtt{i}}^* \times 2^{\{1,\dots,n\}}$ such that

1. for all $i \in \mathcal{X}$, there exists an initial run $p_i \xrightarrow{u|\alpha_i} q_i \xrightarrow{v|\beta_i} q_i$ of $\mathcal{D}_i$ on uv;
2. for all $i \in \{1, \dots, n\} \setminus \mathcal{X}$, there is no run of $\mathcal{D}_i$ on u;
3. There exists $i, j \in \mathcal{X}$ such that $\mathrm{del}(\alpha_i, \alpha_j) \neq \mathrm{del}(\alpha_i\beta_i, \alpha_j\beta_j)$.

Our characterisation echoes the one of the synchronous setting. It says that whenever there is a critical situation (a critical loop), a realiser must be able to drop some of the sequential transducers, in order to prevent the delays to grow unboundedly, while preserving the residual domain. Formally:

▶ **Theorem 5** (recursive characterisation). *Let $\mathcal{T} = \biguplus_{i=1}^{n} \mathcal{D}_i$ be a multi-sequential transducer over $\Sigma_{\mathtt{i}}, \Sigma_{\mathtt{o}}$. Then $[\![\mathcal{T}]\!]$ is realisable by a sequential transducer, iff, for all critical loops $(u, v, \mathcal{X})$, there exists $\mathcal{Y} \subsetneq \mathcal{X}$ such that*

1. *$\forall i, j \in \mathcal{Y}$, $del(\alpha_i, \alpha_j) = del(\alpha_i\beta_i, \alpha_j\beta_j)$ (following the notations of Definition 4),*
2. *$u^{-1}dom(\mathcal{T}) = \bigcup_{i\in\mathcal{Y}} u^{-1}dom(\mathcal{D}_i)$,*
3. *$\bigcup_{i\in\mathcal{Y}} (u, \ell)^{-1}[\![\mathcal{D}_i]\!]$ is realisable by a sequential transducer, where $\ell = \bigwedge_{i\in\mathcal{X}} \alpha_i$.*

Sketch. $\Rightarrow$ Let $\mathcal{U}$ be a sequential transducer realising $[\![\mathcal{T}]\!]$. For every critical loop $(u, v, \mathcal{X})$ of $\mathcal{T}$, the corresponding set $\mathcal{Y}$ is obtained by getting rid of all the transducers that stray arbitrarily far from $\mathcal{U}$ on the input words of the form uv^*. Then, the first property is immediate, and the other two follow from the fact that $\mathcal{U}$ is sequential and realises $[\![\mathcal{T}]\!]$.

$\Leftarrow$ Conversely, assuming that whenever a critical loop is met there exists a set $\mathcal{Y}$ satisfying the three conditions, we prove by induction on the degree n of sequentiality of $[\![\mathcal{T}]\!]$ that Eve has a winning strategy in the $K_{\mathcal{T}}$-synthesis game for $\mathcal{T}$, for some well-chosen value $K_{\mathcal{T}}$ depending on $\mathcal{T}$. By Proposition 3, this entails the existence of a sequential realiser.

Note that in the synthesis game, since $\mathcal{T}$ is a union of sequential transducers, for each accessible vertex (C, D) of Adam, and for every $i \in \{1, \dots, n\}$, there is at most one state q_i of $\mathcal{D}_i$ occurring in $live(D)$, and if there exists such a state, $|D(q_i)| = 1$. As a consequence, Eve's actions in the synthesis game, which consist in dropping a subset of pairs (state,delay), actually correspond here to "dropping" a subset of sequential transducers.

If $n = 1$, then $\mathcal{T}$ is sequential, and the strategy of Eve that consists in never dropping $\mathcal{T}$ is winning. Now, suppose that $n > 1$. In order to demonstrate that Eve has a winning strategy, we show that for every input word chosen by Adam, either Eve can keep track of all the transducers in the $K_{\mathcal{T}}$-synthesis game, which ensures her a win, or she can drop some transducers on the way, while reaching a state from which she has a winning strategy.

Let $u \in \Sigma_{\mathtt{i}}^*$, and let (C_0, D_0) be the state reached by Eve on input u if she drops nothing. If (C_0, D_0) is not part of the $K_{\mathcal{T}}$-synthesis game, i.e., for some $q \in C_0$, $D_0(q) = \{w\}$ with $|w| > K_{\mathcal{T}}$, this implies the existence of a decomposition $u_1u_2u_3$ of u such that $(u_1, u_2, \mathcal{X})$ is a critical loop for some $\mathcal{X} \subseteq \{1, \dots, n\}$. Then, by hypothesis, there exists a subset $\mathcal{Y} \subsetneq \mathcal{X}$ which satisfies the three conditions of the theorem, hence $\mathcal{T}' = \biguplus_{i\in\mathcal{Y}} (u_1, \ell)^{-1}[\![\mathcal{D}_i]\!]$ is realisable by a sequential transducer. In particular, $\mathcal{T}'$ satisfies the conditions on critical loops (implication

$\Rightarrow$ shown before), and, by the induction hypothesis (since $\mathcal{T}'$ is $|\mathcal{Y}|$-sequential and $|\mathcal{Y}| < n$), Eve has a winning strategy in the $K_{\mathcal{T}'}$-synthesis game for $\mathcal{T}'$ from the initial vertex. Lifting this strategy to the $K_{\mathcal{T}}$-synthesis game for $\mathcal{T}$ yields a winning strategy for Eve from the state (C, D'), where (C, D) is the state reached by Eve on input u_1u_2 if she drops nothing, and D' is obtained from D by dropping all the transducers that are not part of $\mathcal{Y}$. ◀

The proof of Theorem 5 shows that if a multi-sequential specification is realisable, Eve wins the K-synthesis game for K computable from the specification, as stated in Proposition 6. As explained in Section 4, solving the k-synthesis game for ascending values of k then provides a practical way to synthesise a realiser, but the complexity is not optimal.

▶ **Proposition 6** (bounded delay). *Let S be a specification defined by an n-sequential transducer $\mathcal{T}$. Then S is realisable by some sequential transducer iff Eve wins the K-synthesis game for $K = L(6M)^{n^2}$, where L is the longest output occurring on a transition of $\mathcal{T}$, and M is the maximal number of states of a sequential transducer of $\mathcal{T}$.*

▶ **Theorem 7.** *A realisable specification S defined by a multi-sequential transducer $\mathcal{T}$ with m states admits a realiser of size doubly exponential in m. Moreover, there exists a family $(S_n)_{n\in\mathbb{N}}$ of realisable specifications such that for every $n \in \mathbb{N}$, S_n is definable by a multi-sequential transducer of size polynomial in n, and every sequential transducer realising S_n has a size that is doubly exponential in n.*

Proof. Let $S \subset \Sigma^* \times \Gamma^*$ be a realisable specification defined by an n-sequential transducer $\mathcal{T}$ with a set of states Q of size m. Note that $n \leq m$, hence, by Proposition 6, Eve wins the K-synthesis game for some K exponential in m. Then, the construction presented in the proof of Proposition 3 exposes a realiser whose set of states Q' consists of Adam's vertices that are reachable in the K-synthesis game. For every such vertex $(C, D) \in 2^Q \times (Q \to 2^{\Gamma^*})$, since $\mathcal{T}$ is n-sequential, there is at most n sates $q \in Q$ satisfying $D(q) \neq \emptyset$. Moreover, for every such state we have $D(q) = \{w\}$ for some $w \in \Gamma^*$ satisfying $|w| \leq K$. Therefore, the size of Q' is bounded by $2^m(m(|\Gamma|^{K+1}))^n$, which is doubly exponential in m.

In order to expose the family $(S_n)_{n\in\mathbb{N}}$, we use the notion of j-pairs, presented in [22]. For every $n \in \mathbb{N}$, let us consider the alphabet $I_n = \{1, \ldots, n\}$. A *bad j-pair* of a word $u = i_1 \ldots i_m \in I_n^*$ is a pair of positions $1 \leq k < k' \leq m$ such that $i_k = i_{k'} = j$, and for all $k < \ell < k'$, $i_\ell \leq j$. Then every $u \in I_n^*$ satisfying $|u| \geq 2^n$ admits a bad j-pair for some $1 \leq j \leq n$, and there exists a word, denoted by ψ_n, that has size $2^n - 1$, and contains no j-pair (see [22]). We now consider the finite alphabet $\Sigma = \{a, b\}$. For every $n \in \mathbb{N}$, let Σ_n denote the alphabet $I_n \times \Sigma$. We denote by $\pi_1 : \Sigma_n^* \to I_n^*$ and $\pi_2 : \Sigma_n^* \to \Sigma^*$ the projections on the first, respectively second component. Let $f : \Sigma_n^* \to \Sigma^*$ be the function mapping $w \in \Sigma_n^*$ to the word obtained by taking the last letter of $\pi_2(w)$ and putting it at the beginning, i.e., $f(w) = \sigma v$ where $\sigma \in \Sigma$ and $v \in \Sigma^*$ satisfy $\pi_2(w) = v\sigma$. We consider the specification

$$S_n = \{(w, f(w)) | w \in \Sigma_n^*\} \cup \{(w, \epsilon) | w \in \Sigma_n^* \text{ contains a bad } j\text{-pair for some } 1 \leq j \leq n\}.$$

Then S_n is definable by an $(n+2)$-sequential transducers with $3(n+2)$ states, since the function f is definable by the union of 2 sequential transducers of size 3, and for every $1 \leq j \leq n$, the set of words $w \in I_n^*$ containing a bad j-pair is recognisable by a deterministic automaton of size 3. Moreover, since every word $u \in I_n^*$ of size greater than 2^n admits a bad j-pair for some j, S_n is realised by the sequential transducer mapping every word $w \in \Sigma_n^*$ satisfying $|w| < 2^n$ to $f(w)$, and every $w \in \Sigma_n^*$ satisfying $|w| \geq 2^n$ to ϵ.

We now show that every sequential transducer $\mathcal{D}$ realising S_n has at least 2^{2^n-1} states. Let $\mathcal{D} = ((\Sigma, Q, I, F, \Delta), \rho, \tau)$ be a sequential transducer realising S_n. For every $v \in \Sigma^*$ such that $|v| = 2^n - 1$, let $\psi_v \in \Sigma_n^*$ denote the word satisfying $\pi_1(\psi_v) = \psi_n$ and $\pi_2(\psi_v) = v$. We

now show that for every pair of distinct words $v_1, v_2 \in \Sigma^*$ of size $2^n - 1$, the states reached by $\mathcal{D}$ on input ψ_{v_1} and ψ_{v_2} are distinct. This allows us to conclude the proof, since Σ^* contains 2^{2^n-1} such words. Given $v \in \Sigma^*$ satisfying $|v| = 2^n - 1$, let $\rho_v : p_0 \xrightarrow{\psi_v|v'} p_v$ denote the accepting run of $\mathcal{D}$ on input ψ_v. Then $v' = \epsilon$, since if the first letter of v' was an a, $\mathcal{D}$ would not be able to produce an acceptable output on input $\psi_v \cdot (1, b)$, and a similar contradiction would be reached if the first letter of v' was a b. Therefore, the output associated to ψ_v is produced by the terminal function of $\mathcal{D}$, i.e., $\tau(p_v) = f(\psi_v)$. Since f is injective, for every pair of distinct words $v_1, v_2 \in \Sigma^*$ of size $2^n - 1$, $p_{v_1} \neq p_{v_2}$. ◀

We are now ready to show how to decide the realisability of multi-sequential specifications in PSpace. Consider the characterisation given in Theorem 5. We rely on the notion of witness for the non-satisfaction of this characterisation, and we show how to decide the existence of a witness, using a reduction to the emptiness of reversal-bounded counter machines.

The notion of witness intuitively consists in the following ingredients: (1) an unfolding (modeled as a tree) of the recursive characterisation of Theorem 5 and (2) an explicit formulation of delay differences using simple properties of words. Formally, given an n-sequential transducer $\mathcal{T} = \biguplus_{i=1}^{n} \mathcal{D}_i$, where each $\mathcal{D}_i$ is sequential, a *witness* for $\mathcal{T}$ is a finite tree t whose nodes are labelled in $\Sigma_{\mathtt{i}}^* \times \Sigma_{\mathtt{i}}^* \times (2^{\{1,\dots,n\}} \setminus \{\varnothing\})$. For any node x of t, we denote by (u_x, v_x, S_x) its label. For all nodes x, y, z of t, it is required that:

1. (maximality) if x is the root, $S_x = \{1, \dots, n\}$;
2. (consistency) S_x can be split into two disjoint sets N_x, L_x such that for all $i \in N_x$ there is no run of $\mathcal{D}_i$ on u_x, and for all $i \in L_x$ there is a run of $\mathcal{D}_i$ on $u_x v_x$ from its initial state q_0^i, of the form $q_0^i \xrightarrow{u_x|\alpha_{x,i}} p_{x,i} \xrightarrow{v_x|\beta_{x,i}} p_{x,i}$;
3. (monotonicity) if y is a child of x, then $S_y \subsetneq L_x$ and u_x is a prefix of u_y;
4. (partition) if Y is the set of children of x, then $\{S_y \mid y \in Y\}$ partitions L_x;
5. (delays) if y and z are different children of x, for all $i \in S_y$ and $j \in S_z$, either $|\beta_{x,i}| \neq |\beta_{x,j}|$ or, $\beta_{x,i}\beta_{x,j} \neq \epsilon$ and, $\alpha_{x,i}$ and $\alpha_{x,j}$ mismatch[5];
6. (leaves) if x is a leaf, then there is $w \in \Sigma_{\mathtt{i}}^*$ such that $u_x w \in \mathrm{dom}(\mathcal{T})$ and $u_x w \notin \mathrm{dom}(\mathcal{D}_i)$ for all $i \in S_x$.

Intuitively, conditions 2 and 5 require that the words u_x, v_x are critical loops. The delay difference required in the definition of critical loops is not explicit here, but rather replaced by simple properties of words (condition 5), which are easier to check algorithmically. These properties are not strictly equivalent to delay difference, but up to iterating the loop on v_x a sufficient number of times, they are. Conditions $1, 3, 4$ correspond to properties of the subsets met when unfolding the recursive characterisation of Theorem 5. They also allow us to bound linearly the number of nodes of a witness. As announced, all these conditions characterise the unrealisable multi-sequential specifications:

▶ **Lemma 8.** *A multi-sequential specification defined by a trim transducer $\mathcal{T}$ is not realisable by a sequential transducer if and only if there exists a witness for $\mathcal{T}$.*

▶ **Theorem 9.** *The realisability problem by some sequential transducer of a specification defined by a multi-sequential transducer is PSpace-c.*

Sketch. PSpace-hardness has been shown in Section 2. To show PSpace-easyness, we reduce the problem to deciding the emptiness of the language of a counter machine, whose counters make at most 1 reversal (i.e. move from increasing to decreasing mode). This is known to

[5] Two words u, v mismatch if there is a position i such that $i \leq |u|, |v|$ and the ith letter of u differs from the ith letter of v.

be in NLogSpace [16]. Our machine is exponentially large (in the transducer defining the specification), but can be constructed on the fly, hence we get PSpace.

A bit more precisely, we first define the notion of *skeleton* s, which is a witness without the words u_x, v_x, hence there are finitely many skeletons, each one of polynomial size. Given an enumeration $x_1 \dots x_n$ in depth-first order of the nodes of s, we construct a counter machine M_s which recognises sequences of the form $x_1 w_{x_1} \# v_{x_1} \dots x_n w_{x_n} \# v_{x_n}$ such that if we extend any label of a node x in s with the pair of words $(w_{y_1} \dots w_{y_k}, v_x)$, where $y_1 \dots y_k$ is the path from the root to x, we get a witness. Hence, there exists a witness iff there exists a skeleton s such that $L(M_s)$ is non-empty. Our algorithm non-deterministically guesses a skeleton and runs a procedure to check in PSpace the emptiness of M_s.

Let us intuitively explain how M_s works. Conditions $1, 3, 4$ and 6 are regular, so no counter is needed there. Counters are only necessary to check Condition 5, for instance to compute the length of the words $\beta_{x,i}$, and to check the existence of a mismatch between a word $\alpha_{x,i}$ and a word $\alpha_{x,j}$. First, a mismatch position m is guessed, by incrementing for some time two counters $c_{i,x}$ and $c_{j,x}$ in parallel. Then, they are decremented according to the length of outputs produced by simulating the transitions of $\mathcal{D}_i$ and $\mathcal{D}_j$ respectively. When one of them reaches 0, say $c_{i,x}$, we store the mth symbol of the output of $\mathcal{D}_i$ on u_x in memory. We do the same for $c_{j,x}$ and later on check that the two stored symbols are different. ◀

6 Conclusion

We have identified a class of specifications (whose membership is decidable in PTime), for which the sequential realisability problem is PSpace-c, both in the asynchronous and synchronous settings. This is in contrast to the general case, which is ExpTime-c for synchronous specifications, and undecidable in the asynchronous case. Our procedure allows to synthesise a sequential transducer whenever the specification is realisable, and allows for incremental testing, via the solvability of a two-player game parameterised by the longest output allowed to be queued by a realiser before being output.

While the class of multi-sequential specifications is natural, as the closure of graphs of sequential functions under finite unions, we believe that it may also be interesting for practical applications. In particular, Vardi and Lustig have defined the concept of synthesis from component libraries [26], in the synchronous setting, over infinite words. In this setting, given a set of components (synchronous sequential transducers over finite words), a specification S over infinite words, the question is whether the components can be arranged in such a way which realises the specification (by linking the final states of the components to the initial state of another component). This problem was shown to be decidable. We would like to investigate another way of reusing existing components, which is tightly related to multi-sequential specifications: given components $C_1, \dots, C_n$ represented as sequential transducers and a specification S, decide whether there exists a sequential function f such that f and S have the same domain, $f \subseteq \bigcup_i C_i$ and f satisfies S. This is beyond the scope of this paper but we plan to investigate further this question in the near future.

Abstract

We investigate the problem of preselecting a subset of buyers participating in a market so as to optimize the performance of stable outcomes. We consider four scenarios arising from the combination of two stability notions, item and bundle envy-freeness, with the two classical objective functions, i.e., the social welfare and the seller's revenue. When adopting the notion of item envy-freeness, we prove that, for both the two objective functions, the problem cannot be approximated within $n^{1-\varepsilon}$ for any $\varepsilon > 0$, and provide tight or nearly tight approximation algorithms. We also prove that maximizing the seller's revenue is NP-hard even for a single buyer, thus closing an open question. Under bundle envy-freeness, instead, we show how to transform in polynomial time any stable outcome for a market involving only a subset of buyers to a stable one for the whole market without worsening its performance, both for the social welfare and the seller's revenue. Finally, we consider multi-unit markets, where all items are of the same type and are assigned the same price. For this specific case, we show that buyer preselection can improve the performance of stable outcomes in all of the four considered scenarios, and we design corresponding approximation algorithms.

1 Introduction

Determining an efficient pricing strategy is a fundamental problem in many business activities, as it affects both the seller's revenue and the customers' or buyers' satisfaction. Usually, optimal prices are the result of a challenging counterbalancing process: selecting low prices, for instance, may be profitable for the seller when it attracts considerably more customers, but, at the same time, in case of limited supply, it may leave some buyers unsatisfied, thus

generating discontent. In particular, this happens when a customer is negated the right to buy her preferred set of items, or even any item at all, despite the fact that she is willing to pay for the posted prices. In this case she is often called *loser*, as opposed to a customer receiving items, called *winner*. For such a reason, pricing problems are traditionally considered under the hypothesis of **envy-freeness** [25, 32], which prescribes that, once a pricing strategy has been established, items have to be allocated to buyers in such a way that no one would prefer a different set of items.

However, if from the one hand safeguarding the losers' interests shelters the seller from possible future losses due to their dissatisfaction, on the other hand, a result by [7] shows that, in certain markets, an intrinsic and unavoidable hurdle to the construction of a good quality envy-free solution may come from the presence of a set of "disturbing" customers, that is, a set of buyers such that at least one of them gets envious in any assignment of sufficiently high revenue. This observation naturally leads to the following intriguing question: *"What happens if envy-freeness is restricted to apply only to the set of winners? Can the seller raise enough more revenue (with certainty) today to compensate the (uncertain) future loss of potential customers?"*. Such a relaxed form of envy-freeness models indeed the situation in which the seller is allowed the freedom to discard any subset of buyers from the given instance, so as to get rid of envious losers in the assignment she would like to propose. In addition, one might consider such buyers "preselection" as a situation in which the seller advertises about the existence of the market only targeted buyers that, once involved, will all consider the allocation fair; the excluded ones then are simply unaware and won't feel any unfairness.

1.1 Our Contribution

Motivated by the above discussion, we introduce and investigate the *buyer preselection problem* in which, given a pricing problem P with n buyers and m items, we are interested in computing the best possible envy-free solution that can be achieved by removing any arbitrary subset of buyers from P. We consider four scenarios arising from the combination of two stability notions, called item and bundle envy-freeness, respectively, with the two classical objective functions, namely, the social welfare and the seller's revenue.

In an item envy-free allocation, given a pricing of the items, each buyer gets the subset maximizing her utility among all possible subsets that can be created from the set of available items; in a bundle envy-free allocation, no buyer gets a better utility by receiving the bundle allocated to any winner. Observe that these allocations are always guaranteed to exist, as it suffices to assign all items an arbitrarily high price, so that no winner is possible.

For item envy-free allocations and both objective functions, we show that the buyer preselection problem cannot be approximated within $n^{1-\epsilon}$ for every $\epsilon > 0$, unless $\mathsf{P} = \mathsf{ZPP}$. On the positive side, under the objective of social welfare, we design an n-approximation algorithm, while, for the case of revenue maximization, we give an $O(n \log m)$-approximation. In particular, these results are obtained as follows: all but one buyer are discarded from the given instance, so that we are left with a pricing problem with a single buyer. While such a problem is solvable in polynomial time under the objective of social welfare, for revenue maximization, it already exhibits challenging combinatorial structures and, to the best of our knowledge, has been considered before only in [5]. In this paper an $O(\log m)$-approximation is provided, but no lower bounds on the problem complexity are given. We show that the problem is NP-hard, thus solving the corresponding longstanding open problem raised by the authors.

We stress that efficient preselection can be profitable under two orthogonal directions: from the one hand, the removal of a subset of pathological envious buyers may increase the value of the optimal solution; from the other hand, even when this does not happen or it has only a modest impact, simplifying the combinatorial structure defined by the valuation functions of the winners may lead to the design of better approximation algorithms. In fact, for the two preselection problems obtained by considering bundle envy-free allocations, we show how to transform in polynomial time any allocation which is bundle envy-free only for the subset of the winners to a bundle envy-free allocation for all buyers without worsening its performance. Hence, although this transformation implies that, in this case, buyer preselection cannot improve the performance of stable outcomes, it can be used to map any bundle envy-free allocation for a subset of winners obtained through preselection back to a bundle envy-free allocation involving all buyers. Therefore, it can be used as an algorithmic tool for computing good stable outcomes when preselection is not allowed. In fact, it can be first exploited to simplify the combinatorics of the problem, and then for mapping back the computed solution to one encompassing all the buyers.

To this respect, consider for instance the case in which buyers can be partitioned in two (or more) sets A and B (each of which, for instance, containing only unit-demand buyers or only single minded ones or only multi-demand buyers with additive valuations), and such that (i) valuations of players in A and B, if considered separately, allow to compute an r_A-approximate (resp. r_B-approximate) solution of the problem restricted to set A (resp. B) by exploiting known or new simpler algorithms/techniques and (ii) considering the whole instance would make difficult the direct application of such algorithms/technique for solving P. By performing preselection we can easily obtain an $r = 2\max(r_A, r_B)$-approximation for BP(P) (selecting the best solution among the one only for A and the one only for B), and thus, by the transformation, also for the initial problem P.

Finally, we consider the multi-unit case, where all items are of the same type and are assigned the same price. We show how preselection can improve the revenue and the social welfare of both item and bundle envy-free solutions. In particular, for item envy-free allocations, we show a tight multiplicative factor of m for both objective functions. For bundle envy-free allocations, we show a lower multiplicative bound of 2 for both the revenue and the social welfare, and prove that it is tight for the objective of revenue maximization. We also provide tight results on the complexity of computing optimal solutions for the buyer preselection problem under envy-freeness.

Due to space limitations, some proofs are only sketched or omitted.

1.2 Related Work

The literature on envy-free pricing is so vast that it cannot be exhaustively covered here. For such a reason, we simply refer to the achievements which are mostly related to the model of [28] we consider in this paper.

For the social welfare maximization, the VCG mechanism [33, 19, 26] provides an optimal solution to the envy-free pricing problem. However, while this mechanism is efficiently computable in markets with unit-demand buyers, yet for single-minded ones its computation becomes NP-hard. Approximate solutions are still possible in this case thanks to the results of [4]. Also Walrasian Equilibria [34] provide an optimal solution to the problem [6]; however, they are guaranteed to exist only under very stringent hypothesis on the buyers' valuation functions [27].

For the revenue maximization, [28, 29, 18, 5, 10] design logarithmic approximation algorithms for various special cases of the problem. Relative hardness results have been given by [9, 11, 13, 12, 20]. Further variants have been considered by [14, 16, 22, 3, 7, 15].

[23] propose an interesting relaxation of the notion of Walrasian Equilibrium, called Combinatorial Walrasian Equilibrium (CWE), obtained by grouping items into bundles so as to induce a "reduced market" to which, then, applying the notion of Walrasian Equilibrium. They show the existence of a CWE yielding a 2-approximation of the optimal social welfare and that of a CWE yielding a logarithmic approximation of the optimal revenue.

Furthermore, [31] study the case of revenue maximization in markets with multi-unit items under both item and bundle envy-freeness when allowing both item and bundle pricing. Such setting has been extended in [24] where the authors consider a social graph of the buyers and envies can arise only between neighbors.

In our model, by preselecting buyers, we basically require that all the winners are envy-free. Settings in which, in a similar way, envy-freeness is not guaranteed for all buyers, but only for the winners, are studied in [1, 2, 17]. In particular, [17] considers "weak" Walrasian equilibirum, a relaxed version of Walrasian equilibirum in which the goal is that of maximizing the number of envy-free buyers, with the condition that all the winners must be envy-free. [1, 2] consider a relaxed version of envy-freeness: in their model, identical items have to be sold to buyers, with every buyer constituting a node of a given unweighted graph; adjacent winning buyers have to pay similar prices for the received item, while the losers cannot envy. This feature is exploited to achieve higher revenue with respect to the classical case in which there cannot be losers, even if it makes the computational problem harder.

2 Model and Definitions

2.1 Markets

A *market* is a tuple $\Gamma = (N, M, (v_i)_{i \in N})$, where N is a set of n buyers, M is a set of m items, and for every buyer $i \in N$, $v_i : 2^M \to \mathbb{R}_{\geq 0}$ is a *valuation function* expressing, given a set of items $X \subseteq M$, the amount of money that buyer i is willing to pay for X; we assume that $v_i(\emptyset) = 0$ for every buyer $i \in N$.

Depending on the definition of the valuation functions, different types of markets can be modeled. In the most general case, called *market with combinatorial valuations*, function v_i is completely arbitrary for every buyer $i \in N$. In a *market with unit-demand buyers*, $v_i(X) = 0$ for every $i \in N$ and $X \subseteq M$ with $|X| > 1$, that is, every buyer is only interested in singleton sets. In a *market with single-minded buyers*, for every $i \in N$, there exists a unique set of items $X \subseteq M$ such that $v_i(X) \neq 0$, that is, every buyer is only interested in a particular set of items. In a *market with additive valuations*, $v_i(X) = \sum_{j \in X} v_i(\{j\})$ for every $i \in N$ and $X \subseteq M$. We stress that, while the representation of a market with combinatorial valuations may require $\Omega(n2^m)$ bits, $\Theta(nm)$ bits suffice to represent the last three types of markets. Finally, in a *market with multi-unit items*, all the m items are of the same type and so, for every $i \in N$, the valuation function becomes of the form $v_i : \{0, 1, \ldots, m\} \to \mathbb{R}_{\geq 0}$, since it is only required to specify how much a buyer evaluates a set of k items, for every $k \in \{1, \ldots, m\}$ (clearly, $v_i(0) = 0$); thus, also in this case, the market can be represented with $\Theta(nm)$ bits.

2.2 Stable Outcomes

Fix a market Γ. A *price vector* is an m-tuple $\mathbf{p} = (p_1, \ldots, p_m)$ such that, for every $j \in M$, $p_j \geq 0$ is the price of item j.[1] We denote by $\mathbf{0}^m$ the price vector assigning price 0 to all items. Given a price vector $\mathbf{p}$ and a set of items $X \subseteq M$, $u_i(X, \mathbf{p}) = v_i(X) - \sum_{j \in X} p_j$ is

[1] For the case of markets with multi-unit items, it is only required to fix the price of a single item so that vector $\mathbf{p}$ collapses to a real number $p \geq 0$.

the *utility* of buyer i when buying X. The *demand set* of buyer i for the price vector $\mathbf{p}$ is the set $D_i(\mathbf{p}) = \text{argmax}_{X \subseteq M} u_i(X, \mathbf{p})$ of subsets of items maximizing i's utility according to the prices specified by $\mathbf{p}$. An *allocation vector* is an n-tuple $\mathbf{X} = (X_1, \ldots, X_n)$ such that $X_i \subseteq M$ is the set of items sold to buyer i. The allocation vector $\mathbf{X} = (X_1, \ldots, X_n)$ is *feasible* if $X_i \cap X_{i'} = \emptyset$ for each $i \neq i' \in N$. An *outcome* is a pair $(\mathbf{X}, \mathbf{p})$ such that $\mathbf{X}$ is feasible. Denote with $\mathsf{OUT}(\Gamma)$ the set of outcomes of Γ. An outcome $(\mathbf{X}, \mathbf{p})$ is *individually-rational* if $u_i \geq 0$ for every $i \in N$.

Denote as $M(\mathbf{X}) = \bigcup_{i \in N} X_i$ the set of items sold to some buyer according to a feasible allocation vector $\mathbf{X}$. Buyer i is a *winner* if $X_i \neq \emptyset$ and $W(\mathbf{X})$ denotes the set of all winners in $\mathbf{X}$. For an item $j \in M(\mathbf{X})$, denote with $b_{\mathbf{X}}(j)$ the buyer $i \in W(\mathbf{X})$ such that $j \in X_i$. When the allocation vector is clear from the context, we simply write $b(j)$.

The following concepts define two types of stable outcomes for Γ.

▶ **Definition 1.** An individually-rational outcome $(\mathbf{X}, \mathbf{p})$ is **item envy-free** if $u_i(X_i, \mathbf{p}) \geq u_i(T, \mathbf{p})$ for every buyer $i \in N$ and $T \subseteq M$, that is, $X_i \in D_i(\mathbf{p})$ for every $i \in N$.

▶ **Definition 2.** An individually-rational outcome $(\mathbf{X}, \mathbf{p})$ is **bundle envy-free** if $u_i(X_i, \mathbf{p}) \geq u_i(X_j, \mathbf{p})$ for every two buyers $i, j \in N$.

Denote with $\mathsf{IEF}(\Gamma)$ and $\mathsf{BEF}(\Gamma)$, the sets of item envy-free and bundle envy-free outcomes for Γ, respectively. Notice that $\mathsf{IEF}(\Gamma) \subseteq \mathsf{BEF}(\Gamma)$ and $\mathsf{IEF}(\Gamma) \neq \emptyset$ (and so also $\mathsf{BEF}(\Gamma) \neq \emptyset$), since the outcome $(\mathbf{X}, \mathbf{p})$ such that $X_i = \emptyset$ for every $i \in N$ and $p_j = \infty$ for every $j \in M$ is individually-rational and item envy-free.

2.3 Pricing Problems

Fix an outcome $(\mathbf{X}, \mathbf{p})$ for a market Γ. The revenue raised by $(\mathbf{X}, \mathbf{p})$ is $\mathsf{REV}(\mathbf{X}, \mathbf{p}) = \sum_{j \in M(\mathbf{X})} p_j$. The social welfare generated by $(\mathbf{X}, \mathbf{p})$ is $\mathsf{SW}(\mathbf{X}, \mathbf{p}) = \sum_{i \in N} u_i(X_i) + \sum_{j \in M(\mathbf{X})} p_j = \sum_{i \in W(\mathbf{X})} v_i(X_i)$. Note that the social welfare does not depend on the price vector $\mathbf{p}$ and that $\mathsf{SW}(\mathbf{X}, \mathbf{p}) \geq \mathsf{REV}(\mathbf{X}, \mathbf{p})$.

Given a market Γ, let $\mathsf{sol}(\Gamma) \subseteq \mathsf{OUT}(\Gamma)$ denote any subset of outcomes for Γ and $\mathsf{obj} : \mathsf{OUT}(\Gamma) \to \mathbb{R}_{\geq 0}$ denote an objective function associating a non-negative value to every outcome for Γ. Let $opt(\Gamma, \mathsf{sol}, \mathsf{obj}) := \text{argmax}_{(\mathbf{X}, \mathbf{p}) \in \mathsf{sol}(\Gamma)} \{\mathsf{obj}(\mathbf{X}, \mathbf{p})\}$ denote the set of outcomes in $\mathsf{sol}(\Gamma)$ maximizing the objective function obj.

▶ **Definition 3.** The **pricing problem** $P = (\Gamma, \mathsf{sol}, \mathsf{obj})$ is an optimization problem which , given a market Γ, a set of outcomes $\mathsf{sol}(\Gamma)$ and an objective function obj, asks for an outcome $o^*(P) \in opt(P)$.

In this paper, we consider the cases in which $\mathsf{sol}(\Gamma) \in \{\mathsf{IEF}(\Gamma), \mathsf{BEF}(\Gamma)\}$ and $\mathsf{obj} \in \{\mathsf{REV}, \mathsf{SW}\}$.

Oracles. Fix a pricing problem $P = (\Gamma, \mathsf{sol}, \mathsf{obj})$. As we have seen, when Γ is a market with combinatorial valuations, any algorithm for P needs to deal with an input of exponential size. In order to circumvent this problem and remain within the realm of polynomial time algorithms, it is usually assumed that functions v_is are not given as an input of the problem and are replaced by a polynomial time (with respect to n and m) *oracle* providing information about a buyer's valuation function. An oracle is usually assumed to answer two types of questions: a *value query* which, given a buyer $i \in N$ and a set of items X, returns the valuation $v_i(X)$, and a *demand query* which, given a price vector $\mathbf{p}$ and a buyer $i \in N$, returns any set in $D_i(\mathbf{p})$.

We remark that all algorithms of this paper exploiting oracle calls are polynomial also in the sense that they call the oracle a polynomial number of times. Therefore, when also the oracle is polynomially computable, the algorithm computation is fully polynomial.

2.4 The Buyer Preselection Problem

Given a market $\Gamma = (N, M, (v_i)_{i \in N})$ and a subset of buyers $N' \subseteq N$, the submarket of Γ induced by N' is the market $\Gamma(N') = (N', M, (v_i)_{i \in N'})$.

▶ **Definition 4.** The **buyer preselection problem** is an optimization problem $\mathsf{BP}(P)$ which, given a pricing problem $P = (\Gamma, \mathsf{sol}, \mathsf{obj})$ with $\Gamma = (N, M, (v_i)_{i \in N})$, asks for a pair $(N^*(\mathsf{BP}(P)), o^*(\mathsf{BP}(P)))$ such that $N^*(\mathsf{BP}(P)) \in \operatorname{argmax}_{N' \subseteq N}\{opt(\Gamma(N'), \mathsf{sol}, \mathsf{obj})\}$ and $o^*(\mathsf{BP}(P)) \in opt(\Gamma(N^*(\mathsf{BP}(P))), \mathsf{sol}, \mathsf{obj})$, that is, $o^*(\mathsf{BP}(P))$ is the best outcome which can be realized in all possible submarkets of Γ.

Clearly, by definition, for every pricing problem P, $\mathsf{obj}(o^*(P)) \leq \mathsf{obj}(o^*(\mathsf{BP}(P)))$, that is, buyer preselection can only improve the quality of the optimal solution.

3 Results for Item Envy-Free Outcomes

In this section, we consider the buyer preselection problem $\mathsf{BP}(\Gamma, \mathsf{IEF}, \mathsf{obj})$ with $\mathsf{obj} \in \{\mathsf{REV}, \mathsf{SW}\}$. We start by providing a lower bound on its approximability attained by exploiting an approximation-preserving reduction from the maximum independent set problem.

▶ **Theorem 5.** *Let $P = (\Gamma, \mathsf{IEF}, \mathsf{obj})$ be a pricing problem with $\mathsf{obj} \in \{\mathsf{REV}, \mathsf{SW}\}$. For every $\epsilon > 0$, the buyer preselection problem $\mathsf{BP}(P)$ cannot be approximated within $n^{1-\epsilon}$, unless $\mathbf{P} = \mathbf{ZPP}$, even when Γ is a market with single-minded buyers.*

Proof. We prove the claim through an approximation-preserving reduction from the maximum independent set problem, in which, given an undirected graph, it is asked for a subset of nodes, no two of which are adjacent, of maximum cardinality. To this aim, consider an instance of the maximum independent set problem defined by a graph $G = (V, E)$ and denote with $\delta_i(G)$ the set of edges incident to node i. We create a market $\Gamma = (N, M, (v_i)_{i \in N})$ with single-minded buyers as follows: we set $N = V$, $M = E$ and, for every $i \in N$, we define the valuation function v_i in such a way that, for every $X \subseteq M$,

$$v_i(X) = \begin{cases} 1 & \text{if } X = \delta_i(G) \\ 0 & \text{otherwise.} \end{cases}$$

Fix any subset of buyers $N' \subseteq N$. Given an individually-rational outcome $o = (\mathbf{X}, \mathbf{p}) \in \mathsf{OUT}(\Gamma(N'))$, define $V_{\mathsf{REV}}(o) := \{i \in V : \sum_{j \in X_i} p_j > 0\}$ and $V_{\mathsf{SW}}(o) := \{i \in V : v_i(X_i) > 0\}$. By construction of the valuation functions, both $V_{\mathsf{REV}}(o)$ and $V_{\mathsf{SW}}(o)$ have to be independent sets for G. Let $\mathsf{obj} \in \{\mathsf{REV}, \mathsf{SW}\}$. Since $\sum_{j \in X_i} p_j \leq 1$ and $v_i(X_i) \leq 1$ for every $i \in N'$, it follows that

$$\mathsf{obj}(o) \leq |V_{\mathsf{obj}}(o)|. \tag{1}$$

Let $V^* \subseteq V$ be a maximum independent set for G. It is easy to see that the outcome $(\mathbf{X}^*, \mathbf{p}^*)$ such that $X_i^* = \delta_i(G)$ for every $i \in V^*$ and

$$p_j^* = \begin{cases} 1/\delta_i(G) & \text{if } j \in \delta_i(G) \\ 0 & \text{otherwise.} \end{cases}$$

is an item envy-free outcome (actually it is also a Walrasian equilibrium because the market clears, i.e, every unsold item is assigned price zero) for market $\Gamma(N')$. This implies

$$\mathsf{obj}(o^*(\mathsf{BP}(P))) \geq \mathsf{obj}(\mathbf{X}^*, \mathbf{p}^*) = |V^*|. \tag{2}$$

Assume, for the sake of contradiction, that there exists an approximation algorithm for $\mathsf{BP}(P)$ returning an outcome o such that $n^{1-\epsilon}\mathsf{obj}(o) \geq \mathsf{obj}(o^*(\mathsf{BP}(P)))$ for some $\epsilon > 0$. Using (2), we get $n^{1-\epsilon}\mathsf{obj}(o) \geq |V^*|$ which combined with (1) implies that $n^{1-\epsilon}|V_{\mathsf{obj}}(o)| \geq |V^*|$: a contradiction to the inapproximability result for the maximum independent set problem. ◀

As a positive result, we show that, by building upon (approximation) algorithms for pricing problems defined on markets with a unique buyer, it is possible to obtain approximation algorithms for the buyer preselection problem. In particular, the following theorem can be proved by considering the buyer providing, when being alone in the market, the best possible outcome with respect to the considered objective function.

▶ **Lemma 6.** *Given a buyer preselection problem* $\mathsf{BP}(P)$*, where* $P = (\Gamma, \mathsf{IEF}, \mathsf{obj})$ *with* $\mathsf{obj} \in \{\mathsf{REV}, \mathsf{SW}\}$*, if there exists a polynomial time algorithm* $\mathcal{A}$ *returning an outcome for the pricing problem defined on markets with a unique buyer whose objective value is at least an* α *fraction of the optimal social welfare, then* $\mathsf{BP}(P)$ *admits an* αn*-approximation algorithm.*

Proof. Assume that $o^*(\mathsf{BP}(P)) := (\mathbf{X}^*, \mathbf{p}^*)$. For every $i \in N^*(\mathsf{BP}(P))$, define

$$\mathsf{obj}_i(o^*(\mathsf{BP}(P))) = \begin{cases} \sum_{j \in X_i^*} p_j^* & \text{if } \mathsf{obj} = \mathsf{REV}, \\ v_i(X_i^*) & \text{if } \mathsf{obj} = \mathsf{SW}. \end{cases} \tag{3}$$

Consider the preselection algorithm which, given Γ, returns a buyer $i^* \in N$ such that $i^* \in \mathrm{argmax}_{i \in N} \{\max_{X \subseteq M}\{v_i(X)\}\}$. Let $o \in \mathsf{IEF}(\Gamma(\{i^*\}))$ be the outcome returned by $\mathcal{A}$ when executed on the pricing problem $P' = (\Gamma(\{i^*\}), \mathsf{IEF}, \mathsf{obj})$. We have

$$\begin{aligned} \mathsf{obj}(o^*(\mathsf{BP}(P))) &= \sum_{i \in N^*(\mathsf{BP}(P))} \mathsf{obj}_i(o^*(\mathsf{BP}(P))) \\ &\leq \sum_{i \in N^*(\mathsf{BP}(P))} v_i(X_i^*) \\ &\leq n v_{i^*}(X_{i^*}^*) \\ &\leq \alpha n \mathsf{obj}(o), \end{aligned}$$

where the first inequality comes from (3) and the fact that $\sum_{j \in X_i^*} p_j \leq v_i(X_i^*)$ because of individual rationality, the second inequality follows from the definition of i^*, and the third inequality comes from the hypothesis on algorithm $\mathcal{A}$. ◀

As a consequence of Theorem 5 and Lemma 6, we have that the buyer preselection problem $\mathsf{BP}(\Gamma, \mathsf{IEF}, \mathsf{obj})$, with $\mathsf{obj} \in \{\mathsf{REV}, \mathsf{SW}\}$, admits a polynomial time algorithm providing the best possible approximation guarantee, whenever the pricing problem defined on markets with a unique buyer can be solved in polynomial time with respect to the social welfare objective function. For such a reason, in the following subsection, we focus on the solution of the latter problem.

3.1 Pricing Problems Defined on Markets with a Unique Buyer

Throughout this subsection, since there is only one buyer in the market, for the sake of simplicity we remove the pedis 1 from the notation.

As a warmup, we start by considering the simpler case in which $\mathsf{obj} = \mathsf{SW}$.

▶ **Claim 7.** *Let Γ be a market with a single buyer and combinatorial valuations. The pricing problem $(\Gamma, \mathsf{IEF}, \mathsf{SW})$ can be solved in polynomial time.*

In fact, observe that an outcome $(X^*, \mathbf{0}^m)$ such that $X^* \in \operatorname{argmax}_{X \subseteq M} v(X)$ verifies $(X^*, \mathbf{0}^m) \in opt(P)$, and a set $X^* \in \operatorname{argmax}_{X \subseteq M} v(X)$ can be obtained in polynomial time by using the price vector $\mathbf{0}^m$ as the input of an oracle demand query.

We show in the next theorem that the case of $\mathsf{obj} = \mathsf{REV}$ yields an **NP**-hard problem, thus solving a longstanding open problem left by [5] (where in Lemma 7 an approximation algorithm with no hardness result is provided). Theorem 8 can be proved by exploiting a polynomial reduction from 3SAT, in which a given boolean formula ϕ is transformed into a market with a unique buyer, whose items are the literals of ϕ.

▶ **Theorem 8.** *Let Γ be a market with a single buyer and combinatorial valuations. The pricing problem $(\Gamma, \mathsf{IEF}, \mathsf{REV})$ is* **NP***-hard.*

Proof. We prove the claim through a reduction from 3SAT. To this aim, given a boolean formula ϕ, let $\mathsf{V}(\phi)$ denote the set of its variables and $\mathsf{L}(\phi)$ the set of all possible literals on variables in $\mathsf{V}(\phi)$; moreover, denote $\nu = |\mathsf{V}(\phi)|$. Throughout this proof, we assume $\nu \geq 4$. An assignment for ϕ is a function $f : \mathsf{V}(\phi) \to \{0, 1\}$ assigning to each variable of ϕ a boolean value. Denote with $F(\phi)$ the set of all possible assignments for ϕ and with $\phi(f)$ the boolean value obtained by evaluating all literals occurring in ϕ according to f. ϕ is satisfiable if there exists an assignment $f \in F(\phi)$ such that $\phi(f) = 1$ and it is unsatisfiable if, for every assignment $f \in F(\phi)$, $\phi(f) = 0$. Given a set of literals $X \subseteq \mathsf{L}(\phi)$, with a little abuse of notation, we write $X \in F(\phi)$ whenever there exists an assignment $f \in F(\phi)$ such that X contains all and only those literals which are evaluated 0 according to f. A formula ϕ is an instance of 3SAT if ϕ is expressed in Conjunctive Normal Form and each clause is the disjunction of 3 literals, so that ϕ can be completely expressed by listing the set $C = \{c_1, \ldots, c_k\}$ of its clauses, where each clause c_i $(i = 1, \ldots, k)$ is a set of three literals.

Given an instance of 3SAT $\phi := C$, we construct a market $\Gamma = (\{1\}, M, v)$ with a unique buyer such that $M = \mathsf{L}(\phi)$ and the valuation function v is defined as follows:

$$v(X) = \begin{cases} 1 & \text{if } |X| = 1, \\ 3 + \epsilon & \text{if } X \in C, \\ \nu & \text{if } X \in F(\phi), \\ 0 & \text{otherwise,} \end{cases}$$

where $\epsilon > 0$ is arbitrarily small.

Clearly Γ can be constructed in polynomial time with respect to the representation of ϕ. However, in order to complete the reduction, we have to construct an oracle which can answer both demand and value queries in polynomial time. To this aim, observe that, given a set of literals X, checking whether X is a singleton set, or $X \in C$, or $X \in F(\phi)$ can be performed in polynomial time, so that value queries can be efficiently answered. In order to provide an efficient answer to a demand query, we first observe that the cardinalities of sets $\mathsf{L}(\phi)$ and C are polynomial in the representation of ϕ, and therefore, given a pricing vector, a set of items in $\mathsf{L}(\phi)$ and C yielding the highest utility can be efficiently computed by enumeration. Then, in order to compute a set $X \in F(\phi)$ of maximum utility, note that all

the candidate sets have the same valuation so that, in order to return one with the highest utility, we simply need to choose, for each variable in $\mathsf{V}(\phi)$, the related literal having the lowest price. Hence, market Γ can be generated and managed in polynomial time.

Now, in order to complete the proof, we show that there exists an outcome $o \in \mathsf{OUT}(\Gamma)$ such that $\mathsf{REV}(o) = \nu$ if and only if ϕ is satisfiable.

Assume first that ϕ is satisfiable and let f be a satisfying assignment for ϕ. Let X be the set of literals which are evaluated 0 in f and let $\mathbf{p}$ be the pricing vector such that all literals in X are priced 1, while all literals in $\mathsf{L}(\phi) \setminus X$ are priced ∞. By definition, we have $u(X, \mathbf{p}) = 0$, so that $(X, \mathbf{p})$ is individually-rational. Moreover, $(X, \mathbf{p}) \in D(\mathbf{p})$. In fact, for every $X' \neq X$ such that $X' \in F(\phi)$, $u(X', \mathbf{p}) < 0$ since X' has to contain at least one item priced ∞; for every $X' \in C$, $u(X', \mathbf{p}) < 0$ since, as we have $\phi(f) = 1$, X' has to contain at least one item priced ∞; for every $X' \in \mathsf{L}(\phi)$, $u(X', \mathbf{p}) \leq 0$ by construction. Hence, $(X, \mathbf{p}) \in \mathsf{IEF}(\Gamma)$ and $\mathsf{REV}(X, \mathbf{p}) = \nu$.

Secondly, assume that there exists an outcome $(X, \mathbf{p}) \in \mathsf{IEF}(\Gamma)$ such that $\mathsf{REV}(X, \mathbf{p}) = \nu$. By construction of the valuation function, this is possible only if $X \in F(\phi)$ and $\sum_{j \in X} p_j = \nu$, so that $u(X, \mathbf{p}) = 0$. However, since $v(\{\ell\}) = 1$ for every $\ell \in \mathsf{L}(\phi)$, $(X, \mathbf{p}) \in \mathsf{IEF}(\Gamma)$ implies that it must also be $p_j \geq 1$ for each $j \in X$. Hence, we can conclude that $p_j = 1$ for each $j \in X$. Assume, for the sake of contradiction, that ϕ is unsatisfiable. This implies that the assignment induced by all literals in $\mathsf{L}(\phi) \setminus X$ cannot satisfy ϕ, that is, there exists a clause $c_j \in C$ such that $c_j \subseteq X$. This implies $u(c_j, \mathbf{p}) = 3 + \epsilon - 3 = \epsilon > 0$ thus contradicting $(X, \mathbf{p}) \in \mathsf{IEF}(\Gamma)$. Hence, ϕ has to be satisfiable. ◀

On the positive side, [5] derive an $O(\log m)$-approximation algorithm for this problem. An interesting feature of this algorithm is that its performance guarantee holds also with respect to the maximum social welfare which is an upper bound to the maximum revenue, thus allowing the application of Lemma 6.

Hence, by combining Lemma 6 with Claim 7 and the result of [5], we obtain the following upper bounds.

▶ **Theorem 9.** *Let $P = (\Gamma, \mathsf{IEF}, \mathsf{obj})$ be a pricing problem with $\mathsf{obj} \in \{\mathsf{REV}, \mathsf{SW}\}$. The buyer preselection problem $\mathsf{BP}(P)$ admits an n-approximation when $\mathsf{obj} = \mathsf{SW}$, and an $O(n \log m)$-approximation when $\mathsf{obj} = \mathsf{REV}$.*

It is worth noticing that, given the proof of Lemma 6, the preselection claimed in Theorem 9 is someway "oblivious", i.e., it can be obtained by exploiting the minimum possible number of oracle queries, that is only a single oracle (demand) query for each buyer.

In light of the lower bound given in Theorem 5, the upper bounds given in Theorem 9 are asymptotically tight both for $\mathsf{obj} = \mathsf{SW}$ (unless $\mathbf{P} = \mathbf{ZPP}$) and for $\mathsf{obj} = \mathsf{REV}$ when $m = o(n)$ (unless $\mathbf{P} = \mathbf{ZPP}$).

4 Results for Bundle Envy-Free Outcomes

In this section, we consider the buyer preselection problem $\mathsf{BP}(\Gamma, \mathsf{BEF}, \mathsf{obj})$ with $\mathsf{obj} \in \{\mathsf{REV}, \mathsf{SW}\}$. Since we deal with bundle envy-free outcomes, we suppose that the price of any unsold item is infinite. Formally, given an outcome (N, o), where $o = (\mathbf{X}, \mathbf{p})$, for the buyer preselection problem $\mathsf{BP}(\Gamma, \mathsf{BEF}, \mathsf{obj})$ with $\Gamma = (N, M, (v_i)_{i \in N})$, we have that, for any $j \in M \setminus M(\mathbf{X})$, $p_j = \infty$.

We start by considering the buyer preselection problem $\mathsf{BP}(\Gamma, \mathsf{BEF}, \mathsf{REV})$.

The following theorem shows how it is possible to transform a bundle envy-free solution $(\bar{N}, \bar{o})$ with preselection into anther one (without preselection) having a non-smaller revenue.

▶ **Theorem 10.** *Given any solution* $(\bar{N}, \bar{o})$ *for the buyer preselection problem* $\mathsf{BP}(\Gamma, \mathsf{BEF}, \mathsf{REV})$*, with* $\Gamma = (N, M, (v_i)_{i \in N})$*, it is possible to compute in polynomial time an outcome* $o \in \mathsf{BEF}(\Gamma)$ *for problem* P *such that* $\mathsf{REV}(o) \geq \mathsf{REV}(\bar{o})$*.*

Theorem 10 can be proved by exploiting the notion and properties of maximal solutions, i.e, solutions in which no item price can be increased without changing the allocation (notice that an optimal solution is maximal), and by providing a constructive algorithm working on maximal solutions and allocating bundle of items to the players in $N \setminus \bar{N}$ that envy other winners. In particular, we first show that in a maximal solution $(\bar{N}, \bar{o})$ with preselection (i) for any buyer with positive utility, there exists another sold bundle providing her the same utility and (ii) there always exists a winner buyer having utility equal to 0. Given these properties, it is possible to exchange among the buyers the assigned bundles so that an excluded envious buyer can be assigned her preferred sold bundle $\bar{X}_j$ and can be therefore added to the solution without generating envy. Buyer j, getting bundle $\bar{X}_j$ in $(\bar{N}, \bar{o})$, gets another one providing her the same utility (by property (i) such a bundle always exists). This process can be iterated until a winner buyer with utility equal to 0 is reached and removed from the set of winners (it is possible to show that in this process a buyer is never considered twice and therefore by property (ii) it always terminates).

We now consider the buyer preselection problem $\mathsf{BP}(\Gamma, \mathsf{BEF}, \mathsf{SW})$. Analogously to Theorem 10 holding for the revenue maximization case, next theorem shows that a bundle envy-free outcome for the buyer preselection problem can be efficiently transformed in a bundle envy-free outcome, for the corresponding pricing problem (without preselection), having at least the same social welfare.

▶ **Theorem 11.** *Given any solution* $(\bar{N}, \bar{o})$ *for the buyer preselection problem* $\mathsf{BP}(\Gamma, \mathsf{BEF}, \mathsf{SW})$*, with* $\Gamma = (N, M, (v_i)_{i \in N})$*, it is possible to compute in polynomial time an outcome* $o \in \mathsf{BEF}(\Gamma)$ *for problem* P *such that* $\mathsf{SW}(o) \geq \mathsf{SW}(\bar{o})$*.*

Theorem 11 can be proved by considering a new market Γ' with unit-demand buyers, in which the set of buyers is N and there is an item for every bundle sold in $(\bar{N}, \bar{o})$. In fact, given that markets with unit-demand buyers always admit a Walrasian Equilibrium computable in polynomial time and that, by the well known *First Welfare Theorem*, Walrasian equilibria maximize social welfare over all possible outcomes, it can be easily obtained, by suitably setting the price of the items in Γ as a function of those in Γ', a bundle envy-free solution for Γ with no excluded buyer and having the same social welfare of $\bar{o}$.

As a consequence of Theorems 10 and 11, we obtain the following corollary.

▶ **Corollary 12.** *For* $\mathsf{obj} \in \{\mathsf{REV}, \mathsf{SW}\}$*, given an* α*-approximate solution* (N, o) *(with* $\alpha \geq 1$*, notice that when* $\alpha = 1$ *the corollary holds for optimal solutions) for the buyer preselection problem* $\mathsf{BP}(P)$ *with* $P = (\Gamma, \mathsf{BEF}, \mathsf{obj})$ *and* $\Gamma = (N, M, (v_i)_{i \in N})$*, it is possible to compute in polynomial time an outcome* $o' \in \mathsf{BEF}(\Gamma)$ *approximating the optimal solution of* P *by a factor equal to* α*.*

On the one hand, Corollary 12 tells us that, for $\mathsf{obj} \in \{\mathsf{REV}, \mathsf{SW}\}$, any inapproximability result holding for a pricing problem $P = (\Gamma, \mathsf{BEF}, \mathsf{obj})$ directly extends to the buyer preselection problem $\mathsf{BP}(P)$; on the other hand, it tells us that any α-approximation algorithm for $\mathsf{BP}(P)$ is also an α-approximation algorithm for P. Thus, as discussed in the Our Contribution subsection, preselection can be exploited as an algorithmic framework for designing approximation algorithms for the normal market scenario (without preselection).

5 The multi-unit case

In this section we study the multi-unit case, in which all the m items are of the same type. Recall that, for every $i \in N$, the valuation function becomes of the form $v_i : \{1, \ldots, m\} \to \mathbb{R}_{\geq 0}$ and that the market can be represented with $\Theta(nm)$ bits. Furthermore, in this case an allocation vector X can be specified by the number of items assigned to each buyer, i.e. $X = (x_1, \ldots, x_n)$, with $x_i \in \{0, \ldots, m\}$ for any $i = 1, \ldots, n$, and $\sum_{i=1}^{n} x_i \leq m$. Finally, we set the item pricing to p (i.e., all the multi-items have the same price) and the total price for selling x items is px.

A particular situation of multi-unit market, moreover, arises when one assumes *single-minded* buyers; in this case, since, for every player $i = 1, \ldots, n$, valuation function v_i can be completely defined by specifying how much every player valuates the set containing k_i items (being the only set she is interested in), $\Theta(n \log m)$ bits suffice to represent the market.

We first focus on the case of *item envy-free* solutions. Next claim shows that preselection can improve both the revenue and the social welfare of a market with multi-unit items, even in the case of single-minded buyers.

▶ **Claim 13.** *For any $\epsilon > 0$, there exists a market Γ with single-minded buyers and multi-unit items, and a pricing problem $P = (\Gamma, \mathsf{IEF}(\Gamma), \mathsf{obj})$ with $\mathsf{obj} \in \{\mathsf{REV}, \mathsf{SW}\}$, such that $\mathsf{obj}(o^*(\mathsf{BP}(P))) \geq (m - \epsilon)\mathsf{obj}(o^*(P))$.*

In fact, consider a market with only two single-minded buyers. Buyer 1 valuates $1 + \epsilon'$, for a small $\epsilon' > 0$, for receiving any (one) item. Buyer 2 valuates m for receiving all the m items. Notice that, in any item envy-free outcome for the setting without preselection, buyer 2 receives no item. In fact, if buyer 2 receives m items, the item pricing p must be at most 1. Thus, buyer 1 would be envious since she would get no item (i.e., there are no enough items). Therefore, for the market without preselection, the only feasible solutions are selling one item to buyer 1 at price at least 1 and at most $1 + \epsilon'$. Thus the optimal revenue and the optimal social welfare are at most $1 + \epsilon'$. However, if we consider the submarket with only buyer 2, i.e., we exclude buyer 1, we can sell m items at item pricing 1, thus obtaining a revenue and social welfare of m.

We notice that the above bound is tight. It is easy to see that preselection cannot improve the revenue and social welfare of envy-free solutions by a factor greater than m. In fact, it is sufficient to sell items to the buyer i such that $(i, j) = \text{argmax}_{i=1,\ldots,n;j=1,\ldots,m} \frac{v_i(j)}{j}$.

Now we focus on the computation of optimal or approximate solution for the preselection problem in the case of item envy-free outcomes, both for the social welfare and the revenue objective functions.

▶ **Theorem 14.** *Given a pricing problem $P = (\Gamma, \mathsf{IEF}(\Gamma), \mathsf{obj})$, where $\Gamma = (N, M, (v_i)_{i \in N})$ is a market with multi-unit items and $\mathsf{obj} \in \{\mathsf{REV}, \mathsf{SW}\}$, the buyer preselection problem $\mathsf{BP}(P)$ can be optimally solved in polynomial time.*

Proof. Recall that solving the buyer preselection problem $\mathsf{BP}(P)$ corresponds to find a subset N^* of players to admit to the market and an optimal outcome $o^* = (X^*, p^*)$, in which in the considered case of multi-unit items p^* is just the price of a single item.

In order to prove the claim, we first show that it is possible to compute in polynomial time a set $\mathcal{P}$ containing the optimal price p^* for problem $\mathsf{BP}(P)$.

Consider the set $\mathcal{P}$ defined as follows:

$$\begin{aligned} \mathcal{P} \quad = \quad & \{y | v_i(k) - yk = v_i(k') - yk', i \in N, \\ & k, k' \in \{0, 1, \ldots, m\}, k \neq k'\}. \end{aligned}$$

Roughly speaking, for all buyers $i \in N$ and for all couples (k, k') of integers belonging to $\{0, 1, \ldots, m\}$ such that $k \neq k'$, $\mathcal{P}$ contains the solution y of equality $v_i(k) - yk = v_i(k') - yk'$. Clearly, $\mathcal{P}$ can be computed in $O(nm^2)$ time, i.e., in polynomial time in the size of the instance. Now, assume by contradiction that the optimal solution (N^*, o^*) for $\mathsf{BP}(P)$ with the highest possible item price assign to an item price $p^* \notin \mathcal{P}$, and let $p' \in \mathcal{P}$ the smallest element of $\mathcal{P}$ such that $p' > p^*$. Notice that this element $p' \in \mathcal{P}$ has to exist, because p^* must verify, for any $i = 1, \ldots, n$, $v_i(\bar{x}_i) - p^*\bar{x}_i \geq 0$ and y verifying equality $v_i(\bar{x}_i) - y\bar{x}_i = 0$ belongs to $\mathcal{P}$. Since p^* induces an envy-free solution, it has to verify, for every $i = 1, \ldots, n$, constraint $v_i(\bar{x}_i) - p^*\bar{x}_i \geq v_i(j) - p^*j$ for any $j = 0, \ldots, m$; since, $p^* \notin \mathcal{P}$, given how $\mathcal{P}$ is defined, it follows that all above constraints are not verified in a strict manner, i.e. it is verified that, for every $i = 1, \ldots, n$, $v_i(\bar{x}_i) - p^*\bar{x}_i > v_i(j) - p^*j$ for any $j = 0, \ldots, m$. Therefore, p' still continues to verify all envy-free constraints (with some constraints possibly become strict). It follows that we have found a new envy-free outcome o' such that $\mathsf{SW}(o') = \mathsf{SW}(o^*)$ and $\mathsf{REV}(o') > \mathsf{REV}(o^*)$: a contradiction to the fact that o^* was the optimal outcome with the highest possible item price.

Therefore, since the number of values that can be assigned to p^* in order to obtain an optimal outcome is polynomial in the size of the instance, it remains to show that, given a fixed price p^*, it is possible to optimally compute in polynomial time a subset N^* of players to admit to the market and an allocation X^*. In fact, the optimal solution of $\mathsf{BP}(P)$ is given by the best solution among the ones obtained for all the candidate prices belonging to $\mathcal{P}$.

The *0-1 Multiple-Choice Knapsack Problem (0-1 MCKP)* is a generalization of the classical Knapsack problem introduced in [30]. In this problem, we are given α classes $C_1, C_2, \ldots, C_\alpha$ of elements to pack in some knapsack of capacity c. For every $i = 1, \ldots, n$, each element $e \in C_i$ (let $class(e) = i$ be the index of the class to which e belongs) has a profit β_e and a volume γ_e, and the problem is to choose a set E containing *at most* one element from each class such that the profit sum is maximized without the volume sum exceeding capacity c. In [21] it is shown that it can be optimally solved in pseudo-polynomial time, i.e., in time $O(c)$.

We now provide a polynomial reduction from our problem to 0-1 MCKP. Given an instance I of $\mathsf{BP}(P)$ and fixed a price p^*, we construct an instance I' of 0-1 MCKP as follows: We have $\alpha = n$ classes (one class for each buyer) and the capacity $c = m$. Consider, for every buyer $i = 1, \ldots, n$, the number of items providing her with the highest possible utility: let $\bar{U}_i = \arg\max_{k=1,\ldots,m} v_i(k) - kp^*$ be the set containing these values. It is easy to check that, in every item envy-free solution, allocation X must satisfy $x_i \in \bar{U}_i$ for every player $i = 1, \ldots, n$. For every $i = 1, \ldots, n$, consider set $\bar{U}_i$: we add to class C_i an element e for every $k \in \bar{U}_i$ such that $\gamma_e = k$ and

- $\beta_e = k$ if $\mathsf{obj} = \mathsf{REV}$;
- $\beta_e = v_i(k)$ if $\mathsf{obj} = \mathsf{SW}$.

Given a solution for I' with total profit $\beta = \sum_{e \in E} \beta_e$, it is possible to obtain a solution for I with fixed price p^*, i.e., a subset $\bar{N}$ of players to admit to the market and an allocation $\bar{X}$, as follows: $\bar{N}$ contains the players associated to classes containing an element belonging to E, i.e., $\bar{N} = \{i | C_i \cap E \neq \emptyset\}$, and the allocation vector $\bar{X} = (\bar{x}_1, \ldots, \bar{x}_n)$ is such that, for every $i = 1, \ldots, n$, $x_i = \gamma_e$ if there exists an element $e \in C_i \cap E$. Clearly, $\mathsf{obj}((\bar{X}, p^*)) = \beta$. Furthermore, by the way $\bar{U}_i$ is defined, outcome $(\bar{X}, p^*)$ is item envy-free.

Conversely, given a subset $\bar{N}$ of preselected players and an outcome $o = (X, p^*)$ for I, it is possible to obtain a solution for I' as follows: for every $i \in \bar{N}$, add to E element $e \in C_i$ such that $\gamma_e = x_i$ (by recalling the definition of $\bar{U}_i$, it holds that this element e belongs to C_i because outcome o is item envy-free). Clearly, the total profit $\beta = \sum_{e \in E} \beta_e = \mathsf{obj}((X, p^*))$.

The claim follows by noticing that, since $c = m$, the pseudo-polynomial algorithm of [21] is in fact polynomial with respect to the size of the instance of problem $\mathsf{BP}(P)$. ◀

For the special case of single-minded buyers in which an instance of the buyer preselection problem can be represented by $\Theta(n \log m)$ bits, by exploiting the same ideas used for proving Theorem 14, the following theorem provides an **FPTAS**.

▶ **Theorem 15.** *Given a pricing problem* $P = (\Gamma, \mathsf{IEF}(\Gamma), \mathsf{obj})$*, where* $\Gamma = (N, M, (v_i)_{i \in N})$ *is a market with single-minded buyers and multi-unit items, for* $\mathsf{obj} \in \{\mathsf{REV}, \mathsf{SW}\}$*, the buyer preselection problem* $\mathsf{BP}(P)$ *admits a* fully polynomial approximation scheme*.*

We complement the result of Theorem 15 by showing a tight lower bound to the problem of computing the maximum revenue to the case of item envy-free with single-minded buyers and multi-unit items. The following claim can be proved by exploiting a reduction from the Subset Sum problem.

▶ **Claim 16.** *Given a pricing problem* $P = (\Gamma, \mathsf{IEF}(\Gamma), \mathsf{REV})$*, where* $\Gamma = (N, M, (v_i)_{i \in N})$ *is a market with single-minded buyers and multi-unit items, the buyer preselection problem* $\mathsf{BP}(P)$ *is* **NP***-Hard.*

Proof. We use a reduction from the Subset Sum problem, that is defined as follows: given a set of integers and an integer s, does any non-empty subset sum to s? Let n be the number of elements $\{a_1, a_2, \ldots, a_n\}$ in the given instance of the Subset sum problem, and let s be the required sum. We assume that $\sum_{i=1}^{n} a_i > s$, as otherwise the problem is trivial. For all a_i in the input of the Subset sum problem, we create a corresponding buyer i with the following valuation. Buyer i has valuation a_i for receiving a_i items, and zero otherwise. Moreover, we set the number of items $m = s$. In such case, if there is a solution for the Subset sum problem, then by setting the item pricing $p = 1$ and selling to corresponding buyers gives us a feasible and envy-free outcome in which the revenue equals to m. It is easy to see that m is an upper bound to the maximum revenue. On the other hand, if the revenue of the optimal outcome to the buyer preselection problem is equal to m, we can obtain the solution to the subset sum problem. Notice that we can obtain a revenue of m only if we sell exactly m items at item pricing $p = 1$. In fact, at item pricing $p > 1$, we sell no item, and at item pricing $p < 1$, we do not get an optimal solution. ◀

We now focus on the case of *bundle envy-free* solutions. We first notice that the results of Section 4 claiming that bundle envy-free solutions do not improve the quality of outcomes (with respect neither to social welfare nor to revenue maximization) do not hold for the multi-unit case, because in this case it is not possible to change the price of some item without influencing the other ones. We start by showing that preselection can improve both the revenue and the social welfare of a market with multi-unit items, even in the case of single-minded buyers.

▶ **Claim 17.** *For any* $\epsilon > 0$*, there exists a market* Γ *with single-minded buyers and multi-unit items, and a pricing problem* $P = (\Gamma, \mathsf{BEF}(\Gamma), \mathsf{obj})$ *with* $\mathsf{obj} \in \{\mathsf{REV}, \mathsf{SW}\}$*, such that* $\mathsf{obj}(o^*(\mathsf{BP}(P))) \geq (2 - \epsilon)\mathsf{obj}(o^*(P))$*.*

In fact, consider a market with $x + 1$ single-minded buyers. Buyer 1 valuates x for receiving x items. Buyer i, for any $i = 2, 3, \ldots, x + 1$, valuates $1 + \epsilon'$, for a small $\epsilon' > 0$, for receiving any (one) item. Finally, the number of items is $2x - 1$. Notice that, in any bundle envy-free outcome for the setting without preselection, if buyers 1 receives x items, it implies that the item pricing p must be at most 1. It further implies that, in such outcome, no buyer i, for any $i = 2, 3, \ldots, x + 1$, can get items. The reason is that such buyers have positive utility for receiving one item, but the number of items is not sufficient to satisfy all of them. Therefore, the only chance is selling no bundle of one item. Thus, on one hand, without preselection,

the best revenue and social welfare is $x(1+\epsilon')$. It can be obtained by selling one item to buyers i, for any $i = 2, 3, \ldots, x+1$, at price $1+\epsilon'$. On the other hand, if we consider the submarket with only buyers $1, 2, \ldots, x$ (i.e., we exclude one buyer that valuates $1+\epsilon'$ for receiving any (one) item), we can sell $2x-1$ items at item pricing 1, that is x items to buyer 1, and one item to buyers i, for any $i = 2, \ldots, x$, thus obtaining a revenue and social welfare of $2x-1$.

We now show that, for the market with multi-unit items and general valuations, preselection can improve the revenue by a multiplicative factor of at most 2, thus closing in a tight way the previous bound.

▶ **Theorem 18.** *Given a solution $(\bar{N}, \bar{o})$ for the buyer preselection problem $\mathsf{BP}(\Gamma, \mathsf{BEF}, \mathsf{REV})$, with $\Gamma = (N, M, (v_i)_{i\in N})$ being a market with multi-unit items, it is possible to compute in polynomial time an outcome $o \in \mathsf{BEF}(\Gamma)$ for problem P such that $\mathsf{REV}(\bar{o}) \leq 2\mathsf{REV}(o)$.*

Proof. Let $\bar{o} = (\bar{X}, \bar{p})$. In the following we will show how to compute in polynomial time an outcome $o \in \mathsf{BEF}(\Gamma)$ with $o = (X, p)$ such that (i) $p \geq \bar{p}$ and (ii) $|M(X)| \geq \frac{|M(\bar{X})|}{2}$, i.e., outcome o sells at least one half of the items sold by outcome $\bar{o}$ at a price at least equal to $\bar{p}$. Clearly, this directly implies that $\mathsf{REV}(o) \geq \frac{\mathsf{REV}(\bar{o})}{2}$.

For every $j \in \{1, \ldots, m\}$, let a_j be the number of items that could be sold to some buyers in bundles of cardinality j at price $\bar{p}$ (we require that these buyers obtain a non-negative utility for a bundle of j items). More formally, for every $j = 1, \ldots, m$, let $B_j(\bar{X}) = \{i | v_i(j) - j\bar{p} \geq 0\}$ be the subset of players obtaining a non-negative utility for a bundle with j items; then, $a_j = j|B_j(\bar{X})|$.

We divide the proof in two disjoint cases.

- If there exists $j \in \{1, \ldots, m\}$ such that $a_j \geq \frac{|M(\bar{X})|}{2}$, outcome $o = (X, p)$ is such that $x_k = j$ for every $k \in B_j(\bar{X})$, and $x_k = 0$ otherwise. By setting $p = \bar{p}$, by the definition of a_j, we know that a_j items could be sold without generating envy.
  If $a_j \leq m$, we are done.
  If $j \geq \frac{|M(\bar{X})|}{2}$, we can increase the price p so that only buyer i, with i such that $v_i(j) = \max_{k=1}^{n} v_k(j)$, is assigned the bundle (notice that in this way no other buyer is envious).
  It remains to deal with the subcase in which $a_j > m$ and $j < \frac{|M(\bar{X})|}{2}$: We increment price p until the number of buyers x with positive utility is such that $xj \leq m$. We then assign bundles of j items to all buyers with positive utility and to as many buyers with zero utility as possible. Notice that (i) since $j < \frac{|M(\bar{X})|}{2}$ implies that $m - j > \frac{|M(\bar{X})|}{2}$, this process leads to obtain at least $\frac{|M(\bar{X})|}{2}$ assigned items and (ii) again no buyer is envious.
- If for all $j \in \{1, \ldots, m\}$ it holds that $a_j < \frac{|M(\bar{X})|}{2}$, outcome $o = (X, \bar{p})$ (with the same price of outcome $\bar{o}$) is computed as follows.
  For any $i = 1, \ldots, n$ and $k = 1, \ldots, m$, let $u_i^{*k} = \max_{t=1}^{k} v_i(t) - t\bar{p}$ be the maximum possible utility of buyer i for bundles of at most k items and $b_i^{*k} = \min\{j | v_i(j) - j\bar{p} = u_i^{*k}\}$ the minimum size of a bundle of maximum utility for buyer i. Moreover, for any $k = 1, \ldots, m$ and $j = 1, \ldots, k$, let $B_{k,j} = \{i | b_i^{*k} = j\}$ be the set of buyers having j items as their best bundle of maximum utility, among all bundles made up to k items, and resolving ties by selecting the bundle of minimum size.
  Clearly, $B_{k,j}$ can be computed in time $O(poly(n, m))$. For $k = 1, \ldots, m$, consider allocation $X^k = (x_1^k, \ldots, x_n^k)$ such that, for every $i = 1, \ldots, n$, $x_i^j = j$ if $i \in B_{k,j}$ and $x_i^j = 0$ otherwise. By the definition of $B_{k,j}$ it follows that allocation X^k is envy-free. Moreover, it can be easily verified that $|M(X^1)| = a_1$ and, for any $j = 2, \ldots, m$, $|M(X^j)| - |M(X^{j-1})| \leq a_j$.

If $|M(X^m)| \leq m$, the claim trivially follows by setting $X = X^m$ because we are allocating at least all items allocated in $\bar{o}$.
Otherwise, let k' be the minimum value of $k = 2, \ldots, m$ such that $|M(X^{k'})| > m$: the claim follows by setting $X = X^{k'-1}$. In fact, since $|M(X^{k'})| - |M(X^{k'-1})| \leq a_{k'} \leq \frac{|M(\bar{X})|}{2}$, it follows that $|M(X^{k'-1})| \geq m - \frac{|M(\bar{X})|}{2} \geq \frac{|M(\bar{X})|}{2}$. ◀

It is worth noticing that, on the one hand, preselection can be exploited as an algorithmic framework for designing good approximation algorithms (loosing only a moltiplicative factor of 2) for the normal market scenario without preselection; on the other hand, since the optimal revenue with preselection is at most twice the one without, an α-approximation algorithm for the normal market without preselection, is a 2α-approximation one for market with preselection.

6 Final remarks and Future work

Many results holding for the item envy-free outcomes and social welfare objective function extend to the notion of Walrasian equilibria, that are item envy-free outcomes with the additional requirement that the market clears, i.e., every unsold item is assigned price zero. In particular, the inapproximability result of Theorem 5 and the n-approximation algorithm for the buyer preselection problem of Theorem 9 directly extend to Walrasian equilibria. Notice also that for the remaining uncovered cases, that is when the goal is that of optimizing the seller's revenue, there is no reason for requiring market clearance, a condition clearly limiting the power of setting prices so as to maximize the revenue.

The main left open problems are: for markets with a unique buyer, closing the gap between the **NP**-hardness and the logarithmic approximation for the case of revenue maximization and item envy-free solutions; for the multi-unit case with bundle envy-free outcomes, determining an upper bound to the social welfare improvement achievable by preselection and setting the complexity of computing optimal solutions, for both the revenue and the social welfare cases.

Abstract

Motivated by the randomized generation of slowly synchronizing automata, we study automata made of permutation letters and a merging letter of rank $n-1$. We present a constructive randomized procedure to generate synchronizing automata of that kind with (potentially) large alphabet size based on recent results on *primitive* sets of matrices. We report numerical results showing that our algorithm finds automata with much larger reset threshold than a mere uniform random generation and we present new families of automata with reset threshold of $\Omega(n^2/4)$. We finally report theoretical results on randomized generation of primitive sets of matrices: a set of permutation matrices with a 0 entry changed into a 1 is primitive and has exponent of $O(n \log n)$ with high probability in case of uniform random distribution and the same holds for a random set of binary matrices where each entry is set, independently, equal to 1 with probability p and equal to 0 with probability $1-p$, when $np - \log n \to \infty$ as $n \to \infty$.

1 Introduction

A (complete deterministic finite) *automaton* $\mathcal{A}$ on n states can be defined as a set of m binary row-stochastic[2] matrices $\{A_1, \ldots, A_m\}$ that are called the *letters* of the automaton. We say that $\mathcal{A}$ is *synchronizing* if there exists a product of its letters, with repetitions allowed, that has an all-ones column[3] and the length of the shortest of these products is called the *reset*

[1] R. M. Jungers is a FNRS Research Associate. He is supported by the French Community of Belgium, the Walloon Region and the Innoviris Foundation.

[2] A *binary* matrix is a matrix with entries in $\{0, 1\}$. A *row-stochastic* matrix is a matrix with nonnegative entries where the entries of each row sum up to 1. Therefore a matrix is *binary* and *row-stochastic* if each row has exactly one 1.

[3] A column whose entries are all equal to 1.

Table 1 Table on upper bounds on the reset threshold for some classes of automata and examples of automata with large reset threshold belonging to these classes, up to date.

Classes	**Upper b. on rt**	**Families with quadratic rt**
Eulerian automata	n^2-3n+3 Kari [16]	$(n^2-3)/2$ Szykuła and Vorel [27] (4 letters)
Automata with full transition monoid	$2n^2-6n+5$ Gonze et. al. [14]	$n(n-1)/2$ Gonze et. al. [14] (n letters)
One cluster automata	n^2-7n+7 Béal et al. [4]	$(n-1)^2$ Černý [28] (2 letters)
Strongly connected weakly monotone automata	$\lfloor n(n+1)/6 \rfloor$ Volkov [29]	?
Automata with simple idempotents	$2(n-1)^2$ Rystov [25]	$(n-1)^2$ Černý [28] (2 letters) $\geq (n^2+3n-6)/4$ for $n=4k+3$ [Conjectured $(n^2-1)/2$] $\geq (n^2+3n-8)/4$ for $n=4k+1$ [Conjectured $(n^2-1)/2$] $\geq (n^2+2n-4)/4$ for $n=4k$ [Conjectured $(n^2-2)/2$] $\geq (n^2+2n-12)/4$ for $n=4k+2$ [Conjectured $(n^2-10)/2$] **Our contribution** (3 letters)

threshold ($rt(\mathcal{A})$) of the automaton. In other words, an automaton is synchronizing if there exists a word that brings the automaton into a particular state, regardless of the initial one. Synchronizing automata appear in different research fields; for example they are often used as models of error-resistant systems [10, 7] and in symbolic dynamics [18]. For a brief account on synchronizing automata and their other applications we refer the reader to [30]. The importance of synchronizing automata also arises from one of the most longstanding open problems in this field, the Černý conjecture, which affirms that any synchronizing automaton on n states has reset threshold at most $(n-1)^2$. If it is true, the bound is sharp due to the existence of a family of 2-letter automata attaining this value, family discovered by Černý in [28]. Despite great effort, the best upper bound for the reset threshold known so far is $(15617n^3+7500n^2+9375n-31250)/93750$, recently obtained by Szykuła in [26] and thereby beating the 30 years-standing upper bound of $(n^3-n)/6$ found by Pin and Frankl in [11, 22]. Better upper bounds have been obtained for certain families of automata and the search for automata attaining quadratic reset threshold within these families have been the subject of several contributions in recent years. These results are (partly) summarized in Table 1.
Exhaustive search confirmed the conjecture for small values of n (see [3, 9]). The hunt for a possible counterexample to the conjecture turned out not to be an easy task as well; the search space is wide and calculating the reset threshold is computationally hard (see [10, 21]). Automata with reset thresholds close to $(n-1)^2$, called *extremal* or *slowly synchronizing* automata, are also hard to detect and not so many families are known; Bondt et. al. [9] make a thorough analysis of automata with small number of states and we recall, among others, the families found by Ananichev et al. [3], by Gusev and Pribavkina [15], by Kisielewicz and Szykuła [17] and by Dzyga et. al. [19]. These last two examples are, in particular, some

of the few examples of slowly synchronizing automata with more than two letters that can be found in the literature. Almost all the families of slowly synchronizing automata listed above are closely related to the Černý automaton $\mathcal{C}(n) = \{a, b\}$, where a is the cycle over n vertices and b the letter that fixes all the vertices but one, which is mapped to the same vertex as done by a; indeed all these families present a letter that is a cycle over n vertices and the other letters have an action similar to the one of letter b. As these examples seem to have a quite regular structure, it is natural to wonder whether a randomized procedure to generate automata could obtain less structured automata with possibly larger reset thresholds. This probabilistic approach can be rooted back to the work of Erdős in the 60's, where he developed the so-called *Probabilistic Method*, a tool that permits to prove the existence of a structure with certain desired properties by defining a suitable probabilistic space in which to embed the problem; for an account on the probabilistic method we refer the reader to [1]. The simplest way to randomly generate an automaton of m letters is to uniformly and independently sample m binary row-stochastic matrices: unfortunately, Berlinkov first proved in [5] that two uniformly sampled random binary row-stochastic matrices synchronize with high probability (i.e. the probability that they form a synchronizing automaton tends to 1 as the matrix dimension tends to infinity), then Nicaud showed in [20] that they also have reset threshold of order $O(n \log^3 n)$ with high probability. We say that an automaton is *minimally synchronizing* if any proper subset of its letters is not synchronizing; what just presented before implies that a uniformly sampled random automaton of m letters has low reset threshold and is *not* minimally synchronizing with high probability. Summarizing:

- slowly synchronizing automata cannot be generated by a mere uniform randomized procedure;
- minimally synchronizing automata with more than 2 letters are especially of interest as they are hard to find and they do not appear often in the literature, so the behaviour of their reset threshold is still unclear.

With this motivation in place, our paper tackles the following questions:

Q1 Is there a way to randomly generate (minimally) slowly synchronizing automata (with more than two letters)?

Q2 Can we find some automata families with more than two letters, quadratic reset threshold and that do not resemble the Černý family?

Our Contribution. In this paper we give positive answers to both questions **Q1** and **Q2**. For the first one, we rely on the concept of *primitive* set of matrices, introduced by Protasov and Voynov in [24]: a finite set of matrices with nonnegative entries is said to be *primitive* if there exists a product of these matrices, with repetitions allowed, with all positive entries. A product of this kind is called *positive* and the length of the shortest positive product of a primitive set $\mathcal{M}$ is called the *exponent* ($exp(\mathcal{M})$) of the set. Although the Protasov-Voynov primitivity has gained a lot of attention in different fields as in stochastic switching systems [23] and consensus for discrete-time multi-agent systems [8], we are interested in its connection with automata theory. In the following, we say that a matrix is *NZ* if it has neither zero-rows nor zero-columns[4]; a matrix set is said to be *NZ* if all its matrices are NZ.

▶ **Definition 1.** Let $\mathcal{M} = \{M_1, \ldots, M_m\}$ be a binary NZ-matrix set. The *automaton associated to* the set $\mathcal{M}$ is the automaton $\mathcal{A}(\mathcal{M})$ whose letters are all the binary row-stochastic matrices that are entrywise not greater than at least one matrix in $\mathcal{M}$.

[4] Thus a NZ-matrix must have a positive entry in every row and in every column.

Figure 1 The automata $\mathcal{A}(\mathcal{M})$ and $\mathcal{A}(\mathcal{M}^T)$ of Example 2.

▶ **Example 2.** We here provide an example of a primitive set $\mathcal{M} = \{M_1, M_2\}$ and the associated automata $\mathcal{A}(\mathcal{M})$ and $\mathcal{A}(\mathcal{M}^T)$ in both their matrix and graph representations (Figure 1), where $\mathcal{M}^T = \{M_1^T, M_2^T\}$.

$$\mathcal{M} = \left\{ \begin{pmatrix} 0&1&0\\1&0&0\\0&0&1 \end{pmatrix}, \begin{pmatrix} 1&0&1\\0&0&1\\0&1&0 \end{pmatrix} \right\}, \mathcal{A}(\mathcal{M}) = \left\{ \begin{pmatrix} 0&1&0\\1&0&0\\0&0&1 \end{pmatrix}, \begin{pmatrix} 1&0&0\\0&0&1\\0&1&0 \end{pmatrix}, \begin{pmatrix} 0&0&1\\0&0&1\\0&1&0 \end{pmatrix} \right\} = \{a, b, c\},$$

$$\mathcal{A}(\mathcal{M}^T) = \left\{ \begin{pmatrix} 0&1&0\\1&0&0\\0&0&1 \end{pmatrix}, \begin{pmatrix} 1&0&0\\0&0&1\\0&1&0 \end{pmatrix}, \begin{pmatrix} 1&0&0\\0&0&1\\1&0&0 \end{pmatrix} \right\} = \{a, b, c'\}.$$

The following theorem summarizes two results proved by Blondel et. al. ([6], Theorems 16-17) and a result proved by Gerencsér et al. ([12], Theorem 8). Note that we state it for sets of *binary* NZ-matrices but it more generally holds for any set of NZ-matrices with nonnegative entries; this relies on the fact that in the notion of primitivity what counts is the position of the nonnegative entries within the matrices of the set and not their the actual values. In this case we should add to Definition 1 the request of setting to 1 all the positive entries of the matrices of $\mathcal{M}$ before building $\mathcal{A}(\mathcal{M})$.

▶ **Theorem 3.** *Let $\mathcal{M} = \{M_1, \ldots, M_m\}$ a set of binary NZ-matrices of size $n \times n$ and $\mathcal{M}^T = \{M_1^T, \ldots, M_m^T\}$. It holds that $\mathcal{M}$ is primitive if and only if $\mathcal{A}(\mathcal{M})$ (equiv. $\mathcal{A}(\mathcal{M}^T)$) is synchronizing. If $\mathcal{M}$ is primitive, then it also holds that:*

$$\max\Big\{rt\big(\mathcal{A}(\mathcal{M})\big), rt\big(\mathcal{A}(\mathcal{M}^T)\big)\Big\} \leq exp(\mathcal{M}) \leq rt\big(\mathcal{A}(\mathcal{M})\big) + rt\big(\mathcal{A}(\mathcal{M}^T)\big) + n - 1. \tag{1}$$

▶ **Example 4.** For the matrix set $\mathcal{M}$ defined in Example 2, it holds that $exp(\mathcal{M}) = 8$, $rt\big(\mathcal{A}(\mathcal{M})\big) = 4$ and $rt\big(\mathcal{A}(\mathcal{M}^T)\big) = 2$.

Theorem 3 will be extensively used throughout the paper. It shows that primitive sets can be used for generating synchronizing automata and Equation (1) tells us that the presence of a primitive set with large exponent implies the existence of an automaton with large reset threshold; in particular the discovery of a primitive set $\mathcal{M}$ with $exp(\mathcal{M}) \geq 2(n-1)^2 - n + 1$ would disprove the Černý conjecture. On the other hand, the upper bounds on the automata reset threshold mentioned before imply that $exp(\mathcal{M}) = O(n^3)$.
One advantage of using primitive sets is the Protasov-Voynov characterization theorem (see Theorem 6 in Section 2) that describes a combinatorial property that a NZ-matrix set must have in order *not* to be primitive: by constructing a primitive set such that each of its proper subsets has this property, we can make it *minimally primitive*[5].
We decided to focus our attention on what we call *perturbed permutation* sets, i.e. sets made of permutation matrices (binary matrices having exactly one 1 in every row and in every column) where a 0-entry of one of these matrices is changed into a 1. These sets have many interesting properties:

[5] Thus a *minimally primitive* set is a primitive set that does not contain any proper primitive subset.

- they have the least number of positive entries that a NZ-primitive set can have, which intuitively should lead to sets with large exponent;
- the associated automaton $\mathcal{A}(\mathcal{M})$ of a perturbed permutation set $\mathcal{M}$ can be easily computed. It is made of permutation letters and a letter of rank $n-1$ and its alphabet size is just one unit more than the cardinality of $\mathcal{M}$;
- if the matrix set $\mathcal{M}$ is minimally primitive, the automaton $\mathcal{A}(\mathcal{M})$ is minimally synchronizing (or it can be made minimally synchronizing by removing one known letter, as shown in Proposition 9);
- primitivity is easily checked by the Protasov-Voynov algorithm ([24], Proposition 2), and primitivity of $\mathcal{M}$ assures that $\mathcal{A}(\mathcal{M})$ is synchronizing (Theorem 3).

The characterization theorem for primitive sets and the above properties are the main ingredients of our randomized algorithm that finds minimally synchronizing automata of 3 and 4 letters (and can eventually be generalized to m letters); to the best of our knowledge, this is the first time where a constructive procedure for finding minimally synchronizing automata is presented. This is described in Section 3 where numerical results are reported. The random construction let us also find new families of 3-letters automata, presented in Section 4, with reset threshold $\Omega(n^2/4)$ and that do not resemble the Černý automaton, thus answering question **Q2**. Finally, in Section 5 we extend a result on perturbed permutation sets obtained by Gonze et al. in [13]: we show that a random perturbed permutation set is primitive with high probability for any matrix size n (and not just when n is a prime number as in [13]) and that its exponent is of order $O(n \log n)$ still with high probability. A further generalization is then presented for sets of random binary matrices: if each entry of each matrix is set to 1 with probability p and to 0 with probability $1-p$, independently from each other, then the set is primitive and has exponent of order $O(n \log n)$ with high probability for any p such that $np - \log n \to \infty$ as $n \to \infty$.
The proofs of the results presented in this paper have been omitted due to length restrictions.

2 Definitions and notation

In this section we briefly go through some definitions and results that will be needed in the rest of the paper.
We indicate with $[n]$ the set $\{1, \dots, n\}$ and with S_k the set of permutations over k elements; with a slight abuse of notation S_k will also denote the set of the $k \times k$ permutation matrices. An n-state automaton $\mathcal{A} = \{A_1, \dots, A_m\}$ can be represented by a labelled digraph on n vertices with a directed edge from vertex i to vertex j labelled by A_k if $A_k(i,j) = 1$; in this case we also use the notation $iA_k = j$. We remind that a matrix M is *irreducible* if there does not exist a permutation matrix P such that PMP^T is block-triangular; a set $\{M_1, \dots, M_m\}$ is said to be *irreducible* iff the matrix $\sum_{i=1}^m M_i$ is irreducible. The *directed graph associated to* an $n \times n$ matrix M is the digraph D_M on n vertices with a directed edge from i to j if $M(i,j) > 0$. A matrix M is irreducible if and only if D_M is strongly connected, i.e. if and only if there exists a directed path between any two given vertices. A *primitive* set $\mathcal{M}$ is a set of m matrices $\{M_1, \dots, M_m\}$ with nonnegative entries where there exists a product $M_{i_1} \cdots M_{i_l} > 0$ entrywise, for $i_1, \dots, i_l \in [m]$. The length of the shortest of these products is called the *exponent* ($exp(\mathcal{M})$) of the set. Irreducibility is a necessary (but not sufficient) condition for a matrix set to be primitive (see [24], Section 1). Primitive sets of NZ-matrices can be characterized as follows:

▶ **Definition 5.** Let $\Omega = \dot{\bigcup}_{l=1}^{k} \Omega_l$ be a partition of $[n]$ with $k \geq 2$. We say that an $n \times n$ matrix M has a *block-permutation structure on the partition* Ω if there exists a permutation $\sigma \in S_k$ such that $\forall\, l = 1, \ldots, k$ and $\forall\, i \in \Omega_l$, if $M(i,j) > 0$ then $j \in \Omega_{\sigma(l)}$. We say that a set of matrices *has a block-permutation structure* if there exists a partition on which *all* the matrices of the set have a block-permutation structure.

▶ **Theorem 6** ([24], Theorem 1)**.** *An irreducible set of NZ matrices of size $n \times n$ is* not *primitive if and only if the set has a block-permutation structure.*

We end this section with the last definition and our first observation (Proposition 8).

▶ **Definition 7.** A matrix A *dominates* a matrix B if $A(i,j) \geq B(i,j),\ \forall\, i,j$.

▶ **Proposition 8.** *Consider an irreducible set $\{M_1, \ldots, M_m\}$ in which every matrix dominates a permutation matrix. If the set has a block-permutation structure, then all the blocks of the partition must have the same size.*

3 Minimally primitive sets and minimally synchronizing automata

In this section we focus on *perturbed permutation* sets, i.e. matrix sets made of permutation matrices where a 0-entry of one matrix is changed into a 1. We represent a set of this kind as $\mathcal{M} = \{P_1, \ldots, P_{m-1}, P_m + \mathbb{I}_{i,j}\}$, where $P_1, \ldots, P_m$ are permutation matrices, $\mathbb{I}_{i,j}$ is a matrix whose (i,j)-th entry is equal to 1 and all the others entries are equal to 0 and $P_m(i,j') = 1$ for a $j' \neq j$. The first result states that we can easily generate minimally synchronizing automata starting from minimally primitive perturbed permutation sets:

▶ **Proposition 9.** *Let $\mathcal{M} = \{P_1, \ldots, P_{m-1}, P_m + \mathbb{I}_{i,j}\}$ be a minimally primitive perturbed permutation set and let $j' \neq j$ be the integer such that $P_m(i,j') = 1$. The automaton $\mathcal{A}(\mathcal{M})$ (see Definition 1) can be written as $\mathcal{A}(\mathcal{M}) = \{P_1, \ldots, P_{m-1}, P_m, M\}$ with $M = P_m + \mathbb{I}_{i,j} - \mathbb{I}_{i,j'}$. If $\mathcal{A}(\mathcal{M})$ is not minimally sychronizing, then $\bar{\mathcal{A}} = \{P_1, \ldots, P_{m-1}, M\}$ is.*

3.1 A randomized algorithm for constructing minimally primitive sets

If we want to find minimally synchronizing automata, Proposition 9 tells us that we just need to generate minimally primitive perturbed permutation sets; in this section we implement a randomized procedure to build them.

Theorem 6 says that a matrix set is *not* primitive if all the matrices share the same block-permutation structure, therefore a set of m matrices is minimally primitive iff every subset of cardinality $m-1$ has a block-permutation structure on a certain partition; this is the condition we will enforce. As we are dealing with perturbed permutation sets, Proposition 8 tells us that we just need to consider partitions with blocks of the same size; if the blocks of the partition have size n/q, we call it a *q-partition* and we say that the set has a *q-permutation structure*. Given $R, C \subset [n]$ and a matrix M, we indicate with $M(R,C)$ the submatrix of M with rows indexed by R and columns indexed by C. The algorithm first generates a set of permutation matrices satisfying the requested block-permutation structures and then a 0-entry of one of the obtained matrices is changed into a 1; while doing this last step, we will make sure that such change will preserve all the block-permutation structures of the matrix. We underline that our algorithm finds perturbed permutation sets that, *if* are primitive, are minimally primitive. Indeed, the construction itself only ensures minimality and not primitivity: this latter property has to be verified at the end.

3.1.1 The algorithm

For generating a set of m matrices $\mathcal{M} = \{M_1, \dots, M_m\}$ we choose m prime numbers $q_1 \geq \cdots \geq q_m \geq 2$ and we set $n = \prod_{i=1}^{m} q_i$. For $j = 1, \dots, m$, we require the set $\{M_1, \dots, M_{j-1}, M_{j+1}, \dots, M_m\}$ (the set obtained from $\mathcal{M}$ by erasing matrix M_j) to have a q_j-permutation structure; this construction will ensure the minimality of the set. More in detail, for all $j=1, \dots, m$ we will enforce the existence of a q_j-partition $\Omega_{q_j} = \dot{\bigcup}_{i=1}^{q_j} \Omega_i^j$ of $[n]$ on which, for all $k \neq j$, the matrix M_k has to have a block-permutation structure. As stated by Definition 5, this request means that for every $k = 1, \dots, m$ and for every $j \neq k$ there must exist a permutation $\sigma_j^k \in S_{q_j}$ such that for all $i=1, \dots, q_j$ and $l \neq \sigma_j^k(i)$, $M_k(\Omega_i^j, \Omega_l^j)$ is a zero matrix.

The main idea of the algorithm is to initialize every entry of each matrix to 1 and then, step by step, to set to 0 the entries that are not compatible with the conditions that we are requiring. As our final goal is to have a set of permutation matrices, at every step we need to make sure that each matrix dominates at least one permutation matrix, despite the increasing number of zeros among its entries.

▶ **Definition 10.** Given a matrix M and a q-partition $\Omega_q = \dot{\bigcup}_{i=1}^{q} \Omega_i^q$, we say that a permutation $\sigma \in S_q$ is *compatible* with M and Ω_q if for all $i = 1, \dots, q$, there exists a permutation matrix Q_i such that

$$M\left(\Omega_i^q, \Omega_{\sigma(i)}^q\right) \geq Q_i. \tag{2}$$

The algorithm itself is formally presented in Listing 1; we here describe in words how it operates. Each entry of each matrix is initialized to 1. The algorithm has two for-loops: the outer one on $j = 1, \dots, m$, where a q_j-partition $\Omega_{q_j} = \dot{\bigcup}_{i=1}^{q_j} \Omega_i^j$ of $[n]$ is uniformly randomly sampled and then the inner one on $k = 1, \dots, m$ with $k \neq j$ where we verify whether there exists a permutation $\sigma_j^k \in S_{q_j}$ that is compatible with M_k and Ω_{q_j}. If it does exist, then we choose one among all the compatible permutations and the algorithm moves to the next step $k + 1$. If such permutation does not exist, then the algorithm exits the inner for-loop and it randomly selects another q_j-partition Ω'_{q_j} of $[n]$; it then repeats the inner loop for $k = 1, \dots, m$ with $k \neq j$ with this new partition. If after $T1$ steps it is choosing a different q_j-partition Ω'_{q_j} the existence, for each $k \neq j$, of a permutation $\sigma_j'^k \in S_{q_j}$ that is compatible with M_k and Ω'_{q_j} is not established, we stop the algorithm and we say that *it did not converge*. If the inner for-loop is completed, then for each $k \neq j$ the algorithm modifies the matrix M_k by keeping unchanged each block $M_k\left(\Omega_i^j, \Omega_{\sigma_j^k(i)}^j\right)$ for $i = 1, \dots, q_j$ and by setting to zero all the other entries of M_k, where σ_j^k is the selected compatible permutation; the matrix M_k has now a block-permutation structure over the sampled partition Ω_{q_j}. The algorithm then moves to the next step $j + 1$. If it manages to finish the outer for-loop, we have a set of binary matrices with the desired block-permutation structures. We then just need to select a permutation matrix $P_k \leq M_k$ for every $k = 1, \dots, m$ and then to randomly change a 0-entry into a 1 in one of the matrices without modifying its block-permutation structures: this is always possible as the blocks of the partitions are non trivial and a permutation matrix has just n positive entries. We finally check whether the set is primitive.

Here below we present the procedures that the algorithm uses:

(a) $[p, P] = Extractperm(M, met)$

This is the key function of the algorithm. It returns $p=1$ if the matrix M dominates a permutation matrix, it returns $p=0$ and $P=M$ otherwise. In the former case it also returns a permutation matrix P selected among the ones dominated by M according to met; if $met = 2$ the matrix P is sampled uniformly at random, while if $met = 3$ we

make the choice of P deterministic. More in detail, the procedure works as follows: we first count the numbers of 1s in each column and in each row of the matrix M. We then consider the row or the column with the least number of 1s; if this number is zero we stop the procedure and we set $p = 0$, as in this case M does not dominate a permutation matrix. If this number is strictly greater than zero, we choose one of the 1-entries of the row or the column attaining this minimum: if $met = 2$ (**method 2**) the entry is chosen uniformly at random while if $met = 3$ (**method 3**) we take the first 1-entry in the lexicographic order. Suppose that such 1-entry is in position (i, j): we set to zero all the other entries in row i and column j and we iterate the procedure on the submatrix obtained from M by erasing row i and column j. We can prove that this procedure is well-defined and in at most n steps it produces the desired output: $p = 0$ if and only if M does not dominate a permutation matrix and, in case $p = 1$, method 2 indeed sample uniformly one of the permutations dominated by M, while method 3 is deterministic and the permutation obtained usually has its 1s distributed around the main diagonal. Method 3 will play an important role in our numerical experiments in Section 3.2 and in the discovery of new families of automata with quadratic reset threshold in Section 4.

(b) $[a, A] = DomPerm(M, \Omega, met)$
It returns $a = 1$ if there exists a permutation compatible with the matrix M and the partition $\Omega = \dot{\bigcup}_{i=1}^{q} \Omega_i^q$, it returns $a = 0$ and $A = M$ otherwise. In the former case it chooses one of the compatible permutations, say σ, according to met and returns the matrix A equal to M but the entries not in the blocks defined by (2) that are set to zero; A has then a block-permutation structure on Ω. More precisely, $DomPerm$ acts in two steps: it first defines a $q \times q$ matrix B such that, for all $i, k = 1, \ldots, q$,

$$B(i,k) = \begin{cases} 1 & \text{if } M(\Omega_i^q, \Omega_k^q) \text{ dominates a permutation matrix} \\ 0 & \text{otherwise} \end{cases};$$

this can be done by calling $ExtractPerm$ with input $M(\Omega_i^q, \Omega_k^q)$ and met for all $i, k = 1, \ldots, q$. At this point, asking if there exists a permutation compatible with M and Ω is equivalent of asking if B dominates a permutation matrix. Therefore, the second step is to call again $[p, P] = ExtractPerm(B, met)$: if $p = 0$ we set $a = 0$ and $A = M$, while if $p = 1$ we set $a = 1$ and A as described before with $\sigma = P$ (i.e. $\sigma(i) = j$ iff $P(i, j) = 1$); indeed the permutation P is one of the permutations compatible with M and Ω.

(c) $Mset = Addone(P_1, ..., P_m)$
It changes a 0-entry of one of the matrices $P_1, ..., P_m$ into a 1 preserving all its block-permutation structures. The matrix and the entry are chosen uniformly at random and the procedure iterates the choice till it finds a compatible entry (which always exists); it then returns the final perturbed permutation set $Mset$.

(d) $pr = Primitive(Mset)$
It returns $pr = 1$ if the matrix set $Mset = \{M_1, \ldots, M_m\}$ is primitive and $pr = 0$ otherwise. It first verifies if the set is irreducible by checking the strong connectivity of the digraph D_N where $N = \sum_{i=1}^{k} M_i$ (see Section 2) via breadth-first search on every node, then if the set is irreducible, primitivity is checked by the Protasov-Voynov algorithm ([24], Section 4).

All the above routines have polynomial time complexity in n, apart from routine $Primitive$ that has time complexity $O(mn^2)$.

▶ Remark.

1. In all our numerical experiments the algorithm always converged, i.e. it always ended before reaching the stopping value $T1$, for $T1$ large enough. This is probably due to the fact that the matrix dimension n grows exponentially as the number of matrices m increases, which produces enough degrees of freedom. We leave the proof of this fact for future work.

2. A recent work of Alpin and Alpina [2] generalizes Theorem 6 for the characterization of primitive sets to sets that are allowed to be reducible and the matrices to have zero columns but not zero rows. Clearly, automata fall within this category. Without going into many details (for which we refer the reader to [2], Theorem 3), Alpin and Alpina show that an n-state automaton is *not* synchronizing if and only if there exist a partition $\dot{\bigcup}_{j=1}^{s}\Omega_j$ of $[n]$ such that it has a block-permutation structure on a *subset* of that partition. This characterization is clearly less restrictive: it just suffices to find a subset $I \subset [s]$ such that for each letter A of the automaton there exists a permutation $\sigma \in S_I$ such that for all $i \in I$, if $A(i,j) = 1$ then $j \in \Omega_{\sigma(i)}$. Our algorithm could leverage this recent result in order to directly construct minimal synchronizing automata. We also leave this for future work.

3.2 Numerical results

We have seen that once we have a minimally primitive perturbed permutation set, it is easy to generate a minimally synchronizing automaton from it, as stated by Proposition 12. Our goal is to generate automata with large research threshold, but checking this property on many randomly generated instances is prohibitive. Indeed, we recall that computing the reset threshold of an automaton is in general NP-hard [10]. Instead, as a proxy for the reset threshold, we compute the *diameter of the square graph*, which we now introduce:

▶ **Definition 11.** The *square graph* $S(\mathcal{A})$ of an n-state automaton $\mathcal{A}$ is the labelled directed graph with vertex set $V=\{(i,j) : 1 \leq i \leq j \leq n\}$ and edge set E such that $e=\{(i,j),(i',j')\} \in E$ if there exists a letter $A \in \mathcal{A}$ such that $A(i,i') > 0$ and $A(j,j') > 0$, or $A(i,j') > 0$ and $A(j,i') > 0$. In this case, we label the directed edge e by A (multiple labels are allowed). A vertex of type (i,i) is called a *singleton*.

A well-known result ([30], Proposition 1) states that an automaton is synchronizing if and only if in its square graph there exists a path from any non-singleton vertex to a singleton one; the proof of this fact also implies that

$$diam\big(S(\mathcal{A})\big) \leq rt(\mathcal{A}) \leq n \cdot diam\big(S(\mathcal{A})\big), \tag{3}$$

where $diam\big(S(\mathcal{A})\big)$ denotes the *diameter* of $S(\mathcal{A})$ i.e. the maximum length of the shortest path between any two given vertices, taken over all the pairs of vertices. The diameter can be computed in polynomial time, namely $O(mn^2)$ with m the number of letters of the automaton.

We now report our numerical results based on the diameter of the square graph. We compare three methods of generating automata: we call **method 1** the uniform random generation of 2-letter automata made of one permutation matrix and a matrix of rank $n-1$, while **method 2** and **method 3**, already introduced in the previous paragraph, refer to the different ways of extracting a permutation matrix from a binary one in our randomized construction. We set $T1 = 1000$ and for each method and each choice of n we run the algorithm $it(n) = 50n^2$ times, thus producing each time $50n^2$ sets. This choice for $it(n)$ has been made by taking into account two facts: on one hand, it is desirable to keep constant the rate $it(n)/k_m(n)$ between the number of sampled sets $it(n)$ and the cardinality $k_m(n)$ of the set of the perturbed permutation sets made of m matrices. Unfortunately, $k_m(n+1)/k_m(n)$ grows approximately as n^m and so $k_m(n)$ explodes very fast. On the other hand, we have to deal with the limited computational speed of our computers. The choice of $it(n) = 50n^2$ comes as a compromise between these two issues, at least when $n \leq 70$.
Among the $it(n)$ generated sets, we select the primitive ones and we generate their associated automata (Definition 1); we then check which ones are not minimally synchronizing and we make them minimally synchronizing by using Proposition 9. Finally, we compute the square graph diameter of all the minimally synchronizing automata obtained. Figure 2 reports on the y axis the maximal square graph diameter found for each method and for each matrix dimension n when n is the product of three prime numbers (left picture) and when it is a product of four prime numbers (right picture). We can see that our randomized construction manages to reach higher values of the square graph diameter than the mere random generation; in particular, method 3 reaches quadratic diameters in case of three matrices.

We also report in Figure 3 (left) the behavior of the *average* diameter of the minimally synchronizing automata generated on $50n^2$ iterations when n is the product of three prime numbers: we can see that in this case method 2 does not perform better than method 1, while method 3 performs just slightly better. This behavior could have been expected since our primary goal was to randomly generate *at least one* slowly synchronizing automata; this is indeed what happens with method 3, that manages to reach quadratic reset thresholds most of the times.
A remark can be done on the percentage of the generated sets that are *not* primitive; this is reported in Figure 3 (right), where we divide nonprimitive sets into two categories: reducible sets and *imprimitive* sets, i.e. irreducible sets that are not primitive. We can see that the percentage of nonprimitive sets generated by method 1 goes to 0 as n increases, behavior

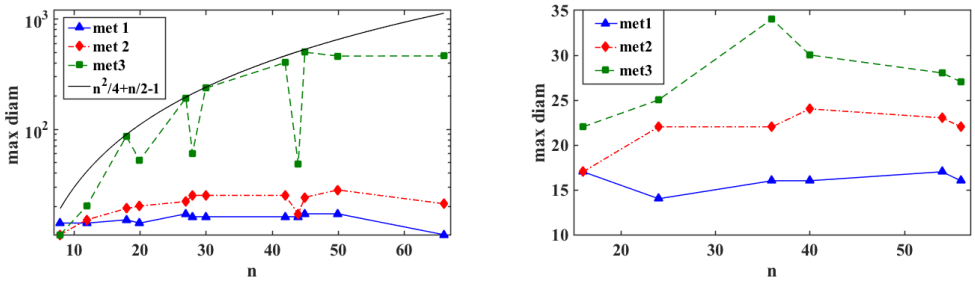

Figure 2 Comparison of our methods (met 2 and 3) with the naive method (met 1) with respect to the maximal diameter found on $50n^2$ iterations. Left: n is the product of three prime numbers; the y axis is in logarithmic scale. Right: n is the product of four prime numbers.

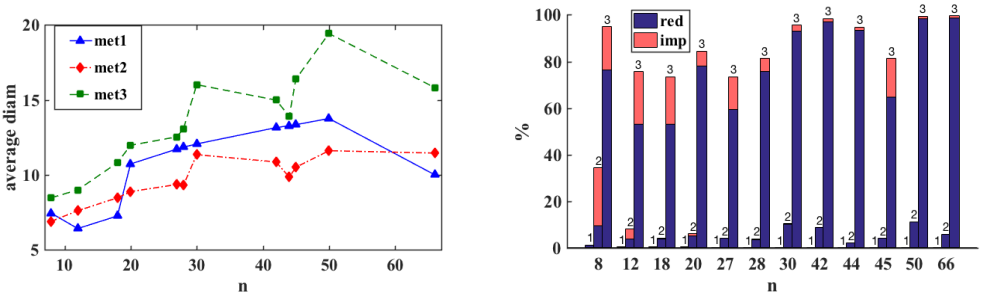

Figure 3 Left: Average diameter found by methods 1, 2 and 3 when n is the product of three prime numbers. Right: Percentage of nonprimitive sets (divided into reducible and imprimitive sets) generated by methods 1, 2 and 3 (indicated above each bar) when n is the product of three prime numbers. For instance, on sets of dimension $n = 20$, method 1 generates 0.35% of nonprimitive sets (0.35% reducible, 0% imprimitive), method 2 generates 6.15% of nonprimitive sets (5.18% reducible, 0.97% imprimitive) and method 3 generates 84.5% of nonprimitive sets (77.9% reducible, 6.6% imprimitive).

that we expected (see Section 5, Theorem 18), while method 2 seems to always produce a not negligible percentage of nonprimitive sets, although quite small. The behavior is reversed for method 3: most of the generated sets are not primitive. This can be interpreted as a good sign. Indeed, nonprimitive sets can be seen as sets with *infinite* exponent; as we are generating a lot of them with method 3, we intuitively should expect that, when a primitive set is generated, it has high chances to have large diameter.

The slowly synchronizing automata found by our randomized construction are presented in the following section. We believe that some parameters of our construction, as the way a permutation matrix is extracted from a binary one or the way the partitions of $[n]$ are selected, could be further tuned or changed in order to generate new families of slowly synchronizing automata; for example, we could think about selecting the ones in the procedure *Extractperm* according to a given distribution. We leave this for future work.

4 New families of automata with quadratic reset threshold

We present here four new families of (minimally synchronizing) 3-letter automata with square graph diameter of order $\Omega(n^2/4)$, which represents a lower bound for their reset threshold. These families are all made of two symmetric permutation matrices and a matrix of rank $n-1$ that merges two states and fixes all the others (a perturbed identity matrix): they thus

lie within the class of automata *with simple idempotents*, class introduced by Rystsov in [25] in which every letter A of the automaton is requested either to be a permutation or to satisfy $A^2 = A$. These families have been found via the randomized algorithm described in Section 3.1 using the deterministic procedure to extract a permutation matrix from a binary one (method 3). The following proposition shows that primitive sets made of a perturbed identity matrix and two symmetric permutations must have a very specific shape; we then present our families, prove closed formulas for their square graph diameter and finally state a conjecture on their reset thresholds. With a slight abuse of notation we identify a permutation matrix Q with its underlying permutation, that is we say that $Q(i) = j$ if and only if $Q(i, j) = 1$; the identity matrix is denoted by I. Note that a permutation matrix is symmetric if and only if its cycle decomposition is made of fixed points and cycles of length 2.

▶ **Proposition 12.** *Let $\mathcal{M}_{ij} = \{\bar{I}_{ij}, Q_1, Q_2\}$ be a matrix set of $n \times n$ matrices where $\bar{I}_{ij} = I + \mathbb{I}_{ij}$, $j \neq i$, is a perturbed identity and Q_1 and Q_2 are two symmetric permutations. If $\mathcal{M}$ is irreducible then, up to a relabelling of the vertices, Q_1 and Q_2 have the following form:*

- *if n is even*

$$Q_1(i) = \begin{cases} 1 & \text{if } i = 1 \\ i+1 & \text{if } i \text{ even}, 2 \leq i \leq n-2 \\ i-1 & \text{if } i \text{ odd}, 3 \leq i \leq n-1 \\ n & \text{if } i = n \end{cases}, \quad Q_2(i) = \begin{cases} i-1 & \text{if } i \text{ even} \\ i+1 & \text{if } i \text{ odd} \end{cases} \tag{4}$$

or

$$Q_1(i) = \begin{cases} n & \text{if } i = 1 \\ i+1 & \text{if } i \text{ even}, 2 \leq i \leq n-2 \\ i-1 & \text{if } i \text{ odd}, 3 \leq i \leq n-1 \\ 1 & \text{if } i = n \end{cases}, \quad Q_2(i) = \begin{cases} i-1 & \text{if } i \text{ even} \\ i+1 & \text{if } i \text{ odd} \end{cases} \tag{5}$$

- *if n is odd*

$$Q_1(i) = \begin{cases} 1 & \text{if } i = 1 \\ i+1 & \text{if } i \text{ even} \\ i-1 & \text{if } i \text{ odd}, 3 \leq i \leq n \end{cases}, \quad Q_2(i) = \begin{cases} i-1 & \text{if } i \text{ even} \\ i+1 & \text{if } i \text{ odd}, 1 \leq i \leq n-2 \\ n & \text{if } i = n \end{cases}. \tag{6}$$

▶ **Proposition 13.** *A matrix set $\mathcal{M}_{ij} = \{\bar{I}_{ij}, Q_1, Q_2\}$ of type (5) is never primitive.*

▶ **Definition 14.** We define $\mathcal{A}_{ij} = \{\underline{I}_{ij}, Q_1, Q_2\}$ to be the associated automaton $\mathcal{A}(\mathcal{M}_{ij})$ of $\mathcal{M}_{ij}$ (see Definition 1), where $\underline{I}_{ij} = I + \mathbb{I}_{ij} - \mathbb{I}_{ii}$.

It is clear that $\mathcal{A}_{ij}$ is with simple idempotents. Figure 4 represents $\mathcal{A}_{1,6}$ with $n = 8$. We set now $\mathcal{E}_n = \mathcal{A}_{1,n-2}$ for $n = 4k$ and $k \geq 2$, $\mathcal{E}'_n = \mathcal{A}_{1,n-4}$ for $n = 4k+2$ and $k \geq 2$, $\mathcal{O}_n = \mathcal{A}_{\frac{n-1}{2},\frac{n+1}{2}}$ for $n = 4k+1$ and $k \geq 1$, $\mathcal{O}'_n = \mathcal{A}_{\frac{n-1}{2},\frac{n+1}{2}}$ for $n = 4k+3$ and $k \geq 1$. The following theorem holds:

▶ **Theorem 15.** *The automaton $\mathcal{E}_n$ has square graph diameter (SGD) of $(n^2 + 2n - 4)/4$, $\mathcal{E}'_n$ has SGD of $(n^2 + 2n - 12)/4$, $\mathcal{O}_n$ has SGD of $(n^2 + 3n - 8)/4$ and $\mathcal{O}'_n$ has SGD of $(n^2 + 3n - 6)/4$. Therefore all the families $\mathcal{E}_n$, $\mathcal{E}'_n$, $\mathcal{O}_n$ and $\mathcal{O}'_n$ have reset threshold of $\Omega(n^2/4)$.*

Figure 5 represents the square graph of the automaton $\mathcal{E}_8$, where its diameter is colored in red. All the singletons but the one that belongs to the diameter have been omitted.

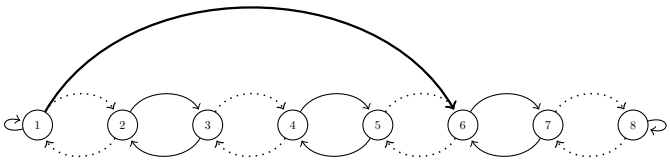

Figure 4 The automata $\mathcal{A}_{1,6}$ with $n = 8$; $rt(\mathcal{A}_{1,6})$=31. Dashed arrows refer to matrix Q_2, normal arrows to matrix Q_1 and bold arrows to matrix $\underline{I}_{1,6}$ where its selfloops have been omitted.

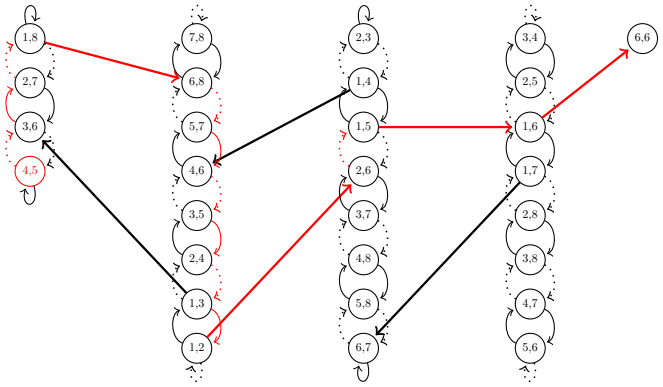

Figure 5 Square graph of automaton $\mathcal{E}_8$, $diam\big(S(\mathcal{E}_8)\big) = 19$. Normal arrows refer to matrix Q_1, dotted arrows to matrix Q_2 and bold arrows to matrix $\underline{I}_{1,6}$, where its selfloops have been omitted. The red path is the diameter.

▶ **Conjecture 16.** *The automaton $\mathcal{E}_n$ has reset threshold of $(n^2-2)/2$, $\mathcal{E}'_n$ has reset threshold of $(n^2-10)/2$ and $\mathcal{O}_n$ and $\mathcal{O}'_n$ have reset threshold of $(n^2-1)/2$. Furthermore, they represent the automata with the largest possible reset threshold among the family $\mathcal{A}_{ij}$ for respectively $n = 4k$, $n = 4k+2$, $n = 4k+1$ and $n = 4k+3$.*

We end this section by remarking that, despite the fact that the randomized construction for minimally primitive sets presented in Section 3 works just when the matrix size n is the product of at least three prime numbers, here we found an extremal automaton of quadratic reset threshold for *any* value of n.

5 Primitivity with high probability

We call *random perturbed permutation* set a perturbed permutation set of $m \geq 2$ matrices constructed with the following randomized procedure:

▶ **Procedure 17.**

1. *We sample m permutation matrices $\{P_1, \ldots, P_m\}$ independently and uniformly at random from the set S_n of all the permutations over n elements;*
2. *A matrix P_i is uniformly randomly chosen from the set $\{P_1, \ldots, P_m\}$. Then, one of its 0-entry is uniformly randomly selected among its 0-entries and changed into a 1. It becomes then a perturbed permutation matrix $\bar{P}_i$;*
3. *The final random perturbed permutation set is the set $\{P_1, \ldots, P_{i-1}, \bar{P}_i, P_{i+1}, \ldots, P_m\}$.*

This procedure is also equivalent to choosing independently and uniformly at random $m-1$ permutation matrices from S_n and one *perturbed* permutation matrix from $\bar{S}_n$ with $\bar{S}_n = \{\bar{P} : \bar{P} = P + \mathbb{I}_{i,j},\ P \in S_n,\ P(i,j') = 1,\ j \neq j'\}$. We say that a property X holds for a random matrix set with *high probability* if the probability that property X holds tends to 1 as the matrix dimension n tends to infinity.

▶ **Theorem 18.** *A random perturbed permutation set constructed via Procedure 17 is primitive and has exponent of order $O(n \log n)$ with high probability.*

Theorem 18 can be extended to random sets of binary matrices. It is clear that focusing just on binary matrices is not restrictive as in the definition of primitivity what counts is just the position of the positive entries within the matrices and not their actual values. Let $B(p)$ denote a random binary matrix where each entry is independently set to 1 with probability p and to 0 with probability $(1-p)$ and let $\mathcal{B}_m(p)$ denote a set of $m \geq 2$ matrices obtained independently in this way. Under some mild assumptions over p, we still have primitivity with high probability:

▶ **Theorem 19.** *For any fixed integer $m \geq 2$, if $np - \log n \longrightarrow \infty$ as $n \to \infty$, then $\mathcal{B}_m(p)$ is primitive and $exp\big(\mathcal{B}_m(p)\big) = O(n \log n)$ with high probability.*

It is interesting to compare this result with the one obtained by Gerencsér et al. in [12]: they prove that, if $exp(n)$ is the maximal value of the exponent among all the binary primitive sets of $n \times n$ matrices, then $\lim_{n\to\infty}(\log exp(n))/n = (\log 3)/3$. This implies that, for n big enough, there must exist some primitive sets whose exponent is close to $3^{n/3}$, but these sets must be very few as Theorem 19 states that they are almost impossible to be detected by a mere random generation. We conclude with a result on when a set of two random binary matrices is *not* primitive with high probability:

▶ **Proposition 20.** *For any fixed integer $m \geq 2$, if $2np - \log n \longrightarrow -\infty$ as $n \to \infty$, then $\mathcal{B}_m(p)$ is reducible with high probability. This implies that $\mathcal{B}_m(p)$ is not primitive with high probability.*

6 Conclusion

In this paper we have proposed a randomized construction for generating slowly minimally synchronizing automata. Our strategy relies on a recent characterization of primitive sets (Theorem 6), together with a construction (Definition 1 and Theorem 3) allowing to build (slowly minimally) synchronizing automata from (slowly minimally) primitive sets. We have obtained four new families of automata with simple idempotents with reset threshold of order $\Omega(n^2/4)$. The *primitive sets approach* to synchronizing automata seems promising and we believe that out randomized construction could be further refined and tweaked in order to produce other interesting automata with large reset threshold, for example by changing the way a permutation matrix is extracted by a binary one. As mentioned at the end of Section 3.1, it would be also of interest to apply the minimal construction directly to automata by leveraging the recent result of Alpin and Alpina ([2], Theorem 3).

Abstract

Many important graph theoretic notions can be encoded as counting graph homomorphism problems, such as partition functions in statistical physics, in particular independent sets and colourings. In this article we study the complexity of $\#_p\text{HomsTo}H$, the problem of counting graph homomorphisms from an input graph to a graph H modulo a prime number p. Dyer and Greenhill proved a dichotomy stating that the tractability of non-modular counting graph homomorphisms depends on the structure of the target graph. Many intractable cases in non-modular counting become tractable in modular counting due to the common phenomenon of cancellation. In subsequent studies on counting modulo 2, however, the influence of the structure of H on the tractability was shown to persist, which yields similar dichotomies.

Our main result states that for every tree H and every prime p the problem $\#_p\text{HomsTo}H$ is either polynomial time computable or $\#_p\mathsf{P}$-complete. This relates to the conjecture of Faben and Jerrum stating that this dichotomy holds for every graph H when counting modulo 2. In contrast to previous results on modular counting, the tractable cases of $\#_p\text{HomsTo}H$ are essentially the same for all values of the modulo when H is a tree. To prove this result, we study the structural properties of a homomorphism. As an important interim result, our study yields a dichotomy for the problem of counting weighted independent sets in a bipartite graph modulo some prime p. These results are the first suggesting that such dichotomies hold not only for the one-bit functions of the modulo 2 case but also for the modular counting functions of all primes p.

1 Introduction

Edge preserving functions between the vertices of two graphs, known as *graph homomorphisms*, generate a powerful language expressing important notions; examples include constraint satisfaction problems and partition functions in statistical physics. As such, the computational

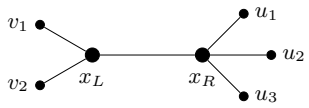

Figure 1 The graph H will be our recurring example and the labelling of the vertices is justified later in the introduction.

complexity of graph homomorphism problems has been studied extensively from a wide range of views. Early results include that of Hell and Nešetřil [14], who study the complexity of HomsToH, the problem of deciding if there exists a homomorphism from an input graph G to a fixed graph H. They show the following dichotomy: if H is bipartite or has a loop, the problem is in P and in every other case HomsToH is NP-complete. In particular, this is of interest since a result of Ladner [15] shows that if P $\neq$ NP, then there exist problems that are neither in P nor NP-hard.

Dyer and Greenhill [5] show a dichotomy for the problem #HomsToH, the problem of counting the homomorphisms from an input graph G to H. Their theorem states that #HomsToH is tractable if H is a complete bipartite graph or a complete graph with loops on all vertices; otherwise #HomsToH is # P-complete. This dichotomy was progressively extended to weighted sums of homomorphisms with integer weights, by Bulatov and Gohe [1]; with real weights, by Goldberg et al. [11]; finally, with complex weights, by Cai, Chen and Lu [2].

We study the complexity of counting homomorphisms modulo a prime p. The set of homomorphisms from the input graph G to the target graph H is denoted by $\mathrm{Hom}(G \to H)$. For each pair of fixed parameters p and H, we study the computational problem $\#_p$HomsToH, that is the problem of computing $|\mathrm{Hom}(G \to H)|$ modulo p. The value of p and the structure of the target graph H influence the complexity of $\#_p$HomsToH. Consider the graph H in Figure 1. Our results show that $\#_p$HomsToH is computable in polynomial time when $p = 2, 3$ while it is hard for any other prime p.

Our main goal is to fully characterise the complexity of $\#_p$HomsToH in a dichotomy theorem. In this manner we aim to determine for which pair of parameters (H, p) the problem is tractable and show that for every other pair of parameters the problem is hard. As the theorem of Ladner [15] extends to the modular counting problems, it is not obvious that there are no instances of $\#_p$HomsToH with an intermediate complexity.

The first study of graph homomorphisms under the setting of modular counting has been conducted by Faben and Jerrum [7]. Their work is briefly described in the following and we assume the reader to be familiar with the notion of an automorphism and its order. We provide the formal introduction in the full version. Given a graph H and an automorphism ϱ of H, H^{ϱ} denotes the subgraph of H induced by the fixpoints of ϱ. We write $H \Rightarrow_k H'$ if there is an automorphism ϱ of order k of H such that $H^{\varrho} = H'$ and we write $H \Rightarrow_k^* H'$ if either H is isomorphic to H' (written $H \cong H'$) or, for some positive integer t, there are graphs $H_1, \ldots, H_t$ such that $H \cong H_1$, $H_1 \Rightarrow_k \cdots \Rightarrow_k H_t$, and $H_t \cong H'$.

Faben and Jerrum showed [7, Lemma 3.3] that if the order of ϱ is a prime p, then $|\mathrm{Hom}(G \to H)|$ is equivalent to $|\mathrm{Hom}(G \to H^{\varrho})|$ modulo p. Furthermore, they showed [7, Theorem 3.7] that there is (up to isomorphism) exactly one graph H^{*p} without automorphisms of order p, such that $H \Rightarrow_p^* H^{*p}$. This graph H^{*p} is called the *order p reduced form* of H (see Figure 4 of the full version). If H^{*p} falls into the polynomial computable cases of the theorem of Dyer and Greenhill, then $\#_p$HomsToH is computable in polynomial time as

well. For $p = 2$, Faben and Jerrum conjectured that these are the only instances computable in polynomial time and that in every other case $\#_2\text{HOMSTO}H$ is $\#_2\,\mathsf{P}$-complete, where $\#_k\,\mathsf{P}$ is the "canonical" hardness class for modular counting problems (see Section 1.1).

▶ **Conjecture 1.1** (Faben and Jerrum [7])**.** Let H be a graph. If its order 2 reduced form H^{*2} has at most one vertex, then $\#_2\text{HOMSTO}H$ is in FP; otherwise, $\#_2\text{HOMSTO}H$ is $\#_2\,\mathsf{P}$-complete.

Faben and Jerrum [7, Theorem 3.8] underlined their conjecture by proving it for the case in which H is a tree. In subsequent works this proof was extended to cactus graphs in [9] and to square-free graphs in [10], by Göbel, Goldberg and Richerby.

The present work follows a direction orthogonal to the aforementioned. Instead of proving the conjecture for richer classes of graphs, we show a dichotomy for all primes, starting again by studying trees.

▶ **Theorem 1.2.** *Let p be a prime and let H be a graph, such that its order p reduced form H^{*p} is a tree. If H^{*p} is a star, then $\#_p\text{HOMSTO}H$ is computable in polynomial time; otherwise, $\#_p\text{HOMSTO}H$ is $\#_p\,\mathsf{P}$-complete.*

Our results are the first to suggest that the conjecture of Faben and Jerrum might apply to counting graph homomorphisms modulo every prime p instead of counting modulo 2. This suggestion, however, remains hypothetical. Borrowing the words of Dyer, Frieze and Jerrum [4]: "One might even rashly conjecture" it "(though we shall not do so)".

To justify our title we give the following corollary, stating a dichotomy for all trees H.

▶ **Corollary 1.3.** *Let p be a prime and let H be a tree. If the order p reduced form H^{*p} of H is a star, then $\#_p\text{HOMSTO}H$ is computable in polynomial time; otherwise, $\#_p\text{HOMSTO}H$ is $\#_p\,\mathsf{P}$-complete.*

We illustrate Theorem 1.2 using the following discussion on Figure 1. The order 2 and the order 3 reduced form of H both are the graph with one vertex, whereas for any other prime the graph stays as such.

The polynomial computable cases follow directly from the results of Faben and Jerrum. Thus, to prove Theorem 1.2 it suffices to show that $\#_p\text{HOMSTO}H$ is $\#_p\,\mathsf{P}$-complete for every tree H that is not a star and has no automorphism of order p. The reductions in [7, 9, 10] show hard instances of $\#_2\text{HOMSTO}H$ by starting from $\#_2$IS, the problem of computing $|\mathcal{I}(G)| \pmod 2$, where $\mathcal{I}(G)$ is the set of independent sets of G. $\#_2$IS was shown to be $\#_2\,\mathsf{P}$ complete by Valiant [18]. Later on, Faben [6] extended this result by proving $\#_k$IS to be $\#_k\,\mathsf{P}$-complete for all integers k. For reasons to be explained in Section 1.3 we do not use this problem as a starting point for our reductions.

We turn our attention to $\#_p$BIS, the problem of counting the independent sets of a bipartite graph modulo p. In the same work Faben [6] includes a construction to show hardness for $\#_p$BIS. We employ the weighted version $\#_p\text{BIS}_{\lambda_\ell,\lambda_r}$ as a starting point for our reduction extending the research on #BIS.

▶ **Problem 1.4.** $\#_p\text{BIS}_{\lambda_\ell,\lambda_r}$

Parameter.	p prime and $\lambda_\ell, \lambda_r \in \mathbb{Z}_p$.
Input.	Bipartite graph $G = (V_L, V_R, E)$.
Output.	$Z_{\lambda_\ell,\lambda_r}(G) = \sum_{I\in\mathcal{I}(G)} \lambda_\ell^{\lvert V_L\cap I\rvert}\lambda_r^{\lvert V_R\cap I\rvert} \pmod p$.

In fact, we obtain the following dichotomy.

▶ **Theorem 1.5.** *Let p be a prime and let λ_ℓ, $\lambda_r \in \mathbb{Z}_p$. If $\lambda_\ell \equiv 0 \pmod p$ or $\lambda_r \equiv 0 \pmod p$, then $\#_p\text{BIS}_{\lambda_\ell,\lambda_r}$ is computable in polynomial time. Otherwise, $\#_p\text{BIS}_{\lambda_\ell,\lambda_r}$ is $\#_p\,\mathsf{P}$-complete.*

In order to prove hardness for $\#_p\text{HomsTo}H$ we employ a reduction in three phases: (i) we reduce the "canonical" $\#_p\,\mathsf{P}$-complete problem $\#_p\text{SAT}$ to $\#_p\text{BIS}_{\lambda_\ell,\lambda_r}$; (ii) we reduce $\#_p\text{BIS}_{\lambda_\ell,\lambda_r}$ to $\#_p\text{PartLabHomsTo}H$, a restricted version of $\#_p\text{HomsTo}H$ which we define in Section 1.3; (iii) we reduce $\#_p\text{PartLabHomsTo}H$ to $\#_p\text{HomsTo}H$.

Section 1.1 provides background knowledge on modular counting. In Section 1.2 we will discuss some related work. A high level proof of our three way reduction is provided in Section 1.3. There we also explain the technical obstacles arising from values of the modulo $p > 2$ and how we overcome them by generalising the techniques used for the case $p = 2$. First, we explain step (i), the reduction from $\#_p\text{SAT}$ to $\#_p\text{BIS}_{\lambda_\ell,\lambda_r}$. Afterwards, we describe step (iii), the reduction from $\#_p\text{PartLabHomsTo}H$ to $\#_p\text{HomsTo}H$ establishing the required notation for the subsequent illustration of step (ii), the reduction from $\#_p\text{BIS}_{\lambda_\ell,\lambda_r}$ to $\#_p\text{PartLabHomsTo}H$. In Section 1.4 we discuss the limits of our techniques, which do not yield a dichotomy modulo any integer k.

1.1 Modular counting

Modular counting was originally studied from the decision problem's point of view. Here, the objective is to determine if the number of solutions is non-zero modulo k. The complexity class $\oplus\,\mathsf{P}$ was first studied by Papadimitriou and Zachos [16] and by Goldschlager and Parberry [12]. $\oplus\,\mathsf{P}$ consists of all problems of the form "is $f(x)$ odd or even?", where $f(x)$ is a function in $\#\,\mathsf{P}$. A result of Toda [17] states that every problem in the polynomial time hierarchy reduces in polynomial time to some problem in $\oplus\,\mathsf{P}$. This result suggests that $\oplus\,\mathsf{P}$-completeness represents strong evidence for intractability.

For an integer k the complexity class $\#_k\,\mathsf{P}$ consists of all problems of the form "compute $f(x)$ modulo k", where $f(x)$ is a function in $\#\,\mathsf{P}$. In the special case of $k = 2$, $\#_2\,\mathsf{P} = \oplus\,\mathsf{P}$, as the instances of $\#_2\,\mathsf{P}$ require a one bit answer. Throughout this paper though, instead of the more traditional notation $\oplus\,\mathsf{P}$, we will use $\#_2\,\mathsf{P}$ to emphasise our interest in computing functions.

If a counting problem can be solved in polynomial time, the corresponding decision and modular counting problems can also be solved in polynomial time. The converse, though, does not necessarily hold. The reason is that efficient counting algorithms rely usually on an exponential number of cancellations that occur in the problem, e.g. compute the determinant of a non-negative matrix. The modulo operator introduces a natural setting for such cancellations to occur.

For instance, consider the $\#\,\mathsf{P}$-complete problem of counting proper 3-colourings of a graph G in the modulo 3 (or even modulo 6) setting. 3-colourings of a graph assigning all three colours can be grouped in sets of size 6, since there are $3! = 6$ permutations of the colours. Thus, the answer to these instances is always a multiple of 6, and therefore "cancels out". It remains to compute the number of 3-colourings assigning less than 3 colours. For the case of using exactly 2 colours we distinguish the following two cases: G is not bipartite and there are no such colourings; G is bipartite and the number of 3-colourings of G that use exactly 2 colours is $3(2^c)$, where c is the number of components of G. Finally, computing the number of proper 3-colourings of G that use exactly one colour is an easy task. Either G has an edge and there are no such colourings, or G has no edges and for every vertex there are 3 colours to choose from.

Valiant [18] observed a surprising phenomenon in the tractability of modular counting problems. He showed that for a restricted version of 3-SAT computing the number of solutions modulo 7 is in FP, but computing this number modulo 2 is $\#_2$ P-complete. This mysterious number 7 was later explained by Cai and Lu [3], who showed that the k-SAT version of Valiant's problem is tractable modulo any prime factor of $2^k - 1$.

1.2 Related work

We have already mentioned earlier work on counting graph homomorphisms. In this section we highlight the work of Faben [6] and the work of Guo et al. [13] on the complexity of the modular counting variant of the constraint satisfaction problem.

▶ **Problem 1.6.** $\#_k\mathrm{CSP}(\mathcal{F})$

Parameter.	$k \in \mathbb{Z}_{>0}$ and a set of functions $\mathcal{F} = \{f_1, \ldots, f_m\}$, where for each $j \in [m]$, $f_j : \{0,1\}^{r_j} \to \mathbb{Z}_p$ and $r_j \in \mathbb{Z}_{>0}$.
Input.	Finite set of constraints over Boolean variables $x_1, \ldots, x_n$ of the form $f_{j_l}(x_{i_{l,1}}, x_{i_{l,2}}, \ldots, x_{i_{l,r_{j_l}}})$.
Output.	$\sum_{x_1,\ldots,x_n \in \{0,1\}} \prod_l f_{j_l}(x_{i_{l,1}}, x_{i_{l,2}}, \ldots, x_{i_{l,r_{j_l}}}) \pmod k$.

Faben showed a dichotomy theorem [6, Theorem 4.11] when the functions in $\mathcal{F}$ have Boolean domain and Boolean range, i.e. $f : \{0,1\} \to \{0,1\}$. Guo et al. extended this dichotomy [13, Theorem 4.1] to $\#_k$CSP, when the functions in $\mathcal{F}$ have Boolean domain $\{0,1\}$ but range in $\mathbb{Z}_k$.

Constraint satisfaction problems generalise graph homomorphism problems, when the domain of the constraint functions is arbitrarily large. In order to illustrate that $\#_k$CSP is a generalisation of $\#_k$HomsToH, let G be an input for $\#_k$HomsToH, for which we describe an equivalent $\#_k$CSP instance. The domain of the constraint satisfaction problem is $D = V(H)$ and $\mathcal{F}$ contains a single binary relation R_H, with $R_H(u,v) = 1$ whenever $(u,v) \in E(H)$ and $R_H(u,v) = 0$ otherwise. Thus, $\#_k$HomsToH is an instance of $\#_k\mathrm{CSP}(\{R_H\})$. The input of $\#_k\mathrm{CSP}(\{R_H\})$ contains a variable x_v for every vertex $v \in V(G)$ and a constraint $R_H(x_u, x_v)$ for every edge $(u,v) \in E(G)$. As can be observed from the construction, every valid homomorphism $\sigma : V(G) \to V(H)$ corresponds to an assignment of the variables $\{x_v\}_{v \in V(G)}$ satisfying every constraint in the CSP.

These results of Faben and of Guo et al. are incomparable to ours. We consider prime values of the modulo and a single binary relation, however the domain of our relations is arbitrarily large. Furthermore, the results of Faben [6, Theorem 4.11] show that the constraint language $\mathcal{F}$ for which $\#_2$CSP is tractable is richer than the constraint language for which $\#_k$CSP is tractable, where $k > 2$. In contrast, our results show that the dichotomy criterion of $\#_p$HomsToH remains the same for all primes p, when H is a tree.

1.3 Beyond one-bit functions

Weighted bipartite independent sets

To explain how we prove Theorem 1.5, consider a bipartite graph $G = (V_L, V_R, E)$ and let $\lambda_\ell = 0$ (the case $\lambda_r = 0$ is symmetric). We observe that every independent set I which contributes a non-zero summand to $Z_{\lambda_\ell,\lambda_r}(G)$ can only contain vertices in V_R ($Z_{\lambda_\ell,\lambda_r}(G)$ is defined in Problem 1.4). This yields the closed form $Z_{\lambda_\ell,\lambda_r}(G) = (\lambda_r + 1)^{|V_R|}$, which

is computable in polynomial time. Regarding the case $\lambda_\ell, \lambda_r \not\equiv 0 \pmod p$, we employ a generalisation of a reduction used by Faben. In [6, Theorem 3.7] Faben reduces $\#_p\text{SAT}$ to $\#_p\text{BIS}_{1,1}$, the problem of counting independent sets of a bipartite graph.

We have to generalise this reduction for the weighted setting, in particular allowing different vertex weights for the vertices of each partition. Furthermore, during the construction we have to keep track of the assignment of vertices to their corresponding part, V_L or V_R. For this purpose we need to show the existence of bipartite graphs B, where $Z_{\lambda_\ell,\lambda_r}(B)$ takes specific values. These graphs are then used as gadgets in our reduction. In the unweighted setting $\#_p\text{BIS}_{1,1}$ the graphs B are complete bipartite graphs. However, in the weighted setting $\#_p\text{BIS}_{\lambda_\ell,\lambda_r}$ complete bipartite graphs are not sufficient. Therefore, we prove the existence of the necessary bipartite gadgets B constructively. Key results appear in Section 2 and the technical proofs appear in Section 3 of the full version.

Pinning

Similar to the existing hardness proofs on modular counting graph homomorphisms we deploy a "pinning" technique. A partial function from a set X to a set Y is a function $f : X' \to Y$ for some $X' \subseteq X$. For any graph H, a *partially H-labelled graph* $J = (G, \tau)$ consists of an *underlying graph* G and a *pinning function* τ, which is a partial function from $V(G)$ to $V(H)$. A homomorphism from a partially labelled graph $J = (G, \tau)$ to H is a homomorphism $\sigma\colon G \to H$ such that, for all vertices $v \in \text{dom}(\tau)$, $\sigma(v) = \tau(v)$. The resulting problem is denoted by $\#_p\text{PartLabHomsTo}H$, that is, given a prime p and graph H, compute $|\text{Hom}(J \to H)| \pmod p$. In Section 3, we show that $\#_p\text{PartLabHomsTo}H$ reduces to $\#_p\text{HomsTo}H$. This allows us to establish hardness for $\#_p\text{HomsTo}H$, by proving hardness for $\#_p\text{PartLabHomsTo}H$. The reduction generalises the pinning reduction of Göbel, Goldberg and Richerby [10] from $\#_2\text{PartLabHomsTo}H$ to $\#_2\text{HomsTo}H$.

We explain how to prove pinning when we restrict the value of the modulo to 2 and the pinning function $\tau(J) = \{u \mapsto v\}$ to "pin" a single vertex. Given two graphs with distinguished vertices (G, u) and (H, v), let $\text{Hom}((G, u) \to (H, v))$ be the set of homomorphisms from G to H mapping u to v. Given a graph with a distinguished vertex (G, u) and a graph H, we define $\mathbf{w}_H(G)$ to be the $\{0, 1\}$-vector containing the entries $|\text{Hom}((G, u) \to (H, v))| \pmod 2$ for each vertex $v \in V(H)$. Observe that for two vertices $v_1, v_2 \in V(H)$, such that $(H, v_1) \cong (H, v_2)$, and any graph G the relevant entries in $\mathbf{w}_G(H)$ will always be equal. Therefore, we can contract all such entries to obtain the *orbit vectors* $\mathbf{v}_H(G)$. Suppose that there exists a graph with a distinguished vertex (Θ, u_Θ), such that $\mathbf{v}_H(\Theta) = 0 \ldots 010 \ldots 0$, where the 1-entry corresponds to the vertex v of H. Given our input J for $\#_2\text{PartLabHomsTo}H$ we can now define an input G for $\#_2\text{HomsTo}H$, such that $|\text{Hom}(J \to H)| \equiv |\text{Hom}((G(J), u) \to (H, v))| \equiv |\text{Hom}(G \to H)| \pmod 2$. G contains a disjoint copy of $G(J)$ and Θ, where the vertices u and u_Θ are identified (recall that u is the vertex of J mapped by $\tau(J)$). Due to the value of $\mathbf{v}_H(\Theta)$ and the structure of G there is an even number of homomorphisms mapping u to any vertex $v' \neq v$, which establishes the claim.

Such a graph Θ, however, is not guaranteed to exist. Instead, we can define a set of operations on the vectors $\mathbf{v}_H$ corresponding to graph operations and show that for any vector in $\{0, 1\}^{|V(H)|}$ there exist a sequence of graphs with distinguished vertices $(\Theta_1, u_1), \ldots, (\Theta_t, u_t)$ that "generate" this vector. Thus, there exists a set of graphs that "generate" $\mathbf{v} = 0 \ldots 010 \ldots 0$, which yields the desired reduction. This technique of [10] exploits the value of the modulo to be 2. Applying this technique to counting modulo any prime p directly, one can establish pinning for asymmetric graphs, that is graphs whose automorphism group contains only the identity. A dichotomy for $\#_p\text{HomsTo}H$, when H is an asymmetric tree appears in the first author's doctoral thesis [8].

In order to go beyond asymmetric graphs, one has to observe that information redundant only in the modulo 2 case is lost from the contraction of the vectors $\mathbf{w}_H$ to the vectors $\mathbf{v}_H$. This works on asymmetric graphs, since then these two vectors are identical. For general graphs we are able to restore pinning for counting homomorphisms modulo any prime p by utilising the non-contracted vectors $\mathbf{w}_H$.

▶ **Theorem 1.7.** *Let p be a prime and let H be a graph. Then $\#_p$PartLabHomsToH reduces to $\#_p$HomsToH via polynomial time Turing reduction.*

To obtain hardness for $\#_p$HomsToH we only need to pin two vertices when H is a tree, i.e. the domain of the pinning function τ has size two. For a study of a more general class of target graphs H (see [10]), the size of the domain has to be larger. As our pinning theorem applies to all primes p, all graphs H and pinning functions of arbitrary domain size, it can potentially be used to show hardness for $\#_p$HomsToH for all primes and any class of target graphs H. The key lemmas are presented in Section 3 and the formal proofs in Section 5 of the full version.

Gadgets

Gadgets are structures appearing in the target graph H that allow to reduce $\#_2$IS to $\#_2$PartLabHomsToH (the hardness of $\#_2$HomsToH is then immediate from Theorem 1.7). For illustrative purposes we simplify the definitions appearing in [10]. $\#_2$HomsToH–gadgets consist of two partially labelled graphs with distinguished vertices (J_1, y), (J_2, y, z) along with two "special" vertices $i, o \in V(H)$. Given the input G for $\#_2$IS, we construct an input G' for $\#_2$PartLabHomsToH as follows. We attach a copy of J_1 to every vertex u of G (identifying u with y) and replace every edge (u, v) of G with a copy of J_2 (identifying u with y and v with z). The properties of J_1 ensure that there is an odd number of homomorphisms from G' to H where the original vertices of G are mapped to i or o, while the number of the remaining homomorphisms cancels out. The properties of J_2 ensure that there is an even number of homomorphisms from G' to H when two adjacent vertices of G are both mapped to i, and an odd number of homomorphisms in every other case. We can now observe that $|\mathcal{I}(G)| \equiv |\mathrm{Hom}\,(G' \to H)| \pmod 2$, as the set of homomorphisms that does not cancel out must map every vertex of G to i or o and no pair of adjacent vertices both to i. Every vertex of G that is in an independent set must be mapped to i, and every vertex that is out of the independent set must be mapped to o.

Generalising the described approach to modulo any prime $p > 2$ one would end up reducing from a restricted $\#_p$CSP instance, containing a binary relation and a unary weight that must be applied to every variable of the instance (this is known as *external field* in statistical physics). Similar to the modulo 2 case the edge interaction is captured by the binary relation and size of the set of "special" vertices by the unary weights. Since for primes $p > 2$ there are more non-zero values than 1 (odd) a study of the external field is no longer trivial in this case. Instead we choose a different approach and reduce from $\#_p\mathrm{BIS}_{\lambda_\ell,\lambda_r}$. This seems to capture the structure that produces hardness in $\#_p$HomsToH in a more natural way.

We formally present our reduction in Section 4. In the following we sketch our proof method and focus our attention on the example graph H in Figure 1. Let $G = (V_L, V_R, E)$ be a bipartite graph. Homomorphisms from G to H must respect the partition of G, i.e. the vertices in V_L can only be mapped to the vertices in $\{x_L, u_1, u_2, u_3\}$ and the vertices in V_R can only be mapped to the vertices in $\{x_R, v_1, v_2\}$, or vice versa. Any homomorphism σ from G to H, which maps the vertex $w \in V(G)$ to any vertex in $\{u_1, u_2, u_3\}$, must map

every neighbour of w to x_R. Similarly, any homomorphism σ from G to H, which maps the vertex $w \in V(G)$ to any vertex in $\{v_1, v_2\}$, must map every neighbour of w to x_L. Thus, homomorphisms from G to H express independent sets of G: $\{u_1, u_2, u_3\}$ represent the vertices of V_L in the independent set and $\{v_1, v_2\}$ represent the vertices of V_R in the independent set, or vice versa. We construct a partially labelled graph J from G to fix the choice of V_L and V_R in the set of homomorphisms from G to H. $G(J)$ contains a copy of G, where every vertex in V_L is attached to the new vertex $\hat{u}$ and every vertex in V_R is attached to the new vertex $\hat{v}$. In addition, $\tau(J) = \{\hat{u} \mapsto x_R, \hat{v} \mapsto x_L\}$ is the pinning function. We observe that the vertices in V_L can only be mapped to vertices in $\{x_L, u_1, u_2, u_3\}$ and vertices in V_R can only be mapped to vertices in $\{x_R, v_1, v_2\}$. This observation yields that the number of homomorphisms from J to H is equivalent to $\sum_{I \in \mathcal{I}(G)} 3^{|V_L \cap I|} 2^{|V_R \cap I|} \pmod p$. Furthermore, the cardinality of the sets $\{u_1, u_2, u_3\}$ and $\{v_1, v_2\}$ introduces weights in a natural way.

For the reduction above we need the following property easily observable in H: there exist two adjacent vertices of degree $a = \lambda_\ell + 1 \not\equiv 1 \pmod p$ and $b = \lambda_r + 1 \not\equiv 1 \pmod p$. Recall that in order to obtain hardness for $\#_p\text{BIS}_{\lambda_\ell, \lambda_r}$ Theorem 1.5 requires $\lambda_\ell, \lambda_r \not\equiv 0 \pmod p$. In fact, as we will show in Section 4, these vertices need not be adjacent. During the construction of J we can replace the edges of G with paths of appropriate length. We call such a structure in H an (a, b, p)-path. In Lemma 4.4 we formally prove that if H has an (a, b, p)-path, then $\#_p\text{HomsTo}H$ is $\#_p\,\mathsf{P}$-hard. In particular, observe that stars cannot contain (a, b, p)-paths. Finally, we show that every non-star tree H contains an (a, b, p)-path, which yields our main result on $\#_p\text{HomsTo}H$ (Lemma 4.2).

1.4 Composites

We outline the obstacles occurring when extending the dichotomy for $\#_k\text{HomsTo}H$ to any integer k. Let H be a graph and let $k = \prod_{i=1}^{m} k_i$, where $k_i = p_i^{r_i}$ is an integer with its prime factorisation. Assuming $\#_k\text{HomsTo}H$ can be solved in polynomial time, then for each $i \in [m]$, $\#_{k_i}\text{HomsTo}H$ can also be solved in polynomial time. The reason is that k_i is a factor of k and we can apply the modulo k_i operator to the answer for the $\#_k\text{HomsTo}H$ instance. The Chinese remainder theorem shows that the converse is also true: if for each $i \in [m]$ we can solve $\#_{k_i}\text{HomsTo}H$ in polynomial time, then we can also solve $\#_k\text{HomsTo}H$ in polynomial time. By the previous observations we can now focus on powers of primes $k = p^r$. Assuming $\#_k\text{HomsTo}H$ is computable in polynomial time yields again that $\#_p\text{HomsTo}H$ is also computable in polynomial time. However, the converse is not always true.

Guo et al. [13] were able to obtain this reverse implication for the constraint satisfaction problem. They showed [13, Lemma 4.1 and Lemma 4.3] that when p is a prime $\#_{p^r}\text{CSP}$ is computable in polynomial time if $\#_p\text{CSP}$ is computable in polynomial time. In the full version we show that their technique cannot be transferred to the $\#_k\text{HomsTo}H$ setting. We show that there is a graph (P_4) such that $\#_2\text{HomsTo}P_4$ is computable in polynomial time, while $\#_4\text{HomsTo}P_4$ is $\#_2\,\mathsf{P}$-hard.

2 Weighted bipartite independent set

We study the complexity of Problem 1.4, the problem of computing the weighted sum over independent sets in a bipartite graph. We begin by identifying the tractable instances.

▶ **Proposition 2.1.** *If* $\lambda_\ell \equiv 0 \pmod p$ *or* $\lambda_r \equiv 0 \pmod p$ *then* $\#_p\mathrm{BIS}_{\lambda_\ell,\lambda_r}$ *is computable in polynomial time.*

To prove the hardness of the remaining cases, we reduce from $\#_p\mathrm{SAT}$. Our reduction starts with a Boolean formula φ and constructs, in two stages, a graph G_φ, such that $Z_{\lambda_\ell,\lambda_r}(G_\varphi) \equiv K|\operatorname{sat}(\varphi)| \pmod p$, where $\operatorname{sat}(\varphi)$ denotes the set of satisfying assignments of φ and K is a constant depending on the values of the weights λ_ℓ and λ_r. In the first stage we define the graph G'_φ. For every variable x_i in φ, G'_φ contains three vertices u_i, $\bar{u}_i$ and w_i to the left vertex set $V_L(G'_\varphi)$ as well as three vertices v_i, $\bar{v}_i$ and z_i to the right vertex set $V_R(G'_\varphi)$. For every clause c_j of φ, G'_φ further contains a vertex y_j in the right vertex set $V_R(G'_\varphi)$. We further introduce the edges forming the cycle $u_iv_iw_i\bar{v}_i\bar{u}_iz_iu_i$ to $E(G'_\varphi)$ for every variable x_i in φ. Additionally for all $i \in [n]$, if x_i appears as a literal in clause c_j of φ, we introduce the edge (u_i, y_j) in G'_φ and if $\bar{x}_i$ appears as a literal in clause c_j, we introduce the edge $(\bar{u}_i, y_j)$ in G'_φ. The left part of Figure 2 illustrates an example of this construction.

The second stage uses copies of a bipartite graph B, which is obtained by the following key lemma.

▶ **Lemma 2.2.** *Let* p *be a prime and* $\lambda_\ell, \lambda_r \in \mathbb{Z}_p^*$. *There exists a bipartite graph* $B = (V_L, V_R, E)$ *with distinguished vertices* $u_L \in V_L$ *and* $v_R \in V_R$, *that satisfies*

1. $Z_{\lambda_\ell,\lambda_r}(B) \equiv 0 \pmod p$,
2. $Z_{\lambda_\ell,\lambda_r}(B - u_L) \not\equiv 0 \pmod p$,
3. $Z_{\lambda_\ell,\lambda_r}(B - v_R) \not\equiv 0 \pmod p$.

In the second and final stage, we construct the graph G_φ. Let (B, u_L, v_R) be the graph obtained from Lemma 2.2. G_φ is a copy of G'_φ together with two copies of B for every variable of φ and one copy of B for every clause. The first n copies $B^1, \dots, B^n$ are connected to G'_φ by identifying the distinguished vertex u_L^i in the left component with $w_i \in V_L(G'_\varphi)$ for all $i \in [n]$. The second n copies $B^{n+1}, \dots, B^{2n}$ are connected to G'_φ by identifying the distinguished vertex v_R^{n+i} in their right components with $z_i \in V_R(G'_\varphi)$ for all $i \in [n]$. The remaining m copies $B^{2n+1}, \dots, B^{2n+m}$ of B are connected to G'_φ by identifying the distinguished vertex v_R^{2n+j} in their right components with $y_j \in V_R(G'_\varphi)$ for all $j \in [m]$. For an example see the right part of Figure 2.

From this construction we obtain the desired result.

▶ **Theorem 1.5.** *Let* p *be a prime and let* λ_ℓ, $\lambda_r \in \mathbb{Z}_p$. *If* $\lambda_\ell \equiv 0 \pmod p$ *or* $\lambda_r \equiv 0 \pmod p$ *then* $\#_p\mathrm{BIS}_{\lambda_\ell,\lambda_r}$ *is computable in polynomial time. Otherwise,* $\#_p\mathrm{BIS}_{\lambda_\ell,\lambda_r}$ *is* $\#_p\,\mathsf{P}$*-complete.*

3 Homomorphisms of partially labelled graphs

We study the following problem.

▶ **Problem 3.1.** $\#_p$PartLabHomsToH.

Parameter.	Graph H and prime p.
Input.	Partially H-labelled graph $J = (G, \tau)$.
Output.	$\lvert\operatorname{Hom}(J \to H)\rvert \pmod p$.

We observe the following theorem for all primes p.

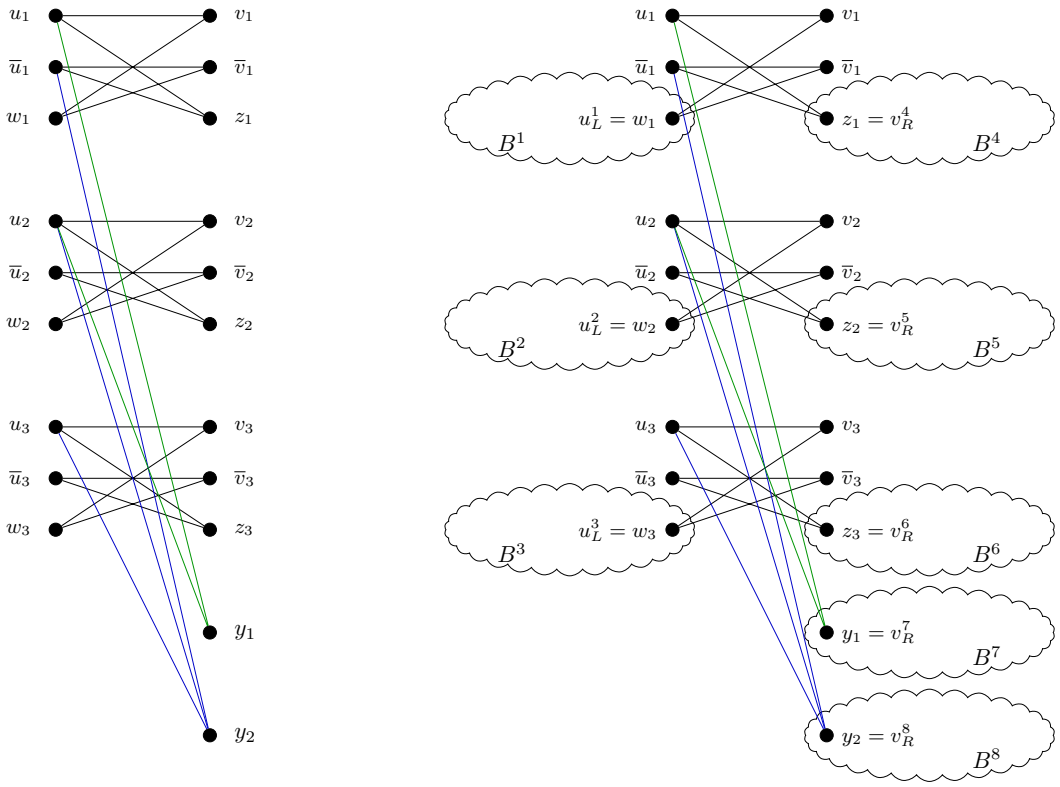

Figure 2 The graphs G'_φ and G_φ for $\varphi = (x_1 \vee x_2) \wedge (\bar{x}_1 \vee x_2 \vee x_3)$.

▶ **Lemma 3.2** (Göbel, Goldberg and Richerby [10]). *Let p be a prime and let $(H, \bar{v})$ and $(H', \bar{v}')$ be graphs having no automorphism of order p, each with r distinguished vertices. Then $(H, \bar{v}) \cong (H', \bar{v}')$ if and only if, for all (not necessarily connected) graphs $(G, \bar{u})$ with r distinguished vertices,*

$$|\operatorname{Hom}((G, \bar{u}) \to (H, \bar{v}))| \equiv |\operatorname{Hom}((G, \bar{u}) \to (H', \bar{v}'))| \pmod{p}.$$

Instead of orbit vectors, which are used in the pinning proof of [10], we employ tuple vectors. The tuple vectors include the sizes of the orbits $\operatorname{Orb}_H(\bar{v})$, for all $v \in V(H)^r$, and this information is vital for the proof of our pinning theorem.

▶ **Definition 3.3.** Let H be a graph with no automorphism of order p, $r \in \mathbb{Z}_{>0}$ and let $\bar{w}_1, \ldots, \bar{w}_\nu$ be an enumeration of $(V(H))^r$, i.e., $\nu = |V(H)|^r$. Let $(G, \bar{u})$ be a graph with r distinguished vertices. We define the *tuple vector* $\mathbf{w}_H(G, \bar{u}) \in (\mathbb{Z}_p)^\nu$ where, for each $j \in [\nu]$, the j-th component of $\mathbf{w}_H(G, \bar{u})$ is given by

$$\left(\mathbf{w}_H(G, \bar{u})\right)_j \equiv |\operatorname{Hom}((G, \bar{u}) \to (H, \bar{w}_j))| \pmod{p}.$$

We say that $(G, \bar{u})$ *implements* this vector.

Not all tuple vectors in $(\mathbb{Z}_p)^\nu$ are implementable. We only require the following set to be implementable.

▶ **Definition 3.4.** Let H be a graph with no automorphism of order p, $r \in \mathbb{Z}_{>0}$ and let $\bar{w}_1, \ldots, \bar{w}_\nu$ be an enumeration of $(V(H))^r$, i.e., $\nu = |V(H)|^r$. Denote by $F(H, r) \subseteq (\mathbb{Z}_p)^\nu$ the set of vectors $\mathbf{w}$, such that, for all $i, j \in [\nu]$ with $(H, \bar{w}_i) \cong (H, \bar{w}_j)$, we have $(\mathbf{w})_i = (\mathbf{w})_j$.

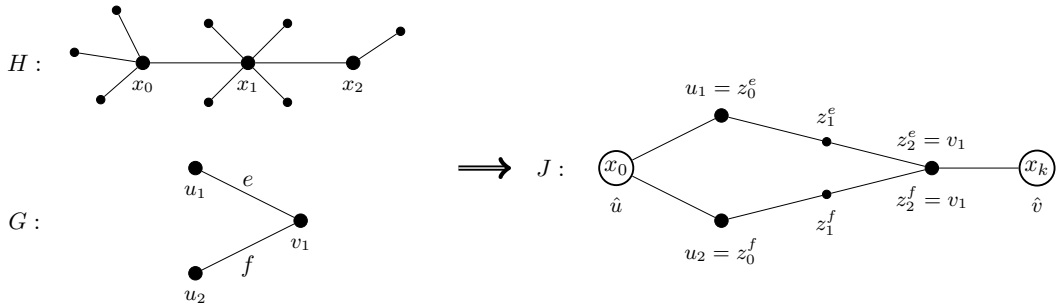

Figure 3 An instance for $p = 5$ of $\#_p\text{BIS}_{3,1}$ reducing to $\#_p\text{PartLabHomsTo}H$. H contains the $(4, 2, 5)$-path $x_0x_1x_2$. G is transformed to the partially labelled graph J, where the mappings of $\tau(J)$ are shown as vertices encircling the target of the mapping.

▶ **Lemma 3.5.** *Let H be a graph with no automorphism of order p, $r \in \mathbb{Z}_{>0}$ and $\bar{w}_1, \ldots, \bar{w}_\nu$ an enumeration of $(V(H))^r$, i.e., $\nu = |V(H)|^r$. Then every $\mathbf{w} \in F(H, r)$ is H-implementable.*

Using the above in the full version we prove the following theorem.

▶ **Theorem 1.7.** *Let p be a prime and let H be a graph. Then $\#_p\text{PartLabHomsTo}H$ reduces to $\#_p\text{HomsTo}H$ via polynomial-time Turing reduction.*

4 Hardness for trees

The structure in H that yields hardness for $\#_p\text{HomsTo}H$ is formally defined as follows.

▶ **Definition 4.1.** Let H be a graph, p be a prime and $a, b \in \mathbb{Z}_p \setminus \{1\}$. Assume H contains a path $P = x_0 \ldots x_k$ for $k > 0$, such that the following hold

1. P is the unique path between x_0 and x_k in H.
2. $\deg_H(x_0) \equiv a \pmod p$ and $\deg_H(x_k) \equiv b \pmod p$.
3. For all $0 < i < k$, $\deg_H(x_i) \equiv 1 \pmod p$.

Then, we will call P an *(a, b, p)-path in H* and denote it Q_H.

▶ **Lemma 4.2.** *Let H be a tree that has no automorphism of order p. Then, either H is a star or there are $a, b \in \mathbb{Z}_p \setminus \{1\}$ such that H contains an (a, b, p)-path.*

In order to show that $\#_p\text{HomsTo}H$ is $\#_p$ P-hard we are going to establish a reduction from $\#_p\text{BIS}_{\lambda_\ell,\lambda_r}$ to $\#_p\text{PartLabHomsTo}H$. Let p be a prime and let H be a tree, target graph in $\#_p\text{PartLabHomsTo}H$. Given a graph $G = (V_L, V_R, E)$ input for $\#_p\text{BIS}_{\lambda_\ell,\lambda_r}$, we construct a partially labelled graph J, input for $\#_p\text{PartLabHomsTo}H$, such that $Z_{\lambda_\ell,\lambda_r}(G) \equiv |\operatorname{Hom}(J \to H)| \pmod p$. Assume H contains an (a, b, p)-path $Q = x_0 \ldots x_k$ and let $P_k = z_0 \ldots z_k$ be the k-path of length k. For every edge $e \in E$, we take a copy of P_k denoted $P_k^e = z_0^e \ldots z_k^e$. Then, J is constructed starting with G by adding two vertices $\hat{u}$ and $\hat{v}$ and connecting them to every vertex in V_L and V_R, respectively. Subsequently, every edge $e \in E$ is substituted with a the path P_k^e. Finally, the pinning function of J maps $\hat{u}$ to x_0 as well as $\hat{v}$ to x_k. See Figure 3 for an example.

The following lemma gives the key properties of J, which establish the reduction.

▶ **Lemma 4.3.** *Let p be a prime, $G = (V_L, V_R, E)$ a bipartite graph and H be a tree. Assume there are $a, b \in \mathbb{Z}_p \setminus \{1\}$ such that H contains an (a, b, p)-path $Q_H = x_0 \ldots x_k$. We denote the diminished neighbourhoods of x_0 and x_k by $W_L = \Gamma_H(x_0) - x_1$ and $W_R = \Gamma_H(x_k) - x_{k-1}$,*

respectively. Additionally, let J be the partially labelled graph described above. Then, for every homomorphism σ from J to H the following hold.

1. *Let $u \in V_L$ and $v \in V_R$, then $\sigma(u) \in \Gamma_H(x_0)$ and $\sigma(v) \in \Gamma_H(x_k)$, respectively;*
2. *Let $\mathfrak{O}_\sigma = \{u \in V_L \mid \sigma(u) = x_1\} \cup \{v \in V_R \mid \sigma(v) = x_{k-1}\}$ and $\mathfrak{I}_\sigma = (V_L \cup V_R) \setminus \mathfrak{O}_\sigma$. Given another homomorphism σ' from J to H, the relation $\sigma \sim_\mathfrak{I} \sigma'$ if $\mathfrak{I}_\sigma = \mathfrak{I}_{\sigma'}$ is an equivalence relation with equivalence class denoted $[\![\cdot]\!]_\mathfrak{I}$;*
3. *Let $\sigma_1, \ldots, \sigma_\mu$ be representatives from each $\sim_\mathfrak{I}$-equivalence class. Then, the set $\mathcal{I}(G)$ of independent sets of G is exactly the set $\{\, \mathfrak{I}_{\sigma_i} \mid i \in [\mu] \,\}$.*
4. *For the diminished neighbourhoods holds $|[\![\sigma]\!]_\mathfrak{I}| \equiv |W_L|^{|\mathfrak{I}_\sigma \cap V_L|} |W_R|^{|\mathfrak{I}_\sigma \cap V_R|} \pmod p$.*

▶ **Lemma 4.4.** *Let p be a prime and let H be a graph with no automorphism of order p. If there are $a, b \in \mathbb{Z}_p \setminus \{1\}$ such that H has an (a, b, p)-path Q_H then $\#_p\textsc{HomsTo}H$ is $\#_p\,\mathsf{P}$-hard under Turing reductions.*

5 Dichotomy theorems

The results of Faben and Jerrum [7] combined with Lemma 4.4 give the following dichotomy theorem.

▶ **Theorem 1.2.** *Let p be a prime and let H be a graph, such that its order p reduced form H^{*p} is a tree. If H^{*p} is a star, then $\#_p\textsc{HomsTo}H$ is computable in polynomial time; otherwise, $\#_p\textsc{HomsTo}H$ is $\#_p\,\mathsf{P}$-complete.*

To justify our title, we use the following proposition showing that our dichotomy theorem holds for all trees. In [7, Section 5.3] this was stated as an obvious fact, however for the sake of completeness we provide a formal proof.

▶ **Proposition 5.1.** *Let H be a tree and ϱ an automorphism of H. Then the subgraph H^ϱ of H induced by the fixed points of ϱ is also a tree.*

The claim implies that if H is a tree, then its order p reduced form H^{*p} is also a tree. This yields the following corollary.

▶ **Corollary 1.3.** *Let p be a prime and let H be a tree. If the order p reduced form H^{*p} of H is a star, then $\#_p\textsc{HomsTo}H$ is computable in polynomial time; otherwise, $\#_p\textsc{HomsTo}H$ is $\#_p\,\mathsf{P}$-complete.*

To deal with disconnected graphs, Faben and Jerrum [7, Theorem 6.1] show the following theorem.

▶ **Theorem 5.2** (Faben and Jerrum)**.** *Let H be a graph that has no automorphism of order 2. If H' is a connected component of H and $\#_2\textsc{HomsTo}H'$ is $\#_2\,\mathsf{P}$-hard, then $\#_2\textsc{HomsTo}H$ is $\#_2\,\mathsf{P}$-hard.*

The only part where the value 2 of the modulo is required, is the application of their pinning theorem [7, Theorem 4.7]. Since we have already shown the more general Theorem 1.7, we conclude that the theorem holds in the following form.

▶ **Theorem 5.3.** *Let p be a prime and let H be a graph that has no automorphism of order p. If H_1 is a connected component of H and $\#_p\textsc{HomsTo}H_1$ $\#_p\,\mathsf{P}$-hard, then $\#_p\textsc{HomsTo}H$ is $\#_p\,\mathsf{P}$-hard.*

The latter strengthens Theorem 1.2 to the following version.

▶ **Theorem 5.4.** *Let H be a graph whose order p reduced form H^{*p} is a forest. If every component of H^{*p} is a star, $\#_p\text{HOMSTO}H$ is computable in polynomial time, otherwise $\#_p\text{HOMSTO}H$ is $\#_p\,\mathsf{P}$-complete.*

A discussion of our results was already conducted in the introduction. Again we refer the curious reader to the full version of the paper, available at `https://arxiv.org/abs/1802.06103`.

Abstract

In this paper, we consider an on-line scheduling problem that is motivated by applications such as car sharing, in which users submit ride requests, and the scheduler aims to accept requests of maximum total profit using two servers (cars). Each ride request specifies the pick-up time and the pick-up location (among two locations, with the other location being the destination). The length of the time interval between the submission of a request (booking time) and the pick-up time is fixed. The scheduler has to decide whether or not to accept a request immediately at the time when the request is submitted. We present lower bounds on the competitive ratio for this problem and propose a smart greedy algorithm that achieves the best possible competitive ratio.

1 Introduction

In a car-sharing system, a company offers cars to customers for a period of time. Customers can pick up a car in one location, drive it to another location, and return it there. Car booking requests arrive on-line, and the goal is to maximize the profit obtained from satisfied requests. We consider a setting where all driving routes go between two fixed locations, but can be in either direction. For example, the two locations could be a residential area and a nearby shopping mall or central business district. Other applications that provide motivation for the problems we study include car rental, taxi dispatching and boat rental for river crossings.

[1] This work was partially supported by the China Postdoctoral Science Foundation (Grant No. 2016M592811), and the China Scholarship Council (Grant No. 201706280058).

In a real setting, customer requests for car bookings arrive over time, and the decision about each request must be made immediately, without knowledge of future requests. This gives rise to an on-line problem that bears some resemblance to interval scheduling, but in which additionally the pick-up and drop-off locations play an important role: The server that serves a request must be at the pick-up location at the start time of the request and will be located at the drop-off location at the end time of the request. A server can serve two consecutive requests only if the drop-off location of the first request is the same as the pick-up location of the second request, or if there is enough time to travel between the two locations otherwise. We allow 'empty movements' that allow a server to be moved from one location to another while not serving a request. Such empty movements could be implemented by having company staff drive a car from one location to another, or in the future by self-driving cars.

We assume that every request is associated with a profit $r > 0$ that is obtained if the request is accepted. When a server moves while not serving a request, a certain cost c, $0 \leq c \leq r$, is incurred. The goal is to maximize the total profit, which is the sum of the profits of the accepted requests minus the costs incurred for moving servers while not serving a request. We refer to this problem as the *car-sharing problem*. The time interval between the submission of a request (booking time) and the pick-up time is called the *booking interval*. In this paper, we focus on the special case of two servers and assume that the booking interval for each request is a fixed value a that is the same for all requests. We assume that $a \geq t$, where t is the time to move a server from one location to the other.

In [8], the authors studied the car-sharing problem for the special case of a single server, considering both the case of fixed booking intervals and the case of flexible booking intervals, and presented tight results for the competitive ratio. The optimal competitive ratio was shown to be $2r/(r-c)$ for fixed booking intervals and $(3r-c)/(r-c)$ for flexible booking intervals if $0 \leq c < r$, and 1 for fixed booking intervals and proportional to the length of the booking horizon (the range of allowed booking intervals) for flexible booking intervals if $c = r$.

The car-sharing problem belongs to the class of dynamic pickup and delivery problems surveyed by Berbeglia et al. [2]. The problem that is closest to our setting is the on-line dial-a-ride problem (OLDARP) that has been widely studied in the literature. In OLDARP, transportation requests between locations in a metric space arrive over time, but typically it is assumed that requests want to be served 'as soon as possible' rather than at a specific time as in our problem. Known results for OLDARP include on-line algorithms for minimizing the makespan [1, 3] or the maximum flow time [7]. Work on versions of OLDARP where not all requests can be served includes competitive algorithms for requests with deadlines where each request must be served before its deadline or rejected [9], and for settings with a given time limit where the goal is to maximize the revenue from requests served before the time limit [6]. In contrast to existing work on OLDARP, in this paper we consider requests that need to be served at a specific time that is specified by the request when it is released. Another related problem is the k-server problem [5, Ch. 10], but in that problem all requests must be served and requests are served at a specific location.

Off-line versions of car-sharing problems are studied by Böhmová et al. [4]. They show that if all customer requests for car bookings are known in advance, the problem of maximizing the number of accepted requests can be solved in polynomial time using a minimum-cost network flow algorithm. Furthermore, they consider the problem variant with two locations where each customer requests two rides (in opposite directions) and the scheduler must accept either both or neither of the two. They prove that this variant is NP-hard and APX-hard. In contrast to their work, we consider the on-line version of the problem with two servers.

In Section 2, we define the problem, introduce terminology, and present lower bounds on the competitive ratio. If $0 \leq c < r$, the lower bound is 2, and if $c \geq r$, the lower bound is 1. In Section 3, we propose a smart greedy algorithm that achieves the best possible competitive ratio. Section 4 concludes the paper.

2 Problem Formulation and Preliminary Results

2.1 Definitions and Problem Formulation

We consider a setting with only two locations (denoted by 0 and 1) and two servers (denoted by s_1 and s_2). The travel time from 0 to 1 is the same as the travel time from 1 to 0 and is denoted by t. Let R denote a sequence of requests that are released over time. The i-th request is denoted by $r_i = (\tilde{t}_{r_i}, t_{r_i}, p_{r_i})$ and is specified by the *booking time* or *release time* $\tilde{t}_{r_i}$, the *start time* (or *pick-up time*) t_{r_i}, and the pick-up location $p_{r_i} \in \{0, 1\}$. We assume that the booking interval $t_{r_i} - \tilde{t}_{r_i}$ is equal to a fixed value a for all requests $r_i \in R$, and we assume that $a \geq t$ so that an available server always has enough time to travel to the pick-location of a request. If r_i is accepted, the server must pick up the customer at p_{r_i} at time t_{r_i} and drop off the customer at location $\dot{p}_{r_i} = 1 - p_{r_i}$, the *drop-off location* of the request, at time $\dot{t}_{r_i} = t_{r_i} + t$, the *end time* (or *drop-off time*) of the request. We say that the request r_i *starts* at time t_{r_i}. For an interval $[b, d)$, we say that r_i starts in the interval if $t_{r_i} \in [b, d)$.

Each server can only serve one request at a time. Serving a request yields profit $r > 0$. The two servers are initially located at location 0. If the pick-up location p_{r_i} of a request r_i is different from the current location of a server and if at least t time units remain before the start time of r_i, the server can move from its current location to p_{r_i}. We refer to such moves (which do not serve a request) as *empty* moves. An empty move takes time t and incurs a cost of c, $0 \leq c \leq r$, and we say that r_i is *accepted with cost* in this case. If the server is already located at p_{r_i}, we say that r_i is *accepted without cost*. If two requests are such that they cannot both be served by one server, we say that the requests are *in conflict*. We do not require that the algorithm assigns an accepted request to a server immediately, provided that it ensures that one of the two servers will serve the request. In our setting with fixed booking intervals, however, it is not necessary for an algorithm to use this flexibility.

We denote the requests accepted by an algorithm by R', and the i-th request in R', in order of request start times, is denoted by r'_i. The l-th request which is assigned to s_j ($j \in \{1, 2\}$) in R', in order of request start times, is denoted by $r'_{l,j}$. Suppose $r'_{l,j}$ ($j \in \{1, 2\}$) is r'_i. We say that request r'_i is accepted *without cost* if $l = 1$ and $p_{r'_{l,j}} = 0$ or if $l > 1$ and $p_{r'_{l,j}} = \dot{p}_{r'_{l-1,j}}$. Otherwise, r'_i is accepted *with cost*. We denote the profit of serving the requests in R' by $P_{R'}$. If R'_c denotes the subset of R' consisting of the requests that are accepted with cost, we have $P_{R'} = r \cdot |R'| - c \cdot |R'_c|$. The goal of the car-sharing problem is to accept a set of requests R' that maximizes the profit $P_{R'}$. The problem for two servers and two locations is called the *2S2L problem*.

2.2 Online Optimization and Competitive Analysis

From an online perspective, the requests in R and the number of requests in R are unknown, and request r_i only becomes known at time $\tilde{t}_{r_i}$. For any request sequence R, let P_{R^A} denote the objective value produced by an on-line algorithm A, and P_{R^*} that obtained by an optimal scheduler OPT that has full information about the request sequence in advance.

The performance of an online algorithm for 2S2L is measured using competitive analysis (see [5]). The competitive ratio of A is defined as $\rho_A = \sup_R \frac{P_{R^*}}{P_{R_A}}$. We say that A is ρ-competitive if $P_{R^*} \leq \rho \cdot P_{R_A}$ for all request sequences R. Let ON be the set of all on-line algorithms for a problem. A value β is a *lower bound* on the best possible competitive ratio if $\rho_A \geq \beta$ for all A in ON. We say that an algorithm A is optimal if there is a lower bound β with $\rho_A = \beta$.

2.3 Lower Bounds

In this subsection, we present the lower bounds for the 2S2L problem. We use ALG to denote any on-line algorithm and OPT to denote an optimal scheduler. We refer to the servers of ALG as s'_1 and s'_2, and the servers of OPT as s^*_1 and s^*_2, respectively. The set of requests accepted by ALG is referred to as R', and the set of requests accepted by OPT as R^*. For the case $c \geq r$, a lower bound of 1 on the competitive ratio of any algorithm holds trivially.

▶ **Theorem 1.** *For $0 \leq c < r$, no deterministic on-line algorithm for 2S2L can achieve competitive ratio smaller than 2.*

Proof. Initially, the adversary releases r_1 and r_2 with $r_1 = r_2 = (t, t + a, 1)$. We distinguish three cases.

Case 1: ALG accepts r_1 and r_2 (with cost). Note that r_1 and r_2 are assigned to different servers as they are in conflict. The adversary releases requests r_3 and r_4 with $r_3 = r_4 = (\varepsilon + t, a + \varepsilon + t, 0)$ and r_5 and r_6 with $r_5 = r_6 = (\varepsilon + 2t, a + \varepsilon + 2t, 1)$, where $0 < \varepsilon < t$. OPT accepts r_3, r_4, r_5 and r_6 without cost, but ALG cannot accept any of these requests as they are in conflict with r_1 and r_2. We have $P_{R^*} = 4r$ and $P_{R'} \leq 2(r - c)$, and hence $P_{R^*}/P_{R'} \geq 2$.

Case 2: ALG accepts either r_1 or r_2. The adversary accepts r_1 and r_2. We have $P_{R^*} = 2(r-c)$ and $P_{R'} \leq r - c$, and hence $P_{R^*}/P_{R'} \geq 2$.

Case 3: ALG does not accept request r_1 and r_2. In this case, OPT accepts r_1 and r_2 and we have $P_{R^*} = 2(r - c)$ and $P_{R'} = 0$, and hence $P_{R^*}/P_{R'} = \infty$. ◀

3 Upper Bound

In this section, we propose a Smart Greedy Algorithm (SG) for the 2S2L problem, shown in Algorithm 1. Intuitively, if a request is acceptable, the algorithm always accepts it if this increases the profit by r, and it accepts the request only if it starts at least t time units later than the end time of the latest previously accepted request if the profit increase is positive but less than r. The algorithm uses the following notation:

- R'_i is the set of requests accepted by SG before r_i is released, together with the server to which each request is assigned. $R'_i \cup \{r_{i,s'_j}\}$ denotes the union of R'_i and $\{r_{i,s'_j}\}$, where r_{i,s'_j} represents the request r_i assigned to server s'_j, $j \in \{1, 2\}$, without conflict.
- $r^n_{i,j}$ denotes the latest request which was assigned to s'_j, $j \in \{1, 2\}$, before r_i is released. (If there is no such request, take $r^n_{i,j}$ to be a dummy request with drop-off location 0 and drop-off time 0.)
- r_i is *acceptable* if and only if $\exists j \in \{1, 2\} : t_{r_i} - \dot{t}_{r^n_{i,j}} \geq t$ if $p_{r_i} = p_{r^n_{i,j}}$, and $t_{r_i} - \dot{t}_{r^n_{i,j}} \geq 0$ if $p_{r_i} \neq p_{r^n_{i,j}}$.
- r^n_i is the latest request that was accepted before r_i is released. Note that $r^n_i = r^n_{i,j}$ with $j = \arg\max\{t_{r^n_{i,j}} \mid j = 1, 2\}$. Note that $\dot{t}_{r^n_1} = 0$.

Algorithm 1 Smart Greedy Algorithm (SG).

Input: two servers, requests arrive over time with fixed booking interval a.
Step: When request r_i arrives, accept r_i and assign it to the most economical server s'_j if r_i is acceptable and $P_{R'_i \cup \{r_{i,s'_j}\}} - P_{R'_i} = r$ $(j \in \{1,2\})$, or if r_i is acceptable, $P_{R'_i \cup \{r_{i,s'_j}\}} - P_{R'_i} > 0$ $(j \in \{1,2\})$ and $t_{r_i} - \dot{t}_{r_i^n} \geq t$;

- If an accepted request is acceptable by both servers, it is assigned to the *most economical* server, which is the server s'_j with $j = \arg\max\{P_{R'_i \cup \{r_{i,s'_j}\}} \mid j = 1,2\}$. If $P_{R'_i \cup \{r_{i,s'_1}\}} = P_{R'_i \cup \{r_{i,s'_2}\}}$, s'_j is chosen as the server which has accepted r_i^n (or arbitrarily in case r_i^n does not exist).

We use OPT to denote an optimal scheduler. We refer to the servers of SG as s'_1 and s'_2, and the servers of OPT as s_1^* and s_2^*, respectively. For an arbitrary request sequence $R = (r_1, r_2, r_3, \ldots, r_n)$, note that we have $t_{r_i} \leq t_{r_{i+1}}$ for $1 \leq i < n$ because $t_{r_i} - \tilde{t}_{r_i} = a$ is fixed. Denote the requests accepted by OPT by $R^* = \{r_1^*, r_2^*, \ldots, r_{k^*}^*\}$ and the requests accepted by SG by $R' = \{r'_1, r'_2, ...r'_k\}$, indexed in order of non-decreasing start times. Denote the requests accepted by SG which start at location 0 by $R'^0 = \{r'^0_1, r'^0_2, ...r'^0_{k_0}\}$ and the requests accepted by SG which start at location 1 by $R'^1 = \{r'^1_1, r'^1_2, ...r'^1_{k_1}\}$. Denote the requests accepted by OPT which start at location 0 by $R^{*0} = \{r_1^{*0}, r_2^{*0}, ...r_{k_0^*}^{*0}\}$ and the requests accepted by OPT which start at location 1 by $R^{*1} = \{r_1^{*1}, r_2^{*1}, ...r_{k_1^*}^{*1}\}$. Note that $R'^0 \bigcup R'^1 = R'$ and $R^{*0} \bigcup R^{*1} = R^*$.

▶ **Theorem 2.** *Algorithm SG is* 1*-competitive for 2S2L if* $c = r$.

Proof. If $c = r$, accepting a request with cost yields profit $r - c = 0$. Without loss of generality, we can therefore assume that both SG and OPT only accept requests without cost. Observe that this means that both the SG servers (s'_1 and s'_2) and the OPT servers (s_1^* and s_2^*) accept requests with alternating pick-up location, starting with a request with pick-up location 0. Therefore each server can accept at most one more request which starts at location 0 over the requests which start at location 1. That means when OPT accepts w requests which start at location 1, OPT at least accepts w requests which start at location 0, and accepts at most $w + 2$ requests which start at location 0 ($k_1^* \leq k_0^* \leq k_1^* + 2$).

Considering the condition that requests r_j^{*0} and r_j^{*1} are both assigned to the same server for $j < i$ and r_i^{*0} and r_i^{*1} are assigned to different servers (without loss of generality, suppose r_i^{*0} is assigned to s_1^* and r_i^{*1} is assigned to s_2^*), we reassign r_i^{*1} to server s_1^*, reassign all requests in $R^* \backslash (\{r_1^{*0}, r_2^{*0}, ..., r_{i+1}^{*0}\} \bigcup \{r_1^{*1}, r_2^{*1}, ..., r_i^{*1}\})$ that are assigned to s_1^* (denote the set of these requests by $\Re_1$) to server s_2^*, and reassign all requests in $R^* \backslash (\{r_1^{*0}, r_2^{*0}, ..., r_{i+1}^{*0}\} \bigcup \{r_1^{*1}, r_2^{*1}, ..., r_i^{*1}\})$ that are assigned to s_2^* (denote them by $\Re_2$) to server s_1^*. As each server accepts requests with alternating pick-up location, starting with a request with pick-up location 0, we have $\dot{t}_{r'^0_i} \leq t_{r'^1_i}$ (for all $i \leq k'_1$) and $\dot{t}_{r_i^{*0}} \leq t_{r_i^{*1}}$ (for all $i \leq k_1^*$). That means for $i \leq k_1^*$, r_i^{*0} and r_i^{*1} are not in conflict, and hence reassigning r_i^{*1} to server s_1^* is valid. Observe that s_2^* must serve a request which has pick-up location 0 and starts during interval $[t_{r_i^{*0}}, t_{r_i^{*1}} - t]$ and that request is r_{i+1}^{*0}. Because $t_{r_{i+1}^{*0}} \leq t_{r_i^{*1}} - t$ and the first request in $\Re_1$, denoted by r_o, has pick-up location 1 and starts after $t_{r_i^{*1}}$, r_o and r_{i+1}^{*0} are not in conflict. As any two consecutive requests in $\Re_1$ are not in conflict, reassigning all requests of $\Re_1$ to server s_2^* is valid. Note that $t_{r_{i+2}^{*0}} \geq \dot{t}_{r_i^{*1}}$ as OPT accepts at most two requests which start during interval $[t_{r_i^{*0}}, t_{r_i^{*1}}]$ (during interval $[0, t_{r_i^{*1}}]$ if $i = 1$) and have pick-up location 0. Because the first request (r_l) in $\Re_2$ starts at 0 and starts after $\dot{t}_{r_i^{*1}}$, r_l and

r_i^{*1} are not in conflict. As any two consecutive requests in $\Re_2$ are not in conflict, reassigning all requests of $\Re_2$ to server s_1^* is valid. From this it follows that R^* is still a valid solution with the same profit after the reassignment. For simplification of the analysis, we reassign the requests in R^* and R' based on the above process until both request r_i^{*0} and r_i^{*1} are assigned to the same server for $i \leq k_1^*$, and $r_i'^0$ and $r_i'^1$ are assigned to the same server for $i \leq k_1'$. Note that this reassignment does not affect the validity of R^* and R', and P_{R^*} and $P_{R'}$ do not change.

We claim that R^* can be transformed into R' without reducing its profit, thus showing that $P_{R^*} = P_{R'}$. As SG accepts the request r_γ which is the first acceptable request that starts at location 0 and the request r_δ which is the first acceptable request that starts at location 1 (r_δ is the first request in R that starts at location 1 and starts after $\dot{t}_{r_\gamma}$), it is clear that $t_{r_1'^0} \leq t_{r_1^{*0}}$ and $t_{r_1'^1} \leq t_{r_1^{*1}}$. If $r_1'^0 \neq r_1^{*0}$, we can replace r_1^{*0} by $r_1'^0$ in R^{*0}, and if $r_1'^1 \neq r_1^{*1}$, we can replace r_1^{*1} by $r_1'^1$ in R^{*1}.

Now assume, that R' and R^* are identical with respect to $2i$ requests (i requests in R^{*0} and i requests R'^0, and i requests in R^{*1} and i requests in R'^1, where $1 \leq i \leq k_1^*$), and both requests r_j^{*0} and r_j^{*1} are assigned to the same server for $1 \leq j \leq i$.

Without loss of generality, suppose $r_i'^1$ is assigned to s_1^* by OPT and $r_i'^1$ is assigned to s_1' by SG. Observe that s_1^* and s_1' are at location 0 at time $\dot{t}_{r_i'^1}$. We claim that s_2^* (resp. s_2') is at location 0 at time $\dot{t}_{r_{i-1}'^1}$ and $\dot{t}_{r_{i-1}'^1} \leq t_{r_{i+1}^{*0}}$. If $r_{i-1}'^1$ is assigned to s_2^* (resp. s_2'), s_2^* (resp. s_2') is at location 0 at time $\dot{t}_{r_{i-1}'^1}$ and $\dot{t}_{r_{i-1}'^1} = \min\{\dot{t}_{r_{i-1}'^1}, \dot{t}_{r_i'^1}\} \leq t_{r_{i+1}^{*0}}$. If $r_{i-1}'^1$ is assigned to s_1^* (resp. s_1'), we have $\dot{t}_{r_{i-1}'^1} \leq t_{r_i'^0} \leq t_{r_{i+1}^{*0}}$. Observe that OPT does not accept any request which starts in period $(t_{r_{i-1}'^1}, \dot{t}_{r_{i-1}'^1})$. As both SG servers, s_1' and s_2', and OPT servers, s_1^* and s_2^*, accept requests with alternating pick-up location and starting with a request with pick-up location 0, either the pick-up location of the request r_o (where r_o is the last request which starts at or before $t_{r_{i-1}'^1}$ and is assigned to s_2^* (resp. s_2')) is 1, or s_2^* (resp. s_2') does not accept any request which starts before $t_{r_{i-1}'^1}$. Hence s_2^* (resp. s_2') is at location 0 at time $\dot{t}_{r_o}$ ($\leq \dot{t}_{r_{i-1}'^1}$), or at time 0 if r_o does not exist, and stays at that location until time $\dot{t}_{r_{i-1}'^1}$.

If there are two requests r_{i+1}^{*0} and r_{i+1}^{*1}, as s_2' is at location 0 at $\dot{t}_{r_{i-1}'^1}$ and $\dot{t}_{r_{i-1}'^1} \leq t_{r_{i+1}^{*0}}$, there must also be two requests $r_{i+1}'^0$ and $r_{i+1}'^1$ with $t_{r_{i+1}'^0} \leq t_{r_{i+1}^{*0}}$ and $t_{r_{i+1}'^1} \leq t_{r_{i+1}^{*1}}$, as SG could accept r_{i+1}^{*0} and r_{i+1}^{*1} by s_2'. We can replace r_{i+1}^{*0} and r_{i+1}^{*1} by $r_{i+1}'^0$ and $r_{i+1}'^1$ in R^{*0} and R^{*1}. If $k_0^* = k_1^*$, the claim thus follows by induction.

If $k_0^* \neq k_1^*$ ($k_0^* - k_1^* = 1$ or $k_0^* - k_1^* = 2$), then R^{*1} is already identical to R'^1, and the first k_1^* requests of R^{*0} are already identical to the first k_1^* requests of R'^0 by the argument above. If $k_0^* - k_1^* = 1$, there is a request $r_{k_1^*+1}^{*0}$. As s_2' is at location 0 at $\dot{t}_{r_{k_1^*-1}'^1}$ and $\dot{t}_{r_{k_1^*-1}'^1} \leq t_{r_{k_1^*+1}^{*0}}$, there must also be one request $r_{k_1^*+1}'^0$ with $t_{r_{k_1^*+1}'^0} \leq t_{r_{k_1^*+1}^{*0}}$, as SG could accept $r_{k_1^*+1}^{*0}$ by s_2'. We can replace $r_{k_1^*+1}^{*0}$ by $r_{k_1^*+1}'^0$ in R^{*0}, making R^{*0} identical to R'^0. If $k_0^* - k_1^* = 2$, there are two requests $r_{k_1^*+1}^{*0}$ and $r_{k_1^*+2}^{*0}$. Note that $r_{k_1^*+1}^{*0}$ and $r_{k_1^*+2}^{*0}$ must be assigned to different servers by OPT as $k_0^* - k_1^* = 2$. Recall that s_1^* is at location 0 at $\dot{t}_{r_{k_1^*}'^1}$, and s_2^* is at location 0 at $\dot{t}_{r_{k_1^*-1}'^1}$. Hence $t_{r_{k_1^*+1}^{*0}} \geq \dot{t}_{r_{k_1^*-1}'^1}$ and $t_{r_{k_1^*+2}^{*0}} \geq \dot{t}_{r_{k_1^*}'^1}$. As s_1' is at location 0 at $\dot{t}_{r_{k_1^*}'^1}$ and s_2' is at location 0 at $\dot{t}_{r_{k_1^*-1}'^1}$, there must also be two requests $r_{k_1^*+1}'^0$ and $r_{k_1^*+2}'^0$ with $t_{r_{k_1^*+1}'^0} \leq t_{r_{k_1^*+1}^{*0}}$ and $t_{r_{k_1^*+2}'^0} \leq t_{r_{k_1^*+2}^{*0}}$, as SG could accept $r_{k_1^*+1}^{*0}$ by s_2', and accept $r_{k_1^*+2}^{*0}$ by s_1'. We can replace $r_{k_1^*+1}^{*0}$ and $r_{k_1^*+2}^{*0}$ by $r_{k_1^*+1}'^0$ and $r_{k_1^*+2}'^0$ in R^{*0}, making R^{*0} identical to R'^0. As R^{*1} is already identical to R'^1, R^* is identical to R' because $R^* = R^{*0} \bigcup R^{*1}$ and $R' = R'^0 \bigcup R'^1$. ◀

▶ **Theorem 3.** *Algorithm SG is 2-competitive for 2S2L if $c = 0$.*

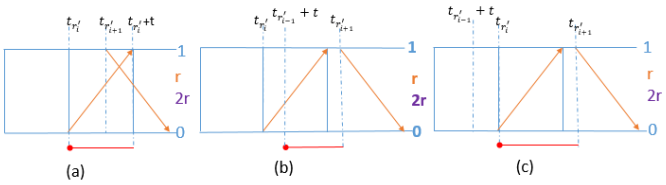

Figure 1 $c = 0$, $|R'| = k > 1$, $1 \le i \le k$.

Proof. We partition the time horizon $[0, \infty)$ into intervals (periods) that can be analyzed independently. Period i, for $1 < i < k$, is the interval $[\max\{\dot{t}_{r'_{i-1}}, t_{r'_i}\}, \max\{\dot{t}_{r'_i}, t_{r'_{i+1}}\})$. Period 1 is $[0, \max\{\dot{t}_{r'_1}, t_{r'_2}\})$, and period k is $[\max\{\dot{t}_{r'_{k-1}}, t_{r'_k}\}, \infty)$. (If $k = 1$, there is only a single period $[0, \infty)$.) Set $t_{r'_{k+1}} = \infty$ and $\dot{t}_{r'_0} = 0$. Let R^*_i denote the set of requests accepted by OPT that start in period i, for $1 \le i \le k$. For all $1 \le i \le k$, if $\max\{\dot{t}_{r'_{i-1}}, t_{r'_i}\} \ge \max\{\dot{t}_{r'_i}, t_{r'_{i+1}}\}$, $R^*_i = \emptyset$, and hence $P_{R^*_i} = 0$. Denote $R'_i = \{r'_i\}$ for $1 \le i \le k$.

For $1 < i \le k$, r'_i starts at time $t_{r'_i}$ and the first request of R^*_i starts during the interval $[\max\{\dot{t}_{r'_{i-1}}, t_{r'_i}\}, \max\{\dot{t}_{r'_i}, t_{r'_{i+1}}\})$ (or the interval $[\max\{\dot{t}_{r'_{k-1}}, t_{r'_k}\}, \infty)$ if $i = k$). Furthermore, r'_1 is the first acceptable request in R, and so the first request of R^*_1 cannot start before $t_{r'_1}$. Hence, for all $1 \le i \le k$, the first request in R^*_i cannot start before $t_{r'_i}$.

We bound the competitive ratio of SG by analyzing each period independently. As $R' = \bigcup_i R'_i$ and $R^* = \bigcup_i R^*_i$, it is clear that $P_{R^*}/P_{R'} \le \alpha$ follows if we can show that $P_{R^*_i}/P_{R'_i} \le \alpha$ for all i, $1 \le i \le k$. For $1 \le i \le k$ we distinguish the following cases in order to bound $P_{R^*_i}/P_{R'_i}$. As $R'_i = \{r_i\}$, $P_{R'_i} = r$ (because $c = 0$). We need to show $P_{R^*_i} \le 2r$.

Case 1: $k = 1$. Without loss of generality, suppose r'_1 is assigned to s'_1. We claim R^* contains at most one request (r'_1). Assume that R^* contains at least two requests and the second request is r_o. As s'_2 is at location 0 at time 0, r_o would be acceptable to SG by s'_2. Hence, there cannot be such a request r_o that starts in period $[0, \infty)$. As we have shown that OPT can accept at most one request (r'_1), we get that $\frac{P_{R^*}}{P_{R'}} \le \frac{r}{r} < 2$.

Case 2: $k > 1$. For all $1 \le i \le k$, we claim that R^*_i contains at most two requests (each server accepts at most one request). Assume that s^*_q ($q \in \{1, 2\}$) accepts at least two requests. Let r_o be the second request (in order of start time) which is assigned to s^*_q in R^*_i. We distinguish three sub-cases. Without loss of generality, suppose r'_i is assigned to s'_1.

Case 2.1: $\dot{t}_{r'_i} > t_{r'_{i+1}}$ (Fig. 1.a shows an example). If $i > 1$, the period i, which is the period $[\max\{\dot{t}_{r'_{i-1}}, t_{r'_i}\}, \max\{\dot{t}_{r'_i}, t_{r'_{i+1}}\}) = [\max\{\dot{t}_{r'_{i-1}}, t_{r'_i}\}, \dot{t}_{r'_i})$, has length less than t. If $i = 1$, note that the period $[t_{r'_1}, \max\{\dot{t}_{r'_1}, t_{r'_2}\}) = [t_{r'_1}, \dot{t}_{r'_1})$ has length less than t and no request of R^*_1 can start before $t_{r'_1}$ during period 1, $[0, \max\{\dot{t}_{r'_1}, t_{r'_2}\})$. Therefore, each server can accept at most one request that starts during period i, and hence R^*_i contains at most two requests.

Case 2.2: $\dot{t}_{r'_i} \le t_{r'_{i+1}}$ and $\dot{t}_{r'_{i-1}} > t_{r'_i}$ (Fig. 1.b shows an example). Observe that s'_1 is at $p_{r'_i}$ at $t_{r'_i}$. As the drop-off time of r'_{i-1} is later than the pick-up time of r'_i, r'_{i-1} must be assigned to s'_2 and we have that s'_2 is at $\dot{p}_{r'_{i-1}}$ at $\dot{t}_{r'_{i-1}}$. As the first request in R^*_i does not start before $\dot{t}_{r'_{i-1}}$, we have $t_{r_o} \ge \dot{t}_{r'_{i-1}} + t$. This means that r_o would be acceptable to s'_2. Therefore, SG accepts either r_o or another request starting before t_{r_o}, and that request becomes r'_{i+1}. Hence, there cannot be such a request r_o that starts in period i.

Case 2.3: $\dot{t}_{r'_i} \le t_{r'_{i+1}}$ and $\dot{t}_{r'_{i-1}} \le t_{r'_i}$ (Fig. 1.c shows an example). As the drop-off time of r'_{i-1} is earlier than the pick-up time of r'_i, s'_2 is at the drop-off location of the request r_l (where r_l denotes the latest request that starts at or before $t_{r'_i}$ and is assigned to s'_2;

if there is no such request, let r_l be a dummy request with $\dot{t}_{r_l} = 0$ and $\dot{p}_{r_l} = 0$) at $\dot{t}_{r_l}$ and $\dot{t}_{r_l} \leq \dot{t}_{r'_{i-1}} \leq t_{r'_i}$. Observe that s'_2 does not accept any request which starts during period $[t_{r'_i}, \dot{t}_{r'_i})$, s'_2 does not start to move before $t_{r'_i}$ for serving the next request, and hence s'_2 is at $\dot{p}_{r_l}$ (0 or 1) at $t_{r'_i}$. As the first request in R^*_i does not start before $t_{r'_i}$, we have $t_{r_o} \geq t_{r'_i} + t$. This means that r_o would be acceptable to s'_2. Therefore, SG accepts either r_o or another request starting before t_{r_o}, and that request becomes r'_{i+1}. Hence, there cannot be such a request r_o that starts in period i.

As we have shown that R^*_i contains at most two requests, we get that $P_{R^*_i} \leq 2r$. Since $P_{R'_i} = r$, we have $P_{R^*_i}/P_{R'_i} \leq 2r/r = 2$. The theorem follows. ◀

▶ **Lemma 4.** *When $0 < c < r$, for all $1 < i \leq k$, one server of SG is at $p_{r'_i}$ at $t_{r'_i}$ and the other server of SG is at 0 or 1 at $\max\{\dot{t}_{r'_{i-1}}, t_{r'_i}\}$.*

Proof. For $1 < i \leq k$, without loss of generality, suppose r'_i is assigned to s'_1. Observe that s'_1 is at $p_{r'_i}$ at $t_{r'_i}$.

If $\dot{t}_{r'_{i-1}} > t_{r'_i}$, then r'_{i-1} must be assigned to s'_2, and hence s'_2 is at $\dot{p}_{r'_{i-1}}$ (0 or 1) at $\dot{t}_{r'_{i-1}}$ $(= \max\{\dot{t}_{r'_{i-1}}, t_{r'_i}\}$).

If $\dot{t}_{r'_{i-1}} \leq t_{r'_i}$, then s'_2 is at 0 or 1 at the drop-off time t' ($t' \leq \dot{t}_{r'_{i-1}}$) of the latest request which is assigned to s'_2 and starts at or before $t_{r'_i}$. (If no such request exists, s'_2 is at 0 at $t' = 0$.) Suppose r_f is the first request that starts at or after $t_{r'_i}$ and is served by s'_2. If r_f does not exist, then s'_2 does not move after $\dot{t}_{r'_{i-1}}$, and s'_2 is at 0 or 1 at $\max\{\dot{t}_{r'_{i-1}}, t_{r'_i}\}$ ($\dot{t}_{r'_{i-1}} \leq t_{r'_i}$). If r_f exists and r_f is accepted with cost, then $t_{r_f} - \dot{t}_{r'_i} \geq t$ ($\dot{t}_{r'_i} \leq \dot{t}_{r^n_f}$) because SG accepts a request r_j with cost only if the condition $t_{r_j} - \dot{t}_{r^n_j} \geq t$ is satisfied. That means s'_2 starts an empty move at or after $\dot{t}_{r'_i}$. If r_f exists and r_f is accepted without cost, then s'_2 starts to move at or after $t_{r'_i}$ ($t_{r_f} \geq t_{r'_i}$). Therefore s'_2 is at 0 or 1 at $t_{r'_i}$ $(= \max\{\dot{t}_{r'_{i-1}}, t_{r'_i}\})$. ◀

▶ **Lemma 5.** *When $0 < c < r$, for all $1 \leq i \leq k$, if r'_i is accepted with cost, then one server of SG is at $p_{r'_i}$ at $t_{r'_i}$ and the other server of SG is at $\dot{p}_{r'_i}$ at $t_{r'_i}$.*

Proof. For $1 \leq i \leq k$, without loss of generality, suppose r'_i is assigned to s'_1. Observe that s'_1 is at $p_{r'_i}$ at $t_{r'_i}$.

If $i = 1$, then $p_{r'_1} = 1$ and s'_2 is at $\dot{p}_{r'_1}$ (location 0) at time 0. Suppose r_o is the first request which is assigned to s'_2. If $p_{r_o} = 0$, then s'_2 starts to move at t_{r_o} ($\geq t_{r'_1}$), and hence s'_2 is at 0 at $t_{r'_i}$. If $p_{r_o} = 1$, then $t_{r_o} \geq \dot{t}_{r'_1} + t$ because by definition SG accepts a request r_j with cost only if the condition $t_{r_j} - \dot{t}_{r^n_j} \geq t$ is satisfied. Observe that s'_2 starts to move at $t_{r_o} - t$ ($\geq \dot{t}_{r'_1}$), and hence s'_2 is at 0 at $t_{r'_i}$.

If $1 < i \leq k$, s'_2 is at 0 or 1 at $\max\{\dot{t}_{r'_{i-1}}, t_{r'_i}\}$ according to Lemma 4. As r'_i is accepted with cost, $t_{r'_i} - \dot{t}_{r'_{i-1}} \geq t$ because SG accepts a request r_j with cost only if the condition $t_{r_j} - \dot{t}_{r^n_j} \geq t$ is satisfied, and hence $\max\{\dot{t}_{r'_{i-1}}, t_{r'_i}\} = t_{r'_i}$. We prove this lemma by contradiction. Assume that s'_2 is at $p_{r'_i}$ at $t_{r'_i}$. Note that r'_i is acceptable to SG by s'_2 without cost, and hence SG assigns r'_i to s'_2 because SG always assigns a request to the most economical server (Recall Algorithm 1). This contradicts our initial assumption that r'_i is assigned to s'_1. ◀

▶ **Lemma 6.** *When $0 < c < r$, for all $1 < i < k$, if r'_i is accepted without cost and r'_{i+1} is accepted with cost, then one server of SG is at $p_{r'_i}$ at $t_{r'_i}$, and the other server of SG is at $\dot{p}_{r'_i}$ at $\max\{\dot{t}_{r'_{i-1}}, t_{r'_i}\}$.*

Proof. For $1 < i < k$, without loss of generality, suppose r'_i is assigned to s'_1. Observe that s'_1 is at $p_{r'_i}$ at $t_{r'_i}$. According to Lemma 4, s'_2 is at 0 or 1 at $\max\{\dot{t}_{r'_{i-1}}, t_{r'_i}\}$. As r'_{i+1} is accepted with cost, $t_{r'_{i+1}} - \dot{t}_{r'_i} \geq t$ because SG accepts a request r_j with cost only if the

condition $t_{r_j} - \dot{t}_{r_j^n} \geq t$ is satisfied. Note that $p_{r'_{i+1}} = p_{r'_i}$, otherwise r'_{i+1} is acceptable to SG by s'_1 without cost.

We prove this lemma by contradiction. Assume that s'_2 is at $p_{r'_i}$ at $\max\{\dot{t}_{r'_{i-1}}, t_{r'_i}\}$. Suppose $r_f = r'_{i+1}$. Observe that $p_{r'_f} = p_{r'_i}$ and $t_{r'_f} \geq \dot{t}_{r'_i} + t \geq \max\{\dot{t}_{r'_{i-1}}, t_{r'_i}\}$. From this it follows that r'_f is acceptable to SG by s'_2 without cost, and hence SG assigns r'_f to s'_2 because SG always assigns a request to the most economical server (Recall Algorithm 1). This contradicts the statement that r'_{i+1} is accepted with cost. ◀

▶ **Lemma 7.** *When $0 < c < r$, for all $1 < i < k$, if r'_i is accepted without cost and r'_{i+1} is accepted with cost, then r'_{i-1} must be accepted without cost.*

Proof. For $1 < i < k$, without loss of generality, suppose r'_{i-1} is assigned to s'_1. Observe that s'_1 is at $p_{r'_{i-1}}$ at $t_{r'_{i-1}}$ (and is at $\dot{p}_{r'_{i-1}}$ at $\dot{t}_{r'_{i-1}}$). We prove this lemma by contradiction. Assume r'_{i-1} is accepted with cost. According to Lemma 5, s'_2 is at $\dot{p}_{r'_{i-1}}$ at $t_{r'_{i-1}}$. As r'_i is accepted without cost, the pick-up location of r'_i is $\dot{p}_{r'_{i-1}}$. Suppose $r_f = r'_{i+1}$. Observe that $t_{r_f} \geq \dot{t}_{r'_i} + t$ (because r_f is accepted with cost) and $p_{r_f} = p_{r'_i} = \dot{p}_{r'_{i-1}}$ (otherwise, the server that has served r'_i could accept r_f without cost).

If r'_i is assigned to s'_1, then s'_2 does not accept any request which starts in period $[\max\{\dot{t}_{r'_{i-2}}, t_{r'_{i-1}}\}, t_{r_f})$, and hence s'_2 is at $\dot{p}_{r'_{i-1}}$ in period $[\max\{\dot{t}_{r'_{i-2}}, t_{r'_{i-1}}\}, t_{r_f} - t)$. If r'_i is assigned to s'_2, then s'_1 does not accept any request which starts in period $[\dot{t}_{r'_{i-1}}, t_{r_f})$, and hence s'_1 is at $\dot{p}_{r'_{i-1}}$ in period $[\dot{t}_{r'_{i-1}}, t_{r_f} - t)$. As r_f is released and $\tilde{t}_{r_f} = t_{r_f} - a \leq t_{r_f} - t$, server s'_q (for a $q \in \{1, 2\}$) is at $\dot{p}_{r'_{i-1}}$ and does not plan to move, hence r_f is acceptable to SG by s'_q without cost. From this it follows that r_f will be accepted by SG without cost because SG always assigns a request to the most economical server. This contradicts the statement that r'_{i+1} is accepted with cost. ◀

For simplification of the analysis, we suppose that the OPT servers make an empty movement only if they do so in order to serve a request r_i such that the pick-up location of r_i is the pick-up location of the previous request which is assigned to the same server, or the pick-up location is 1 if r_i is the first request which is assigned to a server s^*_q ($q \in \{1, 2\}$), and we suppose that for all such requests r_i ($r_i \in R^*$), the OPT server serving r_i makes an empty movement between $t_{r_i} - t$ and t_{r_i}. This simplification does not affect the validity of R^*, and does not decrease P_{R^*}.

▶ **Theorem 8.** *Algorithm SG is 2-competitive for 2S2L if $0 < c < r$.*

Proof. Assume that SG accepts k ($k = |R'|$) requests. We partition the time horizon $[0, \infty)$ into k' ($1 \leq k' \leq k$) intervals (periods) that can be analyzed independently. We partition the time horizon based on Algorithm 2, in such a way that all requests in the first period are accepted with cost (if r'_1 is accepted with cost), and exactly one request of each period (except the first period if r'_1 is accepted with cost), the first request of each period, is accepted without cost. Denote the request number in R' (in order of starting time) of the first request of period j ($1 \leq j \leq k'$) by l_j. For $1 < j < k'$, SG j period is $[t_{r'_{l_j}}, t_{r'_{l_{j+1}}})$. SG 1 period is $[0, t_{r'_{l_2}})$ and SG k' period is $[t_{r'_{l_{k'}}}, \infty)$ (If $k' = 1$, there is only a single period $[0, \infty)$). We set $l_{k'+1} = k + 1$, $t_{r'_0} = 0$ and $t_{r'_{k+1}} = \infty$. Let R'_j ($1 \leq j \leq k'$) denote the set of requests accepted by SG that start in SG j period. For $1 < j \leq k'$, if $t_{r'_{l_{j-1}}} = t_{r'_{l_j}}$, let $R'_{j-1} = \{r'_{l_{j-1}}\}$ and $R'_j = \{r'_{l_j}, r'_{l_j+1}, ..., r'_{l_{j+1}-1}\}$. Note that there are exactly $l_{j+1} - l_j$ ($l_{j+1} - l_j \geq 1$) requests in R'_j ($1 \leq j \leq k'$), and $R'_j = \{r'_{l_j}, r'_{l_j+1}, ..., r'_{l_{j+1}-1}\}$.

For all $1 < j \leq k'$, we have the following property: if $|R'_j| = 1$, then r'_{l_j} is accepted without cost; if $|R'_j| > 1$, then r'_{l_j} is accepted without cost, the remaining requests in R'_j

Algorithm 2 Partition Rule (PR).

Initialization: $k = |R'|$, $k' = 1$, $j = 1$, $l_j = j$ for all $1 \le j \le k$.
For $i = 2$ to k
if r'_i is accepted without cost then
$j = j + 1$, $l_j = i$;
$k' = j$, $l_{k'+1} = k + 1$.

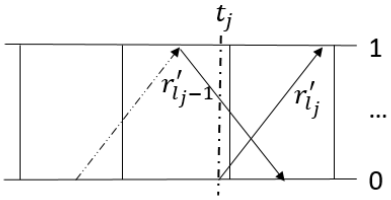

Figure 2 An example of t_j.

are accepted with cost. For $j = 1$, if $r'_1 (= r'_{l_1})$ is accepted with cost, all requests in R'_1 are accepted with cost; if r'_1 is accepted without cost, then except r'_1 all requests in R'_1 are accepted with cost.

▶ **Definition 9.** For $1 < j \le k'$, t_j is defined as follows: $t_j = t_{r'_{l_j}}$ if r'_{l_j-1} is accepted with cost, r'_{l_j} is accepted without cost, $\dot{t}_{r'_{l_j-1}} > t_{r'_{l_j}}$ and $\dot{p}_{r'_{l_j-1}} = p_{r'_{l_j}}$ (Fig. 2 shows an example). Otherwise, $t_j = \max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$. $t_{k'+1} = t_{r'_{k+1}} = \infty$.

For $1 < j \le k'$, $t_{j+1} = t_{r'_{l_{j+1}}}$ or $t_{j+1} = \max\{\dot{t}_{r'_{l_{j+1}-1}}, t_{r'_{l_{j+1}}}\}$, and $t_j = t_{r'_{l_j}}$ or $t_j = \max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$. Because $t_{r'_{l_j}} \le t_{r'_{l_{j+1}}}$ and $\dot{t}_{r'_{l_j-1}} \le t_{r'_{l_{j+1}}}$ (if r'_{l_j-1} and r'_{l_j} are assigned to the same server, then $\dot{t}_{r'_{l_j-1}} \le t_{r'_{l_j}}$; and if r'_{l_j-1} and r'_{l_j} are assigned to different servers, then $\dot{t}_{r'_{l_j-1}} \le t_{r'_{l_{j+1}}}$), $t_j \le t_{j+1}$ if $t_j = \max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$ and $t_{j+1} = t_{r'_{l_{j+1}}}$. As $t_j \le \max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$ and $t_{j+1} \ge t_{r'_{l_{j+1}}}$, we have that $t_j \le t_{j+1}$ always holds. For $1 < j \le k'$, OPT period j is defined as $[t_j, t_{j+1})$. OPT period 1 is defined as $[0, t_2)$ (If $k' = 1$, there is only a single period $[0, \infty)$). Let R^*_j denote the set of requests accepted by OPT that start in OPT period j, and $R^*_i = \emptyset$ if $t_j = t_{j+1}$.

For all $1 < j \le k'$, r'_{l_j} starts at time $t_{r'_{l_j}}$ and the first request of R^*_j starts during the interval $[t_j, t_{j+1})$ where $t_j = t_{r'_{l_j}}$ or $t_j = \max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$ (recall the definition of t_j). Furthermore, r'_1 is the first acceptable request in R, and so the first request of R^*_1 cannot start before r'_1. Hence, for all $1 \le j \le k'$, the first request in R^*_j cannot start before $t_{r'_{l_j}}$.

We bound the competitive ratio of SG by analyzing each period independently. As $R' = \bigcup_{j=1}^{k'} R'_j$ and $R^* = \bigcup_{j=1}^{k'} R^*_j$, it is clear that $P_{R^*}/P_{R'} \le \alpha$ follows if we can show that $P_{R^*_j}/P_{R'_j} \le \alpha$ for all $1 \le j \le k'$. For $1 \le j \le k'$, if $t_j = t_{j+1}$, then $R^*_i = \emptyset$ and hence $P_{R^*_i} = 0$. Otherwise, for $1 \le j \le k'$ we distinguish the following cases in order to bound $P_{R^*_j}/P_{R'_j}$.

Case 1: $j = 1$. The first request of SG period 1 is r'_1. Without loss of generality, suppose r'_1 is assigned to s'_1.

Case 1.1: r'_1 is accepted with cost. Note that all requests in R'_j are accepted with cost and $P_{R'_1} = (l_2 - l_1)(r - c)$ (if $k' = 1$, then $P_{R'} = k(r - c)$). Observe that $p_{r'_i} = 1$ $(1 \le i < l_2)$ and all requests in R'_1 are assigned to s'_1 by the definition of Algorithm 1. As r'_{l_2-1} is accepted with cost, one server is at $p_{r'_{l_2-1}}$ at $t_{r'_{l_2-1}}$ (and this server is at $\dot{p}_{r'_{l_2-1}}$ at $\dot{t}_{r'_{l_2}-1}$),

and the other server is at $\dot{p}_{r'_{l_2-1}}$ at $t_{r'_{l_2-1}}$ (by Lemma 5). As r'_{l_2} is accepted without cost, we have $\dot{p}_{r'_{l_2-1}} = p_{r'_{l_2}}$. If $k' = 1$, $t_2 = \infty$. If $k' > 1$, then $t_2 = t_{r'_{l_2}}$: if $\dot{t}_{r'_{l_2-1}} > t_{r'_{l_2}}$, $t_2 = t_{r'_{l_2}}$ because $p_{r'_{l_2}} = \dot{p}_{r'_{l_2-1}}$, r'_{l_2-1} is accepted with cost and r'_{l_2} is accepted without cost; if $\dot{t}_{r'_{l_2-1}} \leq t_{r'_{l_2}}$, $t_2 = \max\{\dot{t}_{r'_{l_2-1}}, t_{r'_{l_2}}\} = t_{r'_{l_2}}$. As s'_2 does not accept any request which starts before $t_{r'_{l_2}}$ and s'_2 would not accept any request with cost which starts in period $[t_{r'_{l_2}}, \dot{t}_{r'_{l_2}})$ (Recall that Algorithm 1 accepts a request r_j with cost only if $t_{r_j} - \dot{t}_{r^n_j} \geq t$ is satisfied.), s'_2 is at 0 in period $[0, t_{r'_{l_2}}]$. We claim that R^*_j only contains requests which start at 1. Otherwise, the request is acceptable to SG by s'_2 without cost. Assume that R^*_j contains a request r_o which start at location 0. As $t_{r_o} \leq t_2 = t_{r'_{l_2}}$, r_o is acceptable to SG by s'_2 without cost. Therefore, SG accepts either r_o or another request starting before t_{r_o}, and that request becomes r'_{l_2}. Hence, there cannot be such a request r_o in R^*_j.

Note that each server of OPT does not accept any request which starts in period $[0, t_{r'_1})$. For all $l_1 \leq i \leq l_2 - 2$, we claim that each server of OPT can accept at most one request which starts during period $[t_{r'_i}, t_{r'_{i+1}})$ ($l_1 \leq i \leq l_2 - 2$), or period $[t_{r'_{l_2-1}}, t^*)$ (if $k' > 1$, $t^* = t_{r'_{l_2}}$; if $k' = 1$, $t^* = t_{r'_k} + 2t$). Assume that s^*_q ($q \in \{1, 2\}$) accepts at least two requests in one of those periods. Let r_o be the second request (in order of start time) which is assigned to s^*_q and starts during period $[t_{r'_i}, t_{r'_{i+1}})$ ($l_1 \leq i \leq l_2 - 2$) or period $[t_{r'_{l_2-1}}, t^*)$. As the request does not start before $t_{r'_i}$ ($l_1 \leq i \leq l_2 - 1$), we have $t_{r_o} \geq t_{r'_i} + 2t$. r_o is acceptable to SG with cost. Therefore, SG accepts either r_o or another request starting before t_{r_o}, and that request becomes r'_{i+1} ($l_1 \leq i < l_2$). Hence, there cannot be such a request r_o that starts during period $[t_{r'_i}, t_{r'_{i+1}})$ ($l_1 \leq i \leq l_2 - 2$) or period $[t_{r'_{l_2-1}}, t^*)$. Therefore OPT can accept at most $2(l_2 - l_1)$ ($= 2(l_2 - 2 - l_1 + 1 + 1)$) requests that start during period $[t_{r'_1}, t^*)$.

When $k' = 1$, we claim that OPT does not accept any request which starts in period $[t^*, \infty)$. Without loss of generality we assume that OPT accepts at least one request. Let r_o be the request in R^*_1 that starts during period $[t^*, \infty)$. As $t_{r_o} \geq t_{r'_k} + 2t$. r_o is acceptable to SG. Therefore, SG accepts either r_o or another request starting before t_{r_o}, and that request becomes r'_{k+1}. Hence, there cannot be such a request r_o that starts in period $[t^*, \infty)$.

As we have shown that R^*_j contains at most $2(l_2 - l_1)$ requests and the pick-up locations of them are the same (location 1), we get that $P_{R^*_j} \leq 2(l_2 - l_1)(r - c)$. Since $P_{R'_j} = (l_2 - l_1)(r - c)$, we have $P_{R^*_j}/P_{R'_j} \leq 2(l_2 - l_1)(r - c)/((l_2 - l_1)(r - c)) = 2$.

Case 1.2: r'_1 is accepted without cost. If $k = 1$, then $k' = 1$, s'_2 is at 0 in period $[0, \infty)$. If $k > 1$, we claim that r'_2 is also accepted without cost. Assume that r'_2 is accepted with cost, we have $t_{r'_2} - \dot{t}_{r'_1} > t$ because Algorithm 1 accepts a request r_j with cost only if $t_{r_j} - \dot{t}_{r^n_j} \geq t$ is satisfied. If $p_{r'_2} = 0$, r'_2 is acceptable to SG by s'_2 without cost; if $p_{r'_2} = 1$, r'_2 is acceptable to SG by s'_1 without cost. Therefore s'_2 must be accepted by SG without cost because by definition (see Algorithm 1) SG always assigns a request to the most economical server. This contradicts the assumption that r'_2 is accepted with cost. Observe that $t_2 = \max\{\dot{t}_{r'_1}, t_{r'_2}\}$ (Recall from the definition of t_2 that $t_2 = t_{r'_2}$ only if r'_1 is accepted with cost), $|R'_1| = 1$ and hence $P_{R'_1} = r$. As s'_2 does not accept any request which starts before $t_{r'_2}$ and s'_2 would not accept any request with cost which starts in period $[t_{r'_2}, \dot{t}_{r'_2})$ (Recall that Algorithm 1 accepts a request r_j with cost only if $t_{r_j} - \dot{t}_{r^n_j} \geq t$ is satisfied.), s'_2 is at 0 in period $[0, t_{r'_2}]$.

We claim that R^*_1 contains at most two requests (each server serves at most one request). Assume that s^*_q ($q \in \{1, 2\}$) accepts at least two requests. Let r_o be the second request (in order of start time) which is assigned to s^*_q in R^*_1. As the first request in R^*_1 does not

start before $t_{r'_1}$, we have $t_{r_o} \geq t_{r'_1} + t$. If $p_{r_o} = \dot{p}_{r_1}$, r_o is acceptable to SG by s'_1 without cost; if $p_{r_o} = p_{r_1}$, r_o is acceptable to SG by s'_2 without cost. Hence, there cannot be such a request in R^*_1. Since $P_{R'_1} = r$, we have $P_{R^*_1} \leq 2r$, and hence $P_{R^*_1}/P_{R'_1} \leq 2r/r = 2$.

Case 2: $j > 1$ $(1 < j \leq k')$. The first request of SG period j is r'_{l_j}.Without loss of generality, suppose r'_{l_j} is assigned to s'_1. We distinguish the following cases based on $|R'_j|$.

Case 2.1: $|R'_j| = 1$. Note that r'_{l_j} is accepted without cost. We distinguish two sub-cases.

(1) $\dot{t}_{r'_{l_j}} > t_{r'_{l_{j+1}}}$. Because r'_{l_j} $(= r'_{l_{j+1}-1})$ is accepted without cost, $t_{j+1} = \max\{\dot{t}_{r'_{l_j}}, t_{r'_{l_{j+1}}}\} = \dot{t}_{r'_{l_j}}$ (Recall that $t_{j+1} = t_{r'_{l_{j+1}}}$ only if $r'_{l_{j+1}-1}$ is accepted with cost by the definition of t_{j+1}). As OPT period j $[t_j, t_{j+1})$ has length less than t ($t_j = \max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$ or $t_j = t_{r'_{l_j}}$), each server of OPT can accept at most one request in R^*_j, and hence R^*_j contains at most two requests.

(2) $\dot{t}_{r'_{l_j}} \leq t_{r'_{l_{j+1}}}$ $(t_{r'_{l_{j+1}}} = \infty$ if $j = k')$. Note that $t_{j+1} = t_{r'_{l_{j+1}}}$. There are two sub-cases based on the position of s'_2 at $\max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$ (recall that by Lemma 4, s'_2 is at $p_{r'_{l_j}}$ or $\dot{p}_{r'_{l_j}}$ at time $\max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$).

The first sub-case is that s'_2 is at $p_{r'_{l_j}}$ at $\max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$. We claim that R^*_j contains at most two requests (each server serves at most one request). Assume that s^*_q $(q \in \{1, 2\})$ accepts at least two requests. Let r_o be the second request (in order of start time) which is assigned to s^*_q in R^*_j. As the requests in R^*_j do not start before $t_{r'_{l_j}}$, we have $t_{r_o} \geq t_{r'_{l_j}} + t$. If $p_{r_o} = \dot{p}_{r'_{l_j}}$, r_o is acceptable to SG by s'_1 without cost; if $p_{r_o} = p_{r'_{l_j}}$, r_o is acceptable to SG by s'_2 without cost. Therefore, SG accepts either r_o or another request starting before t_{r_o}, and that request becomes r'_{l_j+1}. Hence, there cannot be such a request r_o that starts in OPT period j.

The second sub-case is that s'_2 is at $\dot{p}_{r'_{l_j}}$ at $\max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$. Note that $t_j = \max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$ (Recall from the definition of t_j that $t_j = t_{r'_{l_j}}$ only if $\dot{t}_{r'_{l_j-1}} > t_{r'_{l_j}}$ and $\dot{p}_{r'_{l_j-1}} = p_{r'_{l_j}}$ are satisfied. From this it follows that r'_{l_j-1} must be assigned to s'_2, that means s'_2 is at $\dot{p}_{r'_{l_j-1}}$ $(= p_{r'_{l_j}})$ at $\dot{t}_{r'_{l_j-1}}$ $(= \max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\})$. This contradicts the initial assumption that s'_2 is at $\dot{p}_{r'_{l_j}}$ at $\max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$.). We claim that R^*_j contains at most two requests (each server serves at most one request) and the pick-up locations of these two requests are $p_{r'_{l_j}}$. Assume that R^*_j contains a request r_i which starts at $\dot{p}_{r'_{l_j}}$. As the requests in R^*_j cannot start before t_j $(t_j = \max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\})$, r_i is acceptable to s'_2 (without cost) as s'_2 is at $\dot{p}_{r'_{l_j}}$ at $\max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$. Hence, there cannot be such a request r_i that starts in OPT period j. Next assume that s^*_q $(q \in \{1, 2\})$ accepts at least two requests. Let r_i and r_o be the first and second request (in order of start time) which is assigned to s^*_q in R^*_j. As the requests in R^*_j do not start before $t_{r'_{l_j}}$ and the pick-up location of r_i and r_o both are $p_{r'_{l_j}}$, we have $t_{r_o} \geq t_{r'_{l_j}} + 2t$. If $p_{r_o} = \dot{p}_{r'_{l_j}}$, r_o is acceptable to SG by s'_1 without cost; if $p_{r_o} = p_{r'_{l_j}}$, r_o is acceptable to SG by s'_2 with cost. Therefore, SG accepts either r_o or another request starting before t_{r_o}, and that request becomes r'_{l_j+1} (if it is accepted without cost) or gets added to R'_j (if it is accepted with cost). Hence, there cannot be such a request r_o that starts in OPT period j.

As we have shown that R^*_j contains at most two requests, we get that $P_{R^*_j} \leq 2r$. Since $P_{R'_j} = r$, we have $P_{R^*_j}/P_{R'_j} \leq 2r/r = 2$.

Case 2.2: $|R'_j| > 1$. Note that r'_{l_j} is accepted without cost and r'_{l_j+1} is accepted with cost. We have that s'_2 is at $\dot{p}_{r'_{l_j}}$ at $\max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$ by Lemma 6, and that r'_{l_j-1} is accepted without

cost by Lemma 7. Hence, $t_j = \max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$ (recall from the definition of t_j that $t_j = t_{r'_{l_j}}$ only if r'_{l_j-1} is accepted with cost). As $r'_{l_{j+1}-1}$ is accepted with cost, one server is at $p_{r'_{l_{j+1}-1}}$ at $t_{l_{j+1}-1}$ (and this server is at $\dot{p}_{r'_{l_{j+1}-1}}$ at $\dot{t}_{r'_{l_{j+1}-1}}$), and the other server is at $\dot{p}_{r'_{l_{j+1}-1}}$ at $t_{r'_{l_{j+1}-1}}$ (Recall Lemma 5). As $r'_{l_{j+1}}$ is accepted without cost, we have $\dot{p}_{r'_{l_{j+1}-1}} = p_{r'_{l_{j+1}}}$. If $\dot{t}_{r'_{l_{j+1}-1}} > t_{r'_{l_{j+1}}}$ $(1 \le j < k')$, $t_{j+1} = t_{r'_{l_{j+1}}}$ according to the definition of t_s $(1 \le s \le k')$. If $\dot{t}_{r'_{l_{j+1}-1}} \le t_{r'_{l_{j+1}}}$ $(1 \le j < k')$, $t_{j+1} = \max\{\dot{t}_{r'_{l_{j+1}-1}}, t_{r'_{l_{j+1}}}\} = t_{r'_{l_{j+1}}}$. Hence, $t_{j+1} = t_{r'_{l_{j+1}}}$ $(1 \le j < k')$. Observe that if $j = k'$, $t_{j+1} = t_{r'_{l_{j+1}}} = \infty$.

We claim that R^*_j only contains requests which start at $p_{r'_{l_j}}$. Assume that R^*_j contains a request r_i which starts at $\dot{p}_{r'_{l_j}}$. As the first request in R^*_j cannot start before t_j, we have $t_{r_i} \ge t_j = \max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$. As s'_2 is at $\dot{p}_{r'_{l_j}}$ at $\max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}$ and s'_2 does not accept any request which starts in period $[\max\{\dot{t}_{r'_{l_j-1}}, t_{r'_{l_j}}\}, t_{r_i})$, and hence r_i is acceptable to SG by s'_2 without cost. This contradicts the property of R'_j that except r'_{l_j} all requests in R'_j are accepted with cost. Hence, there cannot be such a request r_i that starts in OPT period j.

We claim that each server of OPT can accept at most one request which starts in period $[t_j, t_{r'_{l_j+1}})$, or period $[t_{r'_i}, t_{r'_{i+1}})$ $(l_j+1 \le i \le l_{j+1}-2)$, or period $[t_{r'_{l_{j+1}-1}}, t^*)$ (if $1 \le j < k'$, $t^* = t_{r'_{l_{j+1}}}$; if $j = k'$, $t^* = t_{r'_k} + 2t$). Assume that s^*_q $(q \in \{1, 2\})$ accepts at least two requests in one of these periods. Let r_o be the second request (in order of start time) which is assigned to s^*_q and starts in one of these periods. As the requests in R^*_j that start in one of these periods do not start before the corresponding $t_{r'_i}$ $(l_j \le i \le l_{j+1} - 1)$ and have the same pick-up location $p_{r'_{l_j}}$, we have $t_{r_o} \ge t_{r'_{l_j}} + 2t$. r_o is acceptable to SG with cost. Therefore, SG accepts either r_o or another request starting before t_{r_o}, that request becomes r'_{i+1} $(l_j \le i \le l_{j+1} - 2)$, or we get a contradiction to $r'_{l_{j+1}-1}$ being the last request that is accepted with cost and starts in period $[t_{r'_{l_{j+1}-1}}, t^*)$ $(i = l_{j+1} - 1)$. Hence, there cannot be such a request r_o that starts in period $[t_j, t_{r'_{l_j+1}})$, or period $[t_{r'_i}, t_{r'_{i+1}})$ $(l_j + 1 \le i \le l_{j+1} - 1)$. Therefore OPT can accept at most $2(l_{j+1} - l_j)$ $(= 2(l_{j+1} - 2 - (l_j + 1) + 1 + 2))$ requests that start in period $[t_{r'_{l_{j+1}}}, t^*)$.

When $j = k'$, we claim that OPT does not accept any request which starts in period $[t^*, \infty)$. Without loss of generality we assume that OPT accepts at least one request. Let r_o be the request in R^*_j which starts during period $[t^*, \infty)$. As $t_{r_o} \ge t_{r'_k} + 2t$, r_o is acceptable to SG with cost. Therefore, SG accepts either r_o or another request starting before t_{r_o}, and that request becomes r'_{k+1}. Hence, there cannot be such a request r_o that starts in period $[t^*, \infty)$.

As we have shown that R^*_j contains at most $2(l_{j+1} - l_j)$ requests and the pick-up locations of them are the same $(p_{r'_{l_j}})$, we get that $P_{R^*_j} \le 2r + 2(l_{j+1} - l_j - 1)(r - c)$. Since $P_{R'_j} = r + (l_{j+1} - l_j - 1)(r - c)$, we have $P_{R^*_j}/P_{R'_j} \le (2r + 2(l_{j+1} - l_j - 1)(r - c))/(r + (l_{j+1} - l_j - 1)(r - c)) = 2$.

Because $P_{R^*_j}/P_{R'_j} \le 2$ holds for all $1 \le j \le k'$, we have $P_{R^*}/P_{R'} \le 2$. This proves the theorem. ◀

4 Conclusion

We have studied an on-line problem with two servers and two locations that is motivated by applications such as car sharing and taxi dispatching. The upper bounds for the 2S2L problem are all achieved by the smart greedy algorithm. A number of directions for future

work arise from this work. If there are k servers, does a kind of greedy algorithm still work well? Furthermore, it would be interesting to extend our results to the case of more than two locations. It would be interesting to determine how the constraints on the servers affect the competitive ratio for the general car-sharing problem with k servers and m locations.

Abstract

We show that the counting class LWPP [8] remains unchanged even if one allows a polynomial number of gap values rather than one. On the other hand, we show that it is impossible to improve this from polynomially many gap values to a superpolynomial number of gap values by relativizable proof techniques.

The first of these results implies that the Legitimate Deck Problem (from the study of graph reconstruction) is in LWPP (and thus low for PP, i.e., $\mathrm{PP}^{\text{Legitimate Deck}} = \mathrm{PP}$) if the weakened version of the Reconstruction Conjecture holds in which the number of nonisomorphic preimages is assumed merely to be polynomially bounded. This strengthens the 1992 result of Köbler, Schöning, and Torán [15] that the Legitimate Deck Problem is in LWPP if the Reconstruction Conjecture holds, and provides strengthened evidence that the Legitimate Deck Problem is not NP-hard.

We additionally show on the one hand that our main LWPP robustness result also holds for WPP, and also holds even when one allows both the rejection- and acceptance- gap-value targets to simultaneously be polynomial-sized lists; yet on the other hand, we show that for the #P-based analog of LWPP the behavior much differs in that, in some relativized worlds, even two target values already yield a richer class than one value does.

1 Introduction

Nothing is more natural than wanting to better understand an object by knowing what it can and cannot do. Whether wondering how fast a (rental?) car can go in reverse or wondering if $\mathrm{NP}^{\mathrm{NP}}$ can without loss of generality be assumed to ask at most one question per nondeterministic path (as it indeed can, as is implicit in the quantifier characterization [27, 30] of $\mathrm{NP}^{\mathrm{NP}}$), we both in life and as theoreticians want to find how robust things are.

We are often particularly happy when a class proves to be quite robust under definitional perturbations. Such robustness on one hand suggests that perhaps there is something broadly natural about the class, and on the other hand such robustness often makes it easier to put the class to use.

This paper shows that the counting classes LWPP and WPP, defined in 1994 in the seminal work of Fenner, Fortnow, and Kurtz [8] on gap-based counting classes, are quite robust. Even though their definitions are in terms of having the gap function (the difference between the number of accepting and rejecting paths of a machine) hit a single target value, we prove (in Section 3) that one can allow a list of up to polynomially many target values without altering the descriptive richness of the class, i.e., without changing the class.

We then apply this to the question of whether the Legitimate Deck Problem is in LWPP.

The Legitimate Deck Problem (a formal definition will be given in Section 4) is the decision problem of determining whether, given a multiset of (unlabeled) graphs, there exists a graph G such that that multiset is precisely (give or take isomorphisms) the multiset of one-node-deleted subgraphs of G (a.k.a. the *deck* of G) [17]. *The Reconstruction Conjecture* [13, 28] – which in the wake of the resolution of the Four-Color Conjecture was declared by the editorial board of the Journal of Graph Theory to be the foremost open problem in graph theory [7] – states that every graph with three or more nodes is uniquely determined (give or take isomorphisms) by its multiset of one-node-deleted subgraphs. The Legitimate Deck Problem was defined in 1978 by Nash-Williams [22], in his paper that framed the algorithmic/complexity issues related to reconstructing graphs – such as telling whether a given deck is legitimate (i.e., is the deck of some graph).

Our application of our LWPP robustness result to the question of whether the Legitimate Deck Problem is in LWPP is the following. The strongest previous evidence of the simplicity of the Legitimate Deck Problem is the 1992 result of Köbler, Schöning, and Torán [15] that the Legitimate Deck Problem is in LWPP (and thus is PP-low, i.e., $\mathrm{PP}^{\text{Legitimate Deck}} = \mathrm{PP}$) if the Reconstruction Conjecture (i.e., that each deck whose elements all have at least two nodes has at most *one* preimage, give or take isomorphisms) holds. Using this paper's main robustness result as a tool, Section 4 proves that the Legitimate Deck Problem is in LWPP (and thus is PP-low) if a weakened version of the Reconstruction Conjecture holds, namely, that each deck has at most *a polynomial number* of nonisomorphic preimages.

This weakened version is not known to be equivalent to the Reconstruction Conjecture itself. And so our result for the first time gives a path to proving that the Legitimate Deck Problem is PP-low that does not require one to, on the way, resolve the foremost open problem in graph theory [7].

We started this section by noting that it is natural to want to know both flexibilities and limitations of classes. Our main result is about flexibility: going from one target gap to instead a polynomial number. But are we leaving money on the table? Could we extend our result to slightly superpolynomial numbers of target gaps, or even to exponential numbers of target gaps? In Section 5 we note that if the robustness of LWPP were to hold up to exponentially many target gaps, then NP would be in LWPP and so would be PP-low (i.e., $\mathrm{PP}^{\mathrm{NP}} = \mathrm{NP}$); yet NP is widely suspected not to be PP-low. We also, by encoding nondeterministic oracle Turing machines by low-degree multivariate polynomials so as to capture the gap functions of those machines, show an oracle relative to which robustness fails for all superpolynomial numbers of target gaps; thus, no extension beyond this paper's polynomial-number-of-target-gaps robustness result for LWPP can be proven by a relativizable proof. And for the #P-based analogue of LWPP, in Section 6 we show that even allowing two target values yields, in some relativized worlds, a richer class than one

target value. We also (in the final part of Section 3) extend our main result to show that the simultaneous expansion to polynomial-sized lists of both the acceptance *and rejection* target-gap lists still, for LWPP and WPP, yields the classes LWPP and WPP.

To summarize: In this paper, we prove that LWPP and WPP are robust enough that they remain unchanged when their single target gap is allowed to be expanded to a polynomial-sized list; we apply this new robustness of LWPP to show that the PP-lowness of the Legitimate Deck Problem follows from a weaker hypothesis than was previously known; we show that our polynomial robustness of LWPP is optimal with respect to relativizable proofs; and we prove a number of related results on limitations and extensions.

2 Preliminaries

We first present the definitions of many of the counting classes that we will be speaking of, taking the definitions from the seminal paper of Fenner, Fortnow, and Kurtz [8].

▶ **Definition 2.1** ([8]).

1. For each nondeterministic polynomial-time Turing machine N, the function $\mathrm{acc}_N : \Sigma^* \to \mathbb{N}$ is defined such that for every $x \in \Sigma^*$, $\mathrm{acc}_N(x)$ equals the number of accepting computation paths of N on input x.
2. For each nondeterministic polynomial-time Turing machine N, the function $\mathrm{rej}_N : \Sigma^* \to \mathbb{N}$ is defined such that for every $x \in \Sigma^*$, $\mathrm{rej}_N(x)$ equals the number of rejecting computation paths of N on input x.
3. For each nondeterministic polynomial-time Turing machine N, the function $\mathrm{gap}_N : \Sigma^* \to \mathbb{Z}$ is defined such that for every $x \in \Sigma^*$,

$$\mathrm{gap}_N(x) = \mathrm{acc}_N(x) - \mathrm{rej}_N(x).$$

▶ **Definition 2.2** ([8]).

$$\mathrm{GapP} = \{\mathrm{gap}_N \mid N \text{ is a polynomial-time nondeterministic Turing machine}\}.$$

▶ **Definition 2.3** ([23, 8]). SPP is the class of all sets A such that there exists a GapP function g such that for all $x \in \Sigma^*$,

$$x \in A \Longrightarrow g(x) = 1$$
$$x \notin A \Longrightarrow g(x) = 0.$$

The following class, WPP, is potentially larger than SPP. Instead of the "target value" 1 for the case $x \in A$, we allow a target value $f(x)$, where f may be any polynomial-time computable function whose image does not contain 0. FP denotes the class of polynomial-time computable functions.

▶ **Definition 2.4** ([8]). WPP is the class of all sets A such that there exists a GapP function g and a function $f \in \mathrm{FP}$ that maps from Σ^* to $\mathbb{Z} - \{0\}$ such that for all $x \in \Sigma^*$,

$$x \in A \Longrightarrow g(x) = f(x)$$
$$x \notin A \Longrightarrow g(x) = 0.$$

The class LWPP is the same as WPP except that the "target function" f may depend on only the *length* of the input.

▶ **Definition 2.5** ([8]). LWPP is the class of all sets A such that there exists a GapP function g and a function $f \in \mathrm{FP}$ that maps from 0^* to $\mathbb{Z} - \{0\}$ such that for all $x \in \Sigma^*$,

$$x \in A \Longrightarrow g(x) = f(0^{|x|})$$
$$x \notin A \Longrightarrow g(x) = 0.$$

Here, as usual, for any $x \in \Sigma^*$, $|x|$ denotes the length of x, and for any $n \in \mathbb{N}$, 0^n is the string consisting of exactly n zeroes.

We now generalize the definition of LWPP to the case of having the target of the GapP function be, for members of the set, not a single value but a collection of values.

One might expect us to formalize this by simply having the polynomial-time computable "what is the target" function output a *list* of the nonzero-integer targets. That would work fine and be equivalent to what we are about to do, as long as we are dealing with lists having at most a polynomial number of elements. However, to be able to speak of even longer lists – as will be important in our negative results offsetting our main result – we use an indexing approach, as follows.

▶ **Definition 2.6.** Let r be any function mapping from $\mathbb{N}$ to $\mathbb{N}$. Then the class r-LWPP is the class of all sets A such that there exists a GapP function g and a function $f \in \mathrm{FP}$ that maps to $\mathbb{Z} - \{0\}$ such that for each $x \in \Sigma^*$,

$$x \in A \Longrightarrow \text{ there exists } i \in \{1, 2, \ldots, r(|x|)\} \text{ such that } g(x) = f(\langle 0^{|x|}, i\rangle)$$
$$x \notin A \Longrightarrow g(x) = 0.$$

The following class, *Poly*-LWPP, will be central to this paper: Our main result is that this class in fact equals LWPP. The "$+\,c$" in Definition 2.7 may seem strange at first. But without it we would have a boundary-case pathology at $n = 0$, namely, the class could not contain any set that contains the empty string.[1]

▶ **Definition 2.7.**

$$\textit{Poly}\text{-LWPP} = \bigcup_{c \in \mathbb{N}^+} (n^c + c)\text{-LWPP}.$$

It is easy to see that 1-LWPP = LWPP, and that, of course, more flexibility as to targets never removes sets from the class, i.e., speaking loosely for the moment as to notation (and the log case will not be defined or used again in this paper, but it is clear from context here what we mean by it; the exponential case's definition can be found in the full version of the paper [12]), 1-LWPP $\subseteq$ 2-LWPP $\subseteq$ 3-LWPP $\subseteq \cdots \subseteq$ *Log*-LWPP $\subseteq$ *Poly*-LWPP $\subseteq$ *Exp*-LWPP. As mentioned above, in this paper we will prove that the first five of these "$\subseteq$"s are in fact all equalities. We will also prove that the sixth "$\subseteq$" cannot be an equality unless NP is PP-low.

We now show that for every function r, r-LWPP is contained in the co-class of the well-known counting class $\mathrm{C}_{=}\mathrm{P}$.

---

[1] The "$+\,c$" in Definition 2.7 also, on its surface, would seem to make a difference at length 1, by allowing lists of size greater than one; however, one could work around that issue. In contrast, the exclusion of the empty string would not be avoidable if our class of polynomials were to be a class – such as n^c – such that all of its members evaluate to 0 at $n = 0$. In any case, our use of $n^c + c$ avoids any special worries at lengths 0 and 1. And since for every polynomial p there is a c such that $(\forall n \in \mathbb{N})[p(n) \leq n^c + c]$, using polynomials just of the form $n^c + c$ is in fact not a restriction.

▶ **Definition 2.8** ([25, 29]). $\mathrm{C_{=}P}$ is the class of all sets A such that there is a nondeterministic polynomial-time Turing machine N and a function $f \in \mathrm{FP}$ such that for each $x \in \Sigma^*$,

$$x \in A \iff \mathrm{acc}_N(x) = f(x).$$

More convenient for us is the following characterization of $\mathrm{C_{=}P}$ using GapP functions.

▶ **Theorem 2.9** ([8]). *For each $A \subseteq \Sigma^*$, $A \in \mathrm{C_{=}P}$ if and only if there exists a function $g \in \mathrm{GapP}$ such that for all $x \in \Sigma^*$,*

$$x \in A \iff g(x) = 0.$$

We thus certainly have the following, which holds simply by taking the GapP function g required in Theorem 2.9 to be the same as the function g in Definition 2.6.

▶ **Theorem 2.10.** *For each function $r : \mathbb{N} \to \mathbb{N}$, r-LWPP $\subseteq \mathrm{coC_{=}P}$.*

3 Main Result: LWPP Stays the Same If for Accepted Inputs We Allow Polynomially Many Gap Values Instead of One

We now state our main result: LWPP altered to allow even a polynomial number of target gap values is still LWPP (i.e., with just one target gap value).

▶ **Theorem 3.1.** *Poly*-LWPP = LWPP.

For the proof, we need the following closure properties shown by Fenner, Fortnow, and Kurtz [8].[2] For function classes $\mathcal{F}_1$ and $\mathcal{F}_2$, $\mathcal{F}_1 \circ \mathcal{F}_2 = \{f_1 \circ f_2 \mid f_1 \in \mathcal{F}_1 \wedge f_2 \in \mathcal{F}_2\}$, where $\circ$ denotes composition.

▶ **Closure Property 3.2** ([8]). $\mathrm{GapP} \circ \mathrm{FP} = \mathrm{GapP}$ *and* $\mathrm{FP} \subseteq \mathrm{GapP}$.

▶ **Closure Property 3.3** ([8]). *If $g \in \mathrm{GapP}$ then $-g \in \mathrm{GapP}$.*

▶ **Closure Property 3.4** ([8]). *If $g \in \mathrm{GapP}$ and q is a polynomial, then the function*

$$h(x) = \prod_{0 \le i \le q(|x|)} g(\langle x, i \rangle)$$

is in GapP.

▶ **Closure Property 3.5** ([8]). GapP *is closed under addition, subtraction, and multiplication.*

Proof of Theorem 3.1. As mentioned previously, it is easy to see that LWPP $\subseteq$ *Poly*-LWPP.

To show *Poly*-LWPP $\subseteq$ LWPP, let A be a set in *Poly*-LWPP defined by $g \in \mathrm{GapP}$, $f \in \mathrm{FP}$, and polynomial $r(n) = n^c + c$ according to Definitions 2.6 and 2.7.

Let h_1 be a function such that for all $x \in \Sigma^*$ and $i \in \mathbb{N}^+$,

$$h_1(\langle x, i \rangle) = f(\langle 0^{|x|}, i \rangle) - g(x).$$

[2] We mention in passing that, regarding Closure Property 3.4, if the polynomial q were allowed to have coefficients that are uncomputable – or that are extremely expensive to compute prefixes of the values of – real numbers, that claimed closure property might fail; we here are, as is typical in such settings, tacitly assuming that the polynomials have rational coefficients.

We have $h_1 \in \text{GapP}$ since $f \in \text{FP} \subseteq \text{GapP}$, $g \in \text{GapP}$, and GapP is closed under subtraction [8]. We define h_2 such that for all $x \in \Sigma^*$,

$$h_2(x) = \prod_{1 \leq i \leq r(|x|)} h_1(\langle x, i \rangle).$$

By Closure Property 3.4, $h_2 \in \text{GapP}$. Note that for all $x \in \Sigma^*$,

$$h_2(x) = \prod_{1 \leq i \leq r(|x|)} \left(f(\langle 0^{|x|}, i \rangle) - g(x) \right).$$

It follows that for every $x \in \Sigma^*$,

$$h_2(x) = \begin{cases} 0 & \text{if there exists } i \in \{1, 2, \ldots, r(|x|)\} \\ & \quad \text{such that } g(x) = f(\langle 0^{|x|}, i \rangle) \\ \prod_{1 \leq i \leq r(|x|)} f(\langle 0^{|x|}, i \rangle) & \text{if } g(x) = 0. \end{cases} \tag{1}$$

Now we define the function $\widehat{g}$ such that for all $x \in \Sigma^*$,

$$\widehat{g}(x) = h_2(x) - \prod_{1 \leq i \leq r(|x|)} f(\langle 0^{|x|}, i \rangle).$$

Using the closure properties, it is easy to see that $\widehat{g} \in \text{GapP}$.

Note that by Eqn. (1), we have that for all $x \in \Sigma^*$,

$$\widehat{g}(x) = \begin{cases} -\prod_{1 \leq i \leq r(|x|)} f(\langle 0^{|x|}, i \rangle) & \text{if there exists } i \in \{1, 2, \ldots, r(|x|)\} \\ & \quad \text{such that } g(x) = f(\langle 0^{|x|}, i \rangle) \\ 0 & \text{if } g(x) = 0. \end{cases} \tag{2}$$

Let $\widehat{f}$ be a function such that for all $\ell \in \mathbb{N}$,

$$\widehat{f}(0^\ell) = -\prod_{1 \leq i \leq r(\ell)} f(\langle 0^\ell, i \rangle).$$

It is easy to see that $\widehat{f} \in \text{FP}$. Keeping in mind Eqn. (2), it follows from the above that for every $x \in \Sigma^*$,

$$\widehat{g}(x) = \begin{cases} \widehat{f}(0^{|x|}) & \text{if } x \in A \\ 0 & \text{otherwise.} \end{cases}$$

Since $\widehat{g} \in \text{GapP}$ and $\widehat{f} \in \text{FP}$, this implies that $A \in \text{LWPP}$. ◀

A theorem analogous to Theorem 3.1 also holds for the corresponding class that allows the target values to depend on the actual input instead on only the length of the input.

▶ **Definition 3.6.**

$$\textit{Poly}\text{-WPP} = \bigcup_{c \in \mathbb{N}^+} (n^c + c)\text{-WPP}.$$

▶ **Theorem 3.7.** $\textit{Poly}\text{-WPP} = \text{WPP}$.

The proof is almost exactly the same as the proof of Theorem 3.1, simply taking into account the fact that for WPP the "gap" function can vary even among inputs of the same length.

We remark that the robustness results stated in Theorems 3.1 and 3.7 do not seem to in any obvious way follow as corollaries to the closure of LWPP under polynomial-time Turing reductions [8] or of WPP under polynomial-time truth-table reductions [26].

Let us now see whether we can extend Theorems 3.1 and 3.7. Suppose we not only allow the target-gap set for acceptance to have polynomially many values, but in addition allow the target-gap set for rejection to have polynomially many values. (In contrast, both LWPP and r-LWPP allow rejection only when the gap's value is 0). Is LWPP so robust that even *that* class is no larger than LWPP? We will now build on our main result to give the answer "yes" to that question, thus extending our main result to this more symmetric case for LWPP and for WPP.

To this end, let us define (r_A, r_R)-LWPP as follows. (One of course can in the clear, analogous way define a similarly loosened version of WPP, (r_A, r_R)-WPP.)

▶ **Definition 3.8.** Let r_A and r_R be any functions mapping from $\mathbb{N}$ to $\mathbb{N}$. Then (r_A, r_R)-LWPP is the class of all sets B such that there exists a GapP function g and functions – each mapping to $\mathbb{Z}$ – $f_A \in \mathrm{FP}$ and $f_R \in \mathrm{FP}$ such that both of the following hold:

1. For each $j \in \mathbb{N}$, $A_j \cap R_j = \emptyset$, where

$$A_j = \{n \mid (\exists i \in \{1, 2, \ldots, r_A(j)\})[f_A(\langle 0^j, i\rangle) = n]\}$$

and

$$R_j = \{n \mid (\exists i \in \{1, 2, \ldots, r_R(j)\})[f_R(\langle 0^j, i\rangle) = n]\}.$$

2. For each $x \in \Sigma^*$,

$$x \in B \Longrightarrow g(x) \in A_{|x|}$$
$$x \notin B \Longrightarrow g(x) \in R_{|x|}.$$

It is not hard to see, via shifting gaps with dummy paths, that the class $(r, 1)$-LWPP equals r-LWPP. However, what can be shown more generally about the classes (r_A, r_R)-LWPP? For example, for which functions $r_{1,A}$, $r_{1,R}$, $r_{2,A}$, and $r_{2,A}$ does it hold that $(r_{1,A}, r_{1,R})$-LWPP $\subseteq$ $(r_{2,A}, r_{2,R})$-LWPP? (There are some literature notions that, in different ways, have at least a somewhat similar flavor to our notion, namely, defining classes by being more flexible regarding acceptance types. In particular, the counting classes CP_S of Cai et al. [4] and the "C-class" framework of Bovet, Crescenzi, and Silvestri [3] have such a flavor. But in contrast with those, our classes here are ones whose definitions are centered on the notion of gaps.) We do not here undertake that general study, but instead resolve what seems the most compelling question, namely, we prove that $(Poly, Poly)$-LWPP = LWPP.

▶ **Definition 3.9.** $(Poly, Poly)$-LWPP $= \bigcup_{c \in \mathbb{N}^+} (n^c + c, n^c + c)$-LWPP.

▶ **Theorem 3.10.** $(Poly, Poly)$-LWPP $= Poly$-LWPP.

The proof of Theorem 3.10 can be found in the full version of the paper [12]. Together with Theorem 3.1, we get the following corollary.

▶ **Corollary 3.11.** $(Poly, Poly)$-LWPP = LWPP.

An analogous statement can also be shown for the analogously defined class $(Poly, Poly)$-WPP:

▶ **Theorem 3.12.** $(Poly, Poly)$-WPP = WPP.

4 Applying the Main Result to Graph Reconstruction

▶ **Definition 4.1.** Let $\langle G_1, G_2, \ldots, G_n\rangle$ be a sequence of graphs and $G = (V, E)$ a graph with $V = \{1, 2, \ldots, n\}$. Suppose that there is a permutation $\pi \in S_n$ such that for each $k \in \{1, 2, \ldots, n\}$, the graph $G_{\pi(k)}$ is isomorphic to the graph $(V - \{k\}, E - \{\{k, \ell\} : \ell \in V\})$ obtained by deleting vertex k from G. Then $\langle G_1, G_2, \ldots, G_n\rangle$ is called a *deck* of G and G is called a *preimage* of the sequence $\langle G_1, G_2, \ldots, G_n\rangle$.

A sequence of graphs $\langle G_1, G_2, \ldots, G_n\rangle$ is called a *legitimate deck* if there exists a graph G that is a preimage of $\langle G_1, G_2, \ldots, G_n\rangle$.

The *Reconstruction Conjecture* (see, e.g., the surveys [2, 21, 1] and the book [18]) says that each legitimate deck consisting of graphs with at least two vertices has exactly one preimage up to isomorphism. This conjecture is a very prominent conjecture in graph theory – as mentioned in Section 1 it is perhaps the most important conjecture in that area – and has been studied for many decades.

Nash-Williams [22], Mansfield [20], Kratsch and Hemachandra [17], and Hemaspaandra et al. [11] introduced various decision problems related to the Reconstruction Conjecture, as part of a stream of work studying the algorithmic and complexity issues of reconstruction. We here are interested mainly in the Legitimate Deck Problem, which is defined as the following decision problem.

Legitimate Deck (a.k.a. the Legitimate Deck Problem) [20]: Given a sequence of graphs $\langle G_1, G_2, \ldots, G_n\rangle$, is $\langle G_1, G_2, \ldots, G_n\rangle$ a legitimate deck?

Mansfield [20] showed that the Graph Isomorphism Problem, GI (given two graphs G_1 and G_2, are they isomorphic?), is polynomial-time many-one reducible to the Legitimate Deck Problem. However, to this day it remains open whether there is a polynomial-time many-one reduction from the Legitimate Deck Problem to GI.

So how hard is the Legitimate Deck Problem? It is easy to see that the Legitimate Deck Problem is in NP. In the following, we will see that there is some evidence that the Legitimate Deck Problem is not NP-hard, and we will improve that evidence.

Let us define the following function problem.

Preimage Counting [16, 17]: Given a sequence of graphs $\langle G_1, G_2, \ldots, G_n\rangle$, compute the number $\mathrm{PCount}(\langle G_1, G_2, \ldots, G_n\rangle)$ of all nonisomorphic preimages for the sequence $\langle G_1, G_2, \ldots, G_n\rangle$.

Köbler, Schöning, and Torán [15] showed the following theorem.

▶ **Theorem 4.2** ([15]). *There is a function $h : 0^* \to \mathbb{N} - \{0\}$ in* FP *such that the function that maps every sequence $\langle G_1, G_2, \ldots, G_n\rangle$ to $h(0^n)$ times the number of nonisomorphic preimages, i.e.,*

$$\langle G_1, G_2, \ldots, G_n\rangle \mapsto h(0^n) \cdot \mathrm{PCount}(\langle G_1, G_2, \ldots, G_n\rangle)$$

is in GapP.

Theorem 4.2 has the following corollary.

▶ **Corollary 4.3** ([15]). *If the Reconstruction Conjecture holds, then the Legitimate Deck Problem is in* LWPP.

Since all LWPP sets are PP-low, that immediately gives some evidence that the Legitimate Deck Problem is not NP-hard.

▶ **Corollary 4.4.** *If the Reconstruction Conjecture holds, then the Legitimate Deck Problem is not* NP*-hard (or even* NP*-Turing-hard) unless* NP *is* PP*-low.*

Unfortunately, we do not know whether the Reconstruction Conjecture holds. However, perhaps we can prove the membership of the Legitimate Deck Problem in LWPP under a *weaker assumption* than the Reconstruction Conjecture, for instance, what if the number of nonisomorphic preimages is not always 0 or 1 (as holds under the Reconstruction Conjecture), but rather is merely relatively small, e.g., some constant or some polynomial in the number of vertices (as must hold for each graph class having bounded minimum degree)? We will now use the results of the previous section to prove that this indeed is the case.

▶ **Conjecture 4.5** (q-Reconstruction Conjecture)**.** *For each legitimate deck there exist at most $q(n)$ nonisomorphic preimages, where n is the number of graphs in the deck.*

For any function r, we now define a complexity class r-$\widehat{\text{LWPP}}$. This class may not seem very natural, but we will see that it is very-well suited to helping us classify the problem Legitimate Deck. In some sense, it is a tool that we will use in our proof, and then will discard by noting that it in fact turns out to be a disguised version of r-LWPP.

▶ **Definition 4.6.** Let r be any function mapping from $\mathbb{N}$ to $\mathbb{N}$. Then the class r-$\widehat{\text{LWPP}}$ is the class of all sets A such that there exists a GapP function g, and a function $f \in \text{FP}$ that maps from 0^* to $\mathbb{Z} - \{0\}$, such that for each $x \in \Sigma^*$,

$$x \in A \implies \text{there exists } i \in \{1, 2, \ldots, r(|x|)\} \text{ such that } g(x) = i \cdot f(0^{|x|})$$
$$x \notin A \implies g(x) = 0.$$

▶ **Theorem 4.7.** *Let q be any nondecreasing function from $\mathbb{N}$ to $\mathbb{N}$. Then the following holds. If the q-Reconstruction Conjecture holds, then the Legitimate Deck Problem is in q-$\widehat{\text{LWPP}}$.*

Proof. Suppose that the q-Reconstruction Conjecture holds. Let $\langle G_1, G_2, \ldots, G_n\rangle$ be an input to the Legitimate Deck Problem. By our assumption, we have that

$$\langle G_1, G_2, \ldots, G_n\rangle \in \text{Legitimate Deck} \implies \text{PCount}(\langle G_1, G_2, \ldots, G_n\rangle) \in \{1, 2, \ldots, q(n)\},$$
and
$$\langle G_1, G_2, \ldots, G_n\rangle \notin \text{Legitimate Deck} \implies \text{PCount}(\langle G_1, G_2, \ldots, G_n\rangle) = 0.$$

Let $h \in \text{FP}$ be the function discussed in Theorem 4.2. Then the function g defined such that for every sequence $\langle G_1, G_2, \ldots, G_n\rangle$,

$$g(\langle G_1, G_2, \ldots, G_n\rangle) = h(0^n) \cdot \text{PCount}(\langle G_1, G_2, \ldots, G_n\rangle)$$

is in GapP. It follows that

$$\langle G_1, G_2, \ldots, G_n\rangle \in \text{Legitimate Deck} \implies g(\langle G_1, G_2, \ldots, G_n\rangle) = h(0^n) \cdot i \text{ for some } i \in \{1, 2, \ldots, q(n)\}, \text{ and}$$
$$\langle G_1, G_2, \ldots, G_n\rangle \notin \text{Legitimate Deck} \implies g(\langle G_1, G_2, \ldots, G_n\rangle) = 0.$$

This almost directly implies that Legitimate Deck $\in q$-$\widehat{\text{LWPP}}$. However, note that to satisfy Definition 4.6, function h must be a function *that depends only on the length of the input*

$\langle G_1, G_2, \ldots, G_n\rangle$. The problem here is that (depending on how exactly we decide to encode the graphs $G_1, G_2, \ldots, G_n$ in the input $\langle G_1, G_2, \ldots, G_n\rangle$) even the value n (the number of graphs in the deck) may depend on the actual input $\langle G_1, G_2, \ldots, G_n\rangle$ and not only on the length of the input $\langle G_1, G_2, \ldots, G_n\rangle$.

Fortunately, there is a way to get around this problem. From the length of the input, we get at least an upper bound for n since we can certainly assume that $n \leq |\langle G_1, G_2, \ldots, G_n\rangle|$. Define a function $\widehat{h}$ such that for each $m \in \mathbb{N}$, $\widehat{h}(0^m)$ is the product of all "h-values" *up to length m*. That is, define function $\widehat{h}$ such that for all $m \in \mathbb{N}$,

$$\widehat{h}(0^m) = \prod_{0 \leq i \leq m} h(0^i).$$

Define function h' such that for all inputs $\langle G_1, G_2, \ldots, G_n\rangle$,

$$h'(\langle G_1, G_2, \ldots, G_n\rangle) = \prod_{0 \leq i \leq |\langle G_1, G_2, \ldots, G_n\rangle| \wedge i \neq n} h(0^i).$$

Now we can see that for all inputs $\langle G_1, G_2, \ldots, G_n\rangle$,

$$g(\langle G_1, G_2, \ldots, G_n\rangle) \cdot h'(\langle G_1, G_2, \ldots, G_n\rangle) = \begin{cases} 0 & \text{if } \langle G_1, G_2, \ldots, G_n\rangle \notin \text{Legitimate Deck} \\ i \cdot \widehat{h}(0^{|\langle G_1, G_2, \ldots, G_n\rangle|}) \text{ for some } i \in \{1, 2, \ldots, q(n)\} & \text{if } \langle G_1, G_2, \ldots, G_n\rangle \in \text{Legitimate Deck.} \end{cases} \tag{3}$$

Note that $\widehat{h}, h' \in$ FP and $g \in$ GapP. By Closure Properties 3.2 and 3.5, the function $x \mapsto g(x) \cdot h'(x)$ is in GapP. Finally, note that since q is nondecreasing and $n \leq |\langle G_1, G_2, \ldots, G_n\rangle|$, we have that $q(n) \leq q(|\langle G_1, G_2, \ldots, G_n\rangle|)$ in Eqn. (3). Thus by Definition 4.6 – with the GapP function g there being our $g(x) \cdot h'(x)$ and the function f there being our $\widehat{h}$ – we have that Legitimate Deck $\in q$-$\widehat{\text{LWPP}}$. ◀

We want to show that if there exists a polynomial q such that the q-Reconstruction Conjecture holds, then Legitimate Deck is in LWPP. To this end, we need the following inclusion.

▶ **Theorem 4.8.** *For each function $r : \mathbb{N} \to \mathbb{N}$, r-$\widehat{\text{LWPP}} \subseteq r$-LWPP.*

Proof. Let A be a set in r-$\widehat{\text{LWPP}}$ via $f_1 \in$ FP and $g \in$ GapP. Let $f_2 \in$ FP be the function defined such that for every $n, i \in \mathbb{N}^+$, $f_2(\langle 0^n, i\rangle) = i \cdot f_1(0^n)$. Then A is in r-LWPP via $f_2 \in$ FP and $g \in$ GapP. ◀

▶ **Corollary 4.9.** *If the q-Reconstruction Conjecture holds for some polynomial q, then the Legitimate Deck Problem is in* LWPP.

Proof. Suppose the q-Reconstruction Conjecture holds for nondecreasing polynomial q. (If q is not nondecreasing but the q-Reconstruction Conjecture holds, then obviously we can replace q with a nondecreasing polynomial q' that on each input n is greater than or equal to $q(n)$ and the q'-Reconstruction Conjecture will hold. So we may w.l.o.g. take it that q is nondecreasing.) By Theorems 4.7 and 4.8, Legitimate Deck $\in q$-$\widehat{\text{LWPP}} \subseteq q$-LWPP and hence Legitimate Deck $\in$ *Poly*-LWPP. With Theorem 3.1, it follows that Legitimate Deck $\in$ LWPP. ◀

This gives us our new, more flexible – though still conditional – evidence that the Legitimate Deck Problem is not NP-hard.

▶ **Corollary 4.10.** *If the q-Reconstruction Conjecture holds for some polynomial q, then the Legitimate Deck Problem is not* NP*-hard (or even* NP*-Turing-hard) unless* NP *is* PP*-low.*

▶ **Definition 4.11** ([17])**.** Let $\mathcal{H}$ be any class of graphs. Then the *Legitimate Deck Problem restricted to* $\mathcal{H}$ consists of all sequences of graphs $\langle G_1, G_2, \ldots, G_n\rangle$ such that $\langle G_1, G_2, \ldots, G_n\rangle$ is a legitimate deck and for each $i \in \{1, 2, \ldots, n\}$, G_i is in $\mathcal{H}$.

Note that the above definition is so flexible that it allows even the case where the preimage(s) may not be in $\mathcal{H}$.

▶ **Theorem 4.12.** *Let $\mathcal{H}$ be any P-recognizable class of graphs such that decks consisting only of graphs in $\mathcal{H}$ have a number of nonisomorphic preimages that is bounded polynomially in the number of graphs in the deck. Then the Legitimate Deck Problem restricted to $\mathcal{H}$ is in* LWPP*.*

Proof. Let $\mathcal{H}$ be any P-recognizable class of graphs and q a nondecreasing polynomial such that decks consisting only of graphs in $\mathcal{H}$ have a number of nonisomorphic preimages that is bounded by $q(n)$, where n is the number of graphs in the deck.

First, we show that the Legitimate Deck Problem restricted to $\mathcal{H}$ is in q-$\widehat{\text{LWPP}}$. Let $\langle G_1, G_2, \ldots, G_n\rangle$ be an input to the Legitimate Deck Problem. Check if for every $i \in \{1, 2, \ldots, n\}$, G_i is in $\mathcal{H}$. If this is not the case then reject in the sense of q-$\widehat{\text{LWPP}}$, i.e., produce a gap of zero. Otherwise, the deck $\langle G_1, G_2, \ldots, G_n\rangle$ has at most $q(n)$ preimages, i.e., $\text{PCount}(\langle G_1, G_2, \ldots, G_n\rangle \leq q(n)$. Proceed as in the proof of Theorem 4.7.

Since by Theorems 4.8 and 3.1, q-$\widehat{\text{LWPP}} \subseteq q$-LWPP $\subseteq$ LWPP, it follows that the Legitimate Deck Problem restricted to $\mathcal{H}$ is in LWPP. ◀

As usual, for each graph G, $\delta(G)$ denotes the degree of a minimum-degree vertex of G.

▶ **Theorem 4.13.** *For each $k \in \mathbb{N}^+$, let*

$$\mathcal{H}_k = \{G \mid G \text{ is a graph such that } \delta(G) \leq k\}.$$

Then the Legitimate Deck Problem restricted to $\mathcal{H}_k$ is in LWPP*.*

Proof. In the proof of their Theorem 6.1, Kratsch and Hemaspaandra [17] showed that for each class of graphs with bounded minimum degree, the number of nonisomorphic preimages is polynomially bounded. Now the theorem follows from Theorem 4.12. ◀

It is interesting to note that for each of the $\mathcal{H}_k$ classes $\text{GI}_{\mathcal{H}_k} \equiv_m^p$ GI trivially holds (for example, via adding to each of the two graphs being tested for isomorphism an isolated node), notwithstanding the fact that intersection with $\mathcal{H}_k$ pulls the Legitimate Deck Problem's complexity into LWPP.

In two of this section's corollaries we used the fact that all LWPP sets are PP-low. We mention that since all LWPP set are also $\text{C}_=$P-low [15, 8], the altered versions of Corollaries 4.4 and 4.10 in which the conclusion is changed from "unless NP is PP-low" to "unless NP is $\text{C}_=$P-low" both hold, respectively due to Köbler, Schöning, and Torán [15] and the present paper.

5 Optimality of the Main Result (Brief Version)

It is easy to see that the proof of Theorem 3.1 breaks down if *Poly*-LWPP is replaced by the analogous class where the size of the set of allowed gap values can be larger than polynomial in the input length. This does not necessarily imply that the corresponding theorem does not hold. However, in this section, we establish that relativizable proof techniques are not sufficient to improve Theorem 3.1 from *Poly*-LWPP to r-LWPP for any function r that is not polynomially bounded. That is, we show that our main result is optimal with respect to what can be proven by relativizable proof techniques.

▶ **Theorem 5.1.** *Let r be any function from $\mathbb{N}$ to $\mathbb{N}$ such that for every $c \in \mathbb{N}$, $r \notin \mathcal{O}(n^c)$. Then there exists an oracle $\mathcal{O}$ such that r-LWPP$^{\mathcal{O}} \not\subseteq$ LWPP$^{\mathcal{O}}$.*

To prove Theorem 5.1, we will encode nondeterministic oracle Turing machines by low-degree multivariate polynomials. This technique is apparently folklore and has been used, for example, by de Graaf and Valiant [6] to construct a relativized world where the quantum complexity class EQP is not contained in the modularity-based complexity class MOD$_{p^k}$P. The general technique of replacing oracle machines by simpler combinatorial objects such as circuits, decision trees, or polynomials and then using properties of such combinatorial objects to show the existence of a desired oracle dates to the seminal work of Furst, Saxe, and Sipser [9], who made the connection between circuit lower bounds and the relativization of the polynomial hierarchy – a connection that has led to the resolution of many previously long-open relativized questions, such as the achievement of an oracle making the polynomial hierarchy infinite [31, 10] and of oracles making the polynomial hierarchy extend exactly k levels [14].

Note: Please see [12] for a complete version of this section, which includes the proof of Theorem 5.1 and additional results showing that LWPP *with an exponential number of target gap values cannot equal* LWPP *without causing highly unlikely structural consequences such as* PP$^{\text{NP}}$ = PP*.*

6 LWPP$^+$ (Brief Version)

Theorem 3.1 of Section 3 established a robustness property of LWPP, namely, that *Poly*-LWPP= LWPP. That is, having one target value for acceptance and having a list of target values for acceptance yield the same class of languages, in the content of LWPP, which, recall, is defined in terms of the values of GapP functions. That robustness result is itself robust in the sense that it holds both in the real world and, it is easy to see, in every relativized world.

On the other hand, this equivalence for LWPP, in terms of descriptive richness, between one target value and a polynomial number of values, may not hold even for quite similar counting-class situations. In particular, in this section we prove that in some relativized worlds, for the analog (which we will call LWPP$^+$) of LWPP defined in terms of #P rather than GapP functions (following Cox and Pay [5], who recently introduced the #P-based analogue of WPP), having even two target values for acceptance (the class Two-LWPP$^+$) yields a richer class of languages than having one value. So it is not the case that single targets and lists of targets inherently function identically as to descriptive richness for counting classes.

▶ **Theorem 6.1.** *There exists an oracle $\mathcal{O}$ such that* (LWPP$^+$)$^{\mathcal{O}} \subsetneq$ (Two-LWPP$^+$)$^{\mathcal{O}}$*.*

Note: Please see [12] for a complete version of this section, which includes definitions and the proof of our relativized result (Theorem 6.1) showing that, for the #P*-based analogue*

of LWPP*, even two target values may yield a larger class of languages than does one target value, in contrast to what holds for the* LWPP *case.*

7 Conclusions and Open Questions

In this paper, we proved that LWPP and WPP are robust enough that they remain unchanged when their single target gap is allowed to be expanded to polynomial-sized lists. We then applied this new robustness of LWPP to show that the PP-lowness of the Legitimate Deck Problem follows from a weaker hypothesis than was previously known. In doing so, we provided enhanced evidence that the Legitimate Deck Problem is not NP-hard or even NP-Turing-hard. We also showed: that the polynomial-target robustness of LWPP that we have established is optimal (i.e., cannot be extended to any superpolynomial number of targets) with respect to relativizable proofs; that for the #P-based analogue of the (GapP-based) class LWPP, in some relativized worlds even two targets give more languages than one target; that our robustness of LWPP holds even when one simultaneously expands both the acceptance target-gap set and the rejection target-gap set to be polynomial-sized lists; and that our main results also hold for WPP.

Regarding the Reconstruction Conjecture, we proved as a consequence of our results that if there exists a polynomial q such that the q-Reconstruction Conjecture holds, then the Legitimate Deck Problem is both PP-low and $C_=P$-low. Since NP is widely believed not to be PP-low or $C_=P$-low, this provides strengthened evidence that the Legitimate Deck Problem is not NP-hard or even NP-Turing hard (since otherwise even the "Poly"-Reconstruction Conjecture must fail, yet even the far stronger Reconstruction Conjecture is generally believed to hold).

A natural open problem is whether the Legitimate Deck Problem is Σ_k^p-low [24] for some k, i.e., whether for some k it holds that $(\Sigma_k^p)^{\text{Legitimate Deck}} = \Sigma_k^p$. Proving that that holds – though we mention that this has been a known open issue for more than two decades (see [17]) – would imply that the Legitimate Deck Problem cannot be NP-complete (even with respect to more flexible reductions such as Turing reductions and strong nondeterministic reductions [19]) unless the polynomial hierarchy collapses.

Abstract

Motivated by the problem of shape recognition by nanoscale computing agents, we investigate the problem of detecting the geometric shape of a structure composed of hexagonal tiles by a finite-state automaton robot. In particular, in this paper we consider the question of recognizing whether the tiles are assembled into a parallelogram whose longer side has length $\ell = f(h)$, for a given function $f(\cdot)$, where h is the length of the shorter side. To determine the computational power of the finite-state automaton robot, we identify functions that can or cannot be decided when the robot is given a certain number of pebbles. We show that the robot can decide whether $\ell = ah + b$ for constant integers a and b without any pebbles, but cannot detect whether $\ell = f(h)$ for any function $f(x) = \omega(x)$. For a robot with a single pebble, we present an algorithm to decide whether $\ell = p(h)$ for a given polynomial $p(\cdot)$ of constant degree. We contrast this result by showing that, for any constant k, any function $f(x) = \omega(x^{6k+2})$ cannot be decided by a robot with k states and a single pebble. We further present exponential functions that can be decided using two pebbles. Finally, we present a family of functions $f_n(\cdot)$ such that the robot needs more than n pebbles to decide whether $\ell = f_n(h)$.

1 Introduction

The *DNA-based self-assembly* approach [20], in which large structures have to be assembled from DNA tiles in a self-organized fashion, is still quite error prone. Numerous techniques have been studied to reduce the error rates (e.g., [6]), but the research typically focuses on designing DNA tiles or assembly processes that reduce the error of incorrect attachments. Given the progress on designing so-called *DNA walkers* (see, e.g., [22, 24, 25]), it is foreseeable that also simple molecular robots could be used in order to make the assemblies more reliable. For example, such robots may be used to repair structures that did not self-assemble correctly. In order to be able to repair a given structure, it first has to be possible to detect whether a structure is not in a correct shape, which motivates the problem of *shape recognition*. Besides verifying self-assembled DNA structures, shape recognition could also be useful for minimal invasive surgery applications, such as looking for harmful substances or cells in a human body.

Naturally, molecular robots may have very limited capabilities, which is why we are focusing on robots with the computational power of a finite-state automaton. More precisely, we build upon the model introduced in [10] where finite-state automaton robots move on a structure composed of hexagonal tiles, represented as a subgraph of the infinite triangular lattice, and rearrange the tiles into a certain shape. Although shape *formation* with computationally restricted agents, as considered in [10], has been extensively studied in many other models (see, e.g., [5, 13, 17, 26]), to the best of our knowledge, the closely related problem of shape *detection* has never been explicitly studied in our setting.

1.1 Model

We assume that a single *robot* is placed on a finite set of *hexagonal tiles*. Each tile occupies exactly one node of the infinite triangular lattice $G = (V, E)$ (refer to Figure 1). We assume that the subgraph of G induced by all nodes occupied by tiles is connected. Every node $u \in V$ is adjacent to six neighbors, and, as indicated in the figure, we describe the relative positions of adjacent nodes by six compass directions.

Table 1 This table summarizes the results for recognizing whether a given parallelogram has height h and length $\ell = f(h)$ given a certain number of pebbles.

Pebbles	Possible	Impossible	Remarks	Refer to
0	$f(x) = ax + b$	$f(x) = \omega(x)$	a, b constant	Section 3.1
1	$f(x) = a_n x^n + \ldots + a_0$	$f(x) = \omega(x^{6k+2})$	n, a_i constant for all i, k is the number of the robot's states	Section 3.2
2	$f(x) = \underbrace{2^{2^{\cdot^{\cdot^{2^x}}}}}_{s+1}$	—	s constant	Section 3.3
n	$f_n(x)$	$f_{n+1}(x)$	—	Section 3.4

The robot is initially placed on a tile. It can move on the tile structure and carry a (possibly empty) set of *pebbles*, which can be placed on tiles in order to *mark* them. A tile can be marked by at most one pebble.

More specifically, the robot acts as a *deterministic finite automaton* and operates in *look-compute-move* cycles. In the *look* phase the robot can observe the node it occupies and the six neighbors of that node. For each of these nodes it can determine whether it is occupied by a tile and whether a pebble is placed on that tile. In the *compute* phase the robot potentially changes its state and determines its next move according to the observed information and the number of carried pebbles. In the *move* phase the robot can either take a pebble from its current node (if its tile is marked by a pebble), place a pebble it is carrying at that node (if its tile is not already marked and the robot carries at least one pebble), or move to an adjacent occupied node.

Note that even though we describe the algorithms as if the robot knew a global orientation, we do not actually require the robot to have a compass. For the algorithms presented in this paper, it is enough for the robot to be able to maintain its orientation with respect to its initial orientation.

1.2 Related Work

To the best of our knowledge, shape recognition has never been investigated in our model. However, solving problems by traversing a tile structure with simple agents has been studied in many different areas. For instance, [23] considers the problem of deciding whether a structure is simply-connected. Other problems include Gathering and Rendezvous (e.g., [21]), Intruder Caption and Graph Searching (e.g., [2,8]), or Black Hole Search (e.g., [16]).

For many of the above problems it has also been investigated whether pebbles can be helpful. This question is particularly well-studied for the classical Network Exploration Problem (see, e.g., [4]). For example, it is known that a finite automaton robot can neither explore all planar graphs [9] nor find its way out of a planar labyrinth [3] without any pebbles. For the Labyrinth Exploration Problem (see [14,15] for a comprehensive survey), it is known that having a single pebble does not help the robot [11]. However, a robot with two pebbles can solve the problem [1].

1.3 Our Contributions

In this paper we investigate the problem of *shape recognition* by a single robot. Specifically, we begin with testing whether a given tile formation is of a certain simple shape, in particular, a parallelogram. Then, we consider the problem of deciding for a given function $f(\cdot)$ whether the longer side of a parallelogram has length $f(h)$, where h is the shorter side's length. We particularly investigate this problem under the assumption that the robot is given a set of pebbles that can be used to mark certain positions on the tile structure. An overview of our results is given in Table 1, in which we give concrete functions $f(\cdot)$ the robot is able or not able to decide given a certain set of pebbles. Our ultimate goal is to investigate the computational capabilities of a simple robot concerning shape recognition, and to what extent the robot can benefit from employing pebbles.

As we do not make any assumptions on the length of the shorter side h of the parallelogram, we cannot assume that a robot with only a constant number of possible states is able to count up to h, even less so evaluate the function $f(h)$. Thus, if the robot does not have pebbles at its disposal, its only option is to make use of the environment's geometry. For example, the robot can 'measure' h tiles along the longer side of the parallelogram by starting in a corner and moving diagonally until reaching the opposite boundary. Furthermore, the robot can measure $2h$, $3h$, or even ah tiles, for any constant a, along the longer side.

In Section 3.1 we develop this intuition further, and show that the robot can decide whether the longest side of the parallelogram is $\ell = ah + b$, where a and b are constants. On the other hand, we show that the robot without pebbles is not able to recognize a superlinear function. In Sections 3.2 and 3.3 we show that we can tremendously increase the robot's computational power by giving it a single pebble or two pebbles, respectively. Having the ability to mark any tile with a single pebble allows the robot to recognize any polynomial function of constant degree; and being equipped with two pebbles gives the robot the ability to recognize power tower functions, where the height of the power tower is constant or even linear in h. Finally, in Section 3.4 we show that for any number of pebbles there exists a function that requires that many pebbles to be decided by the robot.

2 Recognizing Simple Shapes

First, observe that a single robot can easily detect whether the initial structure is a line, a triangle, a hexagon, or a parallelogram.

Line. For example, to test if a given tile shape is a line, the robot first chooses a direction in which there is a tile (say, w.l.o.g., N), walks in that direction as far as possible (i.e., until there is no tile in that direction anymore), and then traverses the structure into the opposite direction until no longer possible. If it ever encounters a tile to the left or right of any traversed tile, the structure is not a line.

Parallelogram. To test if a given tile shape is a (filled) parallelogram axis-aligned along the directions N and NE (see Figure 2), first, the robot moves to a locally southernmost tile of the structure by moving S and SW as long as there is a tile in any of these directions. It then traverses the shape column by column in a snake-like fashion by repeating the following movements: First, the robot moves N as far as possible; it then moves one step NE; then it moves S as far as possible, and it finally moves one step NE. The above procedure is repeated until a NE movement is impossible. By performing local checks alongside the movements described above the robot can verify whether the tile shape is a parallelogram.

The other simple shapes can be easily tested in a similar fashion.

▶ **Observation 1.** *A robot without any pebble can detect whether the initial tile configuration is a line, a triangle, a hexagon, or a parallelogram.*

3 Recognizing Parallelograms with Specific Side Ratio

As noted in Observation 1, a single robot without pebbles can verify whether a given shape is a parallelogram. To investigate the computational power of a finite automaton, in this section we consider the problem of deciding whether a parallelogram has a given side ratio. Additionally, we examine how pebbles can be helpful to decide more complex side ratios.

We assume w.l.o.g. that the robot needs to detect whether the given tile configuration is a parallelogram that is axis-aligned along the north and north-east direction, as indicated in Figure 2. We denote a maximal sequence of consecutive tiles from N to S as a *column* and a maximal sequence of consecutive tiles from SW to NE as a *row*. Let h be the size of each column, i.e., the parallelogram's *height*, ℓ be the size of each row, i.e., the parallelogram's *length*, and let $h \leq \ell$. We number the columns of the parallelogram from 0 to $\ell - 1$ growing in the north-eastern direction.

3.1 A Robot without any Pebble

First, we point out that a single robot can detect whether the structure is a parallelogram in which its length ℓ is a linear function of its height h.

▶ **Theorem 2.** *A single robot can detect whether the tile configuration is a parallelogram with $\ell = ah + b$ for any constants $a, b \in \mathbb{N}$.*

Proof. First, the robot verifies whether the structure is a parallelogram. If so, the robot moves to the northernmost tile of column 0. It then traverses the tile structure in two stages to verify the ratio of the sides. In the first stage, the robot "measures" the distance ah along the length of the parallelogram moving in a zig-zag fashion as depicted in Figure 2. In the second stage the robot measures the second term b. More specifically, in the first stage, the robot repeats the following movements in a loop: (1) move SE as far as possible, (2) move N as far as possible, and (3) make one step NE. After having performed the complete sequence of SE movements a times, the robot moves on to the second stage, in which it makes an additional b NE steps.

If the robot reaches the easternmost column before completing the above procedure, or finally halts on a tile with a neighboring tile at NE, it terminates with a negative result. Otherwise, it terminates with a positive result. It is easy to see that $\ell = ah + b$ if and only if the robot terminates with a positive result. ◀

▶ Remark. The algorithm in the previous theorem can be adapted for $b \in \mathbb{Z}$, i.e., b can also be a negative integer. To achieve that, we halt the execution of the first stage once the robot has performed $|b|$ SE steps, then move SW as far as possible, and continue the first stage from there. Then, $\ell = ah + b$ if and only if the robot eventually reaches the southernmost tile of column $\ell - 1$.

▶ Remark. The algorithm can be further extended to apply in the case of a rational a. Let $a = p/q$ be an irreducible fraction. Instead of moving in a zig-zag fashion in the first stage, the robot alternates between moving p steps NE and q steps S. To exactly end up at the southernmost tile of column $\ell - 1$, the robot needs to skip the very first NE and S step.

We have shown that a single robot can determine whether the length of a parallelogram is given by a certain linear function of its height. However, that is as much as one robot can hope for. Indeed, a single robot is not able to decide whether the length of the parallelogram is given by a superlinear function of its height, as the following theorem states.

▶ **Theorem 3.** *A single robot without any pebbles cannot decide whether the tile configuration is a parallelogram with $\ell = f(h)$, where $f(x) = \omega(x)$.*

Proof. Suppose there is an algorithm that lets the robot decide whether the tiles are arranged into a parallelogram with $\ell = f(h)$ for some superlinear function $f(x) = \omega(x)$. Let k be the total number of states used by the robot in the algorithm. Choose h large enough such that $\lfloor \frac{f(h)-2}{h} \rfloor > k$, which can be done since $f(h) = \omega(h)$.

Consider the execution of the algorithm on a parallelogram P with height h and length $\ell = f(h)$. We will show that there exists another parallelogram with height h and length greater than $f(h)$ on which the robot will eventually terminate in exactly the same state as on P, which contradicts the assumption that the algorithm is correct.

We first place the robot on the northernmost tile of column 0. First, observe that if the robot does not visit column $\ell - 1$ during the execution of the algorithm, it cannot correctly detect the length of the parallelogram. Thus, the robot visits this column at least once.

Consider the execution of the algorithm as a sequence $(p_1, p_2, \dots)$ of tuples of nodes and states $p_i = (u_i, q_i)$. Denote as $\pi_1, \dots, \pi_m$ the subsequences of the execution of the algorithm, where each subsequence starts whenever the robot leaves a node of column 0 or $\ell - 1$, and ends when it enters a node of one of those columns. More specifically, the first and last node of each π_i is a node adjacent to column 0 or $\ell - 1$ and the node immediately before and after each π_i is a node of 0 or $\ell - 1$. Note that in each π_i the robot exclusively moves in the columns between column 0 and $\ell - 1$.

First, consider a subsequence π_i at the beginning of which the robot leaves, and at the end of which, enters the same column 0 (or $\ell - 1$). Let $p_i = (s_i, q_i)$ be the node-state tuple right before the robot enters the subsequence π_i when executing the algorithm on the parallelogram P. Then, the robot would execute exactly the same subsequence π_i on a parallelogram P' with a larger length than the one of P, if it were placed on a node of P' corresponding to s_i with the same state q_i.

Next, consider a subsequence π_j at the beginning of which the robot leaves, w.l.o.g., column 0, and at the end of which it enters $\ell - 1$. Since the robot completely traverses the tile structure from column 0 to $\ell - 1$, there must be a row R_j in which the robot steps on no less than $\lfloor \frac{f(h)-2}{h} \rfloor > k$ tiles. Therefore, there will be two nodes u_j and v_j in the row R_j in which the robot appears in the same state. Let c_u, c_v be the column indices of u_j and v_j, respectively, and define $d_j = |c_v - c_u|$. Let (s_j, q_j) be the node-state tuple of the robot immediately before it enters the subsequence π_j and (s'_j, q'_j) be the node-state tuple of the robot immediately after the subsequence π_j is finished. Then, consider a parallelogram Q with height h and length $f(h) + cd_j$, where $c \in \mathbb{N}_0$. If the robot starts in the same state q_j on the node corresponding to s_j (i.e., the node in column 0 and the row of s_j) in the parallelogram Q, it will move entirely between the westernmost and easternmost column of Q until it reaches the node corresponding to s'_j (i.e., the node of column $f(h) + cd_j$ and the row of s'_j) in Q in state q'_j.

Now consider the execution of the algorithm on a parallelogram P' with height h and length $f(h) + \prod_j d_j$ for each subsequence π_j where the robot completely traverses the parallelogram between column 0 and $\ell - 1$. By the above argument, the robot will enter and leave those columns on the same tile and in the same state as in the execution of the algorithm on P. Thus, executing the same algorithm on the parallelogram P' the robot will ultimately terminate in the same state as if it were on the parallelogram P. Therefore, the robot cannot decide whether the initial tile configuration is a parallelogram with $\ell = f(h)$ for any superlinear function $f(x) = \omega(x)$. ◀

3.2 A Robot with a Single Pebble

In the following, we demonstrate that, in contrast to the negative result of Theorem 3, a single robot can decide any polynomial of constant degree.

▶ **Theorem 4.** *A single robot with a pebble can decide whether the tile configuration is a parallelogram of height h and length $\ell = p(h)$ for any given polynomial $p(\cdot)$ of constant degree n.*

Proof. Define the *falling factorial* of x as $(x)_i := x(x-1)\cdots(x-i+1)$, and transform the input polynomial into the form $p(x) = a_n \cdot (x)_n + a_{n-1} \cdot (x)_{n-1} + \ldots + a_0$. We will show that the robot can move the pebble in phases, by $|a_i \cdot (h)_i|$ steps in each phase i. Let $\mathrm{lcm}_i(x) := \mathrm{lcm}(x, \ldots, x-i+1)$, where lcm is the *least common multiple*, and $g_i(x) := (x)_i / \mathrm{lcm}_i(x)$. From [12] it follows that $\mathrm{lcm}_i(x) \mid (x)_i$, and that $g_i(x)$ is periodic with period $\mathrm{lcm}(1, \ldots, i-1)$, i.e., $g_i(x) = g_i(x + \mathrm{lcm}(1, \ldots, i-1))$. Let $p_i(x)$ be the sum of the first $n-i$ summands of $p(x)$, i.e., $p_i(x) = a_n \cdot (x)_n + a_{n-1} \cdot (x)_{n-1} + \ldots + a_{n-i+1} \cdot (x)_{n-i+1}$.

Initially, the pebble is located on the northernmost tile of column 0. To test whether $\ell = p(h)$, the robot will move the pebble along the northernmost row in phases, until it is eventually shifted $p(h) - 1$ steps to the *NE* from its original position. If upon termination the pebble is located at the northernmost tile of column $\ell - 1$, then $p(h) = \ell$.

The algorithm proceeds in phases $n, \ldots, 0$. We maintain the invariant that after phase i for all $i > 0$, the pebble is located at the northernmost tile of column $p_i(h)$. That is, in phase i, the robot moves the pebble $|a_i \cdot (h)_i|$ steps *NE*, if a_i is positive, and *SW*, otherwise. In the final phase $i = 0$, the robot moves the pebble by $|a_0 - 1|$ steps *NE*, if $a_0 \geq 1$, and *SW*, otherwise. For now, assume that each movement can be carried out without moving the pebble outside of the parallelogram. We will later describe how to lift this restriction.

We now describe how the pebble is moved by $|a_i \cdot (h)_i|$ steps. First, note that $a_i \cdot (h)_i = a_i \cdot g_i(h) \cdot \mathrm{lcm}_i(h)$. The first factor a_i is a constant. The second factor $g_i(h)$ can be determined as follows. We encode all possible values of $g_i(\cdot)$ for all $i \in \{0, \ldots, n\}$ into the robot's memory, which can be done since n is constant and $g_i(\cdot)$ has a constant period. Before the main algorithm's execution, the robot can compute $g_i(h)$ for all i by moving through column 0 from north to south: Starting with $g_i(1)$, in every step to the south the robot computes the subsequent function value until the period of $g_i(\cdot)$ is reached, in which case it restarts with $g_i(1)$. When it reaches the southernmost tile of the column, it knows $g_i(h)$ for all i.

We next show how the robot moves the pebble by $\mathrm{lcm}_i(h)$ steps, which, by repeating the movement $|a_i \cdot g_i(h)|$ times, concludes how the complete movement by $|a_i \cdot (h)_i|$ steps is performed. Assume the pebble is in some column c and $\mathrm{lcm}_i(h) \mid c$ (which we will prove by induction shortly). The robot alternates between the following two operations: (1) move the pebble into column c' by moving it one step *NE*, if $a_i > 0$, or *SE*, otherwise; (2) verify whether $\mathrm{lcm}_i(h) \mid c'$ as follows. The robot first performs the zig-zag movement from the proof of Theorem 2 to verify whether $h \mid c'$, i.e., whether a *NE* movement moves the robot onto a tile occupied by the pebble. It continues to analogously verify whether $h-1 \mid c'$, $h-2 \mid c'$, $\ldots$, $h-i+1 \mid c'$ by performing a modified zig-zag movement an additional $i-1$ times. Here, the zig-zags of the j-th verification are adjusted accordingly by moving j steps to the south prior to each sequence of *SE* movements. The robot stops alternating between the two above operations once the pebble has been moved to a column c' such that $\mathrm{lcm}_i(h) \mid c'$ for the first time. Then, the pebble must have been moved by $\mathrm{lcm}_i(h)$ steps.

It remains to prove that when the robot wants to move the pebble, currently occupying a node of column c, by $\mathrm{lcm}_i(h)$ steps for some i, then $\mathrm{lcm}_i(h) \mid c$. The invariant holds initially for $c = 0$. Now assume it holds immediately after having moved the pebble by $\mathrm{lcm}_i(h)$ steps

into column $c \pm \mathrm{lcm}_i(h)$. By induction hypothesis, $\mathrm{lcm}_i(h) \mid c$. Afterwards, the robot can move the pebble by either $\mathrm{lcm}_i(h)$ steps again, in which case $\mathrm{lcm}_i(h) \mid c \pm \mathrm{lcm}_i(h)$ holds, or it moves it by $\mathrm{lcm}_{i-1}(h)$ steps, and $\mathrm{lcm}_{i-1}(h) \mid c \pm \mathrm{lcm}_i(h)$ holds since $\mathrm{lcm}_{i-1}(h) \mid \mathrm{lcm}_i(h)$.

Finally, we show how the robot can resolve *overflows*, i.e., situations in which the above algorithm would move the pebble outside of the parallelogram. First, note that the execution of the algorithm after an overflow can, in principle, be continued by the robot by "mirroring" all movements beyond the westernmost or easternmost column, carrying them out into reverse direction. Assume that h is sufficiently large such that $|a_i \cdot (h)_i + \ldots + a_0| \leq p(h)$ for all i. For all small $h = O(\max_i(|a_i|))$ we can encode the constantly many possible function values into the robot's state and test them prior to the algorithm's execution by traversing the two sides of the parallelogram once. If throughout the execution of the algorithm the robot ever attempts to move the pebble into a column west of column 0 or east of "virtual" column 2ℓ (while performing the mirroring method from above), it would subsequently not be able to ever move the pebble back into column ℓ (following from the assumption that h is sufficiently large), and consequently $\ell \neq p(h)$. Therefore, the robot can prematurely terminate with a negative result whenever it encounters such a situation. ◀

The next theorem gives a lower bound on the amount of states needed to decide whether $\ell = h^a$, $a \in \mathbb{N}$, thereby proving that no robot with one pebble can decide whether $\ell = f(h)$ for $f(x) = \omega(x^a)\, \forall a \in \mathbb{N}$.

▶ **Theorem 5.** *A robot with k states and a single pebble cannot decide whether the tile configuration is a parallelogram of height h and length $\ell = f(h)$, $f(x) = \omega(x^{6k+2})$.*

Proof. First, we give a brief outline of the following proof. Assuming such a robot exists, we place the robot with its pebble on the northernmost tile of column 0 of a parallelogram P with height h and length $\ell = f(h)$. We begin by subdividing P horizontally into parallelograms of height h which we will refer to as *blocks*. We define the westernmost and easternmost blocks as the *outer blocks* O_ℓ and O_r, respectively, and denote all other blocks as *inner blocks*. We choose the length b of all inner blocks such that when the robot moves through a sequence of inner blocks (from NW to SE or SE to NW), while either carrying the pebble the entire time or not visiting it at all, its row and state repeat every b columns. The outer blocks will have length at least b.

As in the proof of Theorem 3, we consider the execution of the algorithm as a sequence of tuples of nodes and states, and divide it into subsequences $\pi_1, \ldots, \pi_m$. Subsequence π_i starts with the robot carrying the pebble into some outer block, and ends when it reaches the opposite outer block while carrying the pebble. The robot terminates in π_m, and, as this is the final subsequence, before entering the opposite block while carrying the pebble. We define r_{π_i} and q_{π_i} to be the robot's row and state at the beginning of π_i. By considering where the robot places and picks up the pebble, we identify a value d such that r_{π_i} and q_{π_i} remain the same if the robot is executed on a parallelogram P' of height h and length $f(h) + db$, and therefore falsely terminates with a positive result.

We begin the proof by identifying a value b. Consider the robot's execution without the pebble on a parallelogram of height h and infinite length in both directions, starting in row r and state q. If the robot moves by at most kh columns in NW or SE direction, we define $d_{r,q} := 1$. Otherwise, by the pigeonhole principle, there are two columns that are visited on a node of the same row and in the same state. In this case, we define $d_{r,q}$ to be the distance between these two columns. Note that the robot moves arbitrarily far in this case, its row and state repeating every $d_{r,q}$ columns. Let $D := \{d_{r,q}\}$. Analogously, we consider the execution

of the robot if it initially carries the pebble, and define $d^*_{r,q} := 1$, if it ever drops the pebble or moves by at most kh columns in NW or SE direction. Otherwise, there is a repetition every $d^*_{r,q}$ columns, and the robot carries the pebble indefinitely far. Let $D^* := \{d^*_{r,q}\}$.

We now show that $|D| \leq 3k$. If the robot ever is in row r in state q, or row r' in state q', and visits the northernmost (or southernmost) row in the same state q^* in both executions, the executions will be identical afterwards, and therefore, $d_{r,q} = d_{r',q'}$. Hence, there can only be k combinations of rows and states with distinct executions in which the robot visits the northern- or southernmost row, and these executions contribute at most $2k$ distinct distances to D. Now, let q, r, r' such that the robot does not visit the northern- and southernmost row when started in state q in row r or r'. Clearly, the robot performs the exact same actions in both executions. Therefore, $d_{r,q} = d_{r',q}$, and these executions contribute at most k additional distances. Therefore, $|D| \leq 3k$. Analogously, we have $|D^*| \leq 3k$.

We set $b := \prod_{\delta \in D \cup D^*} \delta$. If $b \leq kh$, redefine $b := (kh + 1)b$. It holds that $b = O(h^{6k})$. We subdivide P into a maximum number of blocks such that inner blocks have length b and outer blocks have length greater than b.

We now identify a value d. Consider the subsequence π_i, $i < m$. W.l.o.g., assume the robot moves the pebble from O_ℓ to O_r. Let (r_j, c_j, q_j), $j = 1, \ldots, l$ be the row, column and state in which the pebble is dropped during π_i. We distinguish two cases: In the first case, the robot moves by more than kh columns while carrying the pebble. In this case, it will move until reaching the easternmost column C_r due to having a repetition in its state and row. Therefore, $c_{j+1} - c_j \leq kh$ for $j < l$. In this case, set $d_i = 1$.

In the second case, the robot does never move by more than kh columns to the east while carrying the pebble during π_i. Thus, the pebble is dropped within the first (i.e., western) kh columns of each inner block. P contains $\Omega(f(h)/b) = \omega(h^2) > (kh)^2$ inner blocks, for sufficiently large h. For some column c, we denote its index inside its block as $\tilde{c}$. Hence, for each inner block, there exists a j such that c_j is in that block and $\tilde{c}_j < kh$. There are at most $h \cdot kh \cdot k = (kh)^2$ possibilities for $(r_j, \tilde{c}_j, q_j)$. By the pigeonhole principle, there exist $s < t$ such that $c_s < c_t$ and $(r_s, \tilde{c}_s, q_s) = (r_t, \tilde{c}_t, q_t)$. We set $d_i := (c_t - c_s)/b$, i.e., the number of inner blocks between c_s and c_t, and $d := \prod_{i=1}^{m} d_i$.

Let P' be the parallelogram of height h and length $f(h) + db$. Now we show that $(r_{\pi_{i+1}}, q_{\pi_{i+1}})$ is the same in the execution on P and P' for all $i < m$ and that the robot terminates with the same result during π_m. To that end, we will again look at a subsequence π_i, $i < m$ where, w.l.o.g, the pebble is carried from O_ℓ to O_r and compare the executions on P and P'. Let (r_j, c_j, q_j), $j = 1, \ldots, l$ as above. The first l times the pebble is dropped on P' are identical to those on P, since the only difference in the execution between dropping the pebble at a column c_j, $j \leq l$ and picking it back up again can be when the robot moves to column $\ell - 1$. As argued above, moving to column $\ell - 1$ on P and P' cannot be distinguished by the robot due to a repetition in row and state and by our choice of b. Thus, the pebble is picked up in the same state again.

Next, we need to look at what happens on P' after the pebble has been picked up for the l-th time. Here, we distinguish between the two cases from above. In the first case, the robot carries the pebble by more than kh columns to the east on P before entering O_r and, consequently, continues until reaching column $\ell - 1$. The same behavior occurs on P', only that the robot traverses an additional d blocks and, by our choice of b, enters O_r in the same row and state as on P.

In the second case, it never carries the pebble by more than kh columns to the east during π_i. We identified s, t such that $(r_s, \tilde{c}_s, q_s) = (r_t, \tilde{c}_t, q_t)$, i.e. the pebble is picked up in the same row, block-column, and state. Note that whenever the robot drops the pebble in some

column $\tilde{c}$ of two different inner blocks, it will pick the pebble up again in the same state: This is clearly true if the robot does not visit column 0 and $\ell - 1$ between dropping and placing the pebble. Otherwise, the robot traverses more than kh columns without seeing the pebble, i.e. its row and state repeat every δ columns for some $\delta \in D$. Consequently, by our choice of b, after both drops the robot will return to the pebble (and pick it up) in the same state. Therefore, in both the executions on P and P' the robot will repeatedly drop and pick up the pebble, each repetition occurring d_i blocks to the east from the previous one. As $d_i \mid d$, the robot enters O_r in the same row on P and P' and we thus also have identical $(r_{\pi_{i+1}}, q_{\pi_{i+1}})$.

It only remains to show that the robot terminates with the same result during π_m. W.l.o.g, let π_m begin in O_l on P, and recall that the pebble does not reach O_r before the robot terminates. As argued before, the executions on P and P' can only differ when the robot drops the pebble and moves to the easternmost column of the respective parallelogram. Due to a repetition in state and row, and by our choice of b, the robot again enters the respective easternmost columns in the same state and row, and afterwards picks up the pebble in the same state on both P and P'. Therefore, the robot ultimately terminates in the same state. ◀

3.3 A Robot With Two Pebbles

Next, we show that having two pebbles enables the robot to decide certain exponential functions. Note that by Theorem 5, the following result is optimal in the number of pebbles used.

▶ **Theorem 6.** *A robot with two pebbles can decide whether a given tile configuration is a parallelogram with height $h > 1$ and length*

$\ell = 2^{2^{\cdot^{\cdot^{2^h}}}}$ *, where the power tower is of constant height.*

Proof. Let $s + 1$ be the height of the power tower (i.e., there are s twos in the function) and denote the two pebbles as a and b. Pebble a always resides in the northernmost row of the parallelogram. We use a's column index as a register on which we perform basic arithmetic operations using b as a helper. Note that although the easternmost column of the parallelogram has index $\ell - 1$, we describe the algorithm as if there was an additional column ℓ. A movement from or to column ℓ can easily be simulated by the robot.

The algorithm is divided into three *stages*. The purpose of the first stage is to verify that ℓ is a power of 2. In the second stage, we move a from column ℓ to column $\log^{(s-1)}(\ell)$, where $\log^{(s-1)}(\cdot)$ denotes the application of the logarithm $s - 1$ times. In the third stage, we verify that a is in column 2^h after the second stage. If in any of the three stages the robot detects a violation of any assumption, i.e., if according to the algorithm a would have to be moved beyond column 0 or ℓ, or should be in column 0 or ℓ, but is not, the robot terminates with a negative result.

Before we describe the three stages in more detail, we describe how a's column index can be multiplied or divided by any constant $c \geq 1$, provided that the result is integer and between 0 and ℓ. We first place b at a tile south of a, and then move a into column 0. In case of a multiplication, we then alternatingly move a *NE* by c steps, and b *SE* by one step, until b reaches column 0. In case of a division, we correspondingly move b by c steps and a by one step.

In the first stage, the robot does the following. It first places a at the northernmost tile of column 1. It then repeatedly multiplies by 2 (i.e., multiplies a's column index by 2) using

the above-mentioned strategy. If b reaches column 0 immediately after a has reached column ℓ, ℓ is a power of 2.

At the beginning of the second stage, a is placed at the northernmost tile of column ℓ. The stage is divided into $s-1$ *phases*, where in each phase a is moved from column i to column $\log(i)$. Note that since s is a constant, the robot can count the number of phases. Furthermore, after the first phase ℓ is verified to be a power of 2, and, as we will show later, if a's column index is 2^x at the beginning of a phase, but x is not a power of 2, then the phase fails. Therefore, a's column index is ensured to be a power of 2 at the beginning of each phase.

In each phase, a is moved from some column 2^x to column x in a step-wise fashion. More precisely, in the j-th step it is moved from column $5^{j-1} \cdot 2^{x/2^{j-1}}$ to column $5^j \cdot 2^{x/2^j}$. This is continued until the resulting column index is not divisible by 4 anymore, i.e., when it becomes $5^{\log x} \cdot 2$. The general idea is to use the exponent of 5 as a counter on the number of times x needs to be divided by 2 until it becomes 1, which yields its logarithm. This idea is based on [7, Section 14].

It remains to show how a single step can be performed. First, the robot moves a from column $5^{j-1} \cdot 2^{x/2^{j-1}}$ into column $5^{j-1} \cdot 3^{x/2^j}$ by alternatingly dividing by 4 and multiplying by 3. After each repetition, the robot verifies whether a's column index is divisible by 2. This is done by traversing the northernmost row from west to east until a is reached, and counting the number of steps modulo 2. Note that if $x/2^{j-1}$ is even, which is the case if x is a power of 2, then the division by 4 is always possible. Otherwise, the division by 4 will fail at latest when $x/2^{j-1}$ becomes 1. Once a's column index is not divisible by 2 anymore, a is in column $5^{j-1} \cdot 3^{x/2^j}$.

Analogously, by alternatingly dividing a's column index by 3 and multiplying by 2 as long as the column index is divisible by 3, the robot afterwards moves a into column $5^{j-1} \cdot 2^{x/2^j}$. By multiplying with 5, a is finally moved into column $5^j \cdot 2^{x/2^j}$.

After each step, the robot verifies whether a's column index is divisible by 4. If so, it continues with the next step. Otherwise, $j = \log x$, and thus a must be in column $5^{\log x} \cdot 2$. From there, a can easily be moved into column x by first dividing by 2, and afterwards alternatingly dividing by 5 and multiplying by 2 until the column index is not divisible by 5 anymore.

Note that if a's column index is 2^x at the beginning of some phase, but x is not a power of 2, then at some step $x/2^{j-1}$ will be odd, and, as described above, the algorithm will fail. Further note that for $h \geq 8$, which can be verified beforehand, moving a from column 2^x (where, consequently, x must be at least 8) to $5^{\log x} \cdot 2$ can only decrease a's column index. Therefore, although a might be moved *NE* in the final steps of a phase, it can easily be seen it will be moved sufficiently far *SW* within the first steps such that it is never moved beyond column ℓ. If that happens nonetheless, the robot terminates with a negative result.

Finally, in the third stage, the robot verifies that a is in column 2^h by diving by 2 for h times. To count up to h, b initially resides in row 2 and is moved one step S after each division. When b reaches a southernmost tile, a must lie in column 4, which can easily be verified by the robot. ◀

▶ Remark. The algorithm of the previous theorem can be adapted for any power towers whose height is a linear function $\alpha h + \beta$ for constants α and β. To count the number of phases in the second stage, we move a south after each phase. The highest exponent of the power tower may also be a function linear in h, which can be handled correspondingly in the third stage.

▶ Remark. The algorithm can further be adapted for any other base β. Note that if β is a composite number, we need to apply the operations to its prime factors separately, taking into account their powers. Since it is well-known that for $n \geq 25$ there is always a prime between n and $(1 + 1/5)n$ [19], we can use the two smallest primes that are no prime factors of β instead of 3 and 5 in the second stage of the algorithm.

▶ Remark. In contrast to the negative results of the previous sections, it can be shown that for every computable function f there exists a computable function $f'(x) = \omega(f(x))$ that can be decided using two pebbles. The main idea used in the proof is to simulate a Turing machine to decide $f(x) = y$ for some x and y by simulating a *program machine* [18] as described in the following section. $f'(x)$ is then chosen as a product of prime factors, where the exponent of one prime factor is $f(x)$, and the exponents of the additional factors are chosen to provide exactly the space required for the simulation. Throughout the algorithm's execution, the values of the program machine's registers are represented as the additional prime factor's exponents. If the Turing machine terminates with a positive result, and the given space exactly matches the required space for the simulation, the robot terminates with a positive result.

3.4 A Family of Functions Requiring an Increasing Amount of Pebbles

The discussion from the previous sections naturally brings up the question whether there is a function family whose detection requires an increasing amount of pebbles. In this section, we answer that question positively. As the proofs are fairly straightforward, we mostly state the general ideas, leaving out some details.

In order to simplify analysis, we consider a robot with pebbles operating on a line segment instead of a parallelogram. We also assume that pebbles are distinguishable and can be placed onto the same tile. Note that it is easy to simulate colors of a finite amount of pebbles on a line segment by keeping track of the pebbles' order. Furthermore, the robot can simulate placing two pebbles onto each other by placing the second pebble within constant distance instead and save the offset from its intended position.

First, we introduce the notion of *program machines* as defined in [18, Section 11].

▶ **Definition 7.** A *program machine* consists of a finite set of registers, holding arbitrary numbers from $\mathbb{N}_0$, and a finite program of numbered instructions from the following instruction set.

- $zero(r)$: Set register $r := 0$.
- $increment(r)$: Set register $r := r + 1$.
- $decrementOrJump(r, n)$: If $r = 0$, jump to instruction n. Otherwise set $r := r - 1$.
- $halt$: Stop the execution.

▶ Remark. Using the instructions from Definition 7, it is possible to simulate instructions to copy the value of register r_1 to r_2, and to jump if (or if not) $r_1 = r_2$ [18].

▶ **Lemma 8.** *A 3 register program machine can simulate a deterministic Turing machine with* $\Gamma = \Sigma = \{0, 1\}$.

Proof. It is well known that a Turing machine can be simulated using two stacks containing the tape's bits behind and in front of the head, respectively. These stacks can be viewed as the binary encoding of natural numbers. They will be stored in registers one and two.

Using the third register as a scratch pad, doubling and halving a register is simple. To pop a bit from the stack, we divide by two and look at the remainder. To push a bit onto the stack, we multiply by two and add the bit. For more details, we refer the reader to [18, Section 11]. ◀

Since we are interested in a robot moving on a finite space, we now define *bounded program machines*.

▶ **Definition 9.** A *bounded program machine* is a program machine whose first register is initialized to the input x. The other registers are initialized to 0. No register may exceed x.

The following observation follows from the fact that a robot can easily simulate a bounded program machine using pebbles, and vice versa.

▶ **Observation 10.** *The computational power of a robot with n pebbles on a line of length $x \geq n$ is between that of an n and an $n+1$ register bounded program machine with input x.*

The next two lemmas show that deterministic linear bounded automata are essentially equivalent in their computational capabilities to bounded program machines and that the number of registers relates to the number of tape symbols needed. This enables us to apply well-known results from complexity theory to our model. We use the definition of deterministic linear bounded automata from [7] as Turing machines that never leave the cells in which their input was placed. Inputs are restricted to $\{0,1\}^*$.

▶ **Lemma 11.** *A deterministic linear bounded automaton with $|\Gamma| = n$ and $\Sigma = \{0,1\}$ with input $x \in \Sigma^*$ can be simulated using a $1 + 2\lceil \log n \rceil$ register bounded program machine with input $x' := (1x)_2$.*

Proof. The construction from Lemma 8 ensures that no register will be increased beyond x' when simulating the linear bounded automaton. The two stacks will now contain elements in Γ. We encode the symbols in binary and store their representation using $2\lceil \log n \rceil$ registers. ◀

▶ **Lemma 12.** *An n register bounded program machine with input $(1x)_2, x \in \{0,1\}^*$ can be simulated by a deterministic linear bounded automaton with 2^n tape symbols and input x.*

Proof. The tape stores the binary representation of the registers' values, each symbol representing one bit of n registers. Operations from Definition 7 are now trivial to perform. ◀

Finally, it can be shown that there exists a family of languages requiring deterministic linear bounded automata with an increasing amount of tape symbols. These will directly translate to sets of accepted line lengths.

▶ **Lemma 13.** *There exists a family of context sensitive languages $S_n \subseteq \{0,1\}^*$ not accepted by any deterministic linear bounded automaton with fewer than n symbols [7, Corollary 2].*

Together with Observation 10, the previous lemmas imply the following theorem.

▶ **Theorem 14.** *There exists a family $L_n \subseteq \mathbb{N}$ such that a robot exists that can detect whether a line has length $\ell \in L_n$ using a finite number of pebbles but none using less than n pebbles.*

To construct a family of functions for deciding side ratios of a parallelogram, we can set

$$f_n(h) = \begin{cases} 1, & h \in L_n \\ 2, & h \notin L_n \end{cases}.$$

▶ Remark. The resulting parallelogram differs from the previous examples in that its length is only 1 or 2. Note that the robot can perform the simulation of the bounded program machine using the parallelograms height, and a length of 2 does not give it too much power. Furthermore, we can modify the function family such that $\ell \geq h$ while still requiring n pebbles to decide $f_n(h)$.

4 Future Work

In this paper we have identified some simple functions that can or cannot be decided with a given set of pebbles. Beyond our study in Section 3.4, we are interested to find functions, such as superexponentials, that require more than only two pebbles. Furthermore, it is an interesting question whether, instead or in addition to using pebbles, multiple robots can help in shape recognition problems. For example, it is still an open question whether two robots, which are activated in an arbitrary order, are more powerful than a single robot with a pebble. Apart from that, there are many different model assumptions under which our problems can be investigated.

In this work we primarily focused on detecting parallelograms of certain side ratios. As our ultimate goal is to investigate shape recognition in general, we are very interested to examine whether our results and algorithms are applicable to other shapes as well. For example, it may be possible to recognize more complex structures such as irregular hexagons with certain side ratios, or to even come up with a more generic procedure to recognize larger families of shapes. Furthermore, rasterized disks or ellipses might be interesting shapes to consider. Other intriguing problems related to shape recognition include testing symmetry or simply-connectedness of a tile structure.

Abstract

In this paper we study recently introduced conflict version of the classical Feedback Vertex Set (FVS) problem. For a family of graphs $\mathcal{F}$, we consider the problem $\mathcal{F}$-CF-Feedback Vertex Set ($\mathcal{F}$-CF-FVS, for short). The $\mathcal{F}$-CF-FVS problem takes as an input a graph G, a graph $H \in \mathcal{F}$ (where $V(G) = V(H)$), and an integer k, and the objective is to decide if there is a set $S \subseteq V(G)$ of size at most k such that $G - S$ is a forest and S is an independent set in H. Observe that if we instantiate $\mathcal{F}$ to be the family of edgeless graphs then we get the classical FVS problem. Jain, Kanesh, and Misra [CSR 2018] showed that in contrast to FVS, $\mathcal{F}$-CF-FVS is W[1]-hard on general graphs and admits an FPT algorithm if $\mathcal{F}$ is the family of d-degenerate graphs. In this paper, we relate $\mathcal{F}$-CF-FVS to the Independent Set problem on special classes of graphs, and obtain a complete dichotomy result on the Parameterized Complexity of the problem $\mathcal{F}$-CF-FVS, when $\mathcal{F}$ is a hereditary graph family. In particular, we show that $\mathcal{F}$-CF-FVS is FPT parameterized by the solution size if and only if $\mathcal{F}$+Cluster IS is FPT parameterized by the solution size. Here, $\mathcal{F}$+Cluster IS is the Independent Set problem in the (edge) union of a graph $G \in \mathcal{F}$ and a cluster graph H (G and H are explicitly given). Next, we exploit this characterization to obtain new FPT results as well as intractability results for $\mathcal{F}$-CF-FVS. In particular, we give an FPT algorithm for $\mathcal{F}$+Cluster IS when $\mathcal{F}$ is the family of $K_{i,j}$-free graphs. We show that for the family of bipartite graph $\mathcal{B}$, $\mathcal{B}$-CF-FVS is W[1]-hard, when parameterized by the solution size. Finally, we consider, for each $0 < \epsilon < 1$, the family of graphs $\mathcal{F}_\epsilon$, which comprise of graphs G such that $|E(G)| \leq |V(G)|^{2-\epsilon}$, and show that $\mathcal{F}_\epsilon$-CF-FVS is W[1]-hard, when parameterized by the solution size, for every $0 < \epsilon < 1$.

1 Introduction

Feedback Vertex Set (FVS) is one of the classical NP-hard problems that has been subjected to intensive study in algorithmic paradigms that are meant for coping with NP-hard problems, and particularly in the realm of Parameterized Complexity. In this problem, given a graph G and an integer k, the objective is to decide if there is $S \subseteq V(G)$ of size at most k such that $G - S$ is a forest. FVS has received a lot of attention in the realm of Parameterized Complexity. This problem is known to be in FPT, and the best known algorithm for it runs in time $\mathcal{O}(3.618^k n^{\mathcal{O}(1)})$ [8, 13]. Several variant and generalizations of Feedback Vertex Set such as Weighted Feedback Vertex Set [2, 7], Independent Feedback Vertex Set [1, 14], Connected Feedback Vertex Set [15], and Simultaneous Feedback Vertex Set [3, 6] have been studied from the viewpoint of Parameterized Complexity.

Recently, Jain et al. [12] defined an interesting generalization of well-studied vertex deletion problems – in particular for FVS. The CF-Feedback Vertex Set (CF-FVS, for short) problem takes as input graphs G and H, and an integer k, and the objective is to decide if there is a set $S \subseteq V(G)$ of size at most k such that $G - S$ is a forest and S is an independent set in H. The graph H is also called a *conflict graph*. Observe that the CF-FVS problem generalizes classical graph problems, Feedback Vertex Set and Independent Feedback Vertex Set. A natural way of defining CF-FVS will be by fixing a family $\mathcal{F}$ from which the conflict graph H is allowed to belong. Thus, for every fixed $\mathcal{F}$ we get a new CF-FVS problem. In particular we get the following problem.

$\mathcal{F}$-CF-Feedback Vertex Set ($\mathcal{F}$-CF-FVS)	**Parameter:** k
Input: A graph G, a graph $H \in \mathcal{F}$ (where $V(G) = V(H)$), and an integer k.	
Question: Is there a set $S \subseteq V(G)$ of size at most k, such that $G - S$ is a forest and S is an independent set in H?	

Jain et al. [12] showed that $\mathcal{F}$-CF-FVS is W[1]-hard when $\mathcal{F}$ is a family of all graphs and admits FPT algorithm when the input graph H is from the family of d-degenerate graphs and the family of nowhere dense graphs. The most natural question that arises here is the following.

Question 1: For which graph families $\mathcal{F}$, $\mathcal{F}$-CF-FVS is FPT?

Our Results. Starting point of our research is Question 1. We obtain a complete dichotomy result on the Parameterized Complexity of the problem $\mathcal{F}$-CF-FVS (for hereditary $\mathcal{F}$) in terms of another well-studied problem, namely, the Independent Set problem – the wall of intractability. Towards stating our results, we start by defining the problem $\mathcal{F}$+Cluster IS, which is of independent interest. A *cluster graph* is a graph formed from the disjoint union of complete graphs (or cliques).

$\mathcal{F}$+Cluster Independent Set ($\mathcal{F}$+Cluster IS)	**Parameter:** k
Input: A graph $G \in \mathcal{F}$, a cluster graph H (where $V(G) = V(H)$), and an integer k, such that H has exactly k connected components.	
Question: Is there a set $S \subseteq V(G)$ of size k, such that S is an independent set in both G and in H?	

We note that $\mathcal{F}$+Cluster IS is the Independent Set problem on the edge union of two graphs, where one of the graphs is from the family of graphs $\mathcal{F}$ and the other one is a cluster graph. Here, additionally we know the partition of edges into two sets, E_1 and E_2 such that the graph induced on E_1 is in $\mathcal{F}$ and the graph induced on E_2 is a cluster graph. We note that $\mathcal{F}$+Cluster IS has been studied in the literature for $\mathcal{F}$ being the family of interval graphs (with no restriction on the number of clusters) [18]. They showed the problem to be FPT. Recently, Bentert et al. [4] generalized the result from interval graphs to chordal graphs. This problem arises naturally in the study of scheduling problems. We refer the readers to [18, 4] for more details on the application of $\mathcal{F}$+Cluster IS.

We are now ready to state our results. We show that $\mathcal{F}$-CF-FVS is in FPT if and only if $\mathcal{F}$+Cluster IS is in FPT, where $\mathcal{F}$ is a family of hereditary graphs. We obtain a complete characterization of when the $\mathcal{F}$-CF-FVS problem is in FPT, for hereditary graph families. To prove the forward direction, i.e., showing that $\mathcal{F}$+Cluster IS is in FPT implies $\mathcal{F}$-CF-FVS is in FPT, we design a branching based algorithm, which at the base case generates instances of $\mathcal{F}$+Cluster IS, which is solved using the assumed FPT algorithm for $\mathcal{F}$+Cluster IS. Thus, we give "fpt-turing-reduction" from $\mathcal{F}$-CF-FVS to $\mathcal{F}$+Cluster IS. It is worth to note that there are very few known reductions of this nature. To show that $\mathcal{F}$-CF-FVS is in FPT implies that $\mathcal{F}$+Cluster IS is in FPT, we give an appropriate reduction from $\mathcal{F}$+Cluster IS to $\mathcal{F}$-CF-FVS, which proves the statement. We note that our result that $\mathcal{F}$-CF-FVS is in FPT implies $\mathcal{F}$+Cluster IS is in FPT, holds for all families of graphs.

Next, we consider two families of graphs. We first design FPT algorithm for the corresponding $\mathcal{F}$+Cluster IS problem. For the second class we give a hardness result. First, we consider the problem $K_{i,j}$-free+Cluster IS, which is the $\mathcal{F}$+Cluster IS problem for the family of $K_{i,j}$-free graphs. We design an FPT algorithm for $K_{i,j}$-free+Cluster IS based on branching together with solving the base cases using a greedy approach. This adds another family of graphs, apart from interval and chordal graphs, such that $\mathcal{F}$+Cluster IS is FPT.

We note that $K_{i,j}$-free graphs have at most $n^{2-\epsilon}$ edges, where n is the number of vertices in the input graph and $\epsilon = \epsilon(i,j) > 0$ [17, 11]. We complement our FPT result on $K_{i,j}$-free+Cluster IS with the W[1]-hardness result of the $\mathcal{F}$+Cluster IS problem when $\mathcal{F}$ is the family of graphs with at most $n^{2-\epsilon}$ edges. This result is obtained by giving an appropriate reduction from the problem Multicolored Biclique, which is known to be W[1]-hard [8, 10]. We also show that the $\mathcal{F}$+Cluster IS problem is W[1]-hard when $\mathcal{F}$ is the family of bipartite graphs. Again, this result is obtained via a reduction from Multicolored Biclique.

2 Preliminaries

In this section, we state some basic definitions and terminologies from Graph Theory that are used in this paper. For the graph related terminologies which are not explicitly defined here, we refer the reader to the book of Diestel [9].

Graphs. Consider a graph G. By $V(G)$ and $E(G)$ we denote the set of vertices and edges in G, respectively. When the graph is clear from the context, we use n and m to denote the number of vertices and edges in the graph, respectively. For $X \subseteq V(G)$, by $G[X]$ we denote the subgraph of G with vertex set X and edge set $\{uv \in E(G) \mid u, v \in X\}$. Moreover, by $G - X$ we denote graph $G[V(G) \setminus X]$. For $v \in V(G)$, $N_G(v)$ denotes the set $\{u \mid uv \in E(G)\}$, and $N_G[v]$ denotes the set $N_G(v) \cup \{v\}$. By $\mathsf{deg}_G(v)$ we denote the size of $N_G(v)$. A *path* $P = (v_1, \ldots, v_n)$ is an ordered collection of vertices, with endpoints v_1 and v_n, such that there is an edge between every pair of consecutive vertices in P. A *cycle* $C = (v_1, \ldots, v_n)$ is

a path with the edge v_1v_n. Consider graphs G and H. We say that G is an *H-free* graph if no subgraph of G is isomorphic to H. For $u, v \in V(G) \cap V(H)$, we say that u and v are in *conflict* in G with respect to H if $uv \in E(H)$.

3 W-hardness of $\mathcal{F}$-CF-FVS Problems

This section is devoted to showing W-hardness results for $\mathcal{F}$-CF-FVS problems for certain graph classes, $\mathcal{F}$. In Section 3.1, we show one direction of our dichotomy result. That is, if for a family of graphs $\mathcal{F}$, $\mathcal{F}$+Cluster IS is not in FPT when parameterized by the size of solution then $\mathcal{F}$-CF-FVS is also not in FPT when parameterized by the size of solution. This result is obtained by giving a parameterized reduction from $\mathcal{F}$+Cluster IS to $\mathcal{F}$-CF-FVS. Next, we show that the problem $\mathcal{F}$-CF-FVS is W[1]-hard, when parameterized by the size of solution, where $\mathcal{F}$ is the family of bipartite graphs (Section 3.2) or the family of graphs with sub-quadratic number of edges (Section 3.3). These results are obtained by giving an appropriate reduction from the problem Multicolored Biclique, which is known to be W[1]-hard [8, 10].

3.1 $\mathcal{F}$+Cluster IS to $\mathcal{F}$-CF-FVS

In this section, we show that, for a family of graphs $\mathcal{F}$, if $\mathcal{F}$+Cluster IS is not in FPT, then $\mathcal{F}$-CF-FVS is also not in FPT (where the parameters are the solution sizes). To prove this result, we give a parameterized reduction from $\mathcal{F}$+Cluster IS to $\mathcal{F}$-CF-FVS.

Let (G, H, k) be an instance of $\mathcal{F}$+Cluster IS. We construct an instance (G', H', k') of $\mathcal{F}$-CF-FVS as follows. We have $H' = G$, $k' = k$, and $V(G') = V(H)$. Let $\mathcal{C}$ be the set of connected components in H. Recall that we have $|\mathcal{C}| = k$. For each $C \in \mathcal{C}$, we add a cycle (in an arbitrarily chosen order) induced on vertices in $V(C)$ in G'. This completes the description of the reduction. Next, we show the equivalence between the instance (G, H, k) of $\mathcal{F}$+Cluster IS and the instance (G', H', k') of $\mathcal{F}$-CF-FVS.

▶ **Lemma 1.** *(G, H, k) is a* yes *instance of $\mathcal{F}$+Cluster IS if and only if (G', H', k') is a* yes *instance of $\mathcal{F}$-CF-FVS.*

Proof. In the forward direction, let (G, H, k) be a yes instance of $\mathcal{F}$+Cluster IS, and S be one of its solution. Since $H' = G$, therefore, S is an independent set in H'. Let $\mathcal{C}$ be the set of connected components in H. As S is a solution, it must contain exactly one vertex from each $C \in \mathcal{C}$. Moreover, G' comprises of vertex disjoint cycles for each $C \in \mathcal{C}$. Thus S intersects every cycle in G'. Therefore, S is a solution to $\mathcal{F}$-CF-FVS in (G', H', k').

In the reverse direction, let (G', H', k') be a yes instance of $\mathcal{F}$-CF-FVS, and S be one of its solution. Recall that G' comprises of k vertex disjoint cycles, each corresponding to a connected component $C \in \mathcal{C}$, where $\mathcal{C}$ is the set of connected components in H. Therefore, S contains exactly one vertex from each $C \in \mathcal{C}$. Also, $H' = G$, and therefore, S is an independent set in G. This implies that S is a solution to $\mathcal{F}$+Cluster IS in (G, H, k). ◀

Now we are ready to state the main theorem of this section.

▶ **Theorem 2.** *For a family of graphs $\mathcal{F}$, if $\mathcal{F}$+Cluster IS is not in FPT when parameterized by the solution size, then $\mathcal{F}$-CF-FVS is also not in FPT when parameterized by the solution size.*

3.2 W[1]-hardness on Bipartite Graphs

In this section, we show that for the family of bipartite graphs, $\mathcal{B}$, the $\mathcal{B}$-CF-FVS problem is W[1]-hard, when parameterized by the solution size. Throughout this section, $\mathcal{B}$ will denote the family of bipartite graphs. To prove our result, we give a parameterized reduction from the problem Multicolored Biclique to $\mathcal{B}$-CF-FVS. In the following, we formally define the problem Multicolored Biclique.

Multicolored Biclique (MBC) **Parameter:** k
Input: A bipartite graph G, a partition of A into k sets $A_1, A_2, \cdots, A_k$, and a partition of B into k sets $B_1, B_2, \cdots, B_k$, where A and B are a vertex bipartition of G.
Question: Is there a set $S \subseteq V(G)$ such that for each $i \in [k]$ we have $|S \cap A_i| = 1$ and $|S \cap B_i| = 1$, and $G[S]$ is isomorphic to $K_{k,k}$?

Let $(G, A_1, \cdots, A_k, B_1, \cdots, B_k)$ be an instance of Multicolored Biclique. We construct an instance (G', H', k') of $\mathcal{B}$-CF-FVS as follows. We have $V(G') = V(H') = V(G)$, and $E(H') = \{uv \mid u \in \cup_{i\in[k]} A_i, v \in \cup_{i\in[k]} B_i, \text{ and } uv \notin E(G)\}$. Next, for each $i \in [k]$, we add a cycle (in an arbitrary order) induced on vertices in A_i in G'. Similarly, we add for each $i \in [k]$, a cycle induced on vertices in B_i in G'. Notice that G' comprises of $2k$ vertex disjoint cycles, and H' is a bipartite graph. Finally, we set $k' = 2k$. This completes the description of the reduction.

▶ **Lemma 3.** *$(G, A_1, \cdots, A_k, B_1, \cdots, B_k)$ is a* yes *instance of* Multicolored Biclique *if and only if (G', H', k') is a* yes *instance of $\mathcal{B}$-CF-FVS.*

Now we are ready to sate the main theorem of this section.

▶ **Theorem 4.** *$\mathcal{B}$-CF-FVS parameterized by the solution size is W[1]-hard, where $\mathcal{B}$ is the family of bipartite graphs.*

3.3 W[1]-hardness on Graphs with Sub-quadratic Edges

In this section, we show that $\mathcal{F}$-CF-FVS is W[1]-hard, when parameterized by the solution size, where $\mathcal{F}$ is the family of graphs with sub-quadratic edges. To formalize the family of graphs with subquadratic edges, we define the following. For $0 < \epsilon < 1$, we define $\mathcal{F}_\epsilon$ to be the family comprising of graphs G, such that $|E(G)| \leq |V(G)|^{2-\epsilon}$. We show that for every $0 < \epsilon < 1$, the $\mathcal{F}_\epsilon$-CF-FVS problem is W[1]-hard, when parameterized by the solution size. Towards this, for each (fixed) $0 < \epsilon < 1$, we give a parameterized reduction from Multicolored Biclique to $\mathcal{F}_\epsilon$-CF-FVS.

Let $(G, A_1, \cdots, A_k, B_1, \cdots, B_k)$ be an instance of Multicolored Biclique. We construct an instance (G', H', k') of $\mathcal{F}_\epsilon$-CF-FVS as follows. Let $n = |V(G)|$, $m = |E(G)|$, and X be a set comprising of $n^{\frac{2}{2-\epsilon}} - n$ (new) vertices. The vertex set of G' and H' is $X \cup V(G)$. For each $i \in [k]$, we add a cycle (in arbitrary order) induced on vertices in A_i in G'. Similarly, we add for each $i \in [k]$, a cycle induced on vertices in B_i in G'. Also, we add a cycle induced on vertices in X to G'. We have $E(H') = \{uv \mid u \in \cup_{i\in[k]} A_i, v \in \cup_{i\in[k]} B_i, \text{ and } uv \notin E(G)\}$. Finally, we set $k' = 2k + 1$. Notice that since $|V(H')| = n^{\frac{2}{2-\epsilon}}$, and $|E(H')| < n^2$, therefore, $H \in \mathcal{F}_\epsilon$.

▶ **Lemma 5.** *$(G, A_1, \cdots, A_k, B_1, \cdots, B_k)$ is a* yes *instance of* Multicolored Biclique *if and only if (G', H', k') is a* yes *instance of $\mathcal{F}_\epsilon$-CF-FVS.*

Now we are ready to state the main theorem of this section.

▶ **Theorem 6.** *For $0 < \epsilon < 1$, $\mathcal{F}_\epsilon$-CF-FVS parameterized by the solution size is* W[1]-hard.

4 FPT algorithms for $\mathcal{F}$-CF-FVS for Restricted Conflict Graphs

For a hereditary (closed under taking induced subgraphs) family of graphs $\mathcal{F}$, we show that if $\mathcal{F}$+Cluster IS is FPT, then $\mathcal{F}$-CF-FVS is FPT. Throughout this section, whenever we refer to a family of graphs, it will refer to a hereditary family of graphs. To prove our result, for a family of graphs $\mathcal{F}$, for which $\mathcal{F}$+Cluster IS is FPT, we will design an FPT algorithm for $\mathcal{F}$-CF-FVS, using the (assumed) FPT algorithm for $\mathcal{F}$+Cluster IS. We note that this gives us a Turing parameterized reduction from $\mathcal{F}$-CF-FVS to $\mathcal{F}$+Cluster IS. Our algorithm will use the technique of compression together with branching. We note that the method of iterative compression was first introduced by Reed, Smith, and Vetta [16], and in our algorithm, we (roughly) use only the compression procedure from it.

In the following, we let $\mathcal{F}$ to be a (fixed hereditary) family of graphs, for which $\mathcal{F}$+Cluster IS is in FPT. Towards designing an algorithm for $\mathcal{F}$-CF-FVS, we define another problem, which we call $\mathcal{F}$-Disjoint Conflict Free Feedback Vertex Set (to be defined shortly). Firstly, we design an FPT algorithm for $\mathcal{F}$-CF-FVS using an assumed FPT algorithm for $\mathcal{F}$-Disjoint Conflict Free Feedback Vertex Set. Secondly, we give an FPT algorithm for $\mathcal{F}$-Disjoint Conflict Free Feedback Vertex Set using the assumed algorithm for $\mathcal{F}$+Cluster IS. In the following, we formally define the problem $\mathcal{F}$-Disjoint Conflict Free Feedback Vertex Set ($\mathcal{F}$-DCF-FVS, for short)

$\mathcal{F}$-Disjoint Conflict Free Feedback Vertex Set ($\mathcal{F}$-DCF-FVS) **Parameter:** k
Input: A graph G, a graph $H \in \mathcal{F}$, an integer k, a set $W \subseteq V(G)$, a set $R \subseteq V(H) \setminus W$, and a set $\mathcal{C}$, such that the following conditions are satisfied: 1) $V(G) \subseteq V(H)$, 2) $G - W$ is a forest, 3) the number of connected components in $G[W]$ is at most k, and 4) $\mathcal{C}$ is a set of vertex disjoint subsets of $V(H)$.
Question: Is there a set $S \subseteq V(H) \setminus (W \cup R)$ of size at most k, such that $G - S$ is a forest, S is an independent set in H, and for each $C \in \mathcal{C}$, we have $\lvert S \cap C \rvert \neq \emptyset$?

We note that in the definition of $\mathcal{F}$-DCF-FVS, there are three additional inputs (i.e. W, R and C). The purpose and need for these sets will become clear when we describe the algorithm for $\mathcal{F}$-DCF-FVS. In Section 4.1, we will prove the following theorem.

▶ **Theorem 7.** *Let $\mathcal{F}$ be a hereditary family of graphs for which there is an FPT algorithm for $\mathcal{F}$+Cluster IS running in time $f(k)n^{\mathcal{O}(1)}$, where n is the number of vertices in the input graph. Then, there is an FPT algorithm for $\mathcal{F}$-DCF-FVS running in time $16^k f(k)n^{\mathcal{O}(1)}$, where n is the (total) number of vertices in the input graphs.*

In the rest of the section, we show how we can use the FPT algorithm for $\mathcal{F}$-DCF-FVS to obtain an FPT algorithm for $\mathcal{F}$-CF-FVS.

An Algorithm for $\mathcal{F}$-CF-FVS using the algorithm for $\mathcal{F}$-DCF-FVS. Let $I = (G, H, k)$ be an instance of $\mathcal{F}$-CF-FVS. We start by checking whether or not G has a feedback vertex set of size at most k, i.e. a set Z of size at most k, such that $G - Z$ is a forest. For this we employ the algorithm for Feedback Vertex Set running in time $\mathcal{O}(3.619^k n^{\mathcal{O}(1)})$ of Kociumaka and Pilipczuk [13]. Here, n is the number of vertices in the input graph. Notice that if G does not have a feedback vertex set of size at most k, then (G, H, k) is a no instance of $\mathcal{F}$-CF-FVS, and we can output a trivial no instance of $\mathcal{F}$-DCF-FVS. Therefore, we assume that (G, k) is a yes instance of Feedback Vertex Set, and let Z be one of its solution. We note that such a set Z can be computed using the algorithm presented in [13]. We generate an instance I_Y of $\mathcal{F}$-DCF-FVS, for each $Y \subseteq Z$, where Y is the guessed (exact) intersection of the set Z with an assumed (hypothetical) solution to $\mathcal{F}$-CF-FVS in I. We now formally describe the construction of I_Y. Consider a set $Y \subseteq Z$, such that Y is an independent set in H. Let

$G_Y = G - Y$, $H_Y = H - Y$, $k_Y = k - |Y|$, $W_Y = Z \setminus Y$, $R_Y = (N_H(Y) \setminus W_Y) \cap V(H_Y)$, and $\mathcal{C}_Y = \emptyset$. Furthermore, let $I_Y = (G_Y, H_Y, k_Y, W_Y, R_Y, \mathcal{C}_Y)$, and notice that I_Y is a (valid) instance of $\mathcal{F}$-DCF-FVS. Now we resolve I_Y using the (assumed) FPT algorithm for $\mathcal{F}$-DCF-FVS, for each $Y \subseteq Z$, where Y is an independent set in H. It is easy to see that I is a yes instance of $\mathcal{F}$-CF-FVS if and only if there is an independent set $Y \subseteq Z$ in H, such that I_Y is a yes instance of $\mathcal{F}$-DCF-FVS. From the above discussions, we obtain the following lemma.

▶ **Lemma 8.** *Let $\mathcal{F}$ be a family of graphs for which $\mathcal{F}$-DCF-FVS admits an FPT algorithm running in time $f(k)c^k n^{\mathcal{O}(1)}$, where n is the (total) number of vertices in the input graph. Then $\mathcal{F}$-CF-FVS admits an FPT algorithm running in time $f(k)(1+c)^k n^{\mathcal{O}(1)}$, where n is the number of vertices in the input graphs.*

Using Theorem 7 and Lemma 8, we obtain the main theorem of this section.

▶ **Theorem 9.** *Let $\mathcal{F}$ be a hereditary family of graphs for which there is an FPT algorithm for $\mathcal{F}$+Cluster IS running in time $f(k)n^{\mathcal{O}(1)}$, where n is the number of vertices in the input graph. Then, there is an FPT algorithm for $\mathcal{F}$-CF-FVS running in time $17^k f(k)n^{\mathcal{O}(1)}$, where n is the number of vertices in the input graphs of $\mathcal{F}$-CF-FVS.*

4.1 FPT Algorithm for $\mathcal{F}$-DCF-FVS

The goal of this section is to prove Theorem 7. Let $\mathcal{F}$ be a (fixed) hereditary family of graphs, for which $\mathcal{F}$+Cluster IS admits an FPT algorithm. We design a branching based FPT algorithm for $\mathcal{F}$-DCF-FVS, using the (assumed) FPT algorithm for $\mathcal{F}$+Cluster IS.

Let $I = (G, H, k, W, R, \mathcal{C})$ be an instance of $\mathcal{F}$-DCF-FVS. In the following we describe some reduction rules, which the algorithm applies exhaustively, in the order in which they are stated.

▶ **Reduction Rule 1.** *Return that $(G, H, k, W, R, \mathcal{C})$ is a no instance of $\mathcal{F}$-DCF-FVS if one of the following conditions are satisfied:*

1. *if $k < 0$,*
2. *if $k = 0$ and G has a cycle,*
3. *$k = 0$ and $\mathcal{C} \neq \emptyset$,*
4. *$G[W]$ has a cycle,*
5. *if $|\mathcal{C}| > k$, or*
6. *there is $C \in \mathcal{C}$, such that $C \subseteq R$.*

▶ **Reduction Rule 2.** *If $k = 0$, G is acyclic, and $\mathcal{C} = \emptyset$, then return that $(G, H, k, W, R, \mathcal{C})$ is a yes instance of $\mathcal{F}$-DCF-FVS.*

In the following, we state a lemma, which is useful in resolving those instances where the graph G has no vertices.

▶ **Lemma 10.** *Let $(G, H, k, W, R, \mathcal{C})$ be an instance of $\mathcal{F}$-DCF-FVS, where Reduction Rules 1 is not applicable and $G - W$ has no vertices. Then, in polynomial time, we can generate an instance (G', H', k') of $\mathcal{F}$+Cluster IS, such that $(G, H, k, W, R, \mathcal{C})$ is a yes instance of $\mathcal{F}$-DCF-FVS if and only if (G', H', k') is a yes instance of $\mathcal{F}$+Cluster IS.*

Lemma 10 leads us to the following reduction rule.

▶ **Reduction Rule 3.** *If $G - W$ has no vertices, then return the output of algorithm for $\mathcal{F}$+Cluster IS with the instance generated by Lemma 10.*

▶ **Reduction Rule 4.** *If there is a vertex $v \in V(G)$ of degree at most one in G, then return $(G - \{v\}, H, k, W \setminus \{v\}, R, \mathcal{C})$.*

The safeness of Reduction Rule 4 follows from the fact that a vertex of degree at most one does not participate in any cycle.

▶ **Reduction Rule 5.** *Let $uv \in E(G)$ be an edge of multiplicity greater than 2 in G, and G' be the graph obtained from G by reducing the multiplicity of uv in G to 2. Then, return $(G', H, k, W, R, \mathcal{C})$.*

The safeness of Reduction Rule 5 follows from the fact that for an edge, multiplicity of 2 is enough to capture multiplicities of size larger than 2.

▶ **Reduction Rule 6.** *Let $v \in R$ be a degree 2 vertex in G with u and w being its neighbors in G. Furthermore, let G' be the graph obtained from G by deleting v and adding the (multi) edge uw. Then, return $(G', H - \{v\}, k, W, R \setminus \{v\}, \mathcal{C})$.*

The safeness of Reduction Rule 6 follows from the fact that a vertex in R cannot be part of any solution and any cycle (in G) containing v must contain both u and w.

▶ **Reduction Rule 7.** *If there is $v \in (V(G) \cap R)$, such that v has at least two neighbors in the same connected component of W, then return that $(G, H, k, W, R, \mathcal{C})$ is a no instance of $\mathcal{F}$-DCF-FVS.*

▶ **Reduction Rule 8.** *If there is $v \in V(G) \setminus (W \cup R)$, such that v has at least two neighbors in the same connected component of W, then return $(G - \{v\}, H - \{v\}, k - 1, W, R \cup N_H(v), \mathcal{C})$.*

▶ **Reduction Rule 9.** *Let $v \in V(G) \cap R$, such that $N_G(v) \cap W \neq \emptyset$. Then, return $(G, H, k, W \cup \{v\}, R \setminus \{v\}, \mathcal{C})$.*

Let η be the number of connected components in $G[W]$. In the following, we define the measure we use to compute the running time of our algorithm.

$$\mu(I) = \mu((G, H, k, W, R, \mathcal{C})) = k + \eta - |\mathcal{C}|$$

Observe that none of the reduction rules that we described increases the measure, and a reduction rule can be applied only polynomially many time. When none of the reduction rules are applicable, the degree of each vertex in G is at least two, multiplicity of each edge in G is at most two, degree two vertices in G do not belong to the set R, and $G[W]$ and $G - W$ are forests. Furthermore, for each $v \in V(G) \setminus W$, v has at most 1 neighbor (in G) in a connected component of $G[W]$.

In the following, we state the branching rules used by the algorithm. We assume that none of the reduction rules are applicable, and the branching rules are applied in the order in which they are stated. The algorithm will branch on vertices in $V(G) \setminus W$.

▶ **Branching Rule 1.** *If there is $v \in V(G) \setminus W$ that has at least two neighbors (in G), say $w_1, w_2 \in W$. Since Reduction Rule 7 and 8 are not applicable, w_1 and w_2 belong to different connected components of $G[W]$. Also, since Reduction Rule 9 is not applicable, we have $v \notin R$. In this case, we branch as follows.*

- **(i)** *v belongs to the solution. In this branch, we return $(G - \{v\}, H - \{v\}, k - 1, W, R \cup N_H(v), \mathcal{C})$.*
- **(ii)** *v does not belongs to the solution. In this branch, we return $(G, H, k, W \cup \{v\}, R, \mathcal{C})$.*

In one branch when v belongs to the solution, k decreases by 1, and η and $|\mathcal{C}|$ do not change. Hence, μ decreases by 1. In other branch when v is moved to W, number of components in η decreases by at least one, and k and $|\mathcal{C}|$ do not change. Therefore, μ decreases by at least 1. The resulting branching vector for the above branching rule is $(1, 1)$.

If Branching Rule 1 is not applicable, then each $v \in V(G) \setminus W$ has at most one neighbor (in G) in the set W. Moreover, since Reduction Rule 4 is not applicable, each leaf in $G - W$ has a neighbor in W.

In the following, we introduce some notations, which will be used in the description of our branching rules. Recall that $G - W$ is a forest. Consider a connected component T in $G - W$. A path P_{uv} from a vertex u to a vertex v in T is *nice* if u and v are of degree at least 2 in G, all internal vertices (if they exist) of P_{uv} are of degree exactly 2 in G, and v is a leaf in T. In the following, we state an easy proposition, which will be used in the branching rules that we design.

▶ **Proposition 1.** *Let $(G, H, k, W, R, \mathcal{C})$ be an instance of $\mathcal{F}$-DCF-FVS, where none of Reduction Rule 1 to 9 or Branching Rule 1 apply. Then there are vertices $u, v \in V(G) \setminus W$, such that the unique path P_{uv} in $G - W$ is a nice path.*

Consider $u, v \in V(G) \setminus W$, for which there is a nice path P_{uv} in T, where T is a connected component of $G - W$. Since Reduction Rule 4 is not applicable, either u has a neighbor in W, or u has degree at least 2 in T. From the above discussions, together with Proposition 1, we design the remaining branching rules used by the algorithm. We note that the branching rules that we describe next is similar to the one given in [3].

▶ **Branching Rule 2.** *Let $v \in V(G) \setminus W$ be a leaf in $G - W$ for which the following holds. There is $u \in V(G) \setminus W$, such that $N_G(u) \cap W \neq \emptyset$ and there is a nice path P_{uv} from u to v in $G - W$. Let $C = V(P_{uv}) \setminus \{u\}$, u' and v' be the neighbors (in G) of u and v in W, respectively. Observe that since Reduction Rule 9 is not applicable, we have $u, v \notin R$. We further consider the following cases, based on whether or not u' and v' are in the same connected component of $G[W]$.*

Case 2.A. *u' and v' are in the same connected component of $G[W]$. In this case, $G[V(P_{uv}) \cup W]$ contains exactly one cycle, and this cycle contains all vertices of $V(P_{uv})$ (consecutively). Since vertices in W cannot be part of any solution, either u belongs to the solution or a vertex from C belongs to the solution. Moreover, any cycle in G containing v must contain all vertices in $V(P_{uv})$, consecutively. This leads to the following branching rule.*

- **(i)** *u belongs to the solution. In this branch, we return $(G - \{u\}, H - \{u\}, k - 1, W, R \cup N_H(u), \mathcal{C})$.*
- **(ii)** *u does not belong to the solution. In this branch, we return $(G - C, H, k, W, R, \mathcal{C} \cup \{C\})$. In the first branch k decreases by one, and η and $|\mathcal{C}|$ do not change. Therefore, μ decreases by 1. On the second branch $|\mathcal{C}|$ increases by 1, and k and η do not change, and therefore, μ decreases by 1. The resulting branching vector for the above branching rule is $(1, 1)$.*

Case 2.B. *u' and v' are in different connected component of $G[W]$. In this case, we branch as follows.*

- **(i)** *u belongs to the solution. In this branch, we return $(G - \{u\}, H - \{u\}, W, k - 1, R \cup N_H(u), \mathcal{C})$.*
- **(ii)** *A vertex from C is in the solution. In this branch, we return $(G - C, H, k, W, R, \mathcal{C} \cup \{C\})$.*
- **(iii)** *No vertex in $\{u\} \cup C$ is in the solution. In this branch, we add all vertices in $\{u\} \cup C$ to W. That is, we return $(G, H, k, W \cup (\{u\} \cup C), R \setminus (\{u\} \cup C), \mathcal{C})$.*

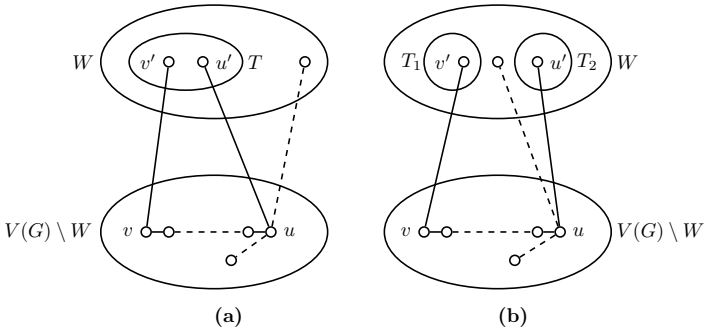

Figure 1 The cases handled by Branching Rule 2, (a) T is a connected component in $G[W]$, similarly in (b) T_1, T_2 are connected components in $G[W]$.

In the first branch k decreases by one, and η and $|\mathcal{C}|$ do not change. Therefore, μ decreases by 1. On the second branch $|\mathcal{C}|$ increases by 1, and k and η do not change, and therefore, μ decreases by 1. In the third branch, η decreases by one, and k and $|\mathcal{C}|$ do not change. The resulting branching vector for the above branching rule is $(1, 1, 1)$.

▶ **Branching Rule 3.** *There is $u \in V(G) \setminus W$ which has (at least) two nice paths, say P_{uv_1} and P_{uv_2} to leaves v_1 and v_2 (in $G - W$). Let $C_1 = V(P_{uv_1}) \setminus \{u\}$ and $C_2 = V(P_{uv_2}) \setminus \{u\}$. We further consider the following cases depending on whether or not v_1 and v_2 have neighbors (in G) in the same connected component of $G[W]$ and $u \in R$.*

Case 3.A. *v_1 and v_2 have neighbors (in G) in the same connected component of $G[W]$ and $u \in R$. In this case, $G[W \cup \{u\} \cup C_1 \cup C_2]$ contains (at least) one cycle, and u cannot belong to any solution. Therefore, we branch as follows.*

- **(i)** *A vertex from C_1 belongs to the solution. In this branch, we return $(G - C_1, H, k, W, R, \mathcal{C} \cup \{C_1\})$.*
- **(ii)** *A vertex from C_2 belongs to the solution. In this branch, we return $(G - C_2, H, k, W, R, \mathcal{C} \cup \{C_2\})$.*

Notice that in both the branches μ decreases by 1, and therefore, the resulting branching vector is $(1, 1)$.

Case 3.B. *v_1 and v_2 have neighbors (in G) in the same connected component of $G[W]$ and $u \notin R$. In this case, $G[W \cup \{u\} \cup C_1 \cup C_2]$ contains (at least) one cycle. We branch as follows.*

- **(i)** *u belongs to the solution. In this branch, we return $(G - \{u\}, H - \{u\}, k - 1, W, R \cup N_H(u), \mathcal{C})$.*
- **(ii)** *A vertex from C_1 belongs to the solution. In this branch, we return $(G - C_1, H, k, W, R, \mathcal{C} \cup \{C_1\})$.*
- **(iii)** *A vertex from C_2 belongs to the solution. In this branch, we return $(G - C_2, H, k, W, R, \mathcal{C} \cup \{C_2\})$.*

Notice that in all the three branches μ decreases by 1, and therefore, the resulting branching vector is $(1, 1, 1)$.

Case 3.C. *If v_1 and v_2 have neighbors in different connected components of $G[W]$ and $u \in R$. In this case, we branch as follows.*

- **(i)** *A vertex from C_1 belongs to the solution. In this branch, we return $(G - C_1, H, k, W, R, \mathcal{C} \cup \{C_1\})$.*

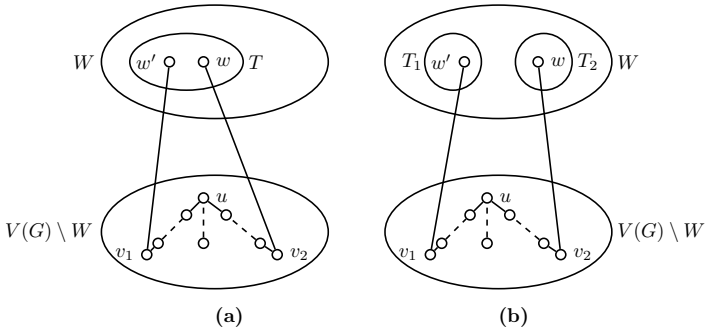

Figure 2 The cases handled by Branching Rule 3, In (a) T is a connected component in $G[W]$, similarly in (b) T_1, T_2 are connected components in $G[W]$.

(ii) *A vertex from* C_2 *belongs to the solution. In this branch, we return* $(G - C_2, H, k, W, R, \mathcal{C} \cup \{C_2\})$.

(iii) *No vertex from* $C_1 \cup C_2$ *belongs to the solution. In this case, we add all vertices in* $\{u\} \cup C_1 \cup C_2$ *to* W. *That is, the resulting instance is* $(G, H, k, W \cup (\{u\} \cup C_1 \cup C_2), R \setminus (\{u\} \cup C_1 \cup C_2), \mathcal{C})$.

Notice that in all the three branches μ *decreases by* 1, *and therefore, the resulting branching vector is* $(1, 1, 1)$.

Case 3.D. *If* v_1 *and* v_2 *have neighbors in different connected components of* $G[W]$ *and* $u \notin R$. *In this case, we branch as follows.*

(i) u *belongs to the solution. In this branch, we return* $(G - \{u\}, H - \{u\}, k - 1, W, R \cup N_H(u), \mathcal{C})$.

(ii) *A vertex from* C_1 *belongs to the solution. In this branch, we return* $(G - C_1, H, k, W, R, \mathcal{C} \cup \{C_1\})$.

(iii) *A vertex from* C_2 *belongs to the solution. In this branch, we return* $(G - C_2, H, k, W, R, \mathcal{C} \cup \{C_2\})$.

(iv) *No vertex from* $\{u\} \cup C_1 \cup C_2$ *belongs to the solution. In this case, we add all vertices in* $\{u\} \cup C_1 \cup C_2$ *to* W. *That is, the resulting instance is* $(G, H, k, W \cup (\{u\} \cup C_1 \cup C_2), R \setminus (\{u\} \cup C_1 \cup C_2), \mathcal{C})$.

Notice that in all the four branches μ *decreases by* 1, *and therefore, the resulting branching vector is* $(1, 1, 1, 1)$.

This completes the description of the algorithm. By showing the correctness of the presented algorithm, together with computation of the running time of the algorithm appropriately, we obtain the proof of Theorem 7.

5 FPT Algorithm for $K_{i,j}$-free+Cluster IS

In this section, we give an FPT algorithm for $K_{i,j}$-free+Cluster IS, which is the $\mathcal{F}$+Cluster IS where $\mathcal{F}$ is family of $K_{i,j}$-free graphs. Here, $i, j \in \mathbb{N}$, $1 \leq i \leq j$. In the following we consider a (fixed) family of $K_{i,j}$-free graphs. To design an FPT algorithm for $\mathcal{F}$+Cluster IS, we define another problem called Large $K_{i,j}$-free+Cluster IS. The problem Large $K_{i,j}$-free+Cluster IS is formally defined below.

LARGE $K_{i,j}$-free+CLUSTER IS	**Parameter:** k
Input: A $K_{i,j}$-free graph G, a cluster graph H (G and H are on the same vertex set), and an integer k, such that the following conditions are satisfied: 1) H has exactly k connected components, and 2) each connected component of H has at least k^k vertices. **Question:** Is there a set $S \subseteq V(G)$ of size k such that S is an independent set in both G and in H?	

In Section 5.1, we design a polynomial time algorithm for the problem LARGE $K_{i,j}$-free+CLUSTER IS. In the rest of this section, we show how to use the polynomial time algorithm for LARGE $K_{i,j}$-free+CLUSTER IS to obtain an FPT algorithm for $K_{i,j}$-free+CLUSTER IS.

▶ **Theorem 11.** *$K_{i,j}$-free+CLUSTER IS admits an FPT algorithm running in time $\mathcal{O}(k^{k^2} n^{\mathcal{O}(1)})$, where n is the number of vertices in the input graph.*

Proof. Let (G, H, k) be an instance of $K_{i,j}$-free+CLUSTER IS, and let $\mathcal{C} = \{C_1, C_2, \cdots, C_k\}$ be the set of connected components in H. If $k \leq 0$, we can correctly resolve the instance in polynomial time (by appropriately outputting yes or no answer). Therefore, we assume $k \geq 1$. If for each $C \in \mathcal{C}$, we have $|V(C)| \geq k^k$, then (G, H, k) is also an instance of LARGE $K_{i,j}$-free+CLUSTER IS, and therefore we resolve it in polynomial time using the algorithm for LARGE $K_{i,j}$-free+CLUSTER IS (Section 5.1). Otherwise, there is $C \in \mathcal{C}$, such that $|V(C)| < k^k$. Any solution to $K_{i,j}$-free+CLUSTER IS in (G, H, k) must contain exactly one vertex from C. Moreover, if a vertex $v \in V(C)$ is in the solution, then none of its neighbors in G and in H can belong to the solution. Therefore, we branch on vertices in C as follows. For each $v \in V(C)$, create an instance $I_v(G - (N_H(v) \cup N_G(v)), H - (N_H(v) \cup N_G(v)), k-1)$ of $K_{i,j}$-free+CLUSTER IS. If number of connected components in $H - N[C]$ is less than $k-1$, then we call such an instance I_v as *invalid* instance, otherwise the instance is a *valid* instance. Notice that for $v \in V(C)$, if I_v is an invalid instance, then v cannot belong to any solution. Thus, we branch on valid instances of I_v, for $v \in V(C)$. Observe that (G, H, k) is a yes instance of $K_{i,j}$-free+CLUSTER IS if and only if there is a valid instance I_v, for $v \in V(C)$, which is a yes instance of $K_{i,j}$-free+CLUSTER IS. Therefore, we output the OR of results obtained by resolving valid instances I_v, for $v \in V(C)$.

In the above we have designed a recursive algorithm for the problem $K_{i,j}$-free+CLUSTER IS. In the following, we prove the correctness and claimed running time bound of the algorithm. We show this by induction on the measure $\mu = k$. For $\mu \leq 0$, the algorithm correctly resolve the instance in polynomial time. This forms the base case of our induction hypothesis. We assume that the algorithm correctly resolve the instance for each $\mu \leq \delta$, for some $\delta \in \mathbb{N}$. Next, we show that the correctness of the algorithm for $\mu = \delta + 1$. We assume that $k > 0$, otherwise, the algorithm correctly outputs the answer. The algorithm either correctly resolves the instance in polynomial time using the algorithm for LARGE $K_{i,j}$-free+CLUSTER IS, or applies the branching step. When the algorithm resolves the instance in polynomial time using the algorithm for LARGE $K_{i,j}$-free+CLUSTER IS, then the correctness of the algorithm follows from the correctness of the algorithm for LARGE $K_{i,j}$-free+CLUSTER IS. Otherwise, the algorithm applies the branching step. The branching is exhaustive, and the measure strictly decreases in each of the branches. Therefore, the correctness of the algorithm follows form the induction hypothesis. This completes the proof of correctness of the algorithm.

For the proof of claimed running time notice that the the worst case branching vector is is given by the k^k vector of all 1s, and at the leaves we resolve the instances in polynomial time. Thus, the claimed bound on the running time of the algorithm follows. ◀

5.1 Polynomial Time Algorithm for Large $K_{i,j}$-free+Cluster IS

Consider a (fixed) family of $K_{i,j}$-free graphs, where $1 \leq i \leq j$. The goal of this section is to design a polynomial time algorithm for Large $K_{i,j}$-free+Cluster IS. Let (G, H, k) be an instance of Large $K_{i,j}$-free+Cluster IS, where G is a $K_{i,j}$-free graph and H is a cluster graph with k connected components. We assume that $k > i + j + 2$, as otherwise, we can resolve the instance in polynomial time (using brute-force). Let $\mathcal{C} = \{C_1, C_2, \cdots, C_k\}$ be the set of connected components in H, such that $|V(C_1)| \geq |V(C_2)| \geq \cdots \geq |V(C_k)|$.

We start by stating/proving some lemmata, which will be helpful in designing the algorithm.

▶ **Lemma 12.** [5] *The number of edges in a $K_{i,j}$-free graph are bounded by $n^{2-\epsilon}$, where $\epsilon = \epsilon(i,j) \in (0,1]$.*

▶ **Lemma 13.** *Let (G, H, k) be an instance of* Large $K_{i,j}$*-free+*Cluster IS*. There exists $v \in V(C_1)$, such that for each $C \in \mathcal{C} \setminus \{C_1\}$, we have $|N_G(v) \cap C| \leq \frac{2j|C|}{k}$.*

Proof. Consider a connected component $C \in \mathcal{C} \setminus \{C_1\}$, and let $x = |C_1|$ and $y = |C|$. Furthermore, let $E(C_1, C) = \{uv \in E(G) \mid u \in C_1, v \in V(C)\}$. In the following, we prove some claims which will be used to obtain the proof of the lemma.

▶ **Claim 14.** $|E(C_1, C)| \leq jy^i + jx$.

Proof. Consider the partition of $V(C_1)$ in two parts, namely, C_h^1 and C_ℓ^1, where $C_h^1 = \{v \in V(C_1) \mid |N_G(v) \cap V(C)| \geq i\}$ and $C_\ell^1 = V(C_1) \setminus C_h^1$.

$$|E(C_1, C)| = \sum_{v \in C_1} |N_G(v) \cap V(C)| = \sum_{v \in C_h^1} |N_G(v) \cap V(C)| + \sum_{v \in C_l^1} |N_G(v) \cap V(C)|.$$

By construction of C_ℓ^1, we have $\sum_{v \in C_\ell^1} |N_G(v) \cap V(C)| < ix$. In the following, we bound $\sum_{v \in C_h^1} |N_G(v) \cap V(C)|$. Since G is a $K_{i,j}$-free graph, therefore, any set of i vertices in $V(C)$ can have at most $j-1$ common neighbors (in G) from $V(C_1)$, and in particular from C_h^1. Moreover, every $v \in C_h^1$ has at least i neighbors in $N_G(v) \cap V(C)$. Therefore, $\sum_{v \in C_h^1} |N_G(v) \cap V(C)| \leq i(j-1)\binom{y}{i}$. Hence, $|E(C_1, C)| \leq i(j-1)\binom{y}{i} + ix \leq i(j-1)\frac{y^i}{i!} + ix \leq jy^i + jx$. ◀

Let $A_{\mathsf{deg}}(C_1, C)$ denote average degree of vertices in set C_1 in $G[E(C_1, C)]$. That is, $A_{\mathsf{deg}}(C_1, C) = \frac{|E(C_1, C)|}{|C_1|}$. In the following claim, we give a bound on $A_{\mathsf{deg}}(C_1, C)$.

▶ **Claim 15.** $A_{deg}(C_1, C) \leq \frac{2jy}{k^2}$.

Proof. From Claim 14, we have $|E(C_1, C)| \leq jy^i + jx$. Therefore, $A_{\mathsf{deg}}(C_1, C) \leq j + \frac{jy^i}{x}$. Using Lemma 12, we have $A_{\mathsf{deg}}(C_1, C) \leq \frac{(x+y)^{2-\epsilon}}{x} \leq 4x^{1-\epsilon}$. To prove the claim, us consider the following cases:

Case 1. $x \geq k^2 y^{i-1}$. In this case, using the inequality $A_{\mathsf{deg}}(C_1, C) \leq j + \frac{jy^i}{x}$, we have $A_{\mathsf{deg}}(C_1, C) \leq j + \frac{jy}{k^2}$. Since $y > k^2$ (and $k > 5$), we have $A_{\mathsf{deg}}(C_1, C) \leq \frac{2jy}{k^2}$.

Case 2. $x < k^2 y^{i-1}$. In this case, we use the inequality $A_{\mathsf{deg}}(C_1, C) \leq 4x^{1-\epsilon}$, to obtain $A_{\mathsf{deg}}(C_1, C) < 4k^{2(1-\epsilon)} y^{(i-1)(1-\epsilon)} < \frac{4k^2 y}{y^{(2-i)+\epsilon(i-1)}}$. Since $y \geq k^k$, we have $y^{(2-i)+\epsilon(i-1)} > \frac{2k^4}{j}$. Therefore, we have $A_{\mathsf{deg}}(C_1, C) < \frac{2jy}{k^2}$. ◀

Algorithm 1 (G, H, k): Greedy algorithm for Large $K_{i,j}$-free+Cluster IS.

1: $t = k$ and $S = \emptyset$;
2: **while** $t > 2j$ **do**
3: Let $C_1, \cdots, C_t$ be the connected components of H, sorted in decreasing order of their sizes;
4: Let $v \in V(C_1)$ be a vertex which satisfies the condition of Lemma 13;
5: Add v to S;
6: Decrease t by 1;
7: $G = G - (N_G(v) \cup N_H[v])$ and $H = H - (N_G(v) \cup N_H[v])$;
8: **end while**
9: Solve (G, H, t) by a brute force algorithm, as $t \leq 2j$;

In the following, we will give a probabilistic argument on the existence of a vertex with the desired properties in the lemma statement. For $v \in V(C_1)$, let $\mathsf{deg}(v, C)$ denote the size of $|N_G(v) \cap V(C)|$. From Claim 15, we have $A_{\mathsf{deg}}(C_1, C) \leq \frac{2jy}{k^2}$. Using Markov's inequality, the upper bound on the probability that $\mathsf{deg}(v, C) \geq \frac{2jy}{k}$ is $P(\mathsf{deg}(v, C) \geq \frac{2jy}{k}) \leq \frac{1}{k}$. Using Boole's inequality (the union bound), the probability that $\mathsf{deg}(v, C)$ is greater than or equal to $\frac{2j|C|}{k}$ for at least one $C \in \mathcal{C} \setminus \{C_1\}$ is bounded by $P(\cup_{C \in \mathcal{C} \setminus \{C_1\}} \mathsf{deg}(v, C) \geq \frac{2j|C|}{k}) \leq \frac{1}{k}.(k-1) < 1$. This implies that probability that $\mathsf{deg}(v, C) \leq \frac{2j|C|}{k}$, for each $C \in \mathcal{C} \setminus \{C_1\}$ is greater than 0. This completes the proof. ◀

We are now ready to describe our algorithm, which is given in Algorithm 1.

▶ **Lemma 16.** *Algorithm 1 for* Large $K_{i,j}$*-free+*Cluster IS *is correct and runs in polynomial time.*

Proof. We first prove the correctness of the algorithm using induction on, t. The base case is when $1 \leq t \leq 2j$. The algorithm correctly resolve the instance using brute force. For the induction hypothesis, we assume that the algorithm is correct for each $t \leq d-1$. Next, we show that the algorithm is correct for $t = d$. Let $C_1, \cdots, C_d$ be the set of connected components in H, sorted in decreasing order of their sizes. By Lemma 13, there is $v \in C_1$, such that for each $C \in \mathcal{C} \setminus \{C_1\}$, we have $\mathsf{deg}(v, C) \leq \frac{2j|C|}{d}$.

We delete all vertices in $N_H[v] \cup N_G(v)$ from G and H. Observe that from each $C \in \mathcal{C} \setminus \{C_1\}$, we have deleted at most $\frac{2j|C|}{d}$ vertices, which are neighbors of v in G. Let $C' = C \setminus (N_H[v] \cup N_G(v)) = C \setminus N_G(v)$. It is enough to show that $|C'| \geq (d-1)^{(d-1)}$. Note that $|C'| \geq |C| - \frac{2j|C|}{d}$. As base case is not applicable, we can assume that $d > 2j$. Hence, $|C'| \geq |C|(1 - \frac{2j}{d}) \geq d^d(1 - \frac{2j}{d}) \geq d^{d-1}(d - 2j) \geq (d-1)^{(d-1)}$.

This concludes the proof of correctness of the algorithm. At each step we either sort the components on the basis of their size or find a vertex of lower degree which can be carried out in polynomial time, or solve the instance using brute force approach, where the solution size we are seeking for is bounded by a constant (at most $2j$). Moreover, the algorithm terminates after at most k iterations. Thus, the running time of the algorithm is bounded by a polynomial in the size of the input. ◀

Using Lemma 16, we obtain the following theorem.

▶ **Theorem 17.** *The problem* Large $K_{i,j}$*-free+*Cluster IS *admits a polynomial time algorithm.*

Abstract

The largest common embeddable subtree problem asks for the largest possible tree embeddable into two input trees and generalizes the classical maximum common subtree problem. Several variants of the problem in labeled and unlabeled rooted trees have been studied, e.g., for the comparison of evolutionary trees. We consider a generalization, where the sought embedding is maximal with regard to a weight function on pairs of labels. We support rooted and unrooted trees with vertex and edge labels as well as distance penalties for skipping vertices. This variant is important for many applications such as the comparison of chemical structures and evolutionary trees. Our algorithm computes the solution from a series of bipartite matching instances, which are solved efficiently by exploiting their structural relation and imbalance. Our analysis shows that our approach improves or matches the running time of the formally best algorithms for several problem variants. Specifically, we obtain a running time of $\mathcal{O}(|T|\,|T'|\Delta)$ for two rooted or unrooted trees T and T', where $\Delta = \min\{\Delta(T), \Delta(T')\}$ with $\Delta(X)$ the maximum degree of X. If the weights are integral and at most C, we obtain a running time of $\mathcal{O}(|T|\,|T'|\sqrt{\Delta}\log(C\min\{|T|,|T'|\}))$ for rooted trees.

1 Introduction

The maximum common subgraph problem asks for a graph with a maximum number of vertices that is isomorphic to induced subgraphs of two input graphs. This problem arises in many domains, where it is important to find the common parts of objects which can be represented as graphs. An example of this are chemical structures, which can be interpreted directly as labeled graphs. Therefore, the problem has been studied extensively in cheminformatics [5, 16, 17]. Although elaborated backtracking algorithms have been developed [16, 2], solving large instances in practice is a great challenge. The maximum common subgraph problem is NP-hard and remains so even when the input graphs are restricted to trees [6]. However, in trees it becomes polynomial-time solvable when the common subgraph is required to be connected, i.e., it must be a tree itself. This problem is then referred to as *maximum common subtree problem* and the first algorithm solving it in polynomial-time is attributed to J. Edmonds [12]. Also requiring that the common subgraph must be connected (or even partially biconnected) several extensions to tree-like graphs have been proposed, primarily for applications in cheminformatics [19, 17, 3]. Some of these approaches are not suitable for practical applications due to high constants hidden in the polynomial running time. Other algorithms are efficient in practice, but restrict the search space to specific common subgraphs. Instead of developing maximum common subgraph algorithms for more general graph classes, which has proven difficult, a different approach is to represent molecules simplified as trees [15]. Then, vertices typically represent groups of atoms and their comparison requires to score the similarity of two vertices by a weight function. This, however, is often not supported by algorithms for tree comparison. Moreover, it maybe desirable to map a path in one tree to a single edge in the other tree, skipping the inner vertices. Formally, this is achieved by *graph homeomorphism* instead of isomorphism.

Various variants for comparing trees have been proposed and investigated [18]. Most of them assume rooted trees, which may be ordered or unordered. Algorithms tailored to the comparison of evolutionary trees typically assume only the leaves to be labeled, while others support labels on all vertices or do not consider labels at all. The well-known agreement subtree problem, for example, considers the case, where only the leaf nodes are labeled, with no label appearing more than once per tree [11]. We discuss the approaches most relevant for our work. Gupta and Nishimura [8] investigated the *largest common embeddable subtree* problem in unlabeled rooted trees. Their definition is based on topological embedding (or homeomorphism) and allows to map edges of the common subtree to vertex-disjoint paths in the input trees. The algorithm uses the classical idea to decompose the problem into subproblems for smaller trees, which are solved via bipartite matching. A solution for two trees with at most n vertices is computed in time $\mathcal{O}(n^{2.5} \log n)$ using a dynamic programming approach. Fig. 1a illustrates the difference between maximum common subgraph and largest common embeddable subtree. Lozano and Valiente [10] investigated the *maximum common embedded subtree* problem, which is based on edge contraction. In both cases the input graphs are rooted unlabeled trees. Note, the definition of their problems is not equivalent. The first is polynomial time solvable, while the second is NP-hard for unordered trees, but polynomial time solvable for ordered trees. Many algorithms do not support trees, where leaves and the inner vertices both have labels. A notable exception is the approach by Kao et al. [9], where only vertices with the same label may be mapped. This algorithm generalizes the approach by Gupta/Nishimura and improves its running time to $\mathcal{O}(\sqrt{d}D \log \frac{2n}{d})$, where D denotes the number of vertex pairs with the same label and d the maximum degree of all vertices.

We consider the problem of finding a *largest weight common subtree embedding* (LaWeCSE), where matching vertices are not required to have the same label, but their degree of agreement is determined by a weight function. We build on the basic ideas of Gupta and Nishimura [8].

To prevent arbitrarily long paths which are mapped to a common edge we study a linear distance penalty for paths of length greater than 1. Note that, by choosing a high distance penalty, we solve the maximum common subtree (MCS) problem as a special case. By choosing weight 1 for equal labels and sufficiently small negative weights otherwise, we solve a problem equivalent to the one studied by Kao et al. [9].

Our contribution. We propose and analyze algorithms for finding largest weight common subtree embeddings. Our method requires to solve a series of bipartite matching instances as subproblem, which dominates the total running time. We build on recent results by Ramshow and Tarjan [13, 14] for unbalanced matchings. Let T and T' be labeled rooted trees with $k := |T|$ and $l := |T'|$ vertices, respectively, and $\Delta := \min\{\Delta(T), \Delta(T')\}$ the smaller degree of the two input trees. For real-valued weight functions we prove a time bound of $\mathcal{O}(kl\Delta)$. For integral weights bounded by a constant C we prove a running time of $\mathcal{O}(kl\sqrt{\Delta}\log(\min\{k,l\}C))$. This is an improvement over the algorithm by Kao et al. [9] if there are only few labels and the maximum degree of one tree is much smaller than the maximum degree of the other. In addition, we support weights and a linear penalty for skipped vertices.

Moreover, the algorithm by Kao et al. [9] is designed for rooted trees only. A straight forward approach to solve the problem for unrooted trees is to try out all pairs of possible roots, which results in an additional $\mathcal{O}(kl)$ factor. However, our algorithm exploits the fact that there are many similar matching instances using techniques related to [1, 4]. This includes computing additional matchings of cardinality two. For unrooted trees and real-valued weight functions we prove the same $\mathcal{O}(kl\Delta)$ time bound as for rooted trees. This leads to an improvement over the formally best algorithm for solving the maximum common subtree problem, for which a time bound of $\mathcal{O}(kl\,(\Delta + \log d))$ has been proven [4].

2 Preliminaries

We consider finite simple undirected graphs unless stated otherwise. Let $G = (V, E)$ be a graph, we refer to the set of *vertices* V by $V(G)$ or V_G and to the set of *edges* by $E(G)$ or E_G. An edge connecting two vertices $u, v \in V$ is denoted by uv or vu. The *order* $|G|$ of a graph G is its number of vertices. The *neighbors* of a vertex v are defined as $N(v) := \{u \in V_G \mid vu \in E_G\}$. The *degree* of a vertex $v \in V_G$ is $\delta(v) := |N(v)|$, the *degree* $\Delta(G)$ of a graph G is the maximum degree of its vertices. In case of a directed graph (*digraph*) we call its edges *arcs*, denoted by (u, v), i.e., an edge from u to v.

A *path* P is a sequence of pairwise disjoint vertices connected through edges (or arcs) and denoted as $P = (v_0, e_1, v_1, \ldots, e_l, v_l)$, where $e_i = v_{i-1}v_i$ (or $e_i = (v_{i-1}, v_i)$), $i \in \{1, \ldots, l\}$. We alternatively specify the vertices $(v_0, \ldots, v_l)$ or edges $(e_1, \ldots, e_l)$ only. The *length* of a path is its number of edges. A connected graph with a unique path between any two vertices is a *tree*. A tree T with an explicit root vertex $r \in V(T)$ is called *rooted* tree, denoted by T^r. In a rooted tree T^r we denote the set of *children* of a vertex v by $C(v)$ and its *parent* by $p(v)$, where $p(r) = r$. For any tree T and two vertices $u, v \in V(T)$ the *rooted subtree* T^u_v is induced by the vertex v and its descendants related to the tree T^u. If the root r is clear from the context, we may abbreviate $T_v := T^r_v$. We refer to the root of a rooted tree T by $r(T)$.

If the vertices of a graph G can be separated into exactly two disjoint sets V, U such that $E(G) \subseteq V \times U$, then the graph is called *bipartite*. In many cases the disjoint sets are already given as part of the input. In this case we write $G = (V \sqcup U, E)$, where $E \subseteq V \times U$.

For a graph $G = (V, E)$ a *matching* $M \subseteq E$ is a set of edges, such that no two edges share a vertex. An edge $e \in M$ is denoted *matched*. A vertex incident to an edge $e \in M$ is denoted *matched*; otherwise it's *free*. For an edge $uv \in M$, the vertex u is the *partner* of v and vice versa. The *cardinality of a matching* M is its number of edges $|M|$. A *weighted graph* is a graph endowed with a function $w : E \to \mathbb{R}$. The weight of a matching M in a weighted graph is $W(M) := \sum_{e \in M} w(e)$. We call a matching M of a weighted graph G a *maximum weight matching* (MWM) if there is no other matching M' of G with $W(M') > W(M)$. A matching M in G is a *MWM of cardinality* k (MWM_k) if there is no other matching M' of cardinality k in G with $W(M') > W(M)$.

For convenience we define the maximum of an empty set as $-\infty$.

3 Gupta and Nishimura's algorithm

In this section we formally define a *Largest Common Subtree Embedding* (LaCSE) and present a brief overview of Gupta and Nishimura's algorithm to compute such an embedding. The following two definitions are based on [8].

▶ **Definition 1** (Topological Embedding)**.** A rooted tree T is *topologically embeddable* in a rooted tree T' if there is an injective function $\psi : V(T) \to V(T')$, such that $\forall a, b, c \in V(T)$

i) If b is a child of a, then $\psi(b)$ is a descendant of $\psi(a)$.

ii) For distinct children b, c of a, the paths from $\psi(a)$ to $\psi(b)$ and from $\psi(a)$ to $\psi(c)$ have exactly $\psi(a)$ in common.

T is *root-to-root topologically embeddable* in T', if $\psi(r(T)) = r(T')$.

▶ **Definition 2** ((Largest) Common Subtree Embedding; (La)CSE)**.** Let T and T' be rooted trees and S be topologically embeddable in both T and T'. For such a S let $\psi : V(S) \to V(T)$ and $\psi' : V(S) \to V(T')$ be topological embeddings.

- Then $\varphi := \psi' \circ \psi^{-1} : \psi(V_S) \to \psi'(V_S)$ is a *Common Subtree Embedding*.
- If there is no other tree S' topologically embeddable in both T and T' with $|S'| > |S|$, then S is a *Largest Common Embeddable Subtree* and φ is a *Largest Common Subtree Embedding*.
- An CSE with $\varphi(r(T)) = r(T')$ is a *root-to-root CSE*.
- A root-to-root CSE is *largest*, if it is of largest weight among all root-to-root common subtree embeddings.

Algorithm from Gupta and Nishimura. Gupta and Nishimura [8] presented an algorithm to compute the size of a largest common embeddable subtree based on dynamic programming, which is similar to the computation of a largest common subtree, described in, e.g., [12, 4]. Let T and T' be rooted trees and $\mathcal{L}$ be a table of size $|T||T'|$. For each pair of vertices $u \in T, v \in T'$ the value $\mathcal{L}(u, v)$ stores the size of a LaCSE between the rooted subtrees T_u and T'_v. Gupta and Nishimura proved, that an entry $\mathcal{L}(u, v)$ is determined by the maximum of the following three quantities.

- $M_1 = \max\{\mathcal{L}(u, c) \mid c \in C(v)\}$
- $M_2 = \max\{\mathcal{L}(b, v) \mid b \in C(u)\}$
- $M_3 = W(M)+1$, where M is a MWM of the complete bipartite graph $(C(u) \sqcup C(v), C(u) \times C(v))$ with edge weight $w(bc) = \mathcal{L}(b, c)$ for each pair $(b, c) \in C(u) \times C(v)$.

Here, M_1 represents the case, where the vertex v is not mapped. To satisfy ii) from Def. 1, we may map at most one child $c \in C(v)$. M_2 represents the case, where u is not mapped and at most one child $b \in C(u)$ is allowed. M_3 represents the case $\varphi(u) = v$. To maximize

the number of mapped descendants we compute a maximum weight matching, where the children of u and v are the vertex sets $C(u)$ and $C(v)$, respectively, of a bipartite graph. The edge weights are determined by the previously computed solutions, i.e., the LaCSEs between the children of u and v and their descendants, namely between T_b and T'_c for each pair of children (b, c). The algorithm proceeds from the leaves to the roots. From the above recursive formula, we get $\mathcal{L}(u, v) = 1$ if u or v is a leaf, which was separately defined in [8].

A maximum value in the table yields the size of a LaCSE. We obtain the size of a root-to-root LaCSE from M_3 of the root vertices $r(T), r(T')$. Note, with storing $\mathcal{O}(|\mathcal{L}|)$ additional data, it is easy to obtain a (root-to-root) LaCSE φ.

▶ **Theorem 3** (Gupta, Nishimura, [8]). *Computing a LaCSE between two rooted trees of order at most n is possible in time $\mathcal{O}(n^{2.5} \log n)$.*

4 Largest Weight Common Subtree Embeddings

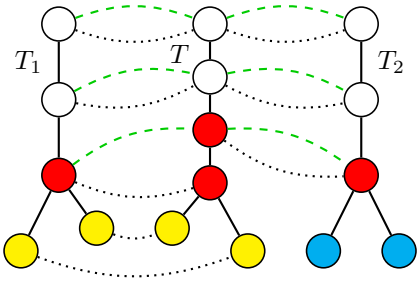
First, we introduce weighted common subtree embeddings between labeled trees. Part of the input is an integral or real weight function on all pairs of the labels. Next, we consider a linear distance penalty for skipped vertices in the input trees. After formalizing the problem and presenting an algorithm, we prove new upper time bounds.

Vertex Labels. In many application domains the vertices of the trees need to be distinguished. A common representation of a vertex labeled tree T is (T, l), where $l : V(T) \to \Sigma$ with Σ as a finite set of labels. Let $\omega : \Sigma \times \Sigma \to \mathbb{R} \cup \{-\infty\}$ assign a weight to each pair of labels. Instead of maximizing the number of mapped vertices, we want to maximize the sum of the weights $\omega(l(u), l(\varphi(u)))$ of all vertices u mapped by a common subtree embedding φ. For simplicity, we will omit l and l' for the rest of this paper and define $\omega(u, v) := \omega(l(u), l'(v))$ for any two vertices $(u, v) \in V(T) \times V(T')$.

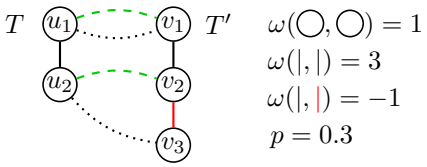
Edge Labels. Although not as common as vertex labels, edge labels are useful to represent different bonds between atoms or relationship between individuals. In a common subtree embedding we do not map edges to edges but paths to paths. Since in an embedding inner vertices on mapped paths do not contribute to the weight, we do the same with edges. I.e., both paths need to have length 1 for their edge labels to be considered. Here again, we want to maximize the weight $\omega(e, e') := \omega(l(e), l'(e'))$ of these edges mapped to each other (additional to the weight of the mapped vertices).

Distance Penalties. Depending on the application purpose it might be desirable that paths do not have an arbitrary length. Here, we introduce a linear distance penalty for paths of length greater than 1. I.e., each inner vertex on a path corresponding to an edge of the common embeddable subtree lowers the weight by a given penalty p. By assigning p the value ∞ we effectively compute a maximum common subtree. The following definition formalizes a LaCSE under a weight function ω and a distance penalty p.

▶ **Definition 4** (Largest Weight Common Subtree Embedding; LaWeCSE). Let (T, l) and (T', l') be rooted vertex and/or edge labeled trees. Let φ be a common subtree embedding between T and T'. Let $\omega : \Sigma \times \Sigma \to \mathbb{R} \cup \{-\infty\}$ assign a weight to each pair of labels. Let $p \in \mathbb{R}^{\geq 0} \cup \{\infty\}$ be a distance penalty. We refer to a path $P = (u_0, e_1, u_1, \ldots, u_k)$ in the tree T corresponding to a single edge in the common embeddable subtree as *topological path*. Let $\varphi(P)$ be the corresponding path $(v_0, e'_1, v_1, \ldots, v_l)$ in T'. Then



(a) Labeled MCS (green dashed lines) and LaCSE (black dotted lines) between T and T_i, $i \in \{1, 2\}$.



(b) The black embedding has weight 1.7, since the vertex v_2 is skipped and therefore the penalty p is applied; the weight between the edges is not added. The green embedding has weight 5; 2 from the vertices, 3 from the topological path (u_1, u_2) mapped to (v_1, v_2).

Figure 1 a) Although 'intuitively' T is more similar to T_1 than to T_2, both MCSs have size 3. However, the LaCSE between T and T_1 has 6 mapped vertices. **b)** Two weighted embeddings; one with a skipped vertex, the other where the edge labels contribute to the weight.

- $\omega_{\mathrm{p}}(P, \varphi(P)) = \omega(e_1, e_1') := \omega(l(e_1), l'(e_1'))$, if $l = k = 1$, or
- $\omega_{\mathrm{p}}(P, \varphi(P)) = -p \cdot (l + k - 2)$, otherwise.
- The *weight* $\mathcal{W}(\varphi)$ is the sum of the weights $\omega(u, \varphi(u))$ of all vertices u mapped by φ plus the weights $\omega_{\mathrm{p}}(P, \varphi(P))$ of all topological paths P.
- If φ is of largest weight among all common subtree embeddings, then φ is a *Largest Weight Common Subtree Embedding* (LaWeCSE).

The definition of root-to-root LaWeCSE is analogue to Def. 2. A closer look at the definition of ω_{p} reveals that each inner vertex (the skipped vertices) on a topological path or its mapped path subtracts p from the embedding's weight. Fig. 1b illustrates two weighted common subtree embeddings.

The dynamic programming approach. To compute a LaWeCSE, we need to store some additional data during the computation. In Gupta and Nishimura's algorithm there is a table $\mathcal{L}$ of size $|T||T'|$ to store the weight of LaCSEs between subtrees of the input trees. In our algorithm we need a table $\mathcal{L}$ of size $2|T||T'|$. An entry $\mathcal{L}(u, v, t)$ stores the weight of a LaWeCSE between the rooted subtrees T_u and T_v' of *type* $t \in \{\curlywedge, \diamond\}$. Type $\curlywedge$ represents a *root-to-root* embedding between T_u and T_v'; $\diamond$ an embedding, where u or v is *skipped*. Skipped in the sense, that at least one of u, v will be an inner vertex when mapping some additional ancestor nodes of u or v during the dynamic programming. For type $\diamond$ we subtract the penalty p from the weight for the skipped vertices before storing it in our table. We obtain the weight of a LaWeCSE and a root-to-root LaWeCSE, respectively, from the maximum value of type $\curlywedge$ and from $\mathcal{L}(r(T), r(T'), \curlywedge)$, respectively. The following lemma specifies the recursive computation of an entry $\mathcal{L}(u, v, t)$.

▶ **Lemma 5.** *Let $u \in V(T)$ and $v \in V(T')$. For $t \in \{\curlywedge, \diamond\}$ let $M_t^T = \max\{\mathcal{L}(b, v, t) \mid b \in C(u)\}$ and $M_t^{T'} = \max\{\mathcal{L}(u, c, t) \mid c \in C(v)\}$. Then*

- *$\mathcal{L}(u, v, \diamond) = \max\{M_\diamond^T, M_\curlywedge^T, M_\diamond^{T'}, M_\curlywedge^{T'}\} - p$*

Let $G = (C(u) \sqcup C(v), C(u) \times C(v))$ be a bipartite graph with edge weights $w(bc) = \max\{\mathcal{L}(b, c, \diamond), \mathcal{L}(b, c, \curlywedge) + \omega(ub, vc)\}$ for each pair $(b, c) \in C(u) \times C(v)$. Then

- *$\mathcal{L}(u, v, \curlywedge) = \omega(u, v) + W(M)$, where M is a MWM on G.*

Proof. Since we defined the maximum of an empty set as $-\infty$, this covers the base case, where one vertex is a leaf, e.g., if u is a leaf, then $\max\{M_\diamond^T, M_\curlywedge^T, M_\diamond^{T'}, M_\curlywedge^{T'}\} = \max\{M_\diamond^{T'}, M_\curlywedge^{T'}\}$. Further, $W(M) = 0$, if G has no positive weight edges. Then $\mathcal{L}(u, v, \curlywedge) = \omega(u, v)$.

The type $\diamond$ represents the case of an embedding between T_u and T'_v which is not root-to-root. From the definition of M_t^T the vertex u is skipped and from the definition of $M_t^{T'}$ the vertex v is skipped, so it is indeed not root-to-root. Since either u or v was skipped, we subtract the penalty p. This ensures we have taken inner vertices of later steps of the dynamic programming into account.

The type $\curlywedge$ implies that u is mapped to v. Each edge in G represents the weight of a LaWeCSE from one child of u to one child of v. A maximum matching yields the best combination which satisfies Def. 1. If a child b of u is mapped to a child c of v, the paths bu and cv have length one. Then from Def. 4 we have to add the weight $\omega(bu, cv)$. Otherwise at least one path has length greater than one and we have to subtract the distance penalty p for each inner vertex. We already did that while computing $\mathcal{L}(b, c, \diamond)$. ◀

Time and space complexity. We next analyze upper time and space bounds. Thereby we distinguish between real- and integer-valued weight functions ω. If we use dynamic programming starting from the leaves to the roots, we need to compute each value $\mathcal{L}(u, v, t)$ only once.

▶ **Theorem 6.** *Let T and T' be rooted vertex and/or edge labeled trees. Let ω be a weight function, $\Delta = \min\{\Delta(T), \Delta(T')\}$, and p be a distance penalty.*

- *A LaWeCSE between T and T' can be computed in time $\mathcal{O}(|T|\,|T'|\Delta\}$ and space $\mathcal{O}(|T|\,|T'|)$.*
- *If the weights are integral and bounded by a constant C, a LaWeCSE can be computed in time $\mathcal{O}(|T|\,|T'|\sqrt{\Delta}\log(C\min\{|T|, |T'|\}))$.*

We first need to provide two results regarding maximum weight matchings.

▶ **Lemma 7** ([14])**.** *Let G be a weighted bipartite graph containing m edges and vertex sets of sizes s and t. W.l.o.g. $s \leq t$. We can compute a MWM on G in time $\mathcal{O}(ms + s^2 \log s)$ and space $\mathcal{O}(m)$. If G is complete bipartite, we may simplify the time bound to $\mathcal{O}(s^2 t)$.*

If the weights are integral and bounded by a constant, the following result for a minimum weight matching was shown in [7]. We solve MWM by multiplying the weights by -1.

▶ **Lemma 8.** *Let G as in Lemma 7 and the weights be integral and bounded by a constant C. We can compute a MWM on G in time $\mathcal{O}(m\sqrt{s}\log C)$. If G is complete bipartite, we may simplify the time bound to $\mathcal{O}(s^{1.5} t \log C)$.*

Unfortunately, there is no space bound given in [7]. However, since their algorithm is based on flows, the space bound is probably $\mathcal{O}(m)$. If we assume this to be correct, the space bound in Theorem 6 applies to integral weights too.

Proof of Theorem 6. We observe that the entries of type $\curlywedge$ in the table $\mathcal{L}$ dominate the computation time. We assume the bipartite graphs on which we compute the MWMs to be complete. We further observe that each edge bc representing the weight of the LaWeCSE between the subtrees T_b and T'_c is contained in exactly one of the matching graphs.

Let us assume real weights first. $\mathcal{L}$ requires $\mathcal{O}(|T|\,|T'|)$ space. We may also compute each MWM within the same space bound. This proves the total space bound. From Lemma 7 the

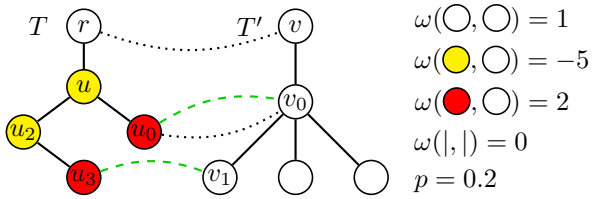


Figure 2 The weight of a LaWeCSE between T^r and T'^v is 2.8 (black dotted lines), since we have one skipped vertex u for penalty 0.2. The weight of a LaWeCSE between T^{u_0} and T'^{v_0} is 3.6 (green dashed lines) for two skipped vertices. The latter one is also a LaWeCSE_u.

time to compute all the MWMs is bounded by

$$\mathcal{O}\left(\sum_{v\in V_{T'}}\sum_{u\in V_T}|C(u)|\,|C(v)|\min\{|C(u)|,|C(v)|\}\right)$$
$$\subseteq \mathcal{O}\left(\sum_{v\in V_{T'}}|C(v)|\sum_{u\in V_T}|C(u)|\Delta\right) = \mathcal{O}(|T|\,|T'|\Delta).$$

Let us assume ω to be integral and bounded by a constant C next. This implies a weight of each single matching edge of at most $\bar{C} := 2C\cdot\min\{|T|,|T'|\}$, since no more than $2\min\{|T|,|T'|\}$ edges and vertices in total may contribute to the weight. Negative weight edges never contribute to a MWM and may safely be omitted. From Lemma 8 the time bound is

$$\mathcal{O}\left(\sum_{v\in V_{T'}}\sum_{u\in V_T}|C(u)|\,|C(v)|\sqrt{\min\{|C(u)|,|C(v)|\}}\log\bar{C}\right)$$
$$\subseteq \mathcal{O}\left(\sum_{v\in V_{T'}}|C(v)|\sum_{u\in V_T}|C(u)|\sqrt{\Delta}\log\bar{C}\right) = \mathcal{O}\left(|T|\,|T'|\sqrt{\Delta}\log(C\min\{|T|,|T'|\})\right). \quad \blacktriangleleft$$

5 Largest Weight Common Subtree Embeddings for Unrooted Trees

In this section we consider a LaWeCSE between unrooted trees. I.e., we want to find two root vertices $r\in V(T)$, $s\in V(T')$ and a common subtree embedding φ between T^r and T'^s such that there is no embedding φ' between $T^{r'}$ and $T'^{s'}$, $r'\in V(T)$, $s'\in V(T')$, with $\mathcal{W}(\varphi')>\mathcal{W}(\varphi)$. We abbreviate this as LaWeCSE_u. In Sect. 5.1 we present a basic algorithm and a first improvement by fixing the root of T. In Sect. 5.2 we speed up the computation by exploiting similarities between the different chosen roots of T'. In each section we prove the correctness and upper time bounds of our algorithms.

5.1 Basic algorithm and fixing one root

The basic idea is to compute for each pair of vertices $(u,v)\in V(T)\times V(T')$ a (rooted) LaWeCSE from T^u to T'^v and output a maximum solution. This is obviously correct and the time bound is $\mathcal{O}(|T|^2\,|T'|^2\Delta)$.

In our previous work [4] we showed how to compute a maximum common subtree between unrooted trees by arbitrarily choosing one root vertex r of T and then computing MCSs between T^r and T'^s for all $s\in V(T')$. The key idea in the proof is that for any maximum

common subtree isomorphism φ between T and T', either r is mapped by φ, or there is a unique vertex $u \in V(T)$ with shortest distance to r, such that all vertices mapped by φ are contained in T_u. The dynamic programming approach for LaWeCSE already considers the maximum solutions between the rooted subtrees of T^r and T'^s. However, Fig. 2 shows that this strategy alone sometimes fails, if we want to find a LaWeCSE_u between the input trees. A LaWeCSE between T^r and T' rooted at any vertex results in a weight of at most 2.8. In contrast, rooting T at u_0 results in a LaWeCSE of weight 3.6.

In a maximum common subtree between trees T and T', let $r \in V(T)$ be an arbitrarily chosen root of T. If any two children u_1, u_2 of their parent node $u \in V(T)$ are mapped to vertices of T', then u is also mapped. This statement is independent from the chosen root $r \in V(T)$, since a common subtree is connected. If we want to compute a (rooted) LaWeCSE, the statement is also true (for the given root). This follows from Def. 1 ii). However, if we choose u_1 as root in a LaWeCSE_u, we may skip u and map u_2, forming the topological path (u_1, u, u_2). Whatever we do, if we skip vertex u as an inner vertex of a topological path, this is the only path containing u; otherwise we violate Def. 1. We record this as a lemma.

▶ **Lemma 9.** *Let T and T' be unrooted trees. Let φ be a LaWeCSE_u from T to T' and $u \in V(T)$ be an inner vertex of a topological path with its neighbors $N(u) = \{u_1, u_2, \ldots, u_k\}$. Then φ maps vertices from exactly two of the rooted subtrees $T^u_{u_1}, \ldots, T^u_{u_k}$ to T'.*

To compute a LaWeCSE_u φ, additionally to the strategy from [4], we need to cover the case, that there is no single vertex u mapped by φ, such that all vertices mapped by φ are contained in T^r_u, cf. Fig. 2 with r as chosen root. In this case let u be the unique inner vertex of a topological path P, such that all vertices mapped by φ are contained in T^r_u. An example is the yellow vertex u in Fig. 2. Further, let $P_1 = (u_0, \ldots, u_{i-1}, u_i = u, u_{i+1}, \ldots, u_k)$ be the topological path containing u and $\varphi(P_1) = P_2 = (v_0, \ldots, v_l)$ with $\varphi(u_0) = v_0$ and $\varphi(u_k) = v_l$.

Then there is a LaWeCSE ϕ_1 between the rooted subtrees $T^r_{u_{i-1}}$ and $T'^{v_1}_{v_0}$ containing u_0 and all its descendants mapped by φ. There is another LaWeCSE ϕ_2 between the rooted subtrees $T^r_{u_{i+1}}$ and $T'^{v_0}_{v_1}$ containing u_k and all its descendants mapped by φ. Note, choosing $T'^{v_{j+1}}_{v_j}$ and $T'^{v_j}_{v_{j+1}}$ for any $j \in \{0, \ldots, l+1\}$ as rooted subtrees yields the same LaWeCSEs ϕ_1 and ϕ_2, i.e., it does not matter where we split the path P_2.

For any vertex $v \in V(T')$ let $\mathcal{L}^v$ refer to the table $\mathcal{L}$ corresponding to T^r and T'^v. Then $L_1 := \max\{\mathcal{L}^{v_1}(u_{i-1}, v_0, t) \mid t \in \{\curlywedge, \diamond\}\}$ is the weight of the LaWeCSE ϕ_1 minus the penalty for the inner vertices $u_1, \ldots, u_{i-1}$; the penalty is 0, if $i = 1$. $L_2 := \max\{\mathcal{L}^{v_0}(u_{i+1}, v_1, t) \mid t \in \{\curlywedge, \diamond\}\}$ is the weight of the LaWeCSE ϕ_2 minus the penalty for the inner vertices $u_{i+1}, \ldots, u_{k-1}$ and $v_1, \ldots, v_{l-1}$. I.e., the penalty p for each inner vertex on the paths excluding u is included in $L_1 + L_2$. Therefore $\mathcal{W}(\varphi) = L_1 + L_2 - p$. Before summarizing this strategy in the following Lemma 10, we exemplify it on Fig. 2.

The LaWeCSE_u φ is depicted by green dashed lines with mapping $u_0 \mapsto v_0$ and $u_3 \mapsto v_1$. The yellow inner vertex u fulfills the condition that T^r_u contains all vertices mapped by φ. We have paths $P_1 = (u_0, u, u_2, u_3)$ and $\varphi(P_1) = P_2 = (v_0, v_1)$. Then $L_1 = \mathcal{L}^{v_1}(u_0, v_0, \curlywedge) = 2$ for the mapping $u_0 \mapsto v_0$. Further $L_2 = \mathcal{L}^{v_0}(u_2, v_1, \diamond) = 1.8$ for the mapping $u_3 \mapsto v_1$ and the skipped vertex u_2. We obtain $\mathcal{W}(\varphi) = L_1 + L_2 - p = 2 + 1.8 - 0.2 = 3.6$.

▶ **Lemma 10.** *Let T and T' be trees. Let $r \in V(T)$ be arbitrarily chosen. Let $\mathcal{W}(r, v)$ be the weight of a LaWeCSE from T^r to T'^v and $\mathcal{T}(u, v, w) = \max\{\mathcal{L}^w(u, v, t) \mid t \in \{\curlywedge, \diamond\}\}$. Then the weight of a LaWeCSE_u is the maximum of the following two quantities.*

- $M_1 = \max\{\mathcal{W}(r, v) \mid v \in V(T')\}$
- $M_2 = \max_{u \in V(T),\ vw \in E(T')}\{\mathcal{T}(u_1, v, w) + \mathcal{T}(u_2, w, v) \mid u_1 \neq u_2 \in C(u)\} - p$

▶ **Lemma 11.** *Let the preconditions be as in Lemma 10. Then M_1 can be computed in time $\mathcal{O}(|T|\,|T'|^2\Delta)$ and M_2 in time $\mathcal{O}(|T|\,|T'|)$; both can be computed in space $\mathcal{O}(|T|\,|T'|)$.*

Proof. For any vertices $s, v \in V(T')$ consider the rooted subtree T'^s_v. Let $p(v)$ be the parent vertex of v with $p(s) = s$. Then $T'^s_v = T'^{p(v)}_v = T'^w_v$ for each vertex $w \in V(T') \setminus V(T'^s_v)$, i.e., w is a vertex of T', which is not contained in the rooted subtree T'^s_v. Therefore we can identify each table entry $\mathcal{L}^s(u, v, t)$ by $\mathcal{L}^{p(v)}(u, v, t)$. In other words, all the table entries needed to compute M_1 are determined first by a node $u \in V(T)$, and second by either an edge $wv \in E(T')$ or the root vertex s. Therefore, the space needed to store all the table entries and thus compute M_1 is $\mathcal{O}(|T|\,|T'|)$. We will use these values to retrieve $\mathcal{T}(u, v, w)$ in constant time.

From Theorem 6 for each $v \in V(T')$ we can compute $\mathcal{W}(r, v)$ in time $\mathcal{O}(|T|\,|T'|\Delta)$. Thus, the time for M_1 is bounded by $\mathcal{O}(|T|\,|T'|^2\Delta)$. For any edge $vw \in E(T')$ we observe that the only rooted subtrees from T' to consider are T'^v_w and T'^w_v. Let $L(b, v)$ and $L(b, w)$, $b \in C(u)$ be the weight of a LaWeCSE from T^r_b to T'^w_v and T'^v_w, respectively. Let G be a bipartite graph with vertices $C(u) \sqcup \{v, w\}$ and edges between these vertices with weights defined by $L(b, v)$ and $L(b, w)$, respectively. Let M be a MWM_2 on G. Then $W(M) = \max\{\mathcal{T}(u_1, v, w) + \mathcal{T}(u_2, w, v) \mid u_1 \neq u_2 \in C(u)\}$. This follows from the construction of G. Note, a MWM_2 contains exactly 2 edges. Let $C(u) = \{b_1, \ldots, b_k\}$ such that $L(b_i, v) \geq L(b_{i+1}, v)$ for any $i < k$. I.e., the vertices b_i are ordered, such that $L(b_1, v)$ and $L(b_2, v)$ have weight at least $L(b_i, v)$ for all $i > 2$. We remove all edges incident to v except b_1v and b_2v. Analog we remove all but the two edges of greatest weight incident to w. Let G' be the graph with those edges removed and M' be a MWM_2 on G'. We next prove $W(M') = W(M)$. Let M be a matching on G. Assume the partner of v is b_i, $i > 2$. Then let $b = b_1$ if b_1 is not the partner of w, and $b = b_2$ otherwise. Replacing $vb_i \in M$ by vb results in a matching M' such that $W(M') \geq W(M)$. We may argue analog for w.

Since G' contains at most 4 edges we may compute M' in constant time. The time to remove the edges from G to G' is $\mathcal{O}(k)$. Therefore the time to compute $\max\{\mathcal{T}(u_1, v, w) + \mathcal{T}(u_2, w, v) \mid u_1 \neq u_2 \in C(u)\}$ for given u and vw is $\mathcal{O}(|C(u)|)$. The time to compute M_2 is $\mathcal{O}(\sum_{u \in V_T, vw \in E_{T'}} |C(u)|) = \mathcal{O}(|T|\,|T'|)$.

We may compute M_2 from $\mathcal{L}$ and additional space $\mathcal{O}(|T|)$, which is $\mathcal{O}(|T|\,|T'|)$ in total. ◀

5.2 Exploiting similarities

In this section we improve the running time from $\mathcal{O}(|T|\,|T'|^2\Delta)$ to $\mathcal{O}(|T|\,|T'|\Delta)$. To this end, we need to speed up the computation in Lemma 5. Specifically, we exploit similarities between the graphs on which we compute the maximum weight matchings. We further need to speed up the computation of $M_t^{T'}$ related to the root vertices from T'. We have to take special care of the sequence, in which we compute the table entries, to avoid circular dependencies.

Speeding up the dynamic programming approach. In Lemma 5 the recursion computes maximum values among certain table entries. We first include the current root $s \in V(T')$ into the notation. We use the definition of $\mathcal{L}^s$ from Sect. 5.1 refering to the table where s is the root of $V(T')$. Let $u \in V(T)$ and $v \in V(T')$ be the vertices in the current recursion of Lemma 5. For all $t \in \{\curlywedge, \diamond\}$ let $M_t^{T,s} = \max\{\mathcal{L}^s(b, v, t) \mid b \in C(u)\}$ and $M_t^{T',s} = \max\{\mathcal{L}^s(u, c, t) \mid c \in C(v)\}$. From the proof of Lemma 11 we know that $T'^s_v = T'^w_v$

for each vertex $w \in V(T') \setminus V(T'^s_v)$. This implies $M_t^{T,s} = M_t^{T,w}$ and $M_t^{T',s} = M_t^{T',w}$ for all w as before. I.e., it is sufficient to distinguish all the $M_t^{T,s}$ and $M_t^{T',s}$ first by a node $u \in V(T)$, and second by either an edge $wv \in E(T')$ or a single vertex $s \in V(T')$.

This observation allows us to upper bound the time to compute all the $M_t^{T,s}$ by

$$\mathcal{O}\left(\sum_{u\in V_T, wv\in E_{T'}} |C(u)| + \sum_{u\in V_T, s\in V_{T'}} |C(u)|\right) = \mathcal{O}\left(\sum_{wv\in E_{T'}} |T| + \sum_{s\in V_{T'}} |T|\right) = \mathcal{O}\left(|T|\,|T'|\right).$$

Let $N(v) = \{c_1, c_2, \dots c_l\}$ and $C_i := \{c_1, \dots, c_{i-1}, c_{i+1}, \dots, c_l\}$ for $1 \le i \le l$, i.e, C_i contains all the vertices from $N(v)$ except c_i. We observe $M_t^{T',v} = \max\{\mathcal{L}^v(u,c,t) \mid c \in N(v)\}$ and $M_t^{T',c_i} = \max\{\mathcal{L}^{c_i}(u,c,t) \mid c \in C_i\} = \max\{\mathcal{L}^v(u,c,t) \mid c \in C_i\}$ for each $i \in \{1,\dots,l\}$. Let j be an index, such that $M_t^{T',v} = \mathcal{L}^v(u,c_j,t)$. Then for each $i \neq j$ we have $M_t^{T',c_i} = M_t^{T',v}$. Therefore, we may compute $M_t^{T',v}$ and M_t^{T',c_i} for all $i \in \{1,\dots,l\}$ in time $\mathcal{O}(\delta(v))$. Hence, the time to compute all the $M_t^{T',s}$ is bounded by $\mathcal{O}\left(\sum_{u\in V_T, v\in V_{T'}} \delta(v)\right) = \mathcal{O}\left(\sum_{u\in V_T} |T'|\right) = \mathcal{O}(|T|\,|T'|)$.

▶ **Lemma 12.** *Assume there is a sequence of all pairs (u,v) such that all necessary values are available to compute $M_t^{T,s}$ and $M_t^{T',s}$ for $s \in N(v) \cup \{v\}$; then the total time is $\mathcal{O}(|T|\,|T'|)$.*

Exploiting similarities between the matching graphs. In Lemma 5 we need to compute a MWM for each $(u,v) \in V(T) \times V(T')$. When considering all roots $s \in V(T')$, we have one matching graph G with vertices $C(u) \sqcup N(v)$, $N(v) = \{c_1, \dots, c_l\}$ as well as l graphs G_{c_i}, $1 \le i \le l$. This follows analog to the observation regarding $M_t^{T',v}$ from the previous paragraph. A graph G_c, $c \in N(v)$, is the same as G except that the vertex c and incident edges are removed. Let $s := \min\{\delta(u), \delta(v)\}$ and $t := \max\{\delta(u), \delta(v)\}$. We now prove a total time bound of $\mathcal{O}(s^2 t)$ for computing a MWM on G as well as on G_c for all $c \in N(v)$. We distinguish two cases.

i) $s \ge \log t$. In our previous work we presented an algorithm to compute a maximum common subtree of maximum weight, a special case of LaWeCSE_u [4]. A subproblem is to compute MWMs on graphs structurally identical to G and G_{c_i}, $1 \le i \le l$. We showed that we can compute all those MWMs in time $\mathcal{O}(st(s + \log t))$. Under the premise $s \ge \log t$ the time bound is $\mathcal{O}(s^2 t)$.

ii) $s < \log t$. Then one vertex set is much smaller than the other. From Lemma 14 we can compute all those MWMs in time $\mathcal{O}(s^4 + s^2 t)$. Under the premise $s < \log t$ that is $\mathcal{O}(s^2 t)$.

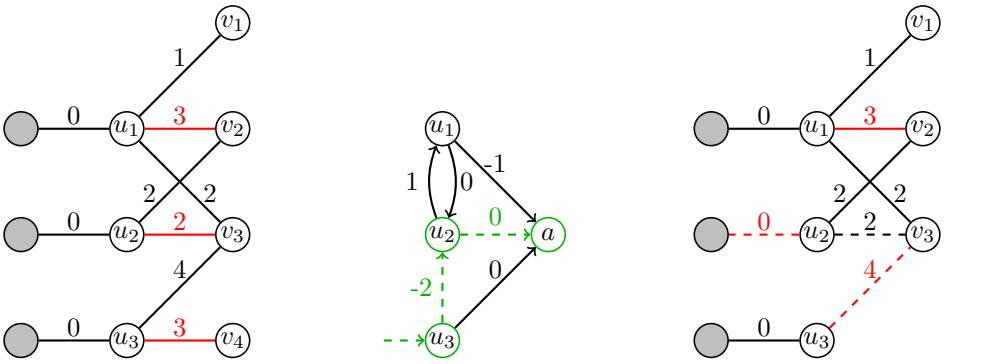
▶ **Lemma 13.** *Assume there is a sequence of all pairs (u,v) such that all necessary values are available to compute the MWMs; then the total time is $\mathcal{O}(|T|\,|T'|\Delta)$.*

Proof. The time to compute all the MWMs is

$$\mathcal{O}\left(\sum_{u\in V_T}\sum_{v\in V_{T'}} \delta(u)\delta(v)\min\{\delta(u),\delta(v)\}\right) \subseteq \mathcal{O}\left(\sum_{u\in V_T}\sum_{v\in V_{T'}} \delta(u)\delta(v)\Delta\right) = \mathcal{O}(|T|\,|T'|\Delta).$$ ◀

▶ **Lemma 14.** *Let G be a weighted bipartite graph with vertex sets U and V, $s := |U| \le |V| =: t$. Let either $C = U$ or $C = V$. We can compute a MWM on G and a MWM on each graph G_c, $c \in C$, in total time $\mathcal{O}(s^4 + s^2 t)$.*

Proof. From Lemma 7 we know there is an algorithm which computes a MWM on G in time $\mathcal{O}(s^2 t)$. This algorithm first copies the s vertices of U and then adds an edge of weight 0



(a) G' and a MWM M' (red).

(b) $\overline{G'_{v_4}}$ and a shortest path P from v_4's partner u_3 to a (green, dashed lines).

(c) A MWM (red) on G'_{v_4} obtained from a single augmenting path (dashed lines).

Figure 3 **(a)** A MWM$_s$, $s = |U| = 3$, on G', which is also a MWM. **(b)** The graph $\overline{G'_{v_4}}$, on which we compute a shortest path from u_3 to a. Such a path corresponds to a augmenting path of maximal weight in G'_{v_4}. **(c)** Applying the path yields a MWM$_3$ on G'_{v_4}, which is also a MWM.

between each vertex of U and its copy. We denote this graph by G'. The algorithm computes a MWM$_s$ M' on G' (M' is also a MWM), which corresponds to a MWM on G. An example is depicted in Figure 3a.

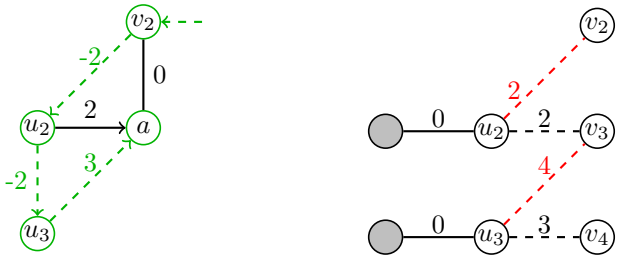
The graph G' with one vertex $c \in C$ removed is denoted by G'_c. If c is not matched, we are done. If c is matched, let u (in case $c \in V$) respectively v (in case $c \in U$) be the partner of c. Let $M'_c := M' \setminus \{cu\}$ or $M'_c := M' \setminus \{cv\}$, respectively. We observe $|M'_c| = s - 1$.

First, assume $c \in V$. In a MWM$_s$ of G'_c each vertex of U including u must be matched. An odd length M'_c-augmenting path P of maximal weight (the path's weight refers to the difference in the matching's weight after augmentation) incident to u yields a MWM$_s$ on G'_c and thus a MWM on G_c. This follows from the fact, that any M'_c-alternating cycle or path on G'_c not incident to u has nonpositive weight; otherwise M' was no MWM. We can find such a path using the Bellman-Ford algorithm in time $\mathcal{O}(st + s^3)$ as follows. Let $\overline{G'_c} = (U \cup \{a\}, A)$ be the digraph, where A is the union of the following two sets of directed arcs.

1. For each alternating path $\bar{u}vu'$ in G'_c, where $\bar{u}, u' \in U, v \in V$, and vu' is matched, we add the arc $(\bar{u}, u')$ with weight $w(vu') - w(\bar{u}v)$.
2. For each vertex $\bar{u} \in U$ let v be a free vertex adjacent to u, such that the edge uv has maximum weight among all such edges. We add an arc (u, a) of weight $-w(uv)$.

The time to construct the graph is bounded by $\mathcal{O}(st)$. Since $\overline{G'_c}$ has $\mathcal{O}(s)$ vertices and $\mathcal{O}(s^2)$ edges, we may compute a shortest path P from c's partner u to a in time $\mathcal{O}(s^3)$. We obtain a MWM on G'_c by augmenting M'_c with the edges that correspond to P in $\overline{G'_c}$. Figure 3b depicts an example for $\overline{G'_c}$, as well as a shortest path P. Figure 3c depicts the resulting MWM. Since at most s vertices of V are matched by M, the total time to compute a MWM on each of the graphs G_c, $c \in V$, is $\mathcal{O}(s^4 + s^2 t)$.

Second, assume $c \in U$. Each vertex in U is matched. Therefore the cardinality of M'_c is $s - 1$. This time we need to find an alternating path of even length (we removed a vertex from U) and of maximal weight incident to c's partner v. Any alternating cycle or path not incident to v cannot augment M'_c to greater weight; otherwise M' was no MWM. This path may have length 0, e.g., if M'_c is a MWM of M'. The total time to compute such a path is $\mathcal{O}(s^3)$ as follows. Let $\overline{G'_c} = (U \cup \{v, a\}, A)$, where A is the union of the following four sets of directed arcs.



(a) $\overline{G'_{u_1}}$ and a shortest path P from u_1's partner v_2 to a (green, dashed).

(b) A MWM (red) on G'_{u_1} (isolated vertices removed) obtained from a single augmenting path (dashed lines).

Figure 4 **(a)** The graph $\overline{G'_{u_1}}$, on which we compute a shortest path from v_2 to a. Such a path corresponds to an augmenting path of maximal weight in G'_{u_1}. **(b)** Applying the path yields a MWM_2 on G'_{u_1}, which is also a MWM.

1. For each edge $vu \in E(G'_c)$, $u \in U$, we add the arc (v, u) with weight $-w(vu)$.
2. For each alternating path $uv'u'$ in G'_c, where $u, u' \in U, v' \in V$, and uv' is matched, we add the arc (u, u') with weight $w(uv') - w(v'u')$.
3. For each matching edge uv', where $u \in U, v' \in V$, we add the arc (u, a) with weight $w(uv')$.
4. We add the arc (v, a) with weight 0.

The time to construct the graph is bounded by $\mathcal{O}(s^2)$. An example is depicted in Figure 4a. Figure 4b depicts the resulting MWM. Since $\overline{G'_c}$ has $\mathcal{O}(s)$ vertices and $\mathcal{O}(s^2)$ edges, we may compute a shortest path P from c's partner v to a in time $\mathcal{O}(s^3)$. Again, P yields the augmenting path in G'_c. Since all the s vertices of U are matched by M, the total time to compute a MWM on each of the graphs G_c, $c \in U$, is $\mathcal{O}(s^4)$. ◀

Sequence of computation. For given vertices $(u, v) \in V(T) \times V(T')$ we denote the matching graph G without removed vertices as *main instance* and the matching graphs G_c as its *sub instances*. Analog for $t \in \{\curlywedge, \diamond\}$ we define $M_t^{T',v}$ as main instance and $M_t^{T',c}$ for each $c \in N(v)$ as its *sub instances*.

Let $u \in V(T)$ and $vw \in E(T')$. We observe, for type $t \in \{\curlywedge, \diamond\}$ the following values depend circularly on each other. To compute $M_t^{T',w}$ recursively for the vertices u, w we need $\mathcal{L}^w(u, v, t)$. Computing $\mathcal{L}^w(u, v, t)$ requires $M_t^{T',v}$ computed recursively for the vertices u, v. The latter one requires $\mathcal{L}^v(u, w, t)$. Finally $\mathcal{L}^v(u, w, t)$ requires $M_t^{T',w}$ computed recursively for the vertices u, w, which was the start of the circular dependency.

We further observe, the MWMs depend on table entries of both types. We may break the dependencies by solving at most one sub instance before solving the main instance, as shown next.

We iterate over all roots $s \in V(T')$ and compute a rooted LaWeCSE between T^r and T'^s as in Lemma 5. During the recursion on vertices (u, v) the following cases may happen.

1. The first instance to compute on (u, v) is a main instance. Then we instantly compute all its sub instances from it.
2. The first instance to compute on (u, v) is a sub instance. Then we compute only the sub instance without deriving it from the main instance.
   - **a.** If the second instance is a main instance, we instantly compute its sub instances.
   - **b.** Otherwise let $c_1 \in N(v)$ and $c_2 \in N(v)$ be the vertices corresponding to the first and second sub instance, respectively. Let us consider table entries first. When

we computed the sub instance corresponding to c_1, all necessary table entries for $M_t^{T',v}$ except $\mathcal{L}^v(u, c_1, t)$ were available. For the second sub instance $\mathcal{L}^v(u, c_1, t)$ is also available. Thus we may instantly compute the main instance and all other sub instances including the one corresponding to c_2. We may argue analog for the MWMs.

▶ **Theorem 15.** *Let T and T' be (unrooted) vertex and/or edge labeled trees. Let ω be a weight function, $\Delta = \min\{\Delta(T), \Delta(T')\}$, and p be a distance penalty. A LaWeCSE$_u$ between T and T' can be computed in time $\mathcal{O}(|T|\,|T'|\Delta)$ and space $\mathcal{O}(|T|\,|T'|)$.*

6 Conclusions

We presented an algorithm which solves the largest weight common subtree embedding problem in time $\mathcal{O}(|T|\,|T'|\Delta)$. For rooted trees of integral weights bounded by a constant we proved a bound of $\mathcal{O}(|T|\,|T'|\sqrt{\Delta}\log(C\min\{|T|, |T'|\}))$. Our approach generalizes the maximum common subtree problem [4] and the largest common subtree embedding problem, both unlabeled [8] and labeled [9], by supporting weights between labels and a distance penalty for skipped vertices.

A remaining open problem is whether the time bound for unrooted trees can be improved when the weights are integral and bounded by a constant. Since weight scaling algorithms for matchings do not work incrementally [13], there is no obvious way to exploit the similarities in the given matching graphs.

Abstract

We give a polynomial delay algorithm for enumerating the minimal transversals of hypergraphs without induced cycles of length 3 and 4. As a corollary, we can enumerate, with polynomial delay, the vertices of any polyhedron $\mathcal{P}(A, \underline{1}) = \{x \in \mathbb{R}^n \mid Ax \geq \underline{1},\ x \geq \underline{0}\}$, when A is a balanced matrix that does not contain as a submatrix the incidence matrix of a cycle of length 4. Other consequences are a polynomial delay algorithm for enumerating the minimal dominating sets of graphs of girth at least 9 and an incremental delay algorithm for enumerating all the minimal dominating sets of a bipartite graph without induced 6 and 8-cycles.

1 Introduction

The task of an *enumeration algorithm* is generating all the feasible solutions of a given property, such as enumerating all the maximal cliques of a graph or all the triangulations of a given set of points in a d-dimensional space. In enumeration algorithms the size of the output is often exponential in the size of the input, therefore, to define the tractability of enumeration problems, the complexity is measured based on the needed total time of the algorithm depending on the size of the input and the size of the output. If the total running time of the algorithm is bounded by a polynomial on the size of the input and the output, the algorithm is called *output-polynomial*. For a good survey of various combinatorial

enumeration problems and their known time complexities see [32]. It is worth noticing that, unless P=NP, there are enumeration problems where no output polynomial enumeration algorithm exist [22, 23].

In the area of enumeration algorithms, enumerating all the inclusion-wise minimal transversals of a hypergraph[2], known as HYPERGRAPH DUALISATION, is a long-standing open problem which arises in different areas of computer science such as data mining [3], game theory [29, 19], artificial intelligence [12, 31], databases [8, 18], learning theory [1] and integer programming [5, 13]. Despite all the attempts, the complexity of the problem is not settled yet. The best-known algorithm for solving HYPERGRAPH DUALISATION in the general case is by Fredman and Khachiyan [14] (see also [24]) which solves the equivalent problem of monotone Boolean duality in quasi-polynomial time. Nevertheless, for several well-structured hypergraph classes, output-polynomial algorithms for HYPERGRAPH DUALISATION is known, *e.g.*, [11, 25, 22] to cite a few. It was also proved in [20] that the HYPERGRAPH DUALISATION is equivalent to the enumeration of minimal dominating sets in graphs, allowing to tackle this old problem in the realm of graph theory (see for instance [20, 16]). In this paper, we investigate the HYPERGRAPH DUALISATION problem in the class of hypergraphs without induced small cycles. A *k-cycle* in a hypergraph $\mathcal{H}$ is a sequence $(x_0, E_0, x_1, E_1, x_2, \cdots, x_{k-1}, E_{k-1}, x_0)$ where the x_i's belong to $V(\mathcal{H})$, the E_i's are in $\mathcal{H}$, $x_0 \in E_{k-1} \cap E_0$ and, for $1 \leq i \leq k-1$, $x_i \in E_i \cap E_{i-1}$. A *chord* in a k-cycles is a pair (x_i, E_j) where $j \notin \{i, (i-1) \mod k\}$. An enumeration algorithm is said to be of *polynomial delay* if the time between two outputs is bounded a polynomial on the input. Our main theorem is the following.

▶ **Theorem 1.** *Let $\mathcal{H}$ be a hypergraph without chordless 3 and 4-cycles. Then, one can enumerate with polynomial delay the minimal transversals of $\mathcal{H}$.*

The first consequence of our main theorem is a polynomial delay algorithm for listing the minimal dominating sets of graphs with girth at least 9, answering a question from [17]. The girth of a graph in G is the shortest chordless cycle[3] in G. Notice that the recent paper [26], proposes an enumeration algorithm, with a constant time delay, which enumerates all the (not necessarily minimal) dominating sets of a given graph of girth at least 9.

▶ **Corollary 2.**

a. *There is a polynomial delay algorithm that enumerates all the minimal dominating sets of a given input graph G of girth at least 9. More precisely, the result holds if G does not contain induced $(4, 5, 6, 7, 8)$-cycles.*

b. *There is an incremental delay algorithm that enumerates all the minimal dominating sets of a given bipartite graph without chordless 6 and 8-cycles.*

Enumeration algorithms also appear in computational geometry. The famous Minkowski-Weyl theorem states that every convex polyhedron can be represented as the intersection of finitely many affine half spaces, known as *H-representation*, and by the Minkowski sum of a polytope and a finitely generated cone, known as *V-representation*, while the two representations are equivalent. There are various open enumeration problems in this area, such as *facet enumeration* and *convex hull problem*. We refer to [15] for more study. One of the important enumeration problems in computational geometry is *vertex enumeration problem*

[2] A hypergraph $\mathcal{H}$ is a collection of subsets of a ground set $V(\mathcal{H})$ and a *transversal* of $\mathcal{H}$ is a subset T of $V(\mathcal{H})$ that intersects all sets in $\mathcal{H}$.

[3] A k-cycle in a graph G is a sequence $(v_1, v_2, \ldots, v_k)$ where v_i and v_{i+1} are adjacent in G and v_1 is adjacent with v_k. A k-cycle $(v_1, \ldots, v_k)$ is chordless if there are no other edges between the v_i's.

which asks for generating all the vertices of a polyhedron given by its H-representation. Khachiyan et al. [23] proved that enumerating all the vertices of a rational polyhedron, given as an intersection of finitely many half spaces is an NP-hard enumeration problem. It's worth mentioning that the complexity of the problem in the case of polytopes (bounded polyhedrons), yet remains open. The hardness of enumerating the vertices of a polyhedron is more interesting when it comes true even for 0/1 polyhedrons (polyhedrons with vertices in $\{0,1\}^n$) [6] which is in contrast with the fact that all the vertices of a 0/1 polytope are enumerable in *polynomial delay* [9]. Regardless of the hardness of vertex enumeration for general polyhedrons, it is interesting to ask for which classes of polyhedrons the problem is tractable.

As a consequence of our main theorem, we also obtain a polynomial delay algorithm for enumerating the vertices of a large subclass of 0/1 polyhedrons given by *balanced* matrices. For doing so we use the known equivalent characterisation in terms of a HYPERGRAPH DUALISATION problem. Let us define the problem formally. Let $A \in \{0,1\}^{m\times n}$ and $\underline{1}$ and $\underline{0}$ be respectively all ones and all zeros vectors with appropriate size and $\mathcal{P}(A,\underline{1}) = \{x \in \mathbf{R}^n \mid Ax \geq \underline{1},\ x \geq \underline{0}\}$ be a polyhedron with only integral vertices. In other words, $\mathcal{P}(A,\underline{1})$ is the *set covering* polyhedron with the 0/1 *ideal* matrix A. It is well-known and not hard to see that the vertices of $\mathcal{P}(A,\underline{1})$ are in bijection with the minimal transversals of the hypergraph $\mathcal{H}[A]$, where the columns of A correspond to vertices of $\mathcal{H}[A]$ and the rows of A are incident vectors of the hyperedges of $\mathcal{H}[A]$ [27]. This gives an equivalence between the vertex enumeration problem for $\mathcal{P}(A,\underline{1})$ and the HYPERGRAPH DUALISATION problem for such hypergraphs $\mathcal{H}[A]$. The existence of the quasi-polynomial algorithm for enumerating the minimal transversals of a hypergraph [14] suggests that the complexity of vertex enumeration for $\mathcal{P}(A,\underline{1})$ is unlikely to be in NP.

In the Recent paper [13], Elbassioni and Makino have given an incremental polynomial time algorithm for enumerating the vertices of $\mathcal{P}(A,\underline{1})$ when A is a 0/1 totally unimodular matrix. Totally unimodular matrices are an important class of matrices for integer programming with the property that every square submatrix of it has determinant 0 or 1. The generating method in [13] is based on enumerating the transversals of the associated hypergraph and Seymour's fundamental decomposition theorem for totally unimodular matrices [30]. As an interesting open problem, one may ask about the existence of an output polynomial algorithm for enumerating the vertices of $\mathcal{P}(A,\underline{1})$ when A is a *balanced* matrix [13]. A 0/1 matrix is *balanced* if it does not contain a submatrix that is the incidence matrix of a cycle of odd length (see [30, Chapter 21] or [10]). Totally unimodular matrices are a proper subset of balanced matrices. A consequence of our main theorem is the following.

▶ **Theorem 3.** *There is a polynomial delay algorithm for listing the vertices of any given* 0/1 *polyhedron* $\mathcal{P}(A,\underline{1})$ *whenever* A *is a balanced matrix without any submatrix that is the incident matrix of a* 4*-cycle.*

As the algorithm needs some technical definitions, we postpone the details of the algorithm to Section 2. The main technical part of the paper is in Section 3 where we prove the main theorem.

2 Definitions and Preliminaries

The power set of a set V is denoted by 2^V, and for two sets A and B, we let $A \setminus B$ denote the set $\{x \in A \mid x \notin B\}$.

A hypergraph $\mathcal{H}$ is a collection of subsets of a finite ground set. The elements of $\mathcal{H}$ are called the *hyperedges* of $\mathcal{H}$ and the *vertex set* of $\mathcal{H}$ is $V(\mathcal{H}) := \bigcup_{E\in\mathcal{H}} E$. Given $S \subseteq V(\mathcal{H})$,

we denote by $\mathcal{H}[S]$ the *hypergraph induced by* S, that is, $\mathcal{H}[S] := \{E \cap S \mid E \in \mathcal{H}\}$. Any subset $\mathcal{H}'$ of $\mathcal{H}$ is called a *sub-hypergraph* of $\mathcal{H}$. Notice that if there exists $E \in \mathcal{H}$ such that $E \subseteq V(\mathcal{H}) \setminus S$, then $\emptyset \in \mathcal{H}[S]$.

Given a hypergraph $\mathcal{H}$ and a subset $S \subseteq V(\mathcal{H})$ of its vertex set, we denote by $\mathcal{H}(S)$ the sub-hypergraph $\{E \in \mathcal{H} \mid S \cap E \neq \emptyset\}$; and for $v \in V(\mathcal{H})$, we write $\mathcal{H}(v)$ instead of $\mathcal{H}(\{v\})$. Notice that $\mathcal{H}(v)$ is the set of hyperedges containing v.

We assume that each hypergraph is given with an ordering $\leq$ of its set of vertices.

A *k-hole* in a hypergraph is a chordless cycle of length k.

A *transversal* (or hitting set) of a hypergraph $\mathcal{H}$ is a set $T \subseteq V(\mathcal{H})$ that has a nonempty intersection with every hyperedge $E \in \mathcal{H}$. A transversal T is said *minimal* if no proper subset of T is a transversal. For $T \subseteq V(\mathcal{H})$ and $x \in T$, we let $\mathcal{P}_T(x) := \{E \in \mathcal{H} \mid E \cap T = \{x\}\}$, and call it the set of *privates* of x with respect to T (we may drop the "with respect to T" when T is clear from the context). We say that $B \subseteq V(\mathcal{H})$ *breaks* $x \in T$, if for every $E \in \mathcal{P}_T(x)$, $E \cap B \neq \emptyset$ and if $B = \{b\}$, we say that b breaks x, for short.

We call $T \subseteq V(\mathcal{H})$ *irredundant* if $\mathcal{P}_T(x) \neq \emptyset$ for all $x \in T$. It is well-known that T is a minimal transversal if and only if T is a transversal and is irredundant. We denote by $\mathsf{tr}(\mathcal{H})$ the set of minimal transversals of $\mathcal{H}$. Observe that if all hyperedges of $\mathcal{H}$ are non-empty, then $\mathsf{tr}(\mathcal{H}) \neq \emptyset$. For more definitions and details on hypergraphs, we refer to [4].

▶ **Definition 4.** For $\ell \in V(\mathcal{H})$ and $E \in \mathcal{H}$ such that $\ell \in E$, we let $S(\ell, E)$, called a *double star*, be the sub-hypergraph $\mathcal{H}(\ell)[E]$. A double star is called *valid* if $(\mathcal{H} \setminus \mathcal{H}(\ell))[V(\mathcal{H}) \setminus E]$ does not contain the empty set.

The notion of double star is defined and used in [10] for the decomposition of balanced matrices. We rephrase it in terms of hypergraphs. Observe also that if a hypergraph is *Sperner* (no hyperedge contains another hyperedge), then every double star is valid. Even though for the Hypergraph Dualisation problem, it is enough to consider Sperner hypergraphs, we prefer giving the definition above for general hypergraphs for a better readability of our algorithms as we manipulate induced sub-hypergraphs. We often use the notation S for the double star $S(\ell, E)$ in customary whenever ℓ and E are clear from the context.

▶ **Fact 5.** *If $\emptyset \notin \mathcal{H}$, then $\mathcal{H}$ has a valid double star and it can be found in polynomial time*

Proof. Let $T \in \mathsf{tr}(\mathcal{H})$, which exists because $\emptyset \notin \mathcal{H}$. Let $\ell \in T$ and $E \in \mathcal{P}_T(\ell)$. Since T is a transversal and $E \cap T = \{\ell\}$, then each hyperedge in $\mathcal{H} \setminus \mathcal{H}(\ell)$ has a nonempty intersection with $T \setminus \{\ell\}$. Now, since $T \setminus \{\ell\} \subseteq V(\mathcal{H}) \setminus E$ because $E \cap T = \{\ell\}$, we can conclude that $(\mathcal{H} \setminus \mathcal{H}(\ell))[V(\mathcal{H}) \setminus E]$ does not contain the $\emptyset$ as a hyperedge. ◀

The algorithm for enumerating minimal transversals uses the standard technique which consists, for a hypergraph $\mathcal{H}$, in choosing a vertex ℓ and enumerate the minimal transversals that do not contain ℓ, denoted by $\mathbf{Inc}(\mathcal{H}, \ell)$, and those that do contain ℓ, denoted by $\mathbf{Exc}(\mathcal{H}, \ell)$. For enumerating the minimal transversals that do not contain ℓ, it suffices to make a recursive call to $\mathcal{H}[V(\mathcal{H}) \setminus \{\ell\}]$, once we ensure that one exists (which can be checked in polynomial time). But, enumerating the minimal transversals containing ℓ is a tough task and is exactly what makes the enumeration of $\mathsf{tr}(\mathcal{H})$ difficult because such a strategy causes to ask at each step the following NP-complete problem [7]: Given $X \subseteq V(\mathcal{H})$, does there exist a minimal transversal including X? In order to avoid this NP-complete problem, we use the following strategy, which depends heavily on the fact that 3-holes and 4-holes are forbidden:

1. We always choose ℓ to be in a valid double star $S(\ell, E)$.
2. We secondly show that, for any minimal transversal T of $\mathcal{H} \setminus S(\ell, E)$, $T \cup \{\ell\}$ is a minimal transversal of $\mathcal{H}$. Such minimal transversals are called *basic*.
3. We then show that any minimal transversal containing ℓ is either basic or can be obtained from a basic one by successively applying a *flipping method*. The flipping method yields a parent-child relation between the minimal transversals containing ℓ.
4. We finally use this parent-child relation to enumerate (with polynomial delay) the minimal transversals containing ℓ.

Let $\mathcal{H}$ be a hypergraph with $n := |V(\mathcal{H})| + \sum_{F \in \mathcal{H}} |F|$. An *enumeration algorithm* for $\mathsf{tr}(\mathcal{H})$ is an algorithm that lists all the minimal transversals without repetitions. An enumeration algorithm $\mathbb{A}$ for $\mathsf{tr}(\mathcal{H})$ which terminates in time $p(n, |\mathsf{tr}(\mathcal{H})|)$ for some polynomial $p(x, y)$ is called *output-polynomial* and it is called *polynomial space* if it uses a space bounded by a polynomial in n. Assume now that $T_1, \ldots, T_m$ are the elements of $\mathsf{tr}(\mathcal{H})$ enumerated in the order in which they are generated by $\mathbb{A}$. Let us denote by $T(\mathbb{A}, i)$ the time $\mathbb{A}$ requires until it outputs T_i, also $T(\mathbb{A}, m+1)$ is the time required by $\mathbb{A}$ until it stops. Let $delay(\mathbb{A}, 1) = T(\mathbb{A}, 1)$ and $delay(\mathbb{A}, i) = T(\mathbb{A}, i) - T(\mathbb{A}, i-1)$. The *delay* of $\mathbb{A}$ is $\max\{delay(\mathbb{A}, i)\}$. Algorithm $\mathbb{A}$ is a *polynomial delay* algorithm if there is a polynomial $p(x)$ such that the delay of $\mathbb{A}$ is at most $p(n)$.

The remainder of this paper is as follows. In Section 3 we define the flipping method, the basic minimal transversals and the resulting parent-child relation. We also prove that if $S(\ell, E)$ is a valid double star, then any minimal transversal containing ℓ can be obtained from a basic minimal transversal by following the parent-child relation. The algorithm for enumerating the children of a minimal transversal containing ℓ is given in Section 3.2.

3 Enumeration of minimal transversals including ℓ from a valid double star $S(\ell, E)$

3.1 Basic transversals, flipping operation and parent-child relation

In this section, we introduce the family of minimal transversals $\mathcal{B}$, called *basic transversals*, which will be used as a *base* for generating all the minimal transversals T containing the vertex ℓ. In the first step, a valid double star $S(\ell, E)$ is fixed for $\mathcal{H}$.

▶ **Fact 6.** *For every minimal transversal T of $(\mathcal{H} \setminus \mathcal{H}(\ell))[V(\mathcal{H}) \setminus E]$, $T \cup \{\ell\}$ is a minimal transversal of $\mathcal{H}$.*

Proof. Since T is a minimal transversal of $(\mathcal{H} \setminus \mathcal{H}(\ell))[V(\mathcal{H}) \setminus E]$, $T \subseteq V(\mathcal{H}) \setminus E$ and each vertex of T has a private in $\mathcal{H} \setminus \mathcal{H}(\ell)$. As $\{\ell\}$ is a minimal transversal of $\mathcal{H}(\ell)$ and $E \cap T = \emptyset$, we can conclude that $T \cup \{\ell\}$ is a minimal transversal of $\mathcal{H}$. ◀

We denote by $\mathcal{B}(\ell, E)$ the set $\{T \cup \{\ell\} \mid T \in \mathsf{tr}((\mathcal{H} \setminus \mathcal{H}(\ell))[V(\mathcal{H}) \setminus E])\}$ and call it the set of *basic transversals* of $\mathcal{H}$. We will show that one can generate all the minimal transversals of $\mathcal{H}$ that contain ℓ by doing flipping operations, starting from $\mathcal{B}(\ell, E)$.

Recall that $S(\ell, E)$ is a fixed double star of a fixed hypergraph $\mathcal{H}$. The objective is to define a way to generate the set of all minimal transversals containing the vertex ℓ, starting with the basic transversals. We first define a parent-child relation based on a flipping operation which results in removing one vertex, from E, at a time. As a consequence, each minimal transversal containing ℓ will be reachable, by following the parent-child relation,

Algorithm 1: GreedyPair.

Input: $T \subseteq V$ and the largest succedent vertex x in T
Output: $(Y, (Z_y)_{y \in Y})$

```
Function GreedyPair(H, T, x)
    Y := ∅;
    while P_T(x) is not empty do
        Choose the smallest y ∈ V(P_T(x)) \ E such that ∃ F ∈ P_T(x),
          F \ E ⊆ {v ∈ V(H) | v ≤ y};
        Y := Y ∪ {y};
        Z_y := {z ∈ T | P_T(z) ⊆ H(y)};
        T := (T ∪ {y}) \ Z_y;
```

from a basic transversal. In a second step, we explain how to generate the children of any minimal transversal containing ℓ. Let's denote by $\mathbf{Inc}(\mathcal{H}, \ell, E)$ the set of minimal transversals of $\mathcal{H}$ containing ℓ where $S(\ell, E)$ is a valid double star of $\mathcal{H}$.

▶ **Definition 7.** Let T be an irredundant set of $\mathcal{H}$. A vertex x in T is called a *succedent vertex* if $x \in E \setminus \{\ell\}$.

Observe that a minimal transversal is basic if and only if it does not contain any succedent vertex. Also, if x is a succedent vertex of $T \in \mathbf{Inc}(\mathcal{H}, \ell, E)$, then $\mathcal{P}_T(x) \subseteq \mathcal{H} \setminus \mathcal{H}(\ell)$ because $\ell \in T$.

▶ **Definition 8.** Let T be an irredundant set containing succedent vertices and let $x \in T$ be the largest succedent vertex of T with respect to the ordering $\leq$. We call $(Y, (Z_y)_{y \in Y})$ a *greedy pair of* $\mathcal{P}_T(x)$ if

1. $Y \subseteq V(\mathcal{P}_T(x)) \setminus E$ and $Z_y \subseteq T$ for each $y \in Y$,
2. Y is a minimal transversal of $\mathcal{P}_T(x)$,
3. for each $y \in Y$, there is a hyperedge $F \in \mathcal{P}_{T_y}(x)$ such that $y \in F$ and $F \setminus E \subseteq \{v \in V(\mathcal{H}) \mid v \leq y\}$, where $T_y := (T \cup \{y' \in Y \mid y' < y\}) \setminus (\cup_{y' < y} Z_{y'})$ for each $y \in Y$,
4. for each $y \in Y$, $Z_y := \{z \in T \mid \mathcal{P}_{T_y}(z) \subseteq \mathcal{H}(y)\}$ with T_y as defined above.

▶ **Fact 9.** *The greedy pair of $\mathcal{P}_T(x)$ is unique and is computed in polynomial time by the function* GreedyPair *depicted in Algorithm 1.*

Proof. It is easy to see that the function GreedyPair in algorithm 1 runs in polynomial time and its output, $(Y, (Z_y)_{y \in Y})$, is a greedy pair. Assume that there is another greedy pair $(Y', (Z'_y)_{y \in Y'})$. It is enough to show that $Y = Y'$ since $(Z_y)_{y \in Y}$ and $(Z'_y)_{y \in Y'}$ are determined completely by Y and Y', respectively. Let us enumerate Y and Y' as $y_1 < y_2 < \cdots < y_k$ and $y'_{i_1} < y'_{i_p} < \cdots < y'_{i_p}$, respectively. Let j the smallest such that $y'_{i_j} \neq y_j$. If y'_{i_j} does not exist, then Y' cannot be a transversal of $\mathcal{P}_T(x)$ and similarly if y_j does not exist. So, let us assume that such a j exists. If $y'_{i_j} < y_j$, then there is an edge $F_{i_j} \in \mathcal{P}_T(x)$ which does not intersect Y because F_{i_j} does not intersect $\{y_1, \ldots, y_{j-1}\}$ and $F_{i_j} \setminus E \subseteq \{w \in V(\mathcal{H}) \mid w < y_{i_j}\}$ (Condition (3) of Definition 8). Similarly, if $y_j < y_{i_j}$, there is an edge $F_j \in \mathcal{P}_T(x)$ which does not intersect Y' as F_j does not intersect $\{y_1, \ldots, y_{j-1}\}$ and $F_j \setminus E \subseteq \{w \in V(\mathcal{H}) \mid w < y_j\}$. In both cases, we contradict the fact that Y or Y' is a transversal of $\mathcal{P}_T(x)$. ◀

If $(Y, (Z_y)_{y \in Y})$ is the greedy pair of $\mathcal{P}_T(x)$, for a minimal transversal T, then Y is intended to replace x in T, but even though $(T \setminus \{x\}) \cup Y$ is a transversal, it is not necessarily minimal.

The set $\cup_{y\in Y} Z_y$ is the set to remove to obtain a minimal transversal. The next lemma allows to prove that $(T \cup Y) \setminus ((\cup_{y\in Y} Z_y) \cup \{x\})$ is a minimal transversal.

▶ **Lemma 10.** *Let T be an irredundant set of $\mathcal{H}$ containing succedent vertices and let x be the largest succedent vertex of T. Let $(Y, (Z_y)_{y\in Y})$ be the greedy pair of $\mathcal{P}_T(x)$ and let $Z := \cup_{y\in Y} Z_y$. Then, the following properties hold:*

a. *For each vertex x' of $T \cap E$ different from x, and each $F' \in \mathcal{P}_T(x')$, we have $F' \cap Y = \emptyset$.*
b. *For each hyperedge $F \in \mathcal{H} \setminus \mathcal{H}(x)$, we have $|F \cap Y| \leq 1$.*
c. *For each $z \in Z$, there is exactly one $y \in Y$ such that $\mathcal{H}(y) \cap \mathcal{P}_T(z) \neq \emptyset$.*
d. *If there are $z_i, z_j \in Z$ and $y \in Y$ such that $\mathcal{H}(y) \cap \mathcal{P}_T(z_i) \neq \emptyset$ and $\mathcal{H}(y) \cap \mathcal{P}_T(z_j) \neq \emptyset$, then there is no hyperedge in $\mathcal{H} \setminus \mathcal{H}(y)$ which includes both z_i and z_j.*
e. *If there are $z \in Z$ and $y \in Y$ such that $\mathcal{H}(y) \cap \mathcal{P}_T(z) \neq \emptyset$, then $\mathcal{H}(x) \cap \mathcal{H}(z) \subseteq \mathcal{H}(x) \cap \mathcal{H}(y)$.*

Proof. All the proofs are by contradicting the fact that $\mathcal{H}$ is $(3, 4)$-hole free.

a. Let $x' \neq x$ be a vertex of $T \cap E$ and $F' \in \mathcal{P}_T(x')$ and $y \in Y \cap F'$. Also, assume that $F \in \mathcal{P}_T(x)$, containing y. By the definition of the double star $S(\ell, E)$, the hyperedge E contains all the succedent vertices and therefore, (y, F, x, E, x', F', y) is a 3-hole in $\mathcal{H}$.
b. Let $F \in \mathcal{H} \setminus \mathcal{H}(x)$ be a hyperedge containing two vertices $y_i \leq y_j$, both from Y. Let $F_i \in \mathcal{P}_Y(y_i) \cap \mathcal{H}(x)$ and $F_j \in \mathcal{P}_Y(y_j) \cap \mathcal{H}(x)$, which exist by the definition of a greedy pair. Then $(y_i, F, y_j, F_j, x, F_i, y_i)$ constitutes a 3-hole in $\mathcal{H}$.
c. Let $N_i \in \mathcal{H}(y_i) \cap \mathcal{P}_T(z)$ and $N_j \in \mathcal{H}(y_j) \cap \mathcal{P}_T(z)$ for two distinct vertices y_i and y_j of Y. Notice that $N_i \neq N_j$ by (b). Let $F_i \in \mathcal{P}_T(x) \cap \mathcal{P}_Y(y_i)$ and $F_j \in \mathcal{P}_T(x) \cap \mathcal{P}_Y(y_j)$. Then $(z, N_i, y_i, F_i, x, F_j, y_j, N_j, z)$ gives a 4-hole in $\mathcal{H}$.
d. Let $z_i, z_j \in Z$ such that there is a vertex $y \in Y$, and $F_i \in \mathcal{H}(y) \cap \mathcal{P}_T(z_i)$ and $F_j \in \mathcal{H}(y) \cap \mathcal{P}_T(z_j)$. Suppose that there is a hyperedge $F \in \mathcal{H} \setminus \mathcal{H}(y)$ that contains both z_i and z_j. Then, $(z_j, F, z_i, F_i, y, F_j, z_j)$ induces a 3-hole in $\mathcal{H}$.
e. Let $F_z \in \mathcal{H}(y) \cap \mathcal{P}_T(z)$ and $N_z \in \mathcal{H}(x) \cap \mathcal{H}(z)$ such that $y \notin N_z$. Let $N_y \in \mathcal{H}(x) \cap \mathcal{H}(y)$. Then, $(x, N_z, z, F_z, y, N_y, x)$ is a 3-hole in $\mathcal{H}$. ◀

From Lemma 10, we can deduce the following.

▶ **Proposition 11.** *Let $T \in \mathbf{Inc}(\mathcal{H}, \ell, E)$ be a non-basic minimal transversal and let x be the largest succedent vertex of T. Let $(Y, (Z_y)_{y\in Y})$ be the greedy pair of $\mathcal{P}_T(x)$. Then, $T^* := (T \cup Y) \setminus ((\cup_{y\in Y} Z_y) \cup \{x\})$ belongs to $\mathbf{Inc}(\mathcal{H}, \ell, E)$. Moreover, T^* has one less succedent vertices than T.*

Proof. Let $Z := \cup_{y\in Y} Z_y$. By definition of T^*, it is clear that $\ell \in T^*$ and it has less succedent vertices than T since x is removed from T. By the definition of the greedy pair, each vertex $y \in Y$ has a private with respect to T^*, and by Lemma 10(a), each vertex of $(T \cap E) \setminus \{x\}$ has a private with respect to T^*. Also, by the definition of the greedy pair, each vertex z of $T \setminus (E \cup Z)$ has a private with respect to T^*. It remains to show that T^* is a transversal. If there is $F \in \mathcal{H}$ such that $F \cap T^* = \emptyset$, then by the definition of Z and by Lemma 10(e), F is not the private of any vertex $z \in Z$ and then, there are at least two distinct vertices z and z' both contained in $F \cap Z$. By Lemma 10(d), $z \in Z_{y_i}$ and $z' \in Z_{y_j}$ for two distinct y_i and y_j in Y. Let y_j be the largest such that there is $z' \in Z_{y_j}$ and $z' \in F$. Then, F necessarily belongs to the private of z' with respect to $(T \cup \{y' \in Y \mid y' < y_j\}) \setminus (\cup_{y'<y_j} Z_{y'})$, which contradicts the fact that $z' \in Z_{y_j}$. This concludes the proof. ◀

We are now ready to define the parent-child relation.

Algorithm 2: Enum$(\mathcal{H}, \leq)$.

Input: A $(3,4)$-hole free hypergraph $\mathcal{H}$ and a linear ordering $\leq$ of $V(\mathcal{H})$.

```
begin
    Let S(ℓ, E) be a valid double star of H
    foreach T ∈ Enum ((H \ H(ℓ))[V(H) \ E], ≤ do
        output (T ∪ {ℓ})
        Enum-Children (T ∪ {ℓ})
    Enum (H[V(H) \ {ℓ}], ≤)
```

▶ **Definition 12.** Let T be a non-basic minimal transversal T in $\mathbf{Inc}(\mathcal{H}, \ell, E)$. Let x be the largest succedent vertex of T and let $(Y, (Z_y)_{y\in Y})$ be the greedy pair of $\mathcal{P}_T(x)$. We call $T^* := (T \cup Y) \setminus ((\cup_{y\in Y} Z_y) \cup \{x\})$ the *parent* of T, and call T the *child* of T^* with respect to $(x, Y, (Z_y)_{y\in Y})$.

The following will be used to characterise the children of any minimal transversal in $\mathbf{Inc}(\mathcal{H}, \ell, E)$.

▶ **Fact 13.** *If T is a child of T^* with respect to $(x, Y, (Z_y)_{y\in Y})$ then for every $y \in Y$, $\mathcal{P}_T(x) \cap \mathcal{P}_{T^*}(y) \neq \emptyset$ and for all $z \in Z_{\min(Y)}$, $\mathcal{P}_T(z) \subseteq \mathcal{P}_{T^*}(\min(Y))$.*

▶ **Lemma 14.** *Let T be a child of T^* with respect to $(x, Y, (Z_y)_{y\in Y})$ and let $y_1 := \min(Y \setminus Y_0)$ where $Y_0 := \{y \in Y \mid \mathcal{P}_{T^*}(y) \subseteq \mathcal{H}(x)\}$. Let $Z' := \cup_{y\in Y\setminus\{y_1\}} Z_y$ and $C_{y_1} := V(\mathcal{H}) \setminus (T^* \cup E \cup \{w \in V(\mathcal{H}) \mid \exists t \in T \setminus Z_{y_1} \text{ s.t. } \mathcal{P}_{T\setminus Z_{y_1}}(t) \subseteq \mathcal{H}(w)\})$. Then, $Z_{y_1} \cup \{x\}$ is a minimal transversal of $\mathcal{P}_{(T^*\cup Z')\setminus(Y\setminus\{y_1\})}(y_1)[C_{y_1} \cup \{x\}]$.*

Proof. Notice first that by Fact 13, for each $z \in Z_{y_1}$, $\mathcal{P}_T(z) \subseteq \mathcal{P}_{T^*}(y_1)$ and since $T \setminus Z_{y_1} = (T^* \setminus Y) \cup (Z' \cup \{x\})$ and T is a minimal transversal, we can conclude that $Z_{y_1} \cup \{x\}$ is an irredundant set of $\mathcal{P}_{(T^*\cup Z')\setminus(Y\setminus\{y_1\})}(y_1)$ by Lemma 10(c). Now, because T is a minimal transversal of $\mathcal{H}$, no $z \in Z_{y_1}$ breaks the private of some $t \in T \setminus Z_{y_1}$. So, $Z_{y_1} \subseteq C_{y_1}$. Assume that there is $F \in \mathcal{P}_{(T^*\cup Z')\setminus(Y\setminus\{y_1\})}(y_1)$ such that $F \cap (Z_{y_1} \cup \{x\}) = \emptyset$. Because $T = (T^* \cup Z' \cup Z_{y_1} \cup \{x\}) \setminus Y$, we would have $T \cap F = \emptyset$, contradicting the fact that T is a minimal transversal. ◀

The proofs of the following are trivial from the definitions.

▶ **Lemma 15.** *For every non-basic minimal transversal T in $\mathbf{Inc}(\mathcal{H}, \ell, E)$, the parent of T can be computed in polynomial time.*

▶ **Proposition 16.** *The directed graph with vertex set $\mathbf{Inc}(\mathcal{H}, \ell, E)$ and arc set the pairs (T^*, T) such that T^* is the parent of T is acyclic.*

The algorithm consists now in doing a DFS traversal of the directed graph of Proposition 16. The description is given in Algorithm 2. In order to prove that it runs with polynomial delay, it remains to show that for each non-basic minimal transversal, its children can be enumerated with polynomial delay.

We will now prove in the next section that the children of any $T \in \mathbf{Inc}(\mathcal{H}, \ell, E)$ can be enumerated with polynomial delay and polynomial space.

3.2 Enumerating the children of $T \in \mathbf{Inc}(\mathcal{H}, \ell, E)$

Remember that $\mathcal{H}$ is given with an ordering $\leq$ of $V(\mathcal{H})$. Also, $S(\ell, E)$ is a valid double star of $\mathcal{H}$. For a minimal transversal $T^* \in \mathbf{Inc}(\mathcal{H}, \ell, E)$, let $\mathbf{Cov}(T^*) := \{x \in E \setminus T^* \mid \text{for each } x' \in T^* \cap E,\ x' \leq x \text{ and } \mathcal{P}_{T^* \cup \{x\}}(x') \neq \emptyset\}$. The set $\mathbf{Cov}(T^*)$ is the set of vertices in E that can be added to T^* without breaking the privates of any $x' \in E \cap T^*$ and are therefore candidates for generating the children of T^*.

Let $x \in \mathbf{Cov}(T^*)$ and let $Y_0 := \{y \in T^* \setminus E \mid \mathcal{P}_{T^*}(y) \subseteq \mathcal{H}(x)\}$.

▶ **Lemma 17.** *If $Y_0 \neq \emptyset$, then $T_0 := (T^* \setminus Y_0) \cup \{x\}$ is a minimal transversal of $\mathcal{H}$.*

Proof. By the definition of Y_0 and of T_0, we can conclude that T_0 is an irredundant set. If there is $N \in \mathcal{H}$ not intersected by T_0, then $N \in \mathcal{H}(y) \cap \mathcal{H}(y')$ for two distinct vertices in Y_0. Let $F \in \mathcal{P}_{T^*}(y)$ and $F' \in \mathcal{P}_{T^*}(y')$. Then, (x, F, y, N, y', F', x) is a 3-hole in $\mathcal{H}$, a contradiction. ◀

▶ **Lemma 18.** *If T is a child of T^* with respect to $(x, Y, (Z_y)_{y \in Y})$, then $Y_0 \subseteq Y$.*

Proof. Let T be a child of T^* with respect to $(x, Y, (Z_y)_{y \in Y})$. We first claim that $Y_0 \cap T = \emptyset$. Suppose that there is $y_0 \in T \cap Y_0$. Since T is a child of T^*, then $T^* = (T \cup Y) \setminus (Z \cup \{x\})$ for some greedy pair $(Y, (Z_y)_{y \in Y}$ with $Z := \cup_{y \in Y} Z_y$. Therefore, $y_0 \notin Y$ and thus $y_0 \in T \setminus (Z \cup \{x\})$. Now, because $\mathcal{P}_{T^*}(y_0) \subseteq \mathcal{H}(x)$, we can conclude that there is $y \in Y$ and $F \in \mathcal{H}(y) \cap \mathcal{H}(y_0)$ with $F \in \mathcal{P}_T(y_0)$. Because $y \in Y$, then there is $F' \in \mathcal{P}_T(x)$ such that $F' \in \mathcal{P}_{T^*}(y_1)$. Therefore, $(x, F_0, y_0, F, y_1, F', x)$ is a 3-hole, contradicting that $\mathcal{H}$ is $(3,4)$-hole free, for some $F_0 \in \mathcal{P}_{T^*}(y_0)$.

If T is a child of T^*, then by the previous claim, we know that $Y_0 \cap T = \emptyset$. Because $T^* = (T \cup Y) \setminus (\{x\} \cup Z)$, we can conclude that Y_0 is necessarily a subset of Y, otherwise it would not be a subset of T^*. ◀

Level-0-child. If $Y_0 \neq \emptyset$ and $T_0 := (T^* \setminus Y_0) \cup \{x\}$ is a child of T^* with respect to $(x, Y_0, \emptyset)$, we call T_0 the *level*-0 child of T^*.

Note. If $Y_0 = \emptyset$, we "symbolically" call $T^* \cup \{x\}$ the *level*-0 child of T^* with respect to $(x, \emptyset, \emptyset)$. Also, we say that $(\emptyset, \emptyset)$ is the greedy pair of $\mathcal{P}_{T^* \cup \{x\}}(x)$. Notice that $T^* \cup \{x\}$ is not a minimal transversal.

We will now characterise the other children of T^*. Before, let us first prove the following which is the base of the characterisation.

▶ **Lemma 19.** *Let T be an irredundant set containing succedent vertices and let x be the largest succedent vertex of T. Let $y_1 \in Y$ be the smallest such that $Z_{y_1} \neq \emptyset$. Then, $(Y, (Z_y)_{y \in Y})$ is the greedy pair of $\mathcal{P}_T(x)$ if and only if $(Y, (Z'_y)_{y \in Y})$ is the greedy pair of $\mathcal{P}_{T \setminus Z_{y_1}}(x)$ where*

$$Z'_y := \begin{cases} Z_y & \text{if } y \neq y_1, \\ \emptyset & \text{otherwise.} \end{cases}$$

Proof. Let $(Y', (W_y)_{y \in Y'})$ be the greedy pair of $\mathcal{P}_{T \setminus Z_{\min(Y)}}(x)$. Because $(W_y)_{y \in Y'}$ is determined by Y', it is enough to prove that $Y = Y'$. Let us enumerate Y as $y_{t_1} < y_{t_2} < \cdots < y_{t_p} < y_1 < y_2 < \cdots < y_k$ with $Z_{y_{t_j}} = \emptyset$ for all $1 \leq j \leq p$. Then, Y' is the sequence $y_{t_1} < y_{t_2} < \cdots < y_{t_p} < y'_{i_1} < y'_{i_2} < \cdots < y'_{i_t}$. Let j be the smallest such that $y'_{i_j} \neq y_j$. Let $F_{i_j} \in \mathcal{P}_{T \setminus Z_{y_1}}(x)$ such that $F_{i_j} \setminus E \subseteq \{v \in V(\mathcal{H}) \mid v \leq y'_{i_j}\}$ and let $F_j \in \mathcal{P}_T(x)$ such that $F_j \setminus E \subseteq \{v \in V(\mathcal{H}) \mid v \leq y_j\}$. Observe that because $\mathcal{P}_T(x) \subseteq \mathcal{P}_{T \setminus Z_{y_1}}(x)$, then

$F_j \in \mathcal{P}_{T\setminus Z_{y_1}}(x)$. If $y_j < y'_{i_j}$, then y_j should necessarily belong to Y', contradicting the choice of j. So $y'_{i_j} < y_j$. Assuming that $F_{i_j} \in \mathcal{P}_T(x) \subseteq \mathcal{P}_{T\setminus Z_{y_1}}(x)$ contradicts the fact that $y'_{i_j} \notin Y$. So, $F_{i_j} \notin \mathcal{P}_T(x)$, *i.e.*, there is $z_1 \in Z_{y_1}$ such that $z_1 \in F_{i_j}$. Let $F_1 \in \mathcal{P}_T(z_1)$. Because $z_1 \in Z_{y_1}$, we have that $F_1 \in \mathcal{H}(y_1)$. Then, $(z_1, F_1, y_1, F_j, x, F_{i_j}, z_1)$ is a 3-hole in $\mathcal{H}$. ◀

Level-i children. Let $R := \{y \in T^* \setminus (E \cup Y_0) \mid \mathcal{P}_{T^*}(y) \cap \mathcal{H}(x) \neq \emptyset\}$. The high-level idea for generating the children of T^* with respect to x consists in, recursively, deleting a *correct* set of vertices $Y_0 \subseteq Y \subseteq R$ from T^* and assigning the privates of vertices in Y to x. The choice of Y is determined by checking whether there is a $Z \in \mathsf{tr}(\cup_{y\in Y}\mathcal{P}_{T^*}(y) \setminus \mathcal{H}(x))$ containing x such that $T := (T^* \setminus Y) \cup Z$ is a minimal transversal and child of T^*, which can be checked. As we will see, this step is independent of the choice of Z. In a second step, we will enumerate the set of suitable minimal transversals Z of $\cup_{y\in Y}\mathcal{P}_{T^*}(y) \setminus \mathcal{H}(x)$.

A collection $\mathcal{I}$ of subsets of a ground set V is an *accessible system* if for each $I \in \mathcal{I}$, there is an $i \in I$ such that $I \setminus \{i\} \in \mathcal{I}$. The two following lemmas show that the set of children of T^* is like an accessible system following the Y-parts of the greedy pairs.

▶ **Lemma 20.** *Suppose that $Y_0 = \emptyset$. Let T be a child of T^* with respect to $(x, Y, (Z_y)_{y\in Y})$, with $Y \subseteq R$. Then, $T' := (T \cup \{\min(Y)\}) \setminus Z_{\min(Y)}$ is a child of T^* with respect to $(x, Y \setminus \{\min(Y)\}, (Z_y)_{y\in Y\setminus\{\min(Y)\}})$.*

Proof. If $|Y| = 1$, then $T' = T^* \cup \{x\}$. That is a symbolic *level-0* child of T^* with respect to $(x, \emptyset, \emptyset)$. If $|Y| \geq 2$, let $y_1 := \min(Y)$. By Fact 13, $\mathcal{P}_T(z) \subseteq \mathcal{P}_{T^*}(y_1)$. Then using Lemma 10(d) and by definition, T' is a transversal of $\mathcal{H}$. In order to prove that it is minimal, we must show T' is irredundant. By the construction of Z_1, if y_1 breaks $t \in T$ then $t \in Z_1$. Also, since $|Y| \geq 2$, by Fact 13, $\mathcal{P}_T(x) \cap \mathcal{P}_{T^*}(y) \neq \emptyset$, when $y \in Y \setminus \{y_1\}$ and by the minimality of T^*, $\mathcal{H}(y_1) \cap \mathcal{P}_{T^*}(y) = \emptyset$. Therefore $\mathcal{P}_{T\cup\{y\}}(x) \neq \emptyset$ and T' is irredundant.

Now, by the GreedyPair Algorithm and uniqueness of the greedy pair, we can easily check that the greedy pair of $\mathcal{P}_{T'}(x)$ is exactly $(Y \setminus \{\min(Y)\}, (Z_y)_{y\in Y\setminus\{\min(Y)\}})$ and $T' \cup (Y \setminus \{\min(Y)\}) \setminus ((Z_y)_{y\in Y\setminus\{\min(Y)\}}) = T^*$ is the parent of T'. ◀

▶ **Lemma 21.** *Suppose that $Y_0 \neq \emptyset$. Let T be a child of T^* with respect to $(x, Y, (Z_y)_{y\in Y})$, with $Y \subseteq R \cup Y_0$ and $|Y \setminus Y_0| \geq 1$. Then, $T' := (T \cup \{\min(Y \setminus Y_0)\}) \setminus Z_{\min(Y\setminus Y_0)}$ is a child of T^* with respect to $(x, Y \setminus \{\min(Y \setminus Y_0)\}, (Z_y)_{y\in Y\setminus\{\min(Y\setminus Y_0)\}})$.*

Proof. Recall by Lemma 18 that $Y_0 \subsetneq Y$. By the similar argument as in Lemma 20, we can conclude that T' is a minimal transversal of $\mathcal{H}$ as in addition $\mathcal{P}_T(x) \setminus (\cup_{y\in Y\setminus Y_0}\mathcal{P}_{T^*}(y)) \neq \emptyset$. Again, GreedyPair Algorithm shows that T' is a child of T^* with respect to $(x, Y \setminus \{\min(Y \setminus Y_0)\}, (Z_y)_{y\in Y\setminus\{\min(Y\setminus Y_0)\}})$. ◀

In the following, we want to characterise the other children of T^*. For $1 \leq i \leq |R|$, we call T a *level-i child* of T^* if T is a child with respect to $(x, Y, (Z_y)_{y\in Y})$ with $|Y \setminus Y_0| = i$. We have seen by Lemmas 20 and 21 that if T is a level-i child of T^* with respect to $(x, Y, (Z_y)_{y\in Y})$, then $(T \setminus Z_{\min(Y\setminus Y_0)}) \cup \{\min(Y \setminus y_0)\}$ is a level-$(i-1)$ child of T^* with respect to $(x, Y \setminus \{\min(Y \setminus Y_0)\}, (Z_y)_{y\in Y\setminus\{\min(Y\setminus Y_0)\}})$. We have already seen how to generate the level-0 child. It remains now to explain how to generate the level-i children from the level-$(i-1)$ children.

Let T be a level-$(i-1)$ child of T^* with respect to $(x, Y, (Z_y)_{y\in Y})$. Let $\mathbf{Correct}(Y) := \{y \in R \setminus Y \mid y < \min(Y \setminus Y_0)\}$. Recall that $\mathbf{Correct}(Y) \subseteq T$. For $y \in \mathbf{Correct}(Y)$, we let $C_y := V(\mathcal{P}_{T\setminus\{x\}}(y)) \setminus (T^* \cup E \cup \{w \in V(\mathcal{H}) \mid \exists t \in T \setminus \{y\} \text{ s.t. } \mathcal{P}_{T\setminus\{y\}}(t) \subseteq \mathcal{H}(w)\})$. The set C_y is the set of vertices that are candidates, other than x, for computing minimal transversals

of $\mathcal{P}_{T^*}(y)$, and such that they do not break the privates of any other vertices in T^*, except those of y. The following characterises the level-i children from level-$(i-1)$ children.

▶ **Proposition 22.** *Let $i \geq 1$. T is a level-i child of T^* if and only if there is T' a level-$(i-1)$ child of T^* with respect to $(x, Y, (Z_y)_{y\in Y})$ and $y_1 \in \mathbf{Correct}(Y)$ such that $(Y \cup \{y_1\}, (Z_y)_{y\in Y})$ is the greedy pair of $\mathcal{P}_{T'\setminus\{y_1\}}(x)$ and $T := (T'\setminus\{y_1\}) \cup Z_{y_1}$ with $Z_{y_1} \cup \{x\}$ a minimal transversal of $\mathcal{P}_{T'\setminus\{x\}}(y_1)[C_{y_1} \cup \{x\}]$.*

Proof. Let T be a level-i child of T^* with respect to $(x, Y, (Z_y)_{y\in Y})$ and let $y_1 := \min(Y \setminus Y_0)$. By Lemma 21, $T' := (T \cup \{y_1\}) \setminus Z_{y_1}$ is a child of T^* with respect to $(x, Y\setminus\{y_1\}, (Z_y)_{y\in Y\setminus\{y_1\}})$ and by Lemma 19, $(Y, (Z'_y)_{y\in Y})$ is the greedy pair of $\mathcal{P}_{T'\setminus\{y_1\}}(x)$ where

$$Z'_y := \begin{cases} Z_y & \text{if } y \neq y_1, \\ \emptyset & \text{otherwise.} \end{cases}$$

By Lemma 14, $Z_{y_1} \cup \{x\}$ is a minimal transversal of $\mathcal{P}_{T'\setminus\{x\}}(y)[C_{y_1} \cup \{x\}]$.

Let T' be a level-$(i-1)$ child of T^* with respect to $(x, Y, (Z_y)_{y\in Y})$ and let $y_1 \in \mathbf{Correct}(Y)$ be such that $(Y \cup \{y_1\}, (Z_y)_{y\in Y})$ is the greedy pair of $\mathcal{P}_{T'\setminus\{y_1\}}(x)$. Let $Z_{y_1} \subseteq C_{y_1}$ such that $Z_{y_1} \cup \{x\}$ is a minimal transversal of $\mathcal{P}_{T'\setminus\{x\}}(y_1)$. Let $T := (T' \setminus \{y_1\}) \cup Z_{y_1}$, which by definition is a transversal of $\mathcal{H}$. By definition of C_{y_1}, no $z \in Z_{y_1}$ breaks the privates, with respect to $T' \setminus \{y_1\}$, of some vertex $t \in T' \setminus \{y\}$ and since $Z_{y_1} \cup \{x\}$ is a minimal transversal of $\mathcal{P}_{T'\setminus\{x\}}(y_1)$, each vertex in $Z_{y_1} \cup \{x\}$ has a private with respect to T. Now, if there are $z, z' \in Z_{y_1} \cup \{x\}$ that break the privates, with respect to T, of some $t \in T' \setminus (\{x\} \cup Z_{y_1})$, then by definition of C_{y_1}, there are $F_1, F_2 \in \mathcal{P}_{T'\setminus\{y_1\}}(t)$, $F \in \mathcal{P}_{Z_{y_1}\cup\{x\}}(z)$, $F' \in \mathcal{P}_{Z_{y_1}\cup\{x\}}(z')$, both belonging to $\mathcal{P}_{T'\setminus\{x\}}(y)$. But, then $(z, F_1, t, F_2, z', F', y, F, z)$ is a 4-hole in $\mathcal{H}$. So, T is a minimal transversal of $\mathcal{H}$. By Lemma 19, $(Y \cup \{y_1\}, (Z'_y)_{y\in Y\cup\{y_1\}})$ is the greedy pair of $\mathcal{P}_T(x)$ where

$$Z'_y := \begin{cases} Z_y & \text{if } y \neq y_1, \\ Z_{y_1} & \text{otherwise.} \end{cases}$$

Therefore, T is a level-i child of T^*. ◀

Combining Lemma 21 and Proposition 22, we are now ready to prove that the algorithm Enum given in Algorithm 2 runs with polynomial delay.

Proof of Theorem 1. We claim that the algorithm Enum depicted in Algorithm 2 and combined with the algorithm Enum-Children enumerates the minimal transversals of a $(3, 4)$-hole free hypergraph with polynomial delay.

For any minimal transversal $T \in \mathsf{tr}(\mathcal{H})$, either $T \in \mathbf{Inc}(\mathcal{H}, \ell, E)$ or T belongs to $\mathsf{tr}(\mathcal{H}[V(\mathcal{H}) \setminus \{\ell\}])$. Since we enumerate both in Lines 3-6, we can conclude that the algorithm enumerates all the minimal transversals of $\mathcal{H}$ because of Proposition 16 and also, each non-basic minimal transversal has a parent. It remains to show that we enumerate all the children of each minimal transversal in $\mathbf{Inc}(\mathcal{H}, \ell, E)$.

Now, the function given in Algorithm 3 first outputs the level-0-child if it exists, otherwise it stops. Then, it calls Algorithm 4, which does a DFS on the tree where you have an arc (T', T) if T' is a level-$(i-1)$ child and T is a level-i child obtained from T' as stated in Proposition 22. One can, therefore, conclude that the algorithm correctly outputs all the children of a minimal transversal in $\mathbf{Inc}(\mathcal{H}, \ell, E)$. We can, therefore, conclude that by combining Algorithms 2, 3 and 4 we output exactly the set of minimal transversals.

Algorithm 3: Enum-Children$(\mathcal{H}, \leq, \ell, E, T)$.

Input: A $(3,4)$-hole free hypergraph $\mathcal{H}$, a linear ordering $\leq$ of $V(\mathcal{H})$, a valid double star $S(\ell, E)$ and $T \in \mathbf{Inc}(\mathcal{H}, \ell, E)$.

```
begin
    foreach x ∈ Cov(T) do
        Let Y_0 := {y ∈ T | P_T(y) ⊆ H(x)} and T_0 := ((T \ Y_0) ∪ {x})
        if (Y_0, ∅) is the greedy pair of P_{T\Y_0}(x) then
            if Y_0 ≠ ∅ then
                output T_0
            Let R := {y ∈ T \ (E ∪ Y_0) | P_T(y) ∩ H(x) ≠ ∅}
            Enum-ChildrenAux (H, ≤, ℓ, E, T_0, x, R, Y_0)
```

Algorithm 4: Enum-ChildrenAux$(\mathcal{H}, \leq, \ell, E, T, x, R, Y)$.

Input: A $(3,4)$-hole free hypergraph $\mathcal{H}$, a linear ordering $\leq$ of $V(\mathcal{H})$, a valid double star $S(\ell, E)$, T a transversal of $\mathcal{H}$, a succedent $x \in T$, R the set of candidates and Y the already chosen candidates.

```
begin
    foreach y ∈ Correct(Y) do
        if Y ∪ {y} is the Y-part of the greedy pair of P_{T\{y}}(x) then
            foreach Z_y containing x in Enum (P_{T\{x}}(x)[C_y ∪ {x}], ≤) do
                output ((T ∪ Z_y) \ {y})
                Enum-ChildrenAux (H, ≤, ℓ, E, (T ∪ Z_y) \ {y}), x, R, Y ∪ {y})
```

Let us now analyse its time complexity. Let $n := |V(\mathcal{H})| + \sum_{E \in \mathcal{H}} |E|$. We first notice that one can combine both algorithms Enum and Enum-ChildrenAux into a single one which will do a DFS traversal of the tree of recursive calls (see for instance [2, 21]). Second, each call of Enum or of Enum-ChildrenAux, after a pre-processing polynomial in n, either outputs a new minimal transversal or exits. Therefore, the tree of combined recursive calls of both algorithms has size bounded by $O(n^c) \cdot |\mathsf{tr}(\mathcal{H})|$, for some universal constant c, *i.e.*, the amortised time complexity of the algorithm is $O(n^c)$. By using the same technique as in [28], which consists in outputting a solution at the beginning when the depth of the recursive call is odd, and at the end when the depth is even, one obtains the desired delay per solution. ◀

4 Related results and Conclusion

Enumerating all the minimal dominating sets of a graph is another interesting task in the area of enumeration algorithms with numerous applications (see for instance [20]). Our algorithm readily can enumerate the minimal dominating sets of graphs of girth at least 9. We refer to [26] and [17] for related works. The result of this paper also, gives an incremental delay algorithm for enumerating all the minimal dominating sets in a bipartite graph without induced cycles of length 6 and 8.

▶ **Corollary 2.**

a. *There is a polynomial delay algorithm that enumerates all the minimal dominating sets of a given input graph G of girth at least 9. More precisely, the result holds if G does not contain induced $(4, 5, 6, 7, 8)$-cycles.*

b. *There is an incremental delay algorithm that enumerates all the minimal dominating sets of a given bipartite graph without chordless 6 and 8-cycles.*

Proof of Corollary 2.

a. Let G be a graph of girth at least 9. Let $\mathcal{N}[G]$ be the hypergraph $\{N[x] \mid x \in V(G)\}$ where $N[x]$ is the set $\{x\} \cup \{y \in V(G) \mid y \text{ a neighbour of } x\}$. It is well-known that D is a minimal dominating set of G if and only if D is a minimal transversal of $\mathcal{N}[G]$. One can easily check that if G does not contain a chordless cycle of length strictly smaller than 9 and greater than 3, then $\mathcal{N}[G]$ cannot contain a chordless 3 or 4-cycle, because a cycle of length 3 in $\mathcal{N}[G]$ can only be obtained by an induced cycle of length at most 6 in G and a cycle of length 4 in $\mathcal{N}[G]$ by an induced cycle of length at most 8 in G. By Theorem 1, one can enumerate with polynomial delay all the minimal transversals of $\mathcal{N}[G]$.

b. Let $G := (R, B, E)$ be a bipartite graph without chordless 6 and 8-cycles. By Theorem 1 one can enumerate all the minimal sets $D \subseteq R$ such that D dominates B (called *red-blue dominating sets* in [16]). By using the flipping method in [17], one reduces the existence of an incremental delay enumeration algorithm for the minimal dominating sets of G to the existence of a polynomial delay enumeration algorithm for the minimal red-blue dominating sets in induced subgraphs of G. This concludes the proof. ◀

As we have already discussed in the introduction, the vertices of the polyhedron $\mathcal{P}(A, \underline{1}) = \{x \in \mathbb{R}^n \mid Ax \geq \underline{1},\ x \geq \underline{0}\}$ are in bijection with the minimal transversals of the corresponding hypergraph $\mathcal{H}[A]$, where the columns of A correspond to the vertices of $\mathcal{H}[A]$ and the rows of A are incident vectors of the hyperedges of $\mathcal{H}[A]$ [27]. If the coefficient matrix A in the polyhedron is balanced, then the corresponding hypergraph does not contain any odd-hole.

▶ **Theorem 3.** *There is a polynomial delay algorithm for listing the vertices of any given 0/1 polyhedron $\mathcal{P}(A, \underline{1})$ whenever A is a balanced matrix without any submatrix that is the incident matrix of a 4-cycle.*

Proof of Theorem 3. Let A be a balanced matrix without any 4-cycle submatrix. Then, $\mathcal{H}[A]$, the hypergraph corresponding to the matrix A as explained above, does not contain chordless cycles of length 3 or 4. By Theorem 1 one can enumerate with polynomial delay the minimal transversals of $\mathcal{H}[A]$, which by [27] correspond to the vertices of $\mathcal{P}(A, \underline{1})$. ◀

We conclude the paper by observing that even though our algorithm in Theorem 1 is a polynomial delay one, it uses exponential space and it should be interesting to know whether one can modify it in order to use polynomial space. However, there are more challenging questions, and in particular, it is still open whether there is an output-polynomial time algorithm for enumerating the vertices of a polyhedron $\mathcal{P}(A, \underline{1})$ when A is balanced. We just notice that one needs another technique to deal with balanced hypergraphs as our technique cannot avoid the requirement of the hypergraph to be without chordless 4-cycles. A more challenging question in this area asks for the existence of an output-polynomial time algorithm for the vertices of bounded polyhedron [13].

In many enumeration algorithms, like ours in this paper or [2, 17], the enumeration is reduced to traverse a graph with vertex set the set of solutions, and the difficulty is usually how to generate the neighbors of a given solution. In our paper, we solve this problem by a rather technical, but nice parent-child relation based on the structure of the hypergraphs.

However, the used techniques in almost all such papers are ad-hoc (despite the nice attempts in [2]) and the area still lacks a general theory on identifying a large family of combinatorial enumeration problems on which such a technique works finely.

Abstract

We consider k mobile agents initially located at distinct nodes of an undirected graph (on n nodes, with edge lengths). The agents have to deliver a single item from a given source node s to a given target node t. The agents can move along the edges of the graph, starting at time 0, with respect to the following: Each agent i has a *weight* ω_i that defines the rate of energy consumption while travelling a distance in the graph, and a *velocity* v_i with which it can move.

We are interested in schedules (operating the k agents) that result in a small *delivery time* $\mathcal{T}$ (time when the item arrives at t), and small *total energy consumption* $\mathcal{E}$. Concretely, we ask for a schedule that: either (i) Minimizes $\mathcal{T}$, (ii) Minimizes lexicographically $(\mathcal{T}, \mathcal{E})$ (prioritizing fast delivery), or (iii) Minimizes $\epsilon \cdot \mathcal{T} + (1-\epsilon) \cdot \mathcal{E}$, for a given $\epsilon \in (0, 1)$.

We show that (i) is solvable in polynomial time, and show that (ii) is polynomial-time solvable for uniform velocities and solvable in time $\mathcal{O}(n + k \log k)$ for arbitrary velocities on paths, but in general is NP-hard even on planar graphs. As a corollary of our hardness result, (iii) is NP-hard, too. We show that there is a 2-approximation algorithm for (iii) using a single agent.

1 Introduction

Technological development has allowed for low-cost mass production of small and simple mobile robots. Autonomous vacuum cleaners, mowers, or drones are some of the best known examples. There are attempts to deploy such autonomous *agents* to deliver physical goods – *packages* [24, 26]. In the future, for delivering over longer distances, a *swarm* of such autonomous agents is a likely option to be adapted, since the energy supply of the agents is limited, or the agents are simply required to operate locally, or simply because the usage of some agents is more costly than others. A careful cooperation and planning of the agents is thus necessary to provide energy, time, and cost efficient delivery. This leads to plentiful optimization problems regarding the operation of the agents.

Here we consider the problem of delivering a single package as quickly as possible from a source node s to a target node t in a graph $G = (V, E)$ with edge lengths by a team of k agents. The agents have individual velocities, with which they can move along the edges of the graph, and also an energy-consumption rate for a travelled unit distance. The goal is to design *centralized algorithms* to coordinate the agents such that the package is delivered from s to t in an efficient way. In the literature, delivery problems focusing solely on energy efficiency have been studied. One research direction considers every agent to have an initial amount of energy (battery) that restricts the agents' movements [1, 11]. The decision problem of whether the agents can deliver the package has been shown to be strongly NP-hard on planar graphs [6, 7] and weakly NP-hard on paths [12], and it remains NP-hard on general graphs even if the agents can exchange energy [13]. The second research direction considers every agent to have unlimited energy supply, and an individual energy-consumption rate per travelled distance [8, 9]. The problem of delivering the package and minimizing the total energy consumption can be solved in time $\mathcal{O}(k + n^3)$ [8].

In this paper, we primarily focus on delivering the package in a quickest possible way, and only secondarily on the total energy that is consumed by the agents. This has not been, to the best of our knowledge, studied before. Specifically, we consider the algorithmic problem of finding a delivery schedule that: (i) minimizes the delivery time, (ii) minimizes the delivery time using the least amount of energy, and (iii) minimizes a linear combination of delivery time and energy consumption.

Our model. We are given an undirected graph $G = (V, E)$ on $n = |V|$ nodes. Each edge $e \in E$ has a positive *length* l_e. The length of a path is the sum of the lengths of its edges. We consider every edge $e = \{u, v\}$ to consist of infinitely many points, where every point is uniquely characterized by its distance from u, which is between 0 and l_e. We consider every such point to subdivide the edge $\{u, v\}$ into two edges of lengths proportional to the position of the point on the edge. The distance $d_G(p, q)$ between two points p and q (nodes or points inside edges) of the graph is the length of a shortest path from p to q in G. There are k mobile agents initially placed on nodes $p_1, \ldots, p_k$ of G. Every agent $i = 1, \ldots, k$ has a *weight* $0 \leq \omega_i < \infty$ and a *velocity* $0 < \upsilon_i \leq \infty$. Agents can traverse the edges of the graph. To traverse an edge e (in either direction), agent i needs time l_e/υ_i and $\omega_i \cdot l_e$ units of energy.

Furthermore there is a single package, initially (at time 0) placed on a source node s, which has to be delivered to a given target node t. Each agent can walk from its current location to the current location of the package (along a path in the graph), pick the package up, carry it to another location (a point of the graph), and drop it there. From this moment, another agent can pick up the package again. Only the moving in the graph takes time – picking up the package and dropping it off is done instantaneously. (The time spent by the package being dropped at a point until picked up again is, however, taken into account.)

We call a schedule that operates the agents such that the package is delivered a *solution*. In such a schedule S, we denote by $d_i(S)$ the total distance travelled by agent i, and by $d_i^*(S)$ the distance travelled by agent i while carrying the package. The total energy consumption of the solution is thus $\mathcal{E}(S) = \sum_{i=1}^{k} \omega_i \cdot d_i(S)$ and the time needed to deliver the package is given by $\mathcal{T}(S) = \sum_{i=1}^{k} d_i^*(S)/\upsilon_i +$ (the overall time the package is not carried). *Fast and energy-efficient* Delivery is the optimization problem of finding a solution that has small delivery time $\mathcal{T}$ as well as total energy consumption $\mathcal{E}$. In particular, we study the following three objectives (see Figure 1 for illustration):

(i) Minimize the delivery time $\mathcal{T}$.

(ii) Lexicographically minimize the tuple $(\mathcal{T}, \mathcal{E})$, i.e. among all solutions with minimum $\mathcal{T}$, find a solution that has minimum energy consumption $\mathcal{E}$.

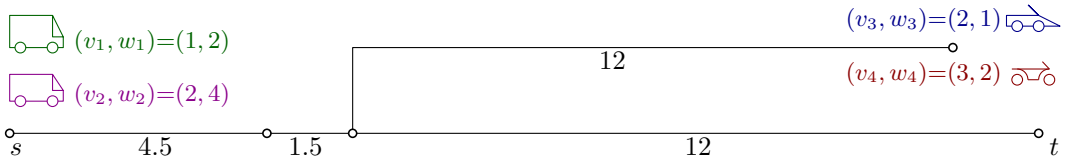

Figure 1 Example for optima of variants of fast *and* energy-efficient DELIVERY:
(ii) Using agents 2 and 4, we get $(\mathcal{T}, \mathcal{E}) = (\max\{6/2, 12/3\} + 12/3,\ 4 \cdot 6 + 2 \cdot 12 + 2 \cdot 12) = (8, 72)$.
(iii) For $\epsilon = \frac{4}{5}$, using agents 1 and 4, we get $\frac{4}{5}\mathcal{T} = \frac{4}{5}(\max\{4.5/1, (12+1.5)/3\} + (1.5+12)/3)$ and $\frac{1}{5}\mathcal{E} = \frac{1}{5}(4.5 \cdot 2 + (12+1.5) \cdot 2 + (1.5+12) \cdot 2)$ for a combined total of $\frac{4}{5}(4.5+4.5) + \frac{1}{5}(9+27+27) = 19.8$.
(iv) Using agents 1 and 3, we get $(\mathcal{E}, \mathcal{T}) = (2 \cdot 6 + 1 \cdot 12 + 1 \cdot 12,\ \max\{6/1, 12/2\} + 12/2) = (36, 12)$.

(iii) Minimize a convex combination $\epsilon \cdot \mathcal{T} + (1-\epsilon) \cdot \mathcal{E}$, for some given value $\epsilon \in (0,1)$.
Recent parallel work studied the following complementary – energy focused – variants:
(iv) Lexicographically minimize the tuple $(\mathcal{E}, \mathcal{T})$, i.e. prioritize the minimization of $\mathcal{E}$ [10].
(v) Minimize the energy consumption $\mathcal{E}$ [8, 9].
In all variants it is natural to (without loss of generality) only consider simple paths as the trajectory of the package, i.e., if at times t_1, t_2 $(0 \le t_1 \le t_2 \le \mathcal{T})$ the package is at the same position p, then it remains at position p for the time in-between $(\forall t \in [t_1, t_2])$. We will make this assumption throughout this paper.

Our contribution. First, in Section 2, we prove for the first time that optimum solutions exist for all mentioned variants of DELIVERY (while previous work on (iv) and (v) implicitly assumed this). Then, in Section 3, we investigate the problem of minimizing the delivery time $\mathcal{T}$ only. We call this optimization problem FASTDELIVERY and show that there is a polynomial-time dynamic program of time complexity $\mathcal{O}(k^2|E| + k|V|^2 + \text{APSP}) \subseteq \mathcal{O}(k^2n^2 + n^3)$, where $\mathcal{O}(\text{APSP})$ is the running time of an all-pair shortest path algorithm for undirected graphs.

In Section 4, we study FASTEFFICIENTDELIVERY, prioritizing the delivery time $\mathcal{T}$ over the energy consumption $\mathcal{E}$. We first show that the problem can be solved in polynomial time for uniform velocities. However, we prove the problem to be NP-hard for general velocities even on planar graphs. We therefore consider the restricted graph class of *paths*, in which we can decompose the problem into uniform velocity instances. For each such instance, we establish a characterization of handover points. Using geometric point-line duality [18] and dynamic planar convex hull techniques [4], we give an $\mathcal{O}(n + k \log k)$ algorithm for paths.

In Section 5, we show that for arbitrary given weights $\epsilon \in (0,1)$, the minimum convex combination $\epsilon \cdot \mathcal{T} + (1-\epsilon) \cdot \mathcal{E}$ can be 2-approximated by a single agent, while NP-hardness follows from an adaptation of the hardness proof in the preceding section. We call the task of minimizing the convex combination COMBINEDDELIVERY. Finally, in Section 6 we discuss several extended models to which our approach can be generalized. Due to the limited space, some proofs are omitted, but are provided in a thesis on several variants of DELIVERY [5].

Comparison to related work. Among the earliest problems related to DELIVERY are the Chinese Postman Problem [19] and the Traveling Salesman Problem [2], in which a single agent has to visit multiple destinations located in edges or nodes of the graph, respectively. The latter has given rise to a class of problems known as Vehicle Routing Problems [25], which are concerned with the distribution of goods by a fleet of (homogeneous) vehicles under additional hard constraints such as time windows. Minimizing the total or the maximum travel distance of a group of agents for several tasks such as the formation of configurations [17] or the visit of designated arcs [20] have been studied for identical agents

as well. Energy-efficient Delivery (without optimization of delivery time) has been recently introduced [8] for an arbitrary number of packages, with handovers restricted to take place at nodes of the graph only. This setting turns out to be NP-hard, but can be solved in polynomial-time for a single package, in which case the restriction of handovers to nodes becomes irrelevant (there is always an optimal solution which does not use any in-edge handovers). To the best of our knowledge, this present paper and a parallel work [10] on variant (iv) are the only ones studying the Delivery problem with agents which have different velocities. Similar to our approach, the latter studies a uniform weight setting first. The uniform weight result is then used as a subroutine in a dynamic program for general weights. Our hardness result shows that such an approach (combination of uniform velocities) is not possible for FastEfficientDelivery, even on planar graphs. Finally, mobile agents with distinct maximal velocities have been getting attention in areas such as searching [3], walking [14] and patrolling [15].

2 Preliminaries

We first formally establish that optimum solutions for all variants of efficient Delivery exist. To this end, each solution which operates agents $i_1, i_2, \ldots, i_\ell$ in this order can be represented by the drop-off locations of these agents only (note that for two consecutive agents i, j, the drop-off location of agent i, denoted by q_i^-, corresponds to the pick-up location of agent j, denoted by q_j^+). Since we allow in-edge handovers, there are infinitely many solutions – however, these can be divided into *finitely* many topologically compact sets. As $\mathcal{E}, \mathcal{T}$ act as continuous functions on these sets, we have in each set a minimum solution.

▶ **Theorem 1** (Existence of optimum solutions)**.** *There exists an optimum solution minimizing the delivery time $\mathcal{T}$ (the energy consumption $\mathcal{E}$, or $\epsilon \cdot \mathcal{T} + (1-\epsilon) \cdot \mathcal{E}$, $(\mathcal{T}, \mathcal{E})$, $(\mathcal{E}, \mathcal{T})$, respectively).*

3 Optimizing delivery time only

Throughout this section, we assume that all agents have weight $\omega_i = 0$. Hence in all three variants of fast energy-efficient Delivery, $\mathcal{E} = 0$ and we are after a solution for delivery with earliest-possible delivery time. We show that FastDelivery is polynomial-time solvable, due to the following characterization of optimum solutions (which exist by Theorem 1):

▶ **Lemma 2.** *For every instance of* FastDelivery*, there is an optimum solution in which (i) the velocities of the involved agents are strictly increasing, (ii) no involved agent arrives at its pick-up location earlier than the package (carried by the preceding agent), and (iii) if more than one agent is involved in transporting the package over an edge $\{u, v\}$ in direction from u to v, then only the first involved agent will ever visit u.*

Proof. All three properties can be shown by exchange arguments. Taking any optimum solution, we turn it into an optimum solution that adheres to the three properties as follows:

(i) Label the agents $1, 2, \ldots, i, \ldots$ in the order in which they transport the package. Let i be the first agent such that $v_i \geq v_{i+1}$. Now we can simply replace agent $i+1$ by letting agent i travel on the same trajectory on which $i+1$ transported the package; and by doing so, we don't increase the delivery time.

(ii) Let i be the first agent that has to wait at its pick-up location for the package to arrive. Instead of waiting, we let i proceed on the original trajectory of the package towards s until it meets the preceding agent $i-1$. Handing over the package at this new spot cannot

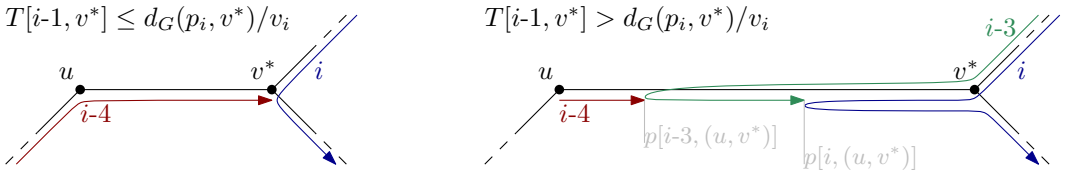

Figure 2 Examples for cases a) and b): (left) Agent i picks up the package at node v^*. (right) Agent i picks up the package inside the edge (u, v^*) at the earliest possible time.

increase the delivery time $\mathcal{T}$, as $v_{i-1} < v_i$ (we only increase velocities along the trajectory). However, $\mathcal{T}$ might remain constant if this increase in velocity is countered by a longer waiting time of the package at the handover to agent $i + 1$.

(iii) Assume that multiple agents bring the package from u to v over the edge $\{u, v\}$, by visiting u first. By assumption (i) the last such agent i has the highest velocity and thus agent i can just as well pick up the package at u without the help of the other agents. ◀

▶ **Corollary 3.** *After a preprocessing step of time $\mathcal{O}(k + |V|)$ – in which we remove in each node all but the agent with maximum velocity v_i – we may assume that $k \leq |V|$.*

Towards a dynamic program. Making use of characterization (i) of Lemma 2, we relabel the agents such that $v_1 \leq v_2 \leq \ldots \leq v_k$. We can then look at subproblems where we only use the first $i - 1$ among all k agents. Assume node v^* is the first node that the new agent i (starting at p_i) passes while actually carrying the package. According to characterizations (ii) and (iii), when defining the recursion, we have to take care of these two cases, see Figure 2:

a) Agent i might arrive at node v^* 'late', the package has already been dropped off there before by one of the agents $1, 2, \ldots, i - 1$ and had been waiting.

b) Agent i might arrive at node v^* 'early', in which case it should walk towards the package to receive it earlier and bring it back to v^* faster (having larger velocity than the currently carrying agent, after all). In this case, agent i picks up the package at a point p which is strictly in the interior of the edge $\{u, v^*\}$ and which is as close to node v^* as possible, i.e., p must be reachable by both agent i *and* the package – carried by only the first $i - 1$ agents – at the *earliest* possible time: $(d(p_i, v^*) + d(v^*, p))/v_i$.

Dynamic Program. First we are interested in the distance between any two nodes in the graph, which we can find with an *all-pair-shortest-paths* algorithm APSP. We denote the time needed for this precomputation by $\mathcal{O}(\text{APSP})$. Then, given the agents in ascending order of their velocities v_i, for each prefix $1, 2, \ldots i$ of the agent order and each node v we define the following subproblem:

$$
\begin{aligned}
S\,[i, v] &= \text{A fastest schedule to bring the package to node } v \text{ using agents } \{1, \ldots, i\}.\\
\mathcal{T}\,[i, v] &= \text{The time needed in } S\,[i, v] \text{ to deliver the package to } v.\\
A\,[i, v] &= \text{Index of the last agent to carry the package in } S\,[i, v].\\
p\,[i, (u, v)] &= \text{The pick-up point } p \text{ strictly inside edge } \{u, v\} \text{ and closest to } v, \text{ reachable}\\
&\quad \text{by } \textit{both} \text{ the package (coming from } u, \text{ delivered by agents } 1, \ldots, i-1)\\
&\quad \textit{and} \text{ agent } i \text{ (coming via } v) \text{ in time } (d(p_i, v) + d(v, p))/v_i \text{ (if applicable).}
\end{aligned}
$$

Note that although our graph only has undirected edges, $p[i, (u, v)]$ considers an *ordered* tuple of nodes (u, v), denoting that the package is transported from u to v. Thus $p[i, (v, u)]$

has the analogous meaning of the package crossing edge $\{u, v\}$ from v towards u. Both $p[i, (u, v)]$ and $p[i, (v, u)]$ might be undefined, as can be seen below.

We compute the optimum delivery times $\mathcal{T}[i, v]$ (together with $A[i, v]$) without explicitly maintaining the schedules $S[i, v]$. A concrete final schedule S can then be retraced from $A[,]$, see Theorem 4. For computing $\mathcal{T}[i, v]$ and $A[i, v]$ we 'guess' the first node v^* of cases a) and b) above by trying each node v as a candidate. We then can compute $\mathcal{T}[i, v]$ and $A[i, v]$ for all other nodes using the pre-computed distances between all pair of nodes:

1. *Initialization:* For all nodes v, we initialize $S[i, v] := S[i-1, v], A[i, v] := A[i-1, v]$ and $\mathcal{T}[i, v] := \mathcal{T}[i-1, v]$. This automatically takes care of case a), where the package arrives at v before agent i can reach v.
2. *In-edge pick-ups:* We go over all node pairs (u, v) such that $\{u, v\} \in E$ and check whether agent i can pick up the package inside $\{u, v\}$ to advance it to node v faster than in schedule $S[i-1, v]$. We do so by checking whether we have $d(p_i, v)/v_i < \mathcal{T}[i-1, v]$ *and* $d(p_i, u)/v_i > \mathcal{T}[i-1, u]$. In this case, agent i receives the package from a previous agent j that brought it from u or from $p[j, (u, v)]$. Thus we get a set P of candidates for $p[i, (u, v)] := \arg\min_{p \in P} \{d(p, v)\}$. The candidate set P consists of all points p strictly inside the edge $\{u, v\}$ such that there exists an agent of index j, $A[i-1, u] \leq j < i$, for which we have

$$\max\left\{\mathcal{T}[i-1, u], \frac{d(p_j, u)}{v_j}\right\} + \frac{d(u, p)}{v_j} = \frac{d(p_i, v) \ + \ d(v, p)}{v_i}$$

   if j is coming from u, *or* – if $p[j, (u, v)]$ is defined –

$$\frac{d(p_j, v) \ + \ d(v, p[j, (u, v)]) \ + \ d(p[j, (u, v)], p)}{v_j} = \frac{d(p_i, v) \ + \ d(v, p)}{v_i}.$$

   Having computed $p[i, (u, v)]$ as the point in P closest to v, we update node v accordingly: Set $\mathcal{T}[i, v] := \min\left\{\mathcal{T}[i, v], \frac{d(p_i, v) + 2d(p[i,(u,v)], v)}{v_i}\right\}$, where using 'min' takes care of cases in which we have multiple incident edges to v that all potentially have in-edge pick-ups by i, and set $A[i, v] = i$ (valid since we consider the case where $d(p_i, v) < \mathcal{T}[i-1, v]$).
3. *Updates:* So far we have computed the subproblems $S[i, v]$ correctly, if node v corresponds to the first node v^* of cases a) and b) (in particular we checked whether the faster agent i can help to advance the package over only one edge). Now we also consider all cases where agent i transports the package over arbitrary distances, by updating all other schedules $S[i, u]$ accordingly: For each node v, for each node u, if $\mathcal{T}[i, u] > \max\{\mathcal{T}[i, v], d(p_i, v)/v_i\} + d(v, u)/v_i$ we set $A[i, u] := i$ and $\mathcal{T}[i, u] := \max\{\mathcal{T}[i, v], d(p_i, v)/v_i\} + d(v, u)/v_i$.

▶ **Theorem 4.** *An optimum schedule for* FastDelivery *of a single package can be computed in time* $\mathcal{O}(k^2|E| + k|V|^2 + \text{APSP}) \subseteq \mathcal{O}(k^2n^2 + n^3)$.

Proof. For each i from 1 to k we can compute all values $A[i, v]$, $\mathcal{T}[i, v]$ in time $\mathcal{O}(|V|)$ for the initialization, $\mathcal{O}(|E|k)$ to check for in-edge pick-ups and $\mathcal{O}(|V|^2)$ for the updates (for which we need precomputed all-pair shortest paths). Overall we get a running time of $\mathcal{O}(\text{APSP} + k^2|E| + k|V|^2)$. The delivery time is then given in $\mathcal{T}[k, t]$. Correctness of the algorithm follows from the definition of the subproblems and the case distinction stemming from Lemma 2. Since we did not explicitly maintain the schedules $S[i, v]$, we retrace the concrete schedule S from $A[,]$ by backtracking: Let i denote the last used agent $A[k, t]$. We can find i's 'first node' v^* in time $\mathcal{O}(|V|)$ by searching for the smallest value $\mathcal{T}[i, u]$ such that

$$\max\{\mathcal{T}[i, u], d(p_i, u)/v_i\} = \mathcal{T}[k, t] - d(u, t)/v_i.$$

If $A[i, v^*] \neq i$, we recurse, otherwise we find the correct adjacent node and all in-edge handovers by looking – for each of the $\mathcal{O}(\deg(v^*))$ many neighbors u of v^* – at the overall $\mathcal{O}(k \deg(v^*))$ many values $p[j, (u, v^*)]$ (where $j \leq i$) and $\mathcal{T}[j, u]$ (where $j < i$). ◀

4 Prioritizing delivery time over energy consumption

In this Section, we want to find the most efficient among all fastest delivery schedules. We call this problem FastEfficientDelivery and will first show that it can be solved in polynomial time for uniform velocities ($\forall i, j \colon v_i = v_j$), due to a characterization of optimum schedules. In contrast, we prove NP-hardness for arbitrary speeds, even on planar graphs. However, for paths we show how one can subdivide general instances into phases of concecutive agents having the same velocity, and achieve an efficient $\mathcal{O}(n + k \log k)$-time algorithm.

4.1 A polynomial-time algorithm for uniform velocities

▶ **Lemma 5.** *Consider* FastEfficientDelivery *on instances with uniform agent velocities and let δ denote the offset of the closest agent's starting position to s. Then there exists an optimum schedule such that the pick-up position q_i^+ of each involved agent i satisfies:*

- $d(s, q_i^+) + d(q_i^+, t) = d(s, t)$*, i.e., q_i^+ lies on a shortest s-t-path, and*
- $d(p_i, q_i^+) \leq \delta + d(s, q_i^+)$*, with equality if q_i^+ lies strictly inside an edge.*

Proof. Since all agents have the same velocity $\overline{v}$, any fastest delivery of the package must follow a shortest path from s to t. Furthermore, since the closest agent could deliver the package on its own in time $(\delta + d(s, t))/\overline{v}$, each involved agent i has to arrive at q_i^+ no later than the package itself, giving $d(p_i, q_i^+) \leq \delta + d(s, q_i^+)$. It remains to show that we can modify every optimum solution into an optimum solution in which we have $d(p_i, q_i^+) = \delta + d(s, q_i^+)$ whenever q_i^+ lies strictly inside an edge $e = \{u, v\}$. Denote by i the first agent for which this is not the case and by $i - 1$ its preceding agent. Assume that the package enters e via u (i.e. $d(s, u) < d(s, v)$). Note that i must have entered e via v, since otherwise the energy consumption could be improved by letting i pick up the package already at u (without increasing the delivery time), contradicting the optimality of our solution. Now we distinguish two cases relating the weights ω_i and ω_{i-1}, yielding either a decrease of the energy consumption, or a possibility to move q_i^+ to a position satisfying the characterization.

- $2\omega_i > \omega_{i-1}$: Moving q_i^+ by $\epsilon > 0$ towards v decreases $\mathcal{E}$ by an amount of $(2\omega_i - \omega_{i-1}) \cdot \epsilon > 0$.
- $2\omega_i \leq \omega_{i-1}$: We move q_i^+ towards u (without increasing neither delivery time nor energy consumption) until we reach $q_i^+ = u$, or q_i^+ inside the edge $\{u, v\}$ such that $d(p_i, q_i^+) = \delta + d(s, q_i^+)$, or $q_i^+ = q_{i-1}^+$. In the last case, discarding agent $i - 1$ from our solution results in an energy consumption decrease of at least $\omega_{i-1} \cdot d(p_{i-1}, q_{i-1}^+) > 0$. ◀

Polynomial-time algorithm. We use the characterization in Lemma 5 to find an optimum solution for FastEfficientDelivery of delivery time $\mathcal{T} = (\delta + d(s, t))/\overline{v}$: For each agent i, we compute the set Q_i of all potential pick-up locations, i.e., the set of points q_i that satisfy Lemma 5. The number of potential locations is $|Q_i| \in \mathcal{O}(|V| + |E|) \subseteq \mathcal{O}(n^2)$. Then we build an auxiliary directed acyclic multi-graph H on a node set $V(H) = \bigcup_{i=1}^{k} Q_i$, of size $|V(H)| \in \mathcal{O}(|V| + k|E|) \subseteq \mathcal{O}(kn^2)$. Each directed edge in $E(H)$ describes how agent i can contribute to the delivery by bringing the package from its starting position q_i to another agent's starting position q_j along a shortest s-t-path: For each pair of nodes $q_i \in Q_i$ and $q_j \in V(H)$ such that $q_i \neq q_j$ and $d(s, q_i) + d(q_i, q_j) + d(q_j, t) = d(s, t)$, we add an arc (q_i, q_j) of

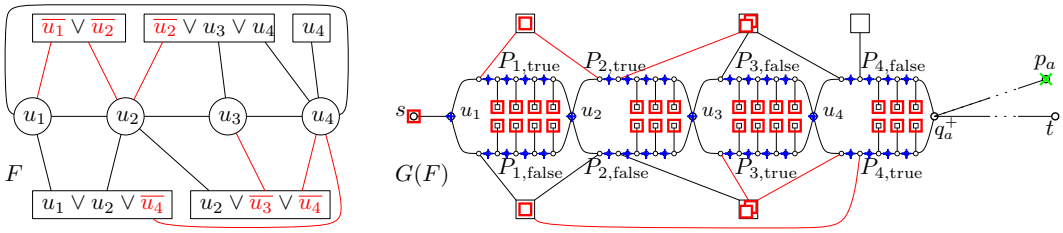

Figure 3 (left) A planar 3CNF formula F, satisfiable by $(u_1, u_2, u_3, u_4) = (\text{true}, \text{false}, \text{false}, \text{true})$. (right) Its transformation into a corresponding delivery graph $G(F)$. The satisfiable assignment of F corresponds to a low-cost delivery in $G(F)$ via paths $P_{1,\text{true}}, P_{2,\text{false}}, P_{3,\text{false}}, P_{4,\text{true}}$, and vice versa. We have slow agents for clauses (□), fast agents for variables/literals (+) and a very fast agent (×).

weight $\omega_i \cdot (d(p_i, q_i) + d(q_i, q_j))$ to $E(H)$. Overall, we have at most $|E(H)| \in \mathcal{O}(k \cdot n^2 \cdot kn^2)$ many arcs. By construction of H, running Dijkstra's shortest path algorithm on the multi-graph H finds a shortest path from s to t corresponding to an optimal solution.

▶ **Theorem 6.** *An optimum solution for* FastEfficientDelivery *can be found in time* $\mathcal{O}(k^2 n^4)$*, assuming all agents have the same velocity.*

4.2 NP-hardness on planar graphs

Contrary to FastDelivery (where we had non-decreasing velocities v_i), when prioritizing delivery time *but still regarding energy consumption*, we can't characterize the order of the agents by their coefficients (v_i, ω_i): Consider an instance in which both the starting position p_a of the absolutely fastest agent a as well as the package destination t are separated from the rest of the graph by two very long edges q_a^+—p_a, q_a^+—t. Then in *every* fastest solution, agent a (with v_a large, e.g. 8) must deliver the package from q_a^+ to t, see Figure 3 (right).

In FastEfficientDelivery, the task is thus to balance slow but efficient agents (with, e.g., $v = 1, \omega = 0$) and fast inefficient agents (with, e.g., $v = 2, \omega = 1$) to collectively deliver the package to a's pick-up location q_a^+ *just-in-time* – i.e., in time $d(p_a, q_a^+)/v_a$ – *without using too much energy*. We can construct suitable instances by a reduction from Planar3SAT [23] *(Sketch)*: Starting from a planar formula F in three-conjunctive normal form, as in Figure 3 (left), we build a delivery graph $G(F)$. This can be done such that the instance is guaranteed to have schedules with minimum delivery time, i.e. with $\mathcal{T} = d(p_a, t)/v_a$. However, there should only be such a minimum-time schedule which simultaneously has low energy consumption $\mathcal{E}$ *if and only if* the formula F has a satisfiable variable assignment.

To this end, we place the fast agents on nodes corresponding to variables and literals. Intuitively, these agents decide on the routing of the package, thus setting the assignment of each variable. The slow agents, on the other hand, are placed on clause nodes, each clause receiving just one agent short of the number of its literals. Intuitively, for a just-in-time delivery to q_a^+ with small energy consumption, each clause has to spend one of its agents for each of its unsatisfied literals. By construction, this is only possible if each clause is satisfied:

▶ **Theorem 7.** FastEfficientDelivery *is* NP*-hard, even on planar graphs.*

4.3 An efficient algorithm for paths

The preceding hardness result raises the question for which restricted graph classes we can expect an efficient algorithm for arbitrary velocity instances. To contribute to this question it is natural to study paths – on paths, the V-shaped p_a—q_a—t component attached to the

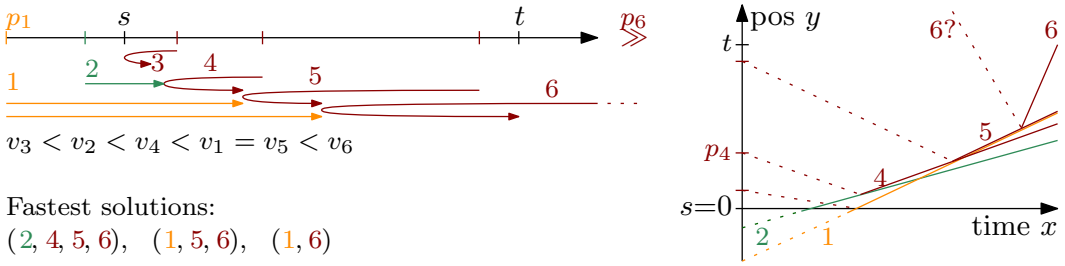

Figure 4 (left) Possible optima: If agent 4 is involved, it must take over the package from agent 2, since agent 3 is too slow. Using agents 2 and 4 to bring the package to agent 5's pick-up position takes the same time as using agent 1 on its own. Agents 1 and 5 have the same velocity, so in terms of delivery time we could use either or even both of them, but agent 1 only if agents 2 and 4 are both not used (otherwise they all consume energy). (right) Fastest solutions correspond to at most 1 agent with $p_i < s$ and a number of agents corresponding to a suffix of the upper envelope.

rest of the graph, as used in the hardness proof, 'collapses' to a line. We show that this allows us to decompose the problem into linearly many uniform velocity instances in time $\mathcal{O}(n + k \log k)$. Theorem 6 then implies that FastEfficientDelivery can be solved in polynomial-time. Improving on this by a careful analysis of paths, we show how to solve each uniform velocity instance in time $\mathcal{O}(n + k \log k)$ as well, and that these instances can be combined in time $\mathcal{O}(k)$, giving an overall $\mathcal{O}(n + k \log k)$-time algorithm.

Decomposition into uniform velocity instances

In the following, we look at the path graph G as the real line, and assume (after performing a depth-first search from s and ordering the starting positions in time $\mathcal{O}(n + k \log k)$) without loss of generality that $s = 0 < t$, that $p_1 \leq p_2 \leq \ldots \leq p_k$ and that $n = k + 2$, as the only relevant nodes on the line are s, t and the starting positions p_i. Note that in an optimum solution of FastEfficientDelivery, no agent i will ever take over the package from another agent j which i overtakes from the left. In particular, this means that we will need at most one agent with starting position $p_i < s$, and that after the package is picked up at s, it will never have to wait between a drop-off by an agent j and a pick-up by the next agent i, since j could continue carrying the package towards i, thus decreasing the overall delivery time. Hence in an optimum schedule we also have for consecutive agents i, j with $s < p_j < p_i$, that $v_j \leq v_i$ (otherwise we can discard i, by this decreasing the delivery time).

Decomposition. Assume that agent i is the agent that delivers the package to t. We represent the trajectory of the package while being carried by i as a ray giving the position y on the real line as a function $f_i(x)$ of the time x passed so far, see Figure 4 (right). We now inductively compute a set containing all functions $f_0, f_1, \ldots, f_k$, where $f_0(x) = s = 0$.

If we have $p_i < 0$, then by the reasoning above, i is the only involved agent, and the function is simply $f_i \colon y = v_i \cdot x + p_i$. For $p_i > s$, the slope v_i of the ray is set, but not its pick-up position. In order to minimize the earliest possible delivery time x (i.e. $f_i(x) = t$), by the non-decreasing velocity property i must pick up the package as early as possible – e.g. in Figure 4 (left), the fastest agent 6 would not get the package from agent 4, but from agent 5 who is able to speed up the transport between agents 4 and 6, thus advancing the last handover position and allowing agent 6 to pick up the package earlier.

Formally, the pick-up position is given by the time-wise first (or in other words leftmost) intersection of a query line $y = p_i - v_i \cdot x$ (modelling the agent moving towards s) with any preceding ray $f_0, \ldots, f_{i-1}$. Let $q_i := (x_i, y_i)$ denote the intersection point of the query

line with the upper envelope of the preceding rays, and denote by f_j a ray of steepest slope v_j among all rays $f_0, \ldots, f_{i-1}$ that contain q_i – e.g. the query line "6?" in Figure 4 (right) intersects both f_1 and f_5 on the upper envelope, and since both have the same slope, we can consider either.

In case $v_j > v_i$, agent i will not be used in an optimal schedule and we set $f_i = 0$. If, however, $v_j \leq v_i$, then f_i is given by the line equality $f_i \colon y = v_i \cdot x + (y_i - v_i \cdot x_i)$. After completion, an optimum schedule corresponds to a path along the rays of our diagram from $(0, 0)$ to the ray reaching $y = t$ at the earliest possible time.

Fast computation and recombination. To quickly compute the equation of each ray f_i, we need to find the intersection of a query line with the upper envelope of $\mathcal{O}(k)$ many rays. Precomputing this envelope as an ordered list of its segments would allow us to speed up the intersection queries from a linear to a binary search (*convex hull trick for dynamic programming* [21]). However, the set of functions that we query here is not known up front. Instead, we apply the classic geometric point-line duality [18]. In this dual setting, the task of finding the leftmost intersection point of a query line with a set of lines turns into finding a right tangent from a query point (the dual of the query line) onto the convex hull of a point set (the dual of the rays f_i). The dynamic planar convex hull data structure by Brodal and Jacob [4, 22] allows point insertions and tangent queries all in $\mathcal{O}(\log k)$ amortized time, giving an overall running time of $\mathcal{O}(k \log k)$. Assuming that we know the optimum schedule for each of the uniform velocity intervals, it remains to recombine these subschedules:

▶ **Lemma 8.** *Arbitrary velocity instances of* FastEfficientDelivery *on paths can be decomposed into and recombined from uniform velocity instances in time* $\mathcal{O}(n + k \log k)$.

A fast algorithm for uniform velocity instances on the line

We are left to solve the case where all agents have the same uniform velocity $\overline{v}$. As before, we denote by δ the offset of the closest agent's starting position to s, and let a denote the corresponding agent. No agent i with $p_i < s$ other than maybe agent a is involved in an optimum schedule (all others would only slow down delivery). Also note that if $p_a < s$, the setting is equivalent to one where a starts at $s + (s - p_a)$, so we can assume (after relabelling the agents) $a = 1$, $\delta = p_1$. This also implies $\mathcal{T} = (\delta + (t - s))/\overline{v}$ and we can ignore agents i that are dominated by earlier, cheaper agents j with $p_j < p_i$ and $\omega_j < \omega_i$.

Towards a dynamic program. We define the point q_i as the leftmost point on the line where agent i can pick up the package without causing a delay, i.e., we have $q_i := \frac{p_i + s - \delta}{2}$ since $p_i - q_i = \delta + (q_i - s)$. Note that $q_1 = s$ and $q_j < q_i$ for $j < i$. Similarly as – but more specific than – in the characterization of uniform instances on general graphs (Lemma 5) we get a limited set of possible pick-up locations:

▶ **Lemma 9.** *There is an optimum solution where each agent i that is involved in advancing the package picks it up at $q_i^+ = q_i$ or at $q_i^+ = p_i$.*

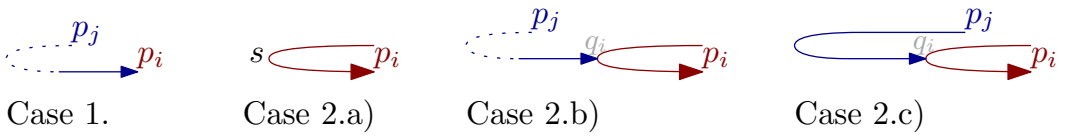

Figure 5 Case distinction in the dynamic program for FastEfficientDelivery on the line. Either agent i is not involved at all, does all on its own or is subsequent to some agent j, where we distinguish between $p_j \leq q_i$ and $p_j > q_i$.

Dynamic program. Lemma 9 suggests that in an inductive approach from left to right it suffices to consider only finitely many handover options. We define the following subproblems:

$$\begin{aligned} S[i] &= \text{An energy-optimal schedule to deliver the package to } p_i \\ &\quad \text{in time } (\delta + (p_i - s))/\overline{v}, \text{ using only the agents } \{1, 2, \ldots, i\}. \\ \mathcal{E}[i] &= \text{Energy consumption of } S[i]. \\ A[i] &= \text{Index of the last package-carrying agent in } S[i]. \\ A'[i] &= \text{Index of the second to last carrying agent in } S[i] \text{ (if any)}. \end{aligned}$$

We will argue how to compute the optimum energy costs $\mathcal{E}[i]$ (and with it $A[i]$ and $A'[i]$) without explicitly maintaining the schedules $S[i]$ ($S[i]$ can later be retraced from $A[i]$ and $A'[i]$). For computing $\mathcal{E}[i]$, $A[i]$ and $A'[i]$, we distinguish four cases (also shown in Figure 5):

1. Agent i is not involved in $S[i]$.
2. Agent i is involved in $S[i]$. Hence by Lemma 9, agent i has pick-up location $q_i^+ = q_i$; and we get the following three variations:
   a. $i = 1$ and agent 1 picks up the package at s itself.
   b. Agent i picks up the package from some other agent j with $p_j \leq q_i$.
   c. Agent i picks up the package from some other agent j with $p_j > q_i$.

In cases 1, 2b) and 2c), we can determine $\mathcal{E}[i]$ in constant time using a single prior entry of the dynamic programming table:

Case 1. If i is not involved in $S[i]$, the best choice for the agent who transports the package to p_i is agent $i-1$, as it is the cheapest one on the last segment $[p_{i-1}, p_i]$ and we have $\mathcal{E}[i-1] \leq \mathcal{E}[j] + (p_{i-1} - p_j) \cdot \omega_j$ for all $j < i-1$ by induction. Hence we can optimize in constant time:

$$\mathcal{E}[i] = \min_{j<i}\{\mathcal{E}[j] + (p_i - p_j) \cdot \omega_j\} = \mathcal{E}[i-1] + (p_i - p_{i-1}) \cdot \omega_{i-1},$$
$$A[i] = i - 1 \text{ and } A'[i] = A[i-1].$$

Case 2.a) This is the base case where the first agent is on its own:

$$\mathcal{E}[1] = 2 \cdot |p_1 - s| \cdot \omega_1 = 2 \cdot \delta \cdot \omega_1, \quad A[1] = \text{none}, \ A'[1] = \text{none}.$$

Case 2.b) If agent i is involved in $S[i]$ and takes over at q_i from an agent j with $p_j \leq q_i$, we want j to minimize $\mathcal{E}[j] + (q_i - p_j) \cdot \omega_j$, the cost of bringing the package to q_i. Now let $i' = \max\{j \mid p_j \leq q_i\}$ be the agent starting closest to the left of q_i. As in Case 1, we argue that i' is the optimum choice for j, as it minimizes the cost on $[p_{i'}, q_i]$ and does not constrain the schedule up to $p_{i'}$ further. Hence, we again get in amortized constant time, i.e., we update i' by incrementing it lazily when going from i to $i+1$:

$$\mathcal{E}[i] = \mathcal{E}[i'] + (q_i - p_{i'}) \cdot \omega_{i'} + 2 \cdot (p_i - q_i) \cdot \omega_i, \quad A[i] = i, \ A'[i] = i'.$$

The most interesting case is the remaining case (2.*c*), where the agent j handing over to i starts in between q_i and p_i. Where can we look up the energy consumption c of an optimum schedule that ends with j bringing the package q_i – the dynamic program being only defined for points p_j? For some j, we might have $A[j] = j$, so $S[j]$ ends by j walking to q_j and back. In that case, we can exploit $q_j < q_i$ and use $\mathcal{E}[j] - (p_j - q_i) \cdot \omega_j$ as a candidate for the energy consumption c. But what if $A[j] \neq j$? As we saw, this implies $A[j] = j - 1$, but in that case we cannot just subtract $(p_j - q_i)\omega_j$: We do not know how $S[j]$ looks like between q_i and p_j. We argue that we do not need to consider these agents j as candidates at all!

▶ **Lemma 10.** *If in some optimal schedule $S[i]$ the agent j preceding i is of type 2.c), then in the schedule $S[j]$ we have $A[j] = j$.*

Proof. Under the assumption of Case 2.c), the cost of agent i is fixed to $2 \cdot (p_i - q_i) \cdot \omega_i$. Agents 1 to $i - 1$ will collaborate in the most efficient way to bring the package up to q_i. By definition of j, j is the last agent bringing the package to q_i. From the decreasing weight property, we know that none of the agents $j + 1$ to $i - 1$ were involved in $S[i]$. So if we take the partial schedule of $S[i]$ up to q_i and extend it by letting j bring the package to p_j, we obtain a feasible candidate schedule S' for $S[j]$ as none of the agents $j + 1$ to i are involved. We now argue that S' is an optimum schedule for $S[j]$. The segment $[q_i, p_j]$ is covered with the minimum possible energy, as j is the *unique* most efficient agent available for $S[j]$. The segment $[s, q_i]$ is also covered cheapest possible as its part of $S[i]$ was optimized over all agents 1 to i, so a superset of the agents available for $S[j]$. Moreover, the uniqueness implies that *all* optimum schedules for $S[j]$ need to end with agent j on $[q_i, p_j]$, hence $A[j] = j$. ◀

Case 2.c) Lemma 10 leaves us with only those agents j whose schedules $S[j]$ we understand sufficiently to modify them into candidates for $S[i]$ under Case 2.c):

$$\mathcal{E}[i] = \min_j \{\mathcal{E}[j] - (p_j - q_i)\omega_j \mid q_i < p_j < p_i \wedge A[j] = j\} + 2(p_i - q_i)\omega_i,$$
$$A[i] = i, \quad A'[i] = \arg\min_j \{\mathcal{E}[j] - (p_j - q_i)\omega_j \mid q_i < p_j < p_i \wedge A[j] = j\}.$$

We can now take $\mathcal{E}[i]$ as the minimum over the four cases 1–2.c) and compute all schedules $S[i]$ by proceeding over all subproblems in increasing order, giving us the energy-optimal schedules for delivering the package to the points p_i in time $(\delta + (p_i - s))/\overline{v}$. How can we use the solutions to the subproblems $\mathcal{E}[i]$ to find the energy $\mathcal{E}$ of an energy-optimal schedule delivering the package to the target t in optimum time $(\delta + (t - s))/\overline{v}$? Let k' be the closest agent on the left of t, i.e., $k' := \arg\max_i p_i \leq t$. Clearly, if in an optimum schedule the package is delivered to t by an agent starting to the left of t, then by the decreasing weight property this agent must be agent k', giving us $\mathcal{E} = \mathcal{E}[k'] + (t - p_{k'}) \cdot \omega_k$.

Delivery to t and agents with $p_i > t$. It remains to take care of agents with starting positions $p_i > t$: As illustrated in Figure 6, multiple agents with $p_i > t$ might be involved in the most efficient delivery. Note that our dynamic programming problem $\mathcal{E}[i]$ is defined independent of t and so we can also easily compute $\mathcal{E}[i]$ for $p_i > t$. Agents i with $q_i > t$ are not useful, however, for a delivery to t, as they arrive in $[s, t]$ only after the package has been delivered. Similar to Lemma 10, we claim that among the remaining agents i only those with $A[i] = i$ need to be considered:

▶ **Lemma 11.** *If an agent i with $p_i > t$ is the last agent in any optimal schedule S from s to t, then $A[i] = i$.*

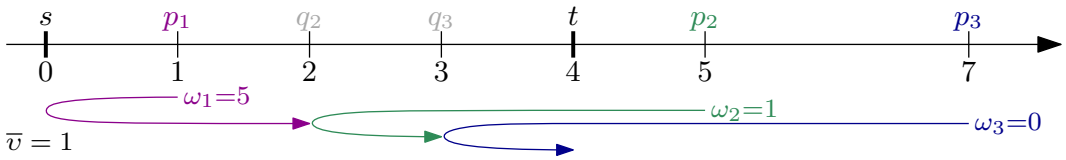

Figure 6 An example, where the only optimum schedule uses both agents on the right of t. The optimum schedule has delivery time $\mathcal{T} = (p_1 + t - s)/\overline{v} = 5/1 = 5$ and energy consumption $\mathcal{E} = p_1 \cdot \omega_1 + (p_2 - q_2 + q_3 - q_2) \cdot \omega_2 + (p_3 - q_3 + t - q_3) \cdot \omega_3 = 3 \cdot 5 + 4 \cdot 1 + 5 \cdot 0 = 19$.

Proof. We have $q_i < t < p_i$. By the decreasing weight property, no agent $j > i$ will be used in S. We extend S to a schedule S' by letting agent i walk from t to p_i. Then S' is a candidate for $S[i]$. Similar to Lemma 10, S' consists of an optimal solution for $[s, t]$ and the strictly cheapest agent on $[t, p_i]$ and hence S' is optimal for $S[i]$ and all optimum schedules for $S[i]$ have $A[i] = i$. The optimum s-t-delivery is thus given by:

$$\mathcal{E} = \min_j \{\mathcal{E}[j] - (p_j - t)\omega_j \mid (q_j < t < p_j \text{ and } A[j] = j) \text{ or } j = k'\},$$

which takes linear time once at the very end. ◀

Details of the dynamic program. The computational bottleneck of our dynamic program is (for each subproblem $\mathcal{E}[i]$) the minimization over the set of options in Case 2.c). Each option evaluates a linear function $f_j(q_i) := \omega_j \cdot q_i + (\mathcal{E}[j] - p_j \cdot \omega_j)$ at position q_i, which can be seen as a lower envelope intersection query. Similarly to before, we use point-line duality and a dynamic convex hull data structure to avoid considering all agents explicitly as predecessors and instead quickly search the best one.

▶ **Lemma 12.** *An optimum schedule for* FastEfficientDelivery *with uniform velocity* $\overline{v}$ *on the line can be computed in* $\mathcal{O}(n + k \log k)$ *time.*

Combining this with Lemma 8 gives the full solution on paths. Note that strictly speaking, in the uniform velocity instances, the package is not available at s at time zero, but is brought there by agents of preceding instances at exactly the time when the first agent can reach it.

▶ **Theorem 13.** *An optimum solution for* FastEfficientDelivery *on paths can be computed in* $\mathcal{O}(n + k \log k)$ *time.*

5 Optimizing convex combinations of objectives

In this section, we look at a convex combination of the two objectives: minimizing both the delivery time $\mathcal{T}$ and the energy consumption $\mathcal{E}$ by minimizing the term $\epsilon \cdot \mathcal{T} + (1 - \epsilon) \cdot \mathcal{E}$, for a given value ϵ, $0 < \epsilon < 1$. We call the problem of minimizing this combined objective CombinedDelivery. As an application of the NP-hardness proof for FastEfficient-Delivery, we get NP-hardness of CombinedDelivery as well: The main idea is to counter small values of ϵ by scaling the weights of the agents by a small factor $\delta(\epsilon)$, thus decreasing the importance of $\mathcal{E}$ alongside $\mathcal{T}$ as well.

▶ **Theorem 14.** CombinedDelivery *is* NP*-hard for all* $\epsilon \in (0, 1)$*, even on planar graphs.*

A 2-approximation for CombinedDelivery using a single agent

Recall that for FastDelivery, the agents involved in an optimum delivery were characterized by increasing velocities v_i, while for FastEfficientDelivery on path graphs, the agents of an optimum solution were characterized by decreasing tuples (v_i^{-1}, ω_i).

Although it is *not* possible to characterize the *order* of the agents in an optimum CombinedDelivery schedule by their velocities and weights alone, we can at least characterize the position of a *minimal* agent, leading to a 2-approximation using a single agent:

▶ **Lemma 15.** *Let without loss of generality $1, 2, \ldots, i$ denote the indices of all involved agents appearing in that order in an optimum* CombinedDelivery *schedule. Then the last agent i is* minimal *in the following sense: $i \in \arg\min_j \left\{\epsilon \cdot v_j^{-1} + (1-\epsilon) \cdot \omega_j\right\}$.*

Proof. Recall that we denote by d_j the total distance travelled by agent j and by d_j^* the distance travelled by agent j while carrying the package. Thus agent j contributes at least $\epsilon \cdot d_j^* \cdot v_j^{-1} + (1-\epsilon) \cdot (d_j \cdot \omega_j) \geq d_j^* \cdot \left(\epsilon v_j^{-1} + (1-\epsilon)\omega_j\right)$ towards $\epsilon\mathcal{T} + (1-\epsilon)\mathcal{E}$. Assume for the sake of contradiction that the minimum value $\epsilon v_j^{-1} + (1-\epsilon)\omega_j$ is not obtained by agent i but by an agent $m < i$. Then we can replace the agents $m+1, \ldots, i$ by agent m, resulting in a decrease in the objective function of at least

$$\begin{aligned}
&\sum_{j=m}^{i} \epsilon d_j^* v_j^{-1} + (1-\epsilon) d_j \omega_j - \sum_{j=m}^{i} d_j^* \left(\epsilon v_m^{-1} + (1-\epsilon)\omega_m\right) \\
&\geq \sum_{j=m}^{i} d_j^* \left(\epsilon v_j^{-1} + (1-\epsilon)\omega_j\right) - \sum_{j=m}^{i} d_j^* \left(\epsilon v_m^{-1} + (1-\epsilon)\omega_m\right) \\
&\geq d_i^* \left(\epsilon v_i^{-1} + (1-\epsilon)\omega_i\right) - d_i^* \left(\epsilon v_m^{-1} + (1-\epsilon)\omega_m\right) > 0,
\end{aligned}$$

contradicting the minimality of the optimum CombinedDelivery schedule. ◀

▶ **Theorem 16.** *There is a 2-approximation for* CombinedDelivery *which uses only a single agent (and thus can be found in polynomial time).*

Proof. Note that agent i contributes at most $\epsilon d_i v_i^{-1} + (1-\epsilon) d_i \omega_i$ towards $\epsilon\mathcal{T} + (1-\epsilon)\mathcal{E}$. Starting from an optimum CombinedDelivery schedule we can replace all agents $1, \ldots, i-1$ along their trajectories by the minimal agent i. This prolongs the travel distance of agent i by $2 \cdot \sum_{j=1}^{i-1} d_j^*$. Overall, we increase the objective function by at most

$$\begin{aligned}
&2\sum_{j=1}^{i-1} d_j^* \left(\epsilon v_i^{-1} + (1-\epsilon)\omega_i\right) - \sum_{j=1}^{i-1} d_j^* \left(\epsilon v_j^{-1} + (1-\epsilon)\omega_j\right) \leq \sum_{j=1}^{i-1} d_j^* \left(\epsilon v_i^{-1} + (1-\epsilon)\omega_i\right) \\
&\leq \sum_{j=1}^{i-1} d_j^* \left(\epsilon v_j^{-1} + (1-\epsilon)\omega_j\right) < \sum_{j=1}^{i} d_j^* \left(\epsilon v_j^{-1} + (1-\epsilon)\omega_j\right) \leq \epsilon\mathcal{T} + (1-\epsilon)\mathcal{E}.
\end{aligned}$$

Hence only using agent i to deliver the package is a 2-approximation for CombinedDelivery. We get a polynomial-time approximation algorithm with approximation ratio 2 by choosing among all k agents the one with minimum value $\left(\epsilon v_j^{-1} + (1-\epsilon)\omega_j\right) \cdot (d(p_j, s) + d(s, t))$. ◀

6 Discussion

Our techniques and results extend to a variety of delivery problems and model generalizations. A key ingredient here is that the order of our dynamic programming subproblems depends only on the parameters the agent has *while carrying the package*. Hence it is possible to, e.g.,

incorporate 2-speed agent models (modeling different speeds [16] with/without carrying the package) or topographical features (modeling edge traversals in uphill/downhill direction).

Furthermore, the 2-approximation given for CombinedDelivery is applicable to FastDelivery as well, and a relaxation of FastEfficientDelivery, in which one allows the optimum delivery time to be achieved with a constant-factor approximation of the energy consumption, stays NP-hard. It is unclear whether FastEfficientDelivery can be *solved efficiently on trees* or whether CombinedDelivery *allows a PTAS*. We consider these two problems the major open questions raised by this work.

Abstract

We give a direct polynomial-time reduction from parity games played over the configuration graphs of collapsible pushdown systems to safety games played over the same class of graphs. That a polynomial-time reduction would exist was known since both problems are complete for the same complexity class. Coming up with a direct reduction, however, has been an open problem. Our solution to the puzzle brings together a number of techniques for pushdown games and adds three new ones. This work contributes to a recent trend of liveness to safety reductions which allow the advanced state-of-the-art in safety checking to be used for more expressive specifications.

1 Introduction

Model-checking games ask whether there is a strategy (or implementation) of a system that can satisfy required properties against an adversary (or environment). They give a natural method for reasoning about systems wrt. popular specification logics such as LTL, CTL, and the μ-calculus. The simplest specifications are reachability or safety properties, where the system either needs to reach a given good state or avoid a bad state (such as a null-pointer dereference). The most expressive logic typically studied is the μ-calculus, which subsumes LTL, CTL, and CTL* [22]. One can reduce μ-calculus model checking in polynomial time to the analysis of parity games (op cit.) via a quite natural product of system and formula.

In the finite-state setting, while reachability and safety games can be solved in linear time and space, the best known algorithms for parity games are quasi-polynomial time [8] or quasi-linear space [18, 13]. For infinite-state games described by pushdown systems, or more generally, collapsible pushdown systems, the complexities match: EXPTIME-complete for solving reachability, safety [5, 32], and parity games [32] over pushdown systems, and n-EXPTIME-complete for order-n collapsible pushdown systems [11, 7, 24, 17].

Pushdown systems are an operational model for programs with (recursive) function calls. In such systems, a configuration has a control state from a finite set and a stack of characters from a finite alphabet (modeling the call stack). Collapsible pushdown systems [17] are an operational model for higher-order recursion as found in most languages (incl. Haskell, JavaScript, Python, C++, Java, ...). They have a nested stack-of-stacks (e.g. an order-2 stack is a stack of stacks) and *collapse links* which provide access to calling contexts.

Given that safety and parity games over collapsible pushdown systems are complete for the same complexity classes, the problems must be inter-reducible in polynomial-time. However, a direct (without a detour via Turing machines) polynomial-time reduction from parity to safety has been an open problem [14]. To see why the reduction is difficult to find, note that a safety game is lost based on a finite prefix of a play while determining the winner of a parity game requires access to the infinitely many elements of a play. Complexity theory tells us that this gap can be bridged by access to the stack, with only polynomial overhead.

Our contribution is such a polynomial-time reduction from parity to safety. From a theoretical standpoint, it explains the matching complexities despite the difference in expressible properties. From a practical standpoint, it may help building model-checking tools for μ-calculus specifications. Indeed, competitive and highly optimized tools exist for analysing reachability and safety properties of higher-order recursion schemes (HorSat [6, 31, 20] and Preface [28] being the current state-of-the-art), but implementing efficient tools for parity games remains a problem [15, 23]. Having the reduction at hand can allow the use of safety tools for checking parity conditions, suggest the transfer of techniques and optimizations from safety to parity, and inspire new algorithms for parity games. Still, a complexity-theoretic result should only be considered a first step towards practical developments.

Reductions from parity to safety have been explored for the finite-state case by Bernet et al. [1], and for pushdown systems by Fridman and Zimmermann [14]. We will refer to them as counter reductions, as they use counters to track the occurrences of odd ranks. These existing reductions are not polynomial. Berwanger and Doyen [2] showed that counter reductions can be made polynomial in the case of finite-state imperfect-information games.

Our solution to the puzzle brings together a number of techniques for pushdown games and contributes three new ones. We first show how to lift the existing counter reductions [1, 14] from first order to higher orders. For this we exploit a rank-awareness property of collapsible pushdown systems [17]. Secondly, we prove the correctness of this lifting by showing that it

commutes with a reduction from order-n to order-$(n-1)$ games [32, 17]. The polynomial-time reduction is then a compact encoding of the lifted counter reduction. It uses the ability of higher-order stacks to encode large numbers [7] and the insight that rank counters have a stack-like behavior, even in their compact encoding.

Much recent work verifies liveness properties via reductions to safety [25, 10, 26, 27, 12] or reachability [21, 4] with promising results. For finite-state generalized parity games, Sohail and Somenzi show that pre-processing via a safety property can reduce the state space that a full parity algorithm needs to explore, giving competitive synthesis results for LTL [30]. In the case of infinite-state systems (including pushdowns), reductions from liveness (but not parity games) have been explored by Biere et al. [3] and Schuppan and Biere [29].

2 Preliminaries

We define games over collapsible pushdown systems (CPDS). For a full introduction see [17]. CPDS are an operational model of functional programs that is equivalent to higher-order recursion schemes (HORS) [17]. Without collapse, they correspond to *safe* HORS [19].

In the following, let $\mathbb{N}$ be the set of natural numbers (including 0) and $[i, j]$ denote the set $\{i, i+1, \ldots, j\}$.

2.1 Higher-Order Collapsible Stacks

Higher-order stacks are a nested stack-of-stacks structure whose stack characters are annotated by collapse links that point to a position in the stack. Intuitively, this position is the context in which the character was created. We describe the purpose of collapse links after some basic definitions.

▶ **Definition 2.1** (Order-n Collapsible Stacks)**.** For $n \geq 1$, let Σ be a finite set of stack characters Σ together with a partition function[3] $\lambda : \Sigma \to [1, n]$. An *order-0 stack* with up-to order-n collapse links is an annotated character $a^i \in \Sigma \times \mathbb{N}$. An *order-$k$ stack* with up-to order-n collapse links is a non-empty sequence $w = [w_1 \ldots w_\ell]_k$ (with $\ell > 0$) such that each w_i is an order-$(k-1)$ stack with up-to order-n collapse links. By $Stacks_n$ we denote the set of order-n stacks with up-to order-n links.

In the sequel, we will refer to stacks in $Stacks_n$ as order-n stacks. By *order-k* stack we will mean an order-k stack with up-to order-n links, where n will be clear from the context.

Given an order-k stack with up-to order-n links $w = [w_1 \ldots w_\ell]_k$, we define below the operation $top_{k'}$ to return the topmost element of the topmost order-k' stack. Note that this element is of order-$(k'-1)$. The top of a stack appears leftmost. The operation bot^i_k removes all but the last i elements from the topmost order-k stack. It does not change the order of the stack and requires $i \in [1, \ell]$.

$$\begin{array}{rclcrcl} top_k(w) & = & w_1 & & bot^i_k(w) & = & [w_{\ell-i+1} \ldots w_\ell]_k \\ top_{k'}(w) & = & top_{k'}(w_1)\ (k' < k) & & bot^i_{k'}(w) & = & [bot^i_{k'}(w_1) w_2 \ldots w_\ell]_k\ (k' < k). \end{array}$$

For technical convenience, we will also define

$$top_{n+1}(w) = w$$

which, we note, does not extend to top_{n+2} or beyond.

[3] Readers familiar with CPDS may expect links to be pairs (k, i) and the alphabet Σ not to be partitioned by link order. The partition assumption is oft-used. It is always possible to tag each character with its link order using $\Sigma \times [1, n]$. Such a partition becomes crucial in Section 4.

The destination of a collapse link i on a with $\lambda(a) = k$ in a stack w is $bot^i_k(w)$, when defined. When $i = 0$, the link is considered *null*. We often omit irrelevant collapse links from characters to improve readability.

When u is a $(k-1)$-stack and $v = [v_1 \dots v_\ell]_n$ is an n-stack with $k \in [1, n]$, we define $u :_k v$ as the stack obtained by adding u on top of the topmost k-stack of v. Formally,

$$u :_k v = [uv_1 \dots v_\ell]_n \ (k = n) \qquad \text{and} \qquad u :_k v = [(u :_k v_1)v_2 \dots v_\ell]_n \ (k < n).$$

▶ **Example 2.2.** When $\lambda(a) = 3$ and $\lambda(b) = 2$ let $w = [[[a^1b^1]_1[b^1]_1]_2[[b^0]_1]_2]_3$ be an order-3 collapsible stack. The destination of the topmost link is $bot^1_3(w) = [[[b^0]_1]_2]_3$. Furthermore, $bot^1_2(w) = [[[b^1]_1]_2[[b^0]_1]_2]_3$ and $top_2(w) = [a^1b^1]_1$. Here, $top_2(w) :_2 bot^1_2(w) = w$.

Operations on Order-n Collapsible Stacks

CPDS are programs with a finite control acting on collapsible stacks via the operations:

$$\mathcal{O}_n = \{push_2, \dots, push_n\} \cup \{push_a, rew_a \mid a \in \Sigma\} \cup \{pop_1, \dots, pop_n\} \cup \{collapse\}.$$

Operations $push_k$ of order $k > 1$ copy the topmost element of the topmost order-k stack. Order-1 push operations $push_a$ push a onto the topmost order-1 stack and annotate it with an order-$\lambda(a)$ collapse link. When executed on a stack w, the link destination is $pop_{\lambda(a)}(w)$. A pop_k removes the topmost element from the topmost order-k stack. The rewrite rew_a modifies the topmost stack character while maintaining the link (rewrite must respect the link order). Collapse, when executed on a^i with $\lambda(a) = k$, pops the topmost order-k stack down to the last i elements, captured by bot^i_k. Formally, for an order-n stack w:

1. $push_k(w) = top_k(w) :_k w$.
2. $push_a(w) = a^{\ell-1} :_1 w$ when $top_{k+1}(w) = [w_1 \dots w_\ell]_k$, where $k = \lambda(a)$ is the link order,
3. $pop_k(w) = v$ when $w = u :_k v$,
4. $collapse(w) = bot^i_k(w)$ when $top_1(w) = a^i$ and $\lambda(a) = k$, and
5. $rew_b(w) = b^i :_1 v$ when $w = a^i :_1 v$ and $\lambda(a) = \lambda(b)$.

Note that since our definition of stacks does not permit empty stacks, pop_k is undefined if v is empty and *collapse* is undefined when $i = 0$. Thus, the empty stack cannot be reached using CPDS operations; instead, the offending operation will simply be unavailable. Likewise if a rewrite operation would change the order of the link.

▶ **Example 2.3.** Recall Example 2.2 and that $w = [[[a^1b^1]_1[b^1]_1]_2[[b^0]_1]_2]_3$. Given the order-3 link 1 of the topmost stack character a, a collapse operation yields $u = [[[b^0]_1]_2]_3$. Now $push_3(u) = [[[b^0]_1]_2[[b^0]_1]_2]_3$. A $push_a$ on this stack results in $v = [[[a^1b^0]_1]_2[[b^0]_1]_2]_3$. We have $pop_3(v) = u = collapse(v)$.

There is a subtlety in the interplay of collapse links and higher-order pushes. For a $push_k$, links pointing outside of $u = top_k(w)$ have the same destination in both copies of u, while links pointing within u point to different sub-stacks.

▶ Remark (*nop*). For convenience we use an operation *nop* which has no effect on the stack. We can simulate it by rew_a where a is the topmost character (by the format of rules, below, we will always know the topmost character when applying an operation). Hence, it is not a proof case.

2.2 Collapsible Pushdown Systems and Games

▶ **Definition 2.4** (CPDS). An order-n *collapsible pushdown system* is a tuple $\mathcal{C}$ given by $(\mathcal{P}, \Sigma, \lambda, \mathcal{R}, p_I, a_I, \rho)$ with $\mathcal{P}$ a finite set of control states with initial control state p_I, Σ a finite stack alphabet with initial stack character a_I and order function λ, $\rho : \mathcal{P} \to \mathbb{N}$ a function assigning ranks to $\mathcal{P}$, and $\mathcal{R} \subseteq (\mathcal{P} \times \Sigma \times \mathcal{O}_n \times \mathcal{P})$ a set of rules. The size is $|\mathcal{C}| = |\mathcal{P}| + |\Sigma|$. The remaining entries polynomially depend on $\mathcal{P}$ and Σ (note that n is fixed).

We attach ranks to CPDS instead of games as we later need the notion of *rank-aware* CPDS.

A *configuration* of a CPDS is a pair $c = \langle p, w\rangle$ with $p \in \mathcal{P}$ and a stack $w \in \mathit{Stacks}_n$. We have a transition $\langle p, w\rangle \longrightarrow \langle p', w'\rangle$ if there is a rule $(p, a, o, p') \in \mathcal{R}$ with $\mathit{top}_1(w) = a$ and $w' = o(w)$. The initial configuration is $\langle p_I, w_I\rangle$ where $w_I = [\dots[a_I^0]_1 \dots]_n$. To begin from another configuration, one can adjust the CPDS rules to build the required stack from the initial configuration. A computation is a sequence of configurations $c_0, c_1, \dots$ where $c_0 = \langle p_I, w_I\rangle$ and $c_i \longrightarrow c_{i+1}$ for all $i \in \mathbb{N}$. Recall, transitions cannot empty a stack or rewrite the order of a link.

▶ **Definition 2.5** (Games over CPDS). A *game over a CPDS* is a tuple $\mathcal{G} = (\mathcal{C}, \mathbb{O}, \mathcal{W})$, where $\mathcal{C}$ is a CPDS, $\mathbb{O} : \mathcal{P} \to \{\mathrm{A}, \mathrm{E}\}$ is a division of the control states of $\mathcal{C}$ by owner Elvis (E) or Agnetha (A), and $\mathcal{W} \subseteq \mathbb{N}^\omega$ is a winning condition. The size of the game is $|\mathcal{G}| = |\mathcal{C}|$.

We call $\mathcal{G}$ a *safety game* if $\rho(p) \in \{1, 2\}$ for all $p \in \mathcal{P}$ and $\mathcal{W} = 2^\omega$. It is a *parity game* if $\mathcal{W}$ is the set of all sequences such that the smallest infinitely occurring rank is even.

We refer to computations as plays and require them to be infinite. This means every configuration $\langle p, w\rangle$ has some successor $\langle p', w'\rangle$. This does not lose generality as we can add to the CPDS transitions to a losing (as defined next) sink state (with self-loop) for $\mathbb{O}(p)$ from any configuration $\langle p, w\rangle$. A play $\langle p_0, w_0\rangle, \langle p_1, w_1\rangle, \langle p_2, w_2\rangle, \dots$ is won by Elvis, if its sequence of ranks satisfies the winning condition, i.e. $\rho(p_0)\rho(p_1)\rho(p_2)\dots \in \mathcal{W}$. Otherwise, Agnetha wins. When a play reaches (p, w), then the owner of p chooses the rule to apply. A *strategy* for player $\Upsilon \in \{\mathrm{E}, \mathrm{A}\}$ is a function $\sigma : (\mathcal{P} \times \mathit{Stacks}_n)^* \to \mathcal{R}$ that returns an appropriate rule based on the prefix of the play seen so far. A play $\langle p_0, w_0\rangle, \langle p_1, w_1\rangle, \langle p_2, w_2\rangle, \dots$ is according to σ if for all i with $\mathbb{O}(p_i) = \Upsilon$ we have $\langle p_i, w_i\rangle \longrightarrow \langle p_{i+1}, w_{i+1}\rangle$ via rule $\sigma(\langle p_0, w_0\rangle, \dots, \langle p_i, w_i\rangle)$. The strategy is winning if all plays according to σ are won by Υ. We say a player *wins* a game if they have a winning strategy from the initial configuration.

2.3 Rank-Aware Collapsible Pushdown Systems

We will often need to access the smallest rank that was seen in a play since some stack was created. *Rank-aware* CPDS record precisely this information [17]. We first define k-ancestors which, intuitively, give the position in the play where the top order-$(k-1)$ stack was pushed. Note, in the definition below, the integer j is unrelated to the collapse links.

▶ **Definition 2.6** (k-Ancestor). Let $k \in [2, n]$ (resp. $k = 1$). Given a play $c_0, c_1, \dots$ we attach an integer j to every order-$(k-1)$ stack as follows. In c_0 all order-$(k-1)$ stacks are annotated by 0. Suppose c_{i+1} was obtained from c_i using operation push_k (resp. push_a). Then the new topmost order-$(k-1)$ stack in c_{i+1} is annotated with i. If c_{i+1} is obtained via a $\mathit{push}_{k''}$ with $k'' > k$, then all annotations on the order-$(k-1)$ stacks in the copied stack are also copied.

The *k-ancestor* with $k \in [1, n]$ of c_i is the configuration c_j where j is the annotation of the topmost order-$(k-1)$ stack in c_i. Let $\mathit{top}_1(c_i) = a^\ell$ and $\lambda(a) = k'$. The *link ancestor* of c_i is the k'-ancestor of the 1-ancestor of c_i.

Applying a pop_k operation will expose (a copy of) the topmost $(k-1)$-stack of the k-ancestor. To understand the notion of a link ancestor, remember that *collapse* executed on a stack whose topmost order-0 stack is a^ℓ with $\lambda(a) = k'$ has the effect of executing $pop_{k'}$ several times. The newly exposed topmost $(k'-1)$-stack is the same that would be exposed if $pop_{k'}$ were applied at the moment the a character was pushed. This exposed stack is the same stack as is topmost on the k'-ancestor of the 1-ancestor of a. We illustrate this with an example.

▶ **Example 2.7.** Assume some c_0. Now take some c_1 containing the stack $w_1 = [[[b^0]_1]_2]_3$. Apply a $push_3$ operation to obtain c_2 with stack $w_2 = [[[b^0]_1]_2[[b^0]_1]_2]_3$. Note, the topmost $[[b^0]_1]_2$ has 3-ancestor c_1.

Now, let $\lambda(a) = 3$ and obtain c_3 with $push_a$, which thus contains the stack $w_3 = [[[a^1b^0]_1]_2[[b^0]_1]_2]_3$ where the a^1 has the 1-ancestor c_2.

We can now apply $push_3$ again to reach c_4 with stack $w_4 = [[[a^1b^0]_1]_2[[a^1b^0]_1]_2[[b^0]_1]_2]_3$. Note that both copies of a^1 have the 1-ancestor c_2. Moreover, the link ancestor of both is c_1. That is, the 3-ancestor of the topmost stack of c_2. In particular, applying *collapse* at c_4 results in a configuration with stack $[[[b^0]_1]_2]_3$, which is the same stack contained in c_1.

In the below, intuitively, the level-k rank is the smallest rank seen since the topmost $(k-1)$ stack was created. Similarly for the link-level rank. Our rank-awareness definition is from [17] but includes level-k ranks as well.

▶ **Definition 2.8** (Level Rank)**.** For a given play $c_0, c_1, \ldots$ the *level-k rank* with $k \in [1, n]$ (resp. *link-level rank*) at a configuration c_i is the smallest rank of a control state in the sequence $c_{j+1}, \ldots, c_i$ where j is the k-ancestor (link ancestor) of c_i.

In the following definition, ℓ is a special symbol to be read as *link*.

▶ **Definition 2.9** (Rank-Aware)**.** A *rank-aware CPDS* is a CPDS $\mathcal{C}$ over stack characters (a, Rk), where a is taken from a finite set and function Rk has type $\mathrm{Rk} : [1, n] \uplus \{\ell\} \to [0, m]$ (with m the highest rank of a state in $\mathcal{C}$). The requirement is that in all computations $c_0, c_1, \ldots$ of the CPDS all configurations $c_i = (p, w)$ with top-of-stack character (a, Rk) satisfy

$$\mathrm{Rk}(k) = \text{ the level-}k\text{ rank at } c_i,\ k \in [1, n], \quad \text{and} \quad \mathrm{Rk}(\ell) = \text{ the link-level rank at } c_i.$$

Below, we slightly generalize a lemma from [17] to include safety games and level-k ranks. Intuitively, we can obtain rank-awareness by keeping track of the required information in the stack characters and control states.

▶ **Lemma 2.10** (Rank-Aware)**.** *Given a parity (resp. safety) game over CPDS $\mathcal{C}$ of order-n, one can construct in polynomial time a rank-aware CPDS $\mathcal{C}'$ of the same order and a parity (resp. safety) game over $\mathcal{C}'$ such that Elvis wins the game over $\mathcal{C}$ iff he wins the game over $\mathcal{C}'$.*

Note, the number of functions Rk is exponential in n. However, since n is fixed the construction is polynomial. In the sequel, we will assume that all CPDS are rank-aware.

3 Main Result and Proof Outline

In the following sections, we define a reduction Poly which takes a parity game $\mathcal{G}$ over a CPDS and returns a safety game $\mathrm{Poly}(\mathcal{G})$ of the same order. The main result follows.

▶ **Theorem 3.1** (From Parity to Safety, Efficient)**.** *Given a parity game $\mathcal{G}$, Elvis wins $\mathcal{G}$ iff he wins* $\mathrm{Poly}(\mathcal{G})$*.* $\mathrm{Poly}(\mathcal{G})$ *is polynomially large and computable in time polynomial in the size of $\mathcal{G}$.*

We outline how to define Poly and prove it correct. First, we give a function $\mathrm{Counter}_B$ reducing an order-n parity game to an equivalent order-n safety game. It extends Fridman and Zimmermann's reduction [14] from first order to higher orders. In the finite-state setting, a related reduction appeared already in [1]. The idea is to count in the stack characters the occurrences of odd ranks. Elvis has to keep the counter values below B, a threshold that is a parameter of the reduction. For completeness, this threshold has to be n-fold exponential in the size of $\mathcal{G}$. Let $\mathrm{Exp}_0(f) = f$ and $\mathrm{Exp}_n(f) = 2^{\mathrm{Exp}_{n-1}(f)}$. We have the following lemma.

▶ **Lemma 3.2** (From Parity to Safety, Inefficient). *Given a parity game $\mathcal{G}$ played over an order-n CPDS, there is a bound $B(\mathcal{G}) = Exp_n(f(|\mathcal{G}|))$ for some polynomial f so that for all $B \geq B(\mathcal{G})$ Elvis wins $\mathcal{G}$ iff he wins the safety game* $\mathrm{Counter}_B(\mathcal{G})$.

The size of $\mathrm{Counter}_B(\mathcal{G})$ is not polynomial, even for constant B. The next step is to give an efficient reduction Poly_B producing a safety game equivalent to $\mathrm{Counter}_B(\mathcal{G})$. In particular $\mathrm{Poly}_{B(\mathcal{G})}(\mathcal{G})$ can be computed in time polynomial only in the size of $\mathcal{G}$, not in $B(\mathcal{G})$. Thus, we can define Poly from the main theorem to be $\mathrm{Poly}(\mathcal{G}) = \mathrm{Poly}_{B(\mathcal{G})}(\mathcal{G})$.

Technically, Poly relies on the insight that counter increments as performed by $\mathrm{Counter}_B$ follow a stack discipline. Incrementing the rth counter resets all counters for $r' > r$ to zero. The upper bound combines this with the fact that collapsible pushdown systems can encode large counters [7]. The second step is summarized as follows.

▶ **Lemma 3.3** (From Inefficient to Efficient). *Elvis wins* $\mathrm{Counter}_B(\mathcal{G})$ *iff he wins* $\mathrm{Poly}_B(\mathcal{G})$. *Moreover,* $\mathrm{Poly}(\mathcal{G}) = \mathrm{Poly}_{B(\mathcal{G})}(\mathcal{G})$ *is polynomial-time computable.*

It should be clear that the above lemmas, once proven, yield the main theorem. For the equivalence stated there, note that $\mathrm{Poly}(\mathcal{G}) = \mathrm{Poly}_{B(\mathcal{G})}(\mathcal{G})$ is equivalent to the game $\mathrm{Counter}_{B(\mathcal{G})}(\mathcal{G})$ by Lemma 3.3. This game, in turn, is equivalent to $\mathcal{G}$ by Lemma 3.2.

The proof of Lemma 3.3 will be direct and is given in Section 7. We explain the proof of Lemma 3.2 here, which relies on a third reduction. We define a function called Order that takes an order-n parity or safety game and produces an equivalent order-$(n-1)$ parity or safety game. The reduction already appears in [17], and generalizes the one from [32]. Let

$$\begin{array}{lcllcl} \mathcal{G}_O & = & \mathrm{Order}(\mathcal{G}), & \mathcal{G}_{C_B} & = & \mathrm{Counter}_B(\mathcal{G}), \\ \mathcal{G}_{O,C_B} & = & \mathrm{Counter}_B(\mathrm{Order}(\mathcal{G})), & \mathcal{G}_{C_B,O} & = & \mathrm{Order}(\mathrm{Counter}_B(\mathcal{G}))\ . \end{array}$$

The proof of Lemma 3.2 chases the diagram below. We rely on the observation that the games $\mathrm{Counter}_B(\mathrm{Order}(\mathcal{G}))$ and $\mathrm{Order}(\mathrm{Counter}_B(\mathcal{G}))$ are equivalent, as stated in Lemma 3.4. The proof of Lemma 3.4 needs the reductions and can be found in Section 6. The commutativity argument yields the following proof, almost in category-theoretic style.

$$\begin{array}{ccc} \mathcal{G} & \text{- - - - - - - - -}\ \mathrm{Counter}_B\ \text{- - - - - - - - -}\rightarrow & \mathcal{G}_{C_B} \\ \big\downarrow \mathrm{Order} & & \big\downarrow \mathrm{Order} \\ \mathcal{G}_O & \longrightarrow\ \mathrm{Counter}_B\ \longrightarrow & \mathcal{G}_{O,C_B} \iff \mathcal{G}_{C_B,O} \end{array}$$

▶ **Lemma 3.4** ($\mathcal{G}_{O,C_B}$ vs. $\mathcal{G}_{C_B,O}$). *Given $B \in \mathbb{N}$ and a parity game $\mathcal{G}$ over an order-n CPDS, Elvis wins* $\mathrm{Counter}_B(\mathrm{Order}(\mathcal{G}))$ *iff Elvis wins* $\mathrm{Order}(\mathrm{Counter}_B(\mathcal{G}))$.

Proof of Lemma 3.2. We induct on the order. At order-1, the result is due to Fridman and Zimmerman [14]. For the induction, without the bound, at order-n, take a winning strategy for Elvis in $\mathcal{G}$. By [17], he has a winning strategy in $\mathcal{G}_O$. By induction, Elvis has a winning

strategy in $\mathcal{G}_{O,C_B}$ and by Lemma 3.4 also in $\mathcal{G}_{C_B,O}$ when B is suitably large. Finally, again by [17], Elvis can win $\mathcal{G}_{C_B}$. I.e., we chase the diagram above from $\mathcal{G}$ to $\mathcal{G}_O$ to $\mathcal{G}_{O,C_B}$ to $\mathcal{G}_{C_B,O}$ and then up to $\mathcal{G}_{C_B}$. To prove the opposite direction, simply follow the path in reverse.

To obtain the required bound, we argue as follows: Intuitively, we have an exponential bound at order-1 by Fridman and Zimmerman. Thus, assume by induction we have a $(n-1)$-fold exponential bound for order-$(n-1)$. From an order-n system we obtain an exponentially large order-$(n-1)$ system for which an n-fold exponential bound is therefore needed. ◀

In Sections 4 and 5, we define Order and Counter$_B$, and show Lemma 3.4 in Section 6. The reduction Poly is defined in Section 7, which also sketches the proof of Lemma 3.3.

4 Order Reduction

We recall the reduction of [17] from order-n to order-$(n-1)$ parity games. This reduction also works for safety games. It is a natural extension of Carayol et al. [9] for higher-order pushdown systems without collapse, which extended Walukiewicz's reduction of pushdown parity games to finite-state parity games [32]. Due to space constraints, we only give the intuition here. It is useful when explaining the motivation behind the constructions in our parity to safety reduction.

Given an order-n CPDS $\mathcal{C}$ and a game $\mathcal{G} = (\mathcal{C}, \mathbb{O}, \mathcal{W})$ we define an order-$(n-1)$ game Order$(\mathcal{G})$ over a CPDS $\mathcal{C}'$. The order-$(n-1)$ CPDS $\mathcal{C}'$ simulates $\mathcal{C}$. The key operations are $push_n$, pop_n, $push_a$ with $\lambda(a) = n$, and *collapse* when the link is order-n. We say these operations are order-n. The remaining operations are simulated directly on the stack of $\mathcal{C}'$.

There is no $push_n$ on an order-$(n-1)$ stack. Instead, observe that if the stack is w before the $push_n$ operation, it will return to w after the corresponding pop_n (should it occur). Thus, we simulate $push_n$ by splitting the play into two branches. The first simulates the play between the $push_n$ and corresponding pop_n. The second simulates the play after the pop_n.

Instead of applying a $push_n$ operation, Elvis makes a claim about the control states the play may pop to. Also necessary is information about the smallest rank seen in the play to the pop. This claim is recorded as a vector of sets of control states $\vec{P} = (P_0, \ldots, P_m)$ which is held in the current control state. Each $p \in P_r$ is a potential future of the play, meaning that the pushed stack may be popped to p and the minimum rank seen since the push could be r. Because Elvis does not have full control of the game, he cannot give a single control state and rank: Agnetha may force him to any of a number of situations.

Once this guess has been made, Agnetha chooses whether to simulate the first play (between the push and the pop) or the second (after the pop). In the first case, $\vec{P}$ is stored in the control state. Then, when the pop occurs, Elvis wins if the destination control state is in P_r where r is the minimum rank seen (his claim was correct). In the second case, Agnetha picks a rank r and moves the play directly to some control state in P_r. This move has rank r (as the minimum rank seen needs to contribute to the parity/safety condition). In both cases, the topmost order-$(n-1)$ stack does not change (as it would be the same in both plays).

To simulate a $push_a$ with $\lambda(a) = n$ and a corresponding *collapse* we observe that the stack reached after the collapse is the same as that after a pop_n applied directly. Thus, the simulation is similar. To simulate the play up to the collapse, the current target set $\vec{P}$ is stored with the new stack character a. Then Elvis wins if a move performs a *collapse* to a control state $p \in P_r$, where r is the smallest rank seen since the order-$(n-1)$ stack, that was topmost at the moment of the original $push_a$, was pushed. To simulate the play after the collapse, we can simulate a pop_n as above.

5 Counter Reduction

We reduce parity to safety games, generalizing Fridman and Zimmermann [14] which extended Bernet et al. [1]. This reduction is not polynomial and we show in Section 7 how to achieve the desired complexity. Correctness is Lemma 3.2 (From Parity to Safety, Inefficient) .

We give the intuition here. The reduction maintains a counter for each odd rank, which can take any value between 0 and B. We also detail the counters below as they are needed in Section 7.

The insight of Bernet et al. is that, in a finite-state parity game of ℓ states, if Agnetha can force the play to pass through some odd rank r for $\ell + 1$ times without visiting a state of lower rank in between, then some state p of rank r is visited twice. Since parity games permit positional winning strategies, Agnetha can repeat the play from p ad infinitum. Thus, the smallest infinitely occurring rank must be r, and Agnetha wins the game.

Thus, Elvis plays a safety game: he must avoid visiting an odd rank too many times without a smaller rank being seen. In the safety game, counters

$$\vec{\alpha} = (\alpha_1, \alpha_3, \ldots, \alpha_m)$$

are added to the states, one for each odd rank. When a rank r is seen, then, if it is odd, α_r is incremented. Moreover, whether r is odd or even, all counters $\alpha_{r'}$ for $r' > r$ are reset to 0.

As the number of configurations is infinite, Bernet's insight does not immediately generalize to pushdown games. However, Fridman and Zimmermann observed that, from Walukiewicz [32], a pushdown parity game can be reduced to a finite-state parity game (of exponential size) as described in the previous section. This finite-state parity game can be further reduced to a safety game with the addition of counters. Their contribution is then to transfer back the counters to the pushdown game, with the following reasoning.

Recall, a push move at $(p, [aw]_1)$ is translated into a branch from a corresponding state $(p, a, \vec{P})$ in the finite-state game. There are several moves from $(p, a, \vec{P})$, some of them simulate the push, the remaining moves simulate the play after the corresponding pop. When augmented with counters the states take the form $(p, a, \vec{P}, \vec{\alpha})$. We see that, when simulating the pop in the finite-state game, the counter values are the same as in the moment when the push is simulated. That is, if we lift the counter construction to the pushdown game, after each pop move we need to reset the counters to their values at the corresponding push. Thus we store the counter values on the stack. For example, for a configuration $(p, [(a, \vec{\alpha})(b, \vec{\alpha}')]_1)$ where the current top of stack is a and the current counter values are $\vec{\alpha}$, the counter values at the moment when a was first pushed are stored on the stack as $\vec{\alpha}'$.

This reasoning generalizes to any order n. We store the counter values on the stack so that, when a pop_k operation occurs, we can retrieve the counter values at the corresponding $push_k$, and similarly for *collapse*. Note also that, when reducing from order-n to order-$(n-1)$, any branch corresponding to a play after a pop passes through a rank r which is the smallest rank seen between the push and pop. Thus, in the safety game, after each pop or collapse we need to update the counter values using r. Hence we require a rank-aware CPDS.

Let m be the maximum rank, and, for convenience, assume it is odd. We maintain a vector of counters $\vec{\alpha} = (\alpha_1, \alpha_3, \ldots, \alpha_m)$, one for each odd rank, stored in the stack alphabet as described above. We update these counters with operations $\oplus_r$ that exist for all $r \in [0, m]$ (including the even ranks). Operation $\oplus_r$ resets the counters $\alpha_{r'}$ with $r' > r$ to zero. If r is odd, it moreover increments α_r. If the bound is exceeded, an overflow occurs. Formally, $\oplus_r(\vec{\alpha}) = \texttt{NaN}$ if r is odd and $\alpha_r + 1 > B$. Otherwise, $\oplus_r(\vec{\alpha}) = \vec{\alpha}'$ where for each $\tilde{r}$

$$\alpha'_{\tilde{r}} = \alpha_{\tilde{r}} \text{ (if } \tilde{r} < r), \quad \alpha'_{\tilde{r}} = \alpha_r + 1 \text{ (if } \tilde{r} = r), \text{ and } \quad \alpha'_{\tilde{r}} = 0 \text{ (if } \tilde{r} > r).$$

6 Equivalence Result

We need equivalence of $\mathcal{G}_{O,C_B} = \text{Counter}_B(\text{Order}(\mathcal{G}))$ and $\mathcal{G}_{C_B,O} = \text{Order}(\text{Counter}_B(\mathcal{G}))$ for Lemma 3.4. The argument is that the two CPDS only differ in order of the components of their control states and stack characters. A subtlety is that when Counter_B is applied first, the contents of $\vec{P}$ are not control states of $\mathcal{G}$, but control states of $\mathcal{G}_{C_B}$. However, the additional information in the control states after Counter_B has to be consistent with $\vec{P}$, which means we can directly translate between guesses over states in the original CPDS, and those over states of the CPDS after the counter reduction.

7 Polynomial Reduction

For a game $\mathcal{G}$ over an order-n CPDS, the counters in the game $\text{Counter}_{B(\mathcal{G})}(\mathcal{G})$ blow up $\mathcal{G}$ by an n-fold exponential factor. To avoid this we use the stack-like behaviour of the counters and a result due to Cachat and Walukiewicz [7], showing how to encode large counter values into the stack of a CPDS with only polynomial overhead (in fact, collapse is not needed).

7.1 Counter Encoding

Cachat and Walukiewicz propose a binary encoding that is nested in the sense that a bit is augmented by its position, and the position is (recursively) encoded in the same way. For example, number 5 stored with 16 bits is represented by $(0,1).(1,0).(2,1).(3,0).(4,0)\ldots(15,0)$. Since four bits are required to index 16 bits, we encode position 4 as $(0,0').(1,0').(2,1').(3,0')$. Finally, position 2 of this encoding stored as $(0,0'').(1,1'')$. The players compete to (dis)prove that the indexing is done properly.

Formally we introduce distinct alphabets to encode counters for all odd ranks r:

$$\Gamma_r \;=\; \hat{\Gamma}_r \cup \{0_r, 1_r\} \;.$$

Here, $\hat{\Gamma}_r$ is a polynomially-large set of characters for the indexing. The set $\{0_r, 1_r\}$ are the bits to encode numbers. Let Γ be the union of all Γ_r.

The values of the counters are stored on the order-1 stack, with the least-significant bit topmost. The indices appear before each bit character. E.g., value 16 for counter r stored with five bits yields a sequence from $\hat{\Gamma}_r^* \,.\, 0_r \,.\, \hat{\Gamma}_r^* \,.\, 0_r \,.\, \hat{\Gamma}_r^* \,.\, 0_r \,.\, \hat{\Gamma}_r^* \,.\, 0_r \,.\, \hat{\Gamma}_r^* \,.\, 1_r$. Actually, the encoding will always use all bits, which means its length will be $(n-1)$-fold exponential.

Cachat and Walukiewicz provide game constructions to assert properties of the counter encodings. For this, play moves to a dedicated control state, from which Elvis wins iff the counters have the specified property. In [7], Elvis plays a reachability game from the dedicated state. We need the dual, with inverted state ownership and a safety winning condition, where the target state of the (former) reachability game has rank 1. Elvis's goal will be to prove the encoding wrong (it violates a property) by means of safety, Agnetha tries to build up the counters correctly and, if asked, demonstrate correctness using reachability.

For all properties, the counter to be checked must appear directly on the top of the stack (topmost on the topmost order-1 stack). If any character outside Γ_r is found, Agnetha loses. When two counters are compared, the first counter must appear directly at the top of the stack, while the second may be separated from the first by any sequence of characters from outside Γ_r (these can be popped away). The first character found from Γ_r begins the next encoding. Agnetha loses the game if none is found. The required properties are listed below.

- Encoding Check ($\mathit{encoding}_r$): For each rank r, we have a control state $\mathit{encoding}_r$. Agnetha can win the safety game from $\langle \mathit{encoding}_r, w\rangle$ only if the topmost sequence of characters from Γ_r is a correct encoding of a counter, in that all indices are present and correct.
- Equals Check (equal_r): For each r, we have a control state equal_r, from which Agnetha can win only if the topmost sequence of characters from Γ_r is identical to the next topmost sequence of Γ_r-characters. I.e., the two topmost rth counter encodings are equal.
- Counter Increment: Cachat and Walukiewicz do not define increment but it can be done via the basic rules of binary addition. We force Agnetha to increment the counter by first using pop_1 to remove characters from $\hat{\Gamma}_r \cup \{1_r\}$ until 0_r is found. Then, Agnetha must rewrite the 0_r to 1_r. Agnetha then performs as many push_a operations as she wishes, where $a \in \hat{\Gamma}_r \cup \{0_r\}$. Next, Elvis can accept this rewriting by continuing with the game, or challenge it by moving to $\mathit{encoding}_r$. This ensures that Agnetha has put enough 0_r characters on the stack (with correct indexing) to restore the number to its full length.

In this encoding one can only increment the topmost counter on the stack. That is, to increment a counter, all counters above it must be erased. Fortunately, $\oplus_r$ resets to zero all counters for ranks $r' > r$, meaning the counter updates follow a stack-like discipline. This enables the encoding to work. To store a character with counter values from the counter reduction $(a, \vec{\alpha})$ with $\vec{\alpha} = \alpha_1, \ldots, \alpha_m$ we store the character a on top and beneath we encode α_m, then α_{m-2} and so on down to α_1.

7.2 The Simulation

The following definition is completed in the following sections. Correctness is stated in Lemma 3.3 (From Inefficient to Efficient) .

▶ **Definition 7.1** (Poly_B)**.** Given a parity game $\mathcal{G} = (\mathcal{C}, \mathbb{O}, \mathcal{W})$ over the order-n CPDS $\mathcal{C} = (\mathcal{P}, \Sigma, \lambda, \mathcal{R}, p_I, a_I, \rho)$ and a bound B n-fold exponential in the size of the game, we define the safety game $\mathrm{Poly}_B(\mathcal{G}) = (\mathcal{C}', \mathbb{O}', 2^\omega)$ where $\mathcal{C}' = (\mathcal{Q}, \Sigma', \lambda', \mathcal{R}', p_I', a_I', \rho')$. The missing components are defined below.

We aim to simulate $\mathrm{Counter}_B(\mathcal{G})$ compactly. This simulation is move-by-move, as follows.

A $\mathit{push}_{(a,\vec{\alpha})}$ of a character with counter values $(a, \vec{\alpha})$ with $\vec{\alpha} = \alpha_1, \ldots, \alpha_m$ (where the max-rank is m) is simulated by first pushing a special character ℓ_k to save the link (with push_{ℓ_k}). Then, since the counter values are a copy of the preceding counter values on the stack, Agnetha pushes an encoding for α_1 using Γ_1 after which Elvis can accept the encoding, check that it is a proper encoding using $\mathit{encoding}_1$, or check that it is a faithful copy of the preceding value of α_1 using equal_1. We do this for all odd ranks through to m. Then the only move is to push a with push_a.

Each push_k and pop_k, with $k \in [2, n]$, is simulated directly by the same operation. For a pop_1 we (deterministically) remove all topmost characters (using pop_1) up to and including the first $\ell_{k'}$ (for some k'). We simulate *collapse* like pop_1, but we apply *collapse* to $\ell_{k'}$.

A $\mathit{rew}_{(a,\vec{\alpha})}$ that does not change the counters can be simulated by rewriting the topmost character. If $\oplus_r$ is applied, we force Agnetha to play as follows. If r is even, Agnetha removes the counters for $r' > r$. She replaces them with zero values by pushing characters from $\hat{\Gamma}_{r'} \cup \{0_{r'}\}$. After each counter is rewritten, Elvis can accept the encoding, or challenge it with $\mathit{encoding}_{r'}$. Finally, a is pushed onto the stack. If r is odd, the counters for r' are removed as before. Then we do an increment as described above, with Elvis losing if the increment fails. Note, it fails only if there is no 0_r in the encoding, which means the counter is at its maximum value and there is an overflow (indicating Elvis loses the parity game). If it succeeds, zero values for the counters $r' > r$ and a are pushed to the stack as before.

Control States and Alphabet

We define the control states $\mathcal{Q}$ with $\mathbb{O}'$ and ρ' as well as the alphabet. First,

$$\mathcal{Q} \;=\; \mathcal{P} \cup (\mathcal{P} \times [0,m]) \cup \{\#,\$\} \cup \mathcal{P}_{CW} \;\cup \mathcal{P}_{OP}\ .$$

where m is the maximum rank. The set $\mathcal{P}_{CW}$ is the control states of the Cachat-Walukiewicz games implementing $\mathit{encoding}_r$ and equal_r. The size is polynomial in $\mathcal{G}$. We have $\mathcal{P}_{OP} =$

$$\left\{ \begin{array}{c} (\mathrm{inc}, r, p), (\mathrm{copy}, r, a, p), (\mathrm{zero}, r, a, p), (\mathrm{pop}_1, \Upsilon, r, p), \\ (\mathrm{inc}, r, a, p), (\mathrm{cchk}, r, a, p), (\mathrm{zchk}, r, a, p), (\mathrm{collapse}, \Upsilon, r, p) \end{array} \;\middle|\; \begin{array}{l} r \in [0,m] \wedge a \in \Sigma \;\wedge \\ p \in \mathcal{P} \;\wedge \Upsilon \in \{\mathrm{A}, \mathrm{E}\} \end{array} \right\}$$

to control the simulation of the operations as sketched above. We describe the states below.

The states in $\mathcal{P}_{CW}$ have the same rank and owner as in the Cachat-Walukiewicz games (more precisely the dual, see above). All other states have rank 2 except # which has rank 1. It (resp. \$) is the losing sink for Elvis (resp. Agnetha). The states in $\mathcal{P} \cup (\mathcal{P} \times [0,m]) \cup \{\#\}$ are used as in $\mathrm{Counter}_B(\mathcal{G})$ to directly simulate $\mathcal{G}$. The owners are as in $\mathcal{G}$.

A state (inc, r, p) begins an application of $\oplus_r$. The top-of-stack character is saved by moving to (inc, r, a, p). The owner of these states does not matter, we give them to Agnetha. In (inc, r, a, p), the stack is popped down to the counter for r. If r is odd, the least significant zero is set to one. Then, control moves to (zero, r, a, p). In (zero, r, a, p), zero counters for ranks r and above are pushed to the stack, followed by a push of a and a return to control state p. The state is owned by Agnetha. The state (zchk, r, a, p) is used by Elvis to accept or challenge that the encoding has been re-established completely. It is owned by Elvis.

The controls (copy, r, a, p) copy the counters for ranks r and above (the current values) and push the copies to the stack, followed by a push of a and a return to control state p. The state is owned by Agnetha. After this phase, the play moves to (cchk, r, a, p) where Elvis can accept or test whether the copy has been done correctly. This state is owned by Elvis.

The controls $(\mathrm{pop}_1, \Upsilon, r, p)$ and $(\mathrm{collapse}, \Upsilon, r, p)$ where $\Upsilon \in \{\mathrm{A}, \mathrm{E}\}$ are used to execute a pop_1 or *collapse*. For the latter, we pop to the next ℓ_k character, perform the collapse and record that the rth counter needs to be incremented. In case the collapse is not possible (because it would empty the stack) play may also move to a sink state that is losing for the player Υ who instigated the collapse. The case of pop_1 pops ℓ_k. The owner in each case is Υ as they will avoid moving to their (losing) sink state if the pop_1 or *collapse* is possible.

The alphabet and initial control state and stack character are

$$\Sigma' = \Sigma \cup \Gamma \cup \Delta \quad \text{and} \quad p'_I = (\mathrm{zero}, 1, a_I, p_I) \quad \text{and} \quad a'_I = \ell_k \text{ where } \lambda(a_I) = k\ .$$

The alphabet is extended by the characters required for the counter and link encodings. Recall that Γ is the union of the counter alphabets, which are of polynomial size. We use $\Delta = \{\ell_1, \ldots, \ell_m\}$ for the link characters. We assign $\lambda'(\ell_k) = k$ and $\lambda'(a) = 1$ for all other a.

The task of the initial state and initial stack character is to establish the encoding of $(a_I, (0, \ldots, 0))$ in $\mathrm{Counter}_B(\mathcal{G})$ and then move to the initial state of $\mathcal{G}$. With the above description, $(\mathrm{zero}, 1, a_I, p_I)$ will establish zeros in all counters (from 1 to m), push the initial character a_I of the given game, and move to state p_I. The initial character ℓ_k is the correct bottom element for the encoding of $(a_I, (0, \ldots, 0))$.

Rules

The rules of $\mathcal{C}'$ follow $\mathcal{C}$ and maintain the counters. $\mathcal{R}'$ contains (only) the following rules. First, we have $\mathcal{R}_{CW}$ which are the (dual of the) rules of Cachat and Walukiewicz implementing $\mathit{encoding}_r$ and equal_r. The rules simulating the operations appear below. Note, pop and collapse use rank-awareness. We give the increment and copy rules after the basic operations.

- Order-k push: $(p, a, push_k, (\text{inc}, \rho(p'), p'))$ when $(p, a, push_k, p') \in \mathcal{R}$.
- Character push: $(p, a, push_{\ell_k}, (\text{copy}, 1, b, p'))$ when $(p, a, push_b, p') \in \mathcal{R}$ and $\lambda(b) = k$.
- Rewrite: $(p, a, rew_b, (\text{inc}, \rho(p'), p'))$ when $(p, a, rew_b, p') \in \mathcal{R}$.
- Pop (> 1): $(p, a, pop_k, (\text{inc}, r, p'))$ when $(p, a, pop_k, p') \in \mathcal{R}$ and $r = \min(\rho(p'), \text{Rk}(k))$.
- Pop ($= 1$) and Collapse: $(p, a, pop_1, (o, \Upsilon, r, p'))$ when $(p, a, o, p') \in \mathcal{R}$ with $\mathbb{O}(p) = \Upsilon$, operation o being pop_1 or *collapse*, and $r = \min(\rho(p'), r')$. Here, if $o = pop_1$ then $r' = \text{Rk}(1)$. Otherwise, if $o = collapse$ then $r' = \text{Rk}(\ell)$.
  Then, we have all rules $((o, \Upsilon, r, p'), a', pop_1, (o, \Upsilon, r, p'))$ for $a' \in \Gamma$. We perform the operation with $((o, \Upsilon, r, p'), \ell_{k'}, o, (\text{inc}, r, p'))$. To allow for the case where the pop or collapse cannot be performed (because the stack would empty), we also have the rules $((o, \text{A}, r, p'), \ell_{k'}, nop, \$)$ and $((o, \text{E}, r, p'), \ell_{k'}, nop, \#)$.
- Sink states: $(\$, a, nop, \$)$ and $(\#, a, nop, \#)$.

To copy counters, for each odd r and $b \in \Gamma_r$ we have $((\text{copy}, r, a, p), *, push_b, (\text{copy}, r, a, p))$. We use $*$ to indicate that the transition exists for all stack symbols. When a counter has been pushed, like in the case of pushing zeros, Agnetha hands over the control to Elvis to check the result: $((\text{copy}, r, a, p), *, nop, (\text{cchk}, r, a, p))$. Elvis can challenge the copied counter or accept it was copied correctly. To challenge, we use $((\text{cchk}, r, a, p), *, nop, equal_r)$. To accept, the behavior depends on r. If $r < m$, we move to copying the next counter $((\text{cchk}, r, a, p), *, nop, (\text{copy}, r + 2, a, p))$. When $r = m$, we finish copying and move to incrementing with rules of the form $((\text{cchk}, r, a, p), *, nop, (\text{inc}, \rho(p), a, p))$.

To increment a counter, we first pop and store the topmost stack character with the rule $((\text{inc}, r, p), a, pop_1, (\text{inc}, r, a, p))$. Agnetha then removes all counters for ranks higher than the given r with the following rules, where $b \in \Gamma_{r'}$ with $r' > r$: $((\text{inc}, r, a, p), b, pop_1, (\text{inc}, r, a, p))$.

When r is even we add back 0 counters once enough have been removed using (with $b \in \Gamma_{r-1}$ if $r > 1$ else $b \in \Delta$) the rules $((\text{inc}, r, a, p), b, nop, (\text{zero}, r + 1, a, p))$. If r is odd, we start incrementing the rth counter with $((\text{inc}, r, a, p), b, pop_1, (\text{inc}, r, a, p))$ for all $b \in \hat{\Gamma}_r \cup \{1_r\}$.

When 0_r is found, we use $((\text{inc}, r, a, p), 0_r, rew_{1_r}, (\text{zero}, r, a, p))$. If no zero bit is found, we have an overflow and move to the sink state with $((\text{inc}, r, a, p), b, nop, \#)$ for $b \in \Gamma_{r-2}$ if $r > 2$ and $b \in \Delta$ otherwise. With $((\text{zero}, r, a, p), *, push_b, (\text{zero}, r, a, p))$ for $b \in \hat{\Gamma}_r \cup \{0_r\}$ we add back zeros to the incremented counter and reset all erased counters. To finish the phase that adds zeros for the rth counter, Agnetha hands over the control to Elvis, $((\text{zero}, r, a, p), *, nop, (\text{zchk}, r, a, p))$.

Elvis can now check if all bits of the counter are present or accept the result. To challenge the encoding, he uses $((\text{zchk}, r, a, p), *, nop, encoding_r)$. When accepting it, if $r < m$, more counters need to be reset. We move to the next using $((\text{zchk}, r, a, p), *, nop, (\text{zero}, r + 2, a, p))$. If $r = m$, there are no more counters to handle and with the rule $((\text{zchk}, r, a, p), *, push_a, p)$ Elvis re-establishes the control state and stack character.

8 Conclusion

We gave a polynomial-time reduction from parity games played over order-n CPDS to safety games over order-n CPDS. Such a reduction has been an open problem [14] (related are also [1, 2]). It builds counters into the stack to count occurrences of odd ranks at the current stack level (without seeing a smaller rank). If this number grows large then Elvis would lose the parity game (if play continued). To obtain a polynomial reduction we use the insight that the counters follow a stack discipline. For correctness, we use a commutativity argument for the rank counter and order reductions. As a theoretical interest, the result explains the matching complexities of parity and safety games over CPDS. From a practical standpoint, the reduction may inspire the use of advanced safety checking tools for, and the transfer of technology from safety to, the empirically harder problem of parity game analysis.

Abstract

The polynomial-time hierarchy (PH) has proven to be a powerful tool for providing separations in computational complexity theory (modulo standard conjectures such as PH does not collapse). Here, we study whether two quantum generalizations of PH can similarly prove separations in the quantum setting. The first generalization, QCPH, uses classical proofs, and the second, QPH, uses quantum proofs. For the former, we show quantum variants of the Karp-Lipton theorem and Toda's theorem. For the latter, we place its third level, $\mathrm{Q}\Sigma_3$, into NEXP using the Ellipsoid Method for efficiently solving semidefinite programs. These results yield two implications for QMA(2), the variant of Quantum Merlin-Arthur (QMA) with two unentangled proofs, a complexity class whose characterization has proven difficult. First, if QCPH = QPH (i.e., alternating quantifiers are sufficiently powerful so as to make classical and quantum proofs "equivalent"), then QMA(2) is in the Counting Hierarchy (specifically, in $\mathrm{P}^{\mathrm{PP}^{\mathrm{PP}}}$). Second, unless QMA(2) = $\mathrm{Q}\Sigma_3$ (i.e., alternating quantifiers do not help in the presence of "unentanglement"), QMA(2) is strictly contained in NEXP.

1 Introduction

The polynomial time hierarchy (PH) [28] is a staple of computational complexity theory, and generalizes P, NP and co-NP with the use of alternating existential ($\exists$) and universal ($\forall$) operators. Roughly, a language $L \subseteq \{0,1\}^*$ is in Σ_i^p, the ith level of PH, if there exists a polynomial-time deterministic Turing machine M that acts as a verifier and accepts i proofs $y_1, \ldots, y_i$ polynomially bounded in size such that:

$$\begin{aligned} x \in L &\Rightarrow \exists y_1 \forall y_2 \exists y_3 \cdots Q_i y_i \text{ such that } M \text{ accepts } (x, y_1, \ldots, y_i), \\ x \notin L &\Rightarrow \forall y_1 \exists y_2 \forall y_3 \cdots \overline{Q}_i y_i \text{ such that } M \text{ rejects } (x, y_1, \ldots, y_i), \end{aligned}$$

where $Q_i = \exists$ if i is odd and $Q_i = \forall$ if i is even, and $\overline{Q}$ denotes the complement of Q. Then, PH is defined as the union over all Σ_i^p for all $i \in \mathbb{N}$. The study of PH has proven remarkably fruitful in the classical setting, from celebrated results such as Toda's Theorem [30], which shows that PH is contained in $\mathrm{P}^{\#\mathrm{P}}$, to the Karp-Lipton Theorem [21], which says that unless PH collapses to its second level, NP does not have polynomial size non-uniform circuits.

As PH has played a role in separating complexity classes (assuming standard conjectures like "PH does not collapse"), it is natural to ask whether *quantum* generalizations of PH can be used to separate *quantum* complexity classes. Here, there is some flexibility in defining "quantum PH", as there is more than one well-defined notion of "quantum NP": The first, Quantum-Classical Merlin Arthur (QCMA) [6], is a quantum analogue of Merlin-Arthur (MA) with a classical proof but quantum verifier. The second, Quantum Merlin Arthur (QMA) [22], is QCMA except with a quantum proof. Generalizing each of these definitions leads to (at least) two possible definitions for "quantum PH", the first using classical proofs (denoted QCPH), and the second using quantum proofs (denoted QPH).

With these definitions in hand, our aim is to separate quantum classes whose complexity characterization has generally been difficult to pin down. A prime example is QMA(2), the variant of QMA with two "unentangled" quantum provers. While the classical analogue of QMA(2) (i.e. an MA proof system with two provers) trivially equals MA, in the quantum regime multiple unentangled provers are conjectured to yield a more powerful proof system (e.g. there exist problems in QMA(2) not known to be in QMA) [24, 10, 9, 1]. For this reason, QMA(2) has received much attention, despite which the strongest bounds known on QMA(2) remain the trivial ones: QMA $\subseteq$ QMA(2) $\subseteq$ NEXP. (Note: QMA $\subseteq$ PP [23, 27].) In this work, we show that, indeed, results about the structure of QCPH or QPH yield implications about the power of QMA(2).

1.1 Results, techniques, and discussion

We begin by informally defining the two quantum generalizations of PH to be studied.

How to define a "quantum PH"? The first definition, QCPH, has its ith level $\mathrm{QC}\Sigma_i$ defined analogously to Σ_i^p, except we replace the Turing machine M with a polynomial-size uniformly generated quantum circuit V such that:

$$\begin{aligned} x \in A_{\text{yes}} &\Rightarrow \exists y_1 \forall y_2 \exists y_3 \cdots Q_i y_i \text{ s.t. } V \text{ accepts } (x, y_1, \ldots, y_i) \text{ with probability} \geq 2/3, \quad (1) \\ x \in A_{\text{no}} &\Rightarrow \forall y_1 \exists y_2 \forall y_3 \cdots \overline{Q}_i y_i \text{ s.t. } V \text{ accepts } (x, y_1, \ldots, y_i) \text{ with probability} \leq 1/3, \quad (2) \end{aligned}$$

where the use of a language L has been replaced with a *promise problem*[1] $A = (A_{\text{yes}}, A_{\text{no}})$ (since $\text{QC}\Sigma_i$ uses a bounded error verifier). The values $2/3$ and $1/3$ are respectively the *completeness* and *soundness* parameters for A and the interval $(1/3, 2/3)$ where no acceptance probabilities are present is termed the *promise gap* for A. Notice that QCPH defined as $\bigcup_{i\in\mathbb{N}} \text{QC}\Sigma_i$, is a generalization of QCMA in that $\text{QC}\Sigma_1 = \text{QCMA}$.

We next define QPH using *quantum* proofs. Here, however, there are various possible definitions one might consider. Can the quantum proofs be *entangled* between alternating quantifiers? (If not, we are enforcing "unentanglement" as in QMA(2). Allowing entanglement, on the other hand, might yield classes similar to QIP; however, note that QIP = QIP(3) (i.e. QIP collapses to a 3-message proof system) [23, 27], and so it is not clear that allowing entanglement leads to an "interesting" hierarchy.) Assuming proofs are unentangled, should the proofs be *pure* or *mixed* quantum states? (For QMA and QMA(2), standard convexity arguments show both classes of proofs are equivalent, but such arguments fail when *alternating* quantifiers are allowed.)

Here, we define QPH to have its ith level, $\text{Q}\Sigma_i$, defined similarly to $\text{QC}\Sigma_i$, except each classical proof y_j is replaced with a mixed quantum state ρ_j on polynomially many qubits. We say a promise problem $A = (A_{\text{yes}}, A_{\text{no}})$ is in $\text{Q}\Sigma_i$ if it satisfies the following conditions:

$$x \in A_{\text{yes}} \Rightarrow \exists\rho_1\forall\rho_2\exists\rho_3\cdots Q_i\rho_i \text{ such that } V \text{ accepts } (x,\rho_1,\ldots,\rho_i) \text{ with probability} \geq 2/3,$$
$$x \in A_{\text{no}} \Rightarrow \forall\rho_1\exists\rho_2\forall\rho_3\cdots \overline{Q}_i\rho_i \text{ such that } V \text{ accepts } (x,\rho_1,\ldots,\rho_i) \text{ with probability} \leq 1/3.$$

Note that $\text{QPH} := \bigcup_{i\in\mathbb{N}} \text{Q}\Sigma_i$, $\text{Q}\Sigma_1 = \text{QMA}$ and $\text{QMA}(2) \subseteq \text{Q}\Sigma_3$ (simply ignore the second proof); where the latter two hold because a lack of alternating quantifiers allows convexity arguments to yield that all proofs can be assumed to be pure. Our results are now stated as follows under three headings.

An analogue of Toda's theorem for QCPH. As previously mentioned, PH is one way to generalize NP using alternations. Another approach is to *count* the number of solutions for an NP-complete problem such as SAT, as captured by #P. Surprisingly, these two notions are related, as shown by the following celebrated theorem of Toda.

▶ **Theorem 1** (Toda's Theorem [30]). $\text{PH} \subseteq \text{P}^{\#\text{P}}$.

In the quantum setting, for QCPH, it can be shown using standard arguments involving enumeration over classical proofs that $\text{QCPH} \subseteq \text{PSPACE}$. However, we are able to provide the following stronger result.

▶ **Theorem 2** (A quantum-classical analogue of Toda's theorem). $\text{QCPH} \subseteq \text{P}^{\text{PP}^{\text{PP}}}$.

Thus, we "almost" recover the original bound of Toda's theorem[2], except we require an oracle for the *second* level of the Counting Hierarchy (CH). CH can be defined with its first level as $\mathbf{C}^p_1 = \text{PP}$ and its kth level for $k \geq 1$ as $\mathbf{C}^p_{k+1} = \text{PP}^{\mathbf{C}^p_k}$.

Why did we move up to the next level of CH? There are two difficulties in dealing with QCPH (see Section 2 for a detailed discussion). The first can be sketched as follows. Classically, many results involving PH, from basic ones implying the collapse of PH to more

[1] Recall that unlike a decision problem, for a promise problem $A = (A_{\text{yes}}, A_{\text{no}})$, it is not necessarily true that for all inputs $x \in \Sigma^*$, either $x \in A_{\text{yes}}$ or $x \in A_{\text{no}}$. In the case of proof systems such as QCPH, when $x \notin A_{\text{yes}} \cup A_{\text{no}}$, V can output an arbitrary answer.

[2] PP is the set of languages decidable in probabilistic polynomial time with unbounded error. Note $\text{P}^{\text{PP}} = \text{P}^{\#\text{P}}$.

advanced statements such as Toda's theorem, use the following recursive idea (demonstrated with Σ_2 for simplicity): By fixing the existentially quantified proof of Σ_2 the remnant reduces to a co-NP problem, i.e. we can recurse to a lower level of PH. In the quantum setting, however, this does not hold – fixing the existentially quantified proof for $\mathrm{QC}\Sigma_2$ does *not* necessarily yield a co-QCMA problem as some acceptance probabilities may fall in the $(1/3, 2/3)$ promise gap which cannot happen for a problem in co-QCMA! (This is due to the same phenomenon that has been an obstacle to resolving whether $\exists \cdot \mathrm{BPP}$ equals MA (see Remark 17).) Thus, we cannot directly generalize recursive arguments from the classical setting to the quantum setting. The second difficulty is trickier to explain briefly (see Section 2.2 for details). Roughly, Toda's proof that $\mathrm{PH} \subseteq \mathrm{P}^{\mathrm{PP}}$ crucially uses the Valiant-Vazirani (VV) theorem [31], which has one-sided error (i.e. VV may map YES instances of SAT to NO instances of UNIQUE-SAT, but NO instances of SAT are always mapped to NO instances of UNIQUE-SAT). The VV theorem for QCMA [5] also has this property, but in addition it can output instances which are "invalid". Essentially, they violate the promise of the problem that the QCMA-VV theorem maps to. Combining such *invalid* instances with *alternating* quantifiers, poses problems in extending the parity arguments used in Toda's proof to the QCPH setting.

To circumvent these difficulties, we exploit a high-level idea from [15] where an oracle for SPECTRAL GAP[3] was used to detect "invalid" QMA instances[4]. In our setting, the "correct" choice of oracle turns out to be a Precise-BQP oracle, where Precise-BQP is roughly BQP with an exponentially small promise gap. Using this, we are able to essentially "remove" the promise gap of QCPH altogether, thus recovering a "decision problem" which does not pose the difficulties above. Specifically, this mapping is achieved by Lemma 18 (Cleaning Lemma), which shows that $\forall i \in \mathbb{N},\ \mathrm{QC}\Sigma_i \subseteq \exists \cdot \forall \cdot \cdots \cdot Q_i \cdot \mathrm{P}^{\mathrm{PP}}$.

Notice that although we use a Precise-BQP oracle above, the Cleaning Lemma shows containment using a PP oracle. This is because, Precise-BQP $\subseteq$ PP as shown in Lemma 14 and Corollary 15. One may ask whether our proof technique would also work with an oracle *weaker* than PP. We show, in Theorem 27, that this is unlikely as the problem of detecting proofs in promise gaps of quantum verifiers is PP-complete.

Finally, an immediate corollary of Theorem 2 and the fact that $\mathrm{QMA}(2) \subseteq \mathrm{QPH}$ is:

▶ **Corollary 3.** *If* $\mathrm{QCPH} = \mathrm{QPH}$*, then* $\mathrm{QMA}(2) \subseteq \mathrm{P}^{\mathrm{PP}^{\mathrm{PP}}}$.

In other words, if alternating quantifiers are so powerful so as to make classical and quantum proofs equivalent in power, then it can be shown that QMA(2) is contained in CH (and thus in PSPACE). For comparison, $\mathrm{QMA} \subseteq \mathrm{P}^{\mathrm{QMA[log]}} \subseteq \mathrm{PP}$ [23, 33, 27, 15].

QPH versus NEXP. We next turn to the study of *quantum* proofs, i.e. QPH. As mentioned above, the best known upper bound on QMA(2) is NEXP – a non-deterministic verifier can simply guess an exponential-size description of the proof. When alternating quantifiers are present, however, this strategy seemingly no longer works. In other words, it is not even clear that QPH $\subseteq$ NEXP! This is in stark contrast to the explicit P^{PP} upper bound for PH [30]. In this section, our goal is to use semidefinite programming to give bounds on some levels of QPH. As we will see, this will yield the existence of a complexity class lying "between" QMA(2) and NEXP.

[3] This problem determines whether the spectral gap of a given local Hamiltonian is "small" or "large".
[4] This was used, in turn, to show in conjunction with [8] that SPECTRAL GAP is $\mathrm{P}^{\text{Unique-QMA[log]}}$-hard.

▶ **Theorem 4** (Informal Statement). *It holds that* $\mathrm{Q}\Sigma_2 \subseteq \mathrm{EXP}$ *and* $\mathrm{Q}\Pi_2 \subseteq \mathrm{EXP}$*, even when the completeness-soundness gap is inverse doubly-exponentially small.*

The proof idea is to map alternating quantifiers to an optimization problem with alternating minimizations and maximizations. Namely, to decide if $x \in A_{\mathrm{yes}}$ or $x \in A_{\mathrm{no}}$ for a $\mathrm{Q}\Sigma_i$ promise problem $A = (A_{\mathrm{yes}}, A_{\mathrm{no}})$, where i is even, we can solve for α defined as the optimal value of the optimization problem:

$$\alpha := \max_{\rho_1} \min_{\rho_2} \max_{\rho_3} \cdots \min_{\rho_i} \langle C, \rho_1 \otimes \rho_2 \otimes \cdots \otimes \rho_i \rangle \tag{3}$$

where C is the POVM operator[5] corresponding to the ACCEPT state of the verifier. This is a non-convex problem, and as such is hard to solve in general. Our approach is to cast the case of $i = 2$ as a semidefinite program (SDP), allowing us to *efficiently* approximate α.

The next natural question is whether a similar SDP reformulation might be used to show whether $\mathrm{Q}\Sigma_3$ or $\mathrm{Q}\Pi_3$ is contained in EXP. Unfortunately, this is likely to be difficult – indeed, if there existed a "nice" SDP for the optimal success probability of $\mathrm{Q}\Sigma_3$ protocols, then it would imply $\mathrm{QMA}(2) \subseteq \mathrm{EXP}$, resolving the longstanding open problem of separating QMA(2) from NEXP (recall $\mathrm{QMA}(2) \subseteq \mathrm{Q}\Sigma_3$). Likewise, a "nice" SDP for $\mathrm{Q}\Pi_3$ would place co-QMA(2) $\subseteq$ EXP.

To overcome this, we resort to non-determinism by stepping up to NEXP. Namely, one can non-deterministically guess the first proof of a $\mathrm{Q}\Sigma_3$ protocol, then approximately solve the SDP for the resulting $\mathrm{Q}\Pi_2$-flavoured computation. Hence, we have the following as a corollary of Theorem 28.

▶ **Theorem 5** (Informal Statement). *It holds true that* $\mathrm{QMA}(2) \subseteq \mathrm{Q}\Sigma_3 \subseteq \mathrm{NEXP}$ *and* co-QMA(2) $\subseteq \mathrm{Q}\Pi_3 \subseteq$ co-NEXP*, even when the completeness-soundness gap is inverse doubly-exponentially small. All the containments hold with equality in the inverse exponentially small completeness-soundness gap setting as* $\mathrm{QMA}(2) = \mathrm{NEXP}$ *in this case* [29].

Three remarks are in order. First, note that our results in this section are independent of the gate set. Second, in principle, it remains plausible that the fourth level of QPH already exceeds NEXP in power. Finally, we have the following implication for QMA(2). Assuming PH does not collapse, alternating quantifiers strictly add power to NP proof systems. If alternating quantifiers similarly add power in the quantum setting, then it would separate QMA(2) from NEXP via the following immediate corollary of Theorem 31.

▶ **Corollary 6.** *If* $\mathrm{QMA}(2) \neq \mathrm{Q}\Sigma_3$*, i.e. if the second universally quantified proof of* $\mathrm{Q}\Sigma_3$ *adds proving power, then* $\mathrm{QMA}(2) \neq \mathrm{NEXP}$*. Similarly, if* co-QMA(2) $\neq \mathrm{Q}\Pi_3$*, then* co-QMA(2) $\neq$ co-NEXP*.*

A quantum generalization of the Karp-Lipton Theorem. Finally, our last result studies a topic which is unrelated to QMA(2) – the well-known Karp-Lipton Theorem [21]. The latter shows that if NP-complete problems can be solved by polynomial-size non-uniform Boolean circuits, then $\Sigma_2 = \Pi_2$, which in turn implies that PH collapses to its second level. Here, a "non-uniform" circuit family means that the generation of a circuit for an input depends on the length of the input. The class of decision problems solved by such circuits is $\mathrm{P}_{/\mathrm{poly}}$.

▶ **Theorem 7** (Karp-Lipton [21]). *If* $\mathrm{NP} \subseteq \mathrm{P}_{/\mathrm{poly}}$ *then* $\Pi_2 = \Sigma_2$*.*

[5] A POVM is a set of Hermitian positive semi-definite operators that sums to the identity. In this case, the POVM has two operators – corresponding to the ACCEPT and REJECT states of the verifier.

In this work, we ask: Does $\mathrm{QCMA} \subseteq \mathrm{BQP}_{/\mathrm{mpoly}}$ imply $\mathrm{QC}\Pi_2 = \mathrm{QC}\Sigma_2$? Here, $\mathrm{BQP}_{/\mathrm{mpoly}}$ is the bounded-error analogue of $\mathrm{P}_{/\mathrm{poly}}$ with polynomial-size non-uniform quantum circuits (see Section 4 for formal definition). Unfortunately, generalizing the proof of the Karp-Lipton theorem is problematic for the same "$\exists \cdot \mathrm{BPP}$ versus MA phenomenon" encountered earlier in extending Toda's result. Namely, the proof of Karp-Lipton proceeds by fixing the outer, universally quantified, proof of a Π_2^p machine, and applying the $\mathrm{NP} \subseteq \mathrm{P}_{/\mathrm{poly}}$ hypothesis to the resulting NP computation. However, for $\mathrm{QC}\Pi_2$, it is not clear that fixing the outer, universally quantified, proof yields a QCMA computation; thus, it is not obvious how to use the hypothesis $\mathrm{QCMA} \subseteq \mathrm{BQP}_{/\mathrm{mpoly}}$.

To sidestep this, our approach is to strengthen the hypothesis. Specifically, using the results of [20] on perfect completeness for QCMA, fixing the outer proof of a $\mathrm{QC}\Pi_2$ computation can be seen to yield a Precise-QCMA "decision problem", where by "decision problem", we mean no proofs for the Precise-QCMA verifier are accepted within the promise gap. Here, Precise-QCMA is QCMA with exponentially small promise gap. We hence obtain:

▶ **Theorem 8** (A quantum-classical Karp-Lipton theorem)**.** *If* $\text{Precise-QCMA} \subseteq \mathrm{BQP}_{/\mathrm{mpoly}}$, *then* $\mathrm{QC}\Pi_2 = \mathrm{QC}\Sigma_2$.

To give this result context, we also show that $\text{Precise-QCMA} \subseteq \mathrm{NP}^{\mathrm{PP}}$ (Lemma 38). However, whether $\mathrm{QC}\Pi_2 = \mathrm{QC}\Sigma_2$ collapses QCPH remains open due to the same "$\exists \cdot \mathrm{BPP}$ versus MA phenomenon".

1.2 Related work

The first work we are aware of which considered a quantum version of PH is that of Yamakami [36], which differs from our setting in that it considers quantum Turing machines (we use quantum circuits) and quantum inputs (we use classical inputs, just like QMA). Gharibian and Kempe [14] next introduced and studied cq-Σ_2, defined as our $\mathrm{QC}\Sigma_2$ except with a quantum universally quantified proof. [14] showed completeness and hardness of approximation results for cq-Σ_2 for (roughly) the following problem: What is the smallest number of terms required in a given local Hamiltonian for it to have a frustrated ground space? More recently, Lockhart and González-Guillén [25] considered a hierarchy (denoted QCPH' here) which *a priori* appears identical to our QCPH, but is apparently not so due to the "$\exists \cdot \mathrm{BPP}$ versus MA phenomenon", which we discuss below.

In this work, the "$\exists \cdot \mathrm{BPP}$ versus MA phenomenon", refers to the following discrepancy (see Remark 17 for details) – unlike with MA, *all* proofs in an $\exists \cdot \mathrm{BPP}$ system *must* be accepted with probability at least 2/3 or at most 1/3 (i.e. no proof is accepted with probability in the gap $(1/3, 2/3)$). The quantum analogue of this phenomenon yields the open question: Is $\exists \cdot \mathrm{BQP} = \mathrm{NP}^{\mathrm{BQP}}$ equal to QCMA? For this reason, it is not clear whether QCPH equals QCPH'. The latter is defined as $\mathrm{QC}\Sigma_1' = \exists \cdot \mathrm{BQP}$, $\mathrm{QC}\Pi_1' = \forall \cdot \mathrm{BQP}$, and

$$\forall m \geq 1, \mathrm{QC}\Sigma_m' = \exists \cdot \mathrm{QC}\Pi_{m-1}'; \qquad \mathrm{QC}\Pi_m' = \forall \cdot \mathrm{QC}\Sigma_{m-1}'.$$

Clearly, for us $\mathrm{QC}\Sigma_1 = \mathrm{QCMA}$ but in [25] $\mathrm{QC}\Sigma_1' = \exists \cdot \mathrm{BQP}$. The benefit from the latter definition is that one avoids the recursion problems discussed earlier – e.g., fixing the first existential proof in $\mathrm{QC}\Sigma_2'$ *does* reduce the problem to a co-QCMA computation, unlike the case with $\mathrm{QC}\Sigma_2$. Hence, recursive arguments from the context of PH can be easily extended to show that, for instance, QCPH' collapses to $\mathrm{QC}\Sigma_2'$ when $\mathrm{QC}\Sigma_2' = \mathrm{QC}\Pi_2'$. On the other hand, the advantage of our definition of QCPH is that it generalizes a natural quantum complexity class like QCMA.

Let us also remark on Toda's theorem in the context of QCPH′ (for clarity, Toda's theorem is not studied in [25]). The recursive definition of QCPH′ allows one to obtain Toda's P^{PP} upper bound for QCPH′ with a simple argument:

$$\forall i,\ \mathrm{QC}\Sigma_i' = \mathrm{NP}^{\mathrm{NP}^{\cdot^{\cdot^{\cdot^{\mathrm{BQP}}}}}} = \Sigma_i^{\mathrm{BQP}} \quad \Longrightarrow \quad \forall i, \mathrm{QC}\Sigma_i' \subseteq (\mathrm{P}^{\mathrm{PP}})^{\mathrm{BQP}} = \mathrm{P}^{\mathrm{PP}},$$

where the first equality expressly holds due to the recursive definition of $\mathrm{QC}\Sigma_i'$ but is not known to hold for our $\mathrm{QC}\Sigma_i$; the implication arises by relativizing Toda's theorem; and the last equality holds as BQP is low for PP [13]. In contrast, our Theorem 2 yields $\mathrm{QCPH} \subseteq \mathrm{P}^{\mathrm{PP}^{\mathrm{PP}}}$, raising the question: is QCPH′ = QCPH? A positive answer may help shed light on whether $\exists \cdot \mathrm{BQP}$ equals QCMA; we leave this for future work.

Finally, a quantum version of the Karp-Lipton theorem was covered by Aaronson and Drucker in [3] and further improved by Aaronson, Cojocaru, Gheorghiu, and Kashefi [2], where the consequences of NP-complete problems being solved by small quantum circuits with polynomial sized quantum advice were considered. Their results differ from ours in that different hierarchies are studied, and in their use of quantum advice as opposed to our use of classical advice. Other Karp-Lipton style results for PH involving classes beyond NP show a collapse of PH to MA (usually) if either PP [26, 32], $\mathrm{P}^{\#\mathrm{P}}$ or PSPACE [21] has $\mathrm{P}_{/\mathrm{poly}}$ circuits.

1.3 Open questions

As the study of quantum generalizations of alternating quantifiers is in its infancy, many open questions exist. For example, due to the "$\exists \cdot \mathrm{BPP}$ versus MA phenomenon", we are not able to show "simple" collapse statements such as the following:

▶ **Conjecture 9.** *For $i \geq 1$, if $\mathrm{QC}\Sigma_i = \mathrm{QC}\Pi_i$ for any i, then* QCPH *collapses to the i^{th} level. Moreover, if* QCMA = BQP*, then* QCPH = BQP*.*

Next, can a non-trivial bound on QPH be shown? Here, we have shown that $\mathrm{Q}\Sigma_3 \subseteq \mathrm{NEXP}$; can the complexity of higher levels be bounded? Along these lines, our Theorem 4 shows $\mathrm{Q}\Sigma_2 \subseteq \mathrm{EXP}$; by applying alternative methods for approximating semidefinite programs arising in quantum complexity theory (see, e.g., [19]), we might also conjecture:

▶ **Conjecture 10.** $\mathrm{Q}\Sigma_2 \subseteq \mathrm{PSPACE}$.

Determining where in the complexity zoo QMA(2) lies remains an important open question; assuming alternating quantifiers *do* add proving power to QPH (the analogous assumption for PH is widely believed), our work shows QMA(2) is strictly contained in NEXP. Can this statement be strengthened?

Finally, we remark on defining a hierarchy similar to QCPH, termed MA-PH, where the first level is MA instead of QCMA and the verifier in equations (1) and (2) will be a BPP circuit. Due to the promise nature of the BPP verifier, we conjecture that the same issues faced with QCPH will translate to MA-PH too. Also, as Precise-BPP is equivalent to PP, we can obtain a similar Cleaning Lemma for MA-PH too. Hence, we conjecture that

▶ **Conjecture 11.** $\mathrm{PH} \subseteq \mathrm{MA\text{-}PH} \subseteq \mathrm{QCPH} \subseteq \mathrm{P}^{\mathrm{PP}^{\mathrm{PP}}}$.

Using other techniques that may harness the fact that BPP and MA are contained in PH to obtain a better bound for MA-PH is an interesting open question.

Organization. We begin in Section 2 by showing a quantum-classical analogue of Toda's theorem. Section 3 gives upper bounds on levels of QPH, and Section 4 shows a Karp-Lipton-type theorem. Formal definitions and many proofs are omitted from this version of the paper owing to space constraints.

2 A quantum-classical analogue of Toda's theorem

2.1 Precise-BQP

Our proof of a "quantum-classical Toda's theorem" requires us to define the Precise-BQP class, which we do now. Below, a promise problem is a pair $A = (A_{\text{yes}}, A_{\text{no}})$ such that $A_{\text{yes}}, A_{\text{no}} \subseteq \{0,1\}^*$, $A_{\text{yes}} \cup A_{\text{no}} \subset \{0,1\}^*$ and $A_{\text{yes}} \cap A_{\text{no}} = \emptyset$.

▶ **Definition 12** (Precise-BQP(c,s))**.** A promise problem $A = (A_{\text{yes}}, A_{\text{no}})$ is contained in Precise-BQP(c,s) for polynomial-time computable functions $c, s : \mathbb{N} \mapsto [0,1]$ if there exists a polynomially bounded function $p : \mathbb{N} \mapsto \mathbb{N}$ such that $\forall \ell \in \mathbb{N},\ c(\ell) - s(\ell) \geq 2^{-p(\ell)}$ and a polynomial-time uniform family of quantum circuits $\{V_n\}_{n\in\mathbb{N}}$ whose input is the all zeroes state and output is a single qubit. Furthermore, for an n-bit input x:

- Completeness: If $x \in A_{\text{yes}}$, then V_n accepts with probability at least c.
- Soundness: If $x \in A_{\text{no}}$, then V_n accepts with probability at most s.

In contrast, BQP is defined such that the completeness and soundness parameters are $2/3$ and $1/3$, respectively (alternatively, the gap is least an inverse polynomial in n).

▶ **Observation 13** (Rational acceptance probabilities)**.** *By fixing an appropriate universal gate set (e.g. Hadamard and Toffoli [4]) for the description of V_n in Definition 12, we assume henceforth, without loss of generality, that the acceptance probability of V_n is a rational number that can be represented using at most* $\text{poly}(n)$ *bits (this observation was used in the proof that* QCMA *has perfect completeness i.e., $c = 1$ [20].).*

The following help to characterize the complexity of Precise-BQP.

▶ **Lemma 14.** *For all $c, s \in [0,1]$ and every n-bit input such that $c - s \in \Omega(1/\exp(n))$,* Precise-BQP$(c,s) \subseteq$ PP*.*

▶ **Corollary 15.** *Let $\mathbb{P}$ denote the set of all polynomials $p : \mathbb{N} \mapsto \mathbb{N}$. Then,*

$$\bigcup_{p\in\mathbb{P}} \text{Precise-BQP}\left(\frac{1}{2} + \frac{1}{2^{p(n)}}, \frac{1}{2}\right) = \text{PP}.$$

2.2 Bounding the power of QCPH

Classically, PH can be defined in terms of the existential and universal operators; while it is not clear that one can also define QCPH using these operators, they nevertheless prove useful in bounding the power of QCPH.

▶ **Definition 16** (Existential and universal quantifiers [35, 7])**.** For $\mathcal{C}$ a class of languages, $\exists \cdot \mathcal{C}$ is defined as the set of languages L such that there is a polynomial p and set $A \in \mathcal{C}$ such that for input x, $x \in L \Leftrightarrow [\exists y\,(|y| \leq p(|x|))$ and $\langle x, y\rangle \in A]$. The set $\forall \cdot \mathcal{C}$ is defined similarly with $\exists$ replaced with $\forall$.

▶ **Remark 17** (Languages versus promise problems)**.** *Directly extending Definition 16 to promise problems, gives rise to subtle issues. To demonstrate, recall that* $\exists \cdot \text{P} = \text{NP}$*. Then,*

let (L, A) *for* $L \in \exists \cdot \mathrm{P} = \mathrm{NP}$ *and* $A \in \mathrm{P}$ *be as in Definition 16, such that* T_A *is a polynomial-time Turing machine deciding* A*. If* $x \in L$*, there exists a bounded length witness* y^* *such that* T_A *accepts* $\langle x, y^* \rangle$ *and, for all* $y' \neq y^*$*,* T_A *by definition either accepts or rejects* $\langle x, y' \rangle$*. Now consider instead* $\exists \cdot \mathrm{BPP}$*, which* a priori *seems equal to Merlin-Arthur (*MA*). Applying the same definition of* $\exists$*, we should obtain a* BPP *machine* T_A *such that if* $x \in L$*, then for all* $y' \neq y^*$*,* T_A either accepts or rejects $\langle x, y' \rangle$*. But this means, by definition of* BPP*, that* $\langle x, y' \rangle$ *is either accepted or rejected with probability at least* $2/3$*, respectively. (Equivalently, for any fixed* y*, the machine* $T_{A,y}$ *must be a* BPP *machine, or more generally a machine with the resources available to class* $\mathcal{C}$*.) Unfortunately, the definition of* MA makes no such promise – *any* $y' \neq y^*$ *can be accepted with arbitrary probability when* x *is a* YES *instance. Indeed, whether* $\exists \cdot \mathrm{BPP} = \mathrm{MA}$ *remains an open question [11].*

The following lemma is the main contribution of this section. To set context, adapting the ideas from Toda's proof of $\mathrm{PH} \subseteq \mathrm{P}^{\mathrm{PP}}$ to QCPH is problematic for at least two reasons:

1. Remark 17 says that it is not necessarily true that by fixing a proof y to an MA (resp. QCMA) machine, the resulting machine is a BPP (resp. BQP) machine. This prevents the direct extension of recursive arguments, say from [30] to this regime.
2. The "Quantum Valiant Vazirani (QVV)" theorem for QCMA (and MA) [5] is not a many-one reduction, but a *Turing* reduction. Specifically, it produces a set of quantum circuits $\{ Q_i \}$, *at least one of which* is guaranteed to be a YES instance of some Unique-QCMA promise problem Γ if the input Π to the reduction was a YES instance. Unfortunately, some of the Q_i may violate the promise gap of Γ, which implies that when such Q_i are substituted into the Unique-QCMA oracle O, O returns an arbitrary answer. This does not pose a problem in [5], as one-sided error suffices for that reduction – so long as O accepts at least one Q_i, one safely concludes Π was a YES instance. In the setting of Toda's theorem, however, the use of *alternating* quantifiers turns this one-sided error into two-sided error; this renders the output of O useless, as one can no longer determine whether Π was a YES or NO instance.

To sidestep these issues, we adapt a high-level idea from [15]: With the help of an appropriate *oracle*, one can sometimes detect "invalid proofs" (i.e. proofs in promise gaps of bounded error verifiers) and "remove" them. Indeed, we show that using a PP oracle, one can eliminate the promise-gap of QCPH altogether, thus overcoming the limitations given above. This is accomplished by the following "Cleaning Lemma".

▶ **Lemma 18** (Cleaning Lemma). *For all* $i \geq 0$*,* $\mathrm{QC}\Sigma_i \subseteq \exists \cdot \forall \cdot \cdots \cdot Q_i \cdot \mathrm{P}^{\text{Precise-BQP}} \subseteq \exists \cdot \forall \cdot \cdots \cdot Q_i \cdot \mathrm{P}^{\mathrm{PP}}$*, where* $Q_i = \exists$ *(*$Q_i = \forall$*) if* i *is odd (even). An analogous statement holds for* $\mathrm{QC}\Pi_i$*.*

Proof. Let C be a $\mathrm{QC}\Sigma_i$ verification circuit for a promise problem Π. Let $C_{y_1^*,\ldots,y_i^*}$ denote the quantum circuit obtained from C by fixing values $y_1^*, \ldots, y_i^*$ of the i classical proofs. In general, nothing can be said about the acceptance probability $p_{y_1^*,\ldots,y_i^*}$ of $C_{y_1^*,\ldots,y_i^*}$, except that, by Observation 13, $p_{y_1^*,\ldots,y_i^*}$ is a rational number representable using $p(n)$ bits for some fixed polynomial p. Let S denote the set of all rational numbers in $[0, 1]$ representable using $p(n)$ bits of precision. (Note $|S| \in \Theta(2^{p(n)})$.) Then, for any $a, b \in S$ with $a > b$, the triple $(C_{y_1^*,\ldots,y_i^*}, a, b)$ is a valid QCIRCUIT(a, b) instance, i.e. $C_{y_1^*,\ldots,y_i^*}$ accepts with probability at least a or at most b for $a - b$ an inverse exponential. It follows that using binary search (by varying the values $a, b \in S$ with $a > b$) in conjunction with $\mathrm{poly}(n)$ calls to a QCIRCUIT(a, b) oracle, we may exactly and deterministically compute $p_{y_1^*,\ldots,y_i^*}$. Moreover, since for all such $a > b$, QCIRCUIT$(a, b) \in$ Precise-BQP(a, b), Lemma 14 implies a QCIRCUIT(a, b) oracle call can be simulated with a PP oracle. Denote the binary search subroutine using the PP oracle as B.

Using C and B, we now construct an oracle Turing machine C' as follows. Given any proofs $y_1^*, \ldots, y_i^*$ as input, C' uses B to compute $p_{y_1^*,\ldots,y_i^*}$ for $C_{y_1^*,\ldots,y_i^*}$. If $p_{y_1^*,\ldots,y_i^*} \geq c$, C' accepts with certainty, and if $p_{y_1^*,\ldots,y_i^*} < c$, C' rejects with certainty. Suppose that the circuits C and C' return 1 when they accept and 0 when they reject. Two observations: (1) Since by construction, for any fixed $y_1^*, \ldots, y_i^*$, B makes only makes "valid" QCIRCUIT(a, b) queries (i.e. satisfying the promise of QCIRCUIT(a, b)), C' is a P^{PP} machine (cf. Observation 20). (2) Since $C'_{y_1^*,\ldots,y_i^*}$ accepts if $C_{y_1^*,\ldots,y_i^*}$ accepts with probability at least c, and since $C'_{y_1^*,\ldots,y_i^*}$ rejects if $C_{y_1^*,\ldots,y_i^*}$ accepts with probability at most s, we conclude that

$$\exists y_1 \forall y_2 \cdots Q_i y_i \, \mathrm{Prob}[C(y_1, \ldots, y_i) = 1] \geq c \quad \Leftrightarrow \quad \exists y_1 \forall y_2 \cdots Q_i y_i \; C'(y_1, \ldots, y_i) = 1 \quad (4)$$

$$\forall y_1 \exists y_2 \cdots \overline{Q}_i y_i \, \mathrm{Prob}[C(y_1, \ldots, y_i) = 1] \leq s \quad \Leftrightarrow \quad \forall y_1 \exists y_2 \cdots \overline{Q}_i y_i \; C'(y_1, \ldots, y_i) = 0. \quad (5)$$

(4) and (5) imply that we can simulate Π with a $\exists \cdot \forall \cdot \cdots \cdot Q_i \cdot \mathrm{P}^{\mathrm{PP}}$ computation. The proof for $\mathrm{QC}\Pi_i$ is analogous. ◀

▶ **Remark 19** (Possibility of a stronger containment). *A key question is whether one may replace the* Precise-BQP *oracle in the proof of Lemma 18 with a weaker* BQP *oracle. For example, consider the following alternate definition for oracle Turing machine C': Given proofs $y_1^*, \ldots, y_i^*$, C' plugs $C_{y_1^*,\ldots,y_i^*}$ into a BQP oracle and returns the oracle's answers. It is easy to see that in this case, Equations (4) and (5) hold. However, C' is* not *necessarily a $\mathrm{P}^{\mathrm{BQP}}$ machine, since for some settings of $y_1^*, \ldots, y_i^*$, its input to the* BQP *oracle may violate the BQP promise, hence making the output of C' ill-defined. To further illustrate this subtle point, consider Observation 20. Moreover, in Section 2.3 we show that the task the* Precise-BQP *oracle is used for in Lemma 18 is in fact PP-complete; thus, it is highly unlikely that one can substitute a weaker oracle into the proof above.*

▶ **Observation 20** (When a P machine querying a BQP oracle is not a $\mathsf{P}^{\mathsf{BQP}}$ machine). *The proof of the Cleaning Lemma uses a $\mathrm{P}^{\text{Precise-BQP}}$ machine. Let us highlight a subtle reason why using a weaker* BQP *oracle instead might be difficult (indeed, in Section 2.3 we show that the task we use the* Precise-BQP *oracle for is* PP*-complete). Let M denote the trivially* BQP*-complete problem of determining whether a given polynomial-sized quantum circuit Q accepts with probability at least $2/3$, or accepts with probability at most $1/3$, with the promise that one of the two is the case. Now consider the following polynomial time computation, Π, which is given access to an oracle O_M for M: Π inputs the Hadamard gate H into O_M and outputs O_M's answer. Does it hold that $\Pi \in \mathrm{P}^{\mathrm{BQP}}$? No. Since H violates the promise of BQP, i.e. measuring the output of H yields 0 or 1 with equal probability, the oracle O_M can answer 0 or 1 arbitrarily, and so the output of Π is not well-defined. Having a well-defined output, however, is required for a P^{O_K} computation, where K is any promise class [16].*

▶ **Lemma 21.** *For all $i \geq 0$, the following holds true: $\exists \cdot \forall \cdot \cdots \cdot Q_i \cdot \mathrm{P}^{\mathrm{PP}} \subseteq \Sigma_i^{\mathrm{PP}}$ and $\forall \cdot \exists \cdot \cdots \cdot Q_i \cdot \mathrm{P}^{\mathrm{PP}} \subseteq \Pi_i^{\mathrm{PP}}$ where $Q_i = \exists$ (resp. $Q_i = \forall$) when i is odd (resp. even) in the first containment and vica-versa for the second containment.*

We can now show the main theorem of this section.

▶ **Theorem 22.** $\mathrm{QCPH} \subseteq \mathrm{P}^{\mathrm{PP}^{\mathrm{PP}}}$.

Proof. The claim follows by combining the Cleaning Lemma (Lemma 18), Lemma 21, and Toda's theorem ($\mathrm{PH} \subseteq \mathrm{P}^{\mathrm{PP}}$), whose proof relativizes (see, e.g., page 4 of [12])). ◀

2.3 Detecting non-empty promise gaps is PP-complete

The technique behind the Cleaning Lemma (Lemma 18) can essentially be viewed as using a PP oracle to determine whether a given quantum circuit accepts some input with probability within the promise gap (s, c), where $c - s$ is an inverse polynomial. One can ask whether this rather powerful PP oracle can be replaced with a weaker oracle (see Remark 19)? We answer this in the negative unless one deviates from our specific proof approach; specifically, we show that the problem of detecting non-empty promise gaps is PP-complete, even if the gap is *constant* in size.

To begin, we define QCIRCUIT(c, s), which is trivially Precise-BQP(c, s)-complete when $c - s$ is an inverse exponential. (Take note that when the $c - s$ gap is larger, say inverse polynomial, QCIRCUIT(c, s) is still contained in Precise-BQP(c, s).)

▶ **Definition 23** (QCIRCUIT(c, s))**.** Parameters $c, s : \mathbb{N} \mapsto [0, 1]$ are polynomial-time computable functions such that $c > s$.

- (Input) A classical description of quantum circuit V_n (acting on n qubits, consisting of poly(n) 1 and 2-qubit gates), taking in the all-zeroes state, and outputting a single qubit.
- (Output) Decide if Pr$[V_n$ accepts $] \geq c$ or $\leq s$, assuming one of the two is the case.

▶ **Definition 24** (NON-EMPTY GAP(c, s))**.** Let V_n be an input for QCIRCUIT(c, s). Then, output YES if Prob$[V_n$ accepts $] \in (s, c)$, and NO otherwise.

We now show that NON-EMPTY GAP is PP-complete.

▶ **Lemma 25.** *For all c, s with the $c - s$ gap at least an inverse exponential in input size,* NON-EMPTY GAP$(c, s) \in$ PP*.*

▶ **Lemma 26.** *There exist $c, s \in \Theta(1)$ such that* NON-EMPTY GAP(c, s) *is* PP*-hard.*

▶ **Theorem 27.** *There exist $c, s \in \Theta(1)$ such that* NON-EMPTY GAP(c, s) *is* PP*-complete.*

3 Bounding the power of $\mathbf{Q\Sigma_2}$ and $\mathbf{Q\Sigma_3}$

Let $Q\Sigma_2(c, s)$ (resp., $Q\Pi_2(c, s)$) be defined as $Q\Sigma_2$ (resp., $Q\Pi_2$) with completeness and soundness parameters c and s, respectively. We begin by restating Theorem 4 as follows.

▶ **Theorem 28.** *For any polynomial r, if $c - s \geq 1/2^{2^{r(n)}}$, then $Q\Sigma_2(c, s) \subseteq$ EXP and $Q\Pi_2(c, s) \subseteq$ EXP when c and s are computable in exponential time in the size of the input.*

The two containments in Theorem 28 are proven separately in the following two lemmas.

▶ **Lemma 29.** *Let α be the maximum acceptance probability of a $Q\Sigma_2$ protocol (where the optimization is over the first proof ρ_1). Then one can compute γ such that $|\gamma - \alpha| \leq 1/2^{2^r}$, for any polynomial r, in exponential time.*

▶ **Lemma 30.** *Let α be the* minimum *acceptance probability of a $Q\Pi_2$ protocol (where the optimization is again over the first proof ρ_1). Then one can compute γ such that $|\gamma - \alpha| \leq 1/2^{2^r}$, for any polynomial r, in exponential time.*

We now sketch the exponential time protocol that calculates γ in Lemma 29 (we refer the reader to [17] for standard background in convex optimization). The proof of Lemma 30 is similar.

Proof Sketch. Recall from (3) that the maximum acceptance probability of a $\mathrm{QC}\Sigma_2$ protocol can be expressed as $\alpha := \max_{\rho_1} \min_{\rho_2} \langle C, \rho_1 \otimes \rho_2 \rangle$, where C is the POVM that corresponds to the quantum verification circuit in the $\mathrm{Q}\Sigma_2$ protocol accepting. We wish to decide in exponential time whether $\alpha \geq c$ or $\alpha \leq s$. Since the promise gap satisfies $c - s \geq 1/2^{2^{r(n)}}$, it suffices to approximate α within additive error (say) $\frac{1}{4}(c-s)$ by computing $\gamma \in \mathbb{R}$, in exponential time, such that $|\gamma - \alpha| \leq 1/(4 \cdot 2^{2^{r(n)}})$.

We begin by constructing C' as a numerical approximation to C such that each entry in C' is correct up to exponentially many bits. This can be done independent of the gate set used to describe the verification circuit, V_n, used for the $\mathrm{Q}\Sigma_2$ instance[6]. Then, for some polynomial r, $|\alpha - \alpha'| \leq \frac{1}{2} \cdot 2^{-2^{r(n)/2}}$ for

$$\alpha' := \max_{\rho_1} \min_{\rho_2} \{\langle C', \rho_1 \otimes \rho_2 \rangle : \mathrm{Tr}(\rho_1) = \mathrm{Tr}(\rho_2) = 1,\ \rho_1, \rho_2 \succeq 0\}. \tag{6}$$

Suppose we fix a feasible ρ_1 and solve the inner optimization problem in (6). Then:

$$\alpha'(\rho_1) := \min_{\rho_2} \{\langle C', \rho_1 \otimes \rho_2 \rangle : \mathrm{Tr}(\rho_2) = 1,\ \rho_2 \succeq 0\}.$$

We can rewrite $\langle C', \rho_1 \otimes \rho_2 \rangle$ as $\langle \mathrm{Tr}_1[(\rho_1 \otimes I)C'], \rho_2 \rangle$ where Tr_1 is the partial trace over the register that ρ_1 acts on. Additionally, as $\mathrm{Tr}_1[(\rho_1 \otimes I)C'] = \mathrm{Tr}_1[(\rho_1^{1/2} \otimes I)C(\rho_1^{1/2} \otimes I)]$, this term is Hermitian and positive semidefinite. This implies that the best choice for ρ_2 is a rank-1 projector onto the eigenspace corresponding to least eigenvalue. In other words, $\alpha'(\rho_1) = \lambda_{\min}(\mathrm{Tr}_1[(\rho_1 \otimes I)C'])$ where $\lambda_{\min}(X)$ denotes the least eigenvalue of a Hermitian operator X. For fixed ρ_1, this minimum eigenvalue calculation can be rephrased via the dual optimization program for $\alpha'(\rho_1)$,

$$\alpha'(\rho_1) = \max_{t} \{t : tI \preceq \mathrm{Tr}_1[(\rho_1 \otimes I)C']\}.$$

Re-introducing the maximization over ρ_1, we hence obtain

$$\alpha' = \max_{\rho_1, t} \{t : tI \preceq \mathrm{Tr}_1[(\rho_1 \otimes I)C'],\ \mathrm{Tr}(\rho_1) = 1,\ \rho_1 \succeq 0\}, \tag{7}$$

which is a semidefinite program. By using the ellpsoid method, we can hence solve this semidefinite program (see [17] for details) to obtain estimate γ of α'. Using an analysis similar to [34], we find a γ such that $|\gamma - \alpha'| \leq \epsilon$ with $\epsilon = 2^{-2^{r(n)}}$. ◀

Using the power of non-determinism, we can also bound the power of $\mathrm{Q}\Sigma_3$ and $\mathrm{Q}\Pi_3$.

▶ **Theorem 31.** *For any polynomial r and input size n, if $c - s \geq 1/r(n)$, then*

$$\mathrm{QMA}(2) \subseteq \mathrm{Q}\Sigma_3 \subseteq \mathrm{NEXP} \quad \textit{and} \quad \text{co-}\mathrm{QMA}(2) \subseteq \mathrm{Q}\Pi_3 \subseteq \text{co-}\mathrm{NEXP}, \tag{8}$$

where all classes have completeness and soundness c and s, respectively. Moreover, if we allow smaller gaps (in principle, gaps which are at most inverse singly exponential in n suffice for the first claim below), such as $c - s \geq 1/2^{2^{r(n)}}$, then

$$\mathrm{QMA}(2)(c,s) = \mathrm{Q}\Sigma_3(c,s) = \mathrm{NEXP} \quad \textit{and} \quad \text{co-}\mathrm{QMA}(2)(c,s) = \mathrm{Q}\Pi_3(c,s) = \text{co-}\mathrm{NEXP}. \tag{9}$$

Here, we assume c and s are computable in exponential time in the size of the input.

---

[6] This can be accomplished in exponential time as follows: Replace gate set G with G' by approximating each entry of each gate in G using $2^{s(n)}$ bits of precision, for some sufficiently large, fixed polynomial s. Define C' as C, except each use of a gate $U \in G$ is replaced with its approximation $U' \in G'$. Then, via the well-known bound $\|U_m \cdots U_1 - V_m \cdots V_1\|_\infty \leq \sum_{i=1}^m \|U_i - V_i\|_\infty$ (for unitary U_i, V_i), it follows that $\left\|C' - C\right\|_\infty \in O(\mathrm{poly}(n)/(2^{2^{s(n)}}))$, since V_n contains $\mathrm{poly}(n)$ gates. Here, $\|A\|_\infty = \max_{|\psi\rangle} \|A|\psi\rangle\|_2$ for unit vectors $|\psi\rangle$ denotes the spectral or operator norm. Finally, apply the fact that $\max_{i,j} |A(i,j)| \leq \|A\|_\infty$ (p. 314 of [18]).

4 Karp-Lipton type theorems

The Karp-Lipton [21] theorem showed that if NP $\subseteq$ P$_{/\text{poly}}$ (i.e. if NP can be solved by polynomial-size non-uniform circuits), then $\Sigma_2 = \Pi_2$ (which in turn collapses PH collapses to its second level). Then, building on the conjecture that the polynomial hierarchy is infinite, this result implies that NP $\not\subset$ P$_{/\text{poly}}$ (a stronger claim than P $\neq$ NP as P $\subseteq$ P$_{/\text{poly}}$). Some attempts to separate NP from P use this as a basis to try and prove the stronger claim instead. For instance, this has lead to the approach of proving super-polynomial circuit lower bounds for circuits of NP-complete problems. Here, we show that the proof technique of Karp and Lipton carries over easily to the quantum setting, *provided* one uses the stronger hypothesis Precise-QCMA $\subseteq$ BQP$_{/\text{mpoly}}$ (as opposed to QCMA $\subseteq$ BQP$_{/\text{mpoly}}$). Whether this causes QCPH to collapse to its second level, however, remains open (see Remark 37 below). We begin by formally defining the classes BQP$_{/\text{mpoly}}$ and Precise-QCMA.

▶ **Definition 32** (BQP$_{/\text{mpoly}}$)**.** A promise problem $\Pi = (A_{\text{yes}}, A_{\text{no}})$ is in BQP$_{/\text{mpoly}}$ if there exists a polynomial-sized family of quantum circuits $\{C_n\}_{n\in\mathbb{N}}$ and a collection of binary advice strings $\{a_n\}_{n\in\mathbb{N}}$ with $|a_n| = \text{poly}(n)$, such that for all n and all strings x where $|x| = n$, $\Pr[C_n(|x\rangle, |a_n\rangle) = 1] \geq 2/3$ if $x \in A_{\text{yes}}$ and $\Pr[C_n(|x\rangle, |a_n\rangle) = 1] \leq 1/3$ if $x \in A_{\text{no}}$.

Equivalently, BQP$_{/\text{mpoly}}$ is the set of promise problems solvable by a *non-uniform* family of polynomial-sized bounded error quantum circuits. It is used as a quantum analogue for P$_{/\text{poly}}$ in this scenario. Here, we remark on the use of mpoly instead of poly in Definition 32. Note that BQP$_{/\text{poly}}$ accepts Karp-Lipton style advice i.e. it is a BQP circuit that accepts a poly-sized advice string to provide *some answer* with probability at least 2/3 even if the "advice is bad". On the other hand, BQP$_{/\text{mpoly}}$ accepts Merlin style advice i.e. it is a BQP circuit accepting poly-sized classical advice such that the output is correct with probability at least 2/3 if the "advice is good". Note BQP$_{/\text{poly}}$ versus BQP$_{/\text{mpoly}}$ is analogous to the "$\exists \cdot$BPP versus MA" phenomenon. Moreover, as we are concerned with variations of QCMA, and not $\exists \cdot$BQP, BQP$_{/\text{mpoly}}$ is the right candidate for us.

▶ **Definition 33** (Precise-QCMA)**.** A promise problem $A = (A_{\text{yes}}, A_{\text{no}})$ is said to be in Precise-QCMA(c, s) for polynomial-time computable functions $c, s : \mathbb{N} \mapsto [0, 1]$ if there exists polynomially bounded functions $p, q : \mathbb{N} \mapsto \mathbb{N}$ such that $\forall \ell \in \mathbb{N}$, $c(\ell) - s(\ell) \geq 2^{-q(\ell)}$, and there exists a polynomial-time uniform family of quantum circuits $\{V_n\}_{n\in\mathbb{N}}$ that takes a classical proof $y \in \{0, 1\}^{p(n)}$ and outputs a single qubit. Moreover, for an n-bit input x:

- Completeness: If $x \in A_{\text{yes}}$, then $\exists\ y$ such that V_n accepts y with probability at least c.
- Soundness: If $x \in A_{\text{no}}$, then $\forall\ y$, V_x accepts y with probability at most s.

Define Precise-QCMA $= \bigcup_{c,s}$ Precise-QCMA(c, s).

As an aside, note that QCMA is defined with $c - s \in \Omega(1/\text{poly}(n))$. Recall from the discussion in Section 1.1 that the main obstacle to the recursive arguments that work well for NP in [21] is the "promise problem" nature of QCΠ_2 and QCMA. However, exploiting the perfect completeness of Precise-QCMA[7] and the fact that $\forall c < s' \leq s$, Precise-QCMA$(c, s) \subseteq$ Precise-QCMA(c, s'), we "recover" the notion of a decision problem in a rigorous sense by working with Precise-QCMA as demonstrated below.

[7] The perfect completeness proof for QCMA also works in the inverse exponentially small gap setting [20].

▶ **Claim 34.** *For every promise problem* $\Pi' = (A_{\text{yes}}, A_{\text{no}}) \in \text{Precise-QCMA}(c, s)$ *with verifier* V'*, there exists a verifier* V *(a poly-time uniform quantum circuit family), a polynomial* q *and a decision problem* $\Pi = (A_{\text{yes}}, \{0,1\}^* \setminus A_{\text{yes}})$ *such that* $\Pi \in \text{Precise-QCMA}(1, 1-2^{-q(n)})$ *with verifier* V*. Moreover, for all proofs* y*,* V *accepts* y *with probability either* 1 *or at most* $1-2^{-q(n)}$*.*

Building on this "decision problem" flavour of Precise-QCMA, we first show:

▶ **Lemma 35.** *Suppose* $\text{Precise-QCMA} \subseteq \text{BQP}_{/\text{mpoly}}$*. Then, for every promise problem* $\Pi = (A_{\text{yes}}, A_{\text{no}})$ *in* Precise-QCMA *and every* n*-bit input* x*, there exists a polynomially bounded function* $p : \mathbb{N} \mapsto \mathbb{N}$ *and a bounded error polynomial time non-uniform quantum circuit family* $\{C_n\}_{n\in\mathbb{N}}$ *such that:*

- *if* $x \in A_{\text{yes}}$*, then* C_n *outputs valid proof* $y \in \{0,1\}^{p(n)}$ *such that* (x, y) *is accepted by the corresponding* Precise-QCMA *verifier with probability* 1*;*
- *if* $x \in A_{\text{no}}$*, then* C_n *outputs a symbol* $\perp$ *with probability exponentially close to* 1 *signifying that there is no* $y \in \{0,1\}^{p(n)}$*, such that* (x, y) *is accepted by the corresponding* Precise-QCMA *verifier with probability* 1*.*

We next give a quantum-classical analogue of the Karp-Lipton theorem, whose proof is in the appendix.

▶ **Theorem 36** (A Quantum-Classical Karp-Lipton Theorem)**.** *If* $\text{Precise-QCMA} \subseteq \text{BQP}_{/\text{mpoly}}$ *then* $\text{QC}\Pi_2 = \text{QC}\Sigma_2$*.*

▶ **Remark 37** (Collapse of QCPH?)**.** *An appeal of the classical Karp-Lipton theorem is that it implies that if* $\text{NP} \subseteq \text{P}_{/\text{poly}}$*, then PH collapses to its second level; this is because if* $\Pi_2^p = \Sigma_2^p$*, then* PH *collapses to* Σ_2^p*. Does an analogous statement hold for* QCPH *as a result of Theorem 8? Unfortunately, the answer is not clear. The problem is similar to that outlined in Remark 17. Namely, classically* $\Pi_2^p = \Sigma_2^p$ *collapses* PH *since for any* Π_3^p *decision problem, fixing the first (universally) quantified proof yields a* Σ_2^p *computation. But this can be replaced with a* Π_2^p *computation by assumption, yielding a computation with quantifiers* $\forall\forall\exists$*, which trivially collapses to* $\forall\exists$*, i.e.* $\Pi_3^p \subseteq \Pi_2^p$*. In contrast, for (say)* $\text{QC}\Pi_3$*, similar to the phenomenon in Remark 17, fixing the first (universally) quantified proof does* not *necessarily yield a* $\text{QC}\Sigma_2^p$ *computation. Thus, a recursive application of the assumption* $\text{QC}\Sigma_2^p = \text{QC}\Pi_2^p$ *cannot straightforwardly be applied.*

Since Precise-QCMA plays an important role in Theorem 8, we close with an upper bound on Precise-QCMA.

▶ **Lemma 38.** $\text{Precise-QCMA} \subseteq \text{NP}^{\text{PP}}$*.*

Proof. Let V be a Precise-QCMA verifier. Using Claim 34, we may assume that for any proof y, V either accepts y with probability 1 or rejects with probability at most $1-2^{-q(n)}$. Thus, for any fixed y, the resulting computation V_y is a Precise-BQP computation. This implies $\text{Precise-QCMA} \subseteq \exists \cdot \text{Precise-BQP}$ (see also Remark 17). But by Definition 16, $\exists \cdot \text{Precise-BQP} \subseteq \text{NP}^{\text{Precise-BQP}}$. Combining this with Lemma 14, which says that $\text{Precise-BQP} \subseteq \text{PP}$, yields the claim. ◀

Abstract

Given a set X of n binary words of equal length w, the 3XOR problem asks for three elements $a, b, c \in X$ such that $a \oplus b = c$, where $\oplus$ denotes the bitwise XOR operation. The problem can be easily solved on a word RAM with word length w in time $O(n^2 \log n)$. Using Han's fast integer sorting algorithm (STOC/J. Algorithms, 2002/2004) this can be reduced to $O(n^2 \log \log n)$. With randomization or a sophisticated deterministic dictionary construction, creating a hash table for X with constant lookup time leads to an algorithm with (expected) running time $O(n^2)$. At present, seemingly no faster algorithms are known.

We present a surprisingly simple deterministic, quadratic time algorithm for 3XOR. Its core is a version of the PATRICIA tree for X, which makes it possible to traverse the set $a \oplus X$ in ascending order for arbitrary $a \in \{0,1\}^w$ in linear time. Furthermore, we describe a randomized algorithm for 3XOR with expected running time $O(n^2 \cdot \min\{\frac{\log^3 w}{w}, \frac{(\log \log n)^2}{\log^2 n}\})$. The algorithm transfers techniques to our setting that were used by Baran, Demaine, and Pătraşcu (WADS/Algorithmica, 2005/2008) for solving the related int3SUM problem (the same problem with integer addition in place of binary XOR) in expected time $o(n^2)$. As suggested by Jafargholi and Viola (Algorithmica, 2016), linear hash functions are employed.

The latter authors also showed that assuming 3XOR needs expected running time $n^{2-o(1)}$ one can prove conditional lower bounds for triangle enumeration just as with 3SUM. We demonstrate that 3XOR can be reduced to other problems as well, treating the examples offline SetDisjointness and offline SetIntersection, which were studied for 3SUM by Kopelowitz, Pettie, and Porat (SODA, 2016).

1 Introduction

The 3XOR problem [19] is the following: Given a set X of n binary strings of equal length w, are there elements $a, b, c \in X$ such that $a \oplus b = c$, where $\oplus$ is bitwise XOR? We work with the word RAM (Random Access Machine) [13] model with word length $w = \Omega(\log n)$, and we assume as usual that one input string fits into one word. Then, using sorting, the problem can easily be solved in time $O(n^2 \log n)$. Using Han's fast integer sorting algorithm [18] the time can be reduced to $O(n^2 \log \log n)$. In order to achieve quadratic running time, one could utilize a randomized dictionary for X with expected linear construction time and constant lookup time (like in [12]) or (weakly non-uniform, quite complicated) deterministic static dictionaries with construction time $O(n \log n)$ and constant lookup time as provided in [17]. Once such a dictionary is available, one just has to check whether $a \oplus b \in X$, for all pairs $a, b \in X$. No subquadratic algorithms seem to be known.

It is natural to compare the situation with that for the 3SUM problem, which is as follows:[1] Given a set X of n real numbers, are there $a, b, c \in X$ such that $a + b = c$? There is a very simple quadratic time algorithm for this problem (see Section 3 below). After a randomized subquadratic algorithm was suggested by Grønlund Jørgensen and Pettie [20], improvements ensued [14, 16], and recently Chan [8] gave the fastest deterministic algorithm known, with a running time of $n^2(\log \log n)^{O(1)}/\log^2 n$. The restricted version where the input consists of integers whose bit length does not exceed the word length w is called int3SUM. The currently best randomized algorithm for int3SUM was given by Baran, Demaine, and Pătraşcu [2, 3]; it runs in expected time $O(n^2 \cdot \min\{\frac{\log^2 w}{w}, \frac{(\log \log n)^2}{\log^2 n}\})$ for $w = O(n \log n)$. The 3SUM problem has received a lot of attention in recent years, because it can be used as a basis for conditional lower time bounds for problems, for instance, from computational geometry and data structures [15, 22, 26]. Because of this property, 3SUM is in the center of attention of papers dealing with low-level complexity. Chan and Lewenstein [9] give upper bounds for inputs with a certain structure. Kane, Lovett, and Moran [21] prove near-optimal upper bounds for linear decision trees. Wang [28] considers randomized algorithms for subset sum, trying to minimize the space, and Lincoln et al. [23] investigate time-space tradeoffs in deterministic algorithms for k-SUM. Barba et al. [4] examine a generalization of 3SUM in which the sum function is replaced by a constant-degree polynomial in three variables. Chan [7] shows how to adapt the ideas of the subquadratic int3SUM algorithm to the general position problem.

In contrast, 3XOR received relatively little attention, before Jafargholi and Viola [19] studied 3XOR and described techniques for reducing this problem to triangle enumeration. In this way they obtained conditional lower bounds in a way similar to the conditional lower bounds based on int3SUM.

The main results of this paper are the following: (1) We present a surprisingly simple deterministic algorithm for 3XOR that runs in time $O(n^2)$ (Theorem 5). When X is given in sorted order, it constructs in linear time a version of the PATRICIA tree [25] for X, using only word operations and not looking at single bits at all. This tree then makes it possible to traverse the set $a \oplus X$ in ascending order in linear time, for arbitrary $a \in \{0,1\}^w$. This is sufficient for achieving running time $O(n^2)$. (2) The second result is a randomized algorithm for 3XOR that runs in time $O(n^2 \cdot \min\{\frac{\log^3 w}{w}, \frac{(\log \log n)^2}{\log^2 n}\})$ for $w = O(n \log n)$ (Theorem 7),

[1] There are many different, but equivalent versions of 3SUM and 3XOR, differing in the way the input elements are grouped. Often one sees the demand that the three elements a, b, and c with $a \oplus b = c$ or $a + b = c$, resp., come from different sets.

which is almost the same bound as that of [2] for int3SUM. Finding a deterministic algorithm for 3XOR with subquadratic running time remains an open problem. (3) Finally, we reduce 3XOR to offline SetDisjointness (Theorem 10) and offline SetIntersection (Theorem 11), establishing the conditional lower bound $n^{2-o(1)}$ (as in [22] conditioned on the int3SUM conjecture).

Unfortunately, no (non-trivial) relation between the required (expected) time for 3SUM and 3XOR is known. In particular, we cannot exclude the case that one of these problems can be solved in (expected) time $O(n^{2-\varepsilon})$ for some constant $\varepsilon > 0$ whereas the other one requires (expected) time $n^{2-o(1)}$. Actually, this possibility is the background of some conditional statements on the cost of listing triangles in graphs in [19, Cor. 2]. However, due to the similarity of 3XOR to 3SUM, the question arises whether the recent results on 3SUM can be transferred to 3XOR.

In Section 2, we review the word RAM model and examine 1-universal classes of linear hash functions. In particular, we determine the evaluation cost of such hash functions and we restate a hashing lemma [2] on the expected number of elements in "overfull" buckets. Furthermore, we state how fast one can solve the set intersection problem on word-packed arrays. In Section 3, we construct a special enhanced binary search tree T_X to represent a set X of binary strings of fixed length. This representation makes it possible to traverse the set $a \oplus X$ in ascending order for any $a \in \{0,1\}^w$ in linear time, which leads to a simple deterministic algorithm for 3XOR that runs in time $O(n^2)$. Then, we turn to randomized algorithms and show how to solve 3XOR in subquadratic expected time in Section 4: $O(n^2 \cdot \min\{\frac{\log^3 w}{w}, \frac{(\log\log n)^2}{\log^2 n}\})$ for $w = O(n \log n)$, and $O(n \log^2 n)$ for $n \log n \leq w = O(2^{n \log n})$. Our approach uses the ideas of the subquadratic expected time algorithm for int3SUM presented in [2], i. e., computing buckets and fingerprints, word packing, exploiting word-level parallelism, and using lookup tables to solve the set intersection problem on word-packed arrays. Altogether, we get the same expected running time for $w = O(\log^2 n)$ and a word-length-dependent upper bound on the expected running time for $w = \omega(\log^2 n)$ that is worse by a $\log w$ factor in comparison to the int3SUM setting. Based on these results and the similarity of 3XOR to int3SUM, it seems natural to conjecture that 3XOR requires expected time $n^{2-o(1)}$, too, and so 3XOR is a candidate for reductions to other computational problems just as 3SUM. In Section 5, we describe how to reduce 3XOR to offline SetDisjointness and offline SetIntersection, transferring the results of [22] from int3SUM to 3XOR.

Recently, Bouillaguet et al. [6] studied algorithms "for the 3XOR problem". This is related to our setting, but not identical. These authors study a variant of the "generalized birthday problem", well known in cryptography as a problem to which some attacks on cryptosystems can be reduced, see [6]. Translated into our notation, their question is: Given a *random* set $X \subseteq \{0,1\}^w$ of size $3 \cdot 2^{w/3}$, find, if possible, three different strings $a, b, c \in X$ such that $a \oplus b = c$. Adapting the algorithm from [2], these authors achieve a running time of $O(2^{2w/3}(\log^2 w)/w^2)$, which corresponds to the running time of our algorithm for $n = 3 \cdot 2^{w/3}$. The difference to our situation is that their input is random. This means that the issue of 1-universal families of linear hash functions disappears (a projection of the elements in X on some bit positions does the job) and that complications from weak randomness are absent (e. g., one can use projection into relatively small buckets and use Chernoff bounds to prove that the load is very even with high probability). This means that the algorithm described in [6] does not solve our version of the 3XOR problem.

2 Preliminaries

2.1 The Word RAM Model

As is common in the context of fast algorithms for the int3SUM problem [2], we base our discussion on the *word RAM model* [13]. This is characterized by a word length w. Each memory cell can store w bits, interpreted as a bit string or an integer or a packed sequence of subwords, as is convenient. The word length w is assumed to be at least $\log n$ and at least the bit length of a component of the input. It is assumed that the operations of the *multiplicative instruction set*, i. e., arithmetic operations (addition, subtraction, multiplication), word operations (left shift, right shift), bitwise Boolean operations (AND, OR, NOT, XOR), and random memory accesses can be executed in constant time. We will write $\oplus$ to denote the bitwise XOR operation. A *randomized* word RAM also provides an operation that in constant time generates a uniformly random value in $\{0, 1, \ldots, v-1\}$ for any given $v \leq 2^w$.

2.2 Linear Hash Functions

We consider hash functions $h\colon U \to M$, where the domain ("universe") U is $\{0,1\}^\ell$ and the range M is $\{0,1\}^\mu$ with $\mu \leq \ell$. Both universe and range are vector spaces over $\mathbb{Z}_2$. In [2] and in successor papers on int3SUM "almost linear" hash functions based on integer multiplication and truncation were used, as can be found in [10]. As noted in [19], in the 3XOR setting the situation is much simpler. We may use $\mathcal{H}^{\text{lin}}_{\ell,\mu}$, the set of all $\mathbb{Z}_2$-linear functions from U to M. A function h_A from this family is described by a $\mu \times \ell$ matrix A, and given by $h_A(x) = A \cdot x$, where $x = (x_0, \ldots, x_{\ell-1})^\mathsf{T} \in U$ and $h_A(x) \in M$ are written as column vectors. For all hash functions $h \in \mathcal{H}^{\text{lin}}_{\ell,\mu}$ and all $x, y \in U$ we have $h(x \oplus y) = h(x) \oplus h(y)$, by the very definition of *linearity*. Further, this family is 1-*universal*, indeed, we have $\mathbf{Pr}_{A\in\{0,1\}^{\mu\times\ell}}[\,h_A(x) = h_A(y)\,] = \mathbf{Pr}_{A\in\{0,1\}^{\mu\times\ell}}[\,h_A(x\oplus y) = 0\,] = 2^{-\mu} = 1/|M|$, for all pairs x, y of different keys in U. We remark that the convolution class described in [24], a subfamily of $\mathcal{H}^{\text{lin}}_{\ell,\mu}$, can be used as well, as it is also 1-universal, and needs only $\ell + \mu - 1$ random bits.

The universe we consider here is $\{0,1\}^w$. The time for evaluating a hash function $h \in \mathcal{H}^{\text{lin}}_{w,\mu}$ on one or on several inputs depends on the instruction set and on the way $h = h_A$ is stored. In contrast to the int3SUM setting [2], we are not able to calculate hash values in constant time.

▶ **Lemma 1.** *For $h \in \mathcal{H}^{\text{lin}}_{w,\mu}$ and inputs from $\{0,1\}^w$ we have:*
(a) *$h(x)$ can be calculated in time $O(\mu)$, if* PARITY *of w-bit words is a constant time operation.*
(b) *$h(x)$ can always be calculated in time $O(\mu + \log w)$.*
(c) *$h(x_1), \ldots, h(x_n)$ can be evaluated in time $O(n\mu + \log w)$.*

Proof. (Sketch.) Assume $h = h_A$. For (a) we store the rows of A as w-bit strings, and obtain each bit of the hash value by a bitwise $\wedge$ operation followed by PARITY. For (b) we assume the w columns of A are stored as μ-bit blocks, in $O(\mu)$ words. An evaluation is effected by selecting the columns indicated by the 1-bits of x and calculating the $\oplus$ of these vectors in a word-parallel fashion. In $\log w$ rounds, these vectors are added, halving the number of vectors in each round. For (c), we first pack the columns selected for the n input strings into $O(n\mu)$ words and then carry out the calculation indicated in (b), but simultaneously for all x_i and within as few words as possible. This makes it possible to further exploit word-level parallelism, if μ should be much smaller than w. ◀

We shall use linear, 1-universal hashing for splitting the input set into buckets and for replacing keys by fingerprints in Section 4.

▶ Remark. In the following, we will apply Lemma 1(c) to map n binary strings of length w to hash values of length $\mu = O(\log n)$ in time $O(n \log n + \log w)$. Since $\log w$ will dominate the running time only for huge word lengths, we assume in the rest of the paper that $w = 2^{O(n \log n)}$ and that all hash values can be calculated in time $O(n \log n)$.

▶ Remark. When randomization is allowed, we will assume that we have constructed in expected $O(n)$ time a standard hash table for input set X with constant lookup time [12]. (Arbitrary 1-universal classes can be used for this.)

2.3 A Hashing Lemma for 1-Universal Families

A hash family $\mathcal{H}$ of functions from U to M is called *1-universal* if $\mathbf{Pr}_{h\in\mathcal{H}}[\, h(x) = h(y)\,] \leq 1/|M|$ for all $x, y \in U$, $x \neq y$. We map a set $S \subseteq U$ with $|S| = n$ into M with $|M| = m$ by a random element $h \in \mathcal{H}$. In [2, Lemma 4] it was noted that for 1-universal families the expected number of keys that collide with more than $3n/m$ other keys is bounded by $O(m)$. We state a slightly stronger version of that lemma. (The strengthening is not essential for the application in the present paper.)

▶ **Lemma 2** (slight strengthening of Lemma 4 in [2]). *Let $\mathcal{H}$ be a 1-universal class of hash functions from U to M, with $m = |M|$, and let $S \subseteq U$ with $|S| = n$. Choose $h \in \mathcal{H}$ uniformly at random. For $i \in M$ define $B_i = \{y \in S \mid h(y) = i\}$. Then for $2\frac{n}{m} < t \leq n$ we have:*

$$\mathbf{E}_{h\in\mathcal{H}}[\,|\{x \in S \mid |B_{h(x)}| \geq t\}|\,] < \frac{n}{t - 2\frac{n}{m}}$$

(The bound in [2] was about twice as large. The proof is given in the full version [11].)

In our algorithm, we will be interested in the number of elements in buckets with size at least three times the expectation. Choosing $t = 3\frac{n}{m}$ in Lemma 2, we conclude that the expected number of such elements is smaller than the number of buckets.

▶ **Corollary 3.** *In the setting of Lemma 2 we have* $\mathbf{E}_{h\in\mathcal{H}}[\;|\{\, x \in S \mid |B_{h(x)}| \geq 3n/m \,\}|\;] < m$.

2.4 Set Intersection on Unsorted Word-Packed Arrays

We consider the problem "*set intersection on unsorted word-packed arrays*": Assume k and ℓ are such that $k(\ell + \log k) \leq w$, and that two words a and b are given that both contain k many ℓ-bit strings: a contains $a_0, \ldots, a_{k-1}$ and b contains $b_0, \ldots, b_{k-1}$. We wish to determine whether $\{a_0, \ldots, a_{k-1}\} \cap \{b_0, \ldots, b_{k-1}\}$ is empty or not and find an element in the intersection if it is nonempty.

In [3, proof of Lemma 3] a similar problem is considered: It is assumed that a is sorted and b is *bitonic*, meaning that it is a cyclic rotation of a sequence that first grows and then falls. In this case one sorts the second sequence by a word-parallel version of bitonic merge (time $O(\log k)$), and then merges the two sequences into one sorted sequence (again in time $O(\log k)$). Identical elements now stand next to each other, and it is not hard to identify them. We can use a slightly slower modification of the approach of [3]: We sort both sequences by word-packed bitonic sort [1] (simulating Batcher's *bitonic sort* sorting network [5] on a word-packed array), which takes time $O(\log^2 k)$, and then proceed as before.[2] We obtain the following result.

[2] It is this slower version of packed intersection that causes our randomized 3XOR algorithm to be a little slower than the int3SUM algorithm for $w = \omega(\log^2 n)$.

Algorithm 1: A simple quadratic 3SUM algorithm.

```
1  Algorithm 3SUM(X):
2      sort X as x_1 < ··· < x_n
3      for a ∈ X do
4          (i, j) ← (1, 1)
5          while i ≤ n AND j ≤ n do
6              if a + x_i < x_j then
7                  i ← i + 1
8              else if a + x_i > x_j
                then
9                  j ← j + 1
10             else return (a, x_i, x_j)
11     return no solution
```

Algorithm 2: A quadratic 3XOR algorithm.

```
1  Algorithm 3XOR(X):
2      sort X as x_1 < ··· < x_n
3      T_X ← makeTree(X)
4      for a ∈ X do
5          (i, j) ← (1, 1)
6          (y_i)_{1≤i≤n} ← traverse(T_X, a)
7          while i ≤ n AND j ≤ n do
8              if y_i < x_j then
9                  i ← i + 1
10             else if y_i > x_j then
11                 j ← j + 1
12             else return (a, y_i ⊕ a, x_j)
13     return no solution
```

▶ **Lemma 4.** *Assume $k(\ell + \log k) = O(w)$, and assume that two sequences of ℓ-bit strings, each of length k, are given. Then the t entries that occur in both sequences can be listed in time $O(\log^2 k + t)$.*

A more detailed description is given in the full version [11].

3 A Deterministic 3XOR Algorithm in Quadratic Time

A well known deterministic algorithm for solving the 3SUM problem in time $O(n^2)$ is reproduced in Algorithm 1. After sorting the input X as $x_1 < \cdots < x_n$ in time $O(n \log n)$, we consider each $a \in X$ separately and look for triples of the form $a + b = c$. Such triples correspond to elements of the intersection of $a + X = \{a + x_1, \ldots, a + x_n\}$ and X. Since X is sorted, we can iterate over both X and $a + X$ in ascending order and compute the intersection with an interleaved linear scan.

Unfortunately, the $\oplus$-operation is not order preserving, indeed, $x < y$ does not imply $a \oplus x < a \oplus y$ for the lexicographic ordering on bitstrings – or, indeed, any total ordering on bitstrings. We may sort X and each set $a \oplus X = \{a \oplus x \mid x \in X\}$, for $a \in X$, separately to obtain an algorithm with running time $O(n^2 \log n)$. Using fast deterministic integer sorting [18] reduces this to time $O(n^2 \log \log n)$. In order to achieve quadratic running time, one may utilize a randomized dictionary for X with expected linear construction time and constant lookup time (like in [12]) or (weakly non-uniform, rather complex) deterministic static dictionaries with construction time $O(n \log n)$ and constant lookup time as provided in [17]. Once such a dictionary is available, one just has to check whether $a \oplus b \in X$, for all $a, b \in X$.

Here we describe a rather simple deterministic algorithm with quadratic running time. For this, we utilize a special binary search tree[3] T_X that allows, for arbitrary $a \in \{0,1\}^w$, to traverse the set $a \oplus X = \{a \oplus x \mid x \in X\}$ in lexicographically ascending order, in linear time. For $X \neq \emptyset$, the tree T_X is recursively defined as follows.

[3] The structure of the tree is that of the PATRICIA tree [25] for X.

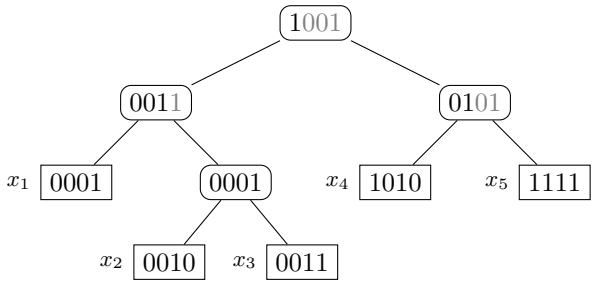

Figure 1 The tree T_X for $X = \{x_1 = 0001, x_2 = 0010, x_3 = 0011, x_4 = 1010, x_5 = 1111\}$. The first 1-bit of the label of an inner node indicates the most significant bit that is not constant among the x-values managed by that subtree (the bits after the first 1-bit are irrelevant). According to the value of this bit, elements are found in the left or right subtree. Apart from the labels of the inner nodes, T_X is essentially the PATRICIA tree [25] for X.

- If $X = \{x\}$, then T_X is $\mathsf{LeafNode}(x)$, a tree consisting of a single leaf with label x.
- If $|X| \geq 2$, let $\mathrm{lcp}(X)$ denote the longest common prefix of the elements of X when viewed as bitstrings. That is, all elements of X coincide on the first $k = |\mathrm{lcp}(X)|$ bits, the elements of some nonempty set $X_0 \subsetneq X$ start with $\mathrm{lcp}(X)0$ and the elements of $X_1 = X - X_0$ start with $\mathrm{lcp}(X)1$. We define $T_X = \mathsf{InnerNode}(T_{X_0}, 0^k1b, T_{X_1})$ for some $b \in \{0,1\}^{w-k-1}$, meaning that T_X consists of a root vertex with label $\ell = 0^k1b$, a left subtree T_{X_0} and a right subtree T_{X_1}. The choice of b is irrelevant, but it is convenient to define the label more concretely as $\ell = (\max X_0) \oplus (\min X_1)$.

Note that along paths of inner nodes down from the root the labels when regarded as integers are strictly decreasing. We give an example in Figure 1 and provide a $O(n \log n)$ time construction of T_X from X in Algorithm 4.

In the context of $T_X = \mathsf{InnerNode}(T_{X_0}, \ell = 0^k1b, T_{X_1})$ as described above, the $(k{+}1)$st bit is the most significant bit where elements of X differ. Crucially, this is also true for the set $a \oplus X$ for any $a \in \{0,1\}^w$. Since the elements of X are partitioned into X_0 and X_1 according to their $(k{+}1)$st bit, either all elements of $a \oplus X_0$ are less than all elements of $a \oplus X_1$, or vice versa, depending on whether the $(k{+}1)$st bit of a is 0 or 1. Using that the $(k{+}1)$st bit of a is 1 iff $a \oplus \ell < a$, this suggests a simple recursive algorithm to produce $a \oplus X$ in sorted order, given as Algorithm 3.

With the data structure T_X in place, the strategy from 3SUM carries over to 3XOR as seen in Algorithm 2. Summing up, we have obtained the following result:

▶ **Theorem 5.** *A deterministic word RAM can solve the* 3XOR *problem in time* $O(n^2)$. ◀

In Algorithm 4 we provide a linear time construction of T_X from a stream containing the sorted array X interleaved with the labels $\ell_i = x_i \oplus x_{i+1}$ (due to sorting the total runtime is $O(n \log n)$). Despite its brevity, the recursive build function is somewhat subtle.

▶ **Claim 6** (Correctness of Algorithm 4). *If build() is called while the stream contains the elements* $(\ell_i, x_{i+1}, \ldots, x_n, \ell_n = \infty)$*, the call consumes a prefix of the stream until* $\mathsf{top}(\mathrm{stream}) = \ell_j$ *where* $j = \min\{j > i \mid \ell_j \geq \ell_i\}$*. It returns* T_X *where* $X = \{x_{i+1}, \ldots, x_j\}$.

Once this is established, the correctness of makeTree immediately follows as for the outer call we have $i = 0$ and $j = n$ (with the understanding that $\infty \geq \infty$).

Proof of Claim 6. By the ℓ-call we mean the (recursive) call to build() with $\mathsf{top}(\mathrm{stream}) = \ell$. In particular the ℓ-call consumes ℓ from the stream and our claim concerns the ℓ_i-call. It is clear from the algorithm that an ℓ-call can only invoke an ℓ'-call if $\ell' < \ell$. Therefore the

Algorithm 3: Given a tree $T = T_X$ and $a \in \{0,1\}^w$, the algorithm yields the elements of $a \oplus X = \{a \oplus x \mid x \in X\}$ in sorted order.

```
1  Algorithm traverse(T, a):
2      if T = LeafNode(x) then
3          yield a ⊕ x
4      else
5          let T = InnerNode(T_0, ℓ, T_1)
6          if a ⊕ ℓ > a then
7              traverse(T_0, a)
8              traverse(T_1, a)
9          else
10             traverse(T_1, a)
11             traverse(T_0, a)
```

Algorithm 4: $O(n \log n)$-time algorithm to construct T_X from X.

```
1  Algorithm makeTree(X):
2      sort X as x_1 < ··· < x_n
3      let ℓ_i = x_i ⊕ x_{i+1},   1 ≤ i < n
4      stream ←
         (∞, x_1, ℓ_1, ..., ℓ_{n−1}, x_n, ∞)
5      return build() where
6      subroutine build():
7          ℓ ← pop(stream)
8          x ← pop(stream)
9          T ← LeafNode(x)
10         while top(stream) < ℓ do
11             ℓ' ← top(stream)
12             T ← InnerNode(T, ℓ', build())
13         return T
```

ℓ_i-call cannot directly or indirectly cause the ℓ_j-call since $\ell_j \geq \ell_i$. At the same time, the ℓ_i-call can only terminate when $\mathsf{top}(\mathit{stream}) \geq \ell_i$. This establishes that $\ell_j = \mathsf{top}(\mathit{stream})$ when the ℓ_i-call ends – the first part of our claim.

Next, note that since X is sorted, there is some m such that we have $X_0 = \{x_{i+1}, \ldots, x_m\}$ and $X_1 = \{x_{m+1}, \ldots, x_j\}$ where $X = X_0 \cup X_1$ is the partition from the definition of T_X. Moreover, ℓ_m is the largest label among $\ell_{i+1}, \ldots, \ell_{j-1}$. This implies that the ℓ_m-call is *directly* invoked from the ℓ_i-call. Just before the ℓ_m-call is made, the ℓ_i-call played out just as though the stream had been $(\ell_i, x_{i+1}, \ldots, x_m, \ell'_m = \infty)$, which would have produced T_{X_0} by induction[4]. However, due to $\ell_m = \mathsf{top}(\text{stream}) < \ell = \ell_i$, instead of returning $T = T_{X_0}$, the while loop is entered (again) and produces $\mathsf{InnerNode}(T = T_{X_0}, \ell = \ell_m, \text{build}())$. The stream for the ℓ_m-call is $(\ell_m, \ldots, x_n, \ell_n)$ and ℓ_j is the first label not smaller than ℓ_m. So, again by induction, the ℓ_m-call produces T_{X_1} and ends with $\mathsf{top}(\text{stream}) = \ell_j$. Given this, it is clear that afterwards the loop condition in the ℓ_i-call is not satisfied (since $\ell_j \geq \ell_i$) and the new $T = T_X$ is returned immediately, establishing the second part of the claim. ◀

4 A Subquadratic Randomized Algorithm

In this section we present a subquadratic expected time algorithm for the 3XOR problem. Its basic structure is the same as in the corresponding algorithm for int3SUM presented in [2]. We use 1-universal families of linear hash functions to split the elements into buckets and to compute short fingerprints. Due to linearity, the bucket of an element c with $c = a \oplus b$ is uniquely determined when knowing the buckets of a and b. Furthermore, if $a \oplus b = c$, then this equation is also true when looking at the fingerprints of these elements. Therefore, packing the fingerprints of all elements of a (not too full) bucket into one word (a word-packed array) allows us to evaluate the latter equation for a lot of triples "in parallel". For this

[4] Formally the induction is on the value of $j - i$. The case of $j - i = 1$ is trivial.

purpose, we exploit word-level parallelism and use lookup tables to solve the set intersection problem on unsorted word-packed arrays. Algorithm 5 illustrates this strategy for large word lengths $w = \Omega((\log^2 n) \log\log n)$.

Changes (in comparison to the int3SUM algorithm) are made where necessary to deal with the different setting. This makes it a little more difficult in some parts of the algorithm (mainly because XOR-ing a sorted sequence with some a will destroy the order) and easier in other parts (in particular where linearity of hash functions is concerned). Altogether, we get an expected running time that is the same as in [2] for $w = O(\log^2 n)$ and slightly worse for larger w. Recall we assume $w = 2^{O(n \log n)}$ throughout.

▶ **Theorem 7.** *A randomized word RAM with word length w can solve the* 3XOR *problem in expected time*

$$O\left(n^2 \cdot \min\left\{\frac{\log^3 w}{w}, \frac{(\log\log n)^2}{\log^2 n}\right\}\right) \quad \text{for } w = O(n \log n),$$

and $O(n \log^2 n)$, otherwise.

The crossover point between the w and the $\log n$ factor is $w = (\log^2 n) \log\log n$. The only difference to the running time of [2] is in an extra factor $\log w$ in the word-length-dependent part.

Proof. We describe the main ideas of the algorithm. For full details, see [11]. If $w = \omega(n \log n)$, we proceed as for $w = \Theta(n \log n)$. We use two levels of hashing.

Good and Bad Buckets. We split X into $R = 2^r = o(n)$ *buckets* $X_u = \{\, x \in X \mid h_1(x) = u \,\}$, $u \in \{0,1\}^r$, using a randomly chosen hash function $h_1 \in \mathcal{H}^{\text{lin}}_{w,r}$. The hash values are calculated once and for all and stored for further use. By linearity, for every solution $a \oplus b = c$ we also have $h_1(a) \oplus h_1(b) = h_1(c)$. Given $a \in X_u$ and $b \in X_v$, we only have to inspect bucket $X_{u \oplus v}$ when looking for a $c \in X$ such that $a \oplus b = c$.

For $a \in X$, the expected size of bucket $X_{h_1(a)}$ is n/R. A bucket of size larger than $3n/R$ is called *bad*, as are elements of bad buckets. All other buckets and elements are called *good*. By Corollary 3, the expected number of bad elements is smaller than R. We can even assume that the total number of bad elements is smaller than $2R$. (By Markov's inequality, we simply have to repeat the choice of h_1 expected $O(1)$ times until this condition is satisfied.)

Fingerprints and Word-Packed Arrays. Furthermore, we use another hash function $h_2 \in \mathcal{H}^{\text{lin}}_{w,p}$ for some appropriately chosen p to calculate p-bit *fingerprints* for all elements in X. If $(3n/R) \cdot p \le w$, we can pack all fingerprints of elements of a good bucket X_u into one word X^*_u. This packed representation is called *word-packed array*. Again by linearity, for every solution $a \oplus b = c$ we have $h_2(a) \oplus h_2(b) = h_2(c)$. On the other hand, the expected number of *colliding triples*, i. e., triples with $a \oplus b \neq c$ but $h_1(a) \oplus h_1(b) = h_1(c)$ and $h_2(a) \oplus h_2(b) = h_2(c)$, is at most $2n^3/(R \cdot 2^p)$. (Since the hash families that we use are 1-universal, the probability that a triple with $a \oplus b \neq c$ is colliding is at most $2/(R \cdot 2^p)$. The additional factor 2 is due to the repeated choice of h_1 until there are fewer than $2R$ bad elements.)

The total time for all the hashing steps described so far is $O(n \cdot (r + p))$, see Section 2.2. We consider two choices of $R = 2^r$ and p, cf. [2, proof of Lemma 3] and [2, proof of Thm. 2]. The first one is better for larger words of length $w = \Omega((\log^2 n) \log\log n)$ whereas the second one yields better results for smaller words. In both cases, we search for triples with a fixed number of bad elements separately. The strategies for finding triples of good elements

correspond to the approach for int3SUM in [2]. However, for triples with at least one bad element we have to rely on a more fine-grained examination than in [2]. For this, we will use hash tables and another lookup table.

Long Words: Exploiting Word-Level Parallelism. If the word length is large enough, i. e., $w = \Omega((\log^2 n) \log\log n)$, we choose $R \approx \lceil 6 \cdot n \cdot (\log w)/w \rceil$ as a power of 2 and $p = \lfloor 2 \cdot \log w \rfloor$ to be able to pack all fingerprints of elements of a good bucket into one word. We examine triples with at most one and at least two bad elements separately, as seen in Algorithm 5.

When looking for triples with at most one bad element, we do the following for every (good or bad) $a \in X$ and $u \in \{0,1\}^r$ where X_u and the corresponding bucket $X_{h_1(a) \oplus u}$ are good (as in [2, proof of Lemma 3] when examining triples of three good elements): We XOR every fingerprint of the word-packed array X_u^* with $h_2(a)$. Then, in time $O(\log^2(n/R) + t) = O(\log^2 w + t)$, we construct a list of t common pairs in this modified word-packed array and $X^*_{h_1(a) \oplus u}$, which is possible by Lemma 4. For each such pair, we only have to check whether it derives from a non-colliding triple. Since we can stop when we find a non-colliding triple and since the expected total number of colliding triples is $O(n^2/(w \log w))$, we are done in expected time $O(n \cdot R \cdot \log^2 w + n^2/(w \log w)) = O(n^2(\log^3 w)/w)$.

In order to examine all triples with at least two bad elements, we provide a hash table for X with expected construction time $O(n)$ and constant lookup time [12]. Now, for each of the at most $4R^2 = O(n^2(\log^2 w)/w^2)$ pairs (a, b) of bad elements we can check if $a \oplus b \in X$ in constant time.[5]

The total expected running time for this parameter choice is $O(n^2(\log^3 w)/w)$.

Short Words: Using Lookup Tables. For word lengths $w = O((\log^2 n) \log\log n)$, we choose $R \approx \lceil 55 \cdot n \cdot (\log\log n)/\log n \rceil$ as a power of 2 and $p = \lfloor 6 \cdot \log\log n \rfloor$ to pack all fingerprints of elements of a good bucket into $(\frac{1}{3} - \varepsilon) \log n$ bits, for some $\varepsilon > 0$.

We start by looking for triples with no bad element. For this, we consider all $\leq R^2$ triples of corresponding good buckets (as in [2, proof of Thm. 2]). We use a lookup table of size $n^{1-\Omega(1)}$ to check whether such a triple of buckets yields a triple of fingerprints (in the word-packed arrays) with $h_2(a) \oplus h_2(b) = h_2(c)$ in constant time. If this is the case, we search for a corresponding triple $a \oplus b = c$ in the buckets of size $O((\log n)/\log\log n)$ in time $O((\log^3 n)/(\log\log n)^3)$. Since one table entry can be computed in time $O((\log^3 n)/(\log\log n)^3)$, setting up the lookup table takes time $n^{1-\Omega(1)}$. Furthermore, the expected $O(n^2/((\log\log n)\log^5 n))$ colliding triples cause additional expected running time $O(n^2/((\log\log n)^4 \log^2 n))$. Since we can stop when we find a non-colliding triple, the total expected time is $O(R^2) = O(n^2(\log\log n)^2/\log^2 n)$.

Searching for triples with exactly one bad element can be done in a similar way. For each bad element $a \in X$ and each good bucket X_u, $u \in \{0,1\}^r$, we XOR all fingerprints in the word-packed array X_u^* with $h_2(a)$ and use a lookup table to check whether it has some fingerprints in common with the word-packed array $X^*_{h_1(a) \oplus u}$ of the corresponding good bucket. If this lookup yields a positive result, we check all pairs in the corresponding buckets in time $O((\log^2 n)/(\log\log n)^2)$. As before, the expected running time is $O(R^2)$, including the expected time $O(n^2/((\log\log n)^3 \log^3 n))$ due to colliding triples.

Examining all triples with at least two bad elements can be done using a hash table as mentioned above in expected time $O(n + R^2)$.

The total expected running time for this parameter choice is $O(n^2(\log\log n)^2/\log^2 n)$. ◀

[5] Note that it would not be possible to derive expected time $O(R^2)$ for checking all pairs of bad elements if we did not start all over if the number of keys in bad buckets is at least $2R$.

Algorithm 5: The randomized subquadratic 3XOR algorithm for the case $w = \Omega((\log^2 n)\log\log n)$. For $w = o((\log^2 n)\log\log n)$ using lookup tables to search for solutions involving at most one bad element yields a faster algorithm.

Algorithm 3XOR(X): // $X \subseteq \{0,1\}^w$, $|X| = n$
  repeat
    // partition X into buckets using h_1:
    pick linear, 1-universal $h_1 : \{0,1\}^w \to \{0,1\}^r$ with $2^r = R \approx \lceil 6n(\log w)/w \rceil$
    $X_u \leftarrow \{x \in X \mid h_1(x) = u\}$ for $u \in \{0,1\}^r$
    $B \leftarrow \{x \in X \mid |X_{h(x)}| > 3\frac{n}{R}\}$ // bad elements in overfull buckets
  until $|B| < 2R$
  // search for solution involving at least two bad elements:
  for $a, b \in B$ **do** // $< 4R^2$ choices
    if $a \oplus b \in X$ **then** // $O(1)$ using appropriate hash table for X
      return $(a, b, a \oplus b)$
  // search for solution involving at most one bad element:
  $X_u \leftarrow \emptyset$ for $u \in \{0,1\}^r$ with $|X_u| > 3\frac{n}{R}$ // empty the bad buckets
  pick linear, 1-universal $h_2 : \{0,1\}^w \to \{0,1\}^p$ with $p = \lfloor 2\log w \rfloor$
  for $u \in \{0,1\}^r$ **do**
    // pack fingerprints of elements of X_u into one word X_u^*
    $X_u^* \leftarrow h_2(X_u) :=$ concatenate $\{h_2(x) \mid x \in X_u\}$
  for $a \in X$ *and* $u \in \{0,1\}^r$ **do** // $n \cdot R$ iterations
    $X_u^{*,a} \leftarrow X_u^* \oplus h_2(a)$ // $h_2(a)$ added to each fingerprint in X_u^*
    for $v \in X_u^{*,a} \cap X^*_{h_1(a)\oplus u}$ **do**
      identify responsible b, c, in particular with $v = h_2(a) \oplus h_2(b) = h_2(c), \quad h_1(b) = u$
      if $a \oplus b = c$ **then**
        return (a, b, c)
  return *no solution*

needs time $O(\log^2(n/R))$ plus size of intersection

5 Conditional Lower Bounds from the 3XOR Conjecture

As already mentioned in Section 1, the best word RAM algorithm for int3SUM currently known [2] can solve this problem in expected time $O(n^2 \cdot \min\{\frac{\log^2 w}{w}, \frac{(\log\log n)^2}{\log^2 n}\})$ for $w = O(n\log n)$. The best deterministic algorithm [8] takes time $n^2(\log\log n)^{O(1)}/\log^2 n$. It is a popular conjecture that every algorithm for 3SUM (deterministic or randomized) needs (expected) time $n^{2-o(1)}$. Therefore, this conjectured lower bound can be used as a basis for conditional lower bounds for a wide range of other problems [15, 19, 22, 26].

Similarly, it seems natural to conjecture that every algorithm for the related 3XOR problem (deterministic or randomized) needs (expected) time $n^{2-o(1)}$. (In Theorem 7, the upper bound for short word lengths is $n^2\frac{(\log\log n)^2}{\log^2 n} = n^{2-(2\log\log n - 2\log\log\log n)/\log n}$ where $(2\log\log n - 2\log\log\log n)/\log n = o(1)$.) Therefore, it is a valid candidate for reductions to other computational problems [19, 27].

The general strategy of the subquadratic int3SUM algorithm [2], already employed in Section 4, is quite similar to the reductions in [22]. Therefore, we are able to reduce 3XOR to offline SetDisjointness and offline SetIntersection, too. Hence, the conditional lower bounds

for the problems mentioned in [22] (and bounds for dynamic problems from [26]) also hold with respect to the 3XOR conjecture. A detailed discussion can be found in [27]. Below, we will outline the general proof strategy.

5.1 Offline SetDisjointness and Offline SetIntersection

We reduce 3XOR to the following two problems.

▶ **Problem 8** (Offline SetDisjointness). ***Input:*** *Finite set C, finite families A and B of subsets of C, $q \in \mathbb{N}$ pairs of subsets $(S, S') \in A \times B$.*
Task: *Find all of the q pairs (S, S') with $S \cap S' \neq \emptyset$.*

▶ **Problem 9** (Offline SetIntersection). ***Input:*** *Finite set C, finite families A and B of subsets of C, $q \in \mathbb{N}$ pairs of subsets $(S, S') \in A \times B$.*
Task: *List all elements of the intersections $S \cap S'$ of the q pairs (S, S').*

5.2 Reductions from 3XOR

By giving an expected time $\leq n^{2-\Omega(1)}$ reduction from 3XOR to offline SetDisjointness and offline SetIntersection, we can prove lower bounds for the latter two problems, conditioned on the 3XOR conjecture.

▶ **Theorem 10.** *Assume* 3XOR *requires expected time $\Omega(n^2/f(n))$ for $f(n) = n^{o(1)}$ on a word RAM. Then for $0 < \gamma < 1$ every algorithm for* offline SetDisjointness *that works on instances with $|C| = \Theta(n^{2-2\gamma})$, $|A| = |B| = \Theta(n \log n)$, $|S| = O(n^{1-\gamma})$ for all $S \in A \cup B$ and $q = \Theta(n^{1+\gamma} \log n)$ requires expected time $\Omega(n^2/f(n))$.*

▶ **Theorem 11.** *Assume* 3XOR *requires expected time $\Omega(n^2/f(n))$ for $f(n) = n^{o(1)}$ on a word RAM. Then for $0 \leq \gamma < 1$ and $\delta > 0$, every algorithm for* offline SetIntersection *which works on instances with $|C| = \Theta(n^{1+\delta-\gamma})$, $|A| = |B| = \Theta(\sqrt{n^{1+\delta+\gamma}})$, $|S| = O(n^{1-\gamma})$ for all $S \in A \cup B$, $q = \Theta(n^{1+\gamma})$ and expected output size $O(n^{2-\delta})$ requires expected time $\Omega(n^2/f(n))$.*

Proof. (For more details, see [27, ch. 6]. Algorithm 6 reduces 3XOR to offline SetDisjointness. The pseudocode implementation for offline SetIntersection is given in [11].) Let $X \subseteq \{0,1\}^w$ be the given 3XOR instance. As in Section 4, we use two levels of hashing.

At first, we hash the elements of X with a randomly chosen hash function $h_1 \in \mathcal{H}^{\text{lin}}_{w,r}$ into $R = 2^r = \Theta(n^\gamma)$ buckets in time $O(n \log n)$. Then, we apply Corollary 3: There are expected $O(R) = O(n^\gamma)$ elements in buckets with more than three times their expected size. For each such bad element, we can naively check in time $O(n \log n)$ whether it is part of a triple (a, b, c) with $a \oplus b = c$ or not. Since $\gamma < 1$, all bad elements can be checked in expected time $\leq n^{2-\Omega(1)}$. Therefore, we can assume that every bucket X_u, $u \in \{0,1\}^r$, has at most $3\frac{n}{R} = O(n^{1-\gamma})$ elements.

The second level of hashing uses two independently and randomly chosen hash functions $h_{21}, h_{22} \in \mathcal{H}^{\text{lin}}_{w,p}$ where $P = 2^{2p} = (5n/R)^2 = O(n^{2-2\gamma})$ for offline SetDisjointness and $P = 2^{2p} = n^{1+\delta}/R = O(n^{1+\delta-\gamma})$ for offline SetIntersection. (The function h_2 with $h_2(x) = h_{21}(x) \circ h_{22}(x)$, where $\circ$ denotes the concatenation of bitstrings, is randomly chosen from a linear and 1-universal class $\mathcal{H}$ of hash functions $\{0,1\}^w \to \{0,1\}^{2p}$.) The hash values can be calculated in time $O(n \log^2 n)$. (The additional $\log n$ factor is only necessary for offline SetDisjointness, since we need to use $\Theta(\log n)$ choices of hash functions h_2 to get an error probability that is small enough.) For each $u \in \{0,1\}^r$ and $v \in \{0,1\}^p$, we create "shifted" buckets $X^{\uparrow}_{u,v} = \{\, h_2(x) \oplus (v \circ 0^p) \mid x \in X_u \,\}$ and $X^{\downarrow}_{u,v} = \{\, h_2(x) \oplus (0^p \circ v) \mid x \in X_u \,\}$. One

such set can be computed in time $O(n^{1-\gamma})$. Therefore, all sets can be computed in time $O(R\sqrt{P}\log n \cdot n^{1-\gamma}) = O(n^{2-\gamma}\log n)$ for offline SetDisjointness and $O(R\sqrt{P}\cdot n^{1-\gamma}) = O(n^{(3+\delta-\gamma)/2})$ for offline SetIntersection.

We can show that for all $u \in \{0,1\}^r$ and $c \in X$, if there are $a, b \in X$ such that $a \oplus b = c$ and $a \in X_u$, then $X^{\uparrow}_{u,h_{21}(c)} \cap X^{\downarrow}_{u\oplus h_1(c),h_{22}(c)} \neq \emptyset$. Therefore, we create the following offline SetDisjointness (offline SetIntersection) instance: $C := \{0,1\}^{2p}$, $A := \{\, X^{\uparrow}_{u,v} \mid u \in \{0,1\}^r, v \in \{0,1\}^p \,\}$, $B := \{\, X^{\downarrow}_{u,v} \mid u \in \{0,1\}^r, v \in \{0,1\}^p \,\}$ and q queries $(X^{\uparrow}_{u,h_{21}(c)}, X^{\downarrow}_{u\oplus h_1(c),h_{22}(c)})$ for all $u \in \{0,1\}^r$ and $c \in X$ in time $\leq n^{2-\Omega(1)}$. (These are $R \cdot n = \Theta(n^{1+\gamma})$ queries for offline SetIntersection. For offline SetDisjointness, we create $R \cdot n$ queries for each of the $\Theta(\log n)$ choices of h_2.)

After the offline SetDisjointness or offline SetIntersection instance has been solved, we can use this answer to compute the answer for X in expected time $\leq n^{2-\Omega(1)}$. We only have to check if a positive answer from offline SetDisjointness (a pair with non-empty intersection) or offline SetIntersection (an element of an intersection) yields a solution triple of X or not.

For offline SetDisjointness, we can show that the probability for a triple to yield a false positive can be made polynomially small if we consider $K = \Theta(\log n)$ choices of h_2 and only examine $(X_u \oplus c) \cap X_{h_1(c)\oplus u}$ if this is suggested by all K corresponding queries. For offline SetIntersection, the expected number of colliding triples is $O(n^{2-\delta})$. By trying to guess a good triple $\Theta(n \log n)$ times before creating the offline SetIntersection instance we can avoid a problem for the expected running time if a 3XOR instance yields an offline SetIntersection instance with output size $\omega(n^{2-\delta})$.

For all relevant values of γ and δ, the total running time is $\leq n^{2-\Omega(1)}$ in addition to the time needed to solve the offline SetDisjointness or offline SetIntersection instance. ◀

6 Conclusions and Remarks

We have presented a simple deterministic algorithm with running time $O(n^2)$. Its core is a version of the PATRICIA tree for $X \subseteq \{0,1\}^w$, which makes it possible to traverse the set $a \oplus X$ in ascending order for arbitrary $a \in \{0,1\}^w$ in linear time. Furthermore, our randomized algorithm solves the 3XOR problem in expected time $O(n^2 \cdot \min\{\frac{\log^3 w}{w}, \frac{(\log\log n)^2}{\log^2 n}\})$ for $w = O(n \log n)$, and $O(n \log^2 n)$ for $n \log n \leq w = O(2^{n \log n})$. The crossover point between the w and the $\log n$ factor is $w = (\log^2 n)\log\log n$. The only difference to the running time of [2] is in an extra factor $\log w$ in the word-length-dependent part. This is due to the necessity to re-sort a word-packed array of size $O(w/\log w)$ in time $O(\log^2 w)$ after we have XOR-ed each of its elements with a (common) element. Finally, we have reduced 3XOR to offline SetDisjointness and offline SetIntersection, establishing conditional lower bounds (as in [22] conditioned on the int3SUM conjecture).

A simple, but important observation, which is used in apparently all deterministic subquadratic time algorithms for 3SUM, is *Fredman's trick*:

$$a + b < c + d \iff a - d < c - b \qquad \text{for all } a, b, c, d \in \mathbb{Z}\,.$$

Unfortunately, such a relation does not exist in our setting, since there is no linear order $\prec$ on $\{0,1\}^w$ such that $a \oplus b \prec c \oplus d \iff a \oplus d \prec c \oplus b$ holds for all $a, b, c, d \in \{0,1\}^w$. Since all elements are self-inverse, for $a = b = c = 0^w$ and any $d \in \{0,1\}^w$, we would get $0^w \prec d \iff d \prec 0^w$. Is there another, "trivial-looking" trick for 3XOR, that establishes a basic approach to solve 3XOR in deterministic subquadratic time?

Algorithm 6: Algorithm reducing 3XOR to offline SetDisjointness, establishing a conditional lower bound on the runtime of offline SetDisjointness.

Reduction 3XOR-to-offlineSetDisjointness(X, γ): // $X \subseteq \{0,1\}^w$, $|X| = n$, $0 < \gamma < 1$
  // partition X into buckets using h_1:
  pick linear, 1-universal $h_1 : \{0,1\}^w \to \{0,1\}^r$ with $2^r = R \approx \lceil n^\gamma \rceil$
  $X_u \leftarrow \{x \in X \mid h_1(x) = u\}$ for $u \in \{0,1\}^r$
  $B \leftarrow \{x \in X \mid |X_{h(x)}| > 3\frac{n}{R}\}$ // bad elements in overfull buckets
  for $b \in B$ **do** // expected $O(R)$ elements
    $X^{\oplus b} \leftarrow \text{sort}\{a \oplus b \mid a \in X\}$
    if $\exists c \in X^{\oplus b} \cap X$ **then**
      return $(c \oplus b, b, c)$
  // create shifted buckets using h^i_{21}, h^i_{22}:
  pick linear, 1-universal $h^i_{21}, h^i_{22} : \{0,1\}^w \to \{0,1\}^p$ with $2^{2p} = P \approx \lceil (5n/R)^2 \rceil = O(n^{2-2\gamma})$ and $0 \le i < \lceil \log n \rceil$
  for $u \in \{0,1\}^r$, $v \in \{0,1\}^p$ *and* $0 \le i < \lceil \log n \rceil$ **do**
    $X^{\uparrow,i}_{u,v} \leftarrow \{(h^i_{21}(a) \oplus v, h^i_{22}(a)) \mid a \in X_u\}$
    $X^{\downarrow,i}_{u,v} \leftarrow \{(h^i_{21}(a), h^i_{22}(a) \oplus v) \mid a \in X_u\}$
  // apply algorithm for offline SetDisjointness:
  $(A, B, C, Q) \leftarrow ((X^{\uparrow,i}_{u,v})_{u,v,i}, (X^{\downarrow,i}_{u,v})_{u,v,i}, \{0,1\}^{2p}, \emptyset)$
  for $c \in X$, $u \in \{0,1\}^r$ *and* $0 \le i < \lceil \log n \rceil$ **do**
    $q \leftarrow (X^{\uparrow,i}_{u,h^i_{21}(c)}, X^{\downarrow,i}_{u \oplus h_1(c), h^i_{22}(c)})$, identified by (c, u, i)
    $Q \leftarrow Q \cup \{q\}$
  $Q' \leftarrow$ offlineSetDisjointness(A,B,C,Q) // $Q' \subseteq Q$
  // calculate solution for the 3XOR instance:
  for $c \in X$ *and* $u \in \{0,1\}^r$ **do**
    if $(c, u, i) \in Q'$ *for all* $0 \le i < \lceil \log n \rceil$ **then**
      $X^{\oplus c}_u \leftarrow \text{sort}\{a \oplus c \mid a \in X_u\}$
      if $\exists b \in X^{\oplus c}_u \cap X_{h_1(c) \oplus u}$ **then**
        return $(b \oplus c, b, c)$
  return *no solution*

Another open question is how the optimal running times for 3SUM and 3XOR are related. At first sight, the two problems seem to be very similar, but the details make the difference. The observations mentioned above (especially the problem of re-sorting slightly modified word-packed arrays and the possible absence of a relation like Fredman's trick) hint at a larger gap than expected. On the other hand, the fact that both problems can be reduced to a wide variety of computational problems in a similar way (e. g. listing triangles in a graph, offline SetDisjointness and offline SetIntersection) increases hope for a more concrete dependance.

Abstract

We give a new and elementary proof that the graphs of treewidth at most two can be seen as a free algebra. This result was originally established through an elaborate analysis of the structure of K_4-free graphs, ultimately reproving the well-known fact that the graphs of treewidth at most two are precisely those excluding K_4 as a minor. Our new proof is based on a confluent and terminating rewriting system for term-labeled graphs and does not involve graph minors anymore. The new strategy is simpler and robust in the sense that it can be adapted to subclasses of treewidth-two graphs, e.g., graphs without self-loops.

1 Introduction

The notion of *treewidth* [9] is a cornerstone of algorithmic graph theory and parameterised complexity: treewidth measures how close a graph is to a forest, and many problems that can be solved in polynomial time on forests but are NP-complete on arbitrary graphs remain polynomial on classes of graphs of bounded treewidth. This is the case for instance for the graph homomorphism problem (and thus k-coloring) [13, 5, 14].

Similar to trees, graphs of bounded treewidth can be described by a variety of syntaxes [8]. Among the open problems, there is the question, for graphs of a given treewidth, of finding a syntax making it possible to get a finite and equational axiomatisation of graph isomorphism [8, page 118]. This question was recently answered positively for directed multigraphs of treewidth at most two [7].

The syntax used in [7] is comprised of two binary operations: *series* and *parallel* composition [12], their neutral elements, and a unary *converse* operation. In this syntax, several terms may denote the same graph (up-to isomorphism); the key result of [7] is that the cor-

responding equational theory is characterized by twelve equational axioms, defining so-called 2p-algebras.

To get this result, the authors define a function $\mathtt{t}$ from graphs to terms and establish that $\mathtt{t}$ is a isomorphism of 2p-algebras. The function $\mathtt{t}$ is defined using an elaborate analysis of the structure of treewidth-two graphs, which requires complicated graph-theoretical arguments that are not directly related to the proposed axiom system. For instance they ultimately reprove the well-known fact that the graphs of treewidth at most two are precisely those graphs excluding K_4 (the complete graph with four vertices) as a minor [12]. The authors also make $\mathtt{t}$ as canonical as possible in order to facilitate the proof that on isomorphic graphs, $\mathtt{t}$ returns terms that are congruent modulo the axioms. This comes at the price of complicating the proofs that $\mathtt{t}$ is a homomorphism of 2p-algebras.

In the present paper, we reprove the result from [7] using a completely different approach inspired by [2]: instead of using an elaborate top-down analysis, we design a graph rewriting system on term-labeled graphs and use it to reduce graphs, in a bottom-up fashion, to a shape where a term can be read off. This process is highly nondeterministic but can be shown confluent modulo the axioms. This results in big simplifications: tree decompositions are only used to show that all treewidth-two graphs can be reduced to the point where a term can be read off, and minors are not used at all in this new approach.

Another important feature of this new proof is that it makes it possible to discover the required axioms almost automatically, mainly during the confluence proof. It is also more robust: it allows us to solve two problems left open in [7], characterizing connected graphs as a free-algebra, and characterizing self-loop free graphs as a free-algebra, in both cases for graphs of treewidth at most two.

The first problem was solved recently [16] using a purely model-theoretic argument: 2p-algebras form a conservative extension of *2pdom-algebras*, the counterpart of 2p-algebras for connected graphs. Our strategy makes it possible to proceed the other way around: we prove the main result for connected graphs and 2pdom-algebras (Sections 3 to 5), before extending it to potentially disconnected graphs and 2p-algebras using a simple and mainly algebraic argument (Section 6).

The second problem was still open. We solve it using a slight variation of the presented proof, which actually leads us to the discovery of the required axioms (Section 7).

2 Preliminaries: 2p- and 2pdom-algebras

We recall the definitions of 2p- and 2pdom-algebras [7, 16]. We let $a, b \dots$ range over the *letters* of a fixed alphabet $\mathcal{A}$. We consider labeled directed graphs with two designated vertices. We just call them graphs in the sequel.

▶ **Definition 1.** A *graph* is a tuple $G = \langle V, E, s, t, l, \iota, o\rangle$, where V is a finite set of *vertices*, E is a finite set of *edges*, $s, t : E \to V$ are maps indicating the *source* and *target* of each edge, $l : E \to \mathcal{A}$ is a map indicating the *label* of each edge, and $\iota, o \in V$ are the designated vertices, respectively called *input* and *output*.

Note that we allow multiple edges between two vertices, as well as self-loops.

▶ **Definition 2.** A *homomorphism* from $G = \langle V, E, s, t, l, \iota, o\rangle$ to $G' = \langle V', E', s', t', l', \iota', o'\rangle$ is a pair $h = \langle f, g\rangle$ of functions $f : V \to V'$ and $g : E \to E'$ that respect the various components: $s' \circ g = f \circ s$, $t' \circ g = f \circ t$, $l = l' \circ g$, $\iota' = f(\iota)$, and $o' = f(o)$.

A *(graph) isomorphism* is a homomorphism whose two components are bijective functions. We write $G \simeq G'$ when there exists an isomorphism between graphs G and G'.

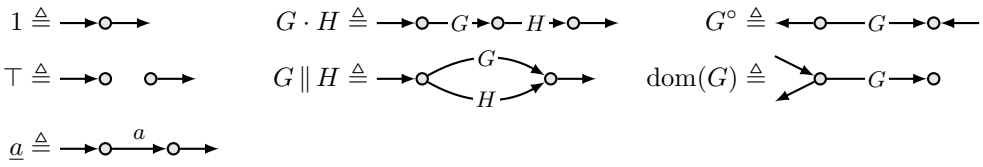

Figure 1 Graph operations.

$$u \parallel (v \parallel w) = (u \parallel v) \parallel w \quad \text{(A1)}$$
$$u \parallel v = v \parallel u \quad \text{(A2)}$$
$$u \cdot (v \cdot w) = (u \cdot v) \cdot w \quad \text{(A4)}$$
$$u \cdot 1 = u \quad \text{(A5)}$$
$$u^{\circ\circ} = u \quad \text{(A6)}$$
$$(u \parallel v)^\circ = u^\circ \parallel v^\circ \quad \text{(A7)}$$
$$(u \cdot v)^\circ = v^\circ \cdot u^\circ \quad \text{(A8)}$$
$$1 \parallel 1 = 1 \quad \text{(A9)}$$
$$\mathrm{dom}(u \parallel v) = 1 \parallel u \cdot v^\circ \quad \text{(A10)}$$
$$u \parallel \top = u \quad \text{(A3)}$$
$$u \cdot \top = \mathrm{dom}(u) \cdot \top \quad \text{(A11)}$$
$$(1 \parallel u) \cdot v = (1 \parallel u) \cdot \top \parallel v \quad \text{(A12)}$$
$$\mathrm{dom}(u \cdot v) = \mathrm{dom}(u \cdot \mathrm{dom}(v)) \quad \text{(A13)}$$
$$\mathrm{dom}(u) \cdot (v \parallel w) = \mathrm{dom}(u) \cdot v \parallel w \quad \text{(A14)}$$

Figure 2 Axioms of 2p-algebras (A1-A12) and 2pdom-algebras (A1,A2,A4-A10,A13,A14).

We consider the following signatures for terms and algebras:

$$\Sigma = \{\cdot_2, \parallel_2, \_^\circ_1, 1_0\} \qquad \Sigma_\top = \Sigma \cup \{\top_0\} \qquad \Sigma_{\mathrm{dom}} = \Sigma \cup \{\mathrm{dom}_1\}$$

We usually omit the $\cdot$ symbol and we assign priorities so that the term $(a \cdot (b^\circ)) \parallel c$ can be written just as $ab^\circ \parallel c$.

Graphs form algebras for those signatures by considering the operations depicted in Figure 1, where input and outputs are represented by unlabelled ingoing and outgoing arrows. The binary operations $(\cdot)$ and $(\parallel)$ respectively correspond to series and parallel composition, converse $(\_^\circ)$ just exchanges input and output, and *domain* $(\mathrm{dom}(\_))$ relocates the output to the input.

A graph is called a *test* if its input and output coincide. The parallel composition of a graph with a test merges the input and output of the former graph. For instance, the graph $\underline{a} \parallel 1$ consists of a single vertex with a self-loop labeled with a. Also note that the graph $\mathrm{dom}(G)$ is isomorphic to the graph $G \cdot \top \parallel 1$. For $\Sigma_\top$-terms, we will therefore consider $\mathrm{dom}(u)$ to be an abbreviation for $u\top \parallel 1$.

▶ **Definition 3.** A 2p-algebra is a $\Sigma_\top$-algebra satisfying axioms A1-A12 from Figure 2. A 2pdom-algebra is a Σ_{dom}-algebra satisfying axioms A1,A2,A4-A10,A13,A14 from Figure 2.

▶ **Lemma 4.** *Every 2p-algebra is a 2pdom-algebra (with* $\mathrm{dom}(u) \triangleq u\top \parallel 1$*).*

Proof. This easy result is implicitly proved in [16]; Coq proofs scripts are available [10]. ◀

▶ **Proposition 5.** *Graphs (up to isomorphism) form a 2p-algebra.*

▶ **Proposition 6.** *Connected graphs form a subalgebra of the* Σ_{dom}*-algebra of graphs.*

Given $\Sigma_\top$-terms u, v with variables in $\mathcal{A}$, we write $2p \vdash u = v$ when the equation is derivable from the axioms of 2p-algebra (equivalently, when the equation universally holds in all 2p-algebras). Similarly for Σ_{dom}-terms and 2pdom-algebras.

By interpreting a letter $a \in \mathcal{A}$ as the graph $\underline{a}$ in Figure 1, we can associate a graph $\mathsf{g}(u)$ to every term over the considered signatures. By Proposition 5, $2p \vdash u = v$ entails $\mathsf{g}(u) \simeq \mathsf{g}(v)$ for all $\Sigma_\top$-terms u, v and similarly for Σ_{dom}-terms and $2pdom$-algebras (using Lemma 4).

▶ **Definition 7.** A $\Sigma_\top$-term u is called a *test* if $2p \vdash u \parallel 1 = u$. A Σ_{dom}-term u is called a *test* if $2pdom \vdash u \parallel 1 = u$. We write $\mathcal{T}$ for the set of tests and $\mathcal{N}$ for the set of non-tests. We let α, β, and γ range over terms that are tests.

Thanks to converse being an involution, there is a notion of duality in 2p-algebras: a valid law remains so when swapping the arguments of products and replacing $\mathrm{dom}(u)$ with $\mathrm{dom}(u^\circ)$.

▶ **Lemma 8.** *The following laws hold in all 2pdom-algebras.*

1. $\mathrm{dom}(u) \parallel 1 = \mathrm{dom}(u)$ *(*$\mathrm{dom}(u)$ *is a test)*
2. $\alpha^\circ = \alpha$
3. $\alpha\beta = \alpha \parallel \beta = \beta\alpha$
4. $(u \parallel v)\alpha = u \parallel v\alpha$

Proof. See long version [11]. ◀

▶ **Lemma 9** ([7, Proposition 1])**.** *The following laws hold in all 2p-algebras*

1. $u\top v \parallel \top w\top = u\top w\top v$
2. $uv \parallel \top w\top = (u \parallel \top w\top)v$
3. $\top u^\circ\top = \top u\top$
4. $\alpha\top\beta \parallel u = \alpha u\beta$

▶ **Lemma 10.** *A* Σ_{dom}*- or* $\Sigma_\top$*-term* u *is a test iff* $\mathsf{g}(u)$ *is a test.*

Proof. The direction from left to right follows with Proposition 5. The converse direction follows by induction on u using the lemmas above. ◀

One useful consequence of the lemma above is that uv is a test iff both u and v are tests and $u \parallel v$ is test if either u or v is a test. Further, $\mathcal{A} \subseteq \mathcal{N}$, i.e., letters are non-tests.

We conclude this preliminary section by defining the subalgebra of treewidth-two graphs.

▶ **Definition 11.** A *simple graph* is a pair $\langle V, R\rangle$ consisting of a finite set V of vertices and an irreflexive and symmetric binary relation R on V. The *skeleton* of a graph G is the simple graph obtained from G by forgetting input, output, labeling, self loops, and edge directions and multiplicities. The *strong skeleton* of a graph is the skeleton of G with an additional edge connecting ι and o.

▶ **Definition 12** ([9])**.** Let G be a simple graph. A *tree decomposition* of G is a tree T where each node $t \in T$ is labeled with a set of vertices B_t such that:

1. For every vertex x of G, the set of nodes t such that $x \in B_t$ is nonempty and connected in T (i.e., forms a subtree)
2. For every xy-edge, there exists some t such that $\{x, y\} \subseteq B_t$.

The *width* of a tree decomposition is the size of its largest set B_t minus one, and the *treewidth* of a graph is the minimal width of a tree decomposition for this graph. The simple graphs of treewidth at most one are the forests. We write TW_2 for the collection of graphs whose strong skeleton has treewidth at most two.

▶ **Proposition 13** ([7])**.** TW_2 *forms a subalgebra of the* $\Sigma_\top$*-algebra of graphs.*

▶ **Corollary 14.** *For every term* u*,* $\mathsf{g}(u) \in \mathsf{TW}_2$*.*

The main results about 2p- and 2pdom-algebras, which we reprove in this paper, are that TW_2 (up to isomorphism) forms the free 2p-algebra (over $\mathcal{A}$) [7] and that the connected graphs in TW_2 form the free 2pdom-algebra [16]. As explained in the introduction, we start with the connected case, which we then extend to deal with disconnected graphs.

3 A Confluent Rewriting System for Term-labeled Graphs

The rewriting system we define to extract terms from graphs works on a generalised form of graphs, whose edges are labeled by terms rather than just letters, and whose vertices are labeled by tests.

We work exclusively with Σ_{dom}-terms and connected graphs in Sections 3 to 5; for these sections we thus abbreviate $2pdom \vdash u = v$ as $u \equiv v$.

▶ **Definition 15.** A *term-labeled graph* is a tuple $G = \langle V, E, s, t, l, \iota, o\rangle$ that is a graph except that l is a function from $V \uplus E$ to Σ_{dom}-terms (we assume V and E to always be disjoint) such that $l(x) \in \mathcal{T}$ for vertices x and $l(e) \in \mathcal{N}$ for edges e. We write $\exp(G)$ for the *expansion* of G obtained by replacing every edge e with $\mathsf{g}(l(e))$ and every vertex x with $\mathsf{g}(l(x))$.

Restricting edge labels to non-tests ensures that replacing edges by the graphs described by their labels does not collapse source and target of the edge. Similarly, replacing vertices by graphs is only meaningful if the replacement is a test.

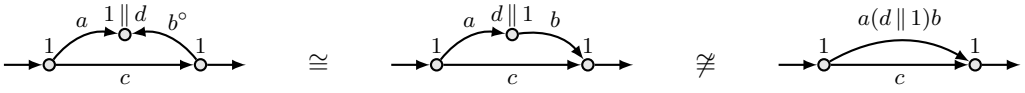
We will compare term-labeled graphs using a notion of isomorphism where labels are compared modulo 2pdom-axioms. A subtlety here is that we should consider as equivalent two graphs where one is obtained from the other by reversing a u-labeled edge and labeling it with u° (this operation preserves the expansion). The following predicate, which we use in the definitions below, captures this idea in a formal way: $L(x, y, e, u)$ means that e can be seen as a u-labeled xy-edge, up to $\equiv$.

$$L(x, y, e, u) \triangleq (s(e) = x \wedge t(e) = y \wedge l(e) \equiv u) \vee (s(e) = y \wedge t(e) = x \wedge l(e) \equiv u^\circ)$$

▶ **Definition 16.** Two term-labeled graphs $G = \langle V, E, s, t, l, \iota, o\rangle$ and $H = \langle V', E', s', t', l', \iota', o'\rangle$ are *weakly isomorphic*, written $G \cong H$, if there is a pair of bijective functions $\langle f, g\rangle$ satisfying

1. $f(\iota) = \iota'$ and $f(o) = o'$.
2. For all vertices $x \in V$, $l(x) \equiv l'(f(x))$.
3. For all edges $e \in E$ and $e' \in E'$ such that $g(e) = e'$, $L(s'(e'), t'(e'), e', l(e))$.

▶ **Example 17.** Weakly isomorphic graphs always have isomorphic expansions. However, the converse is not true: all three graphs below have isomorphic expansions, but only the first two are weakly isomorphic.



We now define the rewriting system on term-labeled graphs, as depicted in Figure 3.

▶ **Definition 18.** Let $G = \langle V, E, s, t, l, \iota, o\rangle$ be a term-labeled graph. We write $G \mapsto G'$ if G' can be obtained from G by applying one of the following rules.

1. If $l(x) = \alpha$, $L(x_1, x, e_1, u)$ and $L(x, x_2, e_2, v)$ where $x \notin \{\iota, o, x_1, x_2\}$ and e_1 and e_2 are the only incident edges of x, then replace e_1 and e_2 with an $u\alpha v$-labeled edge from x_1 to x_2 and remove x.
2. If $l(x) = \alpha$, $l(y) = \beta$ and $L(x, y, e, u)$ where $y \notin \{\iota, o\}$ and e is the only edge incident to y, then change the label of x to $\alpha{\cdot}\mathrm{dom}(u{\cdot}\beta)$ and remove y and e.
3. If $L(x, y, e_1, u)$ and $L(x, y, e_2, v)$ then replace e_1 and e_2 with a $(u \parallel v)$-labeled xy-edge.
4. If $s(e) = t(e) = x$, $l(x) = \alpha$ and $l(e) = u$, then assign label $\alpha(u \parallel 1)$ to x and remove e.

It is straightforward to verify that $\mapsto$ preserves the requirements on edge and vertex labels from Definition 15. We write $\rightsquigarrow$ for the reflexive transitive closure of $\mapsto$ up to $\cong$ (i.e., $G \rightsquigarrow H$ iff either $G \cong H$ or there exists a sequence $G \cong G_1 \mapsto G_2 \cong G_3 \mapsto \ldots \mapsto G_n \cong H$).

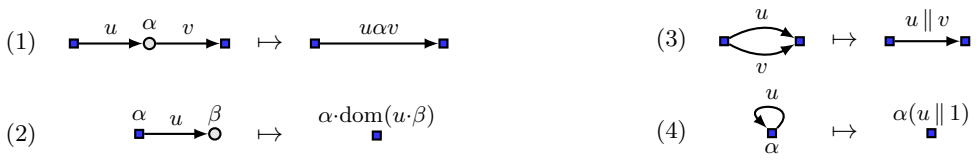


Figure 3 Rewriting system for term-labeled graphs. The square vertices may have additional incident edges. The circular vertices (i.e., those that are removed) must be distinct from input and output and may not have other incident edges.

▶ **Lemma 19.** *The relation* $\mapsto$ *is terminating.*

▶ **Lemma 20.** *If* $G \mapsto G'$*, then* $\exp(G) \simeq \exp(G')$*.*

▶ **Lemma 21.** *If* $G \cong H$ *and* $G \mapsto G'$*, then there exists* H' *such that* $H \mapsto H'$ *and* $G' \cong H'$*.*

We now show that the relation $\mapsto$ is locally confluent up to weak isomorphism. The proof is fundamental: while closing the various critical pairs, we rediscover most of the axioms of 2pdom-algebras. Note that for rules (1) and (3) we do *not* assume that the square vertices are distinct. This introduces some critical pairs (e.g, between rules 3 and 4), but ensures that reductions are preserved in contexts that collapse input and output (Lemma 29 below).

▶ **Lemma 22** (Local Confluence)**.** *If* $G_1 \leftarrow\!\shortmid G \mapsto G_2$*, then there exist* G_1' *and* G_2' *such that* $G_1 \mapsto G_1'$*,* $G_2 \mapsto G_2'$ *and* $G_1' \cong G_2'$*.*

Proof. If the redexes do not overlap, we can reduce G_1 and G_2 to the same graph in one step. It remains to analyze the critical pairs. The nontrivial interactions are as follows:

- Rules 1 and 2 can interact as follows:

  After applying rule 2 on both sides, it suffices to show $\mathrm{dom}(u\alpha v\beta) \equiv \mathrm{dom}(u\alpha\mathrm{dom}(v\beta))$, which is an instance of (A13).
- Rules 1 and 3 can interact as follows:

  After applying rule 4 on the left and rule 2 on the right, it suffices to show that we have $u\alpha v^\circ \parallel 1 \equiv \mathrm{dom}((u \parallel v)\alpha)$. We prove it as follows using Lemma 8(4) and (A10): $\mathrm{dom}((u \parallel v)\alpha) \equiv \mathrm{dom}(u \parallel v\alpha) \equiv 1 \parallel u(v\alpha)^\circ \equiv u\alpha v^\circ \parallel 1$.
- Rules 3 and 4 can interact as follows:

  After applying rule 4 on both sides, it suffices to show $u \parallel v \parallel 1 \equiv (u \parallel 1)(v \parallel 1)$. Since $v \parallel 1$ is a test, this follows with Lemma 8(4) and (A5).

There are a number of other critical pairs that can easily be resolved using (A1)-(A8) (e.g., two overlapping instances of rule 1 that differ in the direction the edges are matched, or overlapping instances of rule 3). Similarly, overlapping instances of rules 2 and 4 remain instances after the first rule has been applied and the resulting graphs only differ in the order of the tests being generated; thus they are weakly isomorphic by Lemma 8(3). ◀

▶ **Proposition 23** (Confluence)**.** *If* $G_1 \leftsquigarrow G \rightsquigarrow G_2$*, then there exists* H *such that* $G_1 \rightsquigarrow H \leftsquigarrow G_2$*.*

&\quad (\gamma_1), (\gamma_2) \Rightarrow (\gamma_1\gamma_2)
\end{aligned}
$$

Figure 5 Test analysis for Σ_{dom}-terms.

▶ **Definition 24.** We call a term-labeled graph *atomic* if it consists of either a single vertex and no edges or two vertices connected by a single edge as depicted in Figure 4. If A is atomic, we write $\underline{A}$ for the term that can extracted from A, i.e., $\alpha u \beta$, $\alpha u^\circ \beta$, or α for the atoms in Figure 4, from left to right.

▶ **Lemma 25.** *If $A \leftsquigarrow G \rightsquigarrow B$ for some atomic graphs A, B, then $\underline{A} \equiv \underline{B}$.*

Proof. We have $A \cong B$ by Proposition 23, since atomic graphs are irreducible. The claim then follows by case analysis on A and B. ◀

4 Reducibility of Term-Graphs

We now show that the rewriting system from the previous section can be used to reduce graphs of the shape $\mathsf{g}(u)$ to atomic graphs. As a consequence, we obtain that $u \equiv v$ iff $\mathsf{g}(u) \simeq \mathsf{g}(v)$ and, hence, that equivalence of Σ_{dom}-terms is decidable.

To show that $\mathsf{g}(u)$ reduces to an atomic graph, we define a function computing for every u an equivalent term that can be obtained as $\underline{A}$ for some atomic graph A. In particular, if u is not a test, it computes "maximal" tests α and β and a non-test v such that $u \equiv \alpha v \beta$.

▶ **Definition 26.** We define a function f from Σ_{dom}-terms to $\mathcal{T} \cup \mathcal{T} \times \mathcal{N} \times \mathcal{T}$ as depicted in Figure 5, as well as functions $\lceil \_ \rceil$ and $\lfloor \_ \rfloor$ interpreting elements of $\mathcal{T} \cup \mathcal{T} \times \mathcal{N} \times \mathcal{T}$ as atomic graphs and terms, respectively: $\lceil (\alpha, u, \beta) \rceil$ is the graph on the left in Figure 4 and $\lceil (\alpha) \rceil$ is the graph on the right, $\lfloor (\alpha, u, \beta) \rfloor \triangleq \alpha u \beta$, and $\lfloor (\gamma) \rfloor \triangleq \gamma$. Note that $\underline{\lceil (\alpha, u, \beta) \rceil} = \lfloor (\alpha, u, \beta) \rfloor$.

A summary of the functions defined so far is given in Figure 6.

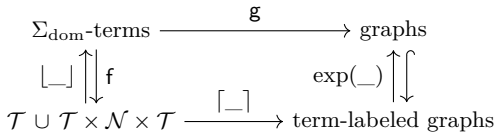

Figure 6 Summary of functions between terms and graphs.

▶ **Lemma 27.** $u \equiv \lfloor \mathsf{f}(u) \rfloor$.

Proof. By induction on u. The cases for a, 1, and $\mathrm{dom}(u)$ are trivial. The case for u° follows with Lemma 8(2). We show the case for $\mathsf{f}(u \parallel v)$ where $\mathsf{f}(u) = (\alpha_u, u', \beta_u)$ and $\mathsf{f}(v) = (\alpha_v, v', \beta_v)$.

$$\begin{aligned}
\lfloor \mathsf{f}(u \parallel v) \rfloor &= \alpha_u \alpha_v (u' \parallel v') \beta_u \beta_v \\
&\equiv (\alpha_u u' \beta_u) \parallel (\alpha_v v' \beta_v) && \text{Lemma 8(4) and commutativity of } \parallel \\
&\equiv \lfloor \mathsf{f}(u) \rfloor \parallel \lfloor \mathsf{f}(v) \rfloor \\
&\equiv u \parallel v && \text{induction hypothesis}
\end{aligned}$$

The remaining cases are straightforward. ◀

We now show that $\mathsf{g}(u)$ (seen as a term-labeled graph) reduces to $\lceil \mathsf{f}(u) \rceil$. To do so, we first extend the graph operations to term-labeled graphs and prove the context lemma below.

▶ **Definition 28.** If a graph G occurs as a term-labeled graph, it is to be read as the graph where every vertex is labeled with 1 (and every edge is labeled with a single letter as before). We extend the operations $\cdot$, $\parallel$ and $\mathrm{dom}(\_)$ to term-labeled graphs. If two vertices x and y are identified by an operation, we label the resulting vertex with $l(x) \cdot l(y)$.

▶ **Lemma 29** (Context Lemma). *If* $G \rightsquigarrow G'$*, then* $G \parallel H \rightsquigarrow G' \parallel H$*,* $G \cdot H \rightsquigarrow G' \cdot H$*,* $H \cdot G \rightsquigarrow H \cdot G'$*, and* $\mathrm{dom}(G) \rightsquigarrow \mathrm{dom}(G')$.

Proof. By induction on $G \rightsquigarrow G'$. First, all operations preserve weak isomorphisms. Second, a redex in G is still a redex in $G \cdot H$, $H \cdot G$, and $\mathrm{dom}(G)$ since G remains unchanged except that one of its nodes may cease to be input or output. Similarly, a redex in G is also a redex in $G \parallel H$ (even if H is a test: we do not require the square vertices in rules 1 and 3 to be distinct so that redexes are preserved under collapsing input and output). ◀

Note that the converse of Lemma 29 does not hold. For instance, $\mathrm{dom}(\underline{a})$ (cf. Figure 1) reduces by rule 2 to a graph G with a single node labeled $1\mathrm{dom}(a1)$. Hence, $\mathrm{dom}(\underline{a}) \rightsquigarrow \mathrm{dom}(G)$ since $G \cong \mathrm{dom}(G)$, but $\underline{a}$ is an atom and thus irreducible.

▶ **Proposition 30** (Reducibility). $\mathsf{g}(u) \rightsquigarrow \lceil \mathsf{f}(u) \rceil$

Proof. By induction on u. The base cases are trivial. For the inductive cases, we use Lemma 29 and the induction hypothesis to reduce the respective subgraphs to atomic graphs. The resulting graphs always reduce to atomic graphs in a single step (cf. [11]). ◀

We can finally characterise the equational theory of 2pdom-algebras:

▶ **Theorem 31.** $2pdom \vdash u = v$ *iff* $\mathsf{g}(u) \simeq \mathsf{g}(v)$.

Proof. The direction from left to right follows with Proposition 5. For the converse direction, assume $\mathsf{g}(u) \simeq \mathsf{g}(v)$. Then $\mathsf{g}(u) \cong \mathsf{g}(v)$ and therefore $\underline{\lceil \mathsf{f}(u) \rceil} \equiv \underline{\lceil \mathsf{f}(v) \rceil}$ by Proposition 30 and Lemma 25. Hence, $u \equiv \lfloor \mathsf{f}(u) \rfloor = \underline{\lceil \mathsf{f}(u) \rceil} \equiv \underline{\lceil \mathsf{f}(v) \rceil} = \lfloor \mathsf{f}(v) \rfloor \equiv v$ using Lemma 27 twice. ◀

As explained in the introduction we did not use minors to obtain this result. Actually, we did not use tree decompositions either: those arise only in the following section, where we need to characterize the image of the function g. This sharply contrasts with the approach from [7], where both tree decompositions and minors are used to obtain the above characterization.

5 The free 2pdom-algebra

In order to show that the connected graphs in TW_2 form the free 2p-algebra, it remains to obtain an inverse to g (up to $\equiv$), i.e., we need to extract terms from such graphs. We again make use of the rewriting system.

In a slight abuse of notation, we also write $G \in \mathsf{TW}_2$ to denote that (the strong skeleton of) a term-labeled graph G has treewidth at most two.

▶ **Lemma 32** (Preservation). *If $G \in \mathsf{TW}_2$ is a connected term-labeled graph and $G \mapsto G'$, then $G' \in \mathsf{TW}_2$ and G' is connected.*

▶ **Lemma 33** (Progress). *If $G \in \mathsf{TW}_2$ is a connected term-labeled graph, then either there exists some G' such that $G \mapsto G'$ or G is atomic.*

Proof. W.l.o.g., we can assume that rules 3 and 4 do not apply. Thus, it suffices to show that either ι and o are the only vertices of G or that there is some vertex distinct from input and output that has at most two neighbors. Let T be a tree decomposition of the strong skeleton of G of width at most two, and remove leafs of T that are included in their unique neighbor (T remains a tree-decomposition). If T has only one node (say t) then $\{\iota, o\} \subseteq B_t$. Hence, if there is another vertex, it has degree at most two. Otherwise, let t be a leaf and let z be a vertex appearing only in B_t. Without loss of generality, we can assume $z \notin \{\iota, o\}$. (If $z = \iota$ then $o \in B_t$, due to the ιo-edge in the strong skeleton; hence, for any other leaf, neither ι nor o can be the vertex unique to that leaf.) Since z appears only on B_t it has at most two neighbors. ◀

▶ **Definition 34.** We define a function t' from connected term-labeled graphs of treewidth at most two to terms as follows: $\mathsf{t}'(G) \triangleq \underline{A}$ for some atomic graph such that $G \mapsto^* A$. A suitable atomic graph A can be computed by blindly applying the rules (Lemmas 32 and 33): all choices lead to equivalent terms (Lemma 25). For connected (standard) graphs G, we write $\mathsf{t}(G)$ for $\mathsf{t}'(G')$ where G' is G seen as a term-labeled graph.

▶ **Lemma 35.** *If $G \in \mathsf{TW}_2$ is a term-labeled graph and $G \rightsquigarrow H$, then $\mathsf{t}'(G) \equiv \mathsf{t}'(H)$.*

Proof. Follows with Lemma 25. ◀

As an immediate consequence of the lemma above we also have:

▶ **Proposition 36.** *If $G, H \in \mathsf{TW}_2$ are are connected and $G \simeq H$, then $\mathsf{t}(G) \equiv \mathsf{t}(H)$.*

We now show that t and g are inverses up to term equivalence and isomorphism respectively.

▶ **Proposition 37.** *For all Σ_{dom}-terms u, $\mathsf{t}(\mathsf{g}(u)) \equiv u$.*

Proof. We have $\mathsf{t}(\mathsf{g}(u)) \equiv \underline{\lceil \mathsf{f}(u) \rceil} = \lfloor \mathsf{f}(u) \rfloor$ by Proposition 30 and Lemma 35. The claim then follows with Lemma 27. ◀

▶ **Proposition 38.** *If $G \in \mathsf{TW}_2$ is connected, then $\mathsf{g}(\mathsf{t}(G)) \simeq G$.*

Proof. We have $\mathsf{t}(G) = \underline{A}$ for some A such that $G \mapsto^* A$. Hence, $\exp(A) \simeq G$ (Lemma 20). The claim follows since $\mathsf{g}(\underline{A}) \simeq \exp(A)$ for all atoms A. ◀

The function g is a Σ_{dom}-homomorphism by definition. By the above results, this is actually an isomorphism between the $2pdom$-algebra of connected graphs in TW_2 and the (canonically) free $2pdom$-algebra of Σ_{dom}-terms quotiented by $\equiv$:

▶ **Theorem 39** ([16]). *The connected graphs in TW_2 (with labels in $\mathcal{A}$) form the free 2pdom-algebra (over $\mathcal{A}$).*

6 The free 2p-algebra

We now extend the results from the previous section to disconnected graphs. That is, we show that the class of all graphs in TW_2 forms the free 2p-algebra [7]. We use for that the previous function t to extract terms from the various connected components of a graph.

In this section, we take $u \equiv v$ to mean $2p \vdash u = v$. Recall that $2p \vdash u = v$ whenever $2pdom \vdash u = v$ (Lemma 4). Hence, all the lemmas from the previous section still apply.

▶ **Definition 40.** Let G be a graph. For vertices x, y of G, we write $G[x, y]$ for the graph G with input set to x and output set to y. We abbreviate $G[x, x]$ as $G[x]$. Further, we write G_x for the connected component of x (as a subgraph of G, with input and output set to x).

▶ **Definition 41.** Let $\mathcal{C}(G)$ be the collection of components G_x obtained by choosing some vertex x for every connected component of G containing neither ι nor o. We define a function $\mathsf{t}^\top$ extracting terms from (possibly disconnected) graphs as follows:

$$c_G \triangleq \mathop{\Big\|}_{H \in \mathcal{C}(G)} \top\cdot\mathsf{t}(H)\cdot\top \qquad \mathsf{t}^\top(G) \triangleq \begin{cases} \mathsf{t}(G_\iota)\cdot\top\cdot\mathsf{t}(G_o) \parallel c_G & \iota \text{ and } o \text{ disconnected} \\ \mathsf{t}(G_\iota[\iota, o]) \parallel c_G & \iota \text{ and } o \text{ connected} \end{cases}$$

Note that the function $\mathsf{t}^\top$ needs to choose shared input/outputs vertices for all disconnected components. For isomorphic arguments, these choices can differ. We begin by showing that this choice does not matter up to term equivalence.

▶ **Lemma 42.** *Let $G \in \mathsf{TW}_2$ be a connected test and let x be a neighbor of ι in G. We have $\mathsf{t}(G)\cdot\top \equiv \mathsf{t}(G[\iota, x])\cdot\top$.*

Proof. Since $G \in \mathsf{TW}_2$, so is $G[\iota, x]$. Hence, $G[\iota, x] \rightsquigarrow \lceil(\alpha, u, \beta)\rceil$ for some terms α,β, and u. Since $G = \mathrm{dom}(G[\iota, x])$, we also have $G \rightsquigarrow \mathrm{dom}(\lceil(\alpha, u, \beta)\rceil)$ by Lemma 29. Moreover, $\mathrm{dom}(\lceil(\alpha, u, \beta)\rceil) \rightsquigarrow \lceil(\alpha\cdot\mathrm{dom}(u\beta))\rceil$ by rule 2. Using Lemma 35 and (A11), we have: $\mathsf{t}(G)\cdot\top \equiv \mathsf{t}'(\lceil(\alpha\cdot\mathrm{dom}(u\beta))\rceil)\cdot\top = (\alpha\cdot\mathrm{dom}(u\beta))\cdot\top \equiv \alpha u\beta\cdot\top = \mathsf{t}'(\lceil(\alpha, u, \beta)\rceil)\cdot\top \equiv \mathsf{t}(G[\iota, x])\cdot\top$ ◀

▶ **Lemma 43.** *Let $G \in \mathsf{TW}_2$ be a connected graph and let x, y be vertices of G. We have $\top\cdot\mathsf{t}(G[x])\cdot\top \equiv \top\cdot\mathsf{t}(G[y])\cdot\top$*

Lemma 43 follows by repeatedly applying Lemma 42 along some xy-path. Both lemmas also appear in [7]. We remark that the proof of Lemma 42 given here, which depends on the definition of t, is considerably simpler than the one in [7]. The proof of Lemma 43 remains essentially unchanged.

▶ **Proposition 44.** *Let $G, H \in \mathsf{TW}_2$. If $G \simeq H$, then $\mathsf{t}^\top(G) \equiv \mathsf{t}^\top(H)$.*

Proof. Follows with Proposition 36 and Lemma 43. ◀

▶ **Proposition 45.** $\mathsf{g}(\mathsf{t}^\top(G)) \simeq G$.

▶ **Lemma 46.** $\mathsf{t}^\top$ *is a homomorphism of 2p-algebras.*

Proof. We already showed that that $\mathsf{t}^\top$ respects graph isomorphisms. It remains to show that $\mathsf{t}^\top$ commutes with all operations.

We show $\mathsf{t}^\top(G{\cdot}H) \equiv \mathsf{t}^\top(G){\cdot}\mathsf{t}^\top(H)$. Let $F \triangleq G{\cdot}H$. We distinguish four cases based on whether ι and o are connected in G and H respectively.

ι and o disconnected in both G and H: In that case, G_o and H_ι are merged into one component of F that is connected neither to the input nor to the output of F. By Lemma 43 and Proposition 36 we therefore have: $c_F \equiv (\top\mathsf{t}(G_o{\cdot}H_\iota)\top) \parallel c_G \parallel c_H$. We reason as follows:

$$\begin{aligned}
\mathsf{t}^\top(F) &\equiv \mathsf{t}(F_\iota){\cdot}\top{\cdot}\mathsf{t}(F_o) \parallel c_F && \iota \text{ and } o \text{ disconnected in F}\\
&\equiv \mathsf{t}(G_\iota){\cdot}\top{\cdot}\mathsf{t}(H_o) \parallel \top{\cdot}\mathsf{t}(G_o{\cdot}H_\iota){\cdot}\top \parallel c_G \parallel c_H && F_\iota \simeq G_\iota,\ F_o \simeq G_o\\
&\equiv \mathsf{t}(G_\iota){\cdot}\top{\cdot}\mathsf{t}(G_o{\cdot}H_\iota){\cdot}\top{\cdot}\mathsf{t}(H_o) \parallel c_G \parallel c_H && \text{Lemma 9(1)}\\
&\equiv \mathsf{t}(G_\iota){\cdot}\top{\cdot}\mathsf{t}(G_o){\cdot}\mathsf{t}(H_\iota){\cdot}\top{\cdot}\mathsf{t}(H_o) \parallel c_G \parallel c_H && \mathsf{t} \text{ is a homomorphim}\\
&\equiv \mathsf{t}^\top(G){\cdot}\mathsf{t}^\top(H) && \text{Lemma 9(2) and its dual}
\end{aligned}$$

ι and o connected in G but not in H: We have $c_F \equiv c_G \parallel c_H$ by Prop. 36 and Lemma 43.

$$\begin{aligned}
\mathsf{t}^\top(F) &\equiv \mathsf{t}(F_\iota){\cdot}\top{\cdot}\mathsf{t}(F_o) \parallel c_F\\
&\equiv \mathsf{t}(\mathrm{dom}(G_\iota[\iota,o]{\cdot}H_\iota)){\cdot}\top{\cdot}\mathsf{t}(H_o) \parallel c_F && F_\iota \simeq \mathrm{dom}(G_\iota[\iota,o]\cdot H_\iota),\ F_o \simeq H_o\\
&\equiv \mathsf{t}(G_\iota[\iota,o]){\cdot}\mathsf{t}(H_\iota){\cdot}\top{\cdot}\mathsf{t}(H_o) \parallel c_F && \text{(A11), } \mathsf{t} \text{ is a homomorphism}\\
&\equiv \mathsf{t}(G_\iota[\iota,o]){\cdot}\mathsf{t}(H_\iota){\cdot}\top{\cdot}\mathsf{t}(H_o) \parallel c_G \parallel c_H\\
&\equiv \mathsf{t}^\top(G){\cdot}\mathsf{t}^\top(H) && \text{Lemma 9(2) and its dual}
\end{aligned}$$

The case where input and output are connected only in H is symmetric and the case where they are connected in both graphs follows from t being a homomorphism.

Proving that $\mathsf{t}^\top$ commutes with the other operations is done in a similar manner. ◀

▶ **Proposition 47.** *For all $\Sigma_\top$-terms u, $\mathsf{t}^\top(\mathsf{g}(u)) \equiv u$.*

Proof. By induction on u, using Lemma 46. ◀

▶ **Theorem 48** ([7])**.** *The graphs in TW_2 (with labels in $\mathcal{A}$) form the free 2p-algebra (over $\mathcal{A}$).*

7 1-free 2p-algebras

We now show that the techniques from the previous sections can be adapted to the setting where 1 (and hence dom(_)) are removed from the signature. We define algebras over the signature $\Sigma_\top^{-1} \triangleq \Sigma_\top \setminus \{1\}$, which we call 1-free 2p-algebras, and show that the graphs of treewidth at most two without self-loops and with distinct input and output form the free 1-free 2p-algebra (over $\mathcal{A}$).

The axioms for 1-free 2p-algebras are A1-A4,A6-A8 plus the following three axioms:

$$(u{\cdot}v \parallel w){\cdot}\top = (u \parallel w{\cdot}v^\circ){\cdot}\top \tag{A15}$$

$$u{\cdot}(v{\cdot}\top \parallel w) = (u \parallel \top{\cdot}v^\circ){\cdot}w \tag{A16}$$

$$u{\cdot}v \parallel \top{\cdot}w = u{\cdot}(v \parallel \top{\cdot}w) \tag{A17}$$

The main complication in adapting our techniques to the 1-free case is that the syntax of 1-free 2p-algebras cannot express tests, even though the algebra of graphs still exhibits tests-like structures. For instance, if G is a test without self-loops, then $G{\cdot}\top$ is a graph of the proposed free 1-free 2p-algebra. To account for this, we distinguish between the type of $\Sigma_{\top}^{-1}$-terms, written Tm, and a type of *(syntactic) tests* defined as follows:

$$\alpha \in \mathsf{Tst} ::= 1 \mid [u] \qquad (u \in \mathsf{Tm})$$

Tests, which are not terms, allow us to describe graphs that are tests. We let $\alpha,\beta,\ldots$ range over tests, and we extend the definition of g to tests by setting $\mathsf{g}(1) = 1$ and $\mathsf{g}([u]) = \mathrm{dom}(\mathsf{g}(u))$. Intuitively, in a test $[u]$, the output of the term u does not matter: u will always be used in contexts where this information disappears, e.g., as in $u\top$; this allows us to treat $[u]$ essentially like $\mathrm{dom}(u)$. It also motivates the following notion of equivalence for tests: $1 \equiv 1$, and $[u] \equiv [v]$ if $u{\cdot}\top \equiv v{\cdot}\top$.

▶ **Lemma 49.** *If $\alpha \equiv \beta$ then $\mathsf{g}(\alpha) \simeq \mathsf{g}(\beta)$.*

We extend the sequential composition to take one or two tests as arguments in a manner that 1 is the neutral element on both sides:

$$\begin{array}{lll} 1{\cdot}v \triangleq v & u{\cdot}1 \triangleq u & 1{\cdot}\alpha \triangleq \alpha \\ [u]{\cdot}v \triangleq u\top \parallel v & u{\cdot}[v] \triangleq u \parallel \top v^\circ & [u]{\cdot}1 \triangleq [u] \\ & & [u]{\cdot}[v] \triangleq [u\top \parallel v] \end{array}$$

Note that $\alpha{\cdot}\beta$ is a test whereas all other variants are terms. The three operations above appropriately preserve test equivalence (e.g., if $\alpha \equiv \beta$, then $u\alpha \equiv u\beta$, $\alpha u \equiv \beta u$, $\gamma\alpha \equiv \gamma\beta$, $\alpha\gamma \equiv \beta\gamma$ for all terms u and tests γ.

The definitions above essentially yield a 2-sorted extension of 1-free 2p-algebras. We prove various laws, including all axioms of 2pdom-algebras that can still be expressed in the 2-sorted setting (using $[\_]$ instead of $\mathrm{dom}(\_)$). Examples of laws that cannot be expressed in the 2-sorted setting are $\mathrm{dom}(\alpha) \equiv \alpha$, and $\mathrm{dom}(u \parallel v) \equiv 1 \parallel uv^\circ$.

▶ **Lemma 50.** *We have the following equivalences:*

1. $u\top \equiv [u]\top$ *and* $\top u \equiv \top[u^\circ]$.
2. $(\alpha u)^\circ \equiv u^\circ\alpha$, $(u\alpha)^\circ \equiv \alpha u^\circ$.
3. $(xy)z \equiv x(yz)$ *(for all x, y, z either test or term).*
4. $[uv] \equiv [u[v]]$
5. $\alpha\beta \equiv \beta\alpha$
6. $\alpha(v \parallel w) \equiv \alpha v \parallel w$.
7. $[uv \parallel w] \equiv [u \parallel wv^\circ]$.

Proof. For all statements involving tests α of unknown shape, we distinguish the cases $\alpha = 1$ (usually trivial) and $\alpha = [w]$ for some w. Claims (1) and (2) are straightforward. By (2) and the laws for converse, we only need to consider 5 of the 8 cases of (3). $(u\alpha)v \equiv u(\alpha v)$ follows with (A16) and $(uv)\alpha \equiv u(\alpha v)$ follows with (A17). For $(\alpha\beta)\gamma \equiv \alpha(\beta\gamma)$ we repeatedly use (A15) with $v = \top$. The remaining cases for associativity are straightforward. Claims (4) and (5) follow with associativity. Claim (6) follows with (A1). Claim (7) follows with (A15). ◀

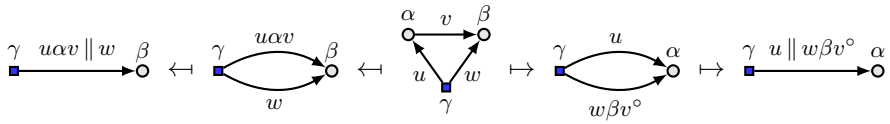
Having recovered most of the laws of 2pdom-algebras, we adapt the rewriting system for 2pdom-algebras (Figure 3) to the 1-free case. We define term-labeled graphs as for 2pdom, with the difference that now vertices are labeled with syntactic tests and edges are labeled with $\Sigma_{\top}^{-1}$-terms (whose graphs are never tests). The rewriting system on term-labeled graphs (Figure 3) is adapted by replacing $\mathrm{dom}(u)$ with $[u]$, removing rule 4, and restricting rules 1

and 3 such that the two outer vertices must be distinct. For rule 1, this is necessary to avoid introducing self loops.

Local confluence adapts, although for one of the pairs we now need two reduction steps to join the two alternatives.

▶ **Lemma 51** (Local Confluence). *If $G_1 \leftarrow\!\shortmid\, G \mapsto G_2$, then there exist G_1' and G_2' such that $G_1 \rightsquigarrow G_1'$, $G_2 \rightsquigarrow G_2'$ and $G_1' \cong G_2'$.*

Proof. The only interesting (new) critical pair is that of overlapping instances of rule 1, where the outer nodes are the same. Due to the restriction that the outer nodes of rule 1 must be distinct, this pair can no longer be joined by applying rule 1. Instead we use rules 3 and 2 as follows:



After applying rule 2 on both sides, it suffices to show $[(u\alpha v \parallel w)\beta] \equiv [(u \parallel w\beta v^\circ)\alpha]$. This follows with Lemma 50(6+7). ◀

In order to adapt Proposition 30, we need to restrict to terms u such that $\mathsf{g}(u)$ is connected. We write Tm' and Tst' for the set of terms and tests respectively, where tests and the extended sequential composition are treated as primitive and $\top$ does not occur. We then employ a function $\mathsf{f} : \mathsf{Tm}' \to \mathsf{Tst}' \times \mathsf{Tm}' \times \mathsf{Tst}'$ that can be seen as a type directed variant of the function in Figure 5.

$$
\begin{aligned}
\mathsf{f}(a) &= (1, a, 1)\\
\mathsf{f}(u^\circ) &= \mathsf{let}\ (\alpha_u, u', \beta_u) := \mathsf{f}(u)\ \mathsf{in}\ (\beta_u, u'^\circ, \alpha_u)\\
\mathsf{f}(u \parallel v) &= \mathsf{let}\ (\alpha_u, u', \beta_u), (\alpha_v, v', \beta_v) := \mathsf{f}(u), \mathsf{f}(v)\ \mathsf{in}\ (\alpha_u\alpha_v, u' \parallel v', \beta_u\beta_v)\\
\mathsf{f}(u{\cdot}v) &= \mathsf{let}\ (\alpha_u, u', \beta_u), (\alpha_v, v', \beta_v) := \mathsf{f}(u), \mathsf{f}(v)\ \mathsf{in}\ (\alpha_u, u'\beta_u\alpha_v v', \beta_v)\\
\mathsf{f}(\gamma{\cdot}u) &= \mathsf{let}\ (\alpha_u, u', \beta_u) := \mathsf{f}(u)\ \mathsf{in}\ (\gamma\alpha_u, u', \beta_u)\\
\mathsf{f}(u{\cdot}\gamma) &= \mathsf{let}\ (\alpha_u, u', \beta_u) := \mathsf{f}(u)\ \mathsf{in}\ (\alpha_u, u', \beta_u\gamma)
\end{aligned}
$$

▶ **Lemma 52.** *If $u \in \mathsf{Tm}'$ and $\alpha \in \mathsf{Tst}'$, then $\mathsf{g}(u) \rightsquigarrow \lceil \mathsf{f}u \rceil$ and $\mathsf{g}(\alpha) \rightsquigarrow \lceil (\alpha) \rceil$.*

Proof. We have a context lemma similar to Lemma 29. The proof then proceeds by mutual induction on u and α. The cases correspond to those of Proposition 30. ◀

We define two extraction functions t_1 and t_2, where t_1 extracts syntactic tests (in Tst') from graphs that are tests and t_2 extracts terms (in Tm') from non-tests. Both functions are defined just like t (Definition 34), exploiting the fact that the rewriting system does not merge or delete input and output. Propositions 37 and 38 then adapt without conceptual changes.

▶ **Proposition 53.**

1. $\mathsf{t}_1(\mathsf{g}(\alpha)) \equiv \alpha$ *for all* $\alpha \in \mathsf{Tst}'$ *and* $\mathsf{t}_2(\mathsf{g}(u)) \equiv u$ *for all* $u \in \mathsf{Tm}'$.
2. *If* $G \in \mathsf{TW}_2$ *is a connected test without self loops, then* $\mathsf{g}(\mathsf{t}_1(G)) \simeq G$.
3. *If* $G \in \mathsf{TW}_2$ *is a connected non-test without self loops, then* $\mathsf{g}(\mathsf{t}_2(G)) \simeq G$.

Using t_1 and t_2, we define a variant of $\mathsf{t}^\top$ extracting $\Sigma_\top^{-1}$-terms from non-tests without self-loops.

▶ **Definition 54.** Let $\mathcal{C}(G)$ as in Definition 41. We define

$$c_G \triangleq \mathop{\Big\|}_{H \in \mathcal{C}(G)} \top \cdot \mathsf{t}_1(H) \cdot \top \qquad \mathsf{t}^\top(G) \triangleq \begin{cases} \mathsf{t}_1(G_\iota) \cdot \top \cdot \mathsf{t}_1(G_o) \parallel c_G & \iota \text{ and } o \text{ disconnected} \\ \mathsf{t}_2(G_\iota[\iota, o]) \parallel c_G & \iota \text{ and } o \text{ connected} \end{cases}$$

That $\mathsf{t}^\top$ respects graph isomorphisms is immediate with Proposition 53. To show $\mathsf{t}^\top$ is a homomorphism of 1-free 2p-algebras, we require a 2-sorted analog to Lemma 9.

▶ **Lemma 55.** *We have the following equivalences:*

1. $\top u^\circ \top \equiv \top u \top$.
2. $\alpha v \equiv \alpha \top \parallel v$.
3. $\alpha \top \beta \equiv \alpha \top \parallel \top \beta$
4. $uv \parallel \top \alpha \top \equiv (u \parallel \top \alpha \top) v$
5. $\alpha \top \beta \parallel \top \gamma \top \equiv \alpha \top \gamma \top \beta$

Note that, due to Lemma 50(1), any equivalence where a test α appears either only as $\alpha\top$ or only as $\top\alpha$ (i.e., in α in Lemma 55(4)), also holds if α is replaced by a term.

The remaining proofs of Section 6 adapt to the 1-free setting by carefully distinguishing between terms and tests, but without any conceptual changes. For instance, we have $\mathsf{t}_1(G)\top \equiv \mathsf{t}_2(G[\iota, x])\top$ for neighbors x of ι.

▶ **Theorem 56.** *The graphs (with labels in $\mathcal{A}$) of treewidth at most two, with distinct input and output, and without self-loops form the free 1-free 2p-algebra (over $\mathcal{A}$).*

The axioms we listed for 1-free 2p-algebras are precisely those needed to prove the 2-sorted 2pdom- and 2p-laws. The proofs of Lemmas 50 and 55 have been verified in the Coq proof assistant [6]. We also used the model generator Mace4 [15] to verify that the axioms of 1-free 2p-algebras are independent. The corresponding scripts can be downloaded from [10].

8 Conclusion and directions for future work

We have proved that graphs in TW_2, connected graphs in TW_2, and self-loop free graphs in TW_2 with distinct input and output respectively form the free 2p-algebra, the free 2pdom-algebra, and the free 1-free 2p-algebra.

To do so, we used a graph rewriting system that makes it possible to extract terms from connected graphs in TW_2, in a bottom-up fashion. This technique is much easier than the one used in [7] in that it is more local and does not require us to study the precise structure of graphs in TW_2 (i.e., through excluded minors).

As explained in the introduction, the result about connected graphs can be reduced to the one about arbitrary graphs by model-theoretic means: one can easily embed a 2pdom-algebra into a 2p-algebra [16], so that 2p-algebras form a conservative extension of 2pdom-algebras. As a corollary of Theorem 56, we get that 2p-algebras also form a conservative extension of 1-free 2p-algebras. It is however unclear how to prove this result directly, by model-theoretic means: terms which are missing in 1-free 2p-algebras (self-loops) can occur deep inside terms of 2p-algebras, unlike terms which are missing in 2pdom-algebras (disconnected components).

As a natural follow-up to this work, we would like to study whether one can characterize the classes of graphs of higher treewidth as free algebras. The present approach seems promising for treewidth at most three: a reasonable rewriting system is known for recognising such graphs [3]. In contrast, trying to exploit the four excluded minors known to characterize treewidth three [4, 3] seems extremely difficult. For larger treewidth, rewriting systems recognizing graphs of a given treewidth can be shown to exist [1]. However, the result is nonconstructive in the same way as the existence of a finite set of excluded minors for each treewidth [17]).

Abstract

We investigate the notion of *pseudodeterminstic approximation algorithms*. A randomized approximation algorithm A for a function f is *pseudodeterministic* if for every input x there is a *unique value* v so that $A(x)$ outputs v with high probability, and v is a good approximation of $f(x)$. We show that designing a pseudodeterministic version of Stockmeyer's well known approximation algorithm for the NP-membership counting problem will yield a new circuit lower bound: if such an approximation algorithm exists, then for every k, there is a language in the complexity class $\mathrm{ZPP}^{\mathrm{NP}}_{tt}$ that does not have n^k-size circuits. While we do not know how to design such an algorithm for the NP-membership counting problem, we show a general result that any randomized approximation algorithm for a counting problem can be transformed to an approximation algorithm that has a *constant number* of *influential* random bits. That is, for most settings of these influential bits, the approximation algorithm will be pseudodeterministic.

1 Introduction

Consider the computational problem: Given an input 1^n, generate an n-bit prime. Is there a *deterministic polynomial-time* algorithm for this problem? Even though primality testing can be done in deterministic polynomial time, we do not know whether a deterministic polynomial-time algorithm exists for this problem. However, a straightforward *probabilistic algorithm* exists for this task: Randomly pick an n-bit integer and output it if it is a prime. The density of primes implies that this algorithm succeeds with inverse polynomial probability. Hence by repeating this procedure polynomially many times, we can output an n-bit prime number with very high probability. A drawback of this algorithm is that the output of the algorithm depends on the random choices it makes. In particular, on two different random choices the algorithm may output two different prime numbers. A natural question to ask is:

[1] Research Supported in part by NSF grant 1421163.
[2] Research Supported in part by NSF grant 1421163.
[3] Research Supported in part by NSF grant 1422668.

is there a randomized, polynomial-time algorithm that on input 1^n outputs a *unique n-bit prime number* on most random choices. Such an algorithm is called a *pseudodeterministic algorithm*. This notion of pseudodeterminism was formulated by Gat and Goldwasser [7], motivated by its applications in distributed computing and cryptography.

Let f be a multi-valued function (i.e. $f(x)$ is a non-empty set). We say that a probabilistic algorithm A computes f if $A(x)$ outputs a value in the set $f(x)$ with high probability. A probabilistic algorithm A for f is *pseudodeterministic* if for every x, there exists *a unique* $u \in f(x)$ such that $A(x)$ outputs u with high probability [7]. The problem of designing pseudodeterministic algorithms is interesting in scenarios where we know of a probabilistic polynomial time algorithm that computes f, but no deterministic algorithm for f is known.

Related Work

Since the work of Gat and Goldwasser, the notion of pseudodeterministic algorithms has received moderate attention [7, 8, 9, 10, 11, 16]. Now we know of pseudodeterministic algorithms for certain algebraic problems such as finding non-residues of $\mathbb{Z}_p$, and finding non-roots of multivariate polynomials [7]. The work of Oliveria and Santhanam gives a pseudodeterministic, sub-exponential time algorithm for generating primes (that works at infinitely many input lengths) [16]. Recently Goldwasser and Grossman obtained a pseudodeterministic NC algorithm that computes perfect matchings in bipartite graphs [9]. The work of Goldreich, Goldwasser and Ron investigates the power and limitations of pseudodeterministic algorithms in the context of general probabilistic algorithms and sub-linear time algorithms [8]. The notion of *pseudodeterminism* has been studied earlier in the literature in the context of approximation algorithms [6], where the authors relate the existence of such algorithms for approximation problems to communication complexity of certain key-agreement problems. They used the term *monic selection* to capture the notion of *pseudodeterminism*. To the best of our knowledge, pseudodeterminism in the context of computing approximations of function has not been studied further.

Our Contribution

In this paper, we investigate pseudodeterministic approximation algorithms. Given a function f whose range is the integers, we say that a probabilistic algorithm A is a *pseudodeterministic approximation algorithm* for f if, for every input x, there is a value v such that $A(x)$ outputs v with high probability and v is a "good approximation" of $f(x)$, (for a formal definition, please see the next section). We consider the following counting problem which we call NP-*membership counting problem*: Given a language L in NP, compute the number of strings in L at a given length. The well-known result due to Stockmeyer [19, 20, 3] shows that NP-membership counting problem can be approximated in $\mathrm{BPP}_{tt}^{\mathrm{NP}}$, where $\mathrm{BPP}_{tt}^{\mathrm{NP}}$ denotes the class of problems solvable in probabilistic polynomial-time with nonadaptive queries to SAT[4]. However, Stockmeyer's algorithm is not pseudodeterministic: the algorithm can output different good approximations on different probabilistic paths. A natural question is: Is there a pseudodeterministic $\mathrm{BPP}_{tt}^{\mathrm{NP}}$ approximation algorithm for NP-membership counting problem? We relate this question to establishing new circuit lower bounds.

Proving circuit lowerbounds is one of the most significant research directions in complexity theory. While it is widely believed that there are languages in NP that cannot be solved by subexponential-size Boolean circuits, we do not even know how to prove that NP does

[4] Even though $\mathrm{BPP}_{tt}^{\mathrm{NP}}$ denotes a class of languages, here we slightly abuse the notation and view it as a function class.

not have linear-size circuits. This leads to investigating the question: "What is the smallest complexity class that provably cannot be solved by a linear-size circuit?" The first result in this direction is due to Kannan [13], who showed that there are languages in the second level of the Polynomial-time Hierarchy (Σ_2^{P}), that do not have linear-size circuits. This result has been improved to show that there are languages in $\mathrm{ZPP}^{\mathrm{NP}}$ that do not have linear-size circuits [4, 15]. Subsequently, Sengupta [5] showed that the complexity class $\mathrm{S}_2^{\mathrm{P}}$ does not have linear-size circuits. This together with Cai's result [5] that $\mathrm{S}_2^{\mathrm{P}} \subseteq \mathrm{ZPP}^{\mathrm{NP}}$, improved the upper bound to $\mathrm{S}_2^{\mathrm{P}}$. It is also known that the complexity class PP has languages that do not have linear-size circuits [21]. Currently a significant open question is to show that the class MA does not have linear-size circuits. A step in this direction is a result due to Santhanam [18] who showed that MA//1 does not have linear-size circuits (MA//1 is a "promise version" of MA: see the next section for a formal definition). We note that in all these circuit lower bound results, "linear-size" can be replaced by "n^k-size circuits" (for a fixed $k \geq 0$).

We ask the following question: Can we show that $\mathrm{ZPP}_{tt}^{\mathrm{NP}}$ has languages that do not have linear-size circuits? Note that $\mathrm{MA} \subseteq \mathrm{ZPP}_{tt}^{\mathrm{NP}} \subseteq \mathrm{ZPP}^{\mathrm{NP}}$ and hence it is a natural question. In this work, we show that this goal can be achieved if we can design a psedodeterminstic version of Stockmeyer's approximate counting algorithm for the NP-membership counting problem.

Theorem. *If there is a pseudodeterministic* $\mathrm{BPP}_{tt}^{\mathrm{NP}}$ *approximation algorithm for the* NP*-membership counting problem, then for every* k *there is a language* L_k *in* $\mathrm{ZPP}_{tt}^{\mathrm{NP}}$ *that does not have* n^k*-size circuits.*

We note that there are oracles with respect to which $\mathrm{ZPP}_{tt}^{\mathrm{NP}}$ has linear-size circuits [1]. Hence a pseudodeterministic algorithm for the NP-membership counting problem will lead to non-relativizable circuit lower bounds.

Can we design a pseudodeterministic $\mathrm{BPP}_{tt}^{\mathrm{NP}}$ approximation algorithm for the NP-membership counting problem? While we are unable to answer this question, we show a very general result: every randomized approximate counting algorithm can be transformed to an approximation algorithm that has a constant number of *influential random bits* in the sense defined recently by Grossman and Liu [12]. Grossman and Liu [12] generalized the notion of pseudodeterministic algorithms to *influential bit algorithms*. They defined this new notion in the context of logspace computation and applied it to certain search problems in randomized logspace. This notion can be adapted to polynomial-time bounded settings. Informally, a probabilistic algorithm A is a $k(n)$*-bit influential algorithm*, if A (on an input x of length n), uses $k(n) + r(n)$ random bits, and for most choices of the first $k(n)$-random bits, A behaves in a pseudodeterministic manner. That is, for most $p \in \Sigma^{k(n)}$, there exists a v such that $A(x, pr)$ outputs v with high probability (where r is randomly chosen from $\Sigma^{r(n)}$). For two different strings p_1 and p_2, the outputs of $A(x, p_1 r)$ and $A(x, p_2 r)$ could differ. However, if we fix a "good" $k(n)$-bit string p, then $A(x, pr_1)$ is the same as $A(x, pr_2)$ for most choices of r_1 and r_2. Note that an algorithm is pseudodeterministic if and only if it is a 0-influential bit algorithm. We show that any randomized relative-error approximate counting algorithm can be made to have a constant number of influential bits. This implies that

Theorem. *There is a* $O(1)$*-bit influential,* $\mathrm{BPP}_{tt}^{\mathrm{NP}}$ *approximation algorithm for the* NP*-membership counting problem.*

2 Preliminaries

We assume familiarity with standard notation and definitions from complexity theory [2].

▶ **Definition 1.** Let f be a function whose range is the integers. We say that a probabilistic algorithm A is an (ϵ, δ)-approximation algorithm for f if for every x, the random variable $A(x)$ has the following property: $\Pr[(1-\epsilon)f(x) \leq A(x) \leq (1+\epsilon)f(x)] \geq (1-\delta)$. We say that A is an (ϵ, δ) *pseudodeterministic approximation algorithm* for f if for every x there exists an integer v such that

$$(1-\epsilon)f(x) \leq v \leq (1+\epsilon)f(x) \text{ and } \Pr[A(x) = v] \geq 1-\delta.$$

In general an approximation algorithm can output different good approximations on different random choices. For an approximation algorithm A to be pseudodeterministic, A has to usually output a *unique* approximation v which is independent of the random string, for every input.

▶ **Definition 2.** Let f be a function whose range is the integers. We say that f has an (ϵ, δ)-$\mathrm{BPP}^{\mathrm{NP}}_{tt}$ *pseudodeterministic approximation algorithm* if there exists an (ϵ, δ), polynomial-time, pseudodeterministic approximation algorithm for f, that makes nonadaptive queries to SAT.

Let $R \subseteq \Sigma^* \times \Sigma^*$ be a binary-relation that is decidable in NP. Let $f_R(x)$ be the number of strings y such that $\langle x, y\rangle \in R$. The class $\sharp\mathrm{NP}$ is defined as $\sharp\mathrm{NP} = \{f_R \mid R \text{ is a relation that is decidable in NP}\}$. The following well-known theorem due to Stockmeyer gives a $\mathrm{BPP}^{\mathrm{NP}}_{tt}$ approximation algorithm for problems in $\sharp\mathrm{NP}$.

▶ **Theorem 3** ([19]). *Every problem in* $\sharp\mathrm{NP}$ *has a* $(1/n, 1/2^n)$-$\mathrm{BPP}^{\mathrm{NP}}_{tt}$ *approximation algorithm.*

Stockmeyer's algorithm is not pseudodeterministic: it may produce different, correct approximations on different random choices.

Recently, Grossman and Liu defined the notion of *influential bits* as a generalization of pseudodeterminism [12]. They defined it in the logspace regime and applied it to search problems in RL. We adapt it to the context of approximation algorithms.

▶ **Definition 4.** Let f be a function whose range is the integers. For a function $k : \mathbb{N} \to \mathbb{N}$, we say that a randomized (ϵ, δ)-approximation algorithm A for f is $k(n)$*-bit influential* if for every x, the following holds: A takes random string $r = st$ where $|s| \leq k(n)$ and for more than $\frac{2}{3}$ of strings s, there exists an integer v_s such that $\Pr_t[A(x, st) = v_s] \geq 1-\delta$ and $(1-\epsilon)f(x) \leq v_s \leq (1+\epsilon)f(x)$.

Note that an algorithm is pseudodeterministic if and only if it is 0-bit influential. Next we define a variant of the complexity class AM.

▶ **Definition 5.** A language L is in $\mathrm{AM}//1$ if there exists a polynomial-time machine V, a polynomial p, and a sequence of bits $b_1, b_2, \cdots$ such that

$$x \in L \Rightarrow \Pr_{r \in \Sigma^{p(n)}}[\exists y \in \Sigma^{p(n)},\ V(xb_n, r, y) = 1] \geq 2/3,$$

$$x \notin L \Rightarrow \Pr_{r \in \Sigma^{p(n)}}[\exists y \in \Sigma^{p(n)},\ V(xb_n, r, y) = 1] \leq 1/3,$$

where n is the length of x.

Santhanam showed that for every k there is a language in AM//1 that does not have n^k-size circuits [18] (Santhanam showed the lower bound for MA//1, but we will only need the AM//1 bound for establishing our result).

▶ **Theorem 6** ([18]). *For every k, there is a language $L_k \in$ AM//1 so that L_k cannot be computed by n^k-size Boolean circuits.*

3 Pseudodeterminism for ♯NP and circuit lower bounds

In this section we show that the existence of a pseudodeterministic version of Stockmeyer's approximate counting algorithm for ♯NP implies new circuit lower bounds.

▶ **Theorem 7.** *If for every function f in ♯NP there exists an $(\frac{1}{10}, \frac{1}{10})$-$\mathrm{BPP}^{\mathrm{NP}}_{tt}$ pseudodeterministic approximation algorithm for f, then for every $k > 0$, there is a language L_k in $\mathrm{ZPP}^{\mathrm{NP}}_{tt}$ such that L_k cannot be computed by n^k-size Boolean circuits.*

Proof of this theorem follows from Lemma 8, and Theorem 9 stated below. Theorem 9 could be of independent interest.

▶ **Lemma 8.** *If for every function f in ♯NP there exists an $(\frac{1}{10}, \frac{1}{10})$-$\mathrm{BPP}^{\mathrm{NP}}_{tt}$ pseudodeterministic approximation algorithm for f, then for every $k > 0$, there is a language L_k in $\mathrm{BPP}^{\mathrm{NP}}_{tt}$ such that L_k cannot be computed by n^k-size Boolean circuits.*

▶ **Theorem 9.** *If* NP *has polynomial-size circuits, then $\mathrm{BPP}^{\mathrm{NP}}_{tt} = \mathrm{ZPP}^{\mathrm{NP}}_{tt}$.*

Assuming Lemma 8 and Theorem 9, Theorem 7 follows from the type of argument due to Kannan [13]. If NP does not have polynomial-size circuits, trivially $\mathrm{ZPP}^{\mathrm{NP}}_{tt}$ does not have n^k-size circuits. Assume that NP has polynomial-size circuits. By Lemma 8 we have $\mathrm{BPP}^{\mathrm{NP}}_{tt}$ does not have n^k-size circuits, and by Theorem 9 $\mathrm{BPP}^{\mathrm{NP}}_{tt}$ is the same as $\mathrm{ZPP}^{\mathrm{NP}}_{tt}$. Hence $\mathrm{ZPP}^{\mathrm{NP}}_{tt}$ does not have n^k-size circuits.

Proof of Lemma 8. Fix a $k > 0$ and let L be a language in AM//1 that does not have n^k-size circuits [18]. Thus there exists a sequence of bits $b_1, b_2, \cdots$, a polynomial p and a polynomial-time machine V such that

$$x \in L \quad \Rightarrow \quad \Pr_{r \in \Sigma^{p(n)}}[\exists y \in \Sigma^{p(n)},\ V(xb_n, r, y) = 1] \geq 2/3, \text{ and}$$
$$x \notin L \quad \Rightarrow \quad \Pr_{r \in \Sigma^{p(n)}}[\exists y \in \Sigma^{p(n)},\ V(xb_n, r, y) = 1] \leq 1/3$$

Consider the following NP relation:

$$R = \{\langle xb, r\rangle \mid r \in \Sigma^{p(|x|)}, b \in \{0,1\}, \exists y \in \Sigma^{p(n)} V(xb, r, y) = 1\}$$

The corresponding ♯NP problem is $f_R(xb) = |\{r \mid \langle xb, r\rangle \in R\}|$. By our hypothesis, there is a $(\frac{1}{10}, \frac{1}{10})$-$\mathrm{BPP}^{\mathrm{NP}}_{tt}$ pseudodeterministic approximation algorithm M for f_R. Let S_{xb} denote the set $\{r \mid \langle xb, r\rangle \in R\}$. Consider the following $\mathrm{BPP}^{\mathrm{NP}}_{tt}$ algorithm.

Input: x and a bit b.
Run M on xb. Let v be the output.
If $v \geq 2^{p(n)-1}$ then accept, else reject.

We will first show that on every input $\langle x, b\rangle$, the above algorithm either accepts with high probability or rejects with high probability. Let $\langle x, b\rangle$ be an input. Since M is a pseudodeterministic algorithm, there is an integer v such that M outputs v with probability at least $\frac{9}{10}$. If v is at least $2^{p(n)-1}$, then the above algorithm accepts, else it rejects. Thus on every input $\langle x, b\rangle$, the above algorithm either accepts with probability $\frac{9}{10}$ or rejects with probability at least $\frac{9}{10}$. Let L' be the language accepted by the above algorithm. Clearly $L' \in \mathrm{BPP}^{\mathrm{NP}}_{tt}$.

▶ **Claim 9.1.** *L' cannot be computed by n^k-size Boolean circuits.*

Assume that L' is accepted by a circuit family of size n^k. We will show that there is an n^k-size circuit family for L, which gives us a contradiction. Fix an input length n and let C_n be a circuit that accepts L' at length $n+1$. The definition of advice guarantees that for each input length, there is some advice string (in our case, a single bit) for which the circuit correctly decides the language. Let b_n be the *correct advice* bit for strings of length n for the language L. Consider the following circuit D_n: $D_n(x)$ is same as $C_n(x, b_n)$. I.e., with b_n hardwired in C_n. Thus D_n on input x (of length n) evaluates C_n on input $\langle x, b_n\rangle$. Clearly the size of D_n is n^k. We now show that the circuit family D_n accepts the language L.

Consider the case that x is in L. Note that $f_R(xb_n)$ is at least $\frac{2}{3}2^{p(n)}$. Thus on input $\langle x, b_n\rangle$ M outputs a number v with probability at least $2/3$ such that $v \geq \frac{9}{10} f_R(xb_n)$. Since $f_R(xb_n)$ is at least $\frac{2}{3}2^{p(n)}$, we have that v is bigger than $2^{p(n)-1}$. Thus M accepts $\langle x, b_n\rangle$ with probability at least $\frac{9}{10}$. Thus $\langle x, b_n\rangle \in L'$, and the circuit C_n accepts $\langle x, b_n\rangle$. Thus D_n accepts x. A similar argument shows that if x is not in L, then D_n rejects x. Since the size of D_n is n^k, we have that L is accepted by n^k-size circuits, which is a contradiction. ◀

Next, we complete the proof of Theorem 9.

Proof of Theorem 9. The argument goes in two steps: (1) under the assumption that NP has polynomial-size circuits, it can be shown that a Boolean function has $S(n)$-size SAT oracle circuits if and only if it has $S'(n)$-size Boolean circuits, where $S'(n)$ and $S(n)$ are polynomially related. (2) A ZPP machine can randomly pick a truth-table t of a Boolean function on $O(\log n)$-bits and verify using the NP oracle that t does not have $2^{\epsilon n}$-size circuits. Use this hard function to construct a pseudorandom generator. Use this PRG to derandomize a $\mathrm{BPP}^{\mathrm{NP}}_{tt}$ computation to $\mathrm{ZPP}^{\mathrm{NP}}_{tt}$. We provide more details.

Since NP has polynomial-size circuits, there is a constant $\ell > 0$ such that SAT has n^ℓ-size circuits. Suppose that a Boolean function g has $2^{\gamma n}$-size SAT-oracle circuit family $\{D_n\}$. Consider D_n. We can convert this into a circuit that does not make oracle calls to SAT. This circuit can generate queries (to SAT) of size at most $2^{\gamma n}$. Since SAT has n^ℓ-size circuits, each query can be answered by a circuit of size $2^{\ell\gamma n}$. Thus if we replace each oracle call in D_n by a circuit of size at most $2^{\ell\gamma n}$, we obtain Boolean circuit of size $2^{\delta n}$ for g where $\delta = 2l\gamma$. This circuit does not make any queries to SAT.

We will use the following derandomization result due to Klivans and Melkebeek [14]

▶ **Theorem 10.** *Let M be a $\mathrm{BPP}^{\mathrm{NP}}_{tt}$ machine that uses $t(n)$ random bits on inputs of length n. For every $\gamma > 0$, there exists b, c and a polynomial-time computable family of functions $\{F_n\}$ such that $F_n : \Sigma^{n^c} \times \Sigma^{b \log n} \to \Sigma^{t(n)}$, and if u is the truth-table of a $c \log n$-bit Boolean function with* SAT*-oracle circuit complexity $\Omega(2^{\gamma n})$, then for every x of length n*

$$\left| \Pr_{r \in \Sigma^{t(n)}}[M(x, r) = 1] - \Pr_{r \in \Sigma^{b \log n}}[M(x, F_n(u, r) = 1] \right| \leq 0.1$$

Let L be a language in $\mathrm{BPP}_{tt}^{\mathrm{NP}}$ and M be a $\mathrm{BPP}_{tt}^{\mathrm{NP}}$ machine that accepts L and runs in $t(n)$ time. Using Theorem 10, the following is a $\mathrm{ZPP}_{tt}^{\mathrm{NP}}$ machine that simulates M: Randomly pick u of size n^c – truth table of a function over $c \log n$ bits. By making a query to the NP oracle, check if u has circuit complexity at least $2^{\epsilon n}$. If not, then output "I do not know". Else, we can conclude that u has SAT-oracle circuit complexity at least $2^{\gamma n}$ for some $\gamma > 0$. Now simulate M using $F_n(u, r)$ as random bits for every $r \in \Sigma^{b \log n}$ and accept if the majority of simulations accept. Since with very high probability a randomly chosen u has circuit complexity at least $2^{\epsilon n}$, by Theorem 10 the simulation is correct. Thus L is in $\mathrm{ZPP}_{tt}^{\mathrm{NP}}$. ◀

We can extend Theorem 7 to a subclass of $\mathrm{ZPP}_{tt}^{\mathrm{NP}}$.

▶ **Theorem 11.** *If for every function f in $\sharp\mathrm{NP}$ there exists an $(\frac{1}{10}, \frac{1}{10})$-$\mathrm{BPP}_{tt}^{\mathrm{NP}}$ pseudodeterministic approximation algorithm, then for every $k > 0$, there is a language L_k in $\mathrm{ZPP}_{tt}^{\mathrm{NP}} \cap \mathrm{S}_2^{\mathrm{P}}$ such that L_k cannot be computed by n^k-size Boolean circuits.*

Proof. If NP does not have polynomial-size circuits, then the statement of the theorem trivially holds. If NP has polynomial-size circuits, then by Sengupta's result [5], the Polynomial-time Hierarchy collapses to $\mathrm{S}_2^{\mathrm{P}}$. Thus $\mathrm{BPP}_{tt}^{\mathrm{NP}}$ is in $\mathrm{S}_2^{\mathrm{P}}$. Thus by Theorem 9, if NP has polynomial-size circuits, then $\mathrm{BPP}_{tt}^{\mathrm{NP}}$ is a subset of $\mathrm{ZPP}_{tt}^{\mathrm{NP}} \cap \mathrm{S}_2^{\mathrm{P}}$. By Lemma 8, under the hypothesis, $\mathrm{BPP}_{tt}^{\mathrm{NP}}$ does not have n^k-size circuits. The theorem follows. ◀

4 Constant-bit Influential algorithm for approximate counting

In this section we show that every probabilistic algorithm that computes an (ϵ, δ)-approximation to a function f can be transformed into a $O(1)$-bit influential algorithm.

▶ **Theorem 12.** *Let $\epsilon \in o(1)$, and $\delta \leq 1/3$. Let f be a function whose range is the integers that admits an (ϵ, δ)-approximation algorithm. Then there is a $O(1)$ influential-bit, $(O(\epsilon), \delta)$-approximation algorithm for f.*

Implicit in the work of Saks and Zhou [17] is a $O(\log n)$-bit influential, *absolute error* approximation algorithm for matrix powering. The main technical tool they use is that of *randomized rounding*. In the *relative error setting* that we are interested in, their rounding scheme does not work. We use an adaptive randomized rounding scheme that can handle relative errors and use this to design a constant-bit influential algorithm. Before we present our proof, we provide a high level overview of Saks and Zhou's proof adapted to our setting, and explain why it is not straight forward to apply in the relative error setting.

Let f be a function from Σ^* to integers such that n-bit integers are mapped to the range $[0, \cdots, 2^n]$. We say that an algorithm A computes (ϵ, δ), *absolute* approximation for f, if for every x, the value of $A(x)$ lies between $f(x) - \epsilon 2^n$ and $f(x) + \epsilon 2^n$ with probability at least $1 - \delta$. Let s be an integer such that $\epsilon 2^n$ is close to 2^{n-s}, thus the approximation error is close to 2^{n-s}. Saks and Zhou consider the following rounding operator $R_{b,s}(x)$, where b is a 4-bit integer. Subtract $2^{n-s} \times b$ from x and replace the last $n - s - 4$ bits of the resulting number with zeros. Saks and Zhou show that if z_1 and z_2 are any two good approximations of $f(x)$ (I.e, both z_1 and z_2 lie between $f(x) - \epsilon 2^n$ and $f(x) + \epsilon 2^n$), then for a random choice of b, $R_{b,s}(z_1) = R_{b,s}(z_2)$, and $R_{b,s}(z_1)$ is still a good approximation of $f(x)$ with high probability. From this it follows that any absolute error approximation algorithm can be made 4-bit influential. In the case of matrix powering, the rounding has to be applied for polynomially many entries, which will lead to an $O(\log n)$-bit influential algorithm for matrix powering.

For the above rounding scheme to work, it is critical that we know the value of s which depends on the value of approximation error which is at most $\epsilon 2^n$. However, in the relative error setting we do not a priori know the value of the approximation error, as it depends on $f(x)$. We could infer the of value of $\epsilon f(x)$ by looking at an output, and try to estimate s. However, since the approximation algorithm can produce multiple outputs, it is not possible to uniquely infer a value for s. We get around these problems by using additional (constant bits) randomness, and an adaptive rounding scheme. We now present a proof of Theorem 12.

Proof. Let f be a function from Σ^* to integers and let A be a (ϵ, δ)-approximation algorithm for f. For ease of presentation, we assume that $f(x) \leq 2^n$, where $n = |x|$. Consider the following algorithm. In this algorithm we set ℓ to 8 and p to $8 - \log(1/\epsilon)$. Note that p is negative. Given a number y in binary, and an integer z, we use $y\rfloor_z$ to denote the value obtained by replacing the last z bits of y with zeros. We use % for the modulo operator: $x\%y$ is the unique integer z in $\{0 \dots y-1\}$ satisfying $yr + z = x$ for some integer r. We say $x \equiv y\%z$ if $x\%y = z\%y$.

1. Input x of length n.
2. Choose m uniformly at random from $\{0 \dots 4\}$.
3. Choose r uniformly at random from $\{1 \dots 2^\ell\}$.
4. Run $A(x)$ and let y be the output.
5. Choose k_y so that $2^{k_y} \leq y < 2^{k_y+1}$.
6. Set $z_y = k_y + p + \{2, 1, 0, -1, -2\}$ so that $z_y \equiv m \ \% \ 5$.
7. Set $r_{z_y} = r \cdot 2^{(z_y - \ell)}$.
8. Output $(y - r_{z_y})\rfloor_{z_y}$.

We prove that this is a $O(1)$-bit influential algorithm for f, where the influential bits describe m and r. Fix an input x. The probability that A outputs a value in the range $[(1-\epsilon)f(x), (1+\epsilon)f(x)]$ is at least $1-\delta$. From now we assume that this event has happened. Let $\{y_1, y_2, \cdots, y_N\}$ be all possible outputs of $A(x)$ such that every $y_i \in (1 \pm \epsilon)f(x)$. Let y_{min} and y_{max} be the smallest and the largest of these values respectively. Since $\epsilon \leq 1/2$, there exists a $k \geq 0$ such that for every y_i, $2^k \leq y_i < 2^{k+2}$. Note that once the input x is fixed, k is also fixed.

We say $m \in \{0, \cdots, 4\}$ is *good* if all z_{y_i} $(1 \leq i \leq N)$ are the same (defined in Line 6). We will establish the following claim.

▶ **Claim 12.1.** *If we choose m randomly from $\{0, 1, 2, 3, 4\}$, m is good with probability $4/5$.*

Proof. Consider y_i and y_j, $i \neq j$. If both y_i and y_j lie between 2^k and 2^{k+1}, then clearly z_{y_i} equals z_{y_j}. Suppose that y_i lies between 2^k and 2^{k+1} and y_j lies between 2^{k+1} and 2^{k+2}. Thus $z_{y_i} \in \{k+p-2, k+p+1, k+p, k+p+1, k+p+2\}$ and $z_{y_j} \in \{k+p-1, k+p, k+p+1, k+p+2, k+p+3\}$. Note that both z_{y_i} and z_{y_j} are equal m modulo 5. If $(k+p-2) \equiv m\%5$, then the value of z_{y_i} equals $k+p-2$ and z_{y_j} equals $k+p+3$ and they differ. In all other cases, z_{y_i} equals z_{y_j}. The probability that randomly chosen $m \equiv (k+p-2)\%5$ is exactly $1/5$. Thus m is good with probability $4/5$. ◀

From now on we will assume that the event "m is good" has happened. Thus $z_{y_1} = z_{y_2} = \cdots = z_{y_N}$. For notational simplicity, we will denote this value by z. Note that r_z is formed by randomly picking $r \in \{1, \cdots 2^\ell\}$ and multiplying with $2^{(z-\ell)}$. We will prove the following claim that will be used later.

▶ **Claim 12.2.** *For every* $X \in [0 \dots 2^z]$,
1. $\frac{X}{2^z} - \frac{1}{2^\ell} \leq \Pr[r_z \leq X] \leq \frac{X}{2^z}$
2. $1 - \frac{X}{2^z} \leq \Pr[r_z > X] \leq 1 - (\frac{X}{2^z} - \frac{1}{2^\ell})$

Proof. Note that r_z is uniformly distributed in $\{\frac{2^z}{2^\ell}, 2 \cdot \frac{2^z}{2^\ell}, 3 \cdot \frac{2^z}{2^\ell}, \dots n^2 \cdot \frac{2^z}{2^\ell}\}$.
Thus, if $i\frac{2^z}{2^\ell} \leq X < (i+1)\frac{2^z}{2^\ell}$, there are i values of r_z that are at most X. We can write i as $\lfloor \frac{X \cdot n^\ell}{2^z} \rfloor \leq \frac{X \cdot 2^\ell}{2^z}$, giving us $\Pr[r_z \leq X] = \frac{i}{2^\ell} \leq \frac{X \cdot 2^\ell}{2^\ell \cdot 2^z} = \frac{X}{2^z}$ and $\Pr[r_z > X] = 1 - \frac{i}{2^\ell} \geq 1 - \frac{X}{2^z}$
Similarly, $i \geq \frac{X \cdot 2^\ell}{2^z} - 1$, so $\Pr[r_z \leq X] = \frac{i}{2^\ell} \geq \frac{X}{2^z} - \frac{1}{2^\ell}$ and $\Pr[r_z > X] = 1 - \frac{i}{2^\ell} \leq 1 - (\frac{X}{2^z} - \frac{1}{2^\ell})$ ◀

▶ **Lemma 13.** *For every good* m*, if we randomly choose* $r \in \{1, \cdots, 2^\ell\}$*, then for at least* $223/256$ *of the possible* r*, the following holds: For every* $i \neq j$ *(*$1 \leq i, j \leq r$*)* $(y_i - r_z)\rfloor_z = (y_j - r_z)\rfloor_z$.

Proof. The $\rfloor_z$ operation can be viewed as dividing the interval $[0, 2^n]$ into subintervals $[0, 2^z - 1], [2^z, 2 \cdot 2^z - 1], [2 \cdot 2^z, 3 \cdot 2^z - 1] \dots [2^n - 2^z, 2^n]$, and mapping the contents of each interval to its left endpoint. Note that $y_{max} - y_{min}$ is at most $2f(x)\epsilon$. Since $f(x) \leq 2^{k+2}$ and $2^z \geq 2^{k+p-2}$, $y_{max} - y_{min}$ is at most $2^{k+3}\epsilon$, which is at most $2^z/8$. Since the size of each interval is 2^z and the difference between y_{max} and y_{min} is less than the size of the interval, either both y_{min} and y_{max} lie in the same interval or lie in two contiguous intervals. We consider both cases.

Case 1. Both y_{max} and y_{min} are in the same interval, say $[i \cdot 2^z, (i+1) \cdot 2^z]$ for some i. If subtracting r_z causes them to be in different intervals, r_z must be large enough to move y_{min} to a new interval, but not so large that y_{max} moves too. That is, $r_z > (y_{min} - i \cdot 2^z)$ and $r_z \leq (y_{max} - i \cdot 2^z)$. They are in the same interval when $r_z \leq (y_{min} - i \cdot 2^z)$ or $r_z > (y_{max} - i \cdot 2^z)$.
So, the probability that y_{min} and y_{max} are in the same interval is

$$\begin{aligned} &\Pr[r_z > (y_{max} - i \cdot 2^z)] + \Pr[r_z \leq (y_{min} - i \cdot 2^z)] \\ &\quad\geq 1 - \frac{y_{max} - i \cdot 2^z}{2^z} + \frac{y_{min} - i \cdot 2^z}{2^z} - \frac{1}{2^\ell} \\ &\quad= 1 - \frac{y_{max} - y_{min}}{2^z} - \frac{1}{2^l} \\ &\quad\geq 223/256 \end{aligned}$$

The first inequality follows from Claim 12.2. The second follows from the conclusion that $y_{max} - y_{min}$ is at most $2^z/8$. The last inequality follows because $\ell = 8$.

Case 2. Now consider the other case, where y_{min} is in the interval $[i \cdot 2^z, (i+1) \cdot 2^z]$ and y_{max} is in $[(i+1) \cdot 2^z, (i+2) \cdot 2^z]$. If subtracting r_z causes y_{max} and y_{min} to be in different intervals, either r_z is not large enough to move y_{max} into the same interval as y_{min}, or r_z is so large that it moves y_{min} into a new interval as well. In this case, the condition is $r_z > (y_{min} - i \cdot 2^z)$ or $r_z \leq (y_{max} - (i+1) \cdot 2^z)$. Then, the probability that y_{min} and y_{max} end up in different intervals is

$$\begin{aligned} &\Pr[r_z > (y_{min} - i \cdot 2^z)] + \Pr[r_z \leq (y_{max} - (i+1) \cdot 2^z)] \\ &\quad\leq 1 - (\frac{y_{min} - i \cdot 2^z}{2^z} - \frac{1}{2^\ell}) + \frac{y_{max} - (i+1) \cdot 2^z}{2^z} \\ &\quad= 1 - \frac{y_{min}}{2^z} + i + \frac{1}{2^\ell} + \frac{y_{max}}{2^z} - i - 1 \\ &\quad= \frac{y_{max} - y_{min}}{2^z} + \frac{1}{2^\ell} \\ &\quad\leq 33/256 \end{aligned}$$

The first inequality follows from Claim 12.2. The second follows from the conclusion that $y_{max} - y_{min}$ is at most $2^z/8$. ◀

Our next claim shows that the operation $\rfloor z$ preserves the approximation (up to a constant factor).

▶ **Claim 13.1.** *If $y \in f(x)(1 \pm \epsilon)$, then $(y - r_z)\rfloor_z \in f(x)(1 \pm O(\epsilon))$.*

Proof. Subtracting r_z and taking the $\rfloor_z$ only decrease, so this is at most y, which is at most $f(x)(1+\epsilon)$. For a given y, the minimum value of $(y - r_z)\rfloor_z$ occurs when r is as large as possible and $\rfloor_z$ changes the last z bits from 1 to 0. r_z is at most 2^z. $\rfloor_z$ can decrease the input by at most 2^z. Thus, $(y - r_z)\rfloor_z$ is at least $y - 2^z - 2^z$. Consider the following inequalities.

$$\begin{aligned} 2^{z+1} &\leq 2^{k+2+p+2} \\ &= 2^{k+13-\log 1/\epsilon} \\ &\leq f(x)(2^{13}\epsilon)(\text{ as } f(x) \geq 2^k) \end{aligned}$$

Since $(y-r_z)\rfloor_z \geq y-2^{z+1}$, and $y \geq f(x)(1-\epsilon)$, we obtain that $(y-r_z)\rfloor_z \geq f(x)(1-2^{14}\epsilon)$. ◀

Now we can finish the proof of Theorem 12. The influential bits of the algorithm are m and r. Note that the number of influential bits is constant. Let us call the set of r for which the consequence of Lemma 13 holds as *good*. Note that for every fixing of good m and r, the output of the algorithm is unique and is a good approximation, with probability at least $1 - \delta$, by Lemma 13 and Claim 13.1. Finally the fraction of bad m and r is at most $1/5 + 33/256$ which is at most $1/3$. Thus the algorithm is a constant-bit influential algorithm.

The statement of Theorem 12 assumed that $\epsilon \in o(1)$. However, the proof goes through for any sufficiently small ϵ. We have the following as a corollary of Theorem 12. ◀

▶ **Theorem 14.** *For every problem in $\sharp$NP, there is a $O(1)$-bit influential, $(1/n, 1/2^n)$-approximation algorithm.*

Abstract

Piecewise testable languages are a subclass of the regular languages. There are many equivalent ways of defining them; Simon's congruence $\sim_k$ is one of the most classical approaches. Two words are $\sim_k$-equivalent if they have the same set of (scattered) subwords of length at most k. A language L is piecewise testable if there exists some k such that L is a union of $\sim_k$-classes.

For each equivalence class of $\sim_k$, one can define a canonical representative in shortlex normal form, that is, the minimal word with respect to the lexicographic order among the shortest words in $\sim_k$. We present an algorithm for computing the canonical representative of the $\sim_k$-class of a given word $w \in A^*$ of length n. The running time of our algorithm is in $\mathcal{O}(|A|\, n)$ even if $k \leq n$ is part of the input. This is surprising since the number of possible subwords grows exponentially in k. The case $k > n$ is not interesting since then, the equivalence class of w is a singleton. If the alphabet is fixed, the running time of our algorithm is linear in the size of the input word. Moreover, for fixed alphabet, we show that the computation of shortlex normal forms for $\sim_k$ is possible in deterministic logarithmic space.

One of the consequences of our algorithm is that one can check with the same complexity whether two words are $\sim_k$-equivalent (with k being part of the input).

1 Introduction

We write $u \preccurlyeq v$ if the word u is a (scattered) subword of v, that is, if there exist factorizations $u = u_1 \cdots u_n$ and $v = v_0 u_1 v_1 \cdots u_n v_n$. In the literature, subwords are sometimes called *piecewise* subwords to distinguish them from factors. Higman showed that, over finite alphabets, the relation $\preccurlyeq$ is a well-quasi-ordering [3]. This means that every language contains only finitely many minimal words with respect to the subword ordering. This led to the consideration of piecewise testable languages. A language L is *piecewise testable* if there exists a finite set of words T such that $v \in L$ only depends on $\{u \in T \mid u \preccurlyeq v\}$; in

[1] Supported by the German Research Foundation (DFG) under grant DI 435/5–2.

other words, the occurrence and non-occurrence of subwords in T determines membership in L. Equivalently, a language L is piecewise testable if it is a finite Boolean combination of languages of the form $A^*a_1A^* \cdots a_nA^*$ with $a_i \in A$ (using the above notation, the sequences $a_1 \cdots a_n$ in this combination give the words in T). The piecewise testable languages are a subclass of the regular languages and they play a prominent role in many different areas. For instance, they correspond to the languages definable in alternation-free first-order logic [20] which plays an important role in database queries. They also occur in learning theory [10, 15] and computational linguistics [2, 14].

In the early 1970s, Simon proved his famous theorem on piecewise testable languages: A language is piecewise testable if and only if its syntactic monoid is finite and $\mathcal{J}$-trivial [18]. An immediate consequence of Simon's Theorem is that it is decidable whether or not a given regular language L is piecewise testable. Already in his PhD thesis [17], Simon considered the complexity of this problem when L is given as a deterministic finite automaton (DFA). His algorithm can be implemented to have a running time of $\mathcal{O}(2^{|A|}n^2)$ for an n-state DFA over the alphabet A. This result was successively improved over the years [1, 9, 19, 21] with the latest algorithm having a running time of $\mathcal{O}(|A|^2\, n)$; see [8]. If the input is a DFA, then the problem is NL-complete [1]; and if the input is a nondeterministic finite automaton, the problem is PSPACE-complete [4]. Restricting the length of the relevant subwords T to some constant k leads to the notion of k-piecewise testable languages. At first sight, it is surprising that, for every fixed $k \geq 4$, deciding whether a given DFA accepts a k-piecewise testable language is coNP-complete [8]; see also [11].

One of the main tools in the original proof of Simon's Theorem is the congruence $\sim_k$ for $k \in \mathbb{N}$. By definition, two words u and v satisfy $u \sim_k v$ if u and v have the same subwords of length at most k. Naturally, the relation $\sim_k$ is nowadays known as *Simon's congruence*. It is easy to see that a language L is piecewise testable if and only if there exists k such that L is a union of $\sim_k$-classes. Understanding the combinatorial properties of $\sim_k$ is one of the main tools in the study of piecewise testable languages. For example, in the proof of his theorem, Simon already used that $(uv)^k \sim_k (uv)^k u$ for all words u, v. Upper and lower bounds on the index of $\sim_k$ were given by Kátai-Urbán et al. [7] and Karandikar et al. [6].

There are two natural approaches for testing whether or not $u \sim_k v$ holds. The first approach constructs a DFA $\mathcal{A}_{k,u}$ for the language $\{w \preccurlyeq u \mid k \geq |w|\}$ of the subwords of u of length at most k and a similar DFA $\mathcal{A}_{k,v}$ for v. Then $u \sim_k v$ if and only if $\mathcal{A}_{k,u}$ and $\mathcal{A}_{k,v}$ accept the same language. This can be tested with Hopcroft's algorithm in time almost linear in the size of the automata [5]. Here, *almost linear* in n means $\mathcal{O}(n \cdot a(n))$ where $a(n)$ is the inverse Ackermann function. It is possible to construct the automata such that $\mathcal{A}_{k,u}$ has at most $k\,|u| + 2$ states, see the remark at the end of Section 2 below. Hence, the resulting test is almost linear in $|A|\ k\ |uv|$ if the alphabet is A.

The second approach to testing $u \sim_k v$ is the computation of normal forms. A normal form is a unique representative of a $\sim_k$-class. In particular, we have $u \sim_k v$ if and only if u and v have the same normal form. By computing the normal forms for both words and then checking whether they are identical, the complexity of this test of $u \sim_k v$ is the same as the computation of the normal forms. We should mention that the computation of normal forms is also interesting in its own right since it can provide some insight into the combinatorial properties of $\sim_k$. Normal forms for $k = 2$ and $k = 3$ were considered by Kátai-Urbán et al. [7] and normal forms for $k = 4$ were given by Pach [12]. An algorithm for computing normal forms for arbitrary k was found only recently by Pach [13]. Its running time is $\mathcal{O}(|A|^k\,(n + |A|))$ for inputs of length n over the alphabet A, that is, polynomial for fixed k and exponential otherwise.

We significantly improve this result by providing an algorithm with a running time in $\mathcal{O}(|A|\, n)$ even if k is part of the input. For every fixed alphabet, the running time is linear, which is optimal. Moreover, the algorithm can easily be adapted to run in deterministic logarithmic space, thereby addressing an open problem from [7]. As a consequence we can check with the same running time (or the same complexity) whether two given words are $\sim_k$-equivalent even if k is part of the input, thereby considerably improving on the above automaton approach.

Our algorithm actually does not compute just some normal form but the *shortlex normal form* of the input word u, *i.e.*, a shortest, and among all shortest the lexicographically smallest, word v such that $u \sim_k v$. Our main tools are so-called *rankers* [16, 22]. For each position i in the input word, the algorithm computes the lengths of the shortest X-rankers and Y-rankers reaching i. One can then derive the shortlex normal form by deleting and sorting certain letters based on these attributes. A more detailed outline of the paper is given in Section 3.

2 Preliminaries

Let A be a finite alphabet. The elements in A are called *letters* and a sequence of letters $u = a_1 \cdots a_\ell$ is a *word* of *length* $|u| = \ell$. The set of all words over the alphabet A is A^*. Throughout this paper, a, b and c are used to denote letters. For a word $a_1 \cdots a_\ell$, the numbers $\{1, \ldots, \ell\}$ are called *positions* of the word, and i is a *c-position* if $a_i = c$. The letter a_i is the *label* of position i. Two positions i and j with $i < j$ are *consecutive* c-positions if $a_i = a_j = c$ and $a_\ell \neq c$ for all $\ell \in \{i+1, \ldots, j-1\}$. A word $a_1 \cdots a_\ell$ is a *subword* of a word $v \in A^*$ if v can be written as $v = v_0 a_1 \cdots v_{\ell-1} a_\ell v_\ell$ for words $v_i \in A^*$. We write $u \preccurlyeq v$ if u is a subword of v. A *congruence* on A^* is an equivalence relation $\sim$ such that $u \sim v$ implies $puq \sim pvq$ for all $u, v, p, q \in A^*$. For $k \in \mathbb{N}$, *Simon's congruence* $\sim_k$ on A^* is defined by $u \sim_k v$ if and only if u and v contain the same subwords of length at most k.

We assume that the letters of the alphabet are totally ordered. A word u is *lexicographically smaller than* v if, for some common $p \in A^*$, there exists a prefix pa of u and a prefix pb of v such that $a < b$. (We apply the lexicographic order only for words of the same length; in particular, we do not care about the case when u is a proper prefix of v.) Given a congruence $\sim$ on A^*, we define the *shortlex normal form* of a word u to be the shortest word v such that $u \sim v$ and such that no other word $w \in A^*$ with $w \sim v$ and $|w| = |v|$ is lexicographically smaller than v. In other words, we first pick the shortest words in the $\sim$-class of u and among those, we choose the lexicographically smallest one.

Our main tools are so-called *rankers* [16, 22]. An X-*ranker* is a nonempty word over the alphabet $\{\mathsf{X}_a \mid a \in A\}$ and a Y-*ranker* is a nonempty word over $\{\mathsf{Y}_a \mid a \in A\}$. The length of a ranker is its length as a word. The modality X_a means ne$\mathsf{X}$t-a and is interpreted as an instruction of the form "go to the next a-position"; similarly, Y_a is a shorthand for Yesterday-a and means "go to the previous a-position". More formally, we let $\mathsf{X}_a(u) = i$ if i is the smallest a-position of u, and we let $r\mathsf{X}_a(u) = i$ for a ranker r if i is the smallest a-position greater than $r(u)$. Symmetrically, we let $\mathsf{Y}_a(u) = i$ if i is the greatest a-position of u and we let $r\mathsf{Y}_a(u) = i$ if i is the greatest a-position smaller than $r(u)$. In particular, rankers are processed from left to right. Note that the position $r(u)$ for a ranker r and a word u can be undefined. If $r(u)$ is defined, then we say that r *reaches* the position $r(u)$. Similarly, r *visits* a position i if $s(u) = i$ for some prefix s of r. A word $b_1 \cdots b_\ell$ *defines* an X-ranker $\mathsf{X}_{b_1} \cdots \mathsf{X}_{b_\ell}$ and a Y-ranker $\mathsf{Y}_{b_\ell} \cdots \mathsf{Y}_{b_1}$. We have $u \preccurlyeq v$ if and only if $r(v)$ is defined for the

X-ranker (resp. Y-ranker) r defined by u. Similarly, if r is the X-ranker defined by u and s is the Y-ranker defined by v, then $uv \preccurlyeq w$ if and only if $r(w) < s(w)$. The correspondence between X-rankers and subwords leads to the following automaton construction.

▶ Remark. Let u be a word of length n. We construct a DFA $\mathcal{A}_{k,u}$ for the language $\{w \preccurlyeq u \mid |w| \leq k\}$. The set of states is $\{(0,0)\} \cup \{1,\dots,k\} \times \{1,\dots,n\}$ plus some sink state which collects all missing transitions. The initial state is $(0,0)$ and all states except for the sink state are final. We have a transition $(\ell,i) \xrightarrow{a} (\ell+1,j)$ if $\ell < k$ and j is the smallest a-position greater than i. The idea is that the first component counts the number of instructions and the second component gives the current position.

3 Attributes and outline of the paper

To every position $i \in \{1,\dots,n\}$ of a word $a_1 \cdots a_n \in A^n$, we assign an *attribute* (x_i, y_i) where x_i is the length of a shortest X-ranker reaching i and y_i is the length of a shortest Y-ranker reaching i. We call x_i the *x-coordinate* and y_i the *y-coordinate* of position i.

▶ **Example 1.** We will use the word $u = bacbaabada$ as a running example throughout this paper. The attributes of the positions in u are as follows:

12	12	11	22	23	32	31	42	11	21
b	a	c	b	a	a	b	a	d	a

The letter a at position 5 can be reached by the Y-ranker $\mathsf{Y}_b\mathsf{Y}_a\mathsf{Y}_a$ and the a at position 6 can be reached by the X-ranker $\mathsf{X}_c\mathsf{X}_a\mathsf{X}_a$. Both rankers visit both positions 5 and 6. No X-ranker visiting position 6 can avoid position 5 and no Y-ranker visiting position 5 can avoid position 6. Deleting either position 5 or 6 reduces the attributes of the other position to $(2,2)$.

We propose a two-phase algorithm for computing the shortlex normal form of a word u within its $\sim_k$-class. The first phase deletes letters and results in a word of minimal length within the $\sim_k$-class of u. The second phase sorts blocks of letters to get the minimal word with respect to the lexicographic ordering. Both phases depend on the attributes. The computation of the attributes and the first phase are combined as follows.

Phase 1a: Compute all x-coordinates from left to right.
Phase 1b: Compute all y-coordinates from right to left while dynamically deleting a position whenever the sum of its coordinates would be bigger than $k+1$.
Phase 2: Swap consecutive letters b and a (with $b > a$) whenever they have the same attributes and the sum of the x- and the y-coordinate equals $k+1$.

As we will show, a crucial property of Phase 1b is that the dynamic process does not mess up the x-coordinates of the remaining positions that were previously computed in Phase 1a.

The **outline** of the paper is as follows. In Section 4, we prove that successively deleting all letters where the sum of the attributes is bigger than $k+1$ eventually yields a length-minimal word within the $\sim_k$-class of the input. This statement has two parts. The easier part is to show that we can delete such a position without changing the $\sim_k$-class. The more difficult part is to show that if no such deletions are possible, the word is length-minimal within its $\sim_k$-class. In particular, no other types of deletions are required. Also note that deleting letters can change the attributes of the remaining letters.

Section 5 has two components. First, we show that commuting consecutive letters does not change the $\sim_k$-class if (a) the two letters have the same attribute and (b) the sum of the x- and the y-coordinate equals $k+1$. Moreover, such a commutation does not change

any attributes. Then, we prove that no other types of commutation are possible within the $\sim_k$-class. This is quite technical to formalize since, a priori, we could temporarily leave the $\sim_k$-class only to re-enter it again with an even smaller word.

Finally, in Section 6, we present an easy and efficient algorithm for computing shortlex normal forms for $\sim_k$. First, we show how to efficiently compute the attributes. Then we combine this computation with a single-pass deletion procedure; in particular, we do not have to successively re-compute the attributes after every single deletion. Finally, an easy observation shows that we only have to sort disjoint factors where the length of each factor is bounded by the size of the alphabet. Altogether, this yields an $\mathcal{O}(|A|\, n)$ algorithm for computing the shortlex normal form of an input word of length n over the alphabet A. Surprisingly, this bound also holds if k is part of the input.

4 Length reduction

In order to reduce words to shortlex normal form, we want to identify positions in the word which can be deleted without changing its $\sim_k$-class. The following proposition gives a sufficient condition for such deletions.

▶ **Proposition 2.** *Consider a word uav with $a \in A$ and $|ua| = i$. If the attribute (x_i, y_i) at position i satisfies $x_i + y_i > k + 1$, then $uav \sim_k uv$.*

Proof. Let $w \preccurlyeq uav$ with $|w| \leq k$. Assume that $w \not\preccurlyeq uv$. Let $w = paq$ such that $p \preccurlyeq u$ and $q \preccurlyeq v$. Note that $pa \not\preccurlyeq u$ and $aq \not\preccurlyeq v$. If $|p| \geq x_i - 1$ and $|q| \geq y_i - 1$, then

$$k \geq |w| = |p| + 1 + |q| \geq (x_i - 1) + 1 + (y_i - 1) = x_i + y_i - 1 > k,$$

a contradiction. Therefore, we have either $|p| < x_i - 1$ or $|q| < y_i - 1$. By left-right symmetry, it suffices to consider $|p| < x_i - 1$. The word pa defines an X-ranker of length less than x_i which reaches position i. This is not possible by definition of x_i. Hence, $w \preccurlyeq uv$. Conversely, if $w \preccurlyeq uv$ for a word w, then obviously we have $w \preccurlyeq uav$. This shows $uav \sim_k uv$. ◀

▶ **Example 3.** Let $u = bacbaabada$ as in Example 1 and let $k = 3$. Note that the attributes (x_i, y_i) at positions $i \in \{5, 6\}$ satisfy the condition $x_i + y_i > k + 1$. By Proposition 2, deleting any of these positions yields a $\sim_k$-equivalent word. However, deleting both positions yields the word $bacbbada \not\sim_k u$ since $cab \preccurlyeq u$ and $cab \not\preccurlyeq bacbbada$.

Consider a position i with attribute (x_i, y_i) in a word u. Let

$$R_i^u = \{r \mid r \text{ is an } \mathsf{X}\text{-ranker with } r(u) = i \text{ and } |r| = x_i\}.$$

We have $R_i^u \neq \emptyset$ by definition of x_i. We define a *canonical* X*-ranker* $r_i^u \in R_i^u$ by minimizing the reached positions, and the minimization procedure goes from right to left: Let $S_{x_i} = R_i^u$ and, inductively, we define S_j as a nonempty subset of S_{j+1} as follows. Let p_j be the minimal position in u visited by the prefixes s of length j of the rankers in S_{j+1}; then S_j contains all rankers in S_{j+1} such that their prefixes of length j visit the position p_j. Since the minimal positions (and their labels) in this process are unique, we end up with $|S_1| = 1$. Now, the ranker r_i^u is given by $S_1 = \{r_i^u\}$. By abuse of notation, we will continue to use the symbol r for arbitrary rankers while r_i^u denotes canonical rankers. The following example shows that minimizing from right to left (and not the other way round) is crucial.

▶ **Example 4.** Let $u = abcabcdaefccabc$. The attributes of the letters are as follows:

13	13	13	22	22	22	11	22	11	11	23	32	21	21	31
a	b	c	a	b	c	d	a	e	f	c	c	a	b	c
1	2	3	4	5	6	7	8	9	10	11	12	13	14	15

The last c is at position 15 and its attribute is $(3, 1)$. It is easy to verify that $\mathsf{X}_e\mathsf{X}_a\mathsf{X}_c$ is an X-ranker of length 3 visiting position 15 and that there is no X-ranker of length 2 reaching this position. The unique Y-ranker of length 1 reaching position 15 is Y_c. We have

$$R^u_{15} = \{\mathsf{X}_d\mathsf{X}_b\mathsf{X}_c, \mathsf{X}_e\mathsf{X}_a\mathsf{X}_c, \mathsf{X}_e\mathsf{X}_b\mathsf{X}_c, \mathsf{X}_f\mathsf{X}_a\mathsf{X}_c, \mathsf{X}_f\mathsf{X}_b\mathsf{X}_c\}\,.$$

Using the above notation, it is easy to see that $S_3 = R^u_{15}$, $S_2 = \{\mathsf{X}_e\mathsf{X}_a\mathsf{X}_c, \mathsf{X}_f\mathsf{X}_a\mathsf{X}_c\}$, and $S_1 = \{\mathsf{X}_e\mathsf{X}_a\mathsf{X}_c\}$. All prefixes of length 2 of rankers in S_2 reach position $p_2 = 13$; the prefix of length 1 of the ranker in S_1 reaches position $p_1 = 9$. The ranker visiting positions 9, 13 and 15 (and no other positions) is $r^u_{15} = \mathsf{X}_e\mathsf{X}_a\mathsf{X}_c$, the unique ranker in S_1.

Also note that the minimal positions m_j visited by prefixes of length j of the rankers in R^u_{15} are $m_1 = 7$, $m_2 = 13$, and $m_3 = 15$; but there is no single ranker of length 3 visiting positions 7, 13, and 15.

While r^u_i is defined in some right-to-left manner, it still has an important left-to-right property when positions of the same label are considered.

▶ **Lemma 5.** *Let $i < j$ be two consecutive c-positions in a word u with attributes (x_i, y_i) and (x_j, y_j), respectively. If $x_j > x_i$, then $r^u_j = r^u_i\mathsf{X}_c$.*

Proof. Since no position ℓ with $i < \ell < j$ is labelled by c, we have $r^u_i\mathsf{X}_c(u) = j$. In particular, $x_j \leq x_i + 1$ and, hence, $x_j = x_i + 1$ by assumption. This shows $R^u_i\mathsf{X}_c \subseteq R^u_j$. Let $r^u_j = r\mathsf{X}_c$. We have $r(u) \geq r^u_i(u)$, since otherwise $r\mathsf{X}_c(u) \leq i < j$, a contradiction. The minimization in the definition of r^u_j now yields $r(u) = r^u_i(u)$. The remaining minimization steps in the definition of r^u_i and r^u_j consider the same rankers and thus the same positions. Hence, $r = r^u_i$. ◀

We now want to prove that the condition introduced in Proposition 2 always results in a shortest word within the corresponding $\sim_k$-class. To this end, we first need the following technical lemma and then prove the main theorem of this section.

▶ **Lemma 6.** *Let $u = a_1 \cdots a_n$ be a word and let $i < j$ be consecutive c-positions. Moreover, let the parameters (x_i, y_i) and (x_j, y_j) satisfy $x_i + y_i \leq k + 1$ and $x_j \leq k$, respectively. For every word v with $u \sim_k v$, we have $r^u_i(v) < r^u_j(v)$.*

Proof. We have $x_i \leq k$ and $x_j \leq k$. Therefore, both $r^u_i(v)$ and $r^u_j(v)$ are defined because this only depends on subwords of length at most k which are identical for u and v. Since $j = r^u_i\mathsf{X}_c(u)$, we have $x_j \leq x_i + 1$. If $x_j = x_i + 1$, then $r^u_j = r^u_i\mathsf{X}_c$ by Lemma 5 and hence $r^u_i(v) < r^u_j(v)$. Therefore, we can assume $x_j \leq x_i$. Suppose that $r^u_i(v) \geq r^u_j(v)$. Let $q\mathsf{Y}_c$ be a Y-ranker with $q\mathsf{Y}_c(u) = i$ and $|q\mathsf{Y}_c| = y_i$. Let w_i be the word which defines r^u_i, let w_j be the word which defines r^u_j, and let z be the word which defines q. We have:

$$\begin{aligned}
& w_i z \preccurlyeq u && \text{since } r^u_i(u) = i < q(u)\\
\Rightarrow\ & w_i z \preccurlyeq v && \text{since } |w_i z| = x_i + y_i - 1 \leq k \text{ and } u \sim_k v\\
\Rightarrow\ & w_j z \preccurlyeq v && \text{since } r^u_i(v) \geq r^u_j(v)\\
\Rightarrow\ & w_j z \preccurlyeq u && \text{since } |w_j z| = x_j + y_i - 1 \leq x_i + y_i - 1 \leq k\\
\Rightarrow\ & q(u) > j\\
\Rightarrow\ & q\mathsf{Y}_c(u) \geq j > i.
\end{aligned}$$

This contradicts $q\mathsf{Y}_c(u) = i$. Therefore, we have $r^u_i(v) < r^u_j(v)$. ◀

▶ **Theorem 7.** *If u is a word such that the attribute (x_i, y_i) of every position i satisfies $x_i + y_i \leq k + 1$, then u has minimal length within its $\sim_k$-class.*

Proof. Let v be any word satisfying $u \sim_k v$. Let ρ map the position j of u to the position $r_j^u(v)$ of v. Consider some letter c occurring in u. Then, by Lemma 6, the function ρ is order-preserving on the set of c-positions in u. In particular, the word v has at least as many occurrences of c as u. This holds for all letters c in u. Hence, $|u| \leq |v|$. ◀

▶ **Example 8.** Consider $u = bacbaabada$ from Example 1 and let $k = 3$. As explained in Example 3, we must not delete both position 5 and position 6. However, we can delete positions 5 and 8 to obtain a $\sim_k$-equivalent word with the following attributes:

12	12	11	22	22	31	11	21
b	a	c	b	a	b	d	a

By Theorem 7, there is no shorter word in the same $\sim_k$-class.

5 Commutation

In the previous section, we described how to successively delete letters of a word in order to obtain a length-minimal $\sim_k$-equivalent word. It remains to show how to further transform a word of minimal length into shortlex normal form. In the first two statements, we give a sufficient condition which allows us to swap letters b and a while preserving the $\sim_k$-class.

▶ **Lemma 9.** *Consider two words $ubav$ and $uabv$ with $a, b \in A$. Let (x_ℓ, y_ℓ) denote the attribute of position ℓ in $ubav$, and let (x'_ℓ, y'_ℓ) denote the attribute of position ℓ in $uabv$. Suppose that $|ub| = i$ and that the attributes (x_i, y_i) and (x_{i+1}, y_{i+1}) satisfy $x_i = x_{i+1}$. Then all positions ℓ satisfy $x'_\ell = x_\ell$.*

Proof. Throughout this proof, we frequently rely on the following simple observation: If rs is a ranker of minimal length reaching position ℓ in a word w, then r is also of minimal length reaching position $r(w)$.

We can assume that $a \neq b$. It suffices to show that no ranker in R_{i+1}^{ubav} visits position i in $ubav$ and no ranker in R_{i+1}^{uabv} visits position i in $uabv$. This implies that for all $\ell \in \{1, \ldots, n\}$, no ranker in R_ℓ^{ubav} or in R_ℓ^{uabv} visits both i and $i+1$ in the corresponding words and thus, we have $R_i^{ubav} = R_{i+1}^{uabv}$ and $R_{i+1}^{ubav} = R_i^{uabv}$ as well as $R_\ell^{ubav} = R_\ell^{uabv}$ for $\ell \notin \{i, i+1\}$. Note that all rankers in R_i^{ubav} and in R_{i+1}^{ubav} have length $x_i = x_{i+1}$.

Suppose, for the sake of contradiction, that a ranker $r \in R_{i+1}^{ubav}$ visits position i in $ubav$. Then, we can write $r = s\mathsf{X}_b\mathsf{X}_a$ with $s\mathsf{X}_b(ubav) = i$. Note that $|s\mathsf{X}_b| \geq x_i$ by the definition of x_i. Since $x_{i+1} = x_i \leq |s\mathsf{X}_b|$, there exists a ranker of length at most $|s\mathsf{X}_b| < |r|$ reaching position $i+1$ in $ubav$, contradicting the choice of r.

Suppose that a ranker $r \in R_{i+1}^{uabv}$ visits position i in $uabv$. Let $r = s\mathsf{X}_a\mathsf{X}_b$ with $s\mathsf{X}_a(uabv) = i$. Note that $s\mathsf{X}_a(ubav) = i+1$ and, since $x_{i+1} = x_i$, there exists a ranker $\hat{s}$ of length at most $|s\mathsf{X}_a|$ such that $\hat{s}(ubav) = i$. Now, $\hat{s}$ is a ranker of length $|\hat{s}| \leq |s\mathsf{X}_a| < |r|$ with $\hat{s}(uabv) = i+1$, a contradiction to $r \in R_{i+1}^{uabv}$. ◀

▶ **Proposition 10.** *Let $ubav$ be a word with $|ub| = i$ and attributes $(x_i, y_i) = (x_{i+1}, y_{i+1})$ satisfying $x_i + y_i = k + 1$. Then $ubav \sim_k uabv$.*

Proof. Suppose that there exists a word w with $|w| \leq k$ such that $w \preccurlyeq ubav$ but $w \not\preccurlyeq uav$ and $w \not\preccurlyeq ubv$. Then we can write $w = w_1baw_2$ such that $w_1b \preccurlyeq ub$, $w_1b \not\preccurlyeq u$, $aw_2 \preccurlyeq av$, and $aw_2 \not\preccurlyeq v$. Thus, the word w_1b defines an X-ranker r with $r(ubav) = i$ and, similarly, aw_2

defines a Y-ranker s with $s(ubav) = i+1$. We see that $|r|+|s| = |w| \leq k$, but this contradicts $|r| + |s| \geq x_i + y_{i+1} = k + 1$. Therefore, every subword of $ubav$ of length at most k is also a subword of $uabv$.

By Lemma 9 and its left-right dual, the attributes of the positions i and $i+1$ in $uabv$ are both identical to (x_i, y_i). Therefore, the same reasoning as above shows that every subword of $uabv$ of length at most k is also a subword of $ubav$. This shows $ubav \sim_k uabv$. ◀

▶ **Example 11.** Let us reconsider the length-minimal word $u = bacbabda$ from Example 8 and let again $k = 3$. The attributes are as follows:

12	12	11	22	22	31	11	21
b	a	c	b	a	b	d	a

The attributes (x_4, y_4) and (x_5, y_5) at positions 4 and 5 satisfy $x_4 = x_5$, $y_4 = y_5$ and $x_4 + y_4 = k + 1$. By Proposition 10, we obtain $bacabbda \sim_k u$. Note that the attributes (x_1, y_1) and (x_2, y_2) at the first two positions satisfy $x_1 = x_2$, $y_1 = y_2$ but $x_1 + x_2 < k + 1$. And, in fact, $abcbabda \not\sim_k u$ since $abc \preccurlyeq abcbabda$ but $abc \not\preccurlyeq u$.

It remains to show that repeated application of the commutation rule described in Proposition 10 actually suffices to obtain the lexicographically smallest representative of a $\sim_k$-class. The next lemma shows, using canonical rankers, that indeed all length-minimal representatives of a $\sim_k$-class can be transformed into one another using this commutation rule.

▶ **Lemma 12.** *Let $u \sim_k v$ such that both words u and v have minimal length in their $\sim_k$-class. Let (x_ℓ, y_ℓ) denote the attribute of position ℓ of u. Consider two positions $i < j$ of u. If either $(x_i, y_i) \neq (x_j, y_j)$ or $x_i + y_i < k + 1$, then $r_i^u(v) < r_j^u(v)$.*

Proof. If i and j have the same label, then the claim follows from Lemma 6. In the remainder of this proof, let their labels be different. In particular, we cannot have $r_i^u(v) = r_j^u(v)$. Suppose $(x_i, y_i) \neq (x_j, y_j)$ or $x_i + y_i < k + 1$. If $x_i + y_j \geq k + 1$ and $x_j + y_i \geq k + 1$, then, by minimality and Proposition 2, we have $x_i + y_i = k + 1$ and $x_j + y_j = k + 1$. This yields $x_i + y_j = k + 1$ and $x_j + y_i = k + 1$. Thus, $x_i = x_i + x_j + y_j - k - 1 = x_j$ and, similarly, $y_i = y_i + x_j + y_j - k - 1 = y_j$; this shows $(x_i, y_i) = (x_j, y_j)$, a contradiction. Therefore, we have either $x_i + y_j \leq k$ or $x_j + y_i \leq k$.

Let p_i and p_j be the words defining the rankers r_i^u and r_j^u, respectively. Symmetrically to the definition of the canonical X-ranker, we could also define canonical Y-rankers s_i^u and s_j^u such that $s_i^u(u) = i$, $|s_i^u| = y_i$, $s_j^u(u) = j$, and $|s_j^u| = y_j$. If the label c of u at position i is the ℓ-th occurrence of the letter c in u, then, by Lemma 6, both r_i^u and s_i^u end up at the position with the ℓ-th occurrence of the letter c in v. This shows $r_i^u(v) = s_i^u(v)$. Similarly, we see that $r_j^u(v) = s_j^u(v)$. Let q_i and q_j be the words defining the rankers s_i^u and s_j^u, respectively.

First, let $x_i + y_j \leq k$. Then $p_i q_j \preccurlyeq u$ yields $p_i q_j \preccurlyeq v$ since $u \sim_k v$ and $|p_i q_j| = x_i + y_j \leq k$. This shows $r_i^u(v) < s_j^u(v) = r_j^u(v)$, as desired. Let now $x_j + y_i \leq k$ and assume $r_i^u(v) > r_j^u(v)$. Then $p_j q_i \preccurlyeq v$ yields $p_j q_i \preccurlyeq u$ and, thus, $j = r_j^u(u) < s_i^u(u) = i$. This is a contradiction; hence, $r_i^u(v) < r_j^u(v)$. ◀

Using the previous lemma, we can finally show that iterating the commutation procedure from Lemma 9 and Proposition 10 yields the desired shortlex normal form.

▶ **Theorem 13.** *Let $u = a_1 \cdots a_n$ with $a_i \in A$ be a length-minimal word within its $\sim_k$-class. Suppose that the attributes (x_i, y_i) for all positions $i < n$ satisfy the following implication:*

$$\text{If } (x_i, y_i) = (x_{i+1}, y_{i+1}) \text{ and } x_i + y_i = k + 1, \text{ then } a_i \leq a_{i+1}. \tag{1}$$

Then u is the shortlex normal form of its $\sim_k$-class.

Proof. Let v be the shortlex normal form of the $\sim_k$-class of u. We want to show that $u = v$. Let ρ map position i of u to position $r_i^u(v)$ of v. As we have seen in the proof of Theorem 7, the function ρ is bijective. It remains to show that ρ is order-preserving. By contradiction, assume that there are positions i and j of u with $i < j$ such that $\rho(i) > \rho(j)$; let i be minimal with this property and let $i = \rho(j)$, *i.e.*, we choose j to be the preimage of position i in v. We already know that $\rho(i) < \rho(j)$ in all of the following cases:

- $a_i = a_j$ (by Lemma 6),
- $(x_i, y_i) \neq (x_j, y_j)$ (by Lemma 12),
- $x_i + y_i < k + 1$ (again by Lemma 12).

Therefore, the only remaining case is $a_i \neq a_j$, $(x_i, y_i) = (x_j, y_j)$ and $x_i + y_i = k + 1$. First, suppose that $(x_i, y_i) = (x_\ell, y_\ell)$ for all $\ell \in \{i, \ldots, j\}$. Then, by the implication in Equation (1), we have $a_i \leq \cdots \leq a_j$. Since $a_i \neq a_j$, we have $a_i < a_j$. Now, u has the prefix $a_1 \cdots a_i$ and v has the prefix $a_1 \cdots a_{i-1} a_j$. In particular, u is lexicographically smaller than v; this is a contradiction. Next, suppose that there exists a position $\ell \in \{i, \ldots, j\}$ with $(x_i, y_i) \neq (x_\ell, y_\ell)$. Note that $i < \ell < j$. By Lemma 12, we have $\rho(i) < \rho(\ell)$ and $\rho(\ell) < \rho(j)$. In particular, we have $\rho(i) < \rho(j)$ in contradiction to our assumption. Altogether, this shows that $i < j$ and $\rho(i) > \rho(j)$ is not possible, *i.e.*, ρ is order-preserving. Hence, $u = v$. ◀

We summarize our knowledge on shortest elements of a $\sim_k$-class as follows. A word u has minimal length within its $\sim_k$-class if and only if all attributes (x_i, y_i) satisfy $x_i + y_i \leq k + 1$. The canonical rankers define a bijective mapping between any two shortest words u and v of a common $\sim_k$-class. This map preserves the labels and the attributes. It is almost order preserving, with the sole exception that $i < j$ could lead to $r_i^u(v) > r_j^u(v)$ whenever the attributes in u satisfy both $x_i + y_i = k + 1$ and $(x_i, y_i) = (x_\ell, y_\ell)$ for all $\ell \in \{i, \ldots, j\}$.

6 Computing shortlex normal forms

The results from the previous sections immediately lead to the following algorithm for computing shortlex normal forms. First, we successively delete single letters of the input word until the length is minimal. Let $a_1 \cdots a_n$ be the resulting word. In the second step, we lexicographically sort maximal factors $a_i \cdots a_j$ with attributes $(x_i, y_i) = \cdots = (x_j, y_j)$ and $x_i + y_i = k + 1$. We now improve the first step of this algorithm.

Algorithm 1 Computing the x-coordinates of $a_1 \cdots a_n$.

```
1: for all a ∈ A do n_a ← 1
2: for i ← 1, ..., n do
3:     suppose a_i = c
4:     x_i ← n_c
5:     n_c ← n_c + 1
6:     for all a ∈ A do n_a ← min(n_a, n_c)
```

The following lemma proves the correctness of Algorithm 1. Its running time is in $\mathcal{O}(|A|\, n)$ since there are n iterations of the main loop, and each iteration updates $|A|$ counters.

▶ **Lemma 14.** *Algorithm 1 computes the correct x-coordinates of the attributes of $a_1 \cdots a_n$.*

Proof. The algorithm reads the input word from left to right, letter by letter. In each step it updates some of its counters n_a. The semantics of the counters n_a is as follows: if the next letter a_i is c, then x_i is n_c. This invariant is true after the initialization in the first line.

Algorithm 2 Computing the y-coordinates of $a_1 \cdots a_n$ plus deletion.

```
1: for all a ∈ A do n_a ← 1
2: for i ← n, ..., 1 do
3:     suppose a_i = c
4:     if x_i + n_c ≤ k + 1 then
5:         y_i ← n_c
6:         n_c ← n_c + 1
7:         for all a ∈ A do n_a ← min(n_a, n_c)
8:     else
9:         position i is marked for deletion
```

Suppose that we start an iteration of the loop at letter $a_i = c$. Then the invariant tells us that $x_i = n_c$. If a_{i+1} were c, then one more step X_c would be needed for a ranker to reach position $i+1$, hence $n_c \leftarrow n_c + 1$. If a_{i+1} were some letter $a \neq c$, then we could either use the ranker corresponding to the old value n_a or we could use the ranker going to position i and from there do an X_a-modality; the latter would yield a ranker whose length is the new value of n_c. We choose the shorter of these two options. Since all counter values were correct before reading position i, there is no other counter n_a which needs to be updated before proceeding with position $i+1$. ◀

With Algorithm 2, we give a procedure for computing the y-coordinates of $a_1 \cdots a_n$ similar to Algorithm 1, but with the modification that we mark some letters for deletion. The positions marked for deletion depend on the number k in Simon's congruence $\sim_k$. The computed y-coordinates are those where all marked letters are actually deleted. We assume that the x-coordinates of the input word are already known.

The algorithm correctly computes the y-coordinates of the word where all marked letters are deleted. This follows from the left-right dual of Lemma 14 and the fact that the counters remain unchanged if a position is marked for deletion.

▶ **Lemma 15.** *Let u be the input for Algorithm 2 and let v be the word with all marked letters removed. Then $u \sim_k v$.*

Proof. Whenever a position i with label c is marked for deletion, the value x_i is correct since no letter to the left of position i is marked for deletion. The counter n_c would be the correct y-coordinate for position i if we deleted all positions which have been marked so far. By Proposition 2 we know that each deletion preserves the $\sim_k$-class. ◀

It remains to show that the x-coordinates are still correct for the resulting word in which all marked letters are deleted.

▶ **Lemma 16.** *Consider a word $u = a_1 \cdots a_n$ with x-coordinate x_ℓ at position ℓ. Let i be the maximal position of u such that $x_i + y_i > k+1$ and let $v = a_1 \cdots a_{i-1} a_{i+1} \cdots a_n$. The x-coordinate of position ℓ of v is denoted by x'_ℓ. Then, for all $j \in \{i+1, \ldots, n\}$, we have $x'_{j-1} = x_j$.*

Proof. It suffices to prove the statement $x'_{j-1} = x_j$ for all positions j of u reachable by a ranker of the form $r\mathsf{X}_c$ with $r(u) = i$ and $c \in A$. By contradiction, suppose that there exists some position $j = r\mathsf{X}_c(u)$ with $x'_{j-1} \neq x_j$ where $r(u) = i$ and $c \in A$; we choose $c \in A$ such that j is minimal with this property. Let $b = a_i$. We have to distinguish two cases.

First suppose that there is no b-position f with $i < f < j$ in u. The ranker r_j^u has to visit position i in u; otherwise $r_j^u(v) = j-1$ and $r_{j-1}^v(u) = j$, a contradiction to $x'_{j-1} \neq x_j$. This implies $x_i < x_j$. Moreover, position i is reachable from j in u with a single Y_b-modality, and hence, we have $x_i + y_i \leq (x_j - 1) + (y_j + 1) \leq k + 1$. This contradicts the choice of i.

Next, let f be the minimal b-position with $i < f < j$. In particular, we have $b \neq c$ because $j \neq f$ is the smallest c-position of u greater than i. Let $r\mathsf{X}_c$ be an X-ranker of length x_j such that $r\mathsf{X}_c(u) = j$. If $r(u) = i$, then $r(v) = f - 1$ and hence $r\mathsf{X}_c(v) = j - 1$. If $r(u) < i$, then the ranker $r\mathsf{X}_c$ does not visit the position i in u and we have $r\mathsf{X}_c(v) = j - 1$. Finally, if $r(u) > i$, then (by choice of c) the position $r(u) < j$ keeps its x-coordinate. In other words, there exists an X-ranker r' with $|r| = |r'|$ and $r'(v) = r(u) - 1$. It follows that $r'\mathsf{X}_c(v) = j - 1$. Therefore, in any case, there exists a ranker s of length at most x_j such that $s(v) = j - 1$. This shows $x'_{j-1} \leq x_j$, and together with $x'_{j-1} \neq x_j$ we obtain $x'_{j-1} < x_j$.

Consider an X-ranker $s\mathsf{X}_c$ of length $x'_{j-1} < x_j$ with $s\mathsf{X}_c(v) = j - 1$. We are still in the situation that there exists a b-position f in u with $i < f < j$. We cannot have $s(v) < i$ since otherwise $s(u) = s(v)$ and, thus, $s\mathsf{X}_c(u) = j$; the latter uses the fact that $b \neq c$. Let now $s(v) \geq i$ and write $s = t\mathsf{X}_d$. We have $t(v) < i$ since otherwise $t\mathsf{X}_c$ would be a shorter X-ranker with $t\mathsf{X}_c(v) = j - 1$. We have $d = b$: if $d \neq b$, then $s(v) = s(u) - 1$ and $s\mathsf{X}_c(u) = j$; this would show $x'_{j-1} \geq x_j$, thereby contradicting $x'_{j-1} < x_j$. It follows that $s(u) = i$ and $s\mathsf{X}_c(u) = j$. As before, this is a contradiction. This completes the proof that $x'_{j-1} = x_j$. ◀

▶ **Example 17.** Let $u = bacbaabada$ be the word from Example 1 and let $k = 3$. Suppose that the alphabet $A = \{a, b, c, d\}$ is ordered by $a < b < c < d$. The attributes of u are as follows:

12	12	11	22	23	32	31	42	11	21
b	a	c	b	a	a	b	a	d	a

Note that each of the attributes (x_i, y_i) at positions $i \in \{5, 6, 8\}$ satisfies the condition $x_i + y_i > k + 1$. As seen in Example 3 we must not delete all these positions. The algorithm only marks positions 6 and 8 for deletion and takes these deletions into account when computing the y-coordinates of the remaining letters:

12	12	11	22	22	3	31	4	11	21
b	a	c	b	a	a	b	a	d	a

The letters are now sorted as in Example 11 and the resulting normal form is *bacabbda*.

The following lemma allows us to improve the estimated time for the sorting step of the main algorithm by showing that any sequence of letters which needs to be sorted contains every letter at most once.

▶ **Lemma 18.** *Consider a word $uaav$ with $a \in A$ and $|ua| = i$. Then $x_i \neq x_{i+1}$ and $y_i \neq y_{i+1}$.*

Proof. Suppose $x_i = x_{i+1}$. Let r_i and r_{i+1} be X-rankers with $r_i(uaav) = i$, $|r_i| = x_i$, $r_{i+1}(uaav) = i + 1$, and $|r_{i+1}| = x_{i+1} = x_i$. Let $r_{i+1} = s\mathsf{X}_a$. If $s(uaav) < i$, then $i + 1 = r_{i+1}(uaav) = s\mathsf{X}_a(uaav) \leq i$. If $s(uaav) = i$, then $|s| = x_i - 1 < x_i = |r_i|$ contradicts the definition of x_i. Therefore, we cannot have $x_i = x_{i+1}$. Symmetrically, we cannot have $y_i = y_{i+1}$. ◀

We are now able to state our main result.

▶ **Theorem 19.** *One can compute the shortlex normal form of a word w of length n, including all attributes of the normal form, with $\mathcal{O}(|A|\, n)$ arithmetic operations and with bit complexity $\mathcal{O}(|A|\, n \log n)$. Alternatively, the computation can be done in deterministic space $\mathcal{O}(|A| \log n)$.*

Proof. The attributes of the normal form can be computed as described in Algorithms 1 and 2. The normal form itself is obtained by filtering out all positions i where the corresponding attribute (x_i, y_i) satisfies $x_i + y_i \leq k + 1$ and by sorting blocks of letters with the same attributes satisfying $x_i + y_i = k + 1$. By Lemma 18, the sorting step can be performed by reading each such block of letters, storing all letters appearing in the block and only outputting all these letters in sorted order once the next block is reached.

If we assume that the comparison of two letters and the modification of the counters is possible in constant time, then running Algorithm 2 on the output of Algorithm 1 takes $\mathcal{O}(|A|\, n)$ steps for input words of length n over alphabet A: for each position of the input word, we need to update $|A|$ counters. Over a fixed alphabet, the resulting algorithm runs in linear time – even if k is part of the input. We could bound all arithmetic operations by $k + 2$, *i.e.*, by replacing the usual addition by $n \oplus m = \min(k + 2, n + m)$. This way, each counter and all results of arithmetic operations would require only $\mathcal{O}(\log k) \subseteq \mathcal{O}(\log n)$ bits. Similarly, $\mathcal{O}(\log |A|) \subseteq \mathcal{O}(\log n)$ bits are sufficient to encode the letters. This leads to a bit complexity of $\mathcal{O}(|A|\, n \log n)$. Note that if $k > n$, then the $\sim_k$-class of the input is a singleton and we can immediately output the input without any further computations. If $|A| > n$, then we could replace A by the letters which occur in the input word.

For the $\mathcal{O}(|A| \log n)$ space algorithm, one can again use Algorithms 1 and 2 to compute the attributes of each position. To compute the shortlex normal form, we do not store all the attributes but use the standard recomputation technique to decide whether a letter gets deleted. The sorting step can be implemented by repeatedly scanning each block of positions with common attributes (x, y) satisfying $x + y = k + 1$. A single scan checks, for a fixed letter $a \in A$, whether a occurs in the block. This is repeated for every $a \in A$ in ascending order. The attributes of the currently investigated block and the current letter a can be stored in space $\mathcal{O}(\log n)$. ◀

7 Summary and Outlook

We considered Simon's congruence $\sim_k$ for piecewise testable languages. The main contribution of this paper is an $\mathcal{O}(|A|\, n)$ algorithm for computing the shortlex normal form of a word of length n within its $\sim_k$-class; surprisingly, this bound also holds if k is part of the input. The algorithm can be adapted to work in deterministic logarithmic space over a fixed alphabet. As a consequence, on input u, v, k, one can test in time $\mathcal{O}(|A|\, |uv|)$ whether $u \sim_k v$ holds. The main tool are the minimal lengths of X-rankers and Y-rankers reaching any position of a word. The key ingredient in the proofs are the so-called canonical rankers.

It would be interesting to see whether the space complexity for an arbitrary alphabet can be further improved from $\mathcal{O}(|A| \log n)$ to nondeterministic log-space or even deterministic log-space if the alphabet A is part of the input. In addition, we still lack corresponding lower bounds for the computation of shortlex normal forms and for the test of whether $u \sim_k v$ holds.

Abstract

Let $\mathrm{vc}(G)$, $\mathrm{fvs}(G)$ and $\mathrm{oct}(G)$ denote, respectively, the size of a minimum vertex cover, minimum feedback vertex set and minimum odd cycle transversal in a graph G. One can ask, when looking for these sets in a graph, how much bigger might they be if we require that they are independent; that is, what is the *price of independence*? If G has a vertex cover, feedback vertex set or odd cycle transversal that is an independent set, then we let, respectively, $\mathrm{ivc}(G)$, $\mathrm{ifvs}(G)$ or $\mathrm{ioct}(G)$ denote the minimum size of such a set. We investigate for which graphs H the values of $\mathrm{ivc}(G)$, $\mathrm{ifvs}(G)$ and $\mathrm{ioct}(G)$ are bounded in terms of $\mathrm{vc}(G)$, $\mathrm{fvs}(G)$ and $\mathrm{oct}(G)$, respectively, when the graph G belongs to the class of H-free graphs. We find complete classifications for vertex cover and feedback vertex set and an almost complete classification for odd cycle transversal (subject to three non-equivalent open cases).

1 Introduction

We define a number of transversals of the vertex set of a graph G. A set $S \subseteq V(G)$ is a *vertex cover* if for every edge $uv \in E(G)$, at least one of u and v is in S, or, equivalently, if the graph $G - S$ contains no edges. A set $S \subseteq V(G)$ is a *feedback vertex set* if for every cycle in G, at least one vertex of the cycle is in S, or, equivalently, if the graph $G - S$ is a forest. A set $S \subseteq V(G)$ is an *odd cycle transversal* if for every cycle in G containing an odd number of vertices, at least one vertex of the cycle is in S, or, equivalently, if the graph $G - S$ is bipartite. For each of these transversals, one usually wishes to investigate how small they can be and there is a vast research literature on this topic.

One can add an additional constraint: require the transversal to be an *independent set*, that is, a set of vertices that are pairwise non-adjacent. It might be possible that no such transversal exists under this constraint. For example, a graph G has an independent vertex cover if and only if G is bipartite. We are interested in the following research question:

> *How is the minimum size of a transversal in a graph affected by adding the requirement that the transversal is independent?*

Of course, this question can be interpreted in many ways; for example, one might ask about the computational complexity of finding the transversals. In this paper, we focus on the following: for the three transversals introduced above, is the size of a smallest possible independent transversal (assuming one exists) bounded in terms of the minimum size of a transversal? That is, one might say, what is the *price of independence*?

To the best of our knowledge, the term price of independence was first used by Camby [4] in a recent unpublished manuscript. She considered dominating sets of graphs (sets of vertices such that every vertex outside the set has a neighbour in the set). As she acknowledged, though first to coin the term, she was building on past work. In fact, Camby and her co-author Plein had given a forbidden induced subgraph characterization of those graphs G for which, for every induced subgraph of G, there are minimum size dominating sets that are already independent [6], and there are a number of further papers on the topic of the price of independence for dominating sets (see the discussion in [4]).

We observe that this incipient work on the price of independence is a natural companion to recent work on the *price of connectivity*, investigating the relationship between minimum size transversals and minimum size connected transversals (which, in contrast to independent transversals, will always exist for the transversals we consider, assuming the input graph is connected). This work began with the work of Cardinal and Levy in their 2010 paper [8] and has since been taken in several directions; see, for example, [1, 5, 7, 9, 11, 12].

In this paper, as we broaden the study of the price of independence by investigating the three further transversals defined above, we will concentrate on classes of graphs defined by a single forbidden induced subgraph H, just as was done for the price of connectivity [1, 12]. That is, for a graph H, we ask what, for a given type of transversal, is the price of independence in the class of H-free graphs? The ultimate aim in each case is to find a dichotomy that allows us to say, given H, whether or not the size of a minimum size independent transversal can be bounded in terms of the size of a minimum transversal. We briefly give some necessary definitions and notation before presenting our results.

A *colouring* of a graph G is an assignment of positive integers (called *colours*) to the vertices of G such that if two vertices are adjacent, then they are assigned different colours. A graph is *k-colourable* if there is a colouring that only uses colours from the set $\{1, \ldots, k\}$. Equivalently, a graph is k-colourable if we can partition its vertex set into k (possibly empty)

independent sets (called *colour classes* or *partition classes*). For $s, t \geq 0$, let $K_{s,t}$ denote the complete bipartite graph with partition classes of size s and t, respectively (note that $K_{s,t}$ is edgeless if $s = 0$ or $t = 0$). For $r \geq 0$, the graph $K_{1,r}$ is also called the $(r+1)$-vertex *star*; if $r \geq 2$ we say that the vertex in the partition class of size 1 is the *central vertex* of this star. For $n \geq 1$, let P_n and K_n denote the path and complete graph on n vertices, respectively. For $n \geq 3$, let C_n denote the cycle on n vertices. For $r \geq 1$, let $K^+_{1,r}$ denote the graph obtained from $K_{1,r}$ by subdividing one edge. The *disjoint union* $G + H$ of two vertex-disjoint graphs G and H is the graph with vertex set $V(G) \cup V(H)$ and edge set $E(G) \cup E(H)$. We denote the disjoint union of r copies of a graph G by rG.

The Price of Independence for Vertex Cover. As mentioned above, a graph has an independent vertex cover if and only if it is bipartite. For a bipartite graph G, let $\mathrm{vc}(G)$ denote the size of a minimum vertex cover, and let $\mathrm{ivc}(G)$ denote the size of a minimum independent vertex cover. Given a class $\mathcal{X}$ of bipartite graphs, we say that $\mathcal{X}$ is ivc-bounded if there is a function $f : \mathbb{Z}_{\geq 0} \to \mathbb{Z}_{\geq 0}$ such that $\mathrm{ivc}(G) \leq f(\mathrm{vc}(G))$ for every $G \in \mathcal{X}$ and we say that $\mathcal{X}$ is ivc-unbounded if no such function exists, that is, if there is a k such that for every $s \geq 0$ there is a graph G in $\mathcal{X}$ with $\mathrm{vc}(G) \leq k$, but $\mathrm{ivc}(G) \geq s$.

In our first main result, proven in Section 2, we determine for every graph H, whether or not the class of H-free bipartite graphs is ivc-bounded.

▶ **Theorem 1.** *Let H be a graph. The class of H-free bipartite graphs is* ivc*-bounded if and only if H is an induced subgraph of $K_{1,r} + rP_1$ or $K^+_{1,r}$ for some $r \geq 1$.*

The Price of Independence for Feedback Vertex Set. A graph has an independent feedback vertex set if and only if its vertex set can be partitioned into an independent set and a set of vertices that induces a forest; graphs that have such a partition are said to be *near-bipartite*. In fact, minimum size independent feedback vertex sets have been the subject of much research from a computational perspective: to find such a set is, in general, NP-hard, but there are fixed-parameter tractable algorithms and polynomial-time algorithms for certain graph classes; we refer to [2] for further details. For a near-bipartite graph G, let $\mathrm{fvs}(G)$ denote the size of a minimum feedback vertex set, and let $\mathrm{ifvs}(G)$ denote the size of a minimum independent feedback vertex set. Given a class $\mathcal{X}$ of near-bipartite graphs, we say that $\mathcal{X}$ is ifvs-bounded if there is a function $f : \mathbb{Z}_{\geq 0} \to \mathbb{Z}_{\geq 0}$ such that $\mathrm{ifvs}(G) \leq f(\mathrm{fvs}(G))$ for every $G \in \mathcal{X}$ and ifvs-unbounded otherwise.

In our second main result, proven in Section 3, we determine for every graph H, whether or not the class of H-free near-bipartite graphs is ifvs-bounded.

▶ **Theorem 2.** *Let H be a graph. The class of H-free near-bipartite graphs is* ifvs*-bounded if and only if H is isomorphic to $P_1 + P_2$, a star or an edgeless graph.*

The Price of Independence for Odd Cycle Transversal. A graph has an independent odd cycle transversal S if and only if it has a 3-colouring, since, by definition, we are requesting that S is an independent set of G such that $G - S$ has a 2-colouring. For a 3-colourable graph G, let $\mathrm{oct}(G)$ denote the size of a minimum odd cycle transversal, and let $\mathrm{ioct}(G)$ denote the size of a minimum independent odd cycle transversal. Given a class $\mathcal{X}$ of 3-colourable graphs, we say that $\mathcal{X}$ is ioct-bounded if there is a function $f : \mathbb{Z}_{\geq 0} \to \mathbb{Z}_{\geq 0}$ such that $\mathrm{ioct}(G) \leq f(\mathrm{oct}(G))$ for every $G \in \mathcal{X}$ and ioct-unbounded otherwise.

In our third main result, proven in Section 4, we address the question of whether or not, for a graph H, the class of H-free 3-colourable graphs is ifvs-bounded. Here, we do not have a complete dichotomy due to three missing cases, as we will discuss at the end of Section 4.

▶ **Theorem 3.** *Let H be a graph. The class of H-free 3-colourable graphs is* ioct*-bounded:*
- *if H is an induced subgraph of P_4 or $K_{1,3} + sP_1$ for some $s \geq 0$ and*
- *only if H is an induced subgraph of $K^+_{1,4}$ or $K_{1,4} + sP_1$ for some $s \geq 0$.*

Further Notation. Let G be a graph. For $x \in V(G)$, the *(open) neighbourhood* $N(v)$ of v is the set of vertices adjacent to v; the *closed neighbourhood* $N[v] = N(v) \cup \{v\}$. For $x \in V(G)$, let $\deg(v) = |N(v)|$ denote the *degree* of v. If $S \subseteq V(G)$, then $N(S) = \{v \in V(G) \setminus S \mid \exists u \in S, uv \in E(G)\}$ and $N[S] = N(S) \cup S$. For two vertices $x, y \in V(G)$, let $\text{dist}(x, y)$ denote the length of a shortest path from x to y (let $\text{dist}(x, y) = \infty$ if x and y are in different connected components of G). For $S \subseteq V(G)$, let $G[S]$ be the *induced subgraph of G on S*, that is, the graph with vertex set S, where two vertices in S are adjacent if and only if they are adjacent in G. For $S \subseteq V(G)$, let $G - S$ denote $G[V(G) \setminus S]$. A vertex $y \in V(G)$ is complete (resp. anti-complete) to a set $X \subseteq V(G)$ if y is adjacent (resp. not adjacent) to every vertex in X. A set $Y \subseteq V(G)$ is complete (resp. anti-complete) to a set $X \subseteq V(G)$ if every vertex of Y is complete (resp. anti-complete) to X. A vertex $v \in V(G)$ is *dominating* if it is complete to $V(G) \setminus \{v\}$. The *complement* $\overline{G}$ of a graph G has the same vertex set as G and an edge between two distinct vertices if and only if these vertices are not adjacent in G. A graph is *complete multi-partite* if its vertex set can be partitioned into independent sets that are complete to each other. For a set of graphs $\{H_1, \ldots, H_s\}$, a graph is said to be $(H_1, \ldots, H_s)$*-free* if it contains no induced subgraph isomorphic to a graph in the set.

2 Vertex Cover

We start with a useful lemma.

▶ **Lemma 4.** *Let $r, s \geq 1$. If G is a $(K_{1,r} + sP_1)$-free bipartite graph with bipartition (X, Y) such that $|X|, |Y| \geq rs + r - 1$, then either:*
- *every vertex of G has degree less than r or*
- *fewer than s vertices of X have more than $s - 1$ non-neighbours in Y and fewer than s vertices of Y have more than $s - 1$ non-neighbours in X.*

Proof. Let G be a $(K_{1,r} + sP_1)$-free bipartite graph with bipartition (X, Y) such that $|X|, |Y| \geq rs + r - 1$. No vertex in X can have both r neighbours and s non-neighbours in Y, otherwise G would contain an induced $K_{1,r} + sP_1$. Therefore every vertex in X has degree either at most $r - 1$ or at least $|Y| - (s - 1) \geq rs + r - s$. By symmetry, we may assume that there is a vertex $x \in X$ of degree at least r. Suppose, for contradiction, that there is a set $X' \subseteq X$ of s vertices, each of which has more than $s - 1$ non-neighbours in Y. Then every vertex of X' has degree at most $r - 1$. Since $\deg(x) \geq rs + r - s = s(r - 1) + r$, there must be a set $Y' \subseteq N(x)$ of r neighbours of x that have no neighbours in X'. Then $G[\{x\} \cup Y' \cup X']$ is a $K_{1,r} + sP_1$, a contradiction. It follows that fewer than s vertices in X have more than $s - 1$ non-neighbours in Y. Since $|X| \geq r + (s - 1)$, there is a set $X'' \subsetneq X$ of r vertices, each of which have at most $s - 1$ non-neighbours in Y. Since $|Y| > r(s - 1)$, there must be a vertex $y \in Y$ that is complete to X'', and therefore has $\deg(y) \geq r$. Repeating the above argument, it follows that fewer than s vertices of Y have more than $s - 1$ non-neighbours in X. This completes the proof. ◀

Recall that a graph has an independent vertex cover if and only if it is bipartite.

▶ **Lemma 5.** *Let $r, s \geq 1$. If G is a $(K_{1,r} + sP_1)$-free bipartite graph, then* $\text{ivc}(G) \leq \text{vc}(G)r + rs$.

Proof. Let G be a $(K_{1,r} + sP_1)$-free bipartite graph. Fix a bipartition (X, Y) of G. Let S be a minimum vertex cover of G, so $|S| = \mathrm{vc}(G)$. We may assume that $\mathrm{vc}(G) \geq 2$, otherwise $\mathrm{ivc}(G) = \mathrm{vc}(G)$, in which case we are done. We may also assume that $|X|, |Y| > \mathrm{vc}(G)r + rs > rs + r - 1$, otherwise X or Y is an independent vertex cover of the required size, and we are done. If every vertex of G has degree at most $r - 1$, then $S' = (S \cap Y) \cup (N(S \cap X))$ is an independent vertex cover in G of size at most $\mathrm{vc}(G)(r - 1)$, and we are done. By Lemma 4, we may therefore assume that fewer than s vertices of X have more than $s-1$ non-neighbours in Y. We will show that this leads to a contradiction. Since $|X|, |Y| \geq \mathrm{vc}(G) + s$, there must be a set S' of $\mathrm{vc}(G) + 1$ vertices in X that have at least $\mathrm{vc}(G) + 1$ neighbours in Y. If a vertex $x \in V(G)$ has degree at least $\mathrm{vc}(G) + 1$, then $|N(x)| > |S|$, so $x \in S$. Therefore every vertex of S' must be in S, contradicting the fact that $|S'| = \mathrm{vc}(G) + 1 > \mathrm{vc}(G) = |S|$. ◀

▶ **Lemma 6.** *Let $r \geq 2$. If G is a $K^+_{1,r}$-free bipartite graph, then* $\mathrm{ivc}(G) \leq (\mathrm{vc}(G))^2(r - 1)$.

Proof. Clearly it is sufficient to prove the lemma for connected graphs G. Let G be a connected $K^+_{1,r}$-free bipartite graph. Fix a bipartition (X, Y) of G. Let S be a minimum vertex cover of G, so $|S| = \mathrm{vc}(G)$. We may assume that $\mathrm{vc}(G) \geq 2$, otherwise $\mathrm{ivc}(G) = \mathrm{vc}(G)$ and we are done. We may also assume that $|X|, |Y| > (\mathrm{vc}(G))^2(r - 1)$, otherwise X or Y is an independent vertex cover of the required size.

If there are two vertices $x, y \in X$ with $\mathrm{dist}(x, y) = 2$ and $\deg(x) \geq \deg(y) + (r - 1)$, then x, y, a common neighbour of x and y, and $r - 1$ vertices from $N(x) \setminus N(y)$ would induce a $K^+_{1,r}$ in G, a contradiction. Therefore, if $x, y \in X$ with $\mathrm{dist}(x, y) = 2$, then $|\deg(x) - \deg(y)| \leq r - 2$, so $|\deg(x) - \deg(y)| \leq (\frac{r-2}{2})\,\mathrm{dist}(x, y)$. By the triangle inequality and induction, it follows that if $x, y \in X$, then $|\deg(x) - \deg(y)| \leq (\frac{r-2}{2})\,\mathrm{dist}(x, y)$. Observe that $\mathrm{vc}(P_{2\,\mathrm{vc}(G)+2}) = \mathrm{vc}(G) + 1$, so G must be $P_{2\,\mathrm{vc}(G)+2}$-free. Since G is connected, it follows that if $x, y \in V(G)$, then $\mathrm{dist}(x, y) < 2\,\mathrm{vc}(G) + 1$. We conclude that if $x, y \in X$, then $|\deg(x) - \deg(y)| \leq \mathrm{vc}(G)(r - 2)$. Note that if a vertex $x \in V(G)$ has degree at least $\mathrm{vc}(G) + 1$, then $|N(x)| > |S|$ and so $x \in S$.

Since $|X| > (\mathrm{vc}(G))^2(r - 1) > \mathrm{vc}(G) = |S|$, there must be a vertex $y \in X \setminus S$. Since $y \in X \setminus S$, it follows that $\deg(y) \leq \mathrm{vc}(G)$. It follows that $\deg(x) \leq \deg(y) + \mathrm{vc}(G)(r - 2) \leq \mathrm{vc}(G)(r - 1)$ for all $x \in X$. We conclude that $S' = (S \cap Y) \cup (N(S \cap X))$ is an independent vertex cover in G of size at most $(\mathrm{vc}(G))^2(r - 1)$. This completes the proof. ◀

We are now ready to prove the main result of this section.

▶ **Theorem 1 (restated).** *Let H be a graph. The class of H-free bipartite graphs is* ivc*-bounded if and only if H is an induced subgraph of $K_{1,r} + rP_1$ or $K^+_{1,r}$ for some $r \geq 1$.*

Proof. If H is an induced subgraph of $K_{1,r} + rP_1$ or $K^+_{1,r}$ for some r, then Lemma 5 or 6, respectively, implies that the class of H-free bipartite graphs is ivc-bounded.

Now let H be a graph and suppose that there is a function $f : \mathbb{Z}_{\geq 0} \to \mathbb{Z}_{\geq 0}$ such that $\mathrm{ivc}(G) \leq f(\mathrm{vc}(G))$ for all H-free bipartite graphs G. We will show that H is an induced subgraph of $K_{1,r} + rP_1$ or $K^+_{1,r}$ for some r.

For $r \geq 1$, $s \geq 2$, let D^r_s denote the graph formed from $2K_{1,s}$ and P_{2r} by identifying the two end-vertices of the P_{2r} with the central vertices of the respective $K_{1,s}$'s (see also Figure 1; a graph of the form D^1_s is said to be a *double-star*). It is easy to verify that $\mathrm{vc}(D^r_s) = r + 1$ and $\mathrm{ivc}(D^r_s) = r + s$. Therefore, for every $r \geq 1$, $D^r_{f(r+1)}$ cannot be H-free by definition of f. Note that for $r, s, t \geq 1$, if $s \leq t$ then D^r_s is an induced subgraph of D^r_t. Therefore, for each $r \geq 1$, there must be an s such that D^r_s is not H-free. In other words, for each $r \geq 1$, H must be an induced subgraph of D^r_s for some s.

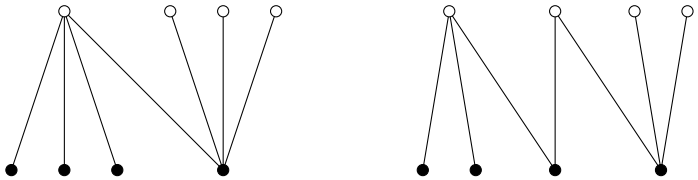

Figure 1 The graphs D_3^1 and D_2^2. The black vertices form a minimum independent vertex cover.

In particular, this means that we may assume that H is an induced subgraph of D_t^1 for some $t \geq 1$. If H contains at most one of the central vertices of the stars that form the D_t^1, then H is an induced subgraph of $K_{1,t} + tP_1$ and we are done, so we may assume H contains both central vertices. If one of these central vertices has at most one neighbour that is not a central vertex, then H is an induced subgraph of $K_{1,t+1}^+$, and we are done. We may therefore assume that H contains an induced D_2^1. However, for every $s \geq 1$, D_s^2 is D_2^1-free and therefore H-free. This contradiction completes the proof. ◀

3 Feedback Vertex Set

Recall that a graph has an independent feedback vertex set if and only if it is near-bipartite.

▶ **Lemma 7.** *If G is a $(P_1 + P_2)$-free near-bipartite graph, then* $\text{ifvs}(G) = \text{fvs}(G)$.

Proof. Let G be a $(P_1 + P_2)$-free near-bipartite graph. Note that $\overline{G}$ is a P_3-free graph, so $\overline{G}$ is a disjoint union of cliques. It follows that G is a complete multi-partite graph, say with a partition of its vertex sets into k non-empty independent sets $V_1, \ldots, V_k$. We may assume that $k \geq 2$, otherwise G is an edgeless graph, in which case $\text{ifvs}(G) = \text{fvs}(G) = 0$ and we are done. Since G is near-bipartite, it contains an independent set I such that $G - I$ is a forest. Note that $I \subseteq V_i$ for some $i \in \{1, \ldots, k\}$. Since near-bipartite graphs are 3-colourable, it follows that $k \leq 3$. Furthermore, if $k = 3$, then $|V_j| = 1$ for some $j \in \{1, 2, 3\} \setminus \{i\}$, otherwise $G - I$ would contain an induced C_4, a contradiction. In other words G is either a complete bipartite graph or the graph formed from a complete bipartite graph by adding a dominating vertex.

First suppose that $k = 2$, so G is a complete bipartite graph. Without loss of generality assume that $|V_1| \geq |V_2| \geq 1$. Let S be a feedback vertex set of G. If there are two vertices in $V_1 \setminus S$ and two vertices in $V_2 \setminus S$, then these vertices would induce a C_4 in $G - S$, a contradiction. Therefore S must contain all but at most one vertex of V_1 or all but at most one vertex of V_2, so $\text{fvs}(G) \geq \min(|V_1| - 1, |V_2| - 1) = |V_2| - 1$. Let I be a set consisting of $|V_2| - 1$ vertices of V_2. Then I is independent and $G - I$ is a star, so I is an independent feedback vertex set. It follows that $\text{ifvs}(G) \leq |V_2| - 1$. Since $\text{fvs}(G) \leq \text{ifvs}(G)$, we conclude that $\text{ifvs}(G) = \text{fvs}(G)$ in this case.

Now suppose that $k = 3$, so G is obtained from a complete bipartite graph by adding a dominating vertex. Without loss of generality assume that $|V_1| \geq |V_2| \geq |V_3| = 1$. Let S be a feedback vertex set of G. By the same argument as in the $k = 2$ case, S must contain all but at most one vertex of V_1 or all but at most one vertex of V_2. If there is a vertex in $V_i \setminus S$ for all $i \in \{1, 2, 3\}$, then these three vertices would induce a C_3 in $G - S$, a contradiction. Therefore S must contain every vertex in V_i for some $i \in \{1, 2, 3\}$. Since $|V_1| \geq |V_2| \geq |V_3| = 1$, it follows that $|S| \geq \min(|V_2| - 1 + |V_3|, |V_2|) = |V_2|$. Therefore $\text{fvs}(G) \geq |V_2|$. Now V_2 is an independent set and $G - V_2$ is a star, so V_2 is an independent feedback vertex set. It follows that $\text{ifvs}(G) \leq |V_2|$. Since $\text{fvs}(G) \leq \text{ifvs}(G)$, we conclude that $\text{ifvs}(G) = \text{fvs}(G)$. ◀

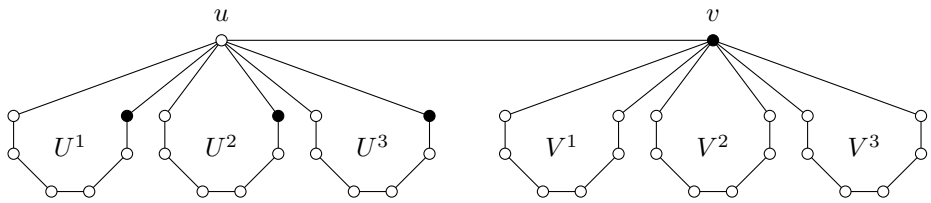

Figure 2 The graph S_3^3.

▶ **Lemma 8.** *If $r \geq 1$ and G is a $K_{1,r}$-free near-bipartite graph, then* $\text{ifvs}(G) \leq (2r^2 - 5r + 3)\,\text{fvs}(G)$.

Proof. Fix integers $k \geq 0$ and $r \geq 1$. Suppose G is a $K_{1,r}$-free near-bipartite graph with a feedback vertex set S such that $|S| = k$. Since G is near-bipartite, $V(G)$ can be partitioned into an independent set V_1 and a set $V(G) \setminus V_1$ that induces a forest in G. Since forests are bipartite, we can partition $V(G) \setminus V_1$ into two independent sets V_2 and V_3.

Suppose $x \in V_i$ for some $i \in \{1,2,3\}$. Then x has no neighbours in V_i since V_i is an independent set. For $j \in \{1,2,3\} \setminus \{i\}$, the vertex x can have at most $r-1$ neighbours in V_j, otherwise G would contain an induced $K_{1,r}$. It follows that $\deg(x) \leq 2(r-1)$ for all $x \in V(G)$.

Let $S' = S$. Let $F' = V(G) \setminus S'$, so $G[F']$ is a forest. To prove the lemma, we will iteratively modify S' until we obtain an independent feedback vertex set S' of G with $|S'| \leq (2r^2 - 5r + 3)|S|$. Every vertex $u \in S'$ has at most $2r-2$ neighbours in F'. Consider two neighbours v, w of u in F'. As F' is a forest, there is at most one induced path in F' from v to w, so there is at most one induced cycle in $G[F' \cup \{u\}]$ that contains all of u, v and w. Therefore $G[F' \cup \{u\}]$ contains at most $\binom{2r-2}{2} = \frac{1}{2}(2r-2)(2r-2-1) = 2r^2 - 5r + 3$ induced cycles. Note that every cycle in G contains at least one vertex of V_1. Therefore, if $s \in S' \cap (V_2 \cup V_3)$, then we can find a set X of at most $2r^2 - 5r + 3$ vertices in $V_1 \setminus S'$ such that if we replace s in S' by the vertices of X, then we again obtain a feedback vertex set. Repeating this process iteratively, for each vertex we remove from $S' \cap (V_2 \cup V_3)$, we add at most $2r^2 - 5r + 3$ vertices to $S' \cap V_1$. We stop the procedure once $S' \cap (V_2 \cup V_3)$ becomes empty, at which point we have produced a feedback vertex set S' with $|S'| \leq (2r^2 - 5r + 3)|S|$. Furthermore, at this point $S' \subseteq V_1$, so S' is independent. It follows that $\text{ifvs}(G) \leq (2r^2 - 5r + 3)\,\text{fvs}(G)$. ◀

Note that all near-bipartite graphs are 3-colourable (use one colour for the independent set and the two other colours for the forest). We prove the following lemma.

▶ **Lemma 9.** *Let $k \geq 3$. The class of C_k-free near-bipartite graphs is* ifvs*-unbounded and* ioct*-unbounded.*

Proof. For $r, s \geq 2$, let S_s^r denote the graph constructed as follows (see also Figure 2). Start with the graph that is the disjoint union of $2s$ copies of P_{2r}, and label these copies $U^1, \ldots, U^s, V^1, \ldots, V^s$. Add a vertex u adjacent to both endpoints of every U^i and a vertex v adjacent to both endpoints of every V^i. Finally, add an edge between u and v.

Every induced cycle in S_s^r is isomorphic to C_{2r+1}, which is an odd cycle. Thus a set $S \subseteq V(S_s^r)$ is a feedback vertex set for S_s^r if and only if it is an odd cycle transversal for S_s^r. It follows that $\text{fvs}(S_s^r) = \text{oct}(S_s^r)$ and $\text{ifvs}(S_s^r) = \text{ioct}(S_s^r)$.

Now $\{u, v\}$ is a minimum feedback vertex set of S_s^r, so $\text{fvs}(S_s^r) = \text{oct}(S_s^r) = 2$. However, any independent feedback vertex set S contains at most one vertex of u and v; say it does not contain u. Then it must contain at least one vertex of each U^i. It follows that $\text{ifvs}(S_s^r) = \text{ioct}(S_s^r) \geq s + 1$. Since for every $s \geq 2$, $k \geq 3$, the graph S_s^k is C_k-free. This completes the proof. ◀

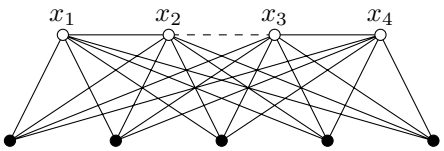

Figure 3 The graphs T_5 and T_5'. The edge x_2x_3 is present in T_5, but not in T_5'.

▶ **Theorem 2 (restated).** *Let H be a graph. The class of H-free near-bipartite graphs is* ifvs*-bounded if and only if H is isomorphic to $P_1 + P_2$, a star or an edgeless graph.*

Proof. If $H = P_1 + P_2$, then the theorem holds by Lemma 7. If H is isomorphic to a star or an edgeless graph, then H is an induced subgraph of $K_{1,r}$ for some $r \geq 1$. In this case the theorem holds by Lemma 8.

Now suppose that the class of H-free near-bipartite graphs is ifvs-bounded. By Lemma 9, H must be a forest. We will show that H is isomorphic to $P_1 + P_2$, a star or an edgeless graph.

We start by showing that H must be $(P_1+P_3, 2P_1+P_2, 2P_2)$-free. Let vertices x_1, x_2, x_3, x_4, in that order, form a path on four vertices. For $s \geq 3$, let T_s be the graph obtained from this path by adding an independent set I on s vertices (see also Figure 3) that is complete to the path and note that T_s is near-bipartite. Then $\{x_1, x_2, x_3\}$ is a minimum feedback vertex set in T_s. However, if S is an independent feedback vertex set, then S contains at most two vertices in $\{x_1, \ldots, x_4\}$. Therefore S must contain at least $s-1$ vertices of I, otherwise $T_s - S$ would contain an induced C_3 or C_4. Therefore $\mathrm{fvs}(T_s) = 3$ and $\mathrm{ifvs}(T_s) \geq s-1$. Note that T_s is $(P_1 + P_3, 2P_1 + P_2, 2P_2)$-free (this is easy to see by casting to the complement and observing that $\overline{T_s}$ is the disjoint union of a P_4 and a complete graph). Therefore H cannot contain $P_1 + P_3$, $2P_1 + P_2$ or $2P_2$ as an induced subgraph, otherwise T_s would be H-free, a contradiction.

Next, we show that H must be P_4-free. For $s \geq 3$ let T_s' be the graph obtained from T_s by removing the edge x_2x_3 (see also Figure 3). Then $\{x_1, x_2, x_3\}$ is a minimum feedback vertex set in T_s', so $\mathrm{fvs}(T_s') = 3$. By the same argument as for T_s, we find that $\mathrm{ifvs}(T_s') \geq s-1$ Now the complement $\overline{T_s'}$ is the disjoint union of a C_4 and a complete graph, so T_s' is P_4-free. Therefore H cannot contain P_4 as an induced subgraph.

We may now assume that H is a $(P_1+P_3, 2P_1+P_2, 2P_2, P_4)$-free forest. If H is connected, then it is a P_4-free tree, so it is a star, in which case we are done. We may therefore assume that H is disconnected. We may also assume that H contains at least one edge, otherwise we are done. Since H is $(2P_1 + P_2)$-free, it cannot have more than two components. Since H is $2P_2$-free, one of its two components must be isomorphic to P_1. Since H is a $(P_1 + P_3)$-free forest, its other component must be isomorphic to P_2. Hence H is isomorphic to $P_1 + P_2$. This completes the proof. ◀

4 Odd Cycle Transversal

Recall that a graph has an independent odd cycle transversal if and only if it is 3-colourable. We show the following two lemmas.

▶ **Lemma 10.** *If G is a P_4-free* 3*-colourable graph, then* $\mathrm{ioct}(G) = \mathrm{oct}(G)$.

Proof. Let G be a P_4-free 3-colourable graph. It suffices to prove the lemma component-wise, so we may assume that G is connected. Note that G cannot contain any induced odd cycles on more than three vertices, as it is P_4-free. Let (V_1, V_2, V_3) be a partition of $V(G)$ into

independent sets. We may assume that G is not bipartite, otherwise $\mathrm{ioct}(G) = \mathrm{oct}(G) = 0$, in which case we are done. As G is connected, P_4-free and contains more than one vertex, its complement $\overline{G}$ must be disconnected. Therefore we can partition the vertex set of G into two parts X_1 and X_2 such that X_1 is complete to X_2. No independent set V_i can have vertices in both X_1 and X_2, so without loss of generality we may assume that $X_1 = V_1$ and $X_2 = V_2 \cup V_3$. Since $G[X_2]$ is a P_4-free bipartite graph, it is readily seen that it is a disjoint union of complete bipartite graphs.

Note that $G - X_1$ is a bipartite graph, so X_1 is an odd cycle transversal of G. Furthermore, X_1 is independent. Now let S be a minimum vertex cover of $G[X_2]$. Observe that $G - S$ is bipartite, so S is an odd cycle transversal of G. Since $G[X_2]$ is the disjoint union of complete bipartite graphs, for every component C of $G[X_2]$, S must contain one part of the bipartition of C, or the other; by minimality of S, it only contains vertices from one of the parts. It follows that S is independent.

We now claim that every minimum odd cycle transversal S of G contains either X_1 or a minimum vertex cover of $G[X_2]$, both of which we have shown are independent odd cycle transversals; by the minimality of S, this will imply that S is equal to one of them. Indeed, suppose for contradiction that there is a vertex $x \in X_1 \setminus S$ and two adjacent vertices $y, z \in X_2 \setminus S$. Then $G[\{x, y, z\}]$ is a C_3 in $G - S$. This contradiction completes the proof. ◀

▶ **Lemma 11.** *If G is a $K_{1,3}$-free 3-colourable graph, then* $\mathrm{ioct}(G) \leq 3\,\mathrm{oct}(G)$.

Proof. Fix an integer $k \geq 0$. Let G be a $K_{1,3}$-free 3-colourable graph with an odd cycle transversal S such that $|S| = k$. Fix a partition of $V(G)$ into three independent sets V_1, V_2, V_3. Without loss of generality assume that $|S \cap V_1| \geq |S \cap V_2|, |S \cap V_3|$, so $|S \cap (V_2 \cup V_3)| \leq \frac{2k}{3}$. Let $S' = S$ and note that $G - S'$ is bipartite by definition of odd cycle transversal. To prove the lemma, we will iteratively modify S' until we obtain an independent odd cycle transversal S' of G with $|S'| \leq 3k$.

Suppose $x \in V_i$ for some $i \in \{1, 2, 3\}$. Then x has no neighbours in V_i since V_i is an independent set. For $j \in \{1, 2, 3\} \setminus \{i\}$, the vertex x can have at most two neighbours in V_j, otherwise G would contain an induced $K_{1,3}$. It follows that $\deg(x) \leq 4$ for all $x \in V(G)$.

As $G - S'$ is a bipartite $K_{1,3}$-free graph, it is a disjoint union of paths and even cycles. Every vertex $u \in S'$ has at most four neighbours in $V(G) \setminus S'$. An induced odd cycle in $G - (S' \setminus \{u\})$ consists of the vertex u and an induced path P in $G - S'$ between two neighbours v, w of u such that $P \cap N(u)$ does not contain any vertices apart from v and w. If u has q neighbours in some component C of $G - S'$, then there can be at most q such paths P that lie in this component. It follows that there are at most four induced odd cycles in $G - (S' \setminus \{u\})$. Note that every induced odd cycle in G contains at least one vertex in each V_i. Therefore, if $s \in S' \cap (V_2 \cup V_3)$, then we can find a set X of at most four vertices in $V_1 \setminus S'$ such that if we replace s in S' by the vertices of X, then we again obtain an odd cycle transversal. Repeating this process iteratively, for each vertex we remove from $S' \cap (V_2 \cup V_3)$, we add at most four vertices to $S' \cap V_1$, so $|S'|$ increases by at most 3. We stop the procedure once $S' \cap (V_2 \cup V_3)$ becomes empty, at which point we have produced an odd cycle transversal S' with $|S'| \leq |S| + 3|S \cap (V_2 \cup V_3)| \leq k + 2 \times \frac{2k}{3} = 3k$. Furthermore, at this point $S' \subseteq V_1$, so S' is independent. It follows that $\mathrm{ioct}(G) \leq 3\,\mathrm{oct}(G)$. ◀

▶ **Lemma 12.** *Let $r, s \geq 1$. Suppose there is a function $f : \mathbb{Z}_{\geq 0} \to \mathbb{Z}_{\geq 0}$ such that* $\mathrm{ioct}(G) \leq f(\mathrm{oct}(G))$ *for every $K_{1,r}$-free 3-colourable graph G. Then* $\mathrm{ioct}(G) \leq \max(\mathrm{oct}(G)r + r^2 + 3rs - 2r, f(\mathrm{oct}(G)))$ *for every $(K_{1,r} + sP_1)$-free 3-colourable graph G.*

Proof. Fix $r, s \geq 1$ and $k \geq 0$. Let G be a $(K_{1,r} + sP_1)$-free 3-colourable graph with a minimum odd-cycle transversal T on k vertices. Fix a partition of $V(G)$ into three independent sets V_1, V_2, V_3. We may assume that $\text{oct}(G) \geq 2$, otherwise $\text{ioct}(G) = \text{oct}(G)$ and we are done. If $|V_i| \leq \max(\text{oct}(G)r + r^2 + 3rs - 2r, f(\text{oct}(G)))$ for some $i \in \{1, 2, 3\}$, then deleting V_i from G yields a bipartite graph, so $\text{ioct}(G) \leq \max(\text{oct}(G)r + r^2 + 3rs - 2r, f(\text{oct}(G)))$ and we are done. We may therefore assume that $|V_i| > \max(\text{oct}(G)r + r^2 + 3rs - 2r, f(\text{oct}(G)))$ for all $i \in \{1, 2, 3\}$. If G is $K_{1,r}$-free, then $\text{ioct}(G) \leq f(\text{oct}(G))$, so suppose that G contains an induced $K_{1,r}$, say with vertex set X. Note that $|X| = r + 1$, and each V_i can contain at most r vertices of X, since every V_i is an independent set.

For every $i \in \{1, 2, 3\}$, there cannot be a set of s vertices in $V_i \setminus X$ that are anti-complete to X, otherwise G would contain an induced $K_{1,r} + sP_1$, a contradiction. For every $i \in \{1, 2, 3\}$, since $|V_i| > \text{oct}(G)r + r^2 + 3rs - 2r \geq r^2 + 3rs$, it follows that $|V_i \setminus X| \geq |V_i| - r > (s-1) + (r+1)(r-1) = (s-1) + |X|(r-1)$. Hence for every $i \in \{1, 2, 3\}$, there must be a vertex $x \in X$ that has at least r neighbours in V_i. Applying this for each i in turn, we find that at least two of the graphs in $\{G[V_1 \cup V_2], G[V_1 \cup V_3], G[V_2 \cup V_3]\}$ contain a vertex of degree at least r; without loss of generality assume that this is the case for $G[V_1 \cup V_2]$ and $G[V_1 \cup V_3]$. Let V_2' and V_3' denote the set of vertices in V_2 and V_3, respectively, that have more than $s-1$ non-neighbours in V_1. By Lemma 4, $|V_2'|, |V_3'| \leq s - 1$.

Suppose a vertex $x \in V_2 \setminus V_2'$ is adjacent to a vertex $y \in V_3 \setminus V_3'$. By definition of V_2' and V_3', the vertices x and y each have at most $s-1$ non-neighbours in V_1. Since $|V_1| - 2(s-1) \geq \text{oct}(G)+1$, it follows that $|N(x) \cap N(y) \cap V_1| \geq \text{oct}(G)+1$ so $N(x) \cap N(y) \cap V_1 \not\subseteq T$. We conclude that at least one of x or y must be in T. In other words, $T \cap ((V_2 \setminus V_2') \cup (V_3 \setminus V_3'))$ is a vertex cover of $G[(V_2 \setminus V_2') \cup (V_3 \setminus V_3')]$, of size at most $\text{oct}(G)$. Therefore $(T \cap ((V_2 \setminus V_2') \cup (V_3 \setminus V_3'))) \cup V_2' \cup V_3'$ is a vertex cover of $G[V_2 \cup V_3]$ of size at most $\text{oct}(G)+2(s-1)$. By Lemma 5, there is an independent vertex cover T' of $G[V_2 \cup V_3]$ of size at most $(\text{oct}(G)+2(s-1))r + rs = \text{oct}(G)r + 3rs - 2r$. Note that by definition of vertex cover, $(V_2 \cup V_3) \setminus T'$ is an independent set, and so $G - T'$ is bipartite. Therefore T' is an independent odd cycle transversal for G of size at most $\text{oct}(G)r + 3rs - 2r$. This completes the proof. ◀

The following result follows immediately from combining Lemmas 11 and 12.

▶ **Corollary 13.** *For $s \geq 1$, $\text{ioct}(G) \leq 3\,\text{oct}(G) + 9s + 3$ for every $(K_{1,3} + sP_1)$-free 3-colourable graph G.*

▶ **Lemma 14.** *The class of $(P_1 + P_4, 2P_2)$-free 3-colourable graphs is* ioct*-unbounded.*

Proof. Let $s \geq 2$. We construct the graph Q_s as follows (see also Figure 4). First, let A, B and C be disjoint independent sets of s vertices. Choose vertices $a \in A$, $b \in B$ and $c \in C$. Add edges so that a is complete to $B \cup C$, b is complete to $A \cup C$ and c is complete to $A \cup B$. Let Q_s be the resulting graph and note that it is 3-colourable with colour classes A, B and C.

Note that $\{a, b\}$ is a minimum odd cycle transversal of Q_s, so $\text{oct}(Q_s) = 2$.

Let S be a minimum independent odd cycle transversal. Then S contains at most one vertex in $\{a, b, c\}$, say S contains neither b nor c. If a vertex $x \in A$ is not in S, then $Q_s[\{x, b, c\}]$ is a C_3 in $Q_s - S$, a contradiction. Hence every vertex of A is in S, and so $\text{ioct}(Q_s) \geq s$.

It remains to show that Q_s is $(P_1 + P_4, 2P_2)$-free. Consider a vertex $x \in A$. Then $Q_s - N[x]$ is an edgeless graph if $x = a$ and $Q_s - N[x]$ is the disjoint union of a star and an edgeless graph otherwise. It follows that $Q_s - N[x]$ is P_4-free. By symmetry, we conclude that Q_s is $(P_1 + P_4)$-free. Now consider a vertex $y \in N(a) \cap B$. Then $Q_s - N[\{a, y\}]$ is empty if $b = y$ and $Q_s - N[\{a, y\}]$ is an edgeless graph otherwise. It follows that $Q_s - N[\{a, y\}]$ is P_2-free. By symmetry, we conclude that Q_s is $2P_2$-free. This completes the proof. ◀

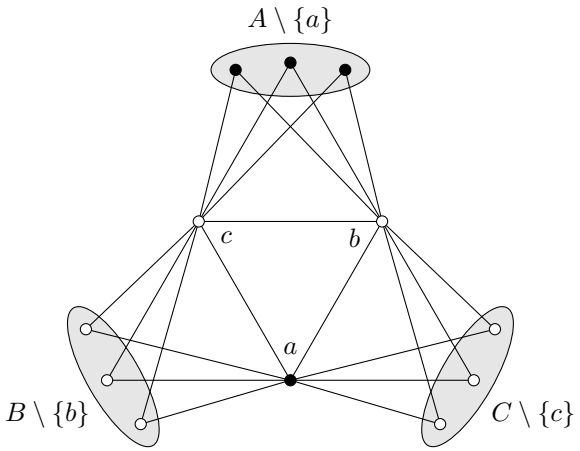

Figure 4 The graph Q_4.

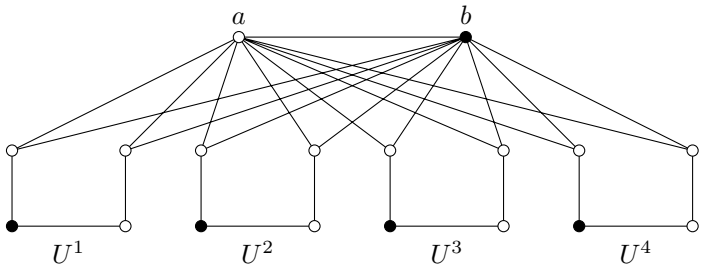

Figure 5 The graph Z_4.

▶ **Lemma 15.** *Let H be a graph with more than one vertex of degree at least 3. Then the class of H-free 3-colourable graphs is* ioct*-unbounded.*

Proof. Let $s \geq 1$. We construct the graph Z_s as follows (see also Figure 5). Start with the disjoint union of s copies of P_4 and label these copies $U^1, \ldots, U^s$. Add an edge ab and make a and b adjacent to the endpoints of every U^i. Let Z_s be the resulting graph and note that Z_s is 3-colourable (colour a and b with Colours 1 and 2, respectively, colour the endpoints of the U^is with Colour 3 and colour the remaining vertices of the U^is with Colours 1 and 2).

Note that $Z_s - \{a, b\}$ is bipartite, so $\{a, b\}$ is a minimum odd cycle transversal and $\mathrm{oct}(Z_s) = 2$. However, any independent odd cycle transversal S contains at most one vertex of a and b; say it does not contain a. For every $i \in \{1, \ldots, s\}$, the graph $Z_s[U^i \cup \{a\}]$ is a C_5. Therefore S must contain at least one vertex from each U^i. It follows that $\mathrm{ioct}(Z_s) \geq s$.

Let H be a graph with more than one vertex of degree at least 3. By Lemma 9, we may assume that H is a forest. It remains to show that Z_s is H-free. Suppose, for contradiction, that Z_s contains H as an induced subgraph and let x and y be two vertices that have degree at least 3 in H. Since H is a forest, x and y must each have three pairwise non-adjacent neighbours in Z_s. The endpoints of each U^i have exactly three neighbours, but two of them (a and b) are adjacent. Without loss of generality we may therefore assume that $x = a$ and $y = b$. Since x has degree at least 3 in H, the vertex x must have a neighbour $z \neq y$ in H and so z must be the endpoint of a U^i. Therefore x, y and z are pairwise adjacent, so $H[\{x, y, z\}]$ is a C_3, contradicting the fact that H is a forest. It follows that Z_s is H-free. This completes the proof. ◀

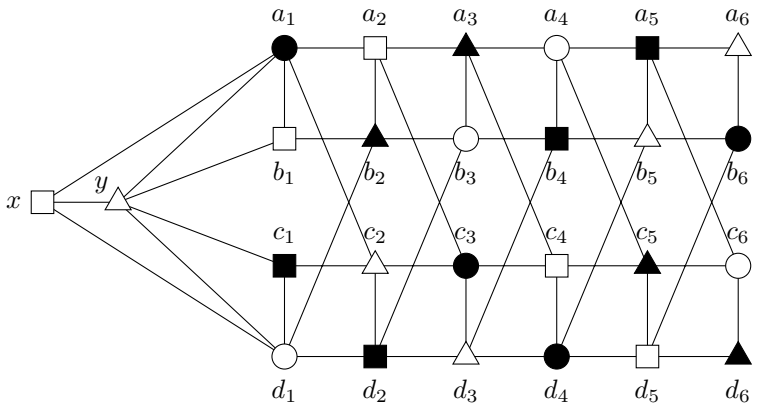

Figure 6 The graph Y_2. Different shapes show the unique 3-colouring of Y_2. Different colours show the 2-colouring of $Y_2 - \{x, y\}$.

▶ **Lemma 16.** *The class of $K_{1,5}$-free 3-colourable graphs is* ioct*-unbounded.*

Proof. Let $s \geq 1$. We construct the graph Y_s as follows (see also Figure 6).

1. Start with the disjoint union of four copies of P_{3s} and label the vertices of these paths $a_1, \ldots, a_{3s}$, $b_1, \ldots, b_{3s}$, $c_1, \ldots, c_{3s}$ and $d_1, \ldots, d_{3s}$ in order, respectively.
2. For each $i \in \{1, \ldots, 3s\}$ add the edges a_ib_i and c_id_i.
3. For each $i \in \{1, \ldots, 3s-1\}$ add the edges a_ic_{i+1} and d_ib_{i+1}.
4. Finally, add an edge xy and make x adjacent to a_1 and d_1 and y adjacent to a_1, b_1, c_1 and d_1.

Let Y_s be the resulting graph.

First note that Y_s is $K_{1,5}$-free. The vertices y, a_1 and d_1 all have degree 5, but their neighbourhood is not independent, so they cannot be the central vertex of an induced $K_{1,5}$. All the other vertices have degree at most 4, so they cannot be the central vertex of an induced $K_{1,5}$ either. Therefore no vertex in Y_s is the central vertex of an induced $K_{1,5}$, so Y_s is $K_{1,5}$-free.

The graph $Y_s - \{x, y\}$ is bipartite with bipartition classes:

1. $\{a_i, c_i \mid 1 \leq i \leq 3s, i \equiv 1 \bmod 2\} \cup \{b_i, d_i \mid 1 \leq i \leq 3s, i \equiv 0 \bmod 2\}$ and
2. $\{a_i, c_i \mid 1 \leq i \leq 3s, i \equiv 0 \bmod 2\} \cup \{b_i, d_i \mid 1 \leq i \leq 3s, i \equiv 1 \bmod 2\}$.

It follows that $\mathrm{oct}(Y_s) = 2$.

Furthermore, Y_s is 3-colourable with colour classes:

1. $\{x\} \cup \{a_i, d_i \mid 1 \leq i \leq 3s, i \equiv 2 \bmod 3\} \cup \{b_i, c_i \mid 1 \leq i \leq 3s, i \equiv 1 \bmod 3\}$
2. $\{y\} \cup \{a_i, d_i \mid 1 \leq i \leq 3s, i \equiv 0 \bmod 3\} \cup \{b_i, c_i \mid 1 \leq i \leq 3s, i \equiv 2 \bmod 3\}$
3. $\{a_i, d_i \mid 1 \leq i \leq 3s, i \equiv 1 \bmod 3\} \cup \{b_i, c_i \mid 1 \leq i \leq 3s, i \equiv 0 \bmod 3\}$

In fact, we will show that this 3-colouring is unique (up to permuting the colours). To see this, suppose that $c : V(Y_s) \to \{1, 2, 3\}$ is a 3-colouring of Y_s. Since x and y are adjacent we may assume without loss of generality that $c(x) = 1$ and $c(y) = 2$. Since a_1 and d_1 are adjacent to both x and y, it follows that $c(a_1) = c(d_1) = 3$. Since b_1 is adjacent to y and a_1, it follows that $c(b_1) = 1$. By symmetry $c(c_1) = 1$.

We prove by induction on i that for every $i \in \{1, \ldots, 3s\}$, $c(a_i) = c(d_i) \equiv i + 2 \bmod 3$ and $c(b_i) = c(c_i) \equiv i \bmod 3$. We have shown that this is true for $i = 1$. Suppose that the claim holds for $i - 1$ for some $i \in \{2, \ldots, 3s\}$. Then $c(a_{i-1}) = c(d_{i-1}) \equiv (i-1) + 2 \bmod 3$ and $c(b_{i-1}) = c(c_{i-1}) \equiv i - 1 \bmod 3$. Since b_i is adjacent to b_{i-1} and d_{i-1}, it follows that $c(b_i) \equiv i \bmod 3$. Since a_i is adjacent to b_i and a_{i-1}, it follows that $c(a_i) \equiv i + 2 \bmod 3$.

By symmetry $c(c_i) \equiv i \bmod 3$ and $c(d_i) \equiv i+2 \bmod 3$. Therefore the claim holds for i. By induction, this completes the proof of the claim and therefore shows that the 3-colouring of Y_s is indeed unique.

Furthermore, note that the colour classes in this colouring have sizes $4s+1$, $4s+1$ and $4s$, respectively. A set S is an independent odd cycle transversal of a graph if and only if it is a colour class in some 3-colouring of this graph. It follows that $\mathrm{ioct}(Y_s) = 4s$. This completes the proof. ◀

We summarise the results of this section in the following theorem.

▶ **Theorem 3 (restated).** *Let H be a graph. The class of H-free* 3*-colourable graphs is* ioct*-bounded:*

- *if H is an induced subgraph of P_4 or $K_{1,3}+sP_1$ for some $s \geq 0$ and*
- *only if H is an induced subgraph of $K_{1,4}^+$ or $K_{1,4}+sP_1$ for some $s \geq 0$.*

Proof. If H is an induced subgraph of P_4 or $K_{1,3}+sP_1$ for some $s \geq 0$, then the class of H-free 3-colourable graphs is ioct-bounded by Lemma 10 or Corollary 13, respectively.

Now suppose that the class of H-free 3-colourable graphs is ioct-bounded. By Lemma 9, H must be a forest. By Lemma 16, H must be $K_{1,5}$-free. Since H is a $K_{1,5}$-free forest, it has maximum degree at most 4. By Lemma 14, H must be $(P_1+P_4, 2P_2)$-free.

First suppose that H is P_4-free, so every component of H is a P_4-free tree. Hence every component of H is a star. In fact, as H has maximum degree at most 4, every component of H is an induced subgraph of $K_{1,4}$. As H is $2P_2$-free, at most one component of H contains an edge. Therefore H is an induced subgraph of $K_{1,4}+sP_1$ for some $s \geq 0$ and we are done.

Now suppose that H contains an induced P_4, say on vertices x_1, x_2, x_3, x_4 in that order and let $X = \{x_1, \ldots, x_4\}$. Since H is a forest, every vertex $v \in V(H) \setminus X$ has at most one neighbour in X. A vertex $v \in V(H) \setminus X$ cannot be adjacent to x_1 or x_4, since H is $2P_2$-free. By Lemma 15, the vertices x_2 and x_3 cannot both have neighbours outside X; without loss of generality assume that x_3 has no neighbours in $V(H) \setminus X$. Since H is (P_1+P_4)-free, every vertex $v \in V(H) \setminus X$ must have at least one neighbour in X, so it must be adjacent to x_2. As H has maximum degree at most 4, it follows that H is an induced subgraph of $K_{1,4}^+$. This completes the proof. ◀

By Lemma 12, for $r, s \geq 1$ the class of $K_{1,r}$-free 3-colourable graphs is ioct-bounded if and only if the class of $(K_{1,r}+sP_1)$-free 3-colourable graphs is ioct-bounded. Therefore, Theorem 3 leaves three open cases, as follows:

▶ **Open Problem 17.** *Is the class of H-free* 3*-colourable graphs* ioct*-bounded when H is:*

1. $K_{1,4}$ *(or equivalently $K_{1,4}+sP_1$ for any $s \geq 1$).*
2. $K_{1,3}^+$ *or*
3. $K_{1,4}^+$.

5 Conclusions

To develop an insight into the price of independence for classical concepts, we have investigated whether or not the size of a minimum independent vertex cover, feedback vertex set or odd cycle transversal is bounded in terms of the minimum size of the not-necessarily-independent variant of each of these transversals for H-free graphs (that have such independent transversals). We have determined the answer for every graph H except for the three missing cases for odd cycle transversal listed in Open Problem 17. While we note that the bounds

we give in some of our results (Lemmas 7 and 10) are tight, in this paper we were mainly concerned with obtaining the dichotomy results on whether there is a bound, rather than trying to find exact bounds.

As results for the price of connectivity implied algorithmic consequences [9, 13], it is natural to ask if our results for the price of independence have similar consequences. The problems Independent Vertex Cover, Independent Feedback Vertex Set and Independent Odd Cycle Transversal ask to determine the minimum size of the corresponding independent transversal. The first problem is readily seen to be polynomial-time solvable. The other two problems are NP-hard for H-free graphs whenever H is not a linear forest [3], just like their classical counterparts Feedback Vertex Set [16, 17] and Odd Cycle Transversal [10] (see also [14, 15]). The complexity of these four problems restricted to H-free graphs is still poorly understood when H is a linear forest. Our results suggest that it is unlikely that we can obtain polynomial algorithms for the independent variants based on results for the original variants, as the difference between $\mathrm{ifvs}(G)$ and $\mathrm{fvs}(G)$ and between $\mathrm{ioct}(G)$ and $\mathrm{oct}(G)$ can become unbounded quickly.

Abstract

In classical secret sharing schemes a dealer shares a secret among a set of participants in such a way that qualified subsets can reconstruct the secret, while forbidden ones do not get any kind of information about it. The basic parameter to optimize is the size of the shares, that is, the amount of secret information that the dealer has to give to participants. In this paper we formalize a notion of *probabilistic* secret sharing schemes, in which qualified subsets can reconstruct the secret but only with a certain controlled probability. We show that, by allowing a bounded error in the reconstruction of the secret, it is possible to *drastically reduce the size* of the shares the participants get (with respect to classical secret sharing schemes). We provide efficient constructions both for threshold access structures on a finite set of participants and for evolving threshold access structures, where the set of participants is potentially infinite. Some of our constructions yield shares of *constant* size (i.e., not depending on the number of participants) and an error probability of successfully reconstructing the secret which can be made as *close to* 1 as desired.

1 Introduction

Secret sharing. A secret sharing scheme is a method through which a *dealer* shares a piece of information (*a secret*) among a set of participants, according to a specific privacy policy. Specifically, each participant, during the sharing phase, receives and securely stores a piece of information, called *share*. Then, in the reconstruction phase, prescribed subsets, called *qualified subsets*, by pooling together their shares or by sending them to a trusted combiner, can recover the secret through the computation of an appropriate reconstruction function. All the other remaining subsets of participants, called *forbidden subsets*, analyzing the shares they have, and applying *any* computation on them, do not get any information whatsoever about the secret. The collection of qualified subsets forms the *access structure* to the secret.

The notion of secret sharing and the first constructions were introduced in 1979, independently by Shamir [34] and Blakley [6]. Both of them considered *threshold* access structures, usually referred to as (k, n)-threshold schemes, where the set of participants has size n, *any* subset of size greater than or equal to k is qualified, and *any* subset of size less than k is forbidden. General access structures were later considered in [22, 23, 23, 4, 35, 25].

Secret sharing schemes have been widely used in cryptographic protocol design and have been extended in many ways in order to exhibit additional properties. For a detailed overview of the field and of the open problems the reader is referred to [2] and to [14].

Visual cryptography (visual secret sharing). Visual cryptography, introduced independently and in different forms in [31, 24], is a sharing technique in which the secret is an image, the shares are images printed on transparencies and the reconstruction is performed by the human visual system by looking at the superposed shares. Notice that, while the image can be seen as a sequence of black and white pixels and thus can encode arbitrary sequences of bits, the reconstruction function is fixed to be the `or` of the shares. Hence, any visual cryptography scheme can be used as a regular secret sharing scheme, i.e., as a scheme that uses the `or` function to reconstruct the secret; on the other hand, the converse is not true, unless the scheme uses the `or` function on the corresponding bits of the shares to reconstruct the secret. In the context of visual cryptography, the notion of probabilistic reconstruction has been widely studied, e.g., [36, 13, 19], since the erroneous reconstruction of a limited number of pixels does not significantly affect the recognizability of the reconstructed secret image.

Evolving access structures. An interesting new variant of secret sharing schemes has been introduced recently in [26, 27]. The authors have considered a setting in which the set of participants is *infinite* and the access structure is defined through a *collection* of access structures, not known at the beginning. More precisely, at any time t, a new participant arrives and new qualified subsets – if any – are added to the existing access structure $\mathcal{A}_{t-1}$, obtaining the new one $\mathcal{A}_t$. The authors of [26, 27] design secret sharing schemes in such a new scenario for threshold access structures, denoted as (k, ∞)-threshold schemes, and for general access structures. The authors of [26, 27] have also shown a nice equivalence between $(2, \infty)$-threshold schemes and prefix-free codes for the integers. Further results have been provided in [32, 28].

Motivations of the present work. Since their introduction, secret sharing schemes have represented a relevant research area in Cryptography. Secret sharing schemes are an important tool by themselves, as well as a building block both in the general solutions for multi-party

computation and in the design of ad-hoc protocols. A central issue in the area has been to provide constructive results and non-existential results towards the possibility of obtaining secret sharing schemes that provide to the users shares *short in size*. For threshold access structures and ramp schemes tight bounds have been provided in [11] and in [9].

Unfortunately, for general access structures what can be done is still an open problem: for many access structures the known constructions deliver to the users shares of exponential size in the number n of participants [5] (see also [30] for recent important improvements). The best lower bound on the size of the shares is instead sublinear as it was proved in [8, 15] using the information theoretic approach introduced in [10]. For the subclass of *linear* general secret sharing schemes recent results of [33] provide exponential lower bounds.

Several papers have considered secret sharing schemes in which the privacy condition has been relaxed, both in a *statistical* sense, i.e., the privacy is not information-theoretic but there is a probability of information leakage, and in a *computational* sense, i.e., the privacy is only guaranteed with respect to computationally bounded adversaries, e.g., [29]. In [16, 20] secret sharing schemes are seen as joint probability distributions of the shares and the secret. This particular view is introduced to study the case of infinite participants and to deal with infinite domains for the shares. The approach leads to a probabilistic notion of security allowing information leakage. So, it is quite different from the approach pursued in this paper. To our knowledge, although the relaxation of the property that qualified subsets can correctly recover the secret has been mentioned in a few papers, no study has focused on the analysis and the design of secret sharing schemes in which the secret can be reconstructed only with a prescribed high probability. Exceptions consist for the specific case of visual cryptography [17] and, notably, the secret sharing scheme of [21]. We remark that the model used in [21], that allows public information, is different from the one considered in this paper.

Hence, it seems natural to ask the following question:

> *Can we reduce the size of the shares held by the participants if we allow a small probability of error in the reconstruction phase?*

In this paper we show that it is possible to give an answer to the above question by providing, among other results, a quantitative trade-off between the probability of a correct reconstruction and the size of the shares.

Our contribution. We proceed as follows: in Section 2, we introduce a formal definition of probabilistic secret sharing schemes that intends to capture the intuition given above. We consider both access structures on a finite set of participants and evolving access structures defined over an infinite set of participants. Then, in Section 3, we discuss probabilistic constructions for the finite case and, in Section 4, we propose a probabilistic construction for a $(2, \infty)$-threshold secret sharing scheme. In Section 5, we describe and analyze some methods to build more general schemes from simpler ones. Our techniques are of general interest since they apply to both deterministic and probabilistic secret sharing schemes. Then, in Section 6, we describe and analyze a direct construction for probabilistic secret sharing schemes, which gives to participants shares of constant size, with respect to the number of participants, and enables the dealer to set the probability of reconstruction as high as he needs. Finally, in Section 7, we provide conclusions and briefly discuss some open problems.

Overview of results and techniques. We define and provide constructions for α-probabilistic secret sharing schemes for threshold access structures, where α denotes *the probability of a correct reconstruction*, both for the finite and the infinite cases, by using a variety of

techniques. Throughout the paper, unless otherwise stated, we assume that the secret is a single bit.

- Focusing on the finite case, where the set of participants is fixed and has size n, we leverage on a nice connection in *visual* secret sharing schemes between deterministic and probabilistic schemes. We show how a probabilistic visual secret sharing scheme can be turned easily into an α-probabilistic secret sharing scheme for the same access structure.
- To deal with evolving access structures, we design a $(2, \infty)$-threshold $\frac{1+p}{2}$-probabilistic secret sharing scheme, where $(p, 1-p)$ is the probability distribution of the secret bit. Our construction is inspired by the $(2, \infty)$-threshold visual cryptography scheme provided in [12], which seems to be the first paper that has considered the problem of constructing a visual secret sharing scheme for an infinite set of participants. It is simple and allows to share a 1-bit secret with shares of 1-bit.
- Successively, in order to construct more general schemes from simpler ones, using a recursive approach, we present two algorithms: the first builds a $(k+1, \infty)$-threshold α-probabilistic secret sharing scheme from a (k, ∞)-threshold β-probabilistic secret sharing scheme. The second builds a $(k+1, \infty)$-threshold α-probabilistic secret sharing scheme from k schemes, i.e., by using, for $j = 2, \ldots, k$, a (j, ∞)-threshold α_j-probabilistic secret sharing scheme. We point out that the algorithms can be used to construct *both* probabilistic schemes and deterministic schemes for evolving access structures. In particular, for both of our methods, if we use the most efficient deterministic $(2, \infty)$-threshold secret sharing scheme provided in [26, 27] and apply to the scheme resulting from the algorithms, the same domain reduction technique which is used in [26, 27], we get deterministic schemes for evolving access structures which achieve the same asymptotic share size of the ones obtained in [26, 27]. Hence, the new schemes can be seen as an *alternative* way for constructing deterministic schemes. On the other hand, for both of our algorithms, starting from our $(2, \infty)$-threshold $\frac{1+p}{2}$-probabilistic secret sharing scheme, we obtain (k, ∞)-threshold α-probabilistic secret sharing schemes which achieve asymptotically the same share size of the deterministic schemes.
- Finally, through a direct construction, which uses the shares of Shamir's scheme, we provide a (k, ∞)-threshold α-probabilistic secret sharing scheme which enables to share a 1-bit secret with shares of *constant size*. Moreover, the scheme exhibits a nice trade-off between the probability α of successfully reconstructing the secret and the size of the underlying field: indeed, α can approach 1 as much as desired by properly choosing the size of $\mathbb{F}_q$. For the case in which k is equal to 2, we explain the differences between this construction and the $(2, \infty)$-threshold $\frac{1+p}{2}$-probabilistic secret sharing scheme presented in Section 4. Finally, we emphasize that our construction also applies to the case of a finite number of participants, and we describe advantages and disadvantages associated with it.

Hence, the probabilistic approach we suggest enables to *beat the lower bounds* on the size of the shares the deterministic threshold schemes are subject to, both for the case of a finite set of participants and for the infinite one.

Related work. Other models for secret sharing schemes have been introduced in the past years in order to reduce the size of the shares held by the participants. More precisely, secret sharing schemes in which the correctness property holds with *no error*, and the privacy property holds with *identical* probability distributions on the shares held by the participants of a forbidden subset, are called *perfect*. *Non-perfect* secret sharing schemes are less restrictive. For example, in a (d, t, n)-ramp scheme [7], the first and most relevant case of non-perfect

secret sharing schemes, forbidden subsets of size less than d do not get any information about the secret, qualified subsets of size greater than or equal to t reconstruct the secret, while subsets whose sizes are *"in between"* get *some* information about the secret. Note that ramp schemes are a *close but different* class of non-perfect schemes, compared to the probabilistic ones we introduce here. Similarly, *computational* secret sharing schemes [29] are another class of non-perfect secret sharing schemes; in such schemes the privacy property requires computationally indistinguishable probability distributions on the shares held by the participants of a forbidden subset. In both cases, it is possible to design schemes with shorter share size compared to the size of the shares in perfect secret sharing schemes.

2 The Models

In this section we introduce the models we work with. We essentially follow and extend the treatment of [2, 26, 27].

Let $\mathcal{P}_n = \{p_1, \ldots, p_n\}$ be a finite set of n participants, and let $2^{\mathcal{P}_n}$ be the set of all the subsets of $\mathcal{P}_n$. A collection of subsets $\mathcal{A} \subseteq 2^{\mathcal{P}_n}$ is *monotone* if, for each subsets $B, C \in \mathcal{P}_n$ such that $B \subseteq C$, the condition $B \in \mathcal{A}$ implies $C \in \mathcal{A}$.

An access structure is defined as follows:

▶ **Definition 1.** An *access structure* $\mathcal{A}$ on the set $\mathcal{P}_n = \{p_1, \ldots, p_n\}$ is a monotone collection of subsets of $\mathcal{P}_n$, i.e., $\mathcal{A} \subseteq 2^{\mathcal{P}_n}$. Subsets in $\mathcal{A}$ are called *qualified*. Subsets not in $\mathcal{A}$ are called *forbidden*.

To avoid overburdening the notation, when it is clear from the context, we use the letter which denotes a subset of participants also to denote the subset of the indices of the participants. We define a probabilistic secret sharing scheme as follows.

▶ **Definition 2.** Let S be a set of secrets such that $|S| \geq 2$, and let α be a positive real value such that $0 < \alpha \leq 1$. An α-probabilistic secret sharing scheme Π for an access structure $\mathcal{A}$ on the set of participants $\mathcal{P}_n$ and set of secrets S consists of a pair of probabilistic polynomial time algorithms $(\mathsf{Share}, \mathsf{Recon})$ where

- Share gets as input a secret $s \in S$ and outputs n shares $sh_1, \ldots, sh_n$
- Recon gets as input the shares of a subset $A \subseteq \mathcal{P}_n$, denoted by $\{sh_i\}_{i \in A}$, and outputs a string

such that the following two requirements are satisfied:

1. **α-correctness:** for every $s \in S$ and every qualified subset $A \in \mathcal{A}$, it holds that

$$Prob[\mathsf{Recon}(\{sh_i\}_{i \in A}) = s] \geq \alpha.$$

2. **perfect privacy:** for every forbidden subset $B \notin \mathcal{A}$ and for every two secrets $s_1, s_2 \in S$, it holds that the probability distributions $\{sh_i^1\}_{i \in B}$ and $\{sh_i^2\}_{i \in B}$, associated to the corresponding secrets, are the same.

▶ Remark. Notice that, when the parameter α is equal to 1, we get the traditional notion of perfect secret sharing scheme, in which the secret is *always* reconstructed by qualified subsets of participants.

▶ Remark. As pointed out in [2], the above definition can be easily relaxed to consider less stringent privacy notions, in which the probability distributions on the set of shares of forbidden subsets are not required to be identical but only statistically close or computationally indistinguishable.

The *share size* of the scheme is the maximum number of bits each participant holds in the worst case, over all participants and all secrets.

In order to introduce evolving schemes, we need to modify the setting and extend some of the previous notions. Basically, we define a sequence of access structures but require that the access structures be monotone: parties are *only added* and qualified subsets *remain qualified in the future*.

Let $\mathcal{P} = \{p_1, p_2, \dots, \}$ be an infinite set of participants.

▶ **Definition 3.** [26, 27] Let $\mathcal{A}$ be an access structure on $\mathcal{P}_n$ and let m be an integer such that $0 < m < n$. We denote by $\mathcal{A}|_m$ the restriction of $\mathcal{A}$ to $\mathcal{P}_m$, i.e., to the first m participants.

The following result holds:

▶ **Claim 4.** *[26, 27] If $\mathcal{A}$ is an access structure on $\mathcal{P}_n$, then $\mathcal{A}|_m$ is an access structure on $\mathcal{P}_m$.*

▶ **Definition 5.** [26, 27] Let $\mathbb{N}$ be the set of the natural numbers. A (possibly infinite) sequence of access structures $\{\mathcal{A}_t\}_{t\in\mathbb{N}}$ is called evolving if, for every $t \in \mathbb{N}$, the following conditions hold:

- $\mathcal{A}_t$ is an access structure over $\mathcal{P}_t$
- $\mathcal{A}_t|_{t-1}$ is equal to $\mathcal{A}_{t-1}$.

At this point, we can extend the definition of a probabilistic secret sharing scheme to evolving access structures:

▶ **Definition 6.** Let S be a set of secrets such that $|S| \geq 2$, and let α be a positive real value such that $0 < \alpha \leq 1$. An α-probabilistic secret sharing scheme Π for an evolving access structure $\{\mathcal{A}_t\}_{t\in\mathbb{N}}$ on the infinite set of participants $\mathcal{P}$ and set of secrets S consists of a pair of probabilistic polynomial time algorithms $(\mathsf{Share}, \mathsf{Recon})$ where

- Share gets as input a secret $s \in S$ and the shares $sh_1, \dots, sh_{t-1}$, generated for participants $p_1, \dots, p_{t-1}$, and outputs the share sh_t for the t-th participant
- Recon gets as input the shares of a subset $A \subseteq \mathcal{P}$, denoted by $\{sh_i\}_{i\in A}$, and outputs a string

such that the following two requirements are satisfied:

1. **α-correctness:** for every $s \in S$, for every $t \in \mathbb{N}$, and for every qualified subset $A \in \mathcal{A}_t$, it holds that

$$Prob[\mathsf{Recon}(\{sh_i\}_{i\in A}) = s] \geq \alpha.$$

2. **perfect privacy:** for every $t \in \mathbb{N}$, for every forbidden subset $B \notin \mathcal{A}_t$ and for every two secrets $s_1, s_2 \in S$, it holds that the probability distributions $\{sh_i^1\}_{i\in B}$ and $\{sh_i^2\}_{i\in B}$, associated to the corresponding secrets, are the same.

The *share size* of the scheme is the maximum number of bits the t-th participant holds in the worst case, over all secrets and previous share assignments.

▶ Remark. When the parameter α is equal to 1, we get the notion of perfect evolving secret sharing scheme, in which the secret is *always* reconstructed by qualified subsets of participants, given in [26, 27]. Notice also that the above definition, when $\mathcal{P}$ is finite and $\mathcal{A}$ is fixed and known at the beginning, i.e., $\mathcal{P} = \mathcal{P}_n$ for a certain n and $\{\mathcal{A}_t\}_{t\in\mathbb{N}} = \mathcal{A}$, it formally *does not* coincide with Definition 2. Indeed, the former generates the shares in *one-shot*, while the latter generates the shares sequentially. However, it is easy to see they are equivalent. Moreover, the considerations we have done on relaxing the privacy notion apply also here.

Notice that in [3] a unified framework for secret sharing schemes has been introduced. It enables to model together perfect, statistically a computationally secure secret sharing schemes. It also models the notion of robustness, i.e., the possibility of reconstructing a secret even if some shares are missing or corrupted, assuming an honest dealer. We point out that the 36 notions the authors have provided do not consider any relaxation of the correctness condition. Moreover, we have preferred to follow [2, 26, 27] in modeling the notion instead of extending [3] because it is easy to work with [2, 26, 27] and, perhaps, results in an abstract easier to read.

3 Probabilistic schemes for the threshold finite case

Visual cryptography schemes are a special type of secret sharing schemes for which, roughly speaking, the Recon algorithm is the `or` function[1]. Several models of visual cryptography have been studied: Kafri and Keren [24] introduced the so-called random grid model, Naor and Shamir [31] coined the term "visual cryptography" providing a deterministic model, Yang [36] introduced the probabilistic model, which actually is equivalent to the model of Kafri and Keren, and Cimato et al. [13] generalized the probabilistic model. Finally, De Prisco and De Santis [19] proved that all these models are related to each other and, thus, they can be seen simply as different ways of looking at the same object. The interested reader is referred to [17] for a recent survey on models, issues, applications and new directions in visual cryptography and to the references therein quoted.

The particular "view" that is of interest in the context of this paper is the probabilistic one: in that model we already have the notion of a probabilistic reconstruction, where a secret pixel is correctly reconstructed only with a given probability. Nevertheless, notice that in the context of visual cryptography the error is less critical than in the context of general secret sharing: indeed, the whole secret which is visually reconstructed consists of many pixels, often thousands, and, even if some of them are incorrectly reconstructed, the only tangible effect is that the secret is reconstructed on a different, usually darker, background.

Anyway, being visual cryptography a special type of secret sharing, we can use visual cryptography schemes as secret sharing schemes. Since there is basically no research on probabilistic secret sharing, it is useful to start by taking probabilistic visual secret sharing scheme and "translating" them into probabilistic secret sharing schemes. We said "translating" instead of "using" because an obvious improvement that can be made is that of using a different Recon function, since in regular secret sharing we are not constrained to using the `or` performed by the human visual system in the reconstruction process.

In [19] it has been proved that any deterministic visual cryptography scheme can be transformed into a probabilistic visual cryptography scheme. By using this result we can transform any deterministic visual cryptography scheme into a probabilistic secret sharing scheme. We explain the technique using an example.

[1] In visual cryptography schemes, the bits of the shares are pixels printed on transparencies and the reconstruction consists in superposing the transparencies; the human visual system performs the `or` operation on the "bits" in the corresponding positions.

Consider a $(3, 4)$-threshold scheme. The following deterministic scheme has been presented in [1]. The scheme is described by two base matrices, B_0 and B_1:

$$B_0 = \begin{bmatrix} 000111 \\ 001011 \\ 001101 \\ 001110 \end{bmatrix} \qquad B_1 = \begin{bmatrix} 000111 \\ 100110 \\ 010110 \\ 001110 \end{bmatrix}$$

The two base matrices define the collections $\mathcal{C}_0$ and $\mathcal{C}_1$, where $\mathcal{C}_b$, $b = 0, 1$, contains all the matrices that can be obtained by permuting in all possible ways the columns of B_b. In order to share the secret the dealer (randomly) chooses a specific permutation and gives to each participant a row of the corresponding matrix of the collection $\mathcal{C}_b$, where b is the secret bit. More specifically, participant i gets the i^{th} row of the selected matrix (permutation).

For example, considering, for simplicity, the identity permutation, if the secret pixel is $b = 0$, that is a white pixel, then participant 1 gets a share where the first three subpixels are white and the last three are black, described with the binary string 000111, while participant 2 gets a share described by 001011, that is, the subpixels are white-white-black-white-black-black; etc. Superposing three shares for the reconstruction, it is guaranteed that, if the secret pixel is white, then the reconstructed version has 4 black subpixels out of 6; while, if the secret pixel is black, then the reconstructed version has 5 black subpixels out of 6. The fact that all permutations are considered ensures security.

A probabilistic visual cryptography scheme can be easily derived from the above deterministic scheme (see [19] for more details). In such a scheme, the secret pixel (bit) is shared by giving to each participant a white (0) or black (1) pixel (bit) according to the following sets[2]:

$$\mathcal{C}_0 = \left\{ \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 1 \\ 1 \\ 1 \end{bmatrix}, \begin{bmatrix} 1 \\ 0 \\ 1 \\ 1 \end{bmatrix}, \begin{bmatrix} 1 \\ 1 \\ 0 \\ 1 \end{bmatrix}, \begin{bmatrix} 1 \\ 1 \\ 1 \\ 0 \end{bmatrix} \right\},$$

$$\mathcal{C}_1 = \left\{ \begin{bmatrix} 0 \\ 1 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 0 \\ 1 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \end{bmatrix}, \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix}, \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix}, \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \end{bmatrix} \right\}.$$

More precisely, if the secret pixel is b, with $b \in \{0, 1\}$, the 4 participants are given shares according to one of the vectors in the set $\mathcal{C}_b$, where the specific vector is chosen *uniformly at random* in the set. The reconstruction function is the `or` of 4 bits. Looking at this scheme as a visual cryptography scheme, we have that a secret white (0) pixel is reconstructed correctly 1/3 of the times, while a secret black (1) pixel is reconstructed correctly 5/6 of the times. Assuming a uniform distribution of the secret pixel, the reconstruction is correct with probability 7/12.

On the other hand, using the `xor` function as Recon we have that in both cases the secret pixel is reconstructed correctly 5/6 of the times. This provides a 5/6-probabilistic scheme for sharing one bit, regardless of the distribution of the secret bit.

[2] Notice that these sets are easily constructed from the base matrices since each member of the set corresponds to a column of the base matrix.

The above "transform" of a visual cryptography scheme into a probabilistic secret sharing scheme can be applied to any visual cryptography scheme. In particular, it is possible to construct schemes for threshold and general access structures defined on a finite set of participants.Unfortunately, the constructions *do not extend* to the evolving case. So, we would like to find schemes that allow to manage an *evolving* set of participants.

As a side note, we point out an interesting fact: in the recent years, it has been shown that visual cryptography schemes can be used for secure computation in non standard settings, in which it is desirable to reduce the trust in digital devices [19, 18]. Here, we are going the other way around: we are using visual cryptography schemes for building probabilistic secret sharing schemes which can be used in standard digital computation.

4 A probabilistic $(2, \infty)$-threshold construction

In this section we present a construction of a probabilistic threshold scheme for the case of $k = 2$. The construction works both for a finite set of participants and for an infinite set of participants; the sharing phase is similar to the one described in Algorithm 2 of [12]. We present it as a $(2, \infty)$-threshold scheme, although the same construction works for a $(2, n)$-threshold scheme, when n is fixed in advance.

Let s be a secret bit. Let p_i be the i-th participant, with i potentially growing to ∞ (or up to a fixed n).

▶ **Construction 7.** *The construction works as follows.*

- *The* Share *algorithm takes as input the index i and produces a share for p_i as follows: for the first participant, that is for $i = 1$, the share is a random bit b_1; for the other participants, that is, for $i > 1$, if the secret is $s = 0$ then the share is b_1, the same bit given to p_1, whereas if the secret is $s = 1$ the share is a new random bit b_i. In other words, if the secret is $s = 0$, then only one random bit is produced and all participants get that random bit as their share, while if the secret is 1 then each participant gets a new random bit.*
- *The* Recon *algorithm takes in input two shares, that is two bits b_i and b_j and outputs 0 if $b_i = b_j$ (the two shares are equal), and 1 if $b_i \neq b_j$ (the two shares are different).*

▶ **Theorem 8.** *Construction 7 builds a $\frac{1+p}{2}$-probabilistic $(2, \infty)$-threshold scheme, where $(p, 1-p)$ is the distribution of the secret bit.*

Proof. We start by proving that the scheme is secure, that is any forbidden set does not have information about the secret bit. Indeed, let $B = \{p_i\}$ be a forbidden set, a set with a single participant, and let $s_1, s_2 \in S$ be two secret bits. The probability distribution of the share that p_i gets for s_1 is the same as the one that p_i gets for s_2. Indeed the share is always a random bit, so in both cases the probability distribution is $(0.5, 0.5)$ over the two possible values.

Next we prove that a qualified subset can reconstruct the secret with $(1+p)/2$-correctness. Let A be a qualified subset. In order to compute $Prob[\mathsf{Recon}(\{sh_i\}_{i\in A}) = s]$, consider the two possible cases, $s = 0$ and $s = 1$. The first one occurs with probability p and the second one with probability $(1-p)$. Thus, we have that:

$$\begin{aligned} Prob[\mathsf{Recon}(\{sh_i\}_{i\in A}) = s] \quad = \quad & p \cdot Prob[\mathsf{Recon}(\{sh_i\}_{i\in A}) = 0 | s = 0] + \\ & (1-p) \cdot Prob[\mathsf{Recon}(\{sh_i\}_{i\in A}) = 1 | s = 1]. \end{aligned}$$

When $s = 0$, all the shares are equal, thus Recon gives 0 as output and the reconstruction is always correct. Hence, $Prob[\mathsf{Recon}(\{sh_i\}_{i\in A}) = 0 | s = 0] = 1$. On the other hand, when

$s = 1$, all the shares are independent random bits, thus Recon gives in output 1 only half of the times, which means that $Prob[\mathsf{Recon}(\{sh_i\}_{i\in A}) = 1|s = 1] = 1/2$.

Therefore, we have that:

$$Prob[\mathsf{Recon}(\{sh_i\}_{i\in A}) = s] = p \cdot 1 + (1-p) \cdot \frac{1}{2} = \frac{1+p}{2}. \quad \blacktriangleleft$$

For $p = 0.5$, we get a scheme with $\frac{3}{4}$-correctness. Notice also that, when $p \neq 0.5$, since we can easily swap 0 and 1, we can always change p to be $1 - p$ to get a better correctness probability.

Finally, it is also easy to see that the above protocol can be strengthened, by using shares of 2 or more bits, constructed along the same line of the former, in order to make the probability of error as low as desired. Precisely, for sharing 0, the dealer chooses c bits uniformly at random and gives them to all participants. On the other hand, for sharing 1, to each new participant are provided c bits, chosen uniformly at random each time.

5 Transforms for general schemes from simpler ones

Once we have provided a probabilistic $(2, \infty)$-threshold construction it is a natural problem to extend it to the probabilistic (k, ∞)-threshold case. In this section we provide two different constructions for the general threshold case. The first one builds on an auxiliary probabilistic (k, ∞)-threshold construction which is used in a black-box way to build a probabilistic $(k + 1, \infty)$-threshold scheme. The probability α of correct reconstruction is preserved. For the second construction we use a family of probabilistic (j, ∞)-threshold schemes, for $j \leq k$, to obtain a probabilistic $(k+1, \infty)$-threshold scheme. The new scheme correctly reconstructs with probability at least the worse reconstruction probability of the schemes from the family.

The interesting aspect of the second construction lies in the fact that parties are grouped in generations of increasing size. The sizes of these generations are left as parameters of the construction and choosing them carefully leads to improvements in the share size with respect to the first construction.

Note that, if all auxiliary schemes provide 1-correctness, then the compiled constructions are also 1-correct; therefore, we are providing alternative constructions for the deterministic evolving (k, ∞)-threshold schemes presented in [26, 27]. In addition, if we apply to our constructions the same domain reduction technique which is used in [26, 27] to reduce the size of the shares, we get deterministic schemes for evolving access structures which achieve the same asymptotic share size of the ones obtained in [26, 27].

We denote by $[n]$ the set $\{1, \ldots, n\}$ and, for consistency of some formulas, $[0]$ denotes the empty set.

5.1 From (k, ∞)-threshold to $(k + 1, \infty)$-threshold

Let $s \in \{0, 1\}$ be the secret. The idea behind this construction is that at the arrival of party t, he receives the value $s \oplus r$, where r is a freshly and uniformly random generated bit. The bit r is then shared by using the (k, ∞) scheme with every party arriving after that moment.

More precisely, let Π denote the auxiliary (k, ∞)-threshold scheme and let Λ be the $(k + 1, \infty)$-threshold we are about to construct. At the time of arrival of party t, the share sh_t for the new scheme Λ is constructed in the following way:

1. A bit $r_t \in \{0,1\}$ is chosen uniformly at random.
2. For every $j \in [t-1]$ a new share $w_{t,j}$ of r_j is computed with Π.
3. The share of party t for the scheme Λ is the following (ordered) set of values:

$$sh_t = \{s \oplus r_t\} \cup \{w_{t,j}\}_{j \in [t-1]}$$

For the Recon algorithm of Λ, assume that $k+1$ parties $P_{t_0}, P_{t_1}, \ldots, P_{t_k}$, which are chronologically ordered, want to reconstruct. Then, the last k parties run the Recon algorithm of Π with inputs $(w_{t_1,t_0}, w_{t_2,t_0}, \ldots, w_{t_k,t_0})$ in order to recover the value r_{t_0}. Once r_{t_0} is recovered it is xored with the value $s \oplus r_{t_0}$, held by P_{t_0}, to recover s.

▶ **Theorem 9.** *If Π is an α-probabilistic scheme for the (k,∞)-threshold access structure then Λ is an α-probabilistic scheme for the $(k+1,\infty)$-threshold access structure.*

Proof. First we prove the security of Λ. Let $\mathcal{F} = \{P_{t_1}, \ldots, P_{t_l}\}$ be a set of $l \leq k$ parties which is chronologically ordered. The only value that party P_{t_j} holds which is related to the secret is $s \oplus r_{t_j}$. But then, as r_{t_j} has only been shared with players arriving later than P_{t_j} and there are at most $k-1$ of them, the value r_{t_j} is a uniformly distributed random bit from the perspective of $\mathcal{F}$ due to the perfect privacy of Π. Therefore, the value $s \oplus r_{t_j}$ is also a uniformly distributed random bit for the set $\mathcal{F}$. Thus, we have shown perfect privacy for Λ.

Next, for α-correctness, notice that the reconstruction algorithm of Π is used precisely once when reconstructing with Λ. If the value r_{t_0} is correctly reconstructed so it is the secret s. Therefore, if r_{t_0} is correctly reconstructed with probability at least α, then the same holds for s. Our result for α-correctness follows from this fact. ◀

▶ Remark. Note that for $\alpha = 1$ we get a transform for regular (i.e. non probabilistic) evolving schemes.

Share size. Let $size_\Pi(sh_t)$ denote the bitlength of the t-th share of the scheme Π. For the scheme Λ the size of the t-th share verifies

$$size_\Lambda(sh_t) = 1 + \sum_{j=1}^{t-1} size_\Pi(sh_j) \leq 1 + (t-1) \cdot size_\Pi(sh_{t-1})$$

where the last inequality holds if we assume that the shares are increasing in size, which is usually the case.

5.2 From $\{(j,\infty)$-threshold$\}_{j=2,\ldots,k}$ to $(k+1,\infty)$-threshold

Let $k \geq 2$ be an integer number. Assume that, for any $j \in \{2,\ldots,k\}$, Π_j is an auxiliary (j,∞)-threshold scheme, and let Λ be the $(k+1,\infty)$-threshold scheme we are about to construct. For consistency of notation, assume that Π_1 is a scheme that provides the secret to every participant. Let $s \in \{0,1\}$ be the secret. In this construction parties are grouped together in *generations*. For every integer $i \geq 1$, generation G_i is a set consisting of g_i consecutive participants. G_1 starts with P_1 while each subsequent generation starts with the participant following the last participant of the previous generation. For generation sizes we only require that they are an increasing sequence and all greater or equal than the target threshold, that is, $k < g_1 \leq g_2 \leq g_3 \leq \ldots$.

When a generation G_m starts, the following values are computed:

1. k random bits $r_1^{(m)}, \ldots, r_k^{(m)}$ are chosen.
2. For every $j \in [k]$, the value $s \oplus r_j^{(m)}$ is shared by using a regular (j, g_m)-threshold scheme, e.g., Shamir's scheme. Let $u_{j,l}^{(m)}$ denote the l-th share.
3. The secret s is shared by using a $(k+1, g_m)$-threshold scheme. Let $u_{k+1,l}^{(m)}$ denote the l-th share.

When the player P_t, which is the l-th player of generation G_m, arrives, the following values are computed:

4. For each $i \in [m-1]$ and $j \in [k]$ a new share for the random bit $r_j^{(i)}$ is computed by using the $(k+1-j, \infty)$-threshold scheme Π_{k+1-j}. Note that it takes as inputs all the shares of $r_j^{(i)}$ previously computed. Let $v_{j,l}^{(i)}$ denote this share.
5. The share of party t is the following (ordered) set of values:

$$\Lambda_t^{(s)} = \{u_{j,l}^{(m)}\}_{j \in [k+1]} \cup \{v_{j,l}^{(i)}\}_{j \in [k], i \in [m-1]}$$

For the Recon algorithm of Λ, assume that a set $\mathcal{F}$ consisting of $k+1$ parties want to reconstruct. Moreover, assume that m is the first index such that a party from G_m is in $\mathcal{F}$. Let split $\mathcal{F}$ in two parts, $\mathcal{F}_0 = \mathcal{F} \cap G_m$ and $\mathcal{F}_1 = \mathcal{F} \setminus \mathcal{F}_0$, that is, $\mathcal{F}_0$ consists of the parties from $\mathcal{F}$ which are in generation G_m and $\mathcal{F}_1$ consists of parties from subsequent generations. Let $k_0 > 0$ be the cardinal of $\mathcal{F}_0$ and $k_1 \geq 0$ the cardinal of $\mathcal{F}_1$. Note that $k_0 + k_1 = k + 1$. Now there are two different cases:

1. If $k_1 = 0$, that is, all players are in generation G_m, they use their $\{u_{k+1,l}^{(m)}\}_l$ shares from the $(k+1, g_m)$-threshold scheme to recover s.
2. If $k_1 > 0$, then the players in $\mathcal{F}_0$ use their $\{u_{k_0,l}^{(m)}\}_l$ shares from the (k_0, g_m)-threshold scheme to recover $s \oplus r_{k_0}^{(m)}$. On the other hand, the players in $\mathcal{F}_1$ use their $\{v_{k_1,l}^{(m)}\}_l$ shares from the (k_1, ∞)-threshold scheme Π_{k_1} to recover $r_{k_0}^{(m)}$. Then, the two values $s \oplus r_{k_0}^{(m)}$ and $r_{k_0}^{(m)}$ are xored together and the secret is recovered.

▶ **Theorem 10.** *If, for every $j \in \{2, \ldots, k\}$, Π_j is an α_j-probabilistic scheme for the (j, ∞)-threshold access structure, then Λ is an α-probabilistic scheme for the $(k+1, \infty)$-threshold access structure, where $\alpha = min_{j=2,\ldots,k}\{\alpha_j\}$.*

Proof. The result follows from a similar analysis than the one for the proof of Theorem 9. For α-correctness note that at most one of the schemes Π_j is used for reconstruction, while the other steps provide 1-correctness. ◀

Share size. The share of party t, which is the l-th participant from generation m includes $k+1$ different shares $\{u_{j,l}^{(m)}\}_{l \in [k+1]}$ for a (j, g_m)-threshold scheme. If instantiated with Shamir's scheme each of them is of size $\lfloor log_2(g_m) \rfloor$. Therefore we have:

$$size_\Lambda(sh_t) = (k+1)\lfloor log_2(g_m) \rfloor + \sum_{i=1}^{m-1} \sum_{j=1}^{k} size_{\Pi_j}(v_{j,l}^{(i)})$$

6 A probabilistic (k, ∞)-threshold construction with constant share size

It is possible to construct probabilistic (k, ∞)-threshold schemes starting from our construction provided in Section 4. In order to do so, we need to first apply iteratively the transforms from Section 5, and then apply the same domain reduction technique of [26, 27]. However, the

probabilistic (k, ∞)-threshold constructions obtained in this way have the same asymptotic share size as the ones in [26, 27]. Thus, it might seem that there is no gain in moving from the deterministic to the probabilistic scenario. However, in the following, we show how to construct schemes with better share size.

More precisely, we propose a probabilistic (k, ∞)-threshold construction with constant size shares, which is known to be impossible in the deterministic scenario, due to the lower bound presented in [26, 27]. Moreover, by choosing the parameters appropriately, the scheme can be made α-correct, with α as closer to 1 as desired, at the expenses of an increase in the size of the underlying field.

Let $q > k$ be a prime power and let $\mathbb{F}_q$ be a finite field with q elements. The idea behind this construction is giving each player an independently chosen at random Shamir share for a (k, q)-threshold scheme. In this case the secret s is an arbitrary element of $\mathbb{F}_q$, that is, $s \in \mathbb{F}_q$.

The scheme works as follows: at the beginning of the execution, a $k-1$ degree polynomial $p(x) \in \mathbb{F}_q$ is chosen as in Shamir's scheme, that is, such that $p(0) = s$. Upon arrival of participant t, a value r_t is chosen uniformly at random from $\mathbb{F}_q \setminus \{0\}$. The share of participant t is the pair $(r_t, p(r_t))$.

For reconstruction, a group of m participants checks if they hold at least k different values from $\mathbb{F}_q$ as the first component of their shares. If this is the case they recover polynomial $p(x)$ by interpolation and output $p(0)$. Otherwise, they output a random value in $\mathbb{F}_q$.

▶ **Theorem 11.** *The previous construction is an α-probabilistic scheme for the (k, ∞)-threshold access structure, where*

$$\alpha = \frac{1}{(q-1)^k} \prod_{i=1}^{k} (q-i)$$

Proof. For security, take into account that $m < k$ participants hold m shares for the Shamir's (k, q) threshold scheme and perfect privacy trivially follows.

For α-correctness, the probability of k different participants getting k different shares and thus being able to correctly reconstruct the secret equals the probability of getting k different items when choosing k times, independently and uniformly at random, from $q-1$ different items, which equals

$$\prod_{i=1}^{k} \frac{q-i}{q-1} = \frac{1}{(q-1)^k} \prod_{i=1}^{k} (q-i)$$

Note also that if $m \geq k$ participants are present upon reconstruction, the probability of getting k different values only increases. The value of α follows from these facts. ◀

Share size. A single share is a pair of two elements of $\mathbb{F}_q$, thus its size equals $2(\lfloor \log q \rfloor + 1)$.

▶ Remark. For a fixed value of k, the probability of correct reconstruction α approaches to 1 when $q \to \infty$. Therefore, it is possible to get a scheme with α as closer to 1 as desired by appropriately choosing the value of q. Of course, increasing the value of q produces an increase in the share size.

▶ Remark. As pointed out in the proof, the participation of more than k parties in the reconstruction phase makes the probability of correctly reconstructing the secret to increase.

Comparison with the scheme from Section 4. Next we provide a brief comparative analysis between our constructions from Sections 4 and 6, when both are used to share secrets of the same size for the $(2, \infty)$-threshold access structure. Assume that $s \in \{0,1\}^l$ is a bitstring of

length l. When using the construction from Section 4 in a direct way, l independent instances are needed in order to share s. Thus, the share size equals l and the probability of perfect reconstruction, for example, assuming the uniform distribution on the secret space, equals $(3/4)^l$. On the other hand, when using the construction from this section with $k = 2$, we can choose q as the smaller prime power such that $q > 2^l$. Then, the share size equals $\lfloor \log q \rfloor$ which will be equal or very close to l. And the probability of correct reconstruction equals

$$\frac{q-1}{q-1} \cdot \frac{q-2}{q-1} = \frac{q-2}{q-1}$$

Note that both constructions have almost the same share size, but the probability α of correct reconstruction for the former scheme tends to 0, while for the latter scheme tends to 1 as l grows. We can conclude, looking at concrete numbers, that our construction from this section performs much better than the one from Section 4, even for small values of l.

7 Conclusions and open problems

We have introduced the notion of α-probabilistic secret sharing schemes and provided two efficient constructions for threshold access structures and for evolving threshold access structures with shares of constant size, with respect to the number of participants, and probability of reconstruction as close to 1 as desired.

Many questions arise from the above study. We point out just two main challenging problems: the first one is how to design efficient probabilistic secret sharing schemes for *general access structures* for an infinite set of participants and which gain (if any) we can get, compared to perfect secret sharing schemes, in terms of share size. The second one is related to the *power* of probabilistic secret sharing schemes. Indeed, in [2] (Section 6), results, attributed to Rudich, show that it is unlikely to obtain efficient secret sharing schemes for certain access structures unless $NP = \text{co-}NP$. The proof uses the *perfect* correctness of the secret sharing schemes. The question is whether or not we can overcome the impossibility results by Rudich with probabilistic secret sharing schemes.

Abstract

Many succinct data structures on the word RAM require precomputed tables to start operating. Usually, the tables can be constructed in sublinear time. In this time, most of a data structure is not initialized, i.e., there is plenty of unused space allocated for the data structure. We present a general framework to store temporarily extra buffers between the user defined data so that the data can be processed immediately, stored first in the buffers, and then moved into the data structure after finishing the tables. As an application, we apply our framework to Dodis, Pătraşcu, and Thorup's data structure (STOC 2010) that emulates c-ary memory and to Farzan and Munro's succinct encoding of arbitrary graphs (TCS 2013). We also use our framework to present an in-place dynamical initializable array.

1 Introduction

Small mobile devices, embedded systems, and big data draw the attention to space- and time-efficient algorithms, e.g., for sorting [4, 23], geometry [1, 3, 10] or graph algorithms [2, 6, 7, 9, 12, 14, 15, 16]. Moreover, there has been also an increased interest in succinct (encoding) data structures [8, 11, 12, 20, 18, 24, 22].

On a word RAM, succinct data structures often require precomputed tables to start operating, e.g., Dodis, Pătraşcu, and Thorup's data structure [8]. It emulates c-ary memory, for an arbitrary $c \geq 2$, on standard binary memory almost without losing space. Before we can store any information in the data structure, suitable lookup tables have to be computed. Hagerup and Kammer [12, Theorem 6.5] showed a solution that allows us to store the incoming information in an extra buffer and read and write values immediately. However, their solution scrambles the data so that extra mapping tables have to be built and used forever to access the data, even after the lookup tables are built. Moreover, Farzan and Munro [11] described a succinct encoding of arbitrary graphs. To store a dense graph, an adjacency matrix is stored in a compact form by decomposing the matrix in tiny submatrices. Each submatrix is represented by an index and the mapping is done via a lookup table. Assume that the tables are not ready, but the information of the graph already arrives in a

[1] Funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – 379157101.

stream. One then can use an extra buffer and store the small matrices in a non-compact way and operate on these matrices until the tables are ready. At the end, the non-compact matrices can be moved from the buffers to the data structure that stores the encoded graph.

Usually, the tables can be constructed in sublinear time. In this time, most of the data structure is not initialized, leaving plenty of allocated space unused. We present a general framework to store a temporarily extra buffer within the initial memory. Even if the initialized space changes, the content in the extra buffers do not change for the user. Intuitively, we describe a way how to use the uninitialized space to store a usual array with random access. In particular, if the buffer is not needed any more and thus is removed, our implementation "leaves" the data structure as if the extra buffer has never existed.

As another application of our framework, we show that in-place initializable arrays can be made dynamic and with every increase of the array size, the new space is always initialized. Our model of computation is the word RAM model with a word length w that allows us to access all input words in $O(1)$ time. Thus, to operate on a dynamic initializable array of maximum size $n_{\max}$ we require that the word size $w = \Omega(\log n_{\max})$.

To obtain a dynamic initializable array, we additionally assume that we can expand and shrink an already allocated memory. The memory can come from an operating system or can be user controlled, i.e., the user can shrink an initializable array temporarily, use the space for some other purpose, and can increase it again if it is needed later.

1.1 Previous Array Implementation

The folklore algorithm [5, 19], which uses two arrays with pointers pointing to each other and one array storing the data, uses $O(nw)$ bits of extra space. Navarro [21] showed an implementation that requires $n + o(n)$ bits of extra space. Recently, Hagerup and Kammer [13] showed that $\lceil (n(t/(2w))^t) \rceil$ extra bits for an arbitrary t suffice if one wants to support access to the array in $O(t)$ time. In particular, by choosing $t = O(\log n)$, the extra space is only one bit. Very recently, Katoh and Goto [17] showed that also constant access time is possible with one extra bit. All these array implementations are designed for static array sizes.

1.2 Our Contributions

First, we present our framework to extend a data structure by an extra buffer. We then apply the framework to two known algorithms [8, 11]. Finally, we make Katoh and Goto's in-place initializable arrays dynamic. For this purpose, we identify problems that happen by a simple increase of the memory used for the array and stepwise improve the implementation to make our array dynamic. Our best solution supports operations READ, WRITE, and INCREASE in constant time and an operation SHRINK in amortized constant time.

Why do we support the shrink operation only in amortized time? The rest of this paragraph is not a precise proof, but gives some intuition what the problems are if the goal is to support constant non-amortized time for initialization, writing and shrinking. To support constant-time initialization of an array we must have knowledge of the regions that are completely written by the user and these regions must store the information which words are written. If we now allow arbitrary shrink operations, then we do not have the space to keep all information. Instead, we must clean the information, but keep this information of the written words that still belong to the dynamic array. If we want to run the shrink operation in non-amortized constant time, the information must be sorted in such a way that the cleaning can be done by simply cutting away a last part of the information. This means

the writing operation must take care that the information is stored "almost sorted". Since we can not sort a stream of elements in $O(1)$ time per element in general, it seems plausible that the writing operation takes $\omega(1)$ time.

The remainder of this paper is structured as follows. We begin with summarizing the important parts of Katoh and Goto's algorithm in Section 2. In Section 3 we present our framework to implement the extra buffer stored inside the unused space of a data structure without using extra space. In Section 4, we extend our framework to dynamic arrays. As an application, we show in Section 5.1 how to increase the array size in constant time. In Sections 5.2 and 5.3, we present the final implementation that also allows us to decrease the array size.

2 In-Place Initializable Array

Katoh and Goto [17] introduced the data structure below and gave an implementation that uses $nw + 1$ bits and supports all operations in constant time.

▶ **Definition 1.** An initializable array $\mathcal{D}$ is a data structure that stores $n \in \mathbb{N}$ elements of the universe $Z \subseteq \mathbb{N}$ and provides the following operations:

- READ(i) $(i \in \mathbb{N})$: Returns the i-th element of $\mathcal{D}$.
- WRITE(i, x) $(i \in \mathbb{N}, x \in Z)$: Sets the i-th element of $\mathcal{D}$ to x.
- INIT(x) $(x \in Z)$: Sets all elements of $\mathcal{D}$ to initv $:= x$.

Let $D[0, \ldots, n]$ be an array storing $\mathcal{D}$. $D[0]$ is used only to store one bit to check if the array $\mathcal{D}$ is fully initialized. If $D[0] = 1$, $\mathcal{D}$ is a normal array, otherwise the following rules apply.

The idea is to split a standard array into blocks of $b = 2$ words and group the blocks into two areas: The blocks before some threshold $t \in \mathbb{N}$ are in the *written area*, the remaining in the *unwritten area*. Moreover, they call two blocks *chained* if the values of their first words point at each others position and if they belong to different areas. In the following, we denote by $d(B)$ the block chained with a block B. Note that $d(d(B)) = B$.

In our paper, we also use chains. Therefore, we shortly describe the meaning of a (un)chained block B in [17]. Compare the following description with Figure 1. If B is in the written area and chained, then B is used to store a value of another initialized block and is therefore defined as uninitialized. If B is in the unwritten area and chained, B contains user written values and the words of B are divided among B and $d(B)$. In this case $d(B)$ was not written by the user. In detail, the second word of B is stored in this word of B, but the first word is stored in the second word of $d(B)$ since the first word is used to store a pointer. If B is in the written area and unchained, B contains user written (or initial) values. If B is in the unwritten area and unchained, B has never been written by the user. Every time the user writes into a block for the first time, i.e., into a word of an (un)chained block in the (un)written area, the written area increases by moving the first block of the unwritten area into the written area and by possibly building or correcting chains.

3 Extra Space during Initialization of Succinct Data Structures

We now consider an arbitrary data structure $\mathcal{D}^*$. The only assumption that we make is that $\mathcal{D}^*$ accesses the memory via a data structure $\mathcal{D}$ realizing an n-word array. For the time being, assume $\mathcal{D}$ is the data structure as described in Section 2 with $D[0, \ldots, n]$ being an array storing $\mathcal{D}$. We define $|U|$ as the number of blocks of the unwritten area. As long as

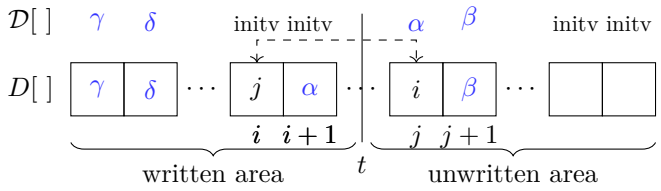

Figure 1 The different states of blocks inside the written and unwritten area. $\mathcal{D}$ represents the users view on the data with *initv* being the initial value, α, β, γ and δ as user written values. D represents the internal view with i and j as indices of D.

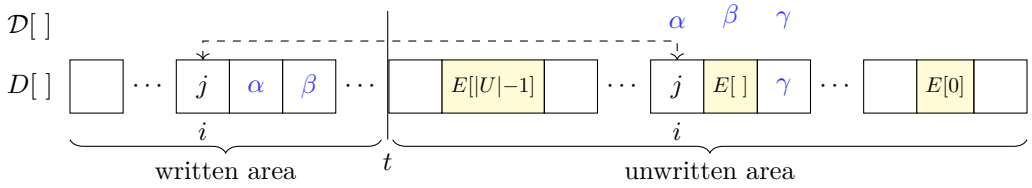

Figure 2 The block size $b = 3$ allows us to move α and β to the chained block such that each block of the unwritten area has one unused word to store the extra data of E.

$\mathcal{D}$ is not fully initialized, i.e, not all array locations have been written since the last INIT operation, and only $m \in \mathbb{N}$ with $m < n$ words are written in $\mathcal{D}$, Theorem 2 shows that the unused storage allocated for $\mathcal{D}$ allows us to store information of an extra array E inside D by increasing the block size to $b > 2$ (Figure 2). The size of E depends on $|U|$ and thus on the current grade of initialization of $\mathcal{D}$. In contrast to $\mathcal{D}$, E is an uninitialized array. Clearly, we can build an initialized array on top of E.

The array size n is not always a multiple of the block size b. By decreasing n and handling less than b words of $\mathcal{D}$ separately, we assume in this paper that n is a multiple of b.

▶ **Theorem 2.** *We can store an extra array E of $(n/b - m)(b-2) \leq |U|(b-2)$ words inside the unused space of an initializable array $\mathcal{D}$ of size n, split into blocks of size b where m is the number of writing operations since the last* INIT *operation. E dynamically shrinks from the end whenever the number of user defined values m increases.*

Proof. Let us consider a block B inside the unwritten area. B and $d(B)$ together provide space for $2b$ words, but the chain between them exists only because the user wrote inside one block (block B, but not in $d(B)$), and thus we need to store b words of user data. Furthermore, B and $d(B)$ each needs one word to store a pointer that represents the chain. By storing as much user data as possible of B in $d(B)$, we have $b-2$ unused words in B – say, words 2 to $b-1$ are unused. Note that, if a block B is unchained, then it contains no user values at all and we have even b unused words. If the user wrote m different words in $\mathcal{D}$, then the threshold t of $\mathcal{D}$ (t is the number of blocks in the written area) is expanded at most m-times. The written area consists of at most m blocks of a total of n/b blocks. Consequently, the unwritten area has $(n/b - m) \leq |U|$ blocks with each having $(b-2)$ unused words. If we start storing $E[0], E[1], ...$ in the unwritten area strictly behind t, the indices of E will shift every time the unwritten area shrinks. Therefore, we store E in reverse and E loses with every shrink the last $b-2$ words, but get static indices. ◀

Note that values like the threshold t and the initial value can be easily stored at the beginning of E. However, we require the size of $\mathcal{D}$ to determine the beginning of E. To store the size we therefore move $D[1]$ also into E and store the size of the array in $D[1]$. During

the usage of D we have to take this into account, but for simplicity we ignore this fact. If the array is fully initialized and thus $D[0] = 1$, we can not store the size anymore, but in this case we do not need to know it.

3.1 Application: c-ary Memory

To use Dodis et al.'s dictionary [8] on n elements, a lookup table Y with $O(\log n)$ entries consisting of $O(\log n)$ bits each must be constructed, which can be done in $O(\log n)$ time. Using tables of the same kind to store powers of c, we can assume that $c = \Omega(n)$ by combining consecutive elements of the input into one element.

Hagerup and Kammer extended Dodis et al.'s dictionary to support constant-time initialization by storing the $k = \Theta(\log n)$ elements that are added first to the dictionary in a trie D^{T} of constant depth $d \geq 4$ and out degree $n^{1/d}$ using $O(n^{\epsilon+1/d} + \log n \log c)$ bits for any $\epsilon > 0$. Interleaved with the first k operations on the dictionary, first the table Y is built and afterwards, the elements in D^{T} are moved to the dictionary.

Since D^{T} is required only temporarily, it is stored within the memory allocated for the dictionary – say in the last part of the memory. The problem that arises is that the last part of the memory can not be used as long as it is still used by D^{T}. This problem is solved by partitioning the memory allocated for the dictionary into sectors and using a complicated mapping function that scrambles the elements to avoid the usage of the last part of the memory. Unfortunately, even after computing the table Y and moving all elements from D^{T} over to the dictionary, the data is still scrambled and each access to the dictionary has to start evaluating the mapping function.

With Theorem 2 as an underlying data structure it is easily possible to implement the dictionary with constant initialization time. Use the extra array E to store temporarily the table D^{T}. Even if we use block size $b = 3$, E has enough space (at least $(n(\log c) - k \log n)/3 \geq (n - k)(\log n)/3$ bits at the end of the construction of Y) to store D^{T}. The mapping function becomes superfluous because the data is not scrambled by the usage of Theorem 2. Furthermore, working on a copied and slightly modified algorithm after the full initialization of $\mathcal{D}$, we can avoid checking the extra bit in $D[0]$.

3.2 Application: Succinct Encoding of Dense Graphs

Farzan and Munro [11] showed a succinct encoding of an $n \times n$-matrix that represents an arbitrary graph with n vertices and m edges. Knowing the number of edges they distinguish between five cases: An almost full case, where the matrix consists of almost only one entries, an extremely dense case, a dense case, a moderate case and an extremely sparse case. For each case, they present a succinct encoding that supports the query operations for adjacency and degree in constant time and iteration over neighbors of a vertex in constant time per neighbor.

We consider only the dense case where table lookup is used. Dense means that $\exists \delta > 0 : n^2 / \log^{1-\delta} n \leq m \leq n^2(1 - 1/(\log^{1-\delta} n)$. As shown in [11], a representation in that case requires $\log \binom{n^2}{m} + O(n^2(\log^{1-\delta} n)) = \log \binom{n^2}{m} + o(\log \binom{n^2}{m})$ bits of memory. To encode the matrix of a graph Farzan and Munro first divide the matrix into small *submatrices* of size $\log^{1-\delta} n \times \log^{1-\delta} n$ for a constant $0 < \delta \leq 1$. For each row and column of these smaller submatrices they calculate a *summary bit* that is 1 if the row and column, respectively, of the submatrix contains at least one 1. The summary bits of a row and column, respectively, of the whole matrix are used to create a *summary vector*. On top of each summary vector they build a rank-select data structure [24] that supports queries on 0's and 1's in constant time. They also build a lookup table to map between possible submatrices and indices as well as to

answer all queries of interest in the submatrix in $O(1)$ time. In a further step, they replace each submatrix by its index. By guaranteeing that the number of possible submatrices is $o(\log n)$, the construction of the lookup table can be done in $O(n)$ time. To simply guarantee this, we restrict δ to be larger than $1/2$. We generalize the result to dynamic graphs by replacing the rank-select data structures with choice dictionaries [12, Theorem 7.6] as follows. We assume that the graph has initially no edges and that there is a stream that consists of edge updates and query operations. With each edge update, the index of the submatrix with the edge changes. To realize the index transition we use a translation table that maps both, the current index of the submatrix and the edge update made, to the new index. We store for each summary vector an *edge counter*, i.e., the number of 1's that was used to calculate each summary bit of it. Whenever an edge is created between two nodes we set the corresponding bit of the row and column, respectively, inside the summary vector to 1 and increment the edge counter. If an edge is removed we decrement the edge counter and determine, using a lookup table, if the submatrix containing this edge has still 1's in the updated row and column, respectively. If it does not, we set the corresponding summary bit inside the summary vector to 0.

If the lookup tables for the submatrices are computed, we can easily answer queries to the current graph similar to [11] since we still use the summary vectors. We can ask for membership to answer adjacency queries. To iterate over the neighbors of a vertex (i.e., over the 1's in the summary vector), we can use the iterator function of the choice dictionary instead of using the select function of the rank-select data structure. The degree query is answered by returning the edge counter.

In the rest of this subsection, the goal is to extend the data structure such that it supports the queries without a delay for the construction of the lookup tables. The idea is to store a submatrix with a 1 entry in the usual, non-compact way in the extra buffer and to add a pointer from the submatrix to a place in the buffer where it is stored. To reduce the space used for the pointers, we group $\log^{\delta} n$ submatrices together to get a *group matrix* of size $\log^{1-\delta} n \times \log n$. Moreover, we use an array A in which we store a pointer of $O(\log n)$ bits for each group. With the first writing operation to one submatrix in a group, the group matrix is stored in the usual, non-compact way in an initialized array, which is stored in the extra buffer (Theorem 2). In the array A, we update the pointer for the group. In addition, we build a choice dictionary on top of each non-empty column and each non-empty row of the group matrix. With each choice dictionary, we also count the number of 1 entries.

Using the counts we can update the summary vectors and the non-compact submatrix allows us to answer adjacency queries. Both can be done in constant time without using lookup tables. To support the neighborhood query, we use choice dictionaries on top of the group matrices. In detail, whenever updating an edge, update the summary vector, add or follow the pointer to the non-compact representation, update it including the choice dictionary and the degree counter.

After $O(n)$ operations the lookup table is computed and, in the same time, the entries in the non-compact matrices are moved to the compact submatrices.

The array A requires $n^2(\log n)/((\log^{1-\delta} n)(\log n)) = O(n^2/\log^{1-\delta} n)$ bits, which is negligible. Moreover, a group matrix with the choice dictionaries requires $O(\log^2 n)$ bits to be stored. Thus, after $O(n)$ operations, the total extra space usage is $O(n \log^2 n)$ bits, which easily fits in the extra buffers of size $\Omega(\log \binom{n^2}{m} - n \log n) = \Omega(n^2/\log^{1-\delta} n - n \log n)$ bits after $O(n)$ operations.

▶ **Theorem 3.** *A graph with n vertices can be stored with $log_2\binom{n}{m} + O(n^2/\log^{1-\delta} n)$ bits supporting edge updates as well as adjacency and degree queries in constant time and iteration over neighbors of a vertex in constant time per neighbor where $m = n^2/\log_2^{1-\delta} n$ and $\delta > 1/2$. A startup time for constructing tables is not necessary.*

Note that, if the whole memory of a graph representation must be allocated in the beginning, i.e., if we do not allow a change of the space bound during the edge updates, then our representation of the dynamical graph (with possibly $n^2/\log_2^{1-\delta} n$ edges) is also succinct.

4 Extra Space for Dynamic Arrays

We now extend our framework to dynamic arrays. The data structure $\mathcal{D}$ (Definition 1) of Katoh and Goto is not dynamic, but assume it is. Then the unwritten area of $\mathcal{D}$ may become larger and smaller and with it the size of the array extra array E (Theorem 2).

Since we start indexing the words belonging to E from the end of $\mathcal{D}$, changing the size of $\mathcal{D}$ will change the index of the words in E. If we start indexing E from the beginning of the unwritten area, all indices change every time the unwritten area shrinks.

To realize an indexed array we introduce a fixed-length array F. To handle the shrink operation, we store F strictly behind the written area so that there is nothing to do if we shrink or expand the size of $\mathcal{D}$. Recall that b is the size of a block words and m is the number of write operations. If the written area grows, we lose $b-2$ unused words of the unwritten area and therefore $b-2$ used words in F. As long as there are unused words in the unwritten area behind F we move the $b-2$ words that we would lose to the first unused words behind F. This will rotate F inside the unwritten area of D.

▶ **Lemma 4.** *We can store a fixed-length array F consisting of ℓ words in the unused space of $\mathcal{D}$ as long as $\ell \leq (n/b - m - 1)(b-2) \leq (|U|-1)(b-2)$. If the condition is violated, then F is destroyed.*

Proof. Let the size of F be smaller than the unused space of $\mathcal{D}$. Whenever the user writes an additional word in $\mathcal{D}$, m increases and the number of the unused words becomes less. Therefore, before extending the written area by one block, we move the $b-2$ words in that block to the unused space of $\mathcal{D}$ behind F. We use the last block in the unwritten area to store the size and a counter to calculate the rotation. Thus, we have one block less in contrast to Theorem 2. F can be of size $\ell \leq (n/b - m - 1)(b-2) \leq (|U|-1)(b-2)$. ◀

For some applications it is interesting to have a dynamic extra storage even if $\mathcal{D}$ is dynamic. We introduce a dynamic set in Lemma 5 that can be stored inside the unwritten area of $\mathcal{D}$ and supports the operations ADD, REMOVE, and ITERATE. The last operation returns a list of all elements in the data structure. The size of dynamic extra storage is dynamically upper bounded by $|U|$.

▶ **Lemma 5.** *We can store a dynamic (multi-)set of maximal $\ell \leq (|U|-1)(b-2)$ elements in the unused space of $\mathcal{D}$. If the condition is violated by write operations of $\mathcal{D}$, elements of the set are removed until the condition holds again.*

Proof. We store a dynamic list strictly behind the written area and shift it cyclically as in the proof of Lemma 4. The difference here is that we have no fixed order so that we can store new elements simply at the beginning of the unused words of $\mathcal{D}$ and increase the size ℓ. The removal of an element may create a gap that can be filled by moving an element and decreasing ℓ. ◀

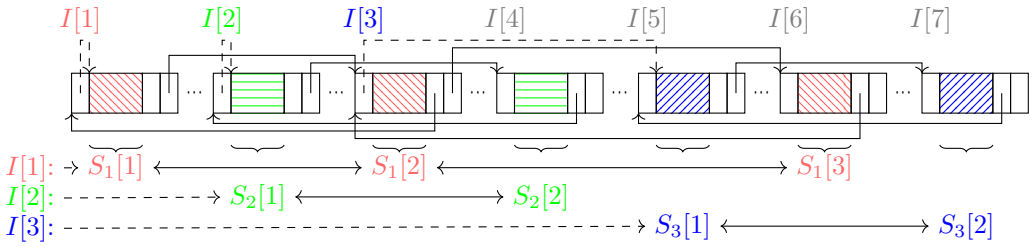

Figure 3 The figure shows a dynamic family consisting of three dynamic sets. The first element of each set can be found in section to which $I[1]$, $I[2]$ and $I[3]$, respectively, points.

For our implementation described in Section 5 we require a (multi-)set with *direct access* to the elements. We can use the position in D as an address for direct access, but this requires that the user implements a *notification function*, which is called by our data structure whenever an element in the list changes its position to inform the user.

▶ **Fact 6.** *Having two chained blocks B and $d(B)$ and a suitable block size b, we can rearrange the user data in the two blocks such that we can store $O(1)$ extra words (information as, e.g., pointers) in both B and in $d(B)$.*

We next show that an algorithm can use several extra data structures in parallel.

▶ **Lemma 7.** *For a $b \geq 2$, $\mathcal{D}$ can have $k \in \mathbb{N}$ extra data structures in parallel where each is of size at most $|U|\lfloor (b-2)/k \rfloor$.*

Proof. Every block of the unwritten area has $b-2$ unused words and every unused word can be used for another data structure. ◀

As we see later, it is useful to have several dynamic sets of elements that are all the same size. The sets can also be (multi-)sets.

▶ **Corollary 8.** *For $b > 2$, $\mathcal{D}$ can store a dynamic family $\mathcal{F}$ consisting of dynamic sets where the sets have in total at most $\lfloor (|U|-3)(b-2)/(s+3) - 1 \rfloor$ elements each of size s.*

Proof. We use the unused words in the unwritten area of $\mathcal{D}$ and partition it into sections of $s+3$ words. Every first word of a section is used for an array I, then s words are used to store an element of a set, and the last two words store pointers of a doubly linked list that connect the element in a doubly-linked list with all other elements in the set. $I[i]$ points to the an element of the ith set. The element is stored in one section. Using the pointers at the end of each section, we can find the next element of the set. The realization is also sketched in Figure 3. The unused words in the last 3 blocks (possibly, fewer blocks suffice) of the unwritten area are used to store some constants: the size t of the written area, the initial value of $\mathcal{D}$, some parameter $p \in \mathbb{N}$, the number of sets in $\mathcal{S}$, and the total number q of items over all sets. Using q we can simply find the section of a new element.

If the written area of $\mathcal{D}$ increases, we have to start moving the first section to a new unused section. We store the position of the new section in p. By knowing t we know how much of the first section has been already moved and where to find the information of the first section. ◀

5 Dynamical Initializable Array

In the next three subsections, we provide implementations to make the in-place initializable array dynamic. Therefore, we extend the initializable array $\mathcal{D}$ by the following two functions to change the current size of the array.

- INCREASE$(n_{\text{old}}, n_{\text{new}}, \text{initv})$ $(n_{\text{old}}, n_{\text{new}} \in \mathbb{N})$: Sets the size of $\mathcal{D}$ from n_{old} to n_{new}. All the elements behind the n_{old}th element in $\mathcal{D}$ are initialized with initv, the initial value of $\mathcal{D}$ defined by the last call of INIT.
- SHRINK$(n_{\text{old}}, n_{\text{new}})$ $(n_{\text{old}}, n_{\text{new}} \in \mathbb{N})$: Sets the size of $\mathcal{D}$ from n_{old} to n_{new}.

In our implementation we handle the array $\mathcal{D}$ differently, according to its size. Recall that w is the word size. As long as $\mathcal{D}$ consists of $n' = O(w)$ elements, we use a bit vector stored in $O(1)$ words to know which words are initialized. On the word RAM we can manipulate it in constant time. To have immediate access to the bit vector we store it in the beginning of the array and move the data located there to the first unused words. If we increase the size of $\mathcal{D}$ to more than $\omega(w)$ elements, we keep the bit vector in some unused words until the first n' words of $\mathcal{D}$ are completely initialized. Having such a bit vector we assume that this is taken into account whenever there is a reading or writing operation, but do not mention it explicitly in the rest of the paper.

If the array $\mathcal{D}$ consists of at least $\omega(w)$ elements, we can not use the solution with the bit vector. Instead, we use chains so that we can distinguish between initialized and uninitialized blocks, even after several shrink and increase operations. We assume in the following that $\mathcal{D}$ consists of $\omega(w)$ elements.

5.1 Increasing the size of $\mathcal{D}$

An increase of the size of $\mathcal{D}$ means allocating additional memory that gives us several new blocks inside the unwritten area. These blocks may contain arbitrary values and these values can point at each other such that they create a so-called unintended chain between a block B_w (written area) and a block B_u (unwritten area). Katoh and Goto *break such unintended chains* by creating a self-chain (pointer at its own position) with B_u whenever they write a value to a block of the written area. Because the increase of $\mathcal{D}$ may be arbitrary, we can not destroy such chains in constant time.

To support large increases of $\mathcal{D}$, we eliminate the possibility of unintended chains by introducing another kind of chain, called *verification chain*. To distinguish the two kinds of chains we name the chain introduced in Section 2 a *data chain*. We define a chain between two blocks B_w and B_u as *intended* exactly if B_w has also a verification chain, otherwise as *unintended*.

To use the verification chain, we first distribute the user data among two chained blocks such that each block of the written area has an unused word (Fact 6). Let L be a dynamic list with direct access stored in $\mathcal{D}$ (Lemma 5). Whenever the block B in the written area has a data chain with a block $d(B)$, we additionally require that it also must have a verification chain with an element of the list L (Figure 4). We denote by $v(B)$ a pointer to the element in L chained with B and use an unused word of B to store $v(B)$. Recall that, whenever the unwritten area shrinks, some elements in L change their position in D. To ensure the validity of the verification chains, we use the notification function of L to update the pointer $k \in \mathbb{N}$ in the effected blocks. The verification pointers in L, stored behind the written area, are not affected by increasing the size of $\mathcal{D}$.

Finally, note that L has enough space to store all verification pointers since only one verification chain is required for each block in the unwritten area, i.e, L is of size $O(|U|)$.

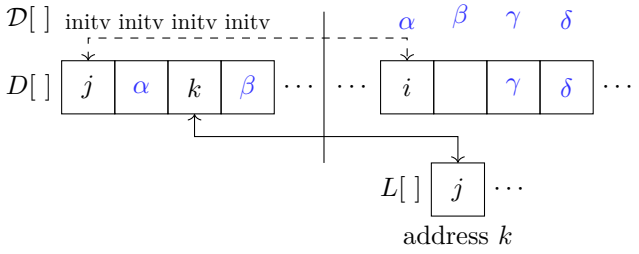

Figure 4 The block B_w (left) has a verification chain with an element of a dynamic list L to verify that the data chain between block B_w and B_u (right) is intended.

5.2 Shrinking the Size of $\mathcal{D}$ at most $O(w)$ Times

Shrinking the size of $\mathcal{D}$ means to free some memory that may be used to store information. We distinguish between two cases. In the first case we shrink the size of $\mathcal{D}$ so much that L is destroyed. In this case we make a *full initialization* of $\mathcal{D}$ as follows.

Since we lose the ability to check for unintended data chains, we first destroy them by iterating over the verification list L, following its pointer to a block B_w, checking if the block $B_u = d(B_w)$ is behind the new size of $\mathcal{D}$. If it is, we initialize B_w with the initial value. Writing the initial value into B_w may created an unintended data chain, which we break. Now the verification list is superfluous and we can iterate over the unwritten area and check for a data chain. If there is one, we move the user values from $d(B)$ into B and initialize $d(B)$, otherwise we initialize B. After the iteration, we set $D[0] = 1$.

Since L will be destroyed by the shrinking operation, the size $|U|$ of the unwritten area behind the shrinking is bounded by $|L|$. Thus, by using the potential function $\psi = (c \cdot \text{length of } L)$ for some constant $c \geq 2$, the amortized cost of the WRITE operation increases by at most $c = O(1)$ and we can easily pay for the full initialization.

In the second case, we reduce the size of $\mathcal{D}$ such that the verification list L is still completely present in $\mathcal{D}$. In this case, all blocks of the written area remain and they still have a verification chain. However, the data chain can point outside of $\mathcal{D}$. If we subsequently re-increase $\mathcal{D}$, some blocks may still have a data chain and also a verification chain. This violates our definition of the INCREASE operation.

To resolve this problem we invalidate the data chains of all blocks outside $\mathcal{D}$ as follows. As long as there is no shrinking operation, we store the same *version number* $v \in \mathbb{N}$ to all data chains. More exactly, let B be a block in the unwritten area chained with a block $d(B)$ in the written area. Then we store the version inside an unused word of $d(B)$ using Fact 6.

Before we execute a shrink operation, we set n_v to the current size of $\mathcal{D}$ and remember it as the size for the current version v. With the shrink operation, we increment the version number by one. Let v' be the version of the chain between B and $d(B)$. We call the chain *valid* if B is before the boundary $n^*_{v'} = \min\{n_v | v \geq v'\}$. Note that $n^*_{v'}$ is the minimal boundary that $\mathcal{D}$ ever had after introducing version number v'.

We obtain the boundaries n^*_v from a data structure M that provides an operation to add the new size of $\mathcal{D}$ after a shrink operation and another operation MINBOUND to check if a chain is valid, i.e., if one endpoint of the chain is or was outside of $\mathcal{D}$. For later usage, M also supports an operation REMOVE.

- ADD(n) ($n \in \mathbb{N}$): Increments an internal version counter v by one and set the boundary $n^*_v = n$. All boundaries n^*_i ($i \in \{1 \dots v-1\}$) larger than n are overwritten by n.
- REMOVE(j) ($0 \leq j \leq v$): Decrements v by j and removes the boundaries of the largest j versions.
- MINBOUND(v) ($0 \leq v < w$): Returns n^*_v, the minimal boundary for v.

▶ **Lemma 9.** *M can be implemented such that it uses $O(w)$ words,* ADD *runs in amortized constant time, and* MINBOUND *and* REMOVE *run in constant time as long as there are only $O(w)$ versions.*

Proof. We have a version counter v^* and a table T where we store the initial boundary for each version. Moreover, we use a stack S that additionally allows us to access the elements of the stack directly and the data structure R from Pătraşcu and Thorup [25]. All three data structures can be implemented using a fixed size array and stored in extra buffers (Lemmas 4 and 7). R consists of all versions v with $n_v = n_v^*$. The stack S store the boundaries of the versions in R in ascending order from the bottom to the top. For a technical reason, S stores also the version with each boundary.

To answer the MINBOUND operation for a version v, we first determine the successor v' of v in R and then return $n_v^* = T[v']$.

Assume that a new boundary $n_v = n$ is added to M for a next version v. Set $T[v] = n$. Before adding a new boundary n_v to S we remove all boundaries from S as long as the top of S is larger than n_v. Whenever removing such a boundary, we remove the corresponding version from R. Finally, we add the new boundary to S and to R. By doing this, we remove all boundaries that are larger than n_v. Now all the versions of these boundaries get n_v as their new boundary.

Finally, it remains to check the running time. We use the potential function $\phi = |S|$ with $|S| \leq w$ being the current size of S. Determining the boundary for a specific version requires looking into R and to check one word in S and T. This does not change ϕ and runs in $O(1)$ time. If the running time for adding or removing versions is not constant, then in all except a last iteration, we remove an element from the stack. Thus, the decrease of ϕ pays for this. ◀

▶ **Corollary 10.** *For every data chain, we can check in constant time if it is valid or not.*

Proof. A chain between some blocks B and $d(B)$ is valid exactly if $d(B) \leq$ MINBOUND(v) is true, where v is the version of the chain and $d(B)$ is the position of the block that belongs to the unwritten area. ◀

Whenever a block in the unwritten area has an invalid chain (caused by shrinking and re-increasing $\mathcal{D}$; determined by MINBOUND), we return the initial value for all words of the block. We want to remark that the structure M can maintain only $O(w)$ versions since it uses a dictionary from Pătraşcu and Thorup [25]. The dictionary is dynamic and supports modification and access in constant time, but only for $O(w)$ entries.

We have to make sure that we have only $O(|U|)$ chains (counting both valid and invalid chains) so that we are able to store them. The problem is that a shrink can invalidate many chains. Therefore, we have to *clean-up* our data structure $\mathcal{D}$ as follows: Whenever we add a chain, we check the validness of three old chains, i.e., chains with an old version number that are stored at the beginning of the unwritten area in L. Invalid chains are removed whereas valid chains are assigned to the current version. To have the time for the clean-up, we also modify the shrink operation such that, after each shrink operation, we make sure that we store at most $|U|/2$ chains. If this is not the case, we run a full initialization. By assuming that every insert into $\mathcal{D}$ pays a coin, this can be done in amortized constant time since the number of chains that we have is bounded by the number of insert operations.

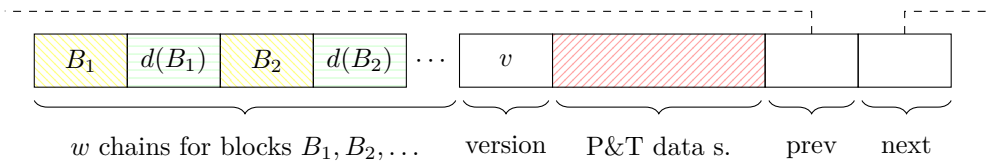

Figure 5 A subgroup that is embedded as an element of the dynamic doubly linked list containing several block positions of a version v that are indexed with a dictionary.

5.3 The General Case

The goal in this section is to limit the number of versions to $O(w)$ such that the data structure M from Lemma 9 can be always used. We achieve this goal by *purifying* the chain information, i.e., for some old version v', we iterate through the chains with a version larger than v', remove invalid data chains and store the remaining chains under v'. Finally, we take v' as the current version. We so remove all versions larger than v', which now can be reused.

Since we have no data structure to find invalid chains out of a large amount of all chains, we partition the chains of each version into small subgroups and use also here the dictionary from Pătraşcu and Thorup [25] to index the block positions B and $d(B)$ that represent the chain. The dictionary from the subgroup with a version v allows us to find a block that lies behind a boundary n_v^* in constant time as long as such a block exists.

In detail, a subgroup always has space for $\Theta(w)$ chains (block positions), the version v, and a data structure from Pătraşcu and Thorup [25] (Figure 5). To organize the subgroups we use a dynamic family S from Corollary 8. For each version v, we create a dynamic set in S. Each set consists of all subgroups of the same version. Instead of having a verification chain with a list L, each chained block in the written area has now a pointer to its subgroup. If the block is indexed in the subgroup, then its chain is verified.

As in the previous section we use the data structure M to store and check the boundaries. Additionally, we store the version v and a table T. The table is used to store, for each version, the number of chains that are currently used. The updates of T are not described below explicitly. Based on the information in T we determine how many versions we can purify. The details of the PURIFY operation are described on the next page.

Note that M and T are of $O(w)$ words and the size of S is linear in the size of the number of chains and thus bounded by $O(|U|)$. Choosing the block size b large enough, but still $b = O(1)$, we can guarantee that all data structures fit into $|U|$ unless $|U| = O(w)$. By running the clean-up of the last section, M and T can be removed if to many writing operations shrink the unwritten area of $\mathcal{D}$ so much that $|U| = O(w)$.

- INITIALIZE(n, initv) Allocate $nw + 1$ bits. Partition the array into blocks of size $b = 6$. If n is not a multiple of b, initialize less than b words and treat them separately. Use the last block(s) to store the threshold $t = 0$, initv, and $v = 1$ in the unused words. Initialize the data structure M and S, store their internally required single words also in the last block(s) and their sets and lists in parallel (Lemma 7).
- READ(i): If $D[0] = 1$, return $D[i]$. Else, check to which area $B = \lfloor i/b \rfloor$ belongs. If B is inside the written area, check if B is verified. If it is, return initv, otherwise $D[i]$.
  If B is inside the unwritten area, check if B is chained with a block $d(B)$. If it is not, return initv, otherwise proceed with checking if $d(B)$ is verified. If it is not, return initv,

otherwise follow the verification pointer and read the version v out of the subgroup. Call M.MINBOUND(V) and return initv if it returned a boundary that is larger than the block position B, otherwise return the right word out of B and $d(B)$.

- WRITE(i, x): If $D[0] = 1$, write at $D[i]$. Otherwise, clean-up three chains as described in the last subsection. Then check to which area $B = \lfloor i/b \rfloor$ belongs. If B is inside the written area, check if B is verified. If it is not, write at $D[i]$ directly. Otherwise, the block may have a data chain with a block $d(B)$. If so, unchain it (like in [17]) by expanding the written area that gives us a new unused block that we use to relocate all values and chains from B. Correct also the chains in the subgroups. If not, just remove B and $d(B)$ from its subgroup. In both cases, B becomes an unused block afterwards. We initialize it and write at $D[i]$ directly. If B is inside the unwritten area, check if B is chained with a block $d(B)$. If it is, check if $d(B)$ is verified and if its chain belonging to a version v is valid (test M.MINBOUND$(v) \geq B$). If all is true, then write x at the right position of B and $d(B)$. If the chain is invalid, delete it from its subgroup and move it into the latest subgroup of the current version. Finally, initialize B and write x as described above.

  But if B is not chained, expand the written area and chain it with the new block. Write both blocks inside the latest subgroup of the current version. Set a verification pointer to the subgroup where the chain is stored. As before, initialize B and write x as described above.

  In all cases, whenever the unwritten area disappears, set $D[0] = 1$.
- INCREASE(n_{old}, n_{new}, initv): If $D[0] = 0$, then copy the words of the last block(s) into the new last block(s). Otherwise, initialize the required data structures as described in INITIALIZE, but set the initial values for the threshold t to $t = \lfloor n_{\text{old}}/b \rfloor$. If $|U| = O(w)$, use the bit vector solution described in the beginning of Section 5.
- PURIFY(n_{new}): Iterate from the current version $v = \lceil w \rceil$ in S down and add up the number of chains stored under a version. Stop at the first version v' that has fewer chains as twice the total number of chains of all versions visited before. Consider versions $v' + 1$ to v and iterate over all subgroups with that version. In each subgroup, check for an invalid chain (B, $d(B)$) by using M, remove it from the subgroup, from the index of the subgroup, and initialize B with initv and repeat this on the subgroup until it has no invalid chains. In the special case where the subgroup has less than w chains, clear the subgroup by moving all chains into the latest subgroup of the version v'.

  Then, change the version number of this subgroup to v', unlink it from its old set and link it into the set of v'. When finished, set the current version number v to v'.
- SHRINK($n_{\text{old}}, n_{\text{new}}$): If the new size of $\mathcal{D}$ either cuts the space used to store the data structures S or M or leaves less than $\Theta(w)$ unused words in the unwritten area, run the full initialization.

  If we do not fully initialize $\mathcal{D}$, we proceed as follows: If we have $\lceil w \rceil$ versions, call PURIFY. Otherwise, create a new set inside S and increment the current version number v by one and check if the last used subgroup has less than w entries. If so, we reuse this subgroup by removing all invalid chains. (In PURIFY we already described the removal.)

Who pays for the purification? The idea is to give a gold coin to each previous set in S, whenever we insert an element. Whenever a set of size x has at least $x/2$ coins, we clean up the set and all sets with a larger version number. Algorithmically we can not check fast enough if a set already has enough coins. Therefore, we wait with the purification until we have $\lceil w \rceil$ versions and check then the condition for every version from the largest version to the smallest until we found the first version with enough coins.

▶ **Theorem 11.** *There is a dynamic array that works in-place and supports the operations* INITIALIZE, READ, WRITE *as well as* INCREASE *in constant time and* SHRINK *in amortized constant time.*

Proof. It remains to show the running times of the operations. Take ψ as the total number of verification chains similar to Subsection 5.2, c_i as the number of chains with the version $i \in \{0, \dots, v-1\}$ and $g = \sum_{i=0}^{v-1} \frac{6i \cdot c_i}{w}$. Moreover, choose τ as the total number of missing elements such that all subgroups are full and $f = (1 - D[0]) \max\{0, 2w - |U|\}$. We use the following potential function $\phi = \psi + v + g + \tau + f$. Note that g corresponds to the usage of the gold coins and f is non-zero only if there are very few blocks in the unwritten area U, but $\mathcal{D}$ is not completely initialized.

- INITIALIZE: We have to set the threshold t and the current version in $O(1)$ time. Thus, $\phi = v = 1$ – note that $f = 0$ by using the bit-vector solution if necessary.
- READ: Checking chains, reading the version number and calling the MINBOUND function of M can be done in constant time and ϕ does not change.
- WRITE: We possibly have to check if a block is chained, verified and valid. We also may create a chain, a verification and insert it into S. All these operations require $O(1)$ time. In total, the number of chains may increase by one $\Delta\psi = O(1)$, $\Delta g = \frac{6v}{w}$ with v being the current version. Thus, $\Delta\phi = O(1)$.
- INCREASE: Copying a few blocks runs in $O(1))$ time and $\Delta\phi = 0$ since $\Delta f = 0$.
- PURIFY: Whenever we run PURIFY we remove the last $v - i$ versions for the largest i with $v_i/2 \leq y := \sum_{i+1}^{v-1} c_i$ is valid. Thus, we first have to search for version i, i.e, we consider $v - i$ versions. Moreover, we then have to iterate over $3y$ chains in $6y/w$ subgroups – a subgroup is always at least half full. In each subgroup we spend $1 + d$ time, where d is the number of deleted chains in each subgroup. This can be done in at most $(v - i) + 6y/w + d^*$ time units where d^* is the total number of deleted chains. In addition, we may have deleted half empty subgroups and moved their chains to the latest subgroup. This can be done in $O(m)$ time if m is the number of moved chains.

  We can pay for the running time since the value of the potential function decreases as follows. By deleting versions larger than i, $\Delta v = -(v - i)$. Since we change the version of all subgroups with a version larger than i to i, i.e., we shrink the version of y chains by at least one, $\Delta g = -6y/w$. In addition, $\Delta(\psi + \tau) \leq -2d^* + (d^* - m) = -d^* - m$ where the $-m$ comes from the fact that half empty subgroups disappear, i.e, are not taken into account in τ. To sum up, the amortized running time is $O(1)$.
- SHRINK: In Subsection 5.2, we already analyzed the case that $\mathcal{D}$ is fully initialized – the only change is that we have further parts in the potential function, but their change is either zero or negative. Otherwise, we have to delete invalid chains in the latest subgroup and update it to the new version, which can be done in $O(1)$ amortized time since $\Delta\psi$ drops linear in the number of deleted chains. Moreover, we have to add a new version to M and possibly delete several older versions. All this can be done in $O(1)$ amortized time. And finally, we may run a PURIFY; again in $O(1)$ amortized time.

We thus have shown all running times as promised in the theorem. ◀

Abstract

We revisit the fundamental problem of dictionary look-up with mismatches. Given a set (dictionary) of d strings of length m and an integer k, we must preprocess it into a data structure to answer the following queries: Given a query string Q of length m, find all strings in the dictionary that are at Hamming distance at most k from Q. Chan and Lewenstein (CPM 2015) showed a data structure for $k = 1$ with optimal query time $\mathcal{O}(m/w + occ)$, where w is the size of a machine word and occ is the size of the output. The data structure occupies $\mathcal{O}(wd \log^{1+\varepsilon} d)$ extra bits of space (beyond the entropy-bounded space required to store the dictionary strings). In this work we give a solution with similar bounds for a much wider range of values k. Namely, we give a data structure that has $\mathcal{O}(m/w + \log^k d + occ)$ query time and uses $\mathcal{O}(wd \log^k d)$ extra bits of space.

1 Introduction

The problem of dictionary look-up was introduced by Minsky and Papert in 1968 and is a fundamental task in many areas such as bioinformatics, information retrieval, and web search. Informally, the task is to store a set of strings referred to as dictionary in small space to maintain the following queries efficiently: Given a query string, return all dictionary strings that are close to it under some measure of distance. In this work we focus on Hamming distance and exact solutions to the problem. Formally, the problem is stated as follows.

Dictionary look-up with k mismatches. We are given a dictionary that is a set of d strings of length m and an integer $k > 0$. The task is to preprocess the dictionary into a data structure that maintains the following queries: Given a string P of length m, return all the strings in the dictionary such that the distance between each of them and P is at most k.

As a natural first step, much effort has been concentrated on the case $k = 1$ [3, 22, 4, 7, 8, 31, 11]. We note that the structure of the problem in this case is very special. Namely, if

two strings have Hamming distance at most one, then there is an integer i such that their prefixes of length i are equal and their suffixes of length $m-i-1$ are equal. Many existing solutions rely heavily on this property and cannot be extended to the case of arbitrary k. The first non-trivial solution for $k > 1$ was given in the seminal paper of Cole, Gottlieb, and Lewenstein [13], who introduced a data structure called *k-errata tree*. The k-errata tree requires $w \cdot \mathcal{O}(md + d\log^k d)$ bits of space and has query time $\mathcal{O}(m + \log^k d + occ)$, where w is the size of a machine word and occ is the size of the output. The subsequent work [10, 9, 25] mainly focused on improving the space complexity of the data structure.

Two works are of particular interest to us. For any $q = o(\log md)$ Belazzougui and Venturini [4] showed a data structure for $k = 1$ with query time $\mathcal{O}(m + occ)$ that uses $2mdH_q + o(md) + 2d\log d$ bits of space, where H_q is the q-th empirical entropy of the concatenation of all strings in the dictionary. It was followed by the work of Chan and Lewenstein [11], who improved the query time to $\mathcal{O}(m/w + occ)$, while using approximately the same amount of bits, $2mdH_q + o(md) + \mathcal{O}(wd\log^{1+\varepsilon} d)$. In the model of Chan and Lewenstein the size σ of the alphabet is constant, the query string arrives in a packed form, meaning that each $w/\log\sigma$ letters are stored in one machine word, under the standard assumption $w = \Theta(\log md)$. The interest in this kind of bounds is explained by the fact that the value mdH_q is a lower bound to the output size of any compressor that encodes each letter of the dictionary strings with a code that only depends on the letter itself and on the q immediately preceding letters [26].

1.1 Our contribution and techniques

We investigate further this line of research and give a new data structure with similar bounds for a much wider range of values k. We adopt the model of Chan and Lewenstein and show a data structure for dictionary look-up with k mismatches that has query time $\mathcal{O}(m/w + \log^k d + occ)$ and uses $2mdH_q + o(md) + \mathcal{O}(wd\log^k d)$ bits of space for all $d > 2$ (Theorem 18). If in addition $k \leq \log(m/w)/\log\log d$, the query time becomes $\mathcal{O}(m/w + occ)$, matching the query time of Chan and Lewenstein.

The basis of our data structure is the k-errata tree of Cole, Gottlieb, and Lewenstein [13]. We first introduce a small but important modification to this data structure that will allow us to reduce the time requirements for non-constant k. At a high level, the k-errata tree is a collection of compact tries, where each trie contains suffixes of a subset of strings in the dictionary. The query algorithm runs $\mathcal{O}(\log^k d)$ prefix search queries in the tries. In Section 4.1 we show that the prefix search queries can be implemented in $\mathcal{O}(m/w)$ shared plus $\mathcal{O}(\log d)$ time per query using $\mathcal{O}(md)$ space beyond the space required by the k-errata tree. Next, in Section 4.2 we show how to improve the space complexity to entropy-bounded. Our main contribution at this step is a new reduction from prefix search queries in the tries of the k-errata trees to prefix search queries on a compact trie containing only a subset of all suffixes of the dictionary strings. Finally, in Section 5 we improve the $\mathcal{O}(\log d)$ time that we spend per each query to $\mathcal{O}(1)$ (amortised) time by a clever use of Karp-Rabin fingerprints, which gives the final result, Theorem 18. We emphasize that we derandomize the query algorithm and that our data structure is deterministic, regardless the fact that we use Karp-Rabin fingerprints.

1.2 Related work

Many of the works we cited above consider not only the Hamming distance, but also the edit distance. This is in particular true for $k = 1$, when the edit distance and Hamming distance are equivalent. Another interesting direction is heuristic methods for the Hamming and the edit

distances which have worse theoretical guarantees but perform well in practice [12, 6, 23, 27]. Finally, we note that the solutions discussed in this work are beneficial for low-distance regime, i.e. when $k = o(\log d)$. If $k = \omega(\log d)$, one should turn to approximate approaches, such as locality-sensitive hashing (see [2] and references therein).

Several works have studied the question of developing efficient data structures for string processing when the query arrives in a packed form. In particular, Takuya et al. suggested a data structure called packed compact tries [29] to maintain efficient exact dictionary look-ups, and Bille, Gørtz, and Skjoldjensen used similar technique to develop an efficient text index [5].

2 Preliminaries

We assume a constant-size integer alphabet $\{1, 2, \ldots, \sigma\}$. A *string* is a sequence of letters of the alphabet. For a string $S = s_1 s_2 \ldots s_m$ we denote its length m by $|S|$ and its substring $s_i s_{i+1} \ldots s_j$, where $1 \leq i < j \leq m$, by $S[i, j]$. If $i = 1$, the substring $S[1, j]$ is referred to as *prefix* of S. If $j = m$, $S[i, m]$ is called a *suffix* of S. We say that S is given in a *packed form* if each $w/\log \sigma$ letters of S are stored in one machine word, i.e. S occupies $\mathcal{O}(m/w)$ machine words in total. Given a string S in packed form, we can access (a packed representation) of any $\mathcal{O}(w)$-length substring of S in constant time using the shift operation.

A *trie* is a basic data structure for storing a set of strings. A trie is a tree which has the following three properties:

1. Each edge is labelled by a letter of the alphabet;
2. Each two edges outgoing from the same node are labelled with different letters, and the edges are ordered by the letters;
3. Let the label of a node u be equal to the concatenation of the labels of the edges in the root-to-u path. For each string S in the set there is a node of the trie such that its label is equal to S, and the label of each node is equal to a prefix of some string in the set.

At each node we store the set of ids of the strings that are equal to the node's label. The number of nodes in a trie can be proportional to the total length of the strings. To improve the space requirements, we replace each path of nodes with degree one and with no string ids assigned to them with an edge labelled by the concatenation of the letters on the edges in the path. The result is called a *compact trie*. Each node of the trie is represented in the compact trie as well, some as nodes, and some as positions in the edges. We refer to the set of all nodes and the positions in the edges of the compact trie as positions.

▶ **Fact 1.** *A compact trie containing x strings has $\mathcal{O}(x)$ nodes.*

3 The k-errata tree: Reminder and fix

Our definition of the k-errata tree follows closely that of Cole, Gottlieb, and Lewenstein [13], but as explained below we introduce an important fix to the original definition. We try to be as concise as possible, but we feel obliged to provide all the details both because we modify the original definition and because the details are important for our final result.

Intuition. Let us explain the main idea first. Denote the given dictionary of strings by $\mathcal{D}$. The k-errata tree for $\mathcal{D}$ is built recursively. We start with the compact trie T containing all the strings in $\mathcal{D}$ and decompose it into heavy paths.

▶ **Definition 2** ([21]). The *heavy path* of T is the path that starts at the root of T and at each node v on the path branches to the child with the largest number of leaves in its subtree (*heavy* child), with ties broken arbitrarily. The heavy path decomposition is defined recursively, namely it is defined to be a union of the heavy path of T and the heavy path decompositions of the subtrees of T that hang off the heavy path. The first node in a heavy path is referred to as its *head*.

Recall that our task is to find all strings in $\mathcal{D}$ such that the Hamming distance between them and the query string P is at most k. As a first step, we find the longest path that starts at the root of T and is labelled with a prefix of P. Let this path trace heavy paths $H_1, H_2, \ldots, H_j$, leaving the heavy path H_i at a position u_i of T, $1 \leq i \leq j$. We can partition all the strings in $\mathcal{D}$ into three categories:

1. Strings diverging off a heavy path H_i at some node u, where u is located above u_i;
2. Strings in the subtrees of u_i's children that diverge from the heavy path H_{i+1}, for $1 \leq i < j$;
3. Strings in the subtree rooted at u_j.

Consider the set of strings in $\mathcal{D}$ that diverge from a heavy path H_i at a node u. They necessarily have their first mismatch with P there. The first idea is that we can fix that mismatch in each of the strings (decreasing the Hamming distance between them and P by one), and then run a dictionary look-up with $(k-1)$ mismatches on the resulting set of strings. The second idea is that running an independent dictionary look-up query for each node in each heavy path is expensive, so we introduce a grouping on the nodes that reduces the number of queries to logarithmic.

Data structure. We assign each string in $\mathcal{D}$ a credit of k mismatches and start building the k-errata tree in a recursive manner. First, we build the compact trie T for the dictionary $\mathcal{D}$. For each leaf of T we store the ids of the dictionary strings equal to the leaf's label ordered by the mismatch credits. Second, we decompose T into heavy paths. For each node of T we store a pointer to the heavy path it belongs to, and for each heavy path we store a pointer to its head. We will now make use of weight-balanced trees, defined in analogy with weight-balanced search trees.

▶ **Definition 3.** A weight-balanced tree with leaves of weights $w_1, w_2, \ldots, w_h$ (in left-to-right order) is a ternary tree. We build it recursively top-to-down. Let μ be the smallest index such that $w_1 + \cdots + w_\mu > (w_1 + \cdots + w_h)/2$. Then the left subtree hanging from the root is a weight-balanced tree with leaves of weight $w_1, w_2, \ldots, w_{\mu-1}$, the middle contains one leaf of weight w_μ, and the right subtree is a weight-balanced tree with leaves of weight $w_{\mu+1}, \ldots, w_h$.

We build two sets of $(k-1)$-errata trees for each heavy path H of T. We call the trees in the first set vertical, and in the second set horizontal, according to the way we construct them.

We first explain how we build the vertical $(k-1)$-errata trees. Suppose that H contains nodes $v_1, v_2, \ldots, v_h$, and the weight w_i of a node v_i is the number of strings that diverge from H at v_i. As a preliminary step, we build a weight-balanced tree $WBT(H)$ on the nodes in H. Consider a node of $WBT(H)$ containing $v_i, v_{i+1}, \ldots, v_j$ in its subtree. Let δ be the length of the string S written on the path from the head of H to v_j, and a be the first letter on the edge from v_j to v_{j+1}. We build a new set of strings as follows: For each node v_ℓ, $i \leq \ell \leq j$, we take each string that diverges from the path H at v_ℓ, cut off its prefix of length $\delta + 1$, and decrease the credit of the string by the number of mismatches between the cut-off

prefix and $S \circ a$ (the string S appended with the letter a). If the credit of a string becomes negative, we delete it. Finally, we build the $(k-1)$-errata tree for each of the newly created sets of strings.

We now explain how we build the horizontal $(k-1)$-errata trees. We repeat the following for each node $v_j \in H$. Let δ be the length of the label of v_j. Consider the set of all children of v_j except for the node v_{j+1} (the child of v_j that belongs to H). For each child v in this set, we build a new set of strings as follows: We take each string that ends below v, cut off its prefix of length $\delta + 1$, and decrease the credit of the string by 1. Similar to above, if the credit of a string becomes negative, we delete it. We define the weight of each child as the number of strings in the corresponding set. Next, we build the weight-balanced tree on the set of the children, and for each node of the tree consider a set of strings that is a union of the sets of strings below it. Finally, we build the $(k-1)$-errata tree for each of these sets of strings.

▶ Remark. Our modification to the original definition is that we truncate the strings and store the mismatch credits. Because of that, all the strings we work with are suffixes of the dictionary strings, which allows us to process them efficiently.

Queries. A dictionary look-up with k mismatches for a string P is performed in a recursive way as well. For the purposes of recursion, we introduce an extra parameter, μ, and allow to run dictionary look-ups with mismatches from any position u of a trie of the k-errata tree. We will make use of a procedure called PrefixSearch: Given a string and a position u of a trie, PrefixSearch returns the longest path starting at u that is labelled by a prefix of the query string.

Suppose we must answer a dictionary look-up with k mismatches for a string P that starts at a position u. We initialize $\mu = 0$. If $k = 0$, we run a PrefixSearch to find a path in T labelled by P. If such a path exists, we output all the dictionary strings assigned to the end of this path such that their mismatch credit $\geq \mu$. Assume now $k > 0$. If $|P| = 0$, the look-up terminates and we output all the dictionary strings assigned to the current position such that their mismatch credit $\geq \mu$. Otherwise, we run a PrefixSearch to find the longest path π starting at u that is labelled by a prefix of P. Suppose that π passes through heavy paths $H_1, H_2, \ldots, H_j$, leaving H_i at a position u_i, $1 \leq i \leq j$. Note that for $i < j$, u_i is necessarily a node of T, and for $i = j$ it can be a position on an edge.

Recall that for each node of T we store the heavy path it belongs to, and for each heavy path we store its head. The position u_j is the ending node of π. To find u_{j-1}, consider the heavy path H_j containing u_j, by definition, u_{j-1} is the parent of the head of H_j. We find all the nodes u_i, $1 \leq i \leq j$, analogously. Recall that we partitioned the dictionary strings into three types.

Strings of Type 1. We process each path H_i in turn. We select a set of nodes of the weight-balanced tree $WBT(H_i)$ covering the part of H_i from the beginning and up to (but not including) u_i. To do this, we follow the path from the root of $WBT(H_i)$ to u_i and take the nodes that hang off to the left of the path. Consider one of the selected nodes v and its $(k-1)$-errata tree. All the strings in this tree have equal lengths δ. To finish the recursive step, we run a dictionary look-up with $(k-1)$ mismatches for the suffix of P of length δ in this tree.

Strings of Type 2. We take the weight-balanced tree for u_i and select a set of nodes that covers all its leaves except for the head of H_{i+1}. To select this set, we find the path from the root of the weight-balanced tree for u_i to the head of H_{i+1}, and take the nodes that hang off this path. For each of the selected nodes, we run a dictionary look-up with $(k-1)$

mismatches analogously to above. We also run a dictionary look-up with $(k-1)$ mismatches with $\mu = \mu + 1$ starting from the position in H_i that is one letter below u_i.

Strings of Type 3. If u_j is a position on an edge, we run a dictionary look-up query with $(k-1)$ mismatches from the next position on the edge with $\mu = \mu + 1$. If u_j is a node, we run two dictionary look-up queries with $(k-1)$ mismatches. First query is run in the horizontal $(k-1)$-errata tree corresponding to the set of all children of u_j that are not in H_j. The second query is run from a position in H_j that is one letter below u_j with $\mu = \mu + 1$.

Correctness of the algorithm follows from the following observation: first, we account for all dictionary strings. Second, in the case of $(k-1)$-errata trees, we account for the mismatches between the portion of the strings that we truncate and the query string via the mismatch credits. Finally, when we continue the search in the same tree, there is just one mismatch and we account for it by increasing μ.

Analysis. The bounds on the space and the time complexities are summarised below. The proofs of the lemmas, which we provide in the full version of the paper for completeness, follow closely the proofs given by Cole, Gottlieb, and Lewenstein [13].

▶ **Lemma 4.** *The tries of the k-errata tree contain $\mathcal{O}(d \log^k d)$ strings in total.*

▶ **Lemma 5.** *A dictionary look-up with k mismatches for a query string P requires $\mathcal{O}(\log^k d)$ operations* PrefixSearch*. Apart from the time required for these operations, the algorithm spends $\mathcal{O}(\log^k d + occ)$ time.*

In the next section we give an efficient implementation of PrefixSearch under an assumption that P arrives in a packed form. We will use, in particular, the following simple observation.

▶ **Fact 6.** *Each trie of the k-errata tree is built on a set of equal-length suffixes of the dictionary strings. If we run a* PrefixSearch *for a suffix S of the query string P from a position u of a trie τ of the k-errata tree, then the strings in the subtree of u have length $|S|$.*

4 Prefix search for packed strings

We first remind several well-known data structure results that we use throughout the section. A *priority queue* is a data structure like a regular queue, where each element has an integer ("priority") associated with it. In a priority queue, an element with high priority is served before an element with low priority. A priority queue can be implemented as a heap, that for a set of x elements occupies $\mathcal{O}(wx)$ bits of space and has query time $\mathcal{O}(\log x)$.

A *predecessor data structure* on a set of integers supports the following queries: Given an integer z, return the largest integer in the set that is at most z. For a set of x integer keys, the predecessor data structure can be implemented as a binary search tree in $\mathcal{O}(wx)$ bits of space to support the predecessor queries in time $\mathcal{O}(\log x)$. (We do not use solutions such as [17, 30] to avoid dependency on m, which will be important for our final result.)

A *dictionary data structure* stores a set of integers. A dictionary look-up receives an integer z and outputs "yes" if z belongs to the set.

▶ **Lemma 7** ([28])**.** *Let S be any given set of x integers. There is a dictionary over S that occupies $\mathcal{O}(wx)$ bits of space, and has query time $\mathcal{O}(1)$.*

We will also need *lowest common ancestor queries* on tries. Given two nodes u, v of a trie, their lowest common ancestor is a node of maximal depth that contains both u and v in its subtree.

▶ **Lemma 8** ([18]). *A trie of size x can be preprocessed in $\mathcal{O}(wx)$ bits of space to maintain lowest common ancestor queries in $\mathcal{O}(1)$ time.*

Finally, we need *weighted level ancestor queries* on tries. A weighted level ancestor query receives a node u and an integer ℓ, and must output the deepest ancestor u' of u such that the length of the label of u' is at most ℓ. We will use the weighted level ancestor queries on tries for fast navigation: Suppose that we know a leaf labelled by a string S, then to find a position labelled by a prefix S' of S we can use one weighted level ancestor query instead of performing a PrefixSearch for S'. To avoid dependency on m, we use the following simple folklore solution instead of [20, 1, 14].

▶ **Lemma 9.** *A trie of size x can be preprocessed in $\mathcal{O}(wx)$ bits of space to maintain weighted level ancestor queries in $\mathcal{O}(\log x)$ time.*

Proof. We consider the heavy path decomposition of the trie. For each node we store a pointer to the head of the heavy path containing it, and for each path we build a binary search tree containing the length of the labels of the nodes in it. Suppose we are to answer a weighted level ancestor query for a node u and an integer ℓ. The path from the root of the trie to u (which contains all the ancestors of u) traverses a subset of heavy paths. The size of this subset is $\mathcal{O}(\log x)$, because each time we switch paths the weight of the current node decreases by at least a factor of two. We iterate over this set of paths to find the path that contains the answer u', and then use the binary search tree to find the location of u' in the path. Both steps take $\mathcal{O}(\log x)$ time. ◀

4.1 Linear space

As a warm-up we show a linear-space implementation of PrefixSearch that improves the runtime of dictionary look-up queries to $\mathcal{O}(m/w + \log^{k+1} d + occ)$. Formally, we will show the following result.

▶ **Theorem 10.** *Assume a constant-size alphabet. For a dictionary $\mathcal{D}$ of $d > 2$ strings of length m, there is a data structure for dictionary look-up with k mismatches that occupies $\mathcal{O}(wmd + wd \log^k d)$ bits of space and has query time $\mathcal{O}(m/w + \log^{k+1} d + occ)$, where $w = \Theta(\log md)$ is the size of a machine word.*

Let Suf be the set of all suffixes of the strings in $\mathcal{D}$. We build a compact trie $T(\text{Suf})$ on Suf. (In the literature, $T(\text{Suf})$ is referred to as the suffix tree of $\mathcal{D}$.) As the total length of the strings in $\mathcal{D}$ is md, the size of Suf is $\mathcal{O}(md)$, and therefore it occupies $\mathcal{O}(wmd)$ bits of space. We can reduce PrefixSearch queries on the tries of the k-errata tree to PrefixSearch queries on $T(\text{Suf})$. We distinguish between PrefixSearch queries that start at the root of some trie of the k-errata tree (*rooted* queries), and those that start at some inner node or even a position on an edge of a trie of the k-errata tree (*unrooted* queries). Note that unrooted queries are used in the case $k \geq 1$ only.

▶ **Lemma 11.** *After $\mathcal{O}(wmd + wd \log^k d)$ bits of space preprocessing, we can answer a rooted PrefixSearch query for a string Q and any trie of the k-errata tree in $\mathcal{O}(\log d)$ time given the answer to a rooted PrefixSearch for Q in $T(\text{Suf})$.*

▶ **Lemma 12.** *Assume $k \geq 1$. After $\mathcal{O}(wmd + wd \log^k d)$ bits of space preprocessing, we can reduce an unrooted PrefixSearch query for Q that starts at a position u of a trie τ of the k-errata tree to a rooted PrefixSearch for some suffix Q' of Q in a trie τ' of a $(k-1)$-errata tree in $\mathcal{O}(\log d)$ time given the answer to a rooted PrefixSearch query for Q in $T(\text{Suf})$.*

Lemmas 11 and 12 were proved in [13]. For completeness, we give their proofs in the full version of the paper. Suppose we are to answer a dictionary look-up with k mismatches for a string P. Our algorithm traverses the k-errata tree and generates rooted and unrooted PrefixSearch queries. We maintain a priority queue. Each time we need an answer to a PrefixSearch for a string S in $T(\mathrm{Suf})$, we add S to the priority queue. At each step of the algorithm we extract the longest string from the queue and answer the PrefixSearch query for it. Notice that all strings in the queue are suffixes of P and that the maximal length of strings in the queue cannot increase. We can therefore assume that we must answer PrefixSearch queries for the suffixes of P starting at positions $1 = i_1 \leq i_2 \leq \cdots \leq i_z$, where $z = \mathcal{O}(\log^k d)$.

Bille, Gørtz, and Skjoldjensen [5] showed that we can preprocess $T(\mathrm{Suf})$ in linear space to answer PrefixSearch queries for a single query string of length m in $\mathcal{O}(m/w + \log\log md)$ time. As an immediate corollary we obtain that we can answer z PrefixSearch queries in $z \cdot \mathcal{O}(m/w + \log\log md)$ time, but this is too slow for our purposes. Below we develop their ideas to give a more efficient approach.

▶ **Lemma 13.** *$T(\mathrm{Suf})$ can be preprocessed in $\mathcal{O}(wmd)$ bits of space to answer PrefixSearch for the suffixes of P starting at positions $1 = i_1 \leq i_2 \leq \cdots \leq i_z$ in $\mathcal{O}(m/w + z\log d)$ time.*

Proof. We assume that the strings in the dictionary are stored in the packed form. By construction, each edge of a trie of the k-errata is labelled by a substring of a dictionary string. It means that we can store each label as three integers: the id of the string, and the starting and the ending positions of the substring. Next, we preprocess $T(\mathrm{Suf})$ for weighted level ancestor queries (Lemma 9). A node or a position in the trie is called *boundary* if the length of its label is a multiple of $w/\log\sigma$, where w is the size of a machine word and σ is the size of the alphabet. Boundary nodes cut the tree into micro-trees. We only consider the micro-trees containing more than two nodes. We define the label of a leaf of a micro-tree as a machine word that contains a packed representation of the string written on the path from the root of the micro-tree to the leaf. The labels can be treated as integers; for each micro-tree we create a dictionary (Lemma 7) and a predecessor data structure on the labels of its leaves. We also preprocess each micro-tree for lowest common ancestors. Note that the total size of the micro-trees is $\mathcal{O}(md)$, as each edge of $T(\mathrm{Suf})$ contains at most two nodes of the micro-trees. Therefore, the preprocessing requires $\mathcal{O}(wmd)$ bits of space.

We now explain how to answer the PrefixSearch queries for the suffixes of P starting at the positions $1 = i_1 \leq i_2 \leq \cdots \leq i_z$. For i_1, we start at the root of $T(\mathrm{Suf})$. For i_j, $j > 1$, we use the information obtained at the previous step. Namely, suppose that the PrefixSearch for $P[i_{j-1}, m]$ terminated at a position labelled by $P[i_{j-1}, \ell_{j-1}]$. We take any leaf below this position, let it be labelled by a string $S \in \mathrm{Suf}$. Let $P[i_j, \ell'_{j-1}]$ be the longest prefix of $P[i_j, \ell_{j-1}]$ such that its length is a multiple of $w/\log\sigma$. We then start the PrefixSearch from a position u labelled by $P[i_j, \ell'_{j-1}]$. To find the position u, we first find the leaf labelled by $S[i_j - i_{j-1} + 1, |S|] \in \mathrm{Suf}$, and then use a weighted level ancestor query to jump to u in $\mathcal{O}(\log d)$ time. Notice that u is boundary. If u is not a root of a micro-tree, it has a single outgoing edge of length at least $w/\log\sigma$. We compare the first $w/\log\sigma$ letters of the label of this edge and $P[\ell'_{j-1} + 1, \ell'_{j-1} + w/\log\sigma]$ in $\mathcal{O}(1)$ time by comparing the corresponding machine words. If they are equal, we continue from the next boundary node on the edge in a similar manner. Otherwise, we find the first mismatch between the two strings in $\mathcal{O}(1)$ time as follows: First, compute a bitwise XOR of the two strings, and then locate the most significant bit using the technique of [19].

If u is the root of a micro-tree τ, we search for $P[\ell'_{j-1}+1, \ell'_{j-1}+w/\log\sigma]$ in the dictionary of τ. If it is in the dictionary and corresponds to a leaf v, we continue to v. Otherwise, we find its predecessor pred and successor succ using the predecessor data structure. The

PrefixSearch must terminate either on the path from u to the leaf of the micro-tree labelled by pred, or on the path from u to the leaf of the micro-tree labelled by succ. We compute the longest common prefix of $P[\ell'_{j-1}+1, \ell'_{j-1}+w/\log\sigma]$ with pred and with succ using bitvector operations in $\mathcal{O}(1)$ time as explained above, take the longest of the two, and find the position labelled by it in $\mathcal{O}(\log d)$ time using a weighted level ancestor query.

The running time of each prefix search query is proportional to the number of $(w/\log\sigma)$-length blocks of P that we compare with the labels of the edges of $T(\mathrm{Suf})$. Notice that each two different PrefixSearch queries share at most one block of letters. Therefore, as the size of the alphabet σ is constant, the total running time of z PrefixSearch queries is $\mathcal{O}(m/w + z\log d)$. ◀

Lemmas 4, 5, 11, 12, and 13 give Theorem 10.

4.2 Entropy-bounded space

In this section we improve the space requirements of our implementation of PrefixSearch and show the following theorem.

▶ **Theorem 14.** *Assume a constant-size alphabet. For a dictionary of $d > 2$ strings of lengths m and any $q = o(\log md)$, let H_q be the q-th empirical entropy of the concatenation of all the dictionary strings. There is a data structure for dictionary look-ups with k mismatches that uses $mdH_q + o(md) + \mathcal{O}(wd\log^k d)$ bits of space and has query time $\mathcal{O}(m/w + \log^{k+1} d + occ)$, where $w = \Theta(\log md)$ is the size of a machine word.*

There are two bottlenecks: First, we need to store the dictionary strings, and second, the tree structure of $T(\mathrm{Suf})$ requires $\Omega(md)$ space. To overcome the first bottleneck, we replace the packed representation of the dictionary strings by the Ferragina-Venturini representation:

▶ **Lemma 15** ([16])**.** *Under the assumption of an alphabet of constant size σ, for any $q = o(\log md)$ there exists a data structure that uses $mdH_q + o(md)$ bits of space and supports constant-time access to any $w/\log\sigma = \Theta(\log md)$-length substring of a dictionary string.*

If $d > 2$ is a constant, if suffices to store the Ferragina-Manzini representation of the dictionary strings to obtain the bounds of Theorem 14. Indeed, when a query string P arrives, we can decide if the Hamming distance between P and a dictionary string is at most k in $\mathcal{O}(m/w + k) = \mathcal{O}(m/w + \log^k d)$ time, using comparison by machine words and bitvector operations. As d is constant, we obtain the desired time bound. Below we assume that $d = \Omega(1)$.

We now deal with the second bottleneck. We will consider a smaller trie $T(\mathrm{Suf}')$ on a subset Suf' of Suf, and will show that PrefixSearch queries on tries of the k-errata tree can be reduced to PrefixSearch queries on this trie. Suf' is defined to be the set of all suffixes of the dictionary strings that start at positions $w\log d/\log\sigma$, $2w\log d/\log\sigma$, and so on. We call such suffixes *sampled*. Below we show that we can reduce PrefixSearch queries in the tries of the k-errata tree to PrefixSearch queries in $T(\mathrm{Suf}')$.

▶ **Lemma 16.** *After $\mathcal{O}(md/\log d + wd\log^k d)$ bits of space preprocessing, we can answer a rooted PrefixSearch query for a string $Q = P[\ell, m]$ in $\mathcal{O}(\log d)$ time given the answer to a rooted PrefixSearch query for a string $P[\ell', m]$ in $T(\mathrm{Suf}')$, where $\ell' \geq \ell$ is the smallest multiple of $w\log d/\log\sigma$.*

Proof. At the preprocessing step, we traverse $T(\mathrm{Suf}')$ and remember the leftmost and the rightmost leaves in each of its subtrees. We also remember the neighbours of each leaf in the left-to-right order, and finally we preprocess the trie for lowest common ancestor queries. As

a second step we preprocess each trie of the k-errata tree for lowest common ancestor and weighted level ancestor queries. We also build the following data structure for each trie of the k-errata tree. For each string S in the trie, let $S = pS'$, where S' is the longest sampled suffix of S. We call p a head of S, and define the rank of S to be the rank of S' in Suf'. We build a compact trie T_{heads} containing the heads of all the strings, and preprocess it as in Lemma 13. If T_{heads} contains x strings, we use $\mathcal{O}(wx)$ bits of space for the preprocessing, i.e. $\mathcal{O}(wd \log^k d)$ bits of space in total. We also associate a predecessor data structure with each of its leaves. The predecessor data structure of a leaf labelled by p contains the ranks of all the strings such that their head is equal to p. The predecessor data structures occupy $\mathcal{O}(wd \log^k d)$ bits of space in total as well.

Suppose we are to answer a rooted PrefixSearch query for a string $Q = P[\ell, m]$ and a trie τ of the k-errata tree. Let T_{heads} be the compact trie containing the heads of the strings in τ. By Fact 6, the length of the heads is $(\ell' - \ell)$. We first read $P[\ell, \ell' - 1]$ in blocks of $w/\log\sigma$ letters in $\mathcal{O}(\log d)$ time, and run a PrefixSearch for it in T_{heads} in $\mathcal{O}(\log d)$ time. If the PrefixSearch terminates in a position u of T_{heads} that is not in a leaf, it remains to find the position corresponding to u in τ, which we can do with one weighted level ancestor query.

Assume now that the PrefixSearch terminates in a leaf of T_{heads}. By the condition of the lemma, we know the answer to the rooted PrefixSearch for $P[\ell', m]$ in $T(\mathrm{Suf}')$. We also store the leftmost and the rightmost leaves in each subtree of $T(\mathrm{Suf}')$, and therefore can find the predecessor of $P[\ell', m]$ in Suf' in $\mathcal{O}(1)$ time. We use the predecessor data structure associated with the leaf to find the predecessor pred and successor succ of $P[\ell', m]$ in $\mathcal{O}(\log d)$ time. To find the position where the PrefixSearch for P terminates, we compute the lengths ℓ_p, ℓ_s of the longest common prefix of $P[\ell', m]$ and pred and of $P[\ell', m]$ and succ. We can compute the longest common prefix of $P[\ell', m]$ and pred (which is a sampled suffix of a dictionary string) in $\mathcal{O}(1)$ time via a lowest common ancestor query on $T(\mathrm{Suf}')$. We then compute ℓ_s in a similar way. If $\ell_p = \ell_s$, we return the lowest common ancestor of pred and succ as the answer. If $\ell_p > \ell_s$, then the answer is the ancestor of $P[\ell, \ell' - 1] \circ \mathsf{pred}$ such that the length of its label is $(\ell' - \ell) + \ell_p$, and we can find it by one weighted level ancestor query. The case $\ell_s > \ell_p$ is analogous. ◀

▶ **Lemma 17.** *Assume $k \geq 1$. After $\mathcal{O}(md/\log d + wd \log^k d)$ bits of space preprocessing, we can answer an unrooted PrefixSearch query for a string $Q = P[\ell, m]$ by reducing it to a rooted PrefixSearch query in $\mathcal{O}(\log d)$ time given the answer to a rooted PrefixSearch query for a string $P[\ell', m]$ in $T(\mathrm{Suf}')$, where $\ell' \geq \ell$ is the smallest multiple of $w \log d/\log\sigma$.*

Proof. During the preprocessing step, we preprocess $T(\mathrm{Suf}')$ for lowest common ancestor queries and each trie of the k-errata tree for weighted level ancestor queries. Let u be the position in a trie τ where we start the PrefixSearch for $P[\ell, m]$. The search path for $P[\ell, m]$ traverses a number of heavy paths. The first path is the path containing u. Let S be the label of the part of the path starting from u. We consider two cases. Suppose first that $\ell' = \ell$. In this case, S is a suffix of one of the dictionary strings starting at a position ℓ', i.e. it is sampled. Therefore, we can find the longest common prefix of $P[\ell', m]$ and S using one lowest common ancestor query on $T(\mathrm{Suf}')$. We can then find the node in the path corresponding to this longest common prefix using one weighted level ancestor query. From there, we can find the starting node of the second heavy path traversed by $P[\ell, m]$ in $\mathcal{O}(1)$ time. It remains to answer a rooted PrefixSearch query in the subtree rooted at this node, which is a trie of a $(k-1)$-errata tree by construction. When we know the answer for this PrefixSearch, we can go back to τ using one weighted level ancestor query. In the second case $\ell' > \ell$. We start by comparing $P[\ell + 1, m]$ and S by blocks of $w/\log\sigma$ letters until we reach the start of a sampled suffix, and then proceed as above. ◀

Suppose that we are to answer a dictionary look-up with k mismatches for a string P. Our algorithm traverses the k-errata tree and generates rooted PrefixSearch queries for the suffixes of P in $T(\mathrm{Suf}')$. We maintain a priority queue. Each time we need an answer to a rooted PrefixSearch for a suffix $Q = P[i, m]$ in $T(\mathrm{Suf}')$, we add Q to the priority queue. At each step we extract the longest string from the queue and answer the PrefixSearch query for it. Since the maximal length of suffixes in the queue cannot increase, we can assume that we must answer PrefixSearch queries for the suffixes of P starting at positions $i_1 \le i_2 \le \cdots \le i_z$, where $z = \mathcal{O}(\log^k d)$. Moreover, for each j the position i_j is a multiple of $w \log d / \log \sigma$. We preprocess $T(\mathrm{Suf}')$ as in Lemma 13, which requires $\mathcal{O}(md/\log d) = o(md)$ bits of space. We first run PrefixSearch for $P[i_1, m]$ in $\mathcal{O}(m/w)$ time. Suppose it follows the path labelled by $P[i_1, \ell_1]$. Let $S \in \mathrm{Suf}'$ be an arbitrary string that ends below the end of this path. We then find the leaf corresponding to $S[i_2 - i_1, |S|]$. By construction of $T(\mathrm{Suf}')$ and because $i_2 - i_1$ is a multiple of $w \log d / \log \sigma$, such a leaf must exist. We then use a weighted level ancestor query to find the end of the path labelled by $P[i_2, \ell_1']$, where $P[i_2, \ell_1']$ is the longest suffix of $P[i_2, \ell_1]$ such that its length is a multiple of $w/\log\sigma$, and continue the PrefixSearch for $P[i_2, m]$ from there, and so on. The total running time is $\mathcal{O}(m/w + z \log d) = \mathcal{O}(m/w + \log^{k+1} d)$.

If $d = \Omega(1)$ as we assumed earlier, lemmas 15, 16, 17, and the discussion above give Theorem 14.

5 Removing extra logarithm from the time complexity

In this section we improve the query time to $\mathcal{O}(m/w + \log^k d + occ)$ and show our final result.

▶ **Theorem 18.** *Assume a constant-size alphabet. For a dictionary of $d > 2$ strings of lengths m and for any $q = o(\log md)$, let H_q be the q-th empirical entropy of the concatenation of all strings in the dictionary. There exists a data structure for dictionary look-ups with k mismatches that uses $2mdH_q + o(md) + \mathcal{O}(wd \log^k d)$ bits of space and has query time $\mathcal{O}(m/w + \log^k d + occ)$, where $w = \Theta(\log md)$ is the size of a machine word.*

As explained in Theorem 14, we can assume $d = \Omega(1)$. Recall that the dictionary look-up with k mismatches is run recursively. The first $(k-2)$ levels of recursion require $\mathcal{O}(\log^{k-2} d)$ PrefixSearch queries and can be implemented in $\mathcal{O}(m/w + \log^{k-1} d)$ time. Therefore, it suffices to improve the runtime of the two last levels of the recursion, where we must perform a batch $\mathcal{O}(\log^{k-1} d)$ dictionary look-up queries with one mismatch. To achieve the desired complexity we use the fact that the queries are related, as explained below.

Preprocessing. For a string $S = s_1 s_2 \dots s_m$ we define its reverse $S^R = s_m \dots s_2 s_1$. First, we build a compact trie on the reverses of all the dictionary strings and preprocess it as described in Lemma 13, which takes $\mathcal{O}(wd)$ bits of space. We store the reverses using the Ferragina-Venturini representation (Lemma 15) in $H_q' md + o(md)$ bits of space, where H_q' is the q-th empirical entropy of the reverse of the concatenation of all the strings in the dictionary. By [15, Theorem A.3], $H_q' md + o(md) = H_q md + o(md)$. For the second step, we need Karp-Rabin fingerprints. We modify the standard definition as we work with packed strings.

▶ **Definition 19** (Karp-Rabin fingerprints [24])**.** Consider a string S and its packed representation $w_1 w_2 \dots w_z$, where each w_i is a machine word. (If $|S|$ is not a multiple of $w/\log\sigma$, we append an appropriate number of zeros.) The Karp–Rabin fingerprint of S is defined as $\varphi = \sum_{i=1}^{z} w_i \cdot r^{z-i} \bmod p$, where p is a fixed prime number and r is a randomly chosen integer in $[0, p-1]$.

From the definition it follows that if the strings are equal, their fingerprints are equal. Furthermore, it is well-known that for any $c > 3$ and $p > (\max\{m/w, d\log^k d\})^c$, the probability of two distinct strings of length $zw \leq \max\{m, wd\log^k d\}$ having the same fingerprint (*collision probability*) is less than $1/(\max\{m/w, d\log^k d\})^{c-1}$. Consider a trie τ of the k-errata tree. By definition, the lengths of the leaf labels in τ is at most m. From the bound on the collision probability it follows that we can choose p and r so that the fingerprints of the reverses of these labels are distinct. For each leaf of τ, we compute the Karp-Rabin fingerprint of the reverse of its label and add it to a dictionary (Lemma 7) associated with τ. Also, using the same p and r, we compute Karp-Rabin fingerprints corresponding to inner nodes of the tries of the k-errata tree. Namely, consider one of such nodes, and let S be its label and δ be the length of the strings in the trie. We take the reverse of S, prepend it with $(\delta - |S|) \bmod w/\log\sigma$ zeros, and compute the Karp-Rabin fingerprint of the resulting string.

Queries. We must run $\mathcal{O}(\log^{k-1} d)$ dictionary look-up queries with one mismatch. Consider one of these queries, let it be a query for a string Q (which must be a suffix of P) in a trie τ and recall the algorithm of Section 3. First, we run a PrefixSearch to find the longest path π that is labelled by a prefix of Q. For this step we can use $T(\mathrm{Suf}')$, as the total number of such queries is $\mathcal{O}(\log^{k-1} d)$ and therefore we can spend $\mathcal{O}(\log d)$ time per each of them. Suppose that π traverses the heavy paths $H_1, H_2, \ldots, H_j$ and leaves the heavy path H_i at a position u_i. We can find the positions u_j in $\mathcal{O}(\log d)$ time once we have found the end of π. The rest of the algorithm can be described as follows. First, we must perform dictionary look-ups with 0 mismatches (i.e., PrefixSearch) in $\mathcal{O}(\log d)$ vertical and $\mathcal{O}(\log d)$ horizontal 0-errata trees (that are tries of the k-errata tree by definition). Second, for each $1 \leq i < j$, we must perform a dictionary look-up with 0 mismatches (PrefixSearch) from a position u'_i that follows u_i in the heavy path H_i. Importantly, each u_i is a node. Finally, we must perform a a dictionary look-up with 0 mismatches (PrefixSearch) from a position u'_j that follows u_j in the heavy path H_j.

We note that to perform the PrefixSearch from the position u'_j we can use $T(\mathrm{Suf}')$, as before, because the total number of such PrefixSearch operations is $\mathcal{O}(\log^{k-1} d)$. We now explain how we perform the PrefixSearch operations in vertical and horizontal 0-errata trees, as well as the PrefixSearch operations from nodes u'_i, $1 \leq i < j$. In total, we must perform $\mathcal{O}(\log^k d)$ such operations, and for each of them the query string is a suffix of P. Let $P[i_1, m], P[i_2, m], \ldots, P[i_z, m]$, $z = \mathcal{O}(\log^k d)$ be the suffixes of P for which we are to run a PrefixSearch. We create a bitvector of length $m = o(md)$ where each i_j^{th} bit is set. We then compute the Karp-Rabin fingerprints of the reverses of $P[i_1, m], P[i_2, m], \ldots, P[i_z, m]$ in $\mathcal{O}(m/w + z)$ time using the following fact.

▶ **Fact 20.** *Given the Karp-Rabin fingerprints of X and Y, where the length of X is a multiple of $w/\log\sigma$, we can compute the Karp-Rabin fingerprint of their concatenation, XY in $\mathcal{O}(1)$ time.*

We iterate over all blocks of the bitvector starting from the last one and maintain the Karp-Rabin fingerprint of the reverse of the suffix of P that starts at the current position. When we start a new block, we update the Karp-Rabin fingerprint. If a block contains set bits (which we can decide in constant time), we extract the positions of all set bits in $\mathcal{O}(1)$ time per bit using the technique of [19], and compute the corresponding Karp-Rabin fingerprints. Also, as a preliminary step, we run a PrefixSearch for P^R in the compact trie on the reverses of the dictionary strings in $\mathcal{O}(m/w + \log d)$ time. Let u be the position where this PrefixSearch terminates.

PrefixSearch in vertical and horizontal 0-errata trees. Assume we must answer a PrefixSearch for $P[i_j, m]$ on a tree τ. We search the fingerprint of the reverse of $P[i_j, m]$ in the dictionary associated with τ. The search will return at most one leaf of the tree. We know that its label is equal to $P[i_j, m]$ with high probability, but we need a deterministic answer. We test the leaf as follows. Let S be one of the dictionary strings such that its id is stored at the leaf. We find the leaf v of the compact tree on the reverses of the dictionary strings that corresponds to the reverse S^R of S. Now, we can compute the length of the longest common prefix of P^R and S^R in constant time via a lowest common ancestor query for u and v and check if it is indeed equal or larger than $|P[i_j, m]|$.

PrefixSearch from u'_i, $1 \leq i < j$. This step is equivalent to the following: Find all the strings in the trie that start with a label of u'_i and end with a given suffix of P. We can compute the Karp-Rabin fingerprints of the reverses of the strings that we are looking for as follows. Positions u_i are necessarily nodes and we store the Karp-Rabin fingerprints of the reverses of their labels. Recall that if S_i was the label of u_i, we prepended the reverse S_i^R of S_i with $(\delta - |S|) \bmod w/\log\sigma$ zeros, where δ is the length of the strings in the trie containing u_i. It follows that we can compute the fingerprint φ_i of the reverse of the label of u'_i prepended with $(\delta - |S_i| - 1) \bmod w/\log\sigma$ zeros in $\mathcal{O}(1)$ time. Knowing φ_i and the fingerprint of the reverse of the suffix of P, we can compute the fingerprint of the strings we are searching for in constant time. We note that prepending with zeros is necessary in order to align the borders of the blocks in the reverse of the label of u'_i and the reverse of the label of the suffix of P. We finish the computation as above, that is we find a leaf such that the fingerprint of the reverse of its label is equal to the fingerprint of the strings we are looking for, and test it using the trie on the reverses of the dictionary strings.

Abstract

We study a family of generalizations of Edge Dominating Set on directed graphs called Directed (p, q)-Edge Dominating Set. In this problem an arc (u, v) is said to dominate itself, as well as all arcs which are at distance at most q *from* v, or at distance at most p *to* u.

First, we give significantly improved FPT algorithms for the two most important cases of the problem, $(0, 1)$-dEDS and $(1, 1)$-dEDS (that correspond to versions of Dominating Set on line graphs), as well as polynomial kernels. We also improve the best-known approximation for these cases from logarithmic to constant. In addition, we show that (p, q)-dEDS is FPT parameterized by $p + q + \mathrm{tw}$, but W-hard parameterized just by tw, where tw is the treewidth of the underlying graph of the input.

We then go on to focus on the complexity of the problem on tournaments. Here, we provide a complete classification for every possible fixed value of p, q, which shows that the problem exhibits a surprising behavior, including cases which are in P; cases which are solvable in quasi-polynomial time but not in P; and a single case ($p = q = 1$) which is NP-hard (under randomized reductions) and cannot be solved in sub-exponential time, under standard assumptions.

1 Introduction

Edge Dominating Set (EDS) is a classical graph problem, equivalent to Minimum Dominating Set on line graphs. Despite the problem's prominence, EDS has until recently received very little attention in the context of directed graphs. In this paper we investigate the complexity of a family of natural generalizations of this classical problem to digraphs, building upon recent work [22].

One of the reasons that EDS has not so far been well studied in digraphs is that there are several natural ways in which the undirected version can be generalized. For example, seeing as EDS is exactly Dominating Set in line graphs, one could define Directed EDS as (Directed) Dominating Set in line digraphs [23]. In this formulation, an arc (u, v) dominates all arcs (v, w); however (v, w) does not dominate (u, v). Another natural way to define the problem would be to consider Dominating Set on the underlying graph of the line digraph, so as to maximize the symmetry of the problem, while still taking into account the directions of arcs. In this formulation, (u, v) dominates arcs coming out of v and arcs coming into u, but not other arcs incident on u, v.

A unifying framework for studying such formulations was recently given in [22], which defined (p, q)-dEDS for any two non-negative integers p, q. In this setting, an arc (u, v) dominates every other arc which lies in a directed path of length at most q that begins at v, or lies in a directed path of length at most p that ends at u. In other words, (u, v) dominates arcs in the forward direction up to distance q, and in the backward direction up to distance p. The interest in defining the problem in such a general manner is that it allows us to capture at the same time Directed Dominating Set on line digraphs ($(0, 1)$-dEDS), Dominating Set on the underlying graph of the line digraph ($(1, 1)$-dEDS), as well as versions corresponding to r-Dominating Set in the line digraph. We thus obtain a family of optimization problems on digraphs, with varying degrees of symmetry, all of which crucially depend on the directions of arcs in the input digraph.

Our contribution. In this paper we advance the state of the art on the complexity of Directed (p, q)-Edge Dominating Set on two fronts.[3]

First, we study the complexity and approximability of the problem in general. The problem is NP-hard for all values of p, q (except $p = q = 0$), even for planar bounded-degree DAGs [22], so it makes sense to study its parameterized complexity and approximability. We show that its two most natural cases, $(1, 1)$-dEDS and $(0, 1)$-dEDS, admit FPT algorithms with running times 9^k and 2^k respectively, where k is the size of the optimal solution. These algorithms significantly improve upon the FPT algorithms given in [22], which uses the fact

[3] We note that in the remainder we always assume that $p \leq q$, as in the case where $p > q$ we can reverse the direction of all arcs and solve (q, p)-dEDS.

Table 2 Complexity status for various values of p and q: on tournaments.

Range of p, q	Complexity
$p = q = 1$	NP-hard [Thm. 13], FPT [Thm. 2], polynomial kernel [Thm. 7]
$p = 2$ or $q = 2$	Quasi-P-time [Thm. 25], W[2]-hard [Thm 24]
remaining cases	P-time [Thm. 26 and 27]

that the treewidth (of the underlying graph of the input) is at most $2k$ and runs dynamic programming over a tree-decomposition of width at most $10k$, obtained by the algorithm of [5]. The resulting running-time estimate for the algorithm of [22] is thus around 25^{10k}. Though both of our algorithms rely on standard branching techniques, we make use of several non-trivial ideas to obtain reasonable bases in their running times. We also show that both of these problems admit polynomial kernels. These are the only cases of the problem which may admit such kernels, since the problem is W-hard for all other values of p, q [22].

Furthermore, we give an 8-approximation for $(1, 1)$-dEDS and a 3-approximation for $(0, 1)$-dEDS. We recall that [22] showed an $O(\log n)$-approximation for general values of p, q, and a matching logarithmic lower bound for the case $\max\{p, q\} \geq 2$. Therefore our result completes the picture on the approximability of the problem by showing that the only two currently unclassified cases belong in APX.

Finally, we consider the problem's complexity parameterized by the treewidth of the underlying graph and show that, even though the problem is FPT when all of p, q, tw are parameters, it is in fact W[1]-hard if parameterized only by tw. (See Table 1).

Our second, and perhaps main contribution in this paper is an analysis of the complexity of the problem on tournaments, which are one of the most well-studied classes of digraphs (see Table 2). One of the reasons for focusing on this class is that the complexity of Dominating Set has a peculiar status on tournaments, as it is solvable in quasi-polynomial time, W[2]-hard, but neither in P nor NP-complete (under standard assumptions). Here we provide a *complete classification* of the problem which paints an even more surprising picture. We show that (p, q)-dEDS goes from being in P for $p + q \leq 1$; to being APX-hard and unsolvable in $2^{n^{1-\epsilon}}$ under the (randomized) ETH for $p = q = 1$; to being equivalent to Dominating Set on tournaments, hence NP-intermediate, quasi-polynomial-time solvable, and W[2]-hard, when one of p and q equals 2; and finally to being polynomial-time solvable again if $\max\{p, q\} \geq 3$ and neither p nor q equals 2. We find these results surprising, because few problems demonstrate such erratic complexity behavior when manipulating their parameters and because, even though in many cases the problem does seem to behave like Dominating Set, the fact that $(1, 1)$-dEDS becomes significantly harder shows that the problem has interesting complexity aspects of its own. The most technical part of this classification is the reduction that establishes the hardness of $(1, 1)$-dEDS, which makes use of several *randomized* tournament constructions, which we show satisfy certain desirable properties with high probability; as a result our reduction itself is randomized.

Due to space restrictions, some of our proofs are omitted here.

Related Work. On undirected graphs Edge Dominating Set, also known as Maximum Minimal Matching, is NP-complete even on bipartite, planar, bounded degree graphs as well as other special cases [34, 24]. It can be approximated within a factor of 2 [19] (or better in some special cases [8, 29, 2]), but not a factor better than 7/6 [9] unless P=NP. The problem has been the subject of intense study in the parameterized and exact algorithms community [32], producing a series of improved FPT algorithms [17, 3, 18, 30]; the current best is given in [25]. A kernel with $O(k^2)$ vertices and $O(k^3)$ edges is also known [21].

For (p, q)-dEDS, [22] shows the problem to be NP-complete on planar DAGs, in P on trees, and W[2]-hard and $c \ln k$-inapproximable on DAGs if $\max\{p, q\} > 1$. The same paper gives FPT algorithms for $\max\{p, q\} \leq 1$. Their algorithm performs DP on a tree-decomposition of width w in $O(25^w)$, and uses the fact that $w \leq 2k$, and the algorithm of [5] to obtain a decomposition of width $10k$.

Dominating Set is known not to admit an $o(\log n)$-approximation [12, 27], and to be W[2]-hard and unsolvable in time $n^{o(k)}$ under the ETH [13, 10]. The problem is significantly easier on tournaments, as the optimal is always at most $\log n$, hence there is a trivial $n^{O(\log n)}$ (quasi-polynomial)-time algorithm. It remains, however, W[2]-hard [14]. The problem thus finds itself in an intermediate space between P and NP, as it cannot have a polynomial-time algorithm unless FPT=W[2], and it cannot be NP-complete under the ETH (as it admits a quasi-polynomial time algorithm). The generalization of Dominating Set where vertices dominate their r-neighborhood has also been well-studied in general [7, 11, 15, 26]. This problem is much easier on tournaments for $r \geq 2$, as the size of the solution is always a constant [4].

2 Definitions and Preliminaries

Graphs and domination. We use standard graph-theoretic notation. If $G = (V, E)$ is a graph, $S \subseteq V$ a subset of vertices and $A \subseteq E$ a subset of edges, then $G[S]$ denotes the subgraph of G induced by S, while $G[A]$ denotes the subgraph of G that includes A and all its endpoints. We let $V = A \dot{\cup} B$ denote the disjoint set union of A and B. For a vertex $v \in V$, the set of neighbors of v in G is denoted by $N_G(v)$, or simply $N(v)$, and $N_G(S) := (\bigcup_{v \in S} N(v)) \setminus S$ will be written as $N(S)$. We define $N[v] := N(v) \cup \{v\}$ and $N[S] := N(S) \cup S$. Depending on the context, we use (u, v) for $u, v \in V$ to denote either an undirected edge connecting two vertices u, v, or an *arc* (a directed edge) with *tail* u and *head* v. An *incoming* (resp. *outgoing*) arc for vertex v is an arc whose head (resp. tail) is v.

In a directed graph $G = (V, E)$, the set of *out-neighbors* (resp.*in-neighbors*) of a vertex v is defined as $\{u \in V : (v, u) \in E\}$ (resp. $\{u \in V : (u, v) \in E\}$) and denoted as $N^+_G(v)$ (resp. $N^-_G(v)$). Similarly as for undirected graphs, $N^+(S)$ and $N^-(S)$ respectively stand for the sets $(\bigcup_{v \in S} N^+(v)) \setminus S$ and $(\bigcup_{v \in S} N^-(v)) \setminus S$. For a subdigraph H of G and subsets $S, T \subseteq V$, we let $\delta_H(S, T)$ denote the set of arcs in H whose tails are in S and heads are in T. We use $\delta^-_H(S)$ (resp. $\delta^+_H(S)$) to denote the set $\delta_H(V \setminus S, S)$ (resp. the set $\delta_H(S, V \setminus S)$). If S is a singleton consisting of a vertex v, we write $\delta^+_H(v)$ (resp. $\delta^-_H(v)$) instead of $\delta^+_H(\{v\})$ (resp. $\delta^-_H(\{v\})$). The *in-degree* $d^-_H(v)$ (respectively *out-degree* $d^+_H(v)$) of a vertex v is defined as $|\delta^-_H(v)|$ (resp. $|\delta^+_H(v)|$)), and we write $d_H(v)$ to denote $d^+_H(v) + d^-_H(v)$. We omit H if it is clear from the context. If H is $G[A]$ for some vertex or arc set of G, then we write A in place of $G[A]$. A *source* (resp. *sink*) is a vertex that has no incoming (resp. outgoing) arcs.

For integers $p, q \geq 0$, an arc $e = (u, v)$ is said to (p, q)-*dominate* itself, and all arcs that are on a directed path of length at most p to u or on a directed path of length at most q from v. The central problem in this paper is Directed (p, q)-Edge Dominating Set ((p, q)-dEDS): given a directed graph $G = (V, E)$, a positive integer k and two non-negative integers p, q, we are asked to determine whether an arc subset $K \subseteq E$ of size at most k exists, such that every arc is (p, q)-dominated by K (a (p, q)-*edge dominating set* of G).

Complexity background. We assume that the reader is familiar with the basic definitions of parameterized complexity, such as the classes FPT and W[1], as well as the Exponential Time Hypothesis (ETH, see [10]). For a problem P, we let OPT_P denote the value of its optimal solution. We also make use of standard graph width measures, such as *vertex cover number* vc, *treewidth* tw and *pathwidth* pw [10].

Tournaments. A *tournament* is a directed graph in which every pair of distinct vertices is connected by a single arc. Given a tournament T, we denote by T^{rev} the tournament obtained from T by reversing the direction of every arc. Every tournament has a *king* (sometimes also called a 2-king), i.e. a vertex from which every other vertex can be reached by a path of length at most 2. One such king is the vertex of maximum out-degree (see e.g. [4]). It is folklore that any tournament contains a *Hamiltonian path*, i.e. a directed path that uses every vertex. The Dominating Set problem can be solved by brute force in time $n^{O(\log n)}$ on tournaments, by the following lemma:

▶ **Lemma 1** ([10]). *Every tournament on n vertices has a dominating set of size $\leq \log n + 1$.*

3 Tractability

3.1 FPT algorithms

In this section, we present FPT branching algorithms for $(0,1)$-dEDS and $(1,1)$-dEDS. Both algorithms operate along similar lines, taking into consideration the particular ways available for domination of each arc.

▶ **Theorem 2.** *The $(1,1)$-d*EDS *problem parameterized by solution size k can be solved in time $O^*(9^k)$.*

Proof. We present an algorithm that works in two phases. In the first phase we perform a branching procedure which aims to locate vertices with positive out-degree or in-degree in the solution. The general approach of this procedure is standard (as long as there is an uncovered arc, we consider all ways in which it may be covered), and uses the fact that at most $2k$ vertices have positive in- or out-degree in the solution. However, in order to speed up the algorithm, we use a more sophisticated branching procedure which picks an endpoint of the current arc (u,v) and *completely guesses* its behavior in the solution. This ensures that this vertex will never be branched on again in the future. Once all arcs of the graph are covered, we perform a second phase, which runs in polynomial time, and by using a maximum matching algorithm finds the best solution corresponding to the current branch.

Let us now describe the branching phase of our algorithm. We construct three sets of vertices V^+, V^-, V^{+-}. The meaning of these sets is that when we place a vertex u in V^+, V^-, or V^{+-} we guess that u has (i) positive out-degree and zero in-degree in the optimal solution; (ii) positive in-degree and zero out-degree in the optimal solution; (iii) positive in-degree and positive out-degree in the optimal solution, respectively. Initially all three sets are empty. When the algorithm places a vertex in one of these sets we say that the vertex has been *marked*.

Our algorithm now proceeds as follows: given a graph $G(V,E)$ and three disjoint sets V^+, V^-, V^{+-} we do the following:

1. If $|V^+| + |V^-| + 2|V^{+-}| > 2k$, reject.
2. While there exists an arc (u,v) with both endpoints unmarked do the following and return the best solution:
   a. Call the algorithm with $V^+ := V^+ \cup \{v\}$ and other sets unchanged.
   b. Call the algorithm with $V^{+-} := V^{+-} \cup \{v\}$ and other sets unchanged.
   c. Call the algorithm with $V^- := V^- \cup \{u\}$ and other sets unchanged.
   d. Call the algorithm with $V^{+-} := V^{+-} \cup \{u\}$ and other sets unchanged.
   e. Call the algorithm with $V^+ := V^+ \cup \{u\}$, $V^- := V^- \cup \{v\}$, and V^{+-} unchanged.

It is not hard to see that Step 1 is correct as as $|V^+| + |V^-| + 2|V^{+-}|$ is a lower bound on the sum of the degrees of all vertices in the optimal and therefore cannot surpass $2k$.

Branching Step 2 is also correct: in order to cover (u, v) the optimal solution must either take an arc coming out of v (2a,2b), or an arc coming into u (2c,2d), or, if none of the previous cases apply, it must take the arc itself (2e).

Once we have applied the above procedure exhaustively, all arcs of the graph have at least one marked endpoint. We say that an arc (u, v) with $u \in V^- \cup V^{+-}$, or with $v \in V^+ \cup V^{+-}$ is covered. We now check if the graph contains an uncovered arc (u, v) with exactly one marked endpoint. We then branch by considering all possibilities for its other endpoint. More precisely, if $u \in V^+$ and v is unmarked, we branch into three cases, where v is placed in V^+, or V^-, or V^{+-} (and similarly if v is the marked endpoint). This branching step is also correct, since the degree specification for the currently marked endpoint does not dominate the arc (u, v), hence any feasible solution must take an arc incident on the other endpoint.

Once the above procedure is also applied exhaustively we have a graph where all arcs either have both endpoints marked, or have one endpoint marked but in a way that if we respect the degree specifications the arc is guaranteed to be covered. What remains is to find the best solution that agrees with the specifications of the sets V^+, V^-, V^{+-}.

We first add to our solution S all arcs $\delta(V^+, V^-)$, i.e. all arcs (u, v) such that $u \in V^+$ and $v \in V^-$, since there is no other way to dominate these arcs. We then define a bipartite graph $H = (V^+ \cup V^{+-}, V^- \cup V^{+-}, \delta(V^+ \cup V^{+-}, V^- \cup V^{+-}))$. That is, H contains all vertices in V^+ along with a copy of V^{+-} on one side, all vertices of V^- and a copy of V^{+-} on the other side and all arcs in E with tails in $V^+ \cup V^{+-}$ and heads in $V^- \cup V^{+-}$. We now compute a minimum edge cover of this graph, that is, a minimum set of edges that touches every vertex. This can be done in polynomial time by finding a maximum matching and then adding an arbitrary incident edge for each unmatched vertex. It is not hard to see that a minimum edge cover of this graph corresponds exactly to the smallest $(1, 1)$ edge dominating set that satisfies the specifications of the sets V^+, V^-, V^{+-}.

To see that the running time of our algorithm is $O^*(9^k)$ we observe that there are two branching steps: either we have an arc (u, v) with both endpoints unmarked; or we have an arc with exactly one unmarked endpoint. In both cases we measure the decrease of the quantity $\ell := 2k - (|V^+| + |V^-| + |V^{+-}|)$. The first case produces two instances with $\ell' := \ell - 1$ (2a,2c), and three instances with $\ell' := \ell - 2$. We therefore have the recurrence $T(\ell) \leq 2T(\ell - 1) + 3T(\ell - 2)$ which gives $T(\ell) \leq 3^\ell$. For the second case, we have three branches, all of which decrease ℓ, therefore we also have $T(\ell) \leq 3^\ell$ in this case. Taking into account that, initially $\ell = 2k$ we get a running time of at most $O^*(9^k)$. ◀

▶ **Theorem 3.** *The* $(0, 1)$*-d*EDS *problem parameterized by solution size* k *can be solved in time* $O^*(2^k)$.

3.2 Approximation algorithms

We present here constant-factor approximation algorithms for $(0, 1)$-dEDS, and $(1, 1)$-dEDS. Both algorithms appropriately utilize a maximal matching.

▶ **Theorem 4.** *There are polynomial-time* 3*-approximation algorithms for* $(0, 1)$*-d*EDS.

▶ **Theorem 5.** *There is a polynomial-time* 8*-approximation algorithm for* $(1, 1)$*-d*EDS.

Proof. Let $G = (V, E)$ be an input directed graph. We partition V into (S, R, T) so that S and T are the sets of sources and sinks respectively, and $R = V \setminus S \setminus T$. We construct an $(1, 1)$-edge dominating set K as follows.

1. Add the arc set $\delta(S,T)$ to K.
2. For each vertex of $v \in R \cap N^+(S)$, choose precisely one arc from $\delta^+(v)$ and add it to K.
3. For each vertex of $v \in R \cap N^-(T)$, choose precisely one arc from $\delta^-(v)$ and add it to K.
4. Let $G' = (R, E')$ be the subdigraph of G whose arc set consists of those arcs not $(1,1)$-dominated by K thus far constructed. Let M be a maximal matching in (the underlying graph of) G'. Let M^- and M^+ be respectively the tails and heads of the arcs in M. To K, we add all arcs of M, an arc of $\delta^-_G(v)$ for every $v \in M^-$, and also an arc of $\delta^+_G(v)$ for every $v \in M^+$.

Clearly, the algorithm runs in polynomial time. In particular, for any vertex v considered at Step 2-4, both $\delta^+(v)$ and $\delta^-(v)$ are non-empty and choosing an arc from a designated set is always possible. We show that K is indeed an $(1,1)$-edge dominating set. Suppose that an arc (u,v) is not $(1,1)$-dominated by K. As the first, second and third step of the construction ensures that any arc incident with $S \cup T$ is $(1,1)$-dominated, we know that (u,v) is contained in the subdigraph G' constructed at step 4. For $(u,v) \notin M$ and M being a maximal matching, one of the vertices u, v must be incident with M. Without loss of generality, we assume v is incident with M (and the other cases are symmetric). If $v \in M^-$, then clearly the arc $e \in M$ whose tail coincides with v would $(1,0)$-dominate (u,v), a contradiction. If $v \in M^+$, then the outgoing arc of v added to K at step 4 would $(1,0)$-dominate (u,v), again reaching a contradiction. Therefore, the constructed set K is a solution to $(1,1)$-dEDS.

To prove the claimed approximation ratio, we first note that $\delta(S,T)$ is contained in any (optimal) solution because any arc of $\delta(S,T)$ can be $(1,1)$-dominated only by itself. Note that these arcs do not $(1,1)$-dominate any other arcs of G. Further, we have $|R \cap N^+(S)| \leq OPT_{(1,1)dEDS} - |\delta(S,T)|$ because in order to $(1,1)$-dominate any arc of the form (s,r) with $s \in S$ and $r \in R$, one must take at least one arc from $\{(s,r)\} \cup \delta^+(r)$. Since the collection of sets $\{(s,r) : s \in S\} \cup \delta^+(r)$ are disjoint over all $r \in R \cap N^+(S)$, the inequality holds. Likewise, it holds that $|R \cap N^-(T)| \leq OPT_{(1,1)dEDS} - |\delta(S,T)|$. In order to $(1,1)$-dominate the entire arc set M, one needs to take at least $|M|/2$ arcs. This is because an arc e can $(1,1)$-dominate at most two arcs of M. That is, we have $|M|/2 \leq OPT_{(1,1)dEDS} - |\delta(S,T)|$ Therefore, it is $|K| \leq |\delta(S,T)| + |R \cap N^+(S)| + |R \cap N^-(T)| + 3|M| \leq 8OPT_{(1,1)dEDS}$. ◀

3.3 Polynomial kernels

We give polynomial kernels for $(1,1)$-dEDS and $(0,1)$-dEDS. We first introduce a relation between the vertex cover number and the size of a minimum $(1,1)$-edge dominating set, shown in [22] and then proceed to show a quadratic-vertex/cubic-edge kernel for $(1,1)$-dEDS.

▶ **Lemma 6** ([22]). *Given a directed graph G, let G^* be the undirected underlying graph of G, $vc(G^*)$ be the vertex cover number of G^*, and K be a minimum $(1,1)$-edge dominating set in G. Then $vc(G^*) \leq 2|K|$.*

▶ **Theorem 7.** *There exists an $O(k^2)$-vertex/$O(k^3)$-edge kernel for $(1,1)$-dEDS.*

Proof. Given a directed graph G, we denote the underlying undirected graph of G by G^*. Let K be a minimum $(1,1)$-edge dominating set and $\mathrm{vc}(G^*)$ be the size of a minimum vertex cover in G^*. First, we find a maximal matching M in G^*. If $|M| > 2k$, we conclude this is a no-instance by Lemma 6 and the well-known fact that $|M| \leq \mathrm{vc}(G^*)$ [20]. Otherwise, let S be the set of endpoints of edges in M. Then S is a vertex cover of size at most $4k$ for the underlying undirected graph of G and $V \setminus S$ is an independent set.

We next explain the reduction step. For each $v \in S$, we arbitrarily mark the first $k+1$ tail vertices of incoming arcs of v with "in" (or all, if the in-degree of v is $\leq k$) and also arbitrarily the first $k+1$ head vertices of outgoing arcs of v with "out" (or all, if the out-degree of v is

$\leq k$). After this marking, if there exists a vertex $u \in V \setminus S$ without marks "in", "out", we can delete it. We next show correctness. First, we can observe that if some $v \in S$ has more than $k+1$ incoming arcs, they must be dominated by an outgoing arc of v. Similarly, if $v \in S$ has more than $k+1$ outgoing arcs, they must be dominated by an incoming arc of v. This means that every arc incident on an unmarked vertex u must be dominated because each vertex v in S adjacent to u has at least $(k+1)$ incoming arcs other than (u, v), or $(k+1)$ outgoing arcs other than (v, u), due to the fact that u is unmarked. Moreover, for an incoming (resp. outgoing) arc of u, there exists an outgoing (resp. incoming) arc of $v \in S$ that dominates all arcs dominated by the incoming (resp. outgoing) arc of u except for arcs incident on u. Thus we need not include any arc incident on u in the solution. By the reduction step, we obtain the reduced graph.

From the above, the size of an independent set, being the subset of $V \setminus S$, is bounded by $4k \cdot 2(k+1) = 8k^2 + 8k$, following the reduction step. Thus, the number of vertices in the reduced graph is at most $4k + 8k^2 + 8k = 8k^2 + 12k$. Moreover, there exist at most $4k \cdot (8k^2 + 12k) = 32k^3 + 48k^2$ arcs between the sets of the vertex cover and the independent set. Therefore, the number of arcs in the reduced graph is at most $\binom{4k}{2} + 32k^3 + 48k^2 = 32k^3 + 56k^2 - 2k$. ◀

Using a more strict relation between vc and the size of a minimum $(0,1)$-edge dominating set, we obtain a linear-vertex/quadratic-edge kernel for $(0,1)$-dEDS.

▶ **Theorem 8.** *There exists an $O(k)$-vertex/$O(k^2)$-edge kernel for $(0,1)$-d*EDS*.*

4 W[1]-hardness by treewidth

In this section we characterize the complexity of (p,q)-dEDS parameterized by treewidth. Our main result is that, even though the problem is FPT when parameterized by $p+q+\mathrm{tw}$, it becomes W[1]-hard if parameterized only by tw. The algorithm is based on standard dynamic programming techniques, while for hardness we reduce from the k-Multicolored Clique problem, which is defined as follows: given a graph $G = (V, E)$, with V partitioned into k independent sets $V = V_1 \uplus \cdots \uplus V_k$, $|V_i| = n, \forall i \in [1,k]$, we are asked to find a subset $S \subseteq V$, such that $G[S]$ forms a clique with $|S \cap V_i| = 1, \forall i \in [1,k]$. The problem k-Multicolored Clique is well-known to be W[1]-complete [16].

Construction. Given an instance $[G = (V, E), k]$ of k-Multicolored Clique, with $V = \bigcup_{\forall i \in [1,k]} V_i$ and $V_i = \{v_0^i, \ldots, v_{n-1}^i\}$ we will construct an instance $[G' = (V', E'), \mathrm{tw}(G')]$ of (p,q)-dEDS parameterized by the treewidth of the underlying undirected graph, with $p = q = 2n$, as follows. We first make k *main cycles* on n vertices $V_i' = \{u_0^i, \ldots, u_{n-1}^i\}$, $\forall i \in [1,k]$, each corresponding to a set $V_i \subseteq V$ and we associate each vertex $v_l^i \in V_i$ with the arc (u_l^i, u_{l+1}^i) from cycle V_i' (its *corresponding* arc). Let $\bar{E}$ be the set of *non-edges* between vertices from different sets from G, i.e. the set of all pairs $(v_l^i, v_o^j) \notin E$.

For each $(v_l^i, v_o^j) \in \bar{E}$ with $i < j$, we will create the following *cross-gadget* $\hat{C}_{l,o}^{i,j}$: we first make five new vertices $a_{l,o}^{i,j}$, $b_{l,o}^{i,j}$, $c_{l,o}^{i,j}$, $d_{l,o}^{i,j}$ and $e_{l,o}^{i,j}$ and then add arcs from $a_{l,o}^{i,j}$ and $c_{l,o}^{i,j}$ to $e_{l,o}^{i,j}$ and from $e_{l,o}^{i,j}$ to $b_{l,o}^{i,j}$ and $d_{l,o}^{i,j}$. We let set $Q_{l,o}^{i,j}$ contain all four of these arcs and refer to them as the *cross-arcs*. We also add both arcs between $a_{l,o}^{i,j}$ and $c_{l,o}^{i,j}$, as well as both arcs between $b_{l,o}^{i,j}$ and $d_{l,o}^{i,j}$. These are referred to as the *flip-arcs*. Finally, we add a path of length $4n-2$ from $b_{l,o}^{i,j}$ to $a_{l,o}^{i,j}$ and a path of length $4n-2$ from $d_{l,o}^{i,j}$ to $c_{l,o}^{i,j}$ (on $4n-3$ new vertices each). We call these the *long paths*.

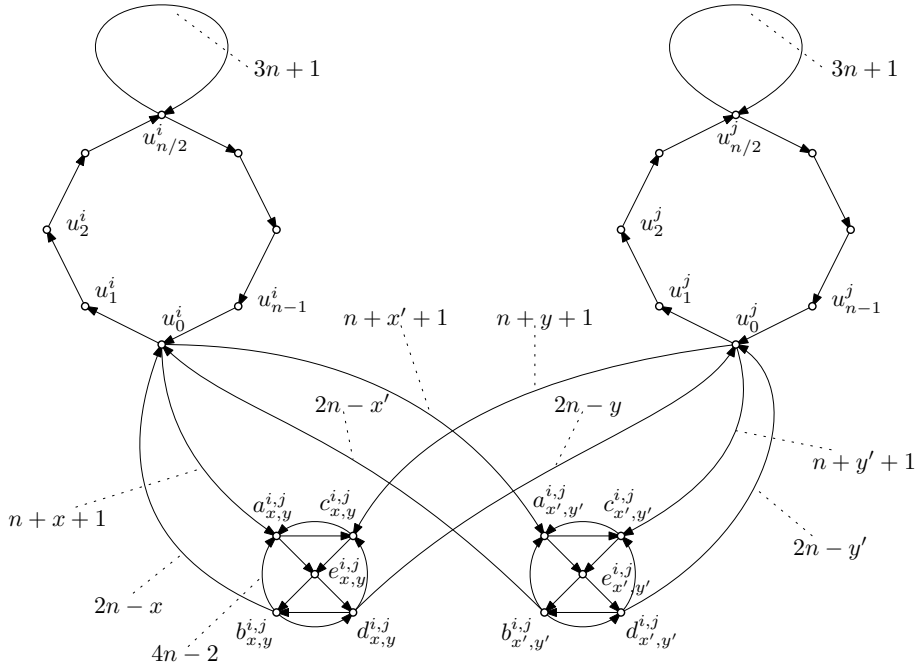

Figure 1 An example of our construction (even n). Dotted lines show the length of each path.

To connect each gadget to the main cycles, we then add a path of length $n+l+1$ (with $n+l$ new vertices) from u^i_0 to $a^{i,j}_{l,o}$ and a path of length $2n-l$ (with $2n-l-1$ new vertices) from $b^{i,j}_{l,o}$ to u^i_0. We also add a path of length $n+o+1$ from u^j_0 to $c^{i,j}_{l,o}$ and a path of length $2n-o$ from $d^{i,j}_{l,o}$ to u^j_0.

Finally, in order to ensure any $(2n, 2n)$-edge dominating set will select at least one arc from each of the k main cycles, we will attach a *guard cycle* to each *middle* vertex of each V'_i: the middle vertex of V'_i is $u^i_{n/2}$ and we attach a cycle of length $3n+1$ to it.[4] This concludes our construction and Figure 1 provides an illustration. Clearly, the construction requires polynomial time.

▶ **Lemma 9.** *If G has a k-multicolored clique of size k, then G' has a $(2n, 2n)$-edge dominating set of size $|\bar{E}| + k$.*

▶ **Lemma 10.** *If G' has a $(2n, 2n)$-edge dominating set of size $|\bar{E}| + k$, then G has a k-multicolored clique of size k.*

▶ **Theorem 11.** *The (p, q)-dEDS problem is W[1]-hard parameterized by the treewidth of the input graph.*

▶ **Theorem 12.** *The (p, q)-dEDS problem can be solved in time $O^*((p+q)^{O(tw)})$ on graphs of treewidth at most tw.*

Proof (Sketch). The proof relies on standard techniques (Dynamic Programming over tree decompositions), so we only sketch the details here. Our algorithm maintains a table for each node of the given tree decomposition, indexed by a set of *state-assignments* to all vertices in

[4] We assume, without loss of generality, that n is even as we can always add a dummy vertex to each subset V_i.

the bag, each entry of which contains the minimum number of selected arcs from the node's terminal subgraph for the state of each vertex to be justified, i.e. for the partial solution described by this set of states to be valid. The state of each vertex in the bag describes its distance to the closest endpoint of a selected arc, i.e. it either has a path of length at most p to the tail of a selected arc, or the head of a selected arc has a path of length at most q to the vertex in question. We also use "promise" states signifying that the partial solution has not yet selected the arc that will be closest to some vertex, by doubling the amount of states we use. It is not hard to see that using such a state representation, we can compute the values of all partial solutions for the problem over the nodes of the tree decomposition in time polynomial on the table's size: the states of introduced vertices must match the distances in the node's subgraph, all partial solutions involving a forgotten vertex must be compared over all its states to retain the minimum, while for join nodes, the state of a vertex must match the "promise" state for the same vertex in the other branch of the join for the partial solutions to be accurately extended. In this way we can check the values of potential global solutions in the table of the root node of the tree decomposition. ◀

5 On Tournaments

A complete complexity classification for the problems (p, q)-dEDS is presented in this section. For $p = q = 1$, the problem is NP-hard under a randomized reduction while being amenable to an FPT algorithm and polynomial kernelization due to the results of Sections 3.1 and 3.3. The hardness reduction is given in Subsection 5.1. When $p = 2$ or $q = 2$, the complexity status of (p, q)-dEDS is equivalent to Dominating Set on tournaments and is discussed in Subsection 5.2. In the remaining cases, when $p + q \leq 1$, or $\max\{p, q\} \geq 3$ while neither of them equals 2, the problems turn out to be in P (Subsection 5.3).

5.1 Hard: when $p = q = 1$

We present a randomized reduction from Independent Set to $(1, 1)$-dEDS. Our reduction preserves the size of the instance up to polylogarithmic factors; as a result it shows that $(1, 1)$-dEDS does not admit a $2^{n^{1-\epsilon}}$ algorithm, under the randomized ETH. Furthermore, our reduction preserves the optimal value, up to a factor $(1 - o(1))$; as a result, it shows that $(1, 1)$-dEDS is APX-hard under randomized reductions.

Before moving on, let us give a high-level overview of our reduction. The first step is to reduce Independent Set to Almost Induced Matching, the problem of finding the maximum set of vertices that induce a graph of maximum degree 1. Our reduction produces an instance of Almost Induced Matching that has several special properties, notably producing a bipartite graph $G = (A, B, E)$. The basic strategy will be then to construct a tournament $T = (V', E')$, where $V' = A \cup B \cup C$, where C is a set of new vertices. All edges of E will be directed from A to B, non-edges of E will be directed from B to A, and all other edges will be set randomly. This intuitively encodes the structure of G in T. The idea is now that a solution S in G (that is, a set of vertices of G that induces a graph with maximum degree 1) will correspond to an edge dominating set in T where all vertices except those of S will have total degree 2, and the vertices of S will have total degree 1. In particular, vertices of $S \cap A$ will have out-degree 1 and in-degree 0, and vertices of $S \cap B$ will have in-degree 1 and out-degree 0.

The random structure of the remaining arcs of the tournament T is useful in two respects: in one direction, given the solution S for G, it is easy to deal with vertices that have degree 1 in $G[S]$: we select the corresponding arc from A to B in T. For vertices of degree 0 however,

we are forced to look for edge-disjoint paths that will allow us to achieve our degree goals. Such paths are guaranteed to exist if C is random and large enough. In the other direction, given a good solution in T, we would like to guarantee that, because the internal structure of A, B, and C is chaotic, the only way to obtain a large number of vertices with low degree is to place those with in-degree 0 in A, and those with out-degree 0 in B.

▶ **Theorem 13.** $(1,1)$-dEDS *on tournaments cannot be solved in polynomial time, unless* $NP \subseteq BPP$. *Furthermore,* $(1,1)$-dEDS *is APX-hard under randomized reductions, and does not admit an algorithm running in time* $2^{n^{1-\epsilon}}$ *for any* ϵ, *unless the randomized ETH is false.*

We first reduce the Independent Set problem on cubic graphs to the following intermediate problem called Almost Induced Matching, commonly known as Maximum Dissociation Number in the literature [33, 31]. A subgraph of G induced on a vertex set $S \subseteq V$ is called an *almost induced matching*, if every vertex $v \in S$ has degree ≤ 1 in $G[S]$.

▶ **Definition 14.** The problem Almost Induced Matching (AIM) takes as input an undirected graph $G = (V, E)$. The goal is to find an almost induced matching having the maximum number of vertices.

▶ **Theorem 15.** *[1, 10]* Independent Set *is APX-hard on cubic graphs. Furthermore,* Independent Set *cannot be solved in time* $2^{o(n)}$ *unless the ETH is false.*

Almost Induced Matching is known to be NP-complete on bipartite graphs of maximum degree 3 and on C_4-free bipartite graphs [6]. It is also NP-hard to approximate on arbitrary graphs within a factor of $n^{1/2-\epsilon}$ for any $\epsilon > 0$ [28]. The next lemma supplements the known hardness results on bipartite graphs and might be of independent interest.

▶ **Lemma 16.** Almost Induced Matching *is APX-hard and cannot be solved in time* $2^{o(n)}$ *under the ETH, even on bipartite graphs of degree at most 4. Furthermore, this hardness still holds if we are promised that* $OPT_{AIM} > 0.6n$ *and that there is an optimal solution* S *that includes at least* $n/20$ *vertices with degree* 0 *in* $G[S]$.

As we use a random construction, the following property of a uniform random tournament is useful. Intuitively, the property established in Lemma 17 states that it is impossible in a large random tournament to have two large sets of vertices X, Y such that all vertices of X have in-degree 0 and out-degree 1 in a $(1,1)$-edge dominating set, while all vertices of Y have in-degree 1 and out-degree 0.

▶ **Lemma 17.** *Let* $T = (V, E)$ *be a random tournament on the vertex set* $\{1, 2, \ldots, n\}$, *in which* (i, j) *is an arc of* T *with probability* $1/2$. *Then the following event happens with high probability: for any two disjoint sets* $X, Y \subseteq V$ *with* $|X| > (\log n)^2$ *and* $|Y| > (\log n)^2$, *there exists a vertex* $x \in X$ *with at least two outgoing arcs to* Y.

▶ **Lemma 18.** *Let* $G = (V = A \dot\cup B \dot\cup C, E)$ *be a random directed graph with* $|A| = |B| = n$ *and* $|C| = 4n$ *such that for any pair* (x, y) *with* $\{x, y\} \cap C \neq \emptyset$ *we have exactly one arc, oriented from* x *to* y, *or from* y *to* x *with probability* $1/2$. *Let* $\ell \geq n/20$ *be a positive integer. Then with high probability, we have: for any two disjoint sets* $X \subseteq A$,$Y \subseteq B$ *with* $|X| = |Y| = \ell$, *there exist* ℓ *vertex-disjoint directed paths from* X *to* Y.

▶ **Theorem 19.** *There is a probabilistic polynomial-time algorithm computing, given an instance* G *of* Almost Induced Matching, *an instance* T *of* $(1,1)$-dEDS *such that with high probability:*

(i) *if* $OPT_{AIM}(G) \geq L_1$, *then* $OPT_{(1,1)dEDS}(T) \leq |V(T)| - L_1/2 + 1$,
(ii) *if* $OPT_{AIM}(G) < L_2 - 5(\log L_2)^2$, *then* $OPT_{(1,1)dEDS}(T) > |V(T)| - L_2/2 + 1$.

Proof of Theorem 13. Let G be an instance of Independent Set on cubic graphs and let G' be the instance of Almost Induced Matching obtained by the construction of Lemma 16. We set ℓ as in the reduction and observe that $OPT_{IS}(G) \geq k$ if and only if $OPT_{AIM}(G') \geq \ell$.

Let G^* be a disjoint union of $10(\log \ell)^2$ copies of G'. Then G^* is a gap instance, whose optimal solution is either at least $10\ell(\log \ell)^2$, or at most $10\ell(\log \ell)^2 - 10(\log \ell)^2 \leq L - 5(\log L)^2$, where $L := 10\ell(\log \ell)^2$. Now Theorem 19 implies that using a probabilistic polynomial-time algorithm for $(1,1)$-dEDS with two-sided bounded errors, one can correctly decide an instance of Independent Set on cubic graphs with bounded errors. We observe that the size of the instance has only increased by a poly-logarithmic factor, hence an algorithm solving the new instance in time $2^{n^{1-\epsilon}}$ would give a randomized sub-exponential time algorithm for 3-SAT.

Finally, for APX-hardness, we observe that we may assume we start our reduction from an Independent Set instance where either $OPT_{IS} \geq k$ or $OPT_{IS} < rk$, for some constant $r < 1$, and for $k = \Theta(n)$. Lemma 16 then gives an instance of Almost Induced Matching where either $OPT_{AIM} \geq L_1$ or $OPT_{AIM} \leq r'L_1 = L_2$, for some (other) constant $r' < 1$. We now use Theorem 19 to create a gap-instance of $(1,1)$-dEDS. ◀

5.2 Equivalent to Dominating Set on tournaments: $p = 2$ or $q = 2$

▶ **Lemma 20.** *On tournaments without a source, we have $OPT_{(0,2)dEDS} \leq OPT_{DS}$.*

Proof. Let $T = (V, E)$ be a tournament with no source and $D \subseteq V$ be a dominating set of T. Then let $K \subseteq E$ be a set containing one arbitrary incoming arc of every vertex in D. We claim K $(0,2)$-dominates all arcs in E: since D is a dominating set, for any vertex $u \notin D$ there must be an arc (v,u) from some $v \in D$. Thus all outgoing arcs (u,w) from such $u \notin D$ are $(0,2)$-dominated by K, as are all arcs (v,u) from $v \in D$. ◀

▶ **Lemma 21.** *Let $T = (V, E)$ be a tournament and let s be a source of T. Then $\delta^+(s)$ is an optimal (p,q)-edge dominating set of T for any $p \leq 1$ and $q \geq 1$.*

Proof. Since s has no incoming arcs, any (p,q)-edge dominating set must select at least one arc from $\{(s,v)\} \cup \delta^+(v)$ for every $v \in V \setminus \{s\}$ in order to (p,q)-dominate (s,v). Because the arc sets $\{(s,v)\} \cup \delta^+(v)$ are mutually disjoint over all $v \in V \setminus \{s\}$, any (p,q)-edge dominating set has size at least $|\delta^+(s)|$. Now, observe that $\delta^+(s)$ $(0,1)$-dominates every arc of T. ◀

▶ **Lemma 22.** *On tournaments on n vertices, for any $p \geq 2$ we have: $OPT_{(p,2)dEDS} \leq OPT_{(2,2)dEDS} \leq 2\log n + 3$.*

Proof. The first inequality trivially holds, so we prove the second inequality. Let $T = (V, E)$ be a tournament on n vertices. If T has no source, then $OPT_{(2,2)dEDS} \leq OPT_{(0,2)dEDS} \leq OPT_{DS} \leq \log n + 1$, where the second and the last inequality follow from Lemma 20 and Lemma 1, respectively. If T^{rev} contains no source, observe that a $(0,2)$-edge dominating set of T^{rev} is a $(2,0)$-edge dominating set of T and the statement holds.

Therefore, we may assume that T has a source s and a sink t. Let $S_1 \subseteq V \setminus \{s\}$ be a dominating set of $T - s$ of size at most $\log n + 1$. Clearly, every arc (u,v) of $T - s$ lies on a directed path of length at most two from some vertex of S_1. Let $D_1 \subseteq E$ be a minimal arc set such that $D_1 \cap \delta^-(v) \neq \emptyset$ for every $v \in S_1$. Since every $v \in S_1$ has positive in-degree, such a set D_1 exists and we have $|D_1| \leq |S_1|$. Observe that D_1 (0,2)-dominates every arc of $T - s$. Applying a symmetric argument to $T^{rev} - t$, we know that there exists an arc set D_2 of size at most $\log n + 1$ which $(2,0)$-dominates every arc of $T - t$. Now $D_1 \cup D_2$ (2,2)-dominates every arc incident with $V \setminus \{s,t\}$. Therefore, $D_1 \cup D_2 \cup \{(s,t)\}$ is a $(2,2)$-dEDS. ◀

▶ **Lemma 23.** *There is an FPT reduction from* Dominating Set *on tournaments parameterized by solution size to* (p,q)-EDS *parameterized by solution size, when* $p = 2$ *or* $q = 2$.

Proof. Without loss of generality we assume that $q = 2$. Let $T = (V, E)$ be an input tournament to Dominating Set, and let k be the solution size. It can be assumed that T has no source. We construct a tournament T' on vertex set $V \cup \{t\}$, in which t is a sink. Given a dominating set D of T, we select an arbitrary arc set K of T' so that $\delta^-_K(v) = 1$ for each $v \in D$. It is easy to see that K $(0,2)$-dominates every arc of T': any arc (u,v) with $u \in D$ is clearly dominated by K. For any arc (u,v) with $u \notin D$, there is $w \in D$ such that $(w,u) \in E$ and thus K $(0,2)$-dominates (u,v).

Conversely, suppose that K is a $(p,2)$-edge dominating set of size at most k and let K^+ be the set of heads of K found in V. Let K^- be the set of vertices $u \in V$ such that $(u,t) \in K$. We have $|K^+ \cup K^-| \leq k$, because each arc of K either contributes an element in K^+ or in K^-. We claim that $K^+ \cup K^-$ is a dominating set of T. Suppose the contrary, therefore there exists $u \in V \setminus (K^+ \cup K^-)$ that is not dominated by $K^+ \cup K^-$. However, the arc (u,t) is dominated by K. We have $(u,t) \notin K$, as $u \notin K^-$. Therefore, since t is a sink, (u,t) is $(0,2)$-dominated by an arc $(v,w) \in K$. This means that either $w = u$, or the arc (w,u) exists. However, $w \in K^+$, which means that u is dominated. ◀

▶ **Theorem 24.** *On tournaments, the problems* $(p,2)$-dEDS *are W[2]-hard for each fixed* p.

Proof. For all problems, we use the reduction from Set Cover to Dominating set on Tournaments given in Theorem 13.14 of [10] and our results follow from the W[2]-hardness of that problem (see also Theorem 13.28 therein) and Lemma 23. ◀

▶ **Theorem 25.** *On tournaments, the problems* $(0,2)$-dEDS, $(1,2)$-dEDS *and* $(2,2)$-dEDS *can be solved in time* $n^{O(\log n)}$.

Proof. For $(0,2)$-dEDS and $(1,2)$-dEDS, the case when a given tournament contains a source can be solved in polynomial time by Lemma 21. If the input tournament contains no source, then by Lemma 20 we have $OPT_{(1,2)dEDS} \leq OPT_{(0,2)dEDS} \leq OPT_{DS}$, which is bounded by $\log n + 1$ by Lemma 1. Lemma 22 states that $OPT_{(p,2)dEDS} \leq 2\log n + 3$. Exhaustive search over vertex subsets of size $O(\log n)$ performs in the claimed runtime. ◀

5.3 P-time solvable: $p + q \leq 1$ or, $2 \notin \{p,q\}$ and $\max\{p,q\} \geq 3$

▶ **Theorem 26.** $(0,1)$-dEDS *can be solved in polynomial time on tournaments.*

Proof. We will show that $OPT_{(0,1)dEDS} = n - 1$ and give a polynomial-time algorithm for finding such an optimal solution. First, given a tournament $T = (V, E)$, to see why $OPT_{(0,1)dEDS} \geq n - 1$ consider any optimal solution $K \subseteq E$: if there exists a pair of vertices $u, v \in V$ with $d^-_K(u) = d^-_K(v) = 0$, i.e. a pair of vertices, neither of which has an arc of K as an incoming arc, then the arc between them (without loss of generality let its direction be (v,u)) is not dominated: as $d^-_K(u) = 0$, the arc itself does not belong in K and as $d^-_K(v) = 0$, there is no arc preceding it that is in K. This leaves (v,u) undominated. Therefore, there cannot be two vertices with no incoming arcs in any optimal solution, implying any solution must include at least $n - 1$ arcs.

To see $OPT_{(0,1)dEDS} \leq n-1$, consider a partition of T into strongly connected components $C_1, \ldots, C_l$, where we can assume these are given according to their topological ordering, i.e. for $1 \leq i < j \leq l$, all arcs between C_i and C_j are directed towards C_j. Let S be the set

of arcs traversed in breadth-first-search (BFS) from some vertex $s \in C_1$ until all vertices of C_1 are spanned. Also let S' be the set of arcs $(s,u), \forall u \in C_i, \forall i \in [2,l]$, i.e. all outgoing arcs from s to every vertex of $C_2, \ldots, C_l$. Note that set S' must contain an arc from s to *every* vertex that is not in C_1: T being a tournament means every pair of vertices has an arc between them and C_1 being the first component in the topological ordering means all arcs between its vertices and those of subsequent components are oriented away from C_1. Then $K \coloneqq S \cup S'$ is a directed $(0,1)$-edge dominating set of size $n-1$ in T: observe that $d^-_K(u) = 1, \forall u \neq s \in T$, i.e. every vertex in T has positive in-degree within K except s. Thus all outgoing arcs from all such vertices u are $(0,1)$-dominated by K, while all outgoing arcs from s are in K, due to the BFS selection for S and the definition of S'.

Since such an optimal solution K can be computed in polynomial time (partition into strongly connected components, BFS), the claim follows. ◀

▶ **Theorem 27.** *For any p, q with $\max\{p,q\} \geq 3$, $p \neq 2$ and $q \neq 2$, (p,q)-dEDS can be solved in polynomial time on tournaments.*

Proof. Suppose without loss of generality that $q \geq 3$, as otherwise we can solve (q,p)-dEDS on T^{rev}, the tournament obtained by reversing the orientation of every arc. In any tournament T, there always exists a *king* vertex, that is, a vertex with a path of length at most 2 to any other vertex in the graph. One such vertex is the vertex of maximum out-degree v. If v is not a source, it suffices to select one of its incoming arcs: since there is a path of length at most 2 from v to any other vertex u in the graph, any outgoing arc from any such u will be $(0,3)$-dominated by this selection. This is clearly optimal.

Suppose now that s is a source. We consider two cases: if $p \leq 1$, then Lemma 21 implies that $\delta^+(s)$ is optimal. Finally, suppose s is a source and $p \geq 3$. If T does not have a sink, then a king of T^{rev} has an incoming arc, which $(0,3)$-dominates T^{rev} as observed above, and thus T has a $(0,3)$-edge dominating set of size 1.

Therefore, we may assume that T has both a source s and a sink t. Let s' and t' be vertices of $V \setminus \{s,t\}$ with maximum out- and in-degree, respectively. Now $\{(s,t),(s,s'),(t',t)\}$ is a $(3,3)$-edge dominating set. This is because s' is a king of $T-s$ and thus every arc (u,v) with $u \neq s$ is $(0,3)$-dominated by (s,s'). Similarly, every arc (u,v) with $v \neq t$ is $(3,0)$-dominated by (t',t). The only arc not $(3,3)$-dominated by these two arcs is (s,t), which is dominated by itself. Examining all vertex subsets of size up to 3, we can compute an optimal $(3,3)$-edge dominating set in polynomial time. ◀

Abstract

We unify several seemingly different graph and digraph classes under one umbrella. These classes are all, broadly speaking, different generalizations of interval graphs, and include, in addition to interval graphs, adjusted interval digraphs, threshold graphs, complements of threshold tolerance graphs (known as 'co-TT' graphs), bipartite interval containment graphs, bipartite co-circular arc graphs, and two-directional orthogonal ray graphs. (The last three classes coincide, but have been investigated in different contexts.) This common view is made possible by introducing reflexive relationships (loops) into the analysis. We also show that all the above classes are united by a common ordering characterization, the existence of a min ordering. We propose a common generalization of all these graph and digraph classes, namely *signed-interval digraphs*, and show that they are precisely the digraphs that are characterized by the existence of a min ordering. We also offer an alternative geometric characterization of these digraphs. For most of the above graph and digraph classes, we show that they are exactly those signed-interval digraphs that satisfy a suitable natural restriction on the digraph, like having a loop on every vertex, or having a symmetric edge-set, or being bipartite. For instance, co-TT graphs are precisely those signed-interval digraphs that have each edge symmetric. We also offer some discussion of future work on recognition algorithms and characterizations.

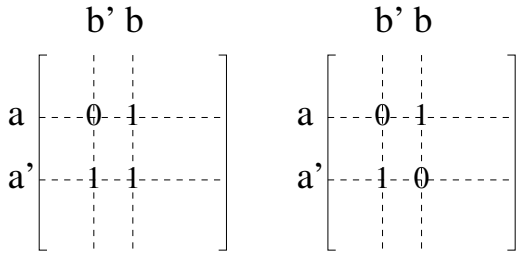

Figure 1 A min ordering of a digraph is an ordering of the vertices such that neither of the depicted submatrices occurs in the corresponding adjacency matrix.

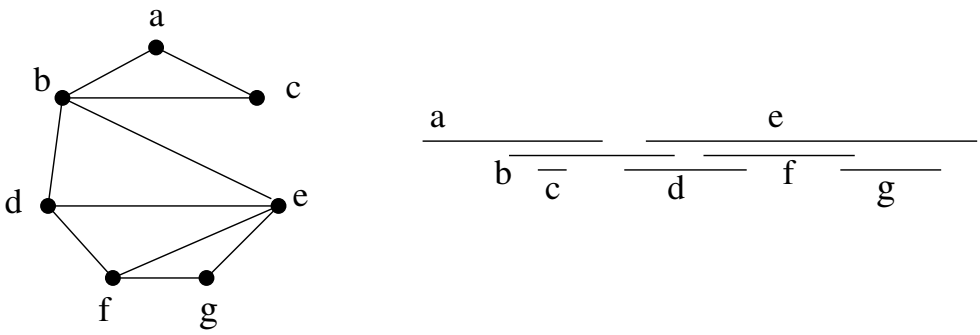

Figure 2 An interval graph and corresponding interval model. There is an implicit loop at each vertex.

1 Introduction

A digraph H is *reflexive* if each $vv \in E(H), v \in V(H)$ (H has all loops); *irreflexive* if no $vv \in E(H)$ (H has no loops); and *symmetric* if $ab \in E(H)$ implies $ba \in E(H)$. In this paper, we shall treat both graphs and digraphs; for simplicity we view graphs as symmetric digraphs. (Thus, graphs can have loops, and irreflexive graphs are loopless.) Loops play an important role in this paper, and this is not common in the literature on graph classes that we consider. They allow us to view several seemingly unrelated graph classes through a common lens.

A *min ordering* of a digraph H is a linear ordering $<$ of the vertices of H, so that $ab \in E(H), a'b' \in E(H)$ and $a < a', b' < b$ implies that $ab' \in E(H)$. In other words, a min ordering is an ordering of the vertices such that when the rows and columns of the adjacency matrix are ordered in this way, neither the matrix whose rows are 01 and 11 nor the matrix whose rows are 01 and 10 appears as a submatrix. (See Figure 1.) Note that the presence or absence of loops (1's on the diagonal of the adjacency matrix) can affect whether the graph has a min ordering.

Our goal in this paper is to promote a class of digraphs (or 0,1-matrices) that is a broad generalization of interval graphs and that retains some of the desirable structural properties of interval graphs. A graph H is an *interval graph* if it is the intersection graph of a family of intervals on the real line, i.e., if there exists a family of intervals $\{[x_v, y_v] | v \in V(H)\}$ such that $uv \in E(H)$ if and only if $[x_u, y_u] \cap [x_v, y_v] \neq \emptyset$. The family of intervals is an *interval model* of H. (See Figure 2.) We note that the definition implies that an interval graph is reflexive. A related concept for bipartite graphs is as follows. A bipartite graph H with parts A, B is an *interval bigraph* if there are intervals $\{[x_a, y_a], a \in A\}$, and $\{[x_b, y_b], b \in B\}$, such that for $a \in A$ and $b \in B$, $ab \in E(H)$ if and only if $[x_a, y_a] \cap [x_b, y_b] \neq \emptyset$.

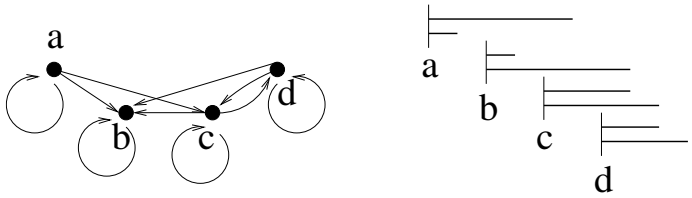

Figure 3 An adjusted interval digraph and a corresponding adjusted interval model. The source interval for each vertex is the upper one.

Interval graphs are important in graph theory and in applications, and are distinguished by several elegant characterizations and efficient recognition algorithms [3, 8, 11, 13, 16, 24, 31]. For this reason, there have been attempts to extend the concept to digraphs [29], with mixed success. (Many of the desirable structural properties are absent.) More recently a more restricted class of digraphs has been found to offer a nicer generalization of interval graphs; these are the adjusted interval digraphs [10]. A digraph H is an *adjusted interval digraph* if there are two families of real intervals, the *source intervals* $\{[x_v, y_v]|v \in V(H)\}$ and the *sink intervals* and $\{[x_v, z_v]|v \in V(H)\}$ such that $uv \in E(H)$ if and only if the source interval for u intersects the sink interval for v. (See Figure 3.) This differs from the class in [29] in that the left endpoint, x_v, must be shared by the two intervals $[x_v, y_v]$ and $[x_v, z_v]$ assigned to v; they are "adjusted." The interval graphs are the special case where $[x_v, y_v] = [x_v, z_v]$ for each $v \in V(H)$. An *adjusted interval model* of H is a set of source and sink intervals that represent H in this way.

Adjacency on a set of intervals can also be defined by interval containment. A graph is a *containment graph of intervals* [31] if there is a family of intervals $\{[x_v, y_v]|v \in V(H)\}$ on the real line such that $uv \in E(H)$ if and only if one of $[x_u, y_u]$ and $[x_v, y_v]$ contains the other. A graph is a containment graph of intervals if and only if it and its complement are both *transitively orientable*, thus if and only if it is a *permutation graph* [31].

For this paper, a more relevant class is a bipartite version of this concept. A bipartite graph H with parts A, B is an *interval containment bigraph* [31] if there are sets of intervals $\{I_a|a \in A\}$, and $\{J_b|b \in B\}$, such that $ab \in E(H)$ if and only if $J_b \subseteq I_a$. These graphs have been studied, from the point of view of another geometric representation, as two-directional orthogonal ray graphs [30]. A bipartite graph H with parts A and B is called a *two-directional orthogonal ray graph* if there exists a set $\{U_a, a \in A\}$ of upwards vertical rays, and a set $\{R_b, b \in B\}$ of horizontal rays to the right such that $ab \in E(H)$ if and only if $U_a \cap R_b \neq \emptyset$. It is known that a bipartite graph is an interval containment graph if and only if it is a two-directional orthogonal ray graph [22], and if and only if its complement is a circular arc graph [9].

It is sometimes convenient to view bipartite graphs as digraphs, with all edges oriented from part A to part B; thus we speak of a *bipartite interval containment digraph*, a *bipartite interval digraph*, or a *two-directional orthogonal ray digraph*. In general, a *bipartite digraph* is a bipartite graph with parts A and B and all arcs being oriented from A to B.

There is an interesting intermediate concept that uses both intersection and containment of intervals to define adjacency. An interval model of an interval graph G can be viewed as two mappings $\{v \to x_v|v \in V(H)\}$ and $\{v \to y_v|v \in V(H)\}$ such that $x_v \leq y_v$ for each $v \in V(H)$, and such that $uv \in E(H)$ if and only if $y_v \leq x_u$ and $y_u \leq x_v$. The constraint $x_v \leq y_v$ comes from the need for $[x_v, y_v]$ to be an interval. The proposition that two intervals intersect is the same as $x_v \leq y_u$ and $x_u \leq y_v$, since this means that neither interval lies entirely to the right of the other.

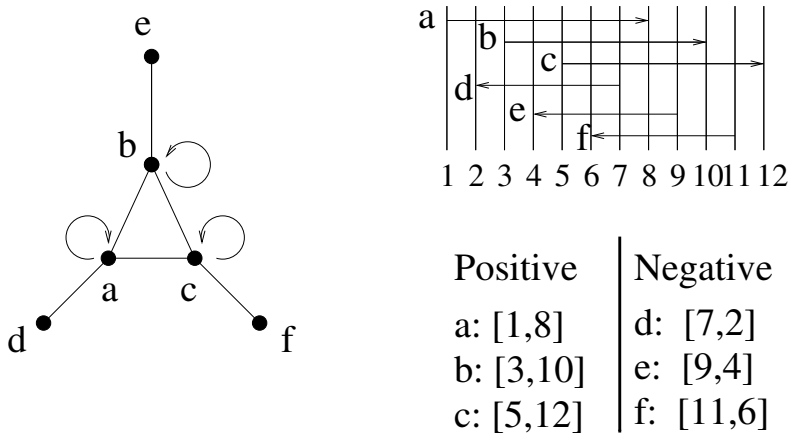

Figure 4 A co-TT graph and a corresponding co-TT model; ab is an edge since $1 \leq 10$ and $3 \leq 8$, ad is an edge since $1 \leq 2$ and $7 \leq 8$. However, bd is not an edge: although $7 \leq 10$, 3 is not less than or equal to 2. The example of this figure is one of the well-known minimal graphs that are not interval graphs, illustrating that the interval graphs are a proper subclass of the co-TT graphs.

A generalization of interval models is obtained by dropping the constraint $x_v \leq y_v$ in this formulation. To develop the motivation for this, we start with the complements of threshold tolerance graphs. A graph H is a *threshold tolerance graph* [27] if its vertices v can be assigned weights w_v and tolerances t_v so that ab is an edge of H if and only if $w_a + w_b > t_a$ or $w_a + w_b > t_b$. (When all t_v are equal, this defines a better known class of *threshold graphs* [5].) *Co-threshold tolerance ('co-TT') graphs* are complements of threshold tolerance graphs. Equivalently, a graph H is a co-TT graph, if there exist real numbers $x_v, y_v, v \in V(H)$, such that $ab \in E(H)$ if and only if $x_a \leq y_b$ and $x_b \leq y_a$ [14]. This differs from the definition of interval graphs in that it is no longer required that $x_v \leq y_v$, illustrating the motivation for dropping the constraint in this case. (See Figure 4.) That these are precisely the co-TT graphs is easily seen by letting $x_v = w_v$ and $y_v = t_v - w_v$. The two mappings $v \to x_v$ and $v \to y_v$, are called the *co-TT model* of H.

One view of a co-TT model is that there are now intervals whose 'beginning' x_v may come after their 'end' y_v. In other words, we may have 'intervals' $[x_v, y_v]$ with $y_v < x_v$. We may view a co-TT model as consisting of intervals $[x_v, y_v], v \in V(H)$, some of which go in the positive direction (have $x_v \leq y_v$) and others go in the negative direction (have $x_v > y_v$). We speak of *positive* or *negative* intervals, and *positive* or *negative* vertices that correspond to them. (In the literature [14, 12, 17, 27], the direction is denoted by *colors* of the intervals: positive intervals, and vertices, are colored *blue*, and negative intervals, and vertices, are colored *red*.) The above definition of adjacency has interesting consequences. Two positive vertices are adjacent if and only if they intersect; in particular, each positive vertex has a loop. Two negative vertices are never adjacent; in particular negative vertices have no loops. Finally, a positive vertex u corresponding to a positive interval $[a, b]$ and a negative vertex v corresponding to a negative interval $[c, d]$ are adjacent if and only if $[d, c]$ is contained in $[a, b]$ (i.e., $a \leq d \leq c \leq b$). We also use the following signed shorthand, which will be useful later: a positive vertex or interval will be called a $+$*-vertex* or $+$*-interval* respectively, and a negative vertex or interval will be called a $-$*-vertex* or $-$*-interval* respectively. It follows from the above discussion that in a co-TT graph, the $+$-vertices induce a reflexive interval graph, the $-$-vertices form an independent set, and the edges between the $+$-vertices and the $-$-vertices form a bipartite interval containment graph.

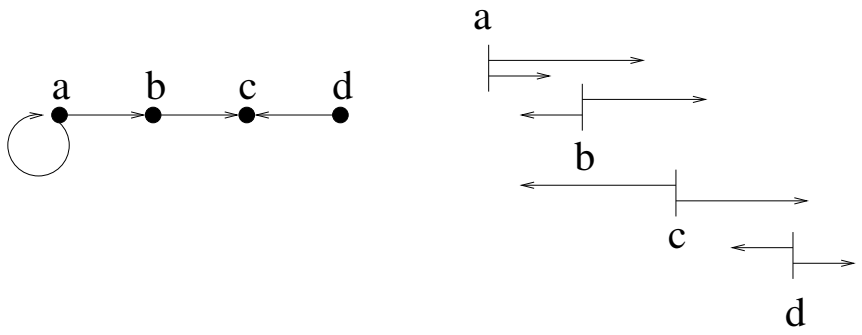

Figure 5 A signed interval digraph and a corresponding signed interval model. The source interval for each vertex is the upper one. There is a loop at a because its positive source interval intersects its positive sink interval. There is an edge from a to b because a's positive source interval contains b's negative sink interval, an edge from b to c because b's positive source interval intersects c's positive sink interval, and an edge from d to c because d's negative source interval is contained in c's positive sink interval.

Note that co-TT graphs are a generalization of interval graphs; the interval graphs are those co-TT graphs where all vertices are positive. In other words, they are the reflexive co-TT graphs.

2 Signed Interval Digraphs

We have now seen extensions of interval graphs in two different directions. First, by taking two (adjusted) intervals instead of just one interval, we were able to extend the definition from reflexive graphs to reflexive digraphs. Second, by admitting intervals $[a, b]$ that go in the negative direction (have $b < a$), we were able to extend the definition from reflexive graphs to graphs that have some vertices with loops and others without. Both these generalizations have proved very fruitful [10, 8, 10, 21, 14, 12, 17, 27].

We now define a new class of digraphs that unifies these extensions. A digraph H is a *signed-interval digraph* if there exist three mappings from $V(H)$ to the real line, $v \to x_v, v \to y_v$, and $v \to z_v$, such that $uv \in E(H)$ if and only if $x_u \leq z_v$ and $x_v \leq y_u$. We call the three mappings $v \to x_v, v \to y_v$, and $x \to z_v$ a *signed-interval model* of H. Alternatively, a signed interval model is obtained in by assigning, for each $v \in V(H)$ a *source interval* $[x_v, y_v]$ and a *sink interval* $[x_v, z_v]$, such that $uv \in E(H)$ if and only if $x_u \leq z_v$ and $x_v \leq y_u$. (See figure 5.) Since it is possible that $x_v > y_v$ and/or $x_v > z_v$, each of $[x_v, y_v]$ and $[x_v, z_v]$ can be negative or positive. Since the source interval and sink interval for v share the endpoint x_v, we retain the property that the intervals are adjusted.

Signed-interval digraphs with all intervals positive, are reflexive, and are adjusted interval digraphs. Signed-interval digraphs with $y_v = z_v$, for all $v \in V(H)$, are symmetric, and are co-TT graphs. Signed-interval digraphs that satisfy both conditions, i.e., with all $x_v \leq y_v = z_v, v \in V(H)$, are interval graphs. Furthermore, we show below that there are no reflexive signed-interval digraphs other than adjusted interval digraphs, no symmetric signed-interval digraphs other than co-TT graphs, and no reflexive and symmetric signed-interval digraphs other than interval graphs.

The structure of signed-interval digraphs can be described in a language similar to what was used for co-TT graphs. Let H be a signed-interval digraph and consider a signed-interval model of H given by the ordered pairs (I_v, J_v) of intervals where $I_v = [x_v, y_v]$ and $J_v = [x_v, z_v]$. For $\alpha, \beta \in \{+, -\}$, we say a vertex v is of type (α, β) if I_v is an α-interval

and J_v is a β-interval. The subdigraph of H induced by $(+,+)$-vertices is an adjusted interval digraph. The $(-,-)$-vertices of H form an independent set. The arcs between the $(+,-)$- and $(-,-)$-vertices form a bipartite interval containment digraph. The arcs between the $(-,+)$- and $(-,-)$-vertices also form a bipartite interval containment digraph. Similar properties hold for the other parts and their connections.

We emphasize that our definition of co-TT graphs differs from the standard definition [12, 14, 27]. In the standard definition, the condition $ab \in E(H) \iff x_a \leq y_b$ and $x_b \leq y_a$ is applied only for $a \neq b$, and so the graphs have no loops. Thus a graph under the standard interpretation is co-TT if and only if with a suitable addition of loops it is co-TT under our definition above. This difference is not important as it was shown in [13] that if a graph H is co-TT (in the standard sense), then it has a co-TT model with negative intervals for all simplicial vertices without true twins and all other intervals positive. Thus there is an easy translation between the co-TT graphs as defined here and the standard irreflexive co-TT graphs: namely, loops are to be placed on all vertices other than simplicial vertices without true twins.

3 Min Orderings

Interval graphs, adjusted interval digraphs, co-TT graphs, and two-directional orthogonal ray digraphs all have min orderings when care is taken to specify which vertices have loops and which do not. [8, 10, 18, 30].

Min orderings are a useful tool for graph homomorphism problems. A *homomorphism* of a digraph G to a digraph H is a mapping $f : V(G) \to V(H)$ such that $f(u)f(v) \in E(H)$ whenever $uv \in E(G)$. If a digraph H has a min ordering, there is a simple polynomial-time algorithm to decide if a given input graph G admits a homomorphism to a fixed digraph H [15, 20]. In fact, the algorithm is well known in the AI community as the arc-consistency algorithm [20]; it is easy to see that it also solves *list homomorphism* problems, where we seek a homomorphism of input G to fixed H taking each vertex of G to one of a 'list' of allowed images. In fact, many (but not all) homomorphism and list homomorphism problems that can be solved in polynomial time can be solved using arc-consistency with respect to a min ordering.

Graph and digraph homomorphism problems are special cases of constraint satisfaction problems. A general tool for solving polynomial time solvable constraint satisfaction problems are the so-called polymorphisms [4]. Without going into the technical details, we mention that min-orderings are equivalent to conservative semilattice polymorphisms [10].

We prove below that a digraph has a min ordering if and only if it is a signed-interval digraph. We also give another geometric characterization of signed-interval digraphs, as bi-arc digraphs. We show that a *reflexive* signed-interval digraphs are precisely adjusted interval digraphs, that *symmetric* signed-interval digraphs are precisely co-TT graphs, that *reflexive and symmetric* signed-interval digraphs are precisely interval graphs, and that *bipartite* signed-interval digraphs are precisely two-directional ray graphs.

The main result of this section is the following.

▶ **Theorem 1.** *A digraph admits a min ordering if and only if it is a signed-interval digraph.*

Before embarking on the proof we offer an alternate definition of a min ordering. Consider any linear ordering $<$ of $V(H)$. To this ordering, we prepend an intial element α, which is a place holder and not a vertex. Thus, $\alpha < x$ for each vertex x. We denote by $O(a)$ the last

vertex b (in the order $<$), such that b is an out-neighbor of a (i.e., such that $ab \in E(H)$), or α if a has no out-neighbor. Similarly, for each vertex b, we denote by $I(b)$ the last vertex a such that a is an in-neighbor of b (i.e., such that $ab \in E(H)$), or α if a has no in-neighbor.

▶ **Proposition 2.** *A linear ordering $<$ of $V(H)$ is a min ordering of a digraph H if and only if the following property holds:*

$$ab \in E(H) \text{ if and only if } a \leq I(b) \text{ and } b \leq O(a).$$

Proof. Suppose first that $<$ is a min ordering of H with α prepended. If $ab \in E(H)$, then by the definition of $O(a), I(b)$ we have $a \leq I(b)$ and $b \leq O(a)$. On the other hand, let $a \leq I(b)$ and $b \leq O(a)$. Note that if $a = I(b)$ or $b = O(a)$ we have $ab \in E(H)$ also by definition. Therefore it remains to consider vertices a, b such that $a < c = I(b)$ and $b < d = O(a)$. Then $ad, cb \in E(H)$ and the min ordering property implies that $ab \in E(H)$. This proves the property.

Conversely, assume that $<$ is a linear ordering of $V(H)$ with α prepended and that the property holds for $<$. We claim it is a min ordering of H. Otherwise some $ab \in E(H), a'b' \in E(H), a < a', b' < b$ would have $ab' \notin E(H)$. This is a contradiction, since we have $a < a' \leq I(b')$ and $b' < b \leq O(a)$. ◀

We proceed to prove the theorem.

Proof. Suppose $<$ is a min ordering of a digraph H with α prepended. We represent each vertex $v \in V(H)$ by the mappings $v \to v, v \to O(v), v \to I(v)$. In other words, v is represented by the two intervals $[v, O(v)]$ and $[v, I(v)]$. It follows from Proposition 2 that $ab \in E(H)$ if and only if $a \leq I(b)$ and $b \leq O(a)$. Thus H is a signed-interval digraph.

Conversely, suppose we have the three mappings $v \to x_v, v \to y_v, v \to z_v$ from $V(H)$ to the real line, such that $ab \in E(H)$ if and only if $x_a \leq z_b$ and $x_b \leq y_a$. Without loss of generality we may assume the points $\{x_v | v \in V(H)\}$ are all distinct. Then we claim that the left to right ordering of the points x_v yields a min ordering $<$ of H. (Specifically, we define $a < b$ if and only if x_a precedes x_b.) Consider now $ab \in E(H), a'b' \in E(H)$, with $a < a', b' < b$. This means that $x_a < x_{a'} \leq z_{b'}$ and $x_{b'} < x_b \leq y_a$, whence we must have $ab' \in E(H)$. ◀

4 An alternate geometric representation

Digraphs that admit a min ordering have another geometric representation. Let C be a circle with two distinguished points (the *poles*) N and S, and let H be a digraph. Let $I_v, v \in V(H)$ and $J_v, v \in V(H)$ be two families of arcs on C such that each I_v contains N but not S, and each J_v contains S but not N. We say that the families I_v and J_v are *consistent* if they have the same clockwise order of their clockwise ends, i.e., the clockwise end of I_a precedes in the clockwise order the clockwise end of I_b if and only if the clockwise end of J_a precedes in the clockwise order the clockwise end of J_b. Suppose two families I_v, J_v are consistent; we define an ordering $<$ on $V(H)$ where $a < b$ if and only if the clockwise end of I_a precedes in the clockwise order the clockwise end of I_b; we call $<$ the ordering *generated by* the consistent families I_v, J_v.

A *bi-arc model* of a digraph H is a consistent pair of families of circular arcs, $I_v, J_v, v \in V(H)$, such that $ab \in E(H)$ if and only if I_a and J_b are disjoint. A digraph H is called a *bi-arc digraph* if it has a bi-arc model.

▶ **Theorem 3.** *A digraph H admits a min ordering if and only if it is a bi-arc digraph.*

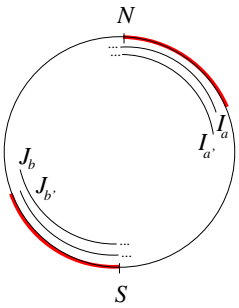

Figure 6 Illustration for the proof of Theorem 3.

Proof. Suppose I_v, J_v form a bi-arc model of H. We claim that the ordering $<$ generated by I_v, J_v is a min ordering of H. Indeed, suppose $a < a'$ and $b' < b$ have $ab, a'b' \in E(H)$. Then $I_{a'}$ spans the area of the circle between N and the clockwise end of I_a, and J_b spans the area of the circle between S and the clockwise end of $J_{b'}$. (See Figure 1.) This implies that I_a and $J_{b'}$ are disjoint: indeed, the counterclockwise end of I_a is blocked from reaching $J_{b'}$ by J_b (since $ab \in E(H)$), and the counterclockwise end of $J_{b'}$ is blocked from reaching I_a by $I_{a'}$ (since $a'b' \in E(H)$). (The clockwise ends are fixed by the ordering $<$.)

Conversely, suppose $<$ is a min ordering of H. We construct families of arcs I_v and J_v, with $v \in V(H)$, as follows. The intervals I_v will contain N but not S, the intervals J_v will contain S but not N. The clockwise ends of I_v are arranged in clockwise order according to $<$, as are the clockwise ends of J_v. The counterclockwise ends will now be organized so that $I_v, J_v, v \in V(H)$, becomes a bi-arc model of H. For each vertex $v \in V(H)$, we define $O(v)$ and $I(v)$ as in the proof of Theorem 1. Then we assign the counterclockwise endpoint of I_v to be N if v has no out-neighbors, or else extend I_v counterclockwise as far as possible without intersecting $J_{O(v)}$, and assign the the counterclockwise endpoint of each J_v to be S if v has no in-neighbors, or else extend J_v counterclockwise as far as possible without intersecting $I_{I(v)}$. We claim this is a bi-arc model of H. Clearly, if $b > O(a)$, then I_a intersects J_b by the construction, and similarly for $a > I(b)$ we have J_b intersecting I_a. This leaves disjoint all pairs I_a, J_b such that $a \leq I(b)$ and $b \leq O(a)$; since $aO(a), I(b)b \in E(H)$, the definition of min ordering implies that $ab \in E(H)$, as required. ◀

▶ **Corollary 4.** *The following statements are equivalent for a digraph H.*

- *H has a min ordering*
- *H is a signed-interval digraph*
- *H is a bi-arc digraph.*

5 0,1-Matrices and bipartite graphs

Irreflexive graphs with at least one edge do not admit a min ordering, since the vertices that are not reflexive form an independent set. However, in the special case of bipartite graphs, a version of min ordering has been studied, and has yielded interesting examples. We will describe that version below, but we first want to explain how to view that definition as a special case of min ordering as defined here.

A useful perspective on min orderings is obtained by considering 0,1-matrices. Square 0,1-matrices naturally correspond to adjacency matrices of digraphs. Let a *simultaneous permutation* of rows and columns of a matrix be one where the permutation of the rows is the

same as the permutation of the columns. An *independent permutation* of rows and columns allows the permutation of the rows to be different from the permutation of the columns.

Let L be the two by two matrix with rows 01 and 11, and let K be the two by two matrix with rows 01 and 10. (These have been given other names in the literature, up to a simultaneous permutation of rows and columns they are the gamma matrix, and the identity matrix.) A matrix M is called K, L*-free* if it does not contain K or L as a submatrix. If M is the adjacency matrix of a digraph H, and if the rows and columns of H are in the order $<$, then M is K, L-free if and only if $<$ is a min ordering. We call a M a *min-orderable matrix* if its rows and columns can be simultaneously permuted to produce a K, L-free matrix. A digraph has a min ordering if and only if its adjacency matrix is min-orderable.

Therefore, we can say much about matrices that are min-orderable.

▶ **Theorem 5.** *A square 0,1-matrix is min-orderable if and only if it is the adjacency matrix of a signed-interval digraph.*

Another natural interpretation of a 0,1-matrix is that it represents adjacencies in a bipartite graph, with rows corresponding to one part and columns to the other part. The *bi-adjacency matrix* of a bipartite graph H with marts A, B has its i, j-th entry is 1 if and only if the i-th vertex in A is adjacent to the j-th vertex in B. Note that for this interpretation it is not required that the matrix be square. For matrices that are not necessarily square, we can still ask for independent permutations of rows and columns, to produce a K, L-free matrix. This suggests a definition of min ordering for bipartite graphs as follows. A *min ordering of a bipartite graph* H with parts A and B is a linear ordering $<_A$ of A and a linear ordering $<_B$ of B so that for any $a, a' \in A, b, b' \in B$ such that $ab \in E(H), a'b' \in E(H)$ and $a < a', b' < b$ we have $ab' \in E(H)$. This is the definition that has been used in the literature; it is clear how it avoids the problems of the general definition.

There is a simple transformation that connects the two interpretations of 0,1-matrices. For a matrix M with k rows and ℓ columns, we define the $(k + \ell)$ by $(k + \ell)$ square matrix M^+ to contain the matrix M in the first k rows and the last ℓ columns, with 0 everywhere else. Then a simultaneous row/column permutation of M^+ corresponds to independent row and column permutations of M. Note that the square matrix M^+ is an adjacency matrix of the digraph obtained from H by directing all edges from H from the first part to the second part. Thus to view the special definition of a min ordering for bipartite graphs as a particular case of the general definition, it suffices to view bipartite graphs as digraphs with all edges oriented from the first part to the second part. We shall say that H is a *bipartite digraph* if it is obtained from a bipartite graph in this way.

A robust class of bipartite graphs is relevant for our discussion. A bipartite graph H with parts A and B is called a *two-directional orthogonal ray graph* if there exists a set $U_a, a \in A$, of upwards vertical rays, and a set $R_b, b \in B$, of horizontal rays to the right such that $ab \in E(H)$ if and only if $U_a \cap R_b \neq \emptyset$. Note that we may, if needed, view a two-directional orthogonal ray graph as a bipartite digraph, with all edges oriented from (say) vertical rays to horizontal rays.

The following theorem is obtained by a combination of results from [9, 22, 30].

▶ **Theorem 6.** *The following statements are equivalent for a bipartite graph H.*

- *H is a two-directional orthogonal ray graph*
- *the complement of H is a circular arc graph*
- *H is an interval containment graph.*

Matrices that can be permuted to avoid small submatrices have been of much interest [1, 23, 25]. This of course corresponds to characterizations of digraphs by forbidden ordered subgraphs [7, 19]. Our focus was on K, L-free matrices. Let the matrix Γ be obtained from

L by simultaneously exchanging the rows and columns; i.e., Γ has rows 11, 10. Let I be the two by two identity matrix. It is easy to see that considering I, Γ-free matrices is equivalent to considering K, L-free matrices, as the permutation that simultaneously reverses rows and columns of matrix M transforms a I, Γ-free matrix to a K, L-free matrix and vice versa. Matrices that are Γ-free have been intensively studied [1, 25], cf. [31]. A bipartite graph H is *chordal bipartite* if it contains no induced cycle other than C_4. A reflexive graph is *strongly chordal* if it contains no induced cycle or induced trampoline. (A *trampoline* is a complete graph on $v_0, v_1, v_2, \ldots, v_{k-1}, k > 2$ with vertices $u_i, i = 0, 1, \ldots, k-1$, each only adjacent to v_i, v_{i+1}, subscripts computed modulo k.) The adjacency matrix of a reflexive graph H can be made Γ-free by simultaneous row / column permutations if and only if H is strongly chordal; the bi-adjacency matrix of a bipartite graph H can be made Γ-free by independent permutations of rows and columns if and only if H is chordal bipartite [1]. These results amount to forbidden structure characterizations of matrices that are permutable (by simultaneous or independent row and column permutations) to a Γ-free format. Algorithms to recognize such matrices efficiently have been given in [25, 28]. For L-free matrices, or equivalently, for I-free matrices a forbidden structure characterization is given in [17]. An $O(n^2)$ recognition algorithm is claimed in [2], cf. [31].

6 Special cases

We now explore what min orderings look like in the special cases we have discussed, namely reflexive graphs, reflexive digraphs, undirected graphs, and bipartite graphs. The results are all corollaries of Theorem 1 and Proposition 2.

▶ **Corollary 7.** *A reflexive graph H is a signed-interval digraph if and only if it is an interval graph.*

▶ **Corollary 8.** *A reflexive digraph H is a signed-interval digraph if and only if it is an adjusted interval digraph.*

Next we focus on symmetric digraphs, i.e., graphs.

▶ **Corollary 9.** *A graph H is a signed-interval digraph, i.e., has a min ordering, if and only if it is a co-TT graph.*

Proof. Consider a co-TT model of H, given by the mappings $v \to x_v, v \to y_v$, setting the third mapping $v \to z_v$ with each $z_v = y_v$, yields a signed-interval digraph model of H. Conversely, assume H is a graph, i.e., a symmetric digraph, that is a signed-interval digraph. Let $<$ be a min ordering of H; we again have $O(v) = I(v)$ for all vertices v. We claim that the mappings $v \to x_v = v, v \to y_v = O(v)$ define a co-TT model. Indeed, from Proposition 2 we have $ab \in E(H)$ if and only if $a \leq O(b) = y_b$ and $b \leq O(a) = y_a$, as required. ◀

Finally, for bipartite graphs we have the following result, stated for convenience in the language of bipartite digraphs. Note that this has only one consequence, that is, when we consider an edge $ab \in E(H)$ we always assume $a \in A$ and $b \in B$.

▶ **Corollary 10.** *A bipartite digraph H is a signed-interval digraph, i.e., has a min ordering, if and only if it is a two-directional orthogonal ray graph.*

Note that two-directional orthogonal ray graphs themselves have two other equivalent characterizations in Theorem 6. The characterization of two-directional orthogonal ray graph by the existence of a min ordering is also observed in [18, 30].

Proof. Suppose H has a signed-interval model given by the three mappings $v \to x_v, v \to y_v, v \to z_v$ such that $ab \in E(H)$ if and only if $x_a \leq z_b$ and $x_b \leq y_a$. We construct a two-directional ray model for H as follows. For each $a \in A$, we take an upwards vertical ray starting in the point P_a with x-coordinate equal to y_a and with y-coordinate equal to x_a. For each $b \in B$, we take a horizontal ray to the right, starting in the point Q_b with x-coordinate x_b and y-coordinate z_b. Now P_a intersects Q_b if and only if $x_b \leq y_a$ and $x_a \leq z_b$, i.e., if and only if $ab \in E(H)$ as required.

Now suppose that H has a two-directional model, i.e., upwards vertical rays $U_a, a \in A$, and horizontal rays to the right $R_b, b \in B$, such that $ab \in E(H)$ if and only if $U_a \cap R_b \neq \emptyset$. We will prove that H has a min ordering, whence it is a signed-interval digraph by Theorem 1. We will define the orders $<$ on A and on B as follows. Assume the starting point of the vertical ray U_a has the (x, y)-coordinates (u_a, v_a), and the starting point of the horizontal ray R_b has the (x, y)-coordinates (r_b, s_b), for $a \in A$, and $b \in B$. It is easy to see that we may assume, without loss of generality, that all $u_a, a \in A$, and $r_b, b \in B$ are distinct, and similarly for $v_a, a \in A$ and $s_b, b \in B$. We define $a < a'$ in A if and only if $v_a < v'_a$, and define $b < b'$ in B if and only if $r_b < r_{b'}$. We show that this is a min ordering of the bipartite digraph H. Otherwise, some $ab \in E(H), a'b' \in E(H), a < a', b' < b$ have $ab' \notin E(H)$. There are two possibilities for $ab' \notin E(H)$; either $u_a < r_{b'}$ or $u_a > r_{b'}, v_a > s_{b'}$. In the former case, $U_a \cap R_b = \emptyset$, in the latter case $U_{a'} \cap R_{b'} = \emptyset$, contradicting the assumptions. ◀

7 Algorithms and characterizations

Interval graphs are known to have elegant characterization theorems [11, 24], cf. [13, 31] and efficient recognition algorithms [3, 6, 16]. Thus one might hope to be able to obtain similar results for their generalizations and digraph analogues. This is true for all the generalizations described in this paper, at least to some degree. In this section we summarize what is known.

The prototypical characterization of interval graphs is the theorem of Lekkerkerker and Boland [24]. In our language, it states that *a reflexive graph H is an interval graph if and only if it contains no asteroidal triple and no induced C_4 or C_5*. An *asteroidal triple* consists of three non-adjacent vertices such that any two are joined by a path not containing any neighbors of the third vertex. An equivalent characterization by the absence of a slightly less concise obstruction is given in [10]. *A reflexive graph H is an interval graph if and only if it contains no invertible pair.* An *invertible pair* is a pair of vertices u, v such that there exist two walks of equal length, P from u to v, and Q from v to u, where the i-th vertex of P is non-adjacent to the $(i+1)$-st vertex of Q (for each i), and also two walks of equal length R, S from v to u and u to v respectively, where the i-th vertex of R is non-adjacent to the $(i+1)$-st vertex of S (for each i). It is not difficult to see that an asteroidal triple is a special case of an invertible pair. A number of variants of the definition of an invertible pair have arisen [10, 12, 17, 18], and they have proved useful to give characterization theorems for various classes. It is proved in [10] that *a reflexive digraph is an adjusted interval digraph if and only if it contains no directed invertible pair.* A *directed version* of an invertible pair is defined in [10] in a manner similar to the above definition of an invertible pair. With yet another *labeled version* of an invertible pair, we have the following obstruction characterization of co-TT graphs: *a graph is a co-TT graph if and only if it contains no labeled invertible pair*, which follows from the characterization in [12] in terms of an interval ordering from [26]. For bipartite graphs, an analogous *bipartite version* of an invertible pair yields the following result. *A bipartite graph is a two-directional orthogonal ray graph if and only if it contains no bipartite invertible pair*, [18]. In fact, in [9] a stronger version is

shown: there is a bipartite analogue of an asteroidal triple, called an *edge-asteroid*, and *a bipartite graph is a two-directional orthogonal ray graph if and only if it contains no induced* 6*-cycle and no edge-asteroid*. Finally, in [21], there is an obstruction characterization for signed-interval digraphs, which is a little more technical than just an invertible pair, [21].

There is a long history of efficient algorithms for the recognition of interval graphs, many of them linear time, starting from [3] and culminating in [6]. A polynomial time algorithm for the recognition of adjusted interval digraphs is given in [10]. It is not known how to obtain a linear time, or even near-linear time algorithm. An $O(n^2)$ algorithm for the recognition of two-directional orthogonal ray graphs follows from Theorem 6 and [26]. A more efficient algorithm in this case is also not known. On the other hand, an $O(n^2)$ algorithm for the recognition of co-TT graphs has been given in [12]. In [21], a polynomial-time algorithm for the recognition of a signed-interval digraph is proposed. (A new version of [21] will be posted on arXiv soon.)

Abstract

A *semiorder* is a model of preference relations where each element x is associated with a utility value $\alpha(x)$, and there is a threshold t such that y is preferred to x iff $\alpha(y) - \alpha(x) > t$. These are motivated by the notion that there is some uncertainty in the utility values we assign an object or that a subject may be unable to distinguish a preference between objects whose values are close. However, they fail to model the well-known phenomenon that preferences are not always transitive. Also, if we are uncertain of the utility values, it is not logical that preference is determined absolutely by a comparison of them with an exact threshold. We propose a new model in which there are two thresholds, t_1 and t_2; if the difference $\alpha(y) - \alpha(x)$ is less than t_1, then y is not preferred to x; if the difference is greater than t_2 then y is preferred to x; if it is between t_1 and t_2, then y may or may not be preferred to x. We call such a relation a (t_1, t_2) double-threshold semiorder, and the corresponding directed graph $G = (V, E)$ a (t_1, t_2) double-threshold digraph. Every directed acyclic graph is a double-threshold digraph; increasing bounds on t_2/t_1 give a nested hierarchy of subclasses of the directed acyclic graphs. In this paper we characterize the subclasses in terms of forbidden subgraphs, and give algorithms for finding an assignment of utility values that explains the relation in terms of a given (t_1, t_2) or else produces a forbidden subgraph, and finding the minimum value λ of t_2/t_1 that is satisfiable for a given directed acyclic graph. We show that λ gives a useful measure of the complexity of a directed acyclic graph with respect to several optimization problems that are NP-hard on arbitrary directed acyclic graphs.

1 Introduction

A poset P can be identified with a transitive digraph on its elements. The poset $P = P(V, <)$ is a *semiorder* [10] if for some utility function $\alpha : V \to \mathbb{R}$ we have $u <_P v$ if and only if $\alpha(v) - \alpha(u) > 1$. Semiorders were introduced as a possible mathematical model for preference in the social sciences. A first possible model for preference is the *weak orders*, in which each element is assigned a utility value, such that u is preferred to v iff the value of u is greater than the value of v. This was viewed as too restrictive; many preference relationships cannot be modeled by a weak order. Semi-orders were designed to model imprecision in the valuation function; we may be indifferent between elements not only if they have exactly the same values, but also if the difference between the values is smaller than some threshold. There is a great deal of literature on the subject of semiorders and preference; see the books [2, 11].

Our original motivation for defining double-threshold digraphs comes from an attempt to deal with an issue in mathematical psychology. Intuitively, it is natural to think that preference is transitive; if one prefers a to b and b to c, then one "should" prefer a to c. However, a variety of evidence exists showing that preferences are not always transitive. This has led to a great deal of discussion; for a summary of this issue, see [3]. Viewpoints range from the idea that the intuitive notion that preference is transitive are simply wrong and must be thrown away entirely to questioning whether what was being measured in the non-transitive findings was really a preference relation. Between these two views, there has been work on finding mathematical models that explain non-transitive preference; Fishburn [3] gives some possible models.

One approach to mathematical modeling is to try to give a reasonable model of extremely non-transitive preference; the famous cyclic voter's paradoxes can be viewed as a model of preference which can allow not just non-transitivity, but also cycles.

Unlike these approaches, we generalize semi-orders to allow non-transitivity, but we require that the given set of preferences continue to be acyclic. In other words, we consider any preference relation represented by a directed acyclic graph (a *dag*). As in the case of semiorders, we assume that reported preferences are influenced by an underlying hidden utility function, which may be approximate, imperfectly known by a subject, or otherwise fail to capture all factors influencing a report of a preference.

One of our objectives is to obtain a measure of the departure of a given arbitrary acyclic set of pairwise preferences from a model where preferences are driven exclusively by an underlying hidden utility function, as well as derive an assignment of utility values that has the most explanatory power, in a sense that we define within a new model that we propose.

We propose a generalization of a semiorder, a *double-threshold semiorder*. We loosen the definition of a semiorder to a broader class of relations that are acyclic but not necessarily transitive, by allowing two thresholds t_1 and t_2 such that $t_1 \leq t_2$, and finding a valuation $\alpha(x)$ for each element x. For two elements x and y, (x, y) is not reported as a preference if $\alpha(y) - \alpha(x) < t_1$, (x, y) can freely be reported as a preference or not if $t_1 \leq \alpha(y) - \alpha(x) \leq t_2$, and (x, y) is reported as a preference if $\alpha(y) - \alpha(x) > t_2$. Let a *satisfying utility function* or a *satisfying assignment of α values* for (t_1, t_2) be a utility function α that meets these constraints. This accommodates within the model the well-known phenomenon in the literature on perception that there can be a range of differences between the minimum difference that is sometimes perceived and the minimum difference that is perceived reliably.

When the relation of the double-threshold semiorder is modeled by a dag, it is called a *double-threshold digraph*. If a dag can be represented with thresholds (t_1, t_2), then it can be represented with any pair (t'_1, t'_2) of thresholds such that $t'_2/t'_1 = t_2/t_1$, since a solution α

for (t_1, t_2) can be turned into a solution for (t'_1, t'_2) by rescaling all α values by the factor $t'_1/t_1 = t'_2/t_2$. Therefore, for any pair (t_1, t_2) of thresholds, the question of whether a particular dag can be represented with them depends on the ratio $r = t_2/t_1$; larger ratios allow representations of more dags.

Henceforth, given a digraph G, let $n(G)$ denote the number of vertices and $m(G)$ the number of edges. When G is understood, we may denote these as n and m. For a dag G, let $\lambda(G)$ denote the minimum ratio of t_2/t_1 such that G has a satisfying utility function for (t_1, t_2). When G models a weak order, $t_1 = 1$ and $t_2 = \epsilon$ for any $\epsilon > 0$ has a satisfying utility function. For this trivial special case, which is easily recognized in linear time, we define $\lambda(G)$ to be 0, the lower bound on the satisfiable ratios t_2/t_1, and call such a dag a *degenerate* dag. All other dags are *nondegenerate*.

When G or the preference relation it models is understood, we denote $\lambda(G)$ simply by λ. For a dag that models a nondegenerate semiorder, $\lambda = 1$; higher values of λ provide a measure of the degree to which a given set of preferences depart from a semiorder. An acyclic preference relation is a (t_1, t_2)-*semiorder* if it has a satisfying utility function for (t_1, t_2), that is, if $t_2/t_1 \geq \lambda$. When such a preference relation is modeled as a digraph, we say the digraph is a (t_1, t_2) *double-threshold digraph*. We show that for any nondegenerate dag G, $\lambda(G)$ can be expressed as a ratio j/i where i and j are integers such that $1 \leq i \leq j < i + j \leq n$ (Theorem 4), allowing t_1, t_2, and the utility function to have small integer values. Also, for any dag, $t_1 = 1$ and $t_2 = n - 1$ is always satisfiable, so $\lambda \leq n - 1$. An example of when the bound is tight is when G is a directed path.

Thus, the classes of dags with λ bounded by different values give a nested hierarchy of dags, starting with weak orders and semiorders. For each class in the hierarchy, we give a characterization of the class in terms of a set of forbidden subgraphs for the class.

When G has no satisfying utility function for t_1, t_2, we show how to return a forbidden subgraph as a certificate of this in $O(nm/r)$ time, where $r = t_2/t_1$, and an $O(nm/\lambda)$ time bound for finding λ (Theorem 18). The algorithm combines elements of the Bellman-Ford single-source shortest paths algorithm [1], Karp's minimum mean cycle algorithm [8], and dynamic programming techniques based on a topological sort of a dag. For $t_2/t_1 = \lambda$, a satisfying assignment, together with a forbidden subgraph for a smaller ratio, give a certificate that $\lambda = t_2/t_1$, and these take $O(nm/\lambda)$ time to produce.

If λ is less than 2, G must be transitive. The converse is not true: it is easy to show that the class of posets does not have bounded λ. Consider a chain $(v_1, v_2, \ldots, v_{n-1})$ in a poset and a vertex v_n that is incomparable to the others; $t_2 \geq t_1(n-2)/2$. Even though they are transitive, some posets are not good models of a preference relation that is based on an underlying utility function.

Although we show that bounding λ can make some NP-complete problems tractable, bounded-ratio double-threshold digraphs are in one sense enormously larger than semiorders. Semiorders correspond to digraphs that can be represented with ratio 1. These classes of digraphs both have implicit representations [12], implying that there are $2^{O(n \log n)}$ such digraphs on a set of n labeled vertices. By contrast, every height 1 digraph can be represented with ratio 1: for each vertex x, assign $\alpha(x) = 0$ if is it a source or $\alpha(x) = 1$ if it is a sink and make the thresholds $t_1 = t_2 = 1$. The number of such digraphs on n labeled vertices, hence the number with ratio λ for any λ greater than or equal to 1, is $2^{\Theta(n^2)}$.

The *underlying undirected graph* of a dag is the symmetric closure, that is, the undirected graph obtained by ignoring the orientations of the edges. In this paper, we say that a dag is *connected* if its underlying undirected graph is connected. Similarly, by a *clique*, *coloring*,

independent set, or *clique cover* of a dag, we mean a clique, coloring, independent set or clique cover of the underlying undirected graph. Hardness results about these problems on undirected graphs also apply to dags, since every undirected graph G is the underlying undirected graph of the dag obtained by assigning an acyclic orientation to G's edges.

Finding a maximum independent set or clique in a dag takes polynomial time if the dag is transitive (a poset), hence if it is a semiorder, but for arbitrary dags, there is no polynomial-time approximation algorithm for finding a independent set or clique whose size is within a factor of $n^{1-\epsilon}$ of the largest unless P = NP [7]. However, for a connected dag G, we give an $O(\lambda m^{\lfloor \lambda+1 \rfloor/2})$ algorithm for finding a maximum clique (Corollary 10), and an approximation algorithm that finds a clique whose size is within a desired factor of i of that of a maximum clique in $O(nm/\lambda + m^{\lfloor \lambda/i+1 \rfloor/2})$ time (Corollary 11).

We show that finding a maximum independent set is still NP-hard when $\lambda \geq 2$, but we give a polynomial-time approximation algorithm that produces an independent set whose size is within a factor of $\lfloor \lambda + 1 \rfloor$ of the optimum (Theorem 12). We give approximation bounds of $\lfloor \lambda + 1 \rfloor$ for minimum coloring and minimum clique cover (Theorems 13 and 14), which also have no polynomial algorithms for finding an $n^{1-\epsilon}$ approximation for arbitrary dags unless P = NP.

Thus, restricting attention to dags such that λ is bounded by a constant makes some otherwise NP-hard problems easy and gives rise to polynomial-time approximation algorithms that cannot exist in general unless P = NP. In each case, the time bound or the approximation bound is an increasing function of λ. This supports the view of λ as a measure of complexity of a dag. By contrast, for most similar attempts to measure complexity of a graph or digraph, the measurement is NP-hard to compute; examples include dimension of a poset, interval number, boxicity, and many others; see [12].

A concept similar to λ was given previously by Gimbel and Trenk in [5]. They developed a generalization of weak orders to partial orders that corresponds to the special case of a $(1, k)$ transitive dag. Not assuming transitivity requires us to use different algorithmic methods, but our bounds improve their bounds for their special case from $O(n^4k)$ and $O(n^6)$ to $O(mn/k)$. Most of their structural results are disjoint from ours because they are relevant to partial orders and their underlying undirected graphs, the *comparability graphs.*

2 Satisfying utility functions and forbidden subgraphs

We give the following formal definition:

▶ **Definition 1.** A dag is a (t_1, t_2) double-threshold digraph if there exists an assignment of a real value $\alpha(v)$ to each vertex v such that whenever (u, v) is an edge, $\alpha(v) - \alpha(u) \geq t_1$ and whenever (u, v) is not an edge, $\alpha(v) - \alpha(u) \leq t_2$.

Whether the constraints can be satisfied can be formulated as the problem of finding a feasible solution to a linear program:

- $\alpha(v) - \alpha(u) \geq t_1$ for each (u, v) such that (u, v) is an edge;
- $\alpha(v) - \alpha(u) \leq t_2$ for each (u, v) such that neither (u, v) nor (v, u) is an edge;
- $\alpha(v) \leq 0$ for all $v \in V(G)$.

The last constraint is added as a convenience; for any satisfying assignment, an arbitrary constant can be subtracted from all of the α values to obtain a new satisfying assignment, so the constraint cannot affect the existence of a feasible solution.

This is a special case of a linear program, a *system of difference constraints*, where each constraint is an upper bound on the difference of two variables. This reduces to the problem of finding the weight of a least-weight path ending at each vertex in a digraph derived from

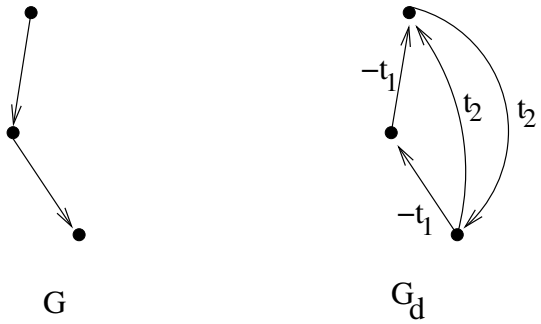

Figure 1 Reduction of finding a satisfying utility function to the single-source least-weight paths problem. Edges of weight t_1 in G_d are acyclic.

the constraints, as described in [1], where there is a satisfying assignment if and only if the digraph of the reduction has no negative-weight cycle. Applying the reduction to the problem of determining whether there is a satisfying utility function on G yields a digraph G_d, where $V(G_d) = V(G)$ (see Figure 1). G_d has an edge (y, x) of weight $-t_1$ for each edge (x, y) of G, and edges (u, v) and (v, u) of weight t_2 for each pair $\{u, v\}$ such that neither of (u, v) and (v, u) is an edge of G. A negative cycle in G_d proves that the system is not satisfiable; otherwise, for each $x \in V$, assigning $\alpha(x)$ to be the minimum weight of any path ending at x gives a satisfying assignment for (t_1, t_2).

The single-source least-weight paths problem where some weights are negative can be solved in $O(nm)$ time, but G_d has $\Theta(n^2)$ edges, so a direct application of this approach takes $\Theta(n^3)$ time to find a satisfying assignment or produce a negative-weight cycle in G_d. We derive tighter bounds below.

In terms of G, a negative cycle of G_d translates to a forbidden subgraph characterization of (t_1, t_2) double-threshold digraphs:

▶ **Definition 2.** Let (u, v) be a *hop* in G if neither (u, v) nor (v, u) is an edge of G. Let a *forcing cycle* be a simple cycle $(v_1, v_2, ..., v_k)$ such that such that for each consecutive pair (v_i, v_{i+1}) (indices mod k), the pair is either a directed edge of G or a hop. Let the *ratio* of the forcing cycle be the ratio of the number of edges to the number of hops.

▶ **Theorem 3.** *For a nondegenerate dag G, the minimum satisfiable ratio λ is equal to the maximum ratio of a forcing cycle in G.*

One consequence of the theorem is that when G is a nondegenerate dag, a satisfying assignment of α values for thresholds (t_1, t_2), together with a forcing cycle with ratio equal to t_2/t_1 gives a certificate that $\lambda(G) = t_2/t_1$, as illustrated in Figure 2.

▶ **Theorem 4.** *For every nondegenerate dag G, $\lambda(G)$ can be expressed as a ratio i/j of integers such that $1 \leq i \leq j < i + j \leq n$.*

Proof. This follows from the fact that $\lambda \geq 1$ and is the ratio of the number j of edges to the number i of hops on a forcing cycle. ◀

Aside from showing that optimum values of t_1 and t_2 can be expressed as small integers, the theorem gives an immediate $O(n^3 \log n)$ bound for finding λ. This is because it implies that the number of possible values j/i that λ can take on is $O(n^2)$, and that these can be generated and sorted in $O(n^2 \log n)$ time. A binary search on this list, spending $O(n^3)$ time at each probe j/i to determine whether G is an (i, j) double-threshold digraph, as described above, can then be used to find λ. Once λ is known, a satisfying assignment of utility values

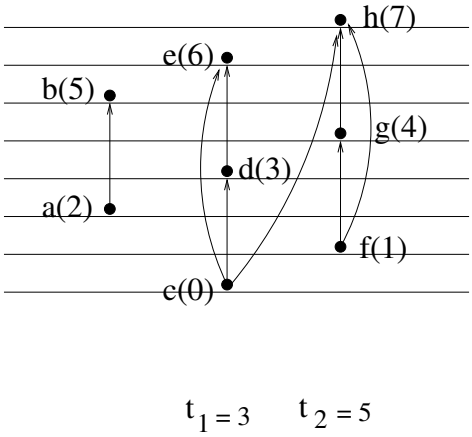

Figure 2 A dag such that $\lambda = 5/3$. The number next to each vertex is the value of the utility function, conforming to $t_1 = 3$ and $t_2 = 5$. The cycle (a, b, c, d, e, f, g, h) is a cycle of directed edges and hops in which the ratio of edges to hops is 5/3. Since $\lambda < 2$, the dag is transitive.

for $t_2/t_1 = \lambda$, together with a forcing cycle with forcing ratio equal to λ gives a certificate that the claimed value of λ is correct. We improve these bounds to $O(nm/\lambda)$ in section 5.

3 *k*-clique extendable orderings

In the book [12], Spinrad introduced the class of *k-clique extendable orderings* of the vertices of graphs, which we explain below. Finding whether a graph has a 2-clique extendable ordering takes polynomial time, but no polynomial time bounds are known for $k \geq 3$. However, we show in the next section that a topological sort of a nondegenerate dag G is a k-clique extendable ordering for $k = \lfloor \lambda(G) \rfloor + 1$, and develop several applications of this result to optimization problems. In this section, we give the details and analysis of the time bound of an algorithm suggested in [12] for finding a maximum clique, given a k-clique extendable ordering.

Two sets *overlap* if they intersect and neither is a subset of the other. Let $\sigma = (v_1, v_2, \ldots, v_n)$ be an ordering of the vertices of a graph, $G = (V, E)$. For $U \subseteq W \subseteq V$ let us say that W *ends with* U if the elements of U are the last elements of W in σ, that is, if no element of $W \setminus U$ occurs after an element of U. W *begins with* U if W ends with U in $(v_n, v_{n-1}, \ldots, v_1)$.

▶ **Definition 5.** An ordering $\sigma = (v_1, v_2, \ldots, v_n)$ of vertices of a graph $G = (V, E)$ is k-clique extendable ordering of G if, whenever X and Y are two overlapping cliques of size k, $|X \cap Y| = k - 1$, and $X \cup Y$ begins with $X \setminus Y = \{a\}$ and ends with $Y \setminus X = \{b\}$ in σ, then a and b are adjacent and $X \cup Y$ is a clique.

This is a generalization of transitivity, since a dag is transitive if and only if its topological sorts are two-clique extendable orderings, hence a graph is a comparability graph if and only if it has a two-clique extendable orderings. In [12], it is shown that three-clique extendable orderings arise naturally in connection with visibility graphs, and that it takes polynomial time to find a maximum clique in a graph, given a three-clique extendable ordering. A polynomial-time generalization for k-clique extendable orderings is implied; we give details and a time bound next.

▶ **Lemma 6.** *If $\sigma = (v_1, v_2, \ldots, v_n)$ is a k-clique extendable ordering of a graph G and X and Y are overlapping cliques of any size greater than or equal to k, such that $|X \cap Y| \geq k - 1$ and $X \cup Y$ begins with $X \setminus Y$ and ends with $Y \setminus X$ in σ, then $X \cup Y$ is a clique.*

Proof. It suffices to show that every element of $X \setminus Y$ is adjacent to every element of $Y \setminus X$. Let x be an arbitrary element of $X \setminus Y$, y be an arbitrary element of $Y \setminus X$, and Z be any $k-1$ elements of $X \cap Y$. Then $\{x\} \cup Z$ and $Z \cup \{y\}$ are two k-cliques and, by the definition of a k-clique extendable ordering, their union is a clique, and x and y are adjacent. ◀

▶ **Corollary 7.** *If $\sigma = (v_1, v_2, \ldots, v_n)$ is a k-clique extendable ordering of a graph G, X is a k-clique ending with $\{v\}$ and Z is a largest clique of G ending with the $(k-1)$-clique $X \setminus \{v\}$, then $Z \cup \{v\}$ is a largest clique of G ending with X.*

Proof. For any clique Y ending with X, $Y \setminus \{v\}$ is a clique ending with $X \setminus \{v\}$. $Z \cup \{v\} = Z \cup X$, which is a clique by Lemma 6. ◀

Corollary 7 is the basis of the recurrence for a dynamic programming algorithm for finding a maximum clique of G, given a k-clique extendable ordering. We enumerate all k-cliques and then label each k-clique K with the maximum size h_K of a clique that ends with K. If $(u_1, u_3, \ldots, u_k)$ is the left-to-right ordering of a k-clique in the ordering, then its label is one plus the maximum of the labels of cliques of the form $(x, u_1, u_2, \ldots, u_{k-1})$. The size of the maximum clique of G is the maximum of the labels. Details and the proof of the following resulting time bound appear in the ArXiv version [6].

▶ **Theorem 8.** *Given a k-clique extendable ordering of a graph G, a maximum clique can be found in $O(km^{k/2})$ time.*

It is easy to see that when the vertices of G have positive weights, the problem of finding a maximum weighted clique can be solved in the same time bound, using a trivial variant of Corollary 7.

4 Optimization problems on dags with bounded λ values

We now show that restricting attention to dags such that λ is bounded by a constant makes some otherwise NP-hard problems easy or gives rise to polynomial-time approximation algorithms that cannot exist for the class of all dags unless P = NP. The NP-hard problems we consider can be trivially solved in linear time on degenerate dags, so we focus on nondegenerate dags.

▶ **Theorem 9.** *Let G be a nondegenerate dag and $k = \lfloor \lambda(G) \rfloor + 1$. A topological sort of G is a k-clique extendable ordering.*

Proof. Let $(v_1, v_2, \ldots, v_n)$ be a topological sort, and let α be a satisfying utility function for (t_1, t_2) such that $t_2/t_1 = \lambda$. Let $(w_1, w_2, \ldots, w_k)$ and $(w_2, w_3, \ldots, w_k, w_{k+1})$ be the left-to-right orderings of two k-cliques K' and K. Then $(w_1, w_2, \ldots, w_{k+1})$ is a directed path in G, hence $\alpha(w_{k+1}) - \alpha(w_1) \geq kt_1 > t_2$, (w_1, w_{k+1}) is an edge and $K \cup K'$ is a clique. ◀

▶ **Corollary 10.** *It takes $O(\lambda m^{\lfloor \lambda+1 \rfloor/2})$ time to find a maximum clique in a connected nondegenerate dag G.*

Proof. To avoid an additive $O(nm/\lambda)$ term, run the dynamic programming algorithm on a topological sort under the assumption that it is a 2-clique extendable ordering in $O(m)$ time by Theorem 8, and return the result if it is a clique. Otherwise, do the same under the assumption that it is a 3-clique extendable ordering, in $O(m^{3/2})$ time. If a max clique has not yet been returned, then $\lambda \geq 3$ by Theorem 9, so compute λ in $O(nm/\lambda) = O(m^2)$ time, which is now subsumed by the bound we want to show. A topological sort is a $\lfloor \lambda \rfloor + 1$ extendable ordering by Theorem 9, so it takes $O(\lambda m^{\lfloor \lambda+1 \rfloor/2})$ time to find a maximum clique by Theorem 8. ◀

Even if λ is bounded by a moderately large constant, this bound could be prohibitive in practice, but it also gives an approximation algorithm that allows a tradeoff between time and approximation factor:

▶ **Corollary 11.** *Given a connected nondegenerate dag G and integer i such that $1 \leq i \leq \lambda$, a clique whose size is within a factor of i of the size of a maximum clique can be found in $O((\lambda/i)m^{(\lfloor \lambda/i \rfloor+1)/2})$ time.*

Proof. Let G' be the result of removing the edges $\{(u,v)|(u,v) \in E(G) \text{ and } \alpha(v)-\alpha(u) < i\}$. A satisfying function α for G and thresholds $(1, \lambda(G))$ is also a satisfying function for G' and thresholds $(i, \lambda(G))$, so $\lambda(G') \leq \lambda(G)/i$. Applying Theorems 8 and 9, we get a maximum clique of G' in $O((\lambda/i)m^{(\lfloor \lambda/i \rfloor+1)/2})$ time. A maximum clique of G induces a directed path $(v_0, v_1, ..., v_k)$ in G, and $\{v_0, v_i, v_{2i}, \ldots, v_{\lfloor k/i \rfloor}\}$ is a clique of G', so the size of a maximum clique in G' is within a factor of i of the size of a maximum clique in G. ◀

If $\lambda(G) < 2$, a maximum independent set in G can be obtained in polynomial time, since G is transitive [4]. However, even when $\lambda(G) = 2$, the problem of determining whether G has an independent set of size k is NP-complete. This is seen as follows. It is NP-complete to decide whether a 3-colorable graph has an independent set of a given size k, even when the 3-coloring is given [9]. Given such a graph G', k, and three-coloring, let C_1, C_2, and C_3 be the three color classes. Every edge e has endpoints in two of the classes; orient e from the endpoint in the class with the smaller subscript to the endpoint in the class with the larger subscript. Doing this for all edges results in a dag G such that $\lambda(G) = 2$, since, for each vertex x, if $x \in C_i$, assigning $\alpha(x) = i$ gives a satisfying assignment of utility values for $t_2 = 2$ and $t_1 = 1$. There is an independent set of size k in G if and only if there is one in G'.

▶ **Theorem 12.** *For G in the class of dags where $\lfloor \lambda(G) \rfloor + 1 \leq k$, there is a polynomial k-approximation algorithm for the problem of finding a maximum independent set in G.*

Proof. Find a satisfying assignment of utility values for (t_1, t_2) such that $t_2/t_1 = \lambda(G)$, then find an interval of the form $[x, x + t_1)$ such that the size of the set Y whose α values are in the interval is maximized. Y is an independent set, since no pair of them has α values that differ by t_1. Return these vertices as an independent set.

For the approximation bound, let X be a maximum independent set. The α values of X lie in an interval of the form $[y, y + t_2]$, which is a subset of the union $[y, y + kt_1)$, of k intervals of the form $[x, x + t_1)$, hence $|X| \leq k|Y|$. ◀

Proofs of the following make similar use of the availability of satisfying α values and are given in the ArXiv version [6].

▶ **Theorem 13.** *For G in the class of dags where $\lfloor \lambda(G) \rfloor + 1 \leq k$, there is a polynomial k-approximation algorithm for the problem of finding a minimum coloring of G.*

▶ **Theorem 14.** *For G in the class of dags where $\lfloor \lambda(G) \rfloor + 1 = k$, there is a polynomial k-approximation algorithm for the problem of finding a minimum clique cover of G.*

5 $O(nm/\lambda)$ bounds for finding satisfying utility functions, λ, and certificates

In this section, we first show how to find a satisfying assignment of utility values for given thresholds (t_1, t_2), in $O(nm/r)$ time, where $r = t_2/t_1$. We then show how to find λ in $O(nm/\lambda)$ time. By solving the second problem to find λ, then selecting (t_1, t_2) such that

$t_2/t_1 = \lambda$ and solving the first, we get the certificates for λ, that is, a satisfying assignment and a cycle such that the ratio of edges to hops is λ, which comes from a zero-weight cycle in G_d.

For both of these problems, we use the following. When G is an arbitrary digraph where each vertex x has a weight $w(x)$ and each edge (y, z) has a weight $w(y, z)$, it takes $O(m)$ time to find $w'(v) = \min(\{\infty\} \cup \{w(u) + w(u, v) | (u, v)$ is an edge of $G\}$ for each vertex v of G. Let us call this the *general relaxation procedure*. In the special case where G is a dag, it takes $O(m)$ time to find $w'(v) = \min_u(\{w(u) + w_{uv})\})$, where w_{uv} is the minimum weight of any path from u to v and $w_{vv} = 0$. This can be used to solve the single-source shortest paths problem on a connected dag in $O(m)$ time [1]. Let us call this the *dag variant* of the relaxation procedure.

In a digraph with edge weights, let the *length* of a walk be the number of occurrences of edges on the walk and its *weight* be the sum of weights of occurrences of edges. If an edge occurs k times on the walk, it contributes k to the length, and if its weight is w, it contributes kw to the weight and kw to the number of (occurrences of) edges of weight w on the walk.

5.1 Finding a satisfying utility function or a forbidden subgraph for (t_1, t_2)

The Bellman-Ford algorithm is a dynamic programming algorithm that works as follows on a connected digraph G where a vertex s has been added that has an edge of weight zero to all other vertices. Let $D(i, v)$ be the minimum weight of any walk from s to v that has at most $i+1$ edges. $D(i, v)$ is just the minimum weight of any walk of length at most i in G ending at v; henceforth we omit s from the discussion. $D(0, v) = 0$ for all $v \in V$. During the "i^{th} pass" the algorithm computes $D(i, v)$ as $min(\{(D(i-1, u) + w(u, v) | (u, v) \in E\})$. This is just an instance of the general relaxation procedure where $w(v) = D(i-1, v)$ and the loop (v, v) is considered to be an edge of weight 0 for each $v \in V$. If there is no negative cycle, there is always a path ending at v that is a minimum-weight walk ending at v, so $D(n-1, v)$ gives the minimum weight of any path ending at v. If there is a negative cycle, this is detected when $D(n, v) < D(n-1, v)$ for some v, indicating a walk of length n of smaller weight of any path, which must have a negative cycle on it. By annotating the dynamic programming entries with suitable pointers, it is possible to find such a cycle within the same bound. The n passes to compute $D(n, v)$ for all v each take $O(m)$ time, for a total of $O(nm)$ time.

To exploit the structure of G_d to improve the running time, we let $B(i, v)$ denote the minimum weight of any path that has at most i edges of weight t_2, rather than at most i edges in total. We use the elements $B(i, v)$, rather than the elements of $D(i, v)$, as the elements of the dynamic programming table. Let us call this *reindexing the dynamic programming table*. We obtain $B(0, v)$ by assigning $w(v) = 0$ and running the dag variant of the relaxation procedure on the edges of weight $-t_1$, since they are acyclic. For pass i such that $i > 0$, any improvements obtained by allowing an i^{th} edge of weight t_2 are computed with the general relaxation procedure, where loops are considered to be edges of weight 0, and, after this, any additional improvements obtained by appending additional edges of weight $-t_1$ are computed by the dag variant of the relaxation procedure.

Because every vertex has a walk of length and weight 0 ending at it, $B(i, v) \leq 0$ for $i \geq 0$. Therefore, for $i > 0$, if $B(i, v) < B(i-1, v)$, the ratio of edges of weight $-t_1$ to edges of weight t_2 is greater than $r = t_2/t_1$. Any such walk must have more than ir edges of weight $-t_1$, hence length greater than $i(r+1)$. Therefore, if there is no negative cycle in G_d, for $i = \lfloor (n-1)/(r+1) \rfloor + 1$, $B(i, v) = D(n-1, v)$, and a negative cycle occurs if $B(i+1, v) < B(i, v)$ for this i and some v. A negative cycle can be found by the standard

technique of annotating the results of the relaxation operations with pointers to earlier results. The advantage of reindexing the table is that the algorithm now takes $O(n/r)$ passes instead of n of them.

To get the $O(nm/r)$ bound, it remains to show how to perform each pass in $O(m)$ time. The bottleneck is evaluating $w'(v) = \min\{\{w(v)\} \cup \{w(u) + t_2 | (u, v)$ is an edge of weight $t_2\}$ for the general relaxation step. Since all of the edges have the same weight, we rewrite this as $w'(v) = min\{w(v), w(x) + t_2\}$ where x minimizes $w(u) = B(i-1, u)$ for all u such that $w(u, v) = t_2$. To evaluate this, we just have to find x. At the beginning of the pass, we radix sort the vertices in ascending order of $B(i-1, *)$, giving list L. To compute $B'(i, v)$, we mark the vertices that have an edge to v, then traverse L until we find x as the first unmarked vertex we encounter, then unmark the vertices that have edges to v. This takes time proportional to the in-degree of v, hence $O(m)$ time for all vertices in the pass.

5.2 Finding λ

To find $\lambda(G)$, we use the fact that that if $t_2/t_1 = \lambda$, the corresponding weighting of G_d will give it a zero-weight cycle in G_d, which gives a forcing cycle of ratio λ in G as a certificate.

For arbitrary (t_1, t_2), let the *mean weight* of a directed cycle or path of length at least one in G_d be the weight of the cycle divided by the number of edges. The minimum mean weight of a cycle is the *minimum cycle mean*. Subtracting a constant c from the weight of all edges in G_d subtracts c from the mean weight of every cycle and path of length at least one. For arbitrary t_1 and t_2, weighting G_d in accordance with $(t_1 + c, t_2 - c)$ in place of (t_1, t_2) has the same effect of subtracting c from the weights of all edges. Thus, for arbitrary (t_1, t_2), if c is the minimum cycle mean of the corresponding weighting of G_d, then $\lambda = (t_2 - c)/(t_1 + c)$. Finding λ reduces to finding the minimum cycle mean in the weighting of G_d obtained from an arbitrarily assigned (t_1, t_2).

In a digraph G with edge weights, let $F(i, v)$ be the minimum weight of any walk of length *exactly* i ending at v. In [8], Karp showed the following:

▶ **Theorem 15.** *The minimum cycle mean of a digraph with edge weights is* $\min_{v \in V} \max_{0 \le i < n}[(F(n, v) - F(i, v))/(n - i)]$.

Karp actually shows this when an arbitrary vertex s is selected and $F(i, v)$ is defined to be the minimum weight of all walks of length i from s to v, but if it is true for walks beginning at an arbitrary vertex s, then it is true when s is allowed to vary over all vertices of V. Omitting s from consideration in this way in his proof gives a direct proof of this variant of his theorem. He reduces the problem to the special case where G is strongly connected by working on each strongly-connected component separately, but the only purpose of this in his proof is to ensure that there is a path from s to all other vertices, and this is unnecessary when s is allowed to vary over all vertices.

$F(i, v)$ can be computed by a variant of Bellman-Ford, by using the recurrence $F(i, v) = \min(\{\infty\} \cup \{F(i-1, u) + w(u, v) | (u, v) \in E\})$ in place of $D(i, v) = \min(\{D(i-1, v)\} \cup \{D(i-1, u) + w(u, v) | (u, v) \in E\})$. The only difference from the algorithm of Section 5.1 is that loops of the form (v, v) are not considered to be edges. Computing $F(n, v)$ for all $v \in V$ takes n passes, each of which applies the general relaxation operation, for a total of $O(nm)$ time.

An obstacle to an $O(nm/\lambda)$ bound that we did not have in Section 5.1 is that in Theorem 15, computing $[(F(n, v) - F(i, v))/(n - i)]$ for $0 \le i < n$ requires $\Theta(n^2)$ computations, which is not $O(nm/\lambda)$.

We again reindex the dynamic programming table (Section 5.1), letting $H(i, v)$ denote the minimum-weight walk ending at v in G_d that has *exactly* i edges of weight t_2. We compute the values in passes, computing $H(i, v)$ for each $v \in V$ during pass i. As in Section 5.1, each pass takes takes $O(m)$ time; the only change is that in the general relaxation step, loops are not considered to be edges. We claim that $O(n/\lambda)$ passes suffice, but a new difficulty is knowing when to stop, since, unlike r of the Section 5.1, λ is not known in advance.

A walk with i edges of weight t_2 and weight $H(i, v)$ has i edges of weight t_2, so it must have $(it_2 - F(i, v))/t_1$ edges of weight $-t_1$. Its length, $l(i, v)$, can be computed as $i + it_2 - F(i, v)$ in $O(1)$ time.

Let a term $H(i, v)$ be *term of interest* if $l(i, v) = n$, that is, if it corresponds to a *walk of interest* of length n. We use the following reindexed variant of Karp's theorem, which says that it suffices to compute an inner maximum over a smaller set, and only for terms of interest. The proof is the one Karp gives, reindexed, and omitting reference to a start vertex s by allowing the start vertex to vary over all vertices. For completeness, we give the modified proof in the ArXiv version [6].

▶ **Theorem 16.** *In G_d, the minimum mean weight of a cycle is equal to* $\min_{\{(i,v)|l(i,v)=n\}} \max_{0\le j<i}(H(i, v) - H(j, v))/(n - l(j, v))$

The solution is given as Algorithm 1. During the i^{th} pass, the algorithm computes $H(i, v)$ for all $v \in V$. Before proceeding to the next pass, it updates a partial computation of the expression of Theorem 16, computing $\max_{0\le j<i}(H(i, v) - H(j, v))/(l(i, v) - l(j, v))$ for each the terms of interest $H(i, v)$ that has been computed during the pass, and keeping track of the minimum of these computations so far. Let a term of interest $H(i, v)$ be *critical* if the minimum cycle mean is equal to $\max_{0\le j<i}(H(i, v) - H(j, v))/(l(i, v) - l(j, v))$. The strategy of the algorithm is to return the minimum it has found so far once it detects that a critical term has been evaluated.

Let a *critical walk* be a walk of length n giving rise to a critical term.

▶ **Lemma 17.** *In G_d, the mean weight of a critical walk is less than or equal to the minimum cycle mean.*

The proof is given in the ArXiv version [6].

▶ **Theorem 18.** *Given a nondegenerate dag G, it takes $O(nm/\lambda)$ time to find $\lambda(G)$.*

Proof. The basis of this is Algorithm 1. For a term of interest, $H(i, v)$, the mean weight of the corresponding walk is $(it_2 - (n - i)t_1)/n$, which is an increasing function of i. Thus, once this exceeds the minimum value, *min*, found so far a critical term has been found and is already reflected in the value of *min*. Thus, Algorithm 1 returns the minimum cycle mean.

The minimum cycle mean is the ratio of edges of weight $-t_1$ to edges of weight t_2 on a cycle of minimum mean. This must also be true for a critical walk, by Lemma 17. This ratio for the walks of interest in pass i is $(n - i)/i$, so the algorithm halts before the first pass i' such that $(n - i')/i' > \lambda$, and $i' = O(n/\lambda)$. Thus, Algorithm 1 halts after $O(n/\lambda)$ passes.

Using the approach of Section 5.1, the operations in a pass take $O(m)$ time except for evaluating $\max_{0\le j<i}(H(i, v) - H(j, v))/(n - l(j, v))$ for terms $H(i, v)$ of interest. For any vertex v, $H(i, v)$ is a term of interest for at most one value of i. Therefore, the cost of evaluating $\max_{0\le j<i}(H(i, v) - H(j, v))/(n - l(j, v))$ for terms of interests is bounded by the total number of dynamic programming table entries $H(j, w)$ for $0 \le j \le i$ and $w \in V$ computed by the algorithm, which is the number n of them computed in each pass times $O(n/\lambda)$ passes. This is $O(n^2/\lambda)$. ◀

Tree Tribes and Lower Bounds for Switching Lemmas

Abstract

Let f be a Boolean function on n variables, $\boldsymbol{\rho}$ a random p-restriction that independently keeps each variable unset (or free) with probability p and otherwise uniformly sets it to 0 or 1, and $\mathrm{DT}_{\mathrm{depth}}(f)$ denote the depth of the smallest depth decision tree for f. Let $\mathrm{R}_d(f|\boldsymbol{\rho})$ be the *resilience* of f to $\boldsymbol{\rho}$ for depth d, defined as

$$\mathrm{R}_d(f|\boldsymbol{\rho}) = \Pr_{\rho \leftarrow \boldsymbol{\rho}}[\mathrm{DT}_{\mathrm{depth}}(f|\rho) \geq d].$$

If $d \gg pn$, all functions have resilience close to 0 since less than d variables would remain unset with high probability. For $d \ll pn$, most functions f on n variables have resilience close to 1, and some functions, like AND and OR, have resilience close to 0. Håstad's Switching Lemma states that for t-DNFs, the resilience $\mathrm{R}_d(f|\boldsymbol{\rho})$ is upper bounded by $(5pt)^d$, and from known upper bounds on the size of constant depth circuits computing the parity function, it follows that there exist t-DNFs whose resilience is close to the bound obtained by Håstad. However, the exact bounds for such maximally resilient DNFs or their structure is unclear, and moreover, the argument is non-constructive.

In this work, we give an explicit construction of functions called Tree Tribes parameterized by an integer t and denoted Ξ_t (on n variables), such that

$$\mathrm{R}_d(\Xi_t|\boldsymbol{\rho}) \leq (4p2^t)^d,$$

and more importantly, the resilience is also *lower* bounded by the same quantity up to constants,

$$\mathrm{R}_d(\Xi_t|\boldsymbol{\rho}) \geq (c_0 p 2^t)^d,$$

for $0 \leq p \leq c_p 2^{-t}$ and $0 \leq d \leq c_d \frac{\log n}{2^t t \log t}$ (where c_0, c_p, c_d are universal constants). As a result, for sufficiently large n and small d, this gives a hierarchy of functions with strictly increasing resilience, and covers the entire region between the two extremes where functions have resilience (close to) 0 or 1.

1 Introduction

One useful and powerful idea to separate a Boolean function g from some set $\mathcal{F}$ of Boolean functions over $\{0,1\}^n$ is to use *restrictions*. By showing that restricted to some subset of $\{0,1\}^n$, the functions in $\mathcal{F}$ become *simple*, but the function g does not become simple, it can be concluded that $g \notin \mathcal{F}$. The extent to which functions in $\mathcal{F}$ become simple is captured by Restriction Lemmas, which informally try to answer the following question: Given a family $\mathcal{F}$ of Boolean functions characterized by some parameter t, and a family $\mathcal{S}$ of distributions over subsets of $\{0,1\}^n$ characterized by some parameter p, how complex does a function $f \in \mathcal{F}$ remain after it is restricted to a subset S chosen according to some distribution $\boldsymbol{\sigma} \in \mathcal{S}$? Defining the measure of complexity of a function and the sets $\mathcal{F}$ and $\mathcal{S}$ gives a Restriction Lemma of a particular type.

To make more concrete statements, let f be a Boolean function on n variables, $\boldsymbol{\sigma}$ a distribution over subsets of $\{0,1\}^n$, and let $f|\sigma$ denote the partial function obtained by restricting f to a subset σ chosen according to $\boldsymbol{\sigma}$. In general, we will use the boldface symbol $\boldsymbol{\sigma}$ to denote both the distribution over subsets and a subset chosen according to $\boldsymbol{\sigma}$, and the interpretation will be clear from context. Let $M : \{0,1\}^{2^n} \to [0,1]$ be some function such that $M(f)$ measures the complexity of a (total) Boolean function f. For a partial function g, $M(g)$ is defined naturally to be the minimum value of $M(f)$ for any total function f that is an extension of g. Given these definitions, we define the *resilience* of a Boolean function f to $\boldsymbol{\sigma}$ for the measure M and threshold $\gamma \in [0,1]$ as follows:

$$\mathrm{R}^M_\gamma(f|\boldsymbol{\sigma}) = \Pr_{\sigma \leftarrow \boldsymbol{\sigma}}[M(f|\sigma) \geq \gamma] = \Pr[M(f|\boldsymbol{\sigma}) \geq \gamma].$$

It is possible to study the variation in the resilience of functions restricted to various different distributions $\boldsymbol{\sigma}$ under measures of complexity M, and in this work, we study it for a particular choice of M and $\boldsymbol{\sigma}$. We will let $M(f)$ be the depth of the smallest depth decision tree for f, and since $M(f) \in [n] = \{0,1,...,n\}$, denoting the threshold specifically as d instead of γ, we will also modify the range of the threshold d and let $d \in [n]$. The restriction $\boldsymbol{\rho}$ is defined as follows: independently for every variable x_i, leave x_i unset with probability p and otherwise uniformly set it to 0 or 1. Note that $\rho \leftarrow \boldsymbol{\rho}$ chooses a p-biased subset of $\{0,1\}^n$. Under the measure M and $\boldsymbol{\rho}$ defined thus, the resilience can be written as:

$$\mathrm{R}_d(f|\boldsymbol{\rho}) = \Pr_{\rho \leftarrow \boldsymbol{\rho}}[\mathrm{DT}_{\mathrm{depth}}(f|\rho) \geq d] = \Pr[M(f|\boldsymbol{\rho}) \geq \gamma]$$

where the measure M is understood to be $\mathrm{DT}_{\mathrm{depth}}$ when omitted from the superscript.

Note that since every variable is independently left unset with probability p, there are $\approx pn$ variables that are left unset with high probability, and so if $d \gg pn$, then for any function f, $\mathrm{R}_d(f|\boldsymbol{\rho}) \approx 0$. Thus, to understand the resilience of different functions, the interesting range is $d \ll pn$, and in general, it will be worthwhile for us to intuitively understand d to be tiny, or about $O(\log \log n)$, since even the statements we make for $d = 1$ will be interesting in themselves. For one extreme, let f be the AND (or OR) function on n bits, and note that $\mathrm{DT}_{\mathrm{depth}}(f) = n$. However, since setting any bit or f to 0 (or 1) reduces it to a constant function, $\mathrm{DT}_{\mathrm{depth}}(f|\boldsymbol{\rho}) > 0$ with probability $(\frac{1+p}{2})^n \approx e^{-n} \approx 0$ (since $p \ll \frac{1}{2}$), and thus $\mathrm{R}_d(f|\boldsymbol{\rho}) \approx 0$ for all $d \geq 1$. On the other extreme, if f is the parity function, it is still the case that $\mathrm{DT}_{\mathrm{depth}}(f) = n$, but under the action of $\boldsymbol{\rho}$, there will be $\geq \frac{1}{2}pn$ variables that are unset with high probability, and $f|\boldsymbol{\rho}$ will be the parity function on the subset of variables, and if $d < \frac{1}{2}pn$, then $\mathrm{R}_d(f|\boldsymbol{\rho}) \approx 1$. In fact, since most functions require a circuit of

large size to decide them, it turns out that for most functions f on n variables, $\mathrm{R}_d(f|\boldsymbol{\rho}) \approx 1$. As a consequence of this, the property of not being reduced to a constant function when restricted to $\boldsymbol{\rho}$ satisfies the largeness condition of natural proofs [8].

This motivates the question about the type of Boolean functions f that have resilience between the two extremes of 0 and 1, and our main interest in this paper would be to understand the structure of such functions in the intermediate region. Upper bounds on $\mathrm{R}_d(f|\boldsymbol{\rho})$ are traditionally called Restriction or Switching Lemmas, which originated with the works of [2] and [1], and were proved in their strongest form by Håstad [3], who showed that if f is a DNF where each term has width t, then $\mathrm{R}_d(f|\boldsymbol{\rho})$ is upper bounded by $(5pt)^d$. Further, this bound can be used to prove tight lower bounds on the size of constant depth circuits deciding the parity function, and since there exist matching upper bounds, it implies that there exist t-DNFs whose resilience is close to $(5pt)^d$ (else it would be possible to get a better lower bound for the size of constant depth circuits deciding parity leading to a contradiction). However, the exact bounds achieved in terms of p, t and d are not known, and even the structure of such maximally resilient t-DNFs is unclear. Moreover, the argument is non-constructive.

Our result

Our main result is an *explicit* construction of functions for which we can prove tight lower and upper bounds on the resilience. The functions that we construct are called Tree Tribes, since they are similar to the Tribes function but on a tree-like structure, and are denoted by Ξ_t where t is an integer parameter. Our main theorem is the following.

▶ **Theorem 1.** *For every integer $t \geq 1$, for every n, there is an explicit function Ξ_t on n variables, such that for all p, t, and d,*

$$R_d(\Xi_t|\boldsymbol{\rho}) \leq (4p2^t)^d,$$

and for $0 \leq p \leq c_p 2^{-t}$ and $0 \leq d \leq c_d \left(\frac{\log n}{2^t t \log t}\right)$,

$$R_d(\Xi_t|\boldsymbol{\rho}) \geq (c_0 p 2^t)^d,$$

where c_p, c_d and c_0 are universal constants.

We would like to remark that the lower bound holds for d at most $\sim 2^{-t} \log n$, which is meaningful for $t \in O(\log \log n)$. However, the non-trivial part of the lower bound is that d is upper bounded by a function not only of t (which in general would be small), but of *both* t and n. Henceforth, when we consider the resilience of different functions, n will be assumed to be very large, and t and d will assumed to be small (about $O(\log \log n)$) compared to n.

An immediate corollary of Theorem 1 is the following:

▶ **Corollary 2.** *Let d and n be fixed. Let $i_1, \ldots, i_r$ be a sequence of integers such that $c_{t0} < i_1 < \ldots < i_r < c_{t1}(\log \log n - \log d)$ and $0 \leq p \leq c_p 2^{-i_r}$. Then the sequence of functions $\{\Xi_{i_j}\}_{j=1}^r$ (each on n variables) has strictly increasing resilience, i.e.*

$$R_d(\Xi_{i_j}|\boldsymbol{\rho}) < R_d(\Xi_{i_{j+1}}|\boldsymbol{\rho}),$$

where c_{t0}, c_{t1}, c_p are universal constants.

And similarly, we can get a resilience heirarchy in the following sense:

▶ **Corollary 3.** *Let d, n and r be fixed. Let t be an integer variable such that $c_{t0} \leq t \leq c_{t1}(\log\log n - \log d)/r$ and p a variable that is some function of t, i.e. $p = p(t)$ and $0 \leq p \leq c_p 2^{-rt}$. Then the sequence of functions $\{\Xi_{it}\}_{i=1}^{r}$ (each on n variables) has strictly increasing resilience, i.e.*

$$R_d(\Xi_{it}|\boldsymbol{\rho}) \in o(R_d(\Xi_{(i+1)t}|\boldsymbol{\rho}),$$

where c_{t0}, c_{t1}, c_p are universal constants.

The proof of the resilience upper bound in Theorem 1 uses a method of *conditioning on variables*, and thus avoids the complex conditioning in [3, 4], and also the combinatorial reasoning in [7, 6], and as a consequence, is *simpler* than both methods. The proof of the resilience lower bound is recursive, and proceeds by analyzing the coefficients of polynomials that arise in the analysis of Tree Tribes. Note that in Theorem 1, since we want to lower bound the probability of the event $\mathrm{DT}_{\mathrm{depth}}(\Xi_t|\boldsymbol{\rho}) \geq d$, we require that the decision tree with the least depth (and thus *every* decision tree) for $\Xi_t|\boldsymbol{\rho}$ must have depth greater than d with sufficient probability. To achieve this, our proof proceeds as follows: If T is the decision tree for Ξ_t, we lower bound the probability of finding *"paths with a split"* in $T|\boldsymbol{\rho}$. A *"path with a split"* is a subtree of $T|\boldsymbol{\rho}$, which consists of a path of distinct variables $y_1, \ldots, y_d$ (where y_1 is closest to the root in $T|\boldsymbol{\rho}$), such that y_d is connected to two leaves with *different* values (more specifically, y_d has a path to a leaf labelled 0 and a leaf labelled 1). Any decision tree for such a subtree of $T|\boldsymbol{\rho}$ must have depth at least d (at least if the variables $y_1, \ldots, y_d$ do not appear elsewhere in the tree), since the OR function is embedded in $T|\boldsymbol{\rho}$ *and* all the variables of T would be distinct in our construction. However, we need a sufficient number of vertices in the tree before we get sufficient probability mass for the event of finding such a path with a split, and this is the reason we get an upper bound on the depth d for which Theorem 1 holds.

We state the Preliminaries in Section 2, the construction of Tree Tribes in Section 3, prove the resilience upper bound in Theorem 1 in Section 4, and the resilience lower bound in Section 5. Due to space constraints, the proofs are relegated to the full version [5].

2 Preliminaries

The extended preliminaries, including the standard definitions of decision trees and random p-restrictions are given in the full version [5], and we state only the non-standard definitions here.

▶ **Definition 4** (Resilience)**.** Let f be a Boolean function on n variables, and ρ a random p-restriction. For $d \in [n]$, we let $\mathrm{R}_d(f|\boldsymbol{\rho})$ be the resilience of f to $\boldsymbol{\rho}$ at depth d, defined as

$$\mathrm{R}_d(f|\boldsymbol{\rho}) = \Pr[\mathrm{DT}_{\mathrm{depth}}(f|\rho) \geq d].$$

If T is some decision tree for some function f, we alternately write $\mathrm{R}_d(T|\boldsymbol{\rho})$ to mean $\mathrm{R}_d(f|\boldsymbol{\rho})$.

▶ **Definition 5** (Clipped decision trees, [6])**.** A decision tree T is t-clipped, if any vertex of T is at a distance of at most t from some leaf.

▶ **Definition 6** (Operators on polynomials)**.** For a univariate polynomial Q in the variable p, denoted as $Q = \sum_{i \geq 0} c_i p^i$ with a finite number of non-zero coefficients, define the operator $[p^i]$ as $[p^i]Q = c_i$ and the operator $[\uparrow p^i]$ as

$$[\uparrow p^i]Q = \sum_{j \geq i} \left([p^j]Q\right) p^{j-i}.$$

▶ **Definition 7** (Absolute maximizer)**.** Given a closed set $\mathcal{D} \subseteq [0,1]$ and some polynomial Q in $\mathbb{R}[p]$, we define the absolute maximizer of $[\uparrow p^i]Q$ by functions G_i as $G_i(Q) = \max_{p\in\mathcal{D}} \left|[\uparrow p^i]Q\right|$.

3 Tree Tribes

We now formally define Tree Tribes and their variants. A specific variant, t-clipped xor Tree Tribe, will be the function that will help us achieve the bounds in Theorem 1.

▶ **Definition 8** (Tree Tribe)**.** A Boolean function f is called a Tree Tribe, denoted by Ξ, if there is a decision tree T deciding f, such that all the variables at all the vertices of T are distinct, and from every vertex of T, there is a path to a leaf labeled 0 and a path to a leaf labeled 1.

An example for a Tree Tribe is the OR function. Given the above definition, it is possible to derive a variety of different Tree Tribes by imposing additional structure, and we define the specific structure that we'll need.

▶ **Definition 9** (Complete clipped decision trees)**.** Denote a complete t-clipped decision tree T on r levels by $W_t(r)$, and define it recursively as follows: $W_t(0)$ is a leaf. $W_t(r)$ consists of vertices $\{v_1, ..., v_t\}$, a leaf denoted by v_{t+1}, and edges $e_{i,0}$ and $e_{i,1}$ for $i \in \{1, ..., t\}$. The vertices v_1 to v_t will be said to belong to layer or level 1. Each edge $e_{i,0}$ is labelled 0 and it will be called a 0-edge, and it connects v_i and v_{i+1}. Each edge $e_{i,1}$ is labelled 1 and it will be called a 1-edge, and it connects v_i to the root of a copy of $W_t(r-1)$ on distinct variables.

▶ **Definition 10** (Clipped xor Tree Tribe)**.** A Boolean function f is called a t-clipped xor Tree Tribe, denoted by $\Xi_t(r)$ for an integer t, if $T(f)$ is a Tree Tribe, and can be expressed as a complete t-clipped decision tree, in which the leaves are labeled by the parity of the edges on the path from the root to the leaf.

Note that we define the level of some variable x in $\Xi_t(r)$ by the recursive step at which it was added to $\Xi_t(r)$. The variables at level 1 are x_1 to x_t, each of which is connected to a copy of $\neg\Xi_t(r-1)$ on distinct variables. The first t variables in each of the t copies of$\neg\Xi_t(r-1)$, a total of t^2 variables, are at level 2, and each of them is connected to a copy of $\Xi_t(r-2)$, and so on. An examples for $\Xi_2(3)$ is shown in the figure below.

Since our aim was to understand the structure of functions that are resilient towards random restrictions, we show that the functions $\Xi_t(r)$ exhibit many nice properties (given in the full version [5]). For instance, the Fourier coefficient of a subset $S \subseteq \{0,1\}^n$ depends *only* on the parameters (level in the tree and distance from root) of the variable in S that represents the vertex farthest from the root in S. These and other properties can be found in [5] along with some remarks on why they turn out to be resilient towards random restrictions.

We now proceed to show that these functions achieve the bounds stated in Theorem 1.

4 Resilience upper bound

We start by by showing the resilience upper bound in Theorem 1. Our bound will hold in general for any function f that has a t-clipped decision tree. It was shown in [6] that for any Boolean function f that has a t clipped decision tree, $\mathrm{R}_d(f|\boldsymbol{\rho}) \leq O(pt2^t)^d$, and we improve the bound to $\mathrm{R}_d(f|\boldsymbol{\rho}) \leq (4p2^t)^d$, an improvement that is necessary for us since it matches the resilience lower bound. As stated earlier, our proof uses a method of *conditioning on variables* that is different and simpler from the complex conditioning in [3, 4], and the combinatorial

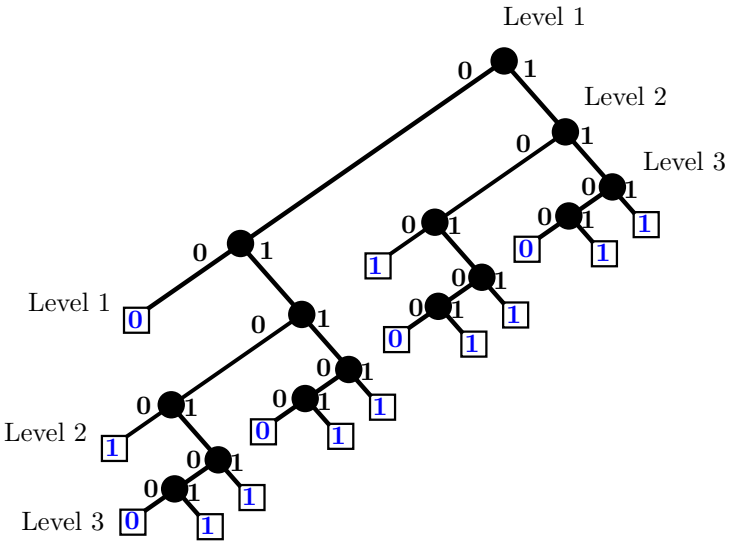

Figure 1 A 2-clipped xor tree tribe on 3 levels, or $\Xi_2(3)$. The variables at each of the vertices are distinct, and the leaves are labelled by the parity of the edges along the root to leaf path. Note that there are 2 vertices at level 1, 4 vertices at level 2, and 8 vertices at level 3.

reasoning in [7, 6], and is also amenable to extension to more general restrictions. The proofs of the lemmas in this section are given in the full version [5].

Let f be a Boolean function that has a t-clipped decision tree T.

▶ **Definition 11.** A decision tree T is (t_0, t)-clipped for $t_0 \leq t$, if the root has distance at most t_0 from some leaf, and every other vertex has distance at most t to some leaf.

▶ **Definition 12.** For positive integers t_0, t, n, d, define the probabilities $\gamma_{d,n}(t_0, t)$ as follows:

$$\gamma_{d,n}(t_0, t) = \max_{\substack{(t_0,t)\text{-clipped trees } T \text{ that} \\ \text{decide any function on } n \text{ variables}}} \mathrm{R}_d(T|\boldsymbol{\rho})$$

It is simple to see that γ is monotone in n.

▶ **Lemma 13.** *If $n' \leq n$, then $\gamma_{d,n'}(t_0, t) \leq \gamma_{d,n}(t_0, t)$.*

4.1 Recurrence for γ

We proceed by writing a recurrence for $\gamma_{d,n}(t_0, t)$.

Let T be the (t_0, t)-clipped decision tree for which $\gamma_{d,n}(t_0, t)$ has maximum value. Let x_1 be the root, and let T_0 and T_1 be subtrees out of the 0 and 1 edges of x_1. Under the action of a random p-restriction $\rho \leftarrow \boldsymbol{\rho}$, if x_1 is assigned 0 by ρ, we get a $(t_0 - 1, t)$ clipped decision tree T_0 on n_0 variables where $n_0 < n$. By the definition of decision trees, since x_1 appears as the root of T, it cannot appear again as a variable in T_0, and thus T_0 is indeed a $(t_0 - 1, t)$-clipped tree. If x_1 is assigned 1 by ρ, similarly, we get a (t, t) clipped decision tree T_1 on n_1 variables where $n_1 < n$.

Let the event $E_{T,d}$ be defined as follows:

$$E_{T,d} \equiv \mathrm{DT}_{\mathrm{depth}}(T|\boldsymbol{\rho}) \geq d.$$

▶ **Lemma 14.** *In case x_1 is assigned $*$ by a random p-restriction $\rho \leftarrow \boldsymbol{\rho}$,*

$$E_{T,d} = E_{T_0,d-1} \bigcup E_{T_1,d-1}.$$

Let $\boldsymbol{\rho} = \boldsymbol{\rho_{x_1}\rho'}$ where $\boldsymbol{\rho'}$ is a random restriction on variables different from x_1, and $q = (1-p)/2$. Thus, we can write the following,

$$\begin{aligned}
\Pr_{\rho\leftarrow\boldsymbol{\rho}}[E_{T,d}] &= \Pr_{\rho\leftarrow\boldsymbol{\rho}}[E_{T,d}|\rho(x_1)=0]\Pr_{\rho\leftarrow\boldsymbol{\rho}}[\rho(x_1)=0] + \Pr_{\rho\leftarrow\boldsymbol{\rho}}[E_{T,d}|\rho(x_1)=1]\Pr_{\rho\leftarrow\boldsymbol{\rho}}[\rho(x_1)=1] \\
&\quad + \Pr_{\rho\leftarrow\boldsymbol{\rho}}[E_{T,d}|\rho(x_1)=*]\Pr_{\rho\leftarrow\boldsymbol{\rho}}[\rho(x_1)=*] \\
&= \Pr_{\rho'\leftarrow\boldsymbol{\rho'}}[E_{T_0,d}]q + \Pr_{\rho'\leftarrow\boldsymbol{\rho'}}[E_{T_1,d}]q + \Pr_{\rho'\leftarrow\boldsymbol{\rho'}}[E_{T_0,d-1}\bigcup E_{T_1,d-1}]p \\
&\le \Pr_{\rho'\leftarrow\boldsymbol{\rho'}}[E_{T_0,d}]q + \Pr_{\rho'\leftarrow\boldsymbol{\rho'}}[E_{T_1,d}]q + \Pr_{\rho'\leftarrow\boldsymbol{\rho'}}[E_{T_0,d-1}]p + \Pr_{\rho'\leftarrow\boldsymbol{\rho'}}[E_{T_1,d-1}]p \qquad (1)
\end{aligned}$$

where the second line follows from Lemma 14 and the fact that the subtrees at x_1 do not contain x_1, and the last line follows from the union bound. Further, rewriting the above inequality in terms of $\gamma_{d,n}(t_0,t)$ and using Lemma 13, we can write,

$$\begin{aligned}
\gamma_{d,n}(t_0,t) &\le q\gamma_{d,n_0}(t_0-1,t) + q\gamma_{d,n_1}(t,t) + p\gamma_{d-1,n_0}(t_0-1,t) + p\gamma_{d-1,n_1}(t,t) \\
&\le q\gamma_{d,n}(t_0-1,t) + q\gamma_{d,n}(t,t) + p\gamma_{d-1,n}(t_0-1,t) + p\gamma_{d-1,n}(t,t).
\end{aligned}$$

The parameters n and t above are implicit, and we can rewrite the recurrence succinctly as

$$\gamma_d(t_0) \le q\gamma_d(t_0-1) + q\gamma_d(t) + p\gamma_{d-1}(t_0-1) + p\gamma_{d-1}(t) \qquad (2)$$

and for every integer d, we set

$$\gamma_d(0) = 0. \qquad (3)$$

We get the following recurrence for γ.

▶ **Lemma 15.** *After m iterations, the recurrence is,*

$$\gamma_d(t_0) \le \sum_{i=0}^{m}\binom{m}{i}q^{m-i}p^i\gamma_{d-i}(t_0-m) + \sum_{i=1}^{m}q^i\gamma_d(t) + \sum_{j=1}^{m}p^j\gamma_{d-j}(t)\left(\sum_{i=0}^{m-j}\binom{j+i}{i}q^i\right) \qquad (4)$$

4.2 Upper bound on γ

Setting $t_0 = t$ and $m = t$ in equation 4 and using 3, we get,

$$\frac{1-2q+q^{t+1}}{1-q}\gamma_d(t) \le \sum_{j=1}^{t}p^j\gamma_{d-j}(t)\left(\sum_{i=0}^{t-j}\binom{j+i}{i}q^i\right).$$

Using the induction hypothesis, for $\mu = \kappa 2^t$, we have that $\gamma_{d-c}(t) \le (\mu p)^{d-c}$ for all p, c, d, t where $p \le \frac{1}{\mu}$. Note that γ is a probability and since $p \le \frac{1}{\mu}$, it is also valid when $c > d$. [1] Then we have,

$$\frac{1-2q+q^{t+1}}{1-q}\gamma_d(t) \le (\mu p)^d\left(\sum_{j=1}^{t}\sum_{i=0}^{t-j}\left(\frac{1}{\mu}\right)^j\binom{j+i}{i}q^i\right). \qquad (5)$$

The next lemma is important, but the proof is relegated to the full version [5].

[1] In fact, whenever $d < t$, we can indeed get much fewer terms in the summation, and get a better bound, although asymptotically it does not make a difference.

▶ **Lemma 16.** *For* $\mu = 4.2^t$,

$$\left(\sum_{j=1}^{t}\sum_{i=0}^{t-j}\left(\frac{1}{\mu}\right)^j\binom{j+i}{i}q^i\right)\left(\frac{1-q}{1-2q+q^{t+1}}\right) \leq 1.$$

Using Lemma 16 in equation 5, we get that $\gamma_d(t) \leq (4p2^t)^d$, which concludes the proof of the resilience upper bound in Theorem 1.

5 Resilience lower bound

We now prove the lower bound on resilience in Theorem 1 which is the main contribution of this work. We prove the bound for t-clipped xor Tree Tribes or $\Xi_t(r)$, by induction on d. However, we cannot use $d = 0$ as the base case, and we discuss this when we do the inductive step. The base case will be $d = 1$, which we solve next. The proofs from this section are given in the full version [5].

5.1 The case for $d = 1$

This base case will turn out the most interesting. Here, we want to show the following.

$$\mathrm{R}_1(\Xi_t(r)|\boldsymbol{\rho}) \geq c_0 p 2^t.$$

If r is small, i.e., if the function has fewer than $\sim 2^t$ variables, then the number of variables assigned $*$ by $\rho \leftarrow \boldsymbol{\rho}$ will be low on average, and the event $\mathrm{DT}_{\mathrm{depth}}(\Xi_t(r)|\boldsymbol{\rho}) \geq 1$ would be extremely unlikely. Thus, we would like to show the following.

▶ **Lemma 17.** *For some universal constants* c_0 *and* c_p, *for* $r \in \Omega(t2^t)$ *and* $0 \leq p \leq c_p 2^{-t}$, *if* $\boldsymbol{\rho}$ *is a random* p*-restriction, then*

$$R_1(\Xi_t(r)|\boldsymbol{\rho}) \geq c_0 p 2^t.$$

Note that in Lemma 17, we require that the decision tree with the *smallest* depth that can compute $\Xi_t(r)|\boldsymbol{\rho}$ has depth greater than 1 with good probability, which means that we require that *any* decision tree representing $\Xi_t(r)|\boldsymbol{\rho}$ must query at least one variable. This will be made possible by a simple observation.

▶ **Lemma 18.** $DT_{depth}(\Xi_t(r)|\boldsymbol{\rho}) \geq 1$ *if and only if there is a path in* $\Xi_t(r)|\boldsymbol{\rho}$ *from the root to a leaf that evaluates to 0 and to a leaf that evaluates to 1.*

▶ **Definition 19.** Let $\Xi_t(r)$ be a t-clipped xor tribe on r levels and $\boldsymbol{\rho}$ a random p-restriction. Letting the parameters p and t be implicit, let $P_0(r)$, $P_1(r)$ and $P_*(r)$ be defined as follows.

$$\begin{aligned} P_0(r) &= \Pr_{\rho}[\Xi_t(r)|\boldsymbol{\rho} \equiv 0], \\ P_1(r) &= \Pr_{\rho}[\Xi(r)|\boldsymbol{\rho} \equiv 1], \\ P_*(r) &= \mathrm{R}_1(\Xi_t(r)|\boldsymbol{\rho}) \\ &= 1 - P_0(r) - P_1(r). \end{aligned} \tag{6}$$

Given Lemma 18, the proof for Lemma 17 proceeds as follows:

Step 1. We write the exact expressions for $P_0(r)$ and $P_1(r)$ as a polynomial in p by using counting arguments and recursion.

Step 2. In the next step, we reason about the constant coefficients of $P_0(r)$ and $P_1(r)$. We derive the expressions for $[1]P_0(r)$ and $[1]P_1(r)$, using which we show:

$$[1]P_0(r) + [1]P(r) = 1.$$

Step 3. In the third step, we first compute the recursive expressions for $[p]P_0(r)$ and $[p]P_1(r)$ and show the the following two claims.

▶ **Lemma 20.** *For every* $r \geq 1$, $-2.2^t \leq [p]P_0(r) \leq 0$ *and* $-2.2^t \leq [p]P_1(r) \leq 0$.

▶ **Lemma 21.** *For* $r \in \Omega(t2^t)$, $[p](P_0(r) + P_1(r)) \leq -c_1 2^t$ *where* $c_1 = \frac{1}{3}$.

The proofs of all the above lemmas are given in the full version [5]. Lemma 21 stated above is an important one, and it states there there is sufficient mass, $\sim 2^t$ in the coefficient of p in $P_0(r) + P_1(r)$. Combining lemma 20 and 21, we get that

$$-4.2^t \leq [p](P_0(r) + P_1(r)) \leq -c_1 2^t.$$

Step 4. In the equation at the end of step 3 above, we almost have sufficient information to conclude Lemma 17, however, we need to reason that higher powers of p in $P_0(r) + P_1(r)$ cannot substantially affect the coefficient of p. We do so by showing that the absolute value of $[\uparrow p^2](P_0(r) + P_1(r))$ is bounded by $O(2^{2t})$. Here we will use the fact that $p \leq c_p 2^{-t}$ where c_p is some universal constant. This lemma is also important, and its proof is given in the full version [5].

▶ **Lemma 22.** *For every* $r \geq 1$, *for* $0 \leq p \leq p_{\max} = \frac{1}{200.2^t}$,

$$G_2(P_0(r) + P_1(r)) \leq 30.2^{2t}.$$

Step 5. Finally we prove Lemma 17.

Proof of Lemma 17. The probability that the decision tree with r levels has depth more than or equal to 1, i.e. it does not become constantly 0 or 1 after being hit by a random restriction is given by

$$P_*(r) = 1 - P_0(r) - P_1(r).$$

For $r \in \Omega(t2^t)$, we can write

$$\begin{aligned} P_*(r) &= 1 - [1](P_0(r) + P_1(r)) - ([p]P_0(r) + [p]P_1(r))\,p - \left([\uparrow p^2](P_0(r) + P_1(r))\right)p^2 \\ &= -([p]P_0(r) + [p]P_1(r))\,p - \left([\uparrow p^2](P_0(r) + P_1(r))\right)p^2 \\ &\geq c_1 2^t p - p_{\max} 2.30.2^{2t} p \\ &= p2^t\left(\frac{1}{3} - \frac{60}{200}\right) \\ &\geq \frac{1}{30}p2^t \end{aligned}$$

where in the second line we used the fact that $[1]P_0(r) + [1]P(r) = 1$, and in the third line we used Lemmas 21 and 22. Note that we get $c_0 = \frac{1}{30}$. ◀

5.2 Inductive step

We remark that $d = 0$ cannot be taken as the base case for induction. In a decision tree T with x_1 as the root and having subtrees T_0 and T_1 out of the 0 and 1 edges respectively, if $\rho \leftarrow \boldsymbol{\rho}$ assigns $*$ to x_1, then $T_0|\rho$ or $T_1|\rho$ having depth greater than 0 does not imply that T has depth greater than 1. If both $T_0|\rho$ and $T_1|\rho$ are constant functions, we would additionally require that they evaluate to *different* values. Thus we cannot use $d = 0$ as the base case.

Doing the inductive step recursively is tricky. This is because we already need about $\sim t2^t$ levels in the tree for the base case to work. Thus, any induction must take care of the fact that once the number of levels are too few, the base case would not hold.

Let us write the recurrence first. Let $\gamma_d(r)$ be the probability that $\Xi_t(r)$ has depth greater than or equal to d under the action of a random restriction.

▶ **Lemma 23.** *Let $\mu = 1 - \gamma_{d-1}(r-1)$. Then,*

$$\gamma_d(r) \geq \sum_{k=1}^{t-1} q \sum_{i=1}^{k} \binom{k}{i} q^{k-i} p^i (1-\mu^{i+1}) + \sum_{i=0}^{t} \binom{t}{i} q^{t-i} p^i (1-\mu^i) + \sum_{k=0}^{t-1} q^{k+1} \gamma_d(r-1). \quad (7)$$

Note that we would use the above recurrence for m steps, since we need to pick up sufficient probability mass from each step. As such, we would want the inductive hypothesis to hold for *all* the m steps. The inductive steps will be different for the cases $t \geq 2$ and $t = 1$, shown in the following lemma.

▶ **Lemma 24.** *For $r \in \Omega(dt2^t)$, $\gamma_d(r) \geq (c_0 p 2^t)^d$.*

In the proof of Lemma 24, we use $O(2^t)$ steps to take the induction from d to $d-1$ levels, and the final $d = 1$ case can be carried out with $O(t2^t)$ levels. Thus, the maximum depth for which our conclusions hold is

$$dt2^t \leq O(r) \leq c_d \frac{\log n}{\log t}$$

or

$$d \leq c_d \left(\frac{\log n}{2^t t \log t} \right).$$

This concludes the proof of Theorem 1.

▶ Remark. If we unroll the induction and see how it worked, for depth d, we find some vertex that is unset by $\boldsymbol{\rho}$ and is connected to a tree that has depth $d-1$ under the action of ρ. For depth $d-1$, we again find an unset variable connected to a tree of depth $d-2$. This carries on until the last step, where we want to find a vertex that has depth greater than or equal to 1, i.e., has a path to both a 0-leaf and a 1-leaf. Thus, as described in the introduction, the whole proof essentially finds a *"path with a split"*.

Abstract

In this paper we use the theory of computing to study fractal dimensions of projections in Euclidean spaces. A fundamental result in fractal geometry is Marstrand's projection theorem, which shows that for every analytic set E, for almost every line L, the Hausdorff dimension of the orthogonal projection of E onto L is maximal.

We use Kolmogorov complexity to give two new results on the Hausdorff and packing dimensions of orthogonal projections onto lines. The first shows that the conclusion of Marstrand's theorem holds whenever the Hausdorff and packing dimensions agree on the set E, even if E is not analytic. Our second result gives a lower bound on the packing dimension of projections of arbitrary sets. Finally, we give a new proof of Marstrand's theorem using the theory of computing.

1 Introduction

The field of fractal geometry studies the fine-grained structure of irregular sets. Of particular importance are fractal dimensions, especially the Hausdorff dimension, $\dim_H(E)$, and packing dimension, $\dim_P(E)$, of sets $E \subseteq \mathbb{R}^n$. Intuitively, these dimensions are alternative notions of size that allow us to quantitatively classify sets of measure zero. The books of Falconer [8] and Mattila [23] provide an excellent introduction to this field.

A fundamental problem in fractal geometry is determining how projection mappings affect dimension [9, 24]. Here we study orthogonal projections of sets onto lines. Let e be a point on the unit $(n-1)$-sphere S^{n-1}, and let L_e be the line through the origin and e. The *projection of E onto L_e* is the set

$$\mathrm{proj}_e E = \{e \cdot x : x \in E\},$$

where $e \cdot x$ is the usual dot product, $\sum_{i=1}^{n} e_i x_i$, for $e = (e_1, \ldots, e_n)$ and $x = (x_1, \ldots, x_n)$. We restrict our attention to lines through the origin because translating the line L_e will not affect the Hausdorff or packing dimension of the projection.

Notice that $\mathrm{proj}_e E \subseteq \mathbb{R}$, so the Hausdorff dimension of $\mathrm{proj}_e E$ is at most 1. It is also simple to show that $\dim_H(\mathrm{proj}_e E)$ cannot exceed $\dim_H(E)$ [8]. Given these bounds, it is natural to ask whether $\dim_H(\mathrm{proj}_e E) = \min\{\dim_H(E), 1\}$. Choosing E to be a line

[1] Research supported in part by National Science Foundation Grants 1247051 and 1545028.

orthogonal to L_e shows that this equality does not hold in general. However, a fundamental theorem due to Marstrand [21] states that, if $E \subseteq \mathbb{R}^2$ is analytic, then for *almost all* $e \in S^1$, the Hausdorff dimension of $\mathrm{proj}_e E$ is maximal. Subsequently, Mattila [22] showed that the conclusion of Marstrand's theorem also holds in higher-dimensional Euclidean spaces.

▶ **Theorem 1** ([21, 22]). *Let $E \subseteq \mathbb{R}^n$ be an analytic set with $\dim_H(E) = s$. Then for almost every $e \in S^{n-1}$,*

$$\dim_H(\mathrm{proj}_e E) = \min\{s, 1\}\,.$$

In recent decades, the study of projections has become increasingly central to fractal geometry [9]. The most prominent technique has been the potential theoretic approach of Kaufman [14]. While this is a very powerful tool in studying the dimension of a set, it requires that the set be analytic. We will show that techniques from theoretical computer science can circumvent this requirement in some cases.

Our approach to this problem is rooted in the effectivizations of Hausdorff dimension [16] by J. Lutz and of packing dimension by Athreya et al. [1]. The original purpose of these effective dimension concepts was to quantify the size of complexity classes, but they also yield geometrically meaningful definitions of dimension for *individual points* in $\mathbb{R}^n$ [18]. More recently, J. Lutz and N. Lutz established a bridge from effective dimensions back to classical fractal geometry by showing that the Hausdorff and packing dimensions of a set $E \subseteq \mathbb{R}^n$ are characterized by the corresponding effective dimensions of the individual points in E, taken relative to an appropriate oracle [17].

This result, a *point-to-set principle* (Theorem 7 below), allows researchers to use tools from algorithmic information theory to study problems in classical fractal geometry. Although this connection has only recently been established, there have been several results demonstrating the usefulness of the point-to-set principle: J. Lutz and N. Lutz [17] applied it to give a new proof of Davies' theorem [4] on the Hausdorff dimension of Kakeya sets in the plane; N. Lutz and Stull [20] applied it to the dimensions of points on lines in $\mathbb{R}^2$ to give improved bounds on generalized Furstenberg sets; and N. Lutz [19] used it to show that a fundamental bound on the Hausdorff dimension of intersecting fractals holds for arbitrary sets.

In this paper, we use algorithmic information theory, via the point-to-set principle, to study the Hausdorff and packing dimensions of orthogonal projections onto lines. Given the statement of Theorem 1, it is natural to ask whether the requirement that E is analytic can be removed. Without further conditions, it cannot; Davies [5] showed that, assuming the continuum hypothesis, there are non-analytic sets for which Theorem 1 fails. Indeed, Davies constructed a set $E^* \subseteq \mathbb{R}^2$ such that $\dim_H(E^*) = 1$ but $\dim_H(\mathrm{proj}_e E^*) = 0$ for every $e \in S^1$.

Our first main theorem shows that if the Hausdorff and packing dimensions of E agree, then we can remove the requirement that E is analytic.

▶ **Theorem 2.** *Let $E \subseteq \mathbb{R}^n$ be any set with $\dim_H(E) = \dim_P(E) = s$. Then for almost every $e \in S^{n-1}$,*

$$\dim_H(\mathrm{proj}_e E) = \min\{s, 1\}\,.$$

Our second main theorem applies to projections of *arbitrary* sets. Davies' construction precludes any non-trivial lower bound on the Hausdorff dimension of projections of arbitrary sets, but we are able to give a lower bound on the *packing* dimension.

▶ **Theorem 3.** *Let $E \subseteq \mathbb{R}^n$ be any set with $\dim_H(E) = s$. Then for almost every $e \in S^{n-1}$,*

$$\dim_P(\mathrm{proj}_e E) \geq \min\{s, 1\}\,.$$

Lower bounds on the packing dimension of projections have been extensively studied for restricted classes sets such as Borel and analytic [6, 7, 10, 12, 26]. To the best of our knowledge, our result is the first non-trivial lower bound of this type for arbitrary sets. It is known that the analogue of Marstrand's theorem for packing dimension does *not* hold [13].

Our other contribution is a new proof of Marstrand's projection theorem (Theorem 1). In addition to showing the power of theoretical computer science in geometric measure theory, this proof introduces a new technique for further research in this area. We show that the assumption that E is analytic allows us to use an earlier, restricted point-to-set principle due to J. Lutz [16] and Hitchcock [11]. While less general than that of J. Lutz and N. Lutz, it is sufficient for this application and involves a simpler oracle. Informally, this allows us to reverse the order of quantifiers in the statement of Theorem 1. This will be both beneficial for further research, as well as clarifying the role of the analytic assumption of E.

2 Preliminaries

We begin with a brief description of algorithmic information quantities and their relationships to Hausdorff and packing dimensions.

2.1 Kolmogorov Complexity in Discrete and Continuous Domains

The *conditional Kolmogorov complexity* of a binary string $\sigma \in \{0,1\}^*$ given a binary string $\tau \in \{0,1\}^*$ is the length of the shortest program π that will output σ given τ as input. Formally, the conditional Kolmogorov complexity of σ given τ is

$$K(\sigma \mid \tau) = \min_{\pi \in \{0,1\}^*} \{\ell(\pi) : U(\pi, \tau) = \sigma\} ,$$

where U is a fixed universal prefix-free Turing machine and $\ell(\pi)$ is the length of π. Any π that achieves this minimum is said to *testify* to, or be a *witness* to, the value $K(\sigma \mid \tau)$. The *Kolmogorov complexity* of a binary string σ is $K(\sigma) = K(\sigma \mid \lambda)$, where λ is the empty string. These definitions extend naturally to other finite data objects, e.g., vectors in $\mathbb{Q}^n$, via standard binary encodings; see [15] for details.

One of the most useful properties of Kolmogorov complexity is that it obeys the *symmetry of information*. That is, for every $\sigma, \tau \in \{0,1\}^*$,

$$K(\sigma, \tau) = K(\sigma) + K(\tau \mid \sigma, K(\sigma)) + O(1) .$$

Kolmogorov complexity can be naturally extended to points in Euclidean space, as we now describe. The *Kolmogorov complexity* of a point $x \in \mathbb{R}^m$ at *precision* $r \in \mathbb{N}$ is the length of the shortest program π that outputs a *precision-r* rational estimate for x. Formally, this is

$$K_r(x) = \min \{K(p) \,:\, p \in B_{2^{-r}}(x) \cap \mathbb{Q}^m\} ,$$

where $B_\varepsilon(x)$ denotes the open ball of radius ε centered on x. The *conditional Kolmogorov complexity of x at precision r given $y \in \mathbb{R}^n$ at precision $s \in \mathbb{R}^n$* is

$$K_{r,s}(x \mid y) = \max \left\{ \min\{K_r(p \mid q) \,:\, p \in B_{2^{-r}}(x) \cap \mathbb{Q}^m\} \,:\, q \in B_{2^{-s}}(y) \cap \mathbb{Q}^n \right\} .$$

When the precisions r and s are equal, we abbreviate $K_{r,r}(x \mid y)$ by $K_r(x \mid y)$. Given any positive real as a precision parameter, we round up to the next integer; for example, $K_r(x)$ denotes $K_{\lceil r \rceil}(x)$ whenever $r \in (0, \infty)$.

We will need the following technical lemmas which show that versions of the symmetry of information hold for Kolmogorov complexity in $\mathbb{R}^n$. The first Lemma 4 was proved in our previous work [20].

▶ **Lemma 4** ([20]). *For every $m, n \in \mathbb{N}$, $x \in \mathbb{R}^m$, $y \in \mathbb{R}^n$, and $r, s \in \mathbb{N}$ with $r \geq s$,*

i. $|K_r(x \mid y) + K_r(y) - K_r(x, y)| \leq O(\log r) + O(\log\log \|y\|)$.

ii. $|K_{r,s}(x \mid x) + K_s(x) - K_r(x)| \leq O(\log r) + O(\log\log \|x\|)$.

▶ **Lemma 5.** *Let $m, n \in \mathbb{N}$, $x \in \mathbb{R}^m$, $z \in \mathbb{R}^n$, $\varepsilon > 0$ and $r \in \mathbb{N}$. If $K^x_r(z) \geq K_r(z) - \varepsilon r$, then the following hold for all $s \leq r$.*

i. $|K^x_s(z) - K_s(z)| \leq \varepsilon r - O(\log r)$.

ii. $|K_{s,r}(x \mid z) - K_s(x)| \leq \varepsilon r - O(\log r)$.

Proof. We first prove item (i). By Lemma 4(ii),

$$\begin{aligned}
\varepsilon r &\geq K_r(z) - K^x_r(z) \\
&\geq K_s(z) + K_{r,s}(z \mid z) - (K^x_s(z) + K^x_{r,s}(z \mid z)) - O(\log r) \\
&\geq K_s(z) - K^x_s(z) + K_{r,s}(z \mid z) - K^x_{r,s}(z \mid z) - O(\log r)\,.
\end{aligned}$$

Rearranging, this implies that

$$\begin{aligned}
K_s(z) - K^x_s(z) &\leq \varepsilon r + K^x_{r,s}(z \mid z) - K_{r,s}(z \mid z) + O(\log r) \\
&\leq \varepsilon r + O(\log r)\,,
\end{aligned}$$

and the proof of item (i) is complete.

To prove item (ii), by Lemma 4(i) we have

$$\begin{aligned}
\varepsilon r &\geq K_r(z) - K_r(z \mid x) \\
&\geq K_r(z) - (K_r(z, x) - K_r(x)) - O(\log r) \\
&\geq K_r(z) - (K_r(z) + K_r(x \mid z) - K_r(x)) - O(\log r) \\
&= K_r(x) - K_r(x \mid z) - O(\log r)\,.
\end{aligned}$$

Therefore, by Lemma 4(ii),

$$\begin{aligned}
K_s(x) - K_{s,r}(x \mid z) &= K_r(x) - K_{r,s}(x \mid x) - (K_r(x \mid z) - K_{r,s,r}(x \mid x, z)) \\
&\leq \varepsilon r + O(\log r) + K_{r,s,r}(x \mid x, z) - K_{r,s}(x \mid x) \\
&\leq \varepsilon r + O(\log r)\,,
\end{aligned}$$

and the proof is complete. ◀

2.2 Effective Hausdorff and Packing Dimensions

J. Lutz [16] initiated the study of effective dimensions by effectivizing Hausdorff dimension using betting strategies called *gales*, which generalize martingales. Subsequently, Athreya et al. defined effective packing dimension, also using gales [1]. Mayordomo showed that effective Hausdorff dimension can be characterized using Kolmogorov complexity [25], and Mayordomo and J. Lutz [18] showed that effective packing dimension can also be characterized in this way. In this paper, we use these characterizations as definitions. The *effective Hausdorff dimension* and *effective packing dimension* of a point $x \in \mathbb{R}^n$ are

$$\dim(x) = \liminf_{r\to\infty} \frac{K_r(x)}{r} \quad \text{and} \quad \mathrm{Dim}(x) = \limsup_{r\to\infty} \frac{K_r(x)}{r}\,.$$

Intuitively, these dimensions measure the density of algorithmic information in the point x. J. Lutz and N. Lutz [17] generalized these definitions by defining the *lower* and *upper conditional dimension* of $x \in \mathbb{R}^m$ given $y \in \mathbb{R}^n$ as

$$\dim(x \mid y) = \liminf_{r\to\infty} \frac{K_r(x \mid y)}{r} \quad \text{and} \quad \mathrm{Dim}(x \mid y) = \limsup_{r\to\infty} \frac{K_r(x \mid y)}{r}\,.$$

2.3 The Point-to-Set Principle

By letting the underlying fixed prefix-free Turing machine U be a universal *oracle* machine, we may *relativize* the definitions in this section to an arbitrary oracle set $A \subseteq \mathbb{N}$. The definitions of $K^A(\sigma|\tau)$, $K^A(\sigma)$, $K^A_r(x)$, $K^A_r(x \mid y)$, $\dim^A(x)$, $\mathrm{Dim}^A(x)$ $\dim^A(x \mid y)$, and $\mathrm{Dim}^A(x \mid y)$ are then all identical to their unrelativized versions, except that U is given oracle access to A. We will frequently consider the complexity of a point $x \in \mathbb{R}^n$ *relative to a point* $y \in \mathbb{R}^m$, i.e., relative to an oracle set A_y that encodes the binary expansion of y is a standard way. We then write $K^y_r(x)$ for $K^{A_y}_r(x)$.

The following *point-to-set principles* show that the classical notions of Hausdorff and packing dimension of a set can be characterized by the effective dimension of its individual points. The first point-to-set principle we use here, which applies to a restricted class of sets, was implicitly proven by J. Lutz [16] and Hitchcock [11].

A set $E \subseteq \mathbb{R}^n$ is a $\mathbf{\Sigma}^0_2$ set if it is a countable union of closed sets. The computable analogue of $\mathbf{\Sigma}^0_2$ is the class Σ^0_2, consisting of sets $E \subseteq \mathbb{R}^n$ such that there is a uniformly computable sequence $\{C_i\}_{i\in\mathbb{N}}$ satisfying

$$E = \bigcup_{i=0}^{\infty} C_i \,,$$

and each set C_i is *computably closed*, meaning that its complement is the union of a computably enumerable set of open balls with rational radii and centers. We will use the fact that every $\mathbf{\Sigma}^0_2$ set is Σ^0_2 relative to some oracle.

▶ **Theorem 6** ([16, 11]). *Let $E \subseteq \mathbb{R}^n$ and $A \subseteq \mathbb{N}$ be such that E is a Σ^0_2 set relative to A. Then*

$$\dim_H(E) = \sup_{x\in E} \dim^A(x) \,.$$

J. Lutz and N. Lutz [17] showed that the Hausdorff and packing dimension of *any* set $E \subseteq \mathbb{R}^n$ is characterized by the corresponding effective dimensions of individual points, relativized to an oracle that is optimal for the set E.

▶ **Theorem 7** (Point-to-set principle [17]). *Let $n \in \mathbb{N}$ and $E \subseteq \mathbb{R}^n$. Then*

$$\dim_H(E) = \min_{A\subseteq\mathbb{N}} \sup_{x\in E} \dim^A(x), \text{ and}$$
$$\dim_P(E) = \min_{A\subseteq\mathbb{N}} \sup_{x\in E} \mathrm{Dim}^A(x) \,.$$

It is worth noting that the point-to-set principle is taking the *minimum* over all oracles, not simply the *infimum*.

3 Bounding the Complexity of Projections

In this section, we will focus on bounding the Kolmogorov complexity of a projected point *at a given precision*. In Section 4, we will use these results in conjunction with the point-to-set principle to prove our main theorems.

We begin by giving intuition of the main idea behind this lower bound. We will show that under certain conditions, given an approximation of $e \cdot z$ and e, we can compute an approximation of the original point z. Informally, these conditions are the following.

1. The complexity $K_r(z)$ of the original point is small.
2. If $e \cdot w = e \cdot z$, then either $K_r(w)$ is large, or w is close to z.

Assuming that both conditions are satisfied, we can recover z from $e \cdot z$ by enumerating over all points u of low complexity such that $e \cdot u = e \cdot z$. By our assumption, any such point u must be a good approximation of z. We now formally state and prove this lemma.

▶ **Lemma 8.** *Suppose that* $z \in \mathbb{R}^n$ $e \in S^{n-1}$, $r \in \mathbb{N}$, $\delta \in \mathbb{R}_+$, *and* $\varepsilon, \eta \in \mathbb{Q}_+$ *satisfy* $r \geq \log(2\|z\| + 5) + 1$ *and the following conditions.*

i. $K_r(z) \leq (\eta + \varepsilon)\, r$.

ii. *For every* $w \in B_1(z)$ *such that* $e \cdot w = e \cdot z$,

$$K_r(w) \geq (\eta - \varepsilon)\, r + (r - t)\delta\,,$$

whenever $t = -\log \|z - w\| \in (0, r]$.

Then for every oracle set $A \subseteq \mathbb{N}$,

$$K_r^{A,e}(e \cdot z) \geq K_r^{A,e}(z) - \frac{n\varepsilon}{\delta} r - K(\varepsilon) - K(\eta) - O_z(\log r)\,.$$

Proof. Suppose z, e, r, δ, ε, η, and A satisfy the hypothesis.

Define an oracle Turing machine M that does the following given oracle (A, e) and input $\pi = \pi_1\pi_2\pi_3\pi_4\pi_5$ such that $U^A(\pi_1) = q \in \mathbb{Q}$, $U(\pi_2) = h \in \mathbb{Q}^n$, $U(\pi_3) = s \in \mathbb{N}$, $U(\pi_4) = \zeta \in \mathbb{Q}$, and $U(\pi_5) = \iota \in \mathbb{Q}$.

For every program $\sigma \in \{0,1\}^*$ with $\ell(\sigma) \leq (\iota + \zeta)s$, in parallel, M simulates $U(\sigma)$. If one of the simulations halts with some output $p = (p_1, \ldots, p_n) \in \mathbb{Q}^n \cap B_{2^{-1}}(h)$ such that $|e \cdot p - q| < 2^{-s}$, then $M^{A,e}$ halts with output p. Let c_M be a constant for the description of M.

Let π_1, π_2, π_3, π_4, and π_5 testify to $K_r^{A,e}(e \cdot z)$, $K_1(z)$, $K(r)$, $K(\varepsilon)$, and $K(\eta)$, respectively, and let $\pi = \pi_1\pi_2\pi_3\pi_4\pi_5$. Let σ be a program of length at most $(\eta+\varepsilon)r$ such that $\|p - z\| \leq 2^{-r}$, where $U(\sigma) = p$. Note that such a program must exist by condition (i) of our hypothesis. Then it is easily verified that

$$|e \cdot z - e \cdot p| \leq 2^{-r}\,.$$

Therefore $M^{A,e}$ is guaranteed to halt on π.

Let $M^{A,e}(\pi) = p = (p_1, \ldots, p_n) \in \mathbb{Q}^n$. Another routine calculation shows that there is some

$$w \in B_{2^{\gamma - r}}(p) \subseteq B_{2^{-1}}(p) \subseteq B_{2^0}(z)$$

such that $e \cdot w = e \cdot z$, where γ is a constant depending only on z and e. Then,

$$\begin{aligned} K_r^{A_e}(w) &\leq |\pi| + c_M \\ &\leq K_r^{A,e}(e \cdot z) + K_1(z) + K(r) + K(\varepsilon) + K(\eta) + c_M \\ &= K_r^{A,e}(e \cdot z) + K(\varepsilon) + K(\eta) + O(\log r)\,. \end{aligned}$$

Rearranging this yields

$$K_r^{A,e}(e \cdot z) \geq K_r^{A,e}(w) - K(\varepsilon) - K(\eta) - O(\log r)\,. \tag{1}$$

Let $t = -\log \|z - w\|$. If $t \geq r$, then the proof is complete. If $t < r$, then $B_{2^{-r}}(p) \subseteq B_{2^{1-t}}(z)$, which implies that $K_r^{A,e}(w) \geq K_{t-1}^{A,e}(z)$. Therefore,

$$K_r^{A,e}(w) \geq K_r^{A,e}(z) - n(r - t) - O(\log r)\,. \tag{2}$$

We now bound $r - t$. By our construction of M,

$$\begin{aligned}(\eta + \varepsilon)r &\geq K(p) \\ &\geq K_r(w) - O(\log r)\,.\end{aligned}$$

By condition (ii) of our hypothesis, then,

$$(\eta + \varepsilon)r \geq (\eta - \varepsilon)r + \delta(r - t)\,,$$

which implies that

$$r - t \leq \frac{2n\varepsilon}{\delta} r + O(\log r)\,.$$

Combining this with inequalities (1) and (2) concludes the proof. ◀

With the above lemma in mind, we wish to give a lower bound on the complexity of points w such that $e \cdot w = e \cdot z$. Our next lemma gives a bound based on the complexity, relative to z, of the direction $e \in S^{n-1}$. This is based on the observation that we can solve for $e = (e_1, \ldots, e_n)$ given w, z and $e_3, \ldots, e_n$. This follows from solving the system of two equations

$$\begin{aligned}e \cdot (z - w) &= 0 \\ e_1^2 + \ldots + e_n^2 &= 1\,.\end{aligned}$$

This suggests that

$$K_r^{z,e_3,\ldots,e_n}(e) \leq K_r^{z,e_3,\ldots,e_n}(w)\,.$$

However, for our purposes, we must be able to recover (an approximation of) e given *approximations* of w and z. Intuitively, the following lemma shows that we can algorithmically compute an approximation of e whose error is linearly correlated with the distance between w and z. We can then bound the complexity of w using a symmetry of information argument.

▶ **Lemma 9.** *Let $z \in \mathbb{R}^n$, $e \in S^{n-1}$, and $r \in \mathbb{N}$. Let $w \in \mathbb{R}^n$ such that $e \cdot z = e \cdot w$. Then there are numbers $i, j \in \{1, \ldots, n\}$ such that*

$$K_r(w) \geq K_t(z) + K_{r-t,r}^{e-\{e_i,e_j\}}(e \mid z) + O(\log r)\,,$$

where $t = -\log \|z - w\|$.

Proof. Let z, w, e, and r be as in the statement of the lemma. We first choose i so that $|z_i - w_i|$ is maximal. We then choose j so that

$$\begin{aligned}&\operatorname{sgn}((z_i - w_i)e_i) \neq \operatorname{sgn}((z_j - w_j)e_j), \text{ and} \\ &|z_j - w_j| > 0\,,\end{aligned}$$

where sgn denotes the sign. Note that such a j must exist since $(z - w) \cdot e = 0$. For the sake of removing notational clutter, we will assume, without loss of generality, that $i = 1$ and $j = 2$.

We first show that

$$K_{r-t,r}^{e_3,\ldots,e_n}(e_2 \mid z) \leq K_r(w \mid z) + O(1)\,. \tag{3}$$

As mentioned in the informal discussion preceding this lemma, note that

$$e_2 = \frac{-b + (-1)^h \sqrt{b^2 - 4ac}}{2a}\,, \tag{4}$$

where

- $h \in \{0,1\}$,
- $a = (z_1 - w_1)^2 + (w_2 - z_2)^2$,
- $b = 2(w_2 - z_2)\sum_{i=3}^{n}(w_i - z_i)e_i$, and
- $c = (\sum_{i=3}^{n}(w_i - z_i)e_i)^2 + (z_1 - w_1)^2\sum_{i=3}^{n} e_i^2 - 1$.

With this in mind, let M be the Turing machine such that, whenever $q = (q_1, \ldots, q_n) \in \mathbb{Q}^n$ and $U(\pi, q) = p = (p_1, \ldots, p_n) \in Q^2$ with $p_1 \neq q_1$,

$$M^{e_3,\ldots,e_n}(\pi, q, j) = \frac{-b' + (-1)^h\sqrt{b'^2 - 4a'c'}}{2a'},$$

where

- $h \in \{0,1\}$,
- $a' = (q_1 - p_1)^2 + (p_2 - q_2)^2$,
- $b' = 2(p_2 - q_2)\sum_{i=3}^{n}(p_i - q_i)d_i$, and
- $c' = (\sum_{i=3}^{n}(p_i - q_i)d_i)^2 + (q_1 - p_1)^2\sum_{i=3}^{n} d_i^2 - 1$, and
- $d = (d_3, \ldots, d_n) \in \mathbb{Q}^{n-2}$ is an nr-approximation of $(e_3, \ldots, e_n)$.

Let $q \in B_{2^{-r}}(z) \cap \mathbb{Q}^n$, and π_q testify to $\hat{K}_r(w \mid q)$. It tedious but straightforward (Lemma 10) to verify that

$$|M^{e_3,\ldots,e_n}(\pi_q, q, h) - e_2| \leq 2^{\alpha+t-r},$$

where α is a constant depending only on e. Hence, inequality (3) holds. Since

$$K_s^{e_3,\ldots,e_n}(e_2) = K_s^{e_3,\ldots,e_n}(e) + O(1)$$

holds for every s, we see that

$$K_{r-t,r}^{e_3,\ldots,e_n}(e \mid z) \leq K_r(w \mid z) + O(1). \tag{5}$$

To complete the proof, we note that

$$\begin{aligned} K_r(w \mid z) &\leq K_{r,t}(w \mid z) + O(\log r) \\ &= K_{r,t}(w \mid w) + O(\log r) \\ &= K_r(w) - K_t(w) + O(\log r) \\ &= K_r(w) - K_t(z) + O(\log r). \end{aligned}$$

The lemma follows from rearranging the above inequality, and combining inequality (5). ◀

The previous lemma uses the following technical lemma, whose proof is omitted due to space considerations.

▶ **Lemma 10.** *Let $z, w \in \mathbb{R}^n$, $e \in S^{n-1}$, and $r \in \mathbb{N}$ such that $e \cdot z = e \cdot w$. Let $q = (q_1, \ldots, q_n) \in \mathbb{Q}^n$ and $p = (p_1, \ldots, p_n) \in \mathbb{Q}^n$ be r-approximations of z and w, respectively. Then*

$$\left|\frac{-b + \sqrt{b^2 - 4ac}}{2a} - \frac{-b' + \sqrt{b'^2 - 4a'c'}}{2a'}\right| \leq 2^{-r+t+\alpha},$$

where a, b, c, a', b' and c' are as defined in Lemma 9, $t = -\log\|z - w\|$ and α is a constant depending only on e.

Finally, to satisfy the condition that $K_r(z)$ is small, we will use an oracle to "artificially" decrease the complexity of z at precision r. We will achieve this by applying the following lemma due to N. Lutz and Stull.

▶ **Lemma 11** ([20]). *Let $n, r \in \mathbb{N}$, $z \in \mathbb{R}^n$, and $\eta \in \mathbb{Q} \cap [0, \dim(z)]$. Then there is an oracle $D = D(n, r, z, \eta)$ and a constant $k \in \mathbb{N}$ depending only on n, z and η satisfying*

i. *For every $t \leq r$,*

$$K_t^D(z) = \min\{\eta r, K_t(z)\} + k \log r \,.$$

ii. *For every $m, t \in \mathbb{N}$ and $y \in \mathbb{R}^m$,*

$$K_{t,r}^D(y \mid z) = K_{t,r}(y \mid z) + k \log r \,,$$

and

$$K_t^{z,D}(y) = K_t^z(y) + k \log r \,.$$

4 Projection Theorems

The main results of the previous section gave us sufficient conditions for strong lower bounds on the complexity of $e \cdot z$ at a given precision, and methods to ensure that the conditions are satisfied. The following theorem encapsulates these results so that we may apply them in the proof of our main theorems.

▶ **Theorem 12.** *Let $z \in \mathbb{R}^n$, $e \in S^{n-1}$, $A \subseteq \mathbb{N}$, $\eta' \in \mathbb{Q} \cap (0,1) \cap (0, \dim(z))$, $\varepsilon' > 0$, and $r \in \mathbb{N}$. Assume the following are satisfied.*

1. *For every $s \leq r$, and $i, j \in \{1, \ldots, n\}$, $K_s^{e-\{e_i, e_j\}}(e) \geq s - \log(s)$.*
2. *$K_r^{A,e}(z) \geq K_r(z) - \varepsilon' r$.*

Then,

$$K_r^{A,e}(e \cdot z) \geq \eta' r - \varepsilon' r - \frac{2n\varepsilon'}{1-\eta'} r - K(2\varepsilon') - K(\eta') - O_z(\log r) \,.$$

Proof. Assume the hypothesis, and let $\eta = \eta'$, $\varepsilon = 2\varepsilon'$ and $\delta = 1 - \eta'$. Let $D_r = D(n, r, z, \eta')$ be the oracle as defined in Lemma 11.

First assume that the conditions of Lemma 8, relative to D_r, hold for z, e, r, η, ε and δ. Then we may apply Lemma 8, which, when combined item (2) and Lemma 11, yields

$$\begin{aligned} K_r^{A,D_r,e}(e \cdot z) &\geq K_r^{A,D_r,e}(z) - \frac{n\varepsilon}{\delta} r - K(\varepsilon) - K(\eta) - O_z(\log r) \\ &\geq K_r^{D_r}(z) - \varepsilon' r - \frac{n\varepsilon}{\delta} r - K(\varepsilon) - K(\eta) - O_z(\log r) \\ &= \eta' r - \varepsilon' r - \frac{2n\varepsilon'}{1-\eta'} r - K(\varepsilon') - K(\eta') - O_z(\log r) \,. \end{aligned}$$

Therefore, to complete the proof, it suffices to show that the conditions of Lemma 8, relative to D_r, hold.

Item (i) of Lemma 8 holds by our construction of D_r. To see that condition (ii) holds, let $w \in B_1(z)$ such that $e \cdot w = e \cdot z$. By Lemma 9, for some $i, j \in \{1, \ldots, n\}$,

$$K_r^{D_r}(w) \geq K_t^{D_r}(z) + K_{r-t,r}^{D_r, e-\{e_i, e_j\}}(e \mid z) + O(\log r) \,,$$

where $t = -\log \|z - w\|$. Therefore, by condition (2) of the hypothesis and Lemma 5,

$$K_r^{D_r}(w) \geq K_t^{D_r}(z) + K_{r-t,r}^{D_r, e-\{e_i, e_j\}}(e) - \varepsilon' r - O(\log r) \,.$$

By combining this with condition (1) of the present lemma and Lemma 11,

$$\begin{aligned} K_r^{D_r}(w) &\geq K_t^{D_r}(z) + K_{r-t,r}^{D_r, e-\{e_i,e_j\}}(e) - \varepsilon' r - O(\log r) \\ &\geq \eta' t + r - t - \varepsilon' r - O(\log r) \\ &= t(\eta' - 1) + r(1 - \varepsilon') - O(\log r) \\ &\geq (\eta - \varepsilon) r + \delta(r - t)\,. \end{aligned}$$

Hence, the conditions of Lemma 8 are satisfied and the proof is complete. ◀

4.1 Projection Theorems For Non-Analytic Sets

Our first main theorem shows that if the Hausdorff and packing dimensions of E are equal, the conclusion of Marstrand's theorem holds. Essentially this assumption guarantees, for every oracle A and direction e, the existence of a point $z \in E$ such that $\dim^{A,e}(z) \geq \dim_H(E) - \varepsilon$. This allows us to use Theorem 12 at all sufficiently large precisions r.

▶ **Theorem 2.** *Let $E \subseteq \mathbb{R}^n$ be any set with $\dim_H(E) = \dim_P(E) = s$. Then for almost every $e \in S^{n-1}$,*

$$\dim_H(\mathrm{proj}_e E) \geq \min\{s, 1\}\,.$$

Proof. Let $E \subseteq \mathbb{R}^n$ be any set with $\dim_H(E) = \dim_P(E) = s$. By the point-to-set principle, there is an oracle $B \subseteq \mathbb{N}$ testifying to $\dim_H(E)$ and $\dim_P(E)$. Let $e \in S^{n-1}$ be any point which is random relative to B. That is, let e be any point such that

$$K_r^{B,e-\{e_i,e_j\}}(e) \geq r - \log r\,,$$

for every $i, j \in \{1, \ldots, n\}$. Note that almost every point satisfies this requirement. Let $A \subseteq \mathbb{N}$ be the oracle testifying to $\dim_H(\mathrm{proj}_e E)$. Then, by the point-to-set principle, it suffices to show that for every $\varepsilon > 0$ there is a $z \in E$ such that

$$\dim^A(e \cdot z) \geq \min\{s, 1\} - \varepsilon\,.$$

To that end, let $\eta' \in \mathbb{Q} \cap (0,1) \cap (0,s)$ and $\varepsilon' > 0$. By the point-to-set principle, there is a $z_{\varepsilon'} \in E$ such that

$$\begin{aligned} s - \frac{\varepsilon'}{4} &\leq \dim^{A,B,e}(z_{\varepsilon'}) \\ &\leq \dim^B(z_{\varepsilon'}) \\ &\leq \mathrm{Dim}^B(z_{\varepsilon'}) \\ &\leq s\,. \end{aligned} \tag{6}$$

We now show that the conditions of Theorem 12 are satisfied, relative to B, for all sufficiently large $r \in \mathbb{N}$. We first note that, by inequality (6) and the definition of effective dimension,

$$\begin{aligned} sr - \frac{\varepsilon'}{4} r - \frac{\varepsilon'}{4} r &\leq K_r^{A,B,e}(z_{\varepsilon'}) \\ &\leq K_r^B(z_{\varepsilon'}) + O(1) \\ &\leq sr + \frac{\varepsilon'}{2} r\,, \end{aligned}$$

for all sufficiently large r. Hence, for all such r,

$$K_r^{A,B,e}(z_{\varepsilon'}) \geq K_r^B(z_{\varepsilon'}) - \varepsilon' r \,. \tag{7}$$

Thus the conditions of Theorem 12, relative to B, are satisfied.

We may therefore apply Theorem 12, resulting in

$$K_r^{A,B,e}(e \cdot z_{\varepsilon'}) \geq \eta' r - \varepsilon' r - \frac{2n\varepsilon'}{1-\eta'} r - K(\varepsilon') - K(\eta') - O_{z_{\varepsilon'}}(\log r) \,.$$

Hence,

$$\begin{aligned}
\dim^A(e \cdot z_{\varepsilon'}) &\geq \dim^{A,B,e}(e \cdot z_{\varepsilon'}) \\
&= \liminf_{r\to\infty} \frac{K_r^{A,B,e}(e \cdot z_{\varepsilon'})}{r} \\
&\geq \liminf_{r\to\infty} \frac{\eta' r - \varepsilon' r - \frac{2n\varepsilon'}{1-\eta'} r - K(\varepsilon') - K(\eta') - O_{z_{\varepsilon'}}(\log r)}{r} \\
&= \eta' - \varepsilon' - \frac{2n\varepsilon'}{1-\eta'} \,.
\end{aligned}$$

Since η' was chosen arbitrarily,

$$\dim^A(e \cdot z) \geq \min\{s, 1\} - \frac{\varepsilon'}{4} \,.$$

As ε' was chosen arbitrarily, by the point-to-set principle,

$$\begin{aligned}
\dim_H(\mathrm{proj}_e E) &\geq \sup_{z\in E} \dim^A(e \cdot z) \\
&\geq \sup_{\varepsilon>0} \dim^A(e \cdot z_{\varepsilon'}) \\
&= \min\{s, 1\} \,,
\end{aligned}$$

and the proof is complete. ◀

Our second main theorem gives a lower bound for the *packing* dimension of a projection for *general* sets. The proof of this theorem again relies on the ability to choose, for every (A, e), a point z whose complexity is unaffected relative to (A, e). This cannot be assumed to hold for every precision r. However, by the point-to-set principle, we can show that this can be done for infinitely many precision parameters r.

▶ **Theorem 3.** *Let $E \subseteq \mathbb{R}^n$ be any set with $\dim_H(E) = s$. Then for almost every $e \in S^{n-1}$,*

$$\dim_P(\mathrm{proj}_e E) \geq \min\{s, 1\} \,.$$

Proof. Let $E \subseteq \mathbb{R}^n$ be any set with $\dim_H(E) = s$. By the point-to-set principle, there is an oracle $B \subseteq \mathbb{N}$ testifying to $\dim_H(E)$ and $\dim_P(E)$. Let $e \in S^{n-1}$ be any point which is random relative to B. Note that almost every point satisfies this requirement. Let $A \subseteq \mathbb{N}$ be the oracle testifying to $\dim_P(\mathrm{proj}_e E)$. Then, by the point-to-set principle, it suffices to show that for every $\varepsilon > 0$ there is a $z \in E$ such that

$$\mathrm{Dim}^A(e \cdot z) \geq \min\{s, 1\} - \varepsilon \,.$$

To that end, let $\eta' \in \mathbb{Q} \cap (0, 1) \cap (0, s)$ and $\varepsilon' > 0$. By the point-to-set principle, there is a $z_{\varepsilon'} \in E$ such that

$$s - \frac{\varepsilon'}{4} \leq \dim^{A,B,e}(z_{\varepsilon'}) \leq \dim^B(z_{\varepsilon'}) \leq s \,. \tag{8}$$

We now show that the conditions of Theorem 12 are satisfied, relative to B, for infinitely many $r \in \mathbb{N}$. We first note that, by equation (8),

$$\begin{aligned} sr - \frac{\varepsilon'}{4}r - \frac{\varepsilon'}{4}r &\leq K_r^{A,B,e}(z_{\varepsilon'}) \\ &\leq K_r^B(z_{\varepsilon'}) + O(1) \\ &\leq sr + \frac{\varepsilon'}{2}r\,, \end{aligned}$$

for infinitely many r. Hence, for all such r,

$$K^{A,B,e}(z_{\varepsilon'}) \geq K^B(z_{\varepsilon'}) - \varepsilon r\,. \tag{9}$$

Thus the conditions of Theorem 12, relative to B, are satisfied for infinitely many $r \in \mathbb{N}$.

We may therefore apply Theorem 12, resulting in

$$K_r^{A,B,e}(e \cdot z_{\varepsilon'}) \geq \eta' r - \varepsilon' r - \frac{2n\varepsilon'}{1-\eta'}r - K(\varepsilon') - K(\eta') - O_{z_{\varepsilon'}}(\log r)\,,$$

for infinitely many $r \in \mathbb{N}$. Hence,

$$\begin{aligned} \mathrm{Dim}^A(e \cdot z_{\varepsilon'}) &\geq \mathrm{Dim}^{A,B,e}(e \cdot z_{\varepsilon'}) \\ &= \limsup_{r\to\infty} \frac{K_r^{A,B,e}(e \cdot z_{\varepsilon'})}{r} \\ &\geq \limsup_{r\to\infty} \frac{\eta' r - \varepsilon' r - \frac{2n\varepsilon'}{1-\eta'}r - K(\varepsilon') - K(\eta') - O_{z_{\varepsilon'}}(\log r)}{r} \\ &= \eta' - \varepsilon' - \frac{2n\varepsilon'}{1-\eta'}\,. \end{aligned}$$

Since η' was chosen arbitrarily

$$\mathrm{Dim}^A(e \cdot z) \geq \min\{s, 1\} - \frac{\varepsilon'}{4}\,.$$

As ε' was chosen arbitrarily, by the point-to-set principle

$$\begin{aligned} \dim_P(\mathrm{proj}_e E) &\geq \sup_{z \in E} \mathrm{Dim}^A(e \cdot z) \\ &\geq \sup_{\varepsilon > 0} \mathrm{Dim}^A(e \cdot z_{\varepsilon'}) \\ &= \min\{s, 1\}\,, \end{aligned}$$

and the proof is complete. ◀

4.2 Marstrand's Projection Theorem

We now give a new, algorithmic information theoretic proof of Marstrand's projection theorem. Recall that

▶ **Theorem 1.** *Let $E \subseteq \mathbb{R}^n$ be analytic with $\dim_H(E) = s$. Then for almost every $e \in S^{n-1}$,*

$$\dim_H(\mathrm{proj}_e E) = \min\{s, 1\}\,.$$

Note the order of the quantifiers. To use the point-to-set principle, we must first choose a direction $e \in S^{n-1}$. We then must show that for every oracle A and $\varepsilon > 0$, there is some $z \in E$ such that

$$\dim^A(e \cdot z) \geq \dim_H(E) - \varepsilon \,.$$

In order to apply Theorem 12, we must guarantee that (A, e) does not significantly change the complexity of z. To ensure this, we will use the point-to-set principle of J. Lutz and Hitchcock (Theorem 6). While this result is less general than the principle of J. Lutz and N. Lutz, the oracle characterizing the dimension of a Σ^0_2 set is easier to work with.

To take advantage of this, we use the following lemma.

▶ **Lemma 13.** *Let $E \subseteq \mathbb{R}^n$ be analytic with $\dim_H(E) = s$. Then there is a $\mathbf{\Sigma}^0_2$ set $F \subseteq E$ such that $\dim_H(F) = s$.*

Proof. It is well known that if $E \subseteq \mathbb{R}^n$ is analytic, then for every $\varepsilon \in (0, s]$, there is a compact subset $E_\varepsilon \subseteq E$ such that $\dim_H(E_\varepsilon) = s - \varepsilon$ (see e.g. Bishop and Peres [2]). Thus, the set

$$F = \bigcup_{i=\lceil 1/s \rceil}^{\infty} E_{1/i}$$

is a $\mathbf{\Sigma}^0_2$ set with $\dim_H(F) = s$. ◀

We will also use the following observation, which is a consequence of the well-known fact from descriptive set theory that Σ classes are closed under computable projections.

▶ **Observation 14.** *Let $E \subseteq \mathbb{R}^n$ and $A \subseteq \mathbb{N}$ be such that E is a Σ^0_2 set relative to A. Then for every $e \in S^{n-1}$, $\mathrm{proj}_e\, E$ is a Σ^0_2 set relative to (A, e).*

Finally, we must ensure that e does not significantly change the complexity of z. For this, we will use the following definition and theorem due to Calude and Zimand [3]. We rephrase their work in terms of points in Euclidean space. Let $n \in \mathbb{N}$, $z \in \mathbb{R}^n$ and $e \in S^{n-1}$. We say that z and e are *independent* if, for every $r \in \mathbb{N}$, $K^e_r(z) \geq K_r(z) - O(\log r)$ and $K^z_r(e) \geq K_r(e) - O(\log r)$.

▶ **Theorem 15** ([3])**.** *For every $z \in \mathbb{R}^n$, for almost every $e \in S^{n-1}$, z and e are independent.*

With these ingredients we can give a new proof Marstrand's projection theorem using algorithmic information theory.

Proof of Theorem 1. Let $E \subseteq \mathbb{R}^n$ be analytic with $\dim_H(E) = s$. By Lemma 13, there is a $\mathbf{\Sigma}^0_2$ set $F \subseteq E$ such that $\dim_H(F) = s$. Let $A \subseteq \mathbb{N}$ be an oracle such that F is Σ^0_2 relative to A. Using Theorem 6, for every $k \in \mathbb{N}$ we may choose a point $z_k \in F$ such that

$$\dim^A(z_k) \geq s - 1/k \,.$$

Let $e \in S^{n-1}$ be a point such that, for every $k \in \mathbb{N}$, the following hold.

- For every r and $t < r$, $K^{A, z_k, e_3 \ldots, e_n}_t(e) \geq t - O(1)$.
- For every r, $K^{A,e}_r(z_k) \geq K^A_r(z_k) - O(\log r)$.

A basic fact of algorithmic randomness states that almost every e satisfies the first item. By Theorem 15, almost every e satisfies the second item. So almost every e satisfies these requirements.

Fix $k \in \mathbb{N}$. Let $\eta' \in \mathbb{Q} \cap (0,1) \cap (0, \dim^A(z_k))$ and $\varepsilon' > 0$. It is clear, by our choices of e and z_k, that the conditions of Theorem 12 are satisfied for all sufficiently large r. We may therefore apply Theorem 12, resulting in

$$K_r^{A,e}(e \cdot z_k) \geq \eta' r - \varepsilon' r - \frac{2n\varepsilon'}{1-\eta'} r - K(2\varepsilon') - K(\eta') - O_z(\log r)\,.$$

Hence,

$$\begin{aligned}
\dim^{A,e}(e \cdot z_k) &= \liminf_{r\to\infty} \frac{K_r^{A,e}(e \cdot z_k)}{r} \\
&\geq \liminf_{r\to\infty} \frac{\eta' r - \varepsilon' r - \frac{2n\varepsilon'}{1-\eta'} r - K(2\varepsilon') - K(\eta') - O_z(\log r)}{r} \\
&= \eta' - \varepsilon' - \frac{2n\varepsilon'}{1-\eta'}\,.
\end{aligned}$$

Since both η' and ε' were chosen independently and arbitrarily, we see that

$$\begin{aligned}
\dim^{A,e}(e \cdot z_k) &\geq \dim^{A,e}(z_k) \\
&\geq \min\{s, 1\} - 1/k\,.
\end{aligned}$$

As k was chosen arbitrarily, Observation 14 and Theorem 6 give

$$\begin{aligned}
\dim_H(\mathrm{proj}_e\, E) &\geq \dim_H(\mathrm{proj}_e\, F) \\
&= \sup_{z\in F} \dim^{A,e}(e \cdot z) \\
&\geq \sup_{k\in\mathbb{N}} \dim^{A,e}(e \cdot z_k) \\
&= \min\{s, 1\}\,,
\end{aligned}$$

and the proof is complete. ◀

Polynomial-Time Equivalence Testing for Deterministic Fresh-Register Automata

Abstract

Register automata are one of the most studied automata models over infinite alphabets. The complexity of language equivalence for register automata is quite subtle. In general, the problem is undecidable but, in the deterministic case, it is known to be decidable and in NP. Here we propose a polynomial-time algorithm building upon automata- and group-theoretic techniques. The algorithm is applicable to standard register automata with a fixed number of registers as well as their variants with a variable number of registers and ability to generate fresh data values (fresh-register automata). To complement our findings, we also investigate the associated inclusion problem and show that it is PSPACE-complete.

1 Introduction

Register automata [9, 15] are one of the simplest models of computation over infinite alphabets. They operate on an infinite domain of data by storing data values in a finite number of registers, where the values are available for future comparisons or updates. The automata can also recognise when a data value does not appear in any of the registers. Fresh-register automata [20] are an extension of register automata that can, in addition, generate data values not seen so far.

In recent years, register-based automata have appeared in a variety of contexts, ranging from database query languages [18] and programming language semantics [14] to run-time verification [7]. Since the very beginning, there has been great interest in extending learning algorithms to register automata [16, 4, 1, 5, 12], driven by applications in verification [11] and system modelling [21].

Register automata are closely related to nominal automata [3], which constitute a nominal counterpart of finite-state machines. Their closure properties and associated decision problems have first been studied in [9, 15]. One of the most fundamental and applicable decision problems is that of language equivalence, not least due to connections with query equivalence,

program equivalence and learning. Unfortunately, it turns out that the equivalence problem for register automata is in general undecidable [15]. Fortunately, it is decidable in the *deterministic* case (by reduction to emptiness using closure properties [9]).

Our paper presents the first polynomial-time algorithm for the problem. The algorithm is actually applicable to a wider class of automata, namely fresh-register automata with a variable number of registers.

To begin with, we exploit the observation that in the deterministic setting, language equivalence and bisimilarity are closely related. Secondly, because in our setting only different values can be stored in different registers [9], we take advantage of symbolic representations of bisimulation relations based on partial permutations. The proposed algorithm attempts to build such a bisimulation relation incrementally. To avoid potential exponential blow-ups, the candidate relations are stored in a concise fashion through generators of symmetric groups. Thanks to the fact that group membership testing works in polynomial-time [6] and subgroup chains can only have linear length [2], we can prove that the process of refining the candidate will terminate in polynomial time. Consequently, the equivalence problem for our variant of fresh-register automata is in P, which improves upon the best upper bound known so far, namely, NP [13].

A natural question is whether the polynomial-time bound could have been obtained via the associated inclusion problem. We give a negative answer to this question by showing that the inclusion problem in our setting is PSPACE-complete.

2 Automata

Let $\mathcal{D}$ be an infinite set (alphabet). Its elements will be called *data values* (in process algebra, the term *names* is used instead). We shall work with a deterministic model of register automata over $\mathcal{D}$. As in [9], we require that different registers contain different data values. To allow for more flexible use of registers, the number of available registers will be allowed to vary according to the current state. Register content can be both erased and created. Creation can be local (new element is guaranteed not to occur in any register) or global (new element is guaranteed not to have been encountered in the whole run). We give the formal definition below. In Remark 5 we discuss the motivation behind various restrictions and their relevance to polynomial-time complexity.

▶ **Definition 1.** Given a natural number r, we write $[1, r]$ for the set $\{i \in \mathbb{N} \mid 1 \leq i \leq r\}$. An r-register assignment is an *injective* function from a subset of $[1, r]$ to $\mathcal{D}$. An **r-deterministic fresh-register automaton** (r-DFRA) is a tuple $\mathcal{A} = \langle \Sigma, Q, q_0, \mu, \delta, F \rangle$, where:

- Σ is a finite alphabet of *tags*;
- Q is a finite set of states, $q_0 \in Q$ is *initial* and $F \subseteq Q$ contains *final* states;
- $\mu : Q \to \mathcal{P}([1, r])$ is the *availability* function indicating which registers are filled at each state, we require $\mu(q_0) = \emptyset$;
- $\delta = \delta_{old} + \delta_{fresh}$ is the transition function, where $\delta_{old} : Q \times \Sigma \times [1, r] \rightharpoonup Q$ controls the use of existing register values and $\delta_{fresh} : Q \times \Sigma \rightharpoonup Q \times [1, r] \times \{\bullet, \circledast\}$ indicates when fresh values are created and how fresh they are.

To preserve the meaning of μ, we insist that $\delta_{old}(q, t, i) = q'$ implies $i \in \mu(q)$ and $\mu(q) \supseteq \mu(q')$ and $\delta_{fresh}(q, t) = (q', i, x)$ implies $\mu(q) \cup \{i\} \supseteq \mu(q')$. Note the use of $\supseteq$ instead of $=$. This allows for register erasures during computation. We shall write $q \xrightarrow{t,i} q'$ for $\delta_{old}(q, t, i) = q'$ and $q \xrightarrow{t,i^x} q'$ for $\delta_{fresh}(q, t) = (q', i, x)$.

Next we formalise how to obtain a labelled transition system for a given r-DFRA.

▶ **Definition 2.** A **labelled transition system** (LTS) over $\mathcal{A}ct$ is a tuple $\mathcal{S} = (\mathcal{A}ct, \mathbb{C}, \rightarrow)$, where $\mathbb{C}$ is a set of *configurations*, $\mathcal{A}ct$ is a set of *action labels*, and $\rightarrow \subseteq \mathbb{C} \times \mathcal{A}ct \times \mathbb{C}$. We write $\kappa \xrightarrow{\ell} \kappa'$ for $(\kappa, \ell, \kappa') \in \rightarrow$. $\mathcal{S}$ is *deterministic* if $\kappa \xrightarrow{\ell} \kappa_1$ and $\kappa \xrightarrow{\ell} \kappa_2$ imply $\kappa_1 = \kappa_2$.

An r-DFRA induces a deterministic LTS as follows.

▶ **Definition 3.** Given an r-DFRA $\mathcal{A} = \langle \Sigma, Q, q_0, \mu, \delta, F \rangle$, we define its set of configurations:

$$\mathbb{C}_{\mathcal{A}} = \{(q, \rho, H) \mid q \in Q,\ \rho : \mu(q) \to \mathcal{D} \text{ is injective, } \mathsf{rng}(\rho) \subseteq H \subseteq_{fin} \mathcal{D}\}$$

We refer to H as *history*. Let $\mathcal{S}(\mathcal{A})$ be the LTS $\langle \Sigma \times \mathcal{D}, \mathbb{C}_{\mathcal{A}}, \rightarrow_{\mathcal{A}} \rangle$, where $\rightarrow_{\mathcal{A}}$ is defined in the following way: a configuration (q_1, ρ_1, H_1) can make a transition to a configuration (q_2, ρ_2, H_2) reading input (t, d), written $(q_1, \rho_1, H_1) \xrightarrow{(t,d)} (q_2, \rho_2, H_2)$, if one of the conditions listed below is satisfied (the last two cases never overlap, because δ_{fresh} is a partial function).

- $d = \rho_1(i)$, $\delta_{old}(q_1, t, i) = q_2$, $\rho_2 = (\rho_1 \upharpoonright \mu(q_2))$ and $H_2 = H_1$
- $d \notin \mathsf{rng}(\rho_1)$, $\delta_{fresh}(q_1, t) = (q_2, i, \bullet)$, $\rho_2 = (\rho_1[i \mapsto d] \upharpoonright \mu(q_2))$ and $H_2 = H_1 \cup \{d\}$
- $d \notin H_1$, $\delta_{fresh}(q_1, t) = (q_2, i, \circledast)$, $\rho_2 = (\rho_1[i \mapsto d] \upharpoonright \mu(q_2))$ and $H_2 = H_1 \cup \{d\}$

Note that $\mathcal{S}(\mathcal{A})$ does not depend on the initial and final parameters q_0 and F.

▶ **Definition 4.** The configuration $\kappa_{\mathcal{A}}^{init} = (q_0, \emptyset, \emptyset)$ will be called *initial*. A sequence of configurations $\kappa_0, \cdots, \kappa_n$ such that $\kappa_0 = \kappa_{\mathcal{A}}^{init}$ and $\kappa_i \xrightarrow{t_i, d_i} \kappa_{i+1}$ $(i = 0, \cdots, n-1)$ is called a run on the data word $(t_0, d_0) \cdots (t_{n-1}, d_{n-1})$. A run is *accepting* if $\kappa_n = (q_n, \rho_n, H_n)$ and $q_n \in F$. We write $\mathcal{L}(\mathcal{A})$ for the set of words from $(\Sigma \times \mathcal{D})^*$ with accepting runs, and call it *the language of* $\mathcal{A}$.

▶ Remark 5. Our definition allows for a variable number of available registers, i.e. it is more permissive than that in [15, 19]. This flexible register regime makes it possible to express certain common computational scenarios more directly: in particular, data values can be discarded ("forgotten") as soon as they are no longer needed (cf. garbage collection). Our result shows that poly-time equivalence testing is still possible with this added flexibility. At the same time, the flexible number of registers simplifies the technical development: one can combine an r_1-DFRA and a r_2-DFRA into a single $\max(r_1, r_2)$-DFRA (see Remark 7) by taking the disjoint union of states and transitions.

We rely on injective register assignments, as in the original definition of Francez and Kaminski [9]. This restriction is important for poly-time complexity, as the presence of multiple copies of the same value in registers could be used to model binary memory content (e.g. 1 is represented by the same value in two registers and 0 by different values). Consequently, this would imply a PSPACE lower bound. The appeal of injectivity lies in the fact no expressivity is lost but the transition function has a particularly simple shape and one can define the deterministic variant without introducing any additional comparisons between registers. While the injective discipline may seem restrictive, it has proved a good match for several prominent formalisms that arise in programming language semantics, and does not limit expressivity (e.g. [1]). For example, one can show that the automata support elegant translations from the pi-calculus [19]. They are also a natural target when it comes to investigating the semantics of programs with unbounded data – this is one of the original motivations mentioned in [9], which was also exploited in our work on the ML programming language [14].

The explicit availability function μ guarantees that whenever a transition refers to existing register content, the relevant value will be available. Allowing for transitions that may block on unavailable values is known to lead to NP-hardness [17], already for emptiness in the

deterministic case. Our variant of automata makes it possible for the automaton to drop multiple data values from registers. Conversely, values can also be created but only one at a time. Of course, such single value creations can be combined to create multiple new values. However, the new values must also occur in labels. One can imagine adding a facility for spontaneous value creation, where locally or globally fresh values would be added to the registers without being present in labels. However, the resultant non-determinism could then be used to prove universality undecidable in the same way as for nondeterministic automata, e.g. the argument from [15] could be repeated by employing spontaneous value creation to guess the location of errors. Like in [1, 12], we assume that the registers are not filled at the beginning and are initialised through transitions.

▶ **Definition 6.** A relation $R \subseteq \mathbb{C} \times \mathbb{C}$ is called a *simulation* if, for all $(\kappa_1, \kappa_2) \in R$, if $\kappa_1 \xrightarrow{t,a} \kappa_1'$ then there is $\kappa_2 \xrightarrow{t,a} \kappa_2'$ such that $(\kappa_1', \kappa_2') \in R$. R is called a **bisimulation** if both R and R^{-1} are simulations. The union of all bisimulations is denoted $\sim$. Two configurations κ_1, κ_2 are bisimilar just if $\kappa_1 \sim \kappa_2$, i.e. there is some bisimulation R containing them.

In this paper we are concerned with the *language equivalence* problem for DFRA, i.e. the question whether, given r_1-DFRA $\mathcal{A}_1$ and r_2-DFRA $\mathcal{A}_2$, we have $\mathcal{L}(\mathcal{A}_1) = \mathcal{L}(\mathcal{A}_2)$. Our approach to the problem is bisimulation-oriented: language equivalence testing of $\mathcal{A}_1$ and $\mathcal{A}_2$ can be viewed as a bisimilarity problem for a single r-DFRA with $r = \max(r_1, r_2)$.

▶ Remark 7. We explain this reduction in a little more detail. First we transform $\mathcal{A}_i$ into $\mathcal{A}_i'$ as follows:

- remove all transitions leading to states from which it is impossible to reach a final state,
- add a new state f_i and designate it as the only final state,
- add transitions from former final states to the new final state on a new tag $t^{\$}$.

Suppose $\mathcal{S}(\mathcal{A}_i') = \langle \Sigma \times \mathcal{D}, \mathbb{C}_{\mathcal{A}_i'}, \rightarrow_{\mathcal{A}_i'} \rangle$ $(i = 1, 2)$ and consider the LTS $\mathcal{S}_{\mathcal{A}_1,\mathcal{A}_2} = \langle \Sigma \times \mathcal{D}, \mathbb{C}_{\mathcal{A}_1'} + \mathbb{C}_{\mathcal{A}_2'}, \rightarrow_{\mathcal{A}_1'} + \rightarrow_{\mathcal{A}_2'} \rangle$. Now language equivalence of the original automata is equivalent to checking whether $\kappa^{init}_{\mathcal{A}_1}$ and $\kappa^{init}_{\mathcal{A}_2}$ are bisimilar in $\mathcal{S}_{\mathcal{A}_1,\mathcal{A}_2}$. If $\mathcal{A}_i' = \langle \Sigma, Q_i, q_0^i, \mu_i, \delta_i, \{f_i\} \rangle$, then let $\mathcal{S}_{\mathcal{A}_1,\mathcal{A}_2} = \mathcal{S}_{\mathcal{A}'}$, where $\mathcal{A}'$ is the $\max(r_1, r_2)$-DFRA defined by $\langle \Sigma, Q_1 + Q_2, q', \mu_1 + \mu_2, \delta_1 + \delta_2, F' \rangle$ for any $q' \in Q_1 + Q_2$ and $F' \subseteq Q_1 + Q_2$. Note, the components q', F' can be chosen arbitrarily, because they do not contribute to the definition of bisimilarity over (the configuration graph of) $\mathcal{S}_{\mathcal{A}'}$.

3 Symbolic bisimulations

In this section we introduce symbolic representations of bisimulation relations, for configuration pairs with common history,[1] based on partial permutations. A *partial permutation* over $[1, n]$ is a bijection between two (possibly different) subsets of $[1, n]$. Let $\mathcal{IS}_n$ stand for the set of partial permutations over $[1, n]$ and $\mathcal{S}_X$ for the group of permutations over X. Let us consider the kind of possible scenarios that may arise in simulating transitions of a DFRA.

- A transition on a value already stored in a register can be matched by a transition on a stored value or a locally fresh transition, but never a globally fresh one.
- A globally fresh transition can be matched by a globally fresh transition or a locally fresh one, but never a transition on a stored value.
- A locally fresh transition can be matched by a transition on a stored value, a locally fresh transition or a globally fresh one.

[1] By Remark 7, it suffices to consider configuration pairs with common history.

The use of partial bijections will help us specify which cases may occur. Although we work with automata over r registers, we shall use partial permutations over $[1, n]$, where $n = 2r$. They will be used to express not only a matching between data values occurring in two sets of r registers (corresponding to two configurations that we examine for bisimilarity) but also to indicate which values forgotten by one set are still remembered by the other.

The number $2r$ may be surprising but it is needed to provide an accurate account of scenarios in which local freshness can be simulated by global freshness. Note that this is possible if the registers of the second configuration contain all the data values that have been forgotten by the first one (i.e. do not appear in its registers any more). Once the size of the history exceeds $2r$, this is no longer possible: because the first configuration has only r registers it will have forgotten more than r data values and, because the second configuration has only r registers, it cannot remember them all. Consequently, we only need to track matches between forgotten values and register content of the other configuration as long as the size of the history does not exceed $2r$. To keep track of such scenarios, it is convenient to imagine that there are $2r$ registers available and use partial permutations to match values in registers with values that were possibly forgotten until the size of the history is at most $2r$. Once that is exceeded, matchings between the real r registers suffice.

Given $\sigma \in \mathcal{IS}_r$ and $q_1, q_2 \in Q$, we write $\sigma \restriction (q_1, q_2)$ for $\sigma \cap (\mu(q_1) \times \mu(q_2))$. Next, in accordance with the use of $2r$ registers discussed above, we introduce notions that will allow us to represent configurations in which only a subset $S \subseteq [1, 2r]$ of the registers is available along with certain values that are not stored any longer. The data values occurring in registers S will occupy the same positions (as specified by S), for other values we impose the convention that they should reside in the leftmost register positions that are unoccupied.

▶ **Definition 8** (Notation). Given $S \subseteq T \subseteq [1, 2r]$, let $S \lhd T \in \mathcal{S}_{2r}$ be the permutation that shifts all elements in $T \setminus S$ to the left (inside the interval $[1, 2r]$) without interfering with S. Formally, if $T \setminus S$ is ordered as $[i_1, \cdots, i_k]$ then:

$$S \lhd T = (i_1\, i'_1); \cdots ; (i_k\, i'_k), \quad \text{where } i'_j \text{ is the } j\text{th smallest element in } [1, 2r] \setminus S.$$

Each $(i\, i')$ denotes a transposition and ; is the composition of permutations. For example, taking $S = \{3, 6\}$ and $T = \{1, 3, 4, 6, 7\}$, the permutation would be $S \lhd T = (1\,1); (4\,2); (7\,4)$ and, therefore, $(S \lhd T)(T) = \{1, 2, 3, 4, 6\}$.
Given $S \subseteq [1, 2r]$ and $h \leq 2r$ with $|S| \leq h$, we define $S^{\lhd h}$ to be the unique T satisfying $S \subseteq T \subseteq [1, 2r]$, $|T| = h$ and $T = (S \lhd T)(T)$. In other words, $S^{\lhd h}$ is obtained by adding $h - |S|$ smallest numbers from $[1, 2r] \setminus S$ to S. For instance, for $S = \{3, 6\}$: $S^{\lhd 2} = S$, $S^{\lhd 3} = \{1, 3, 6\}$, $S^{\lhd 4} = \{1, 2, 3, 6\}$, etc. Finally, given $\sigma \in \mathcal{IS}_{2r}$ and $S_1 \subseteq \mathsf{dom}(\sigma)$, $S_2 \subseteq \mathsf{rng}(\sigma)$:

- we write: $\sigma^{(S_1, S_2)\lhd} = (S_1 \lhd \mathsf{dom}(\sigma))^{-1}; \sigma; (S_2 \lhd \mathsf{rng}(\sigma))$,
- and extend the notation to $q_1, q_2 \in Q$ by: $\sigma^{(q_1, q_2)\lhd} = \sigma^{(\mu(q_1), \mu(q_2))\lhd}$.

Next we shall introduce a symbolic notion of simulation. Pairs of configurations will be represented by elements of $\mathcal{U}_0 = Q \times \mathcal{IS}_{2r} \times Q \times ([0, 2r] \cup \{\infty\})$: each pair is represented by the states it contains and a partial permutation representing the two register assignments (a matching between their common data values). In order to handle the interaction between the two kinds of fresh transitions we also introduce an additional element storing the size of the common history (∞ stands for "bigger than $2r$"). Below we define a subset $\mathcal{U}$ of $\mathcal{U}_0$ that characterises the elements compatible with availability information. Moreover, once the history becomes larger than $2r$, we reduce the matchings to r registers only (see above).

▶ **Definition 9.** Let $\mathcal{U}_0 = Q \times \mathcal{IS}_{2r} \times Q \times ([0, 2r] \cup \{\infty\})$ and:

$$\mathcal{U} = \{ \quad (q_1, \sigma, q_2, h) \in \mathcal{U}_0 \mid \quad h \leq 2r \implies (\mathsf{dom}(\sigma) = \mu(q_1)^{\lhd h} \wedge \mathsf{rng}(\sigma) = \mu(q_2)^{\lhd h}) \\ \wedge \quad h = \infty \implies (\sigma \in \mathcal{IS}_r \wedge \sigma \subseteq \mu(q_1) \times \mu(q_2)) \}$$

Given configurations κ_1, κ_2, with $\kappa_i = (q_i, \rho_i, H)$ for some common H, we define the set of symbolic representations of (κ_1, κ_2) by:

$$\mathsf{symb}(\kappa_1, \kappa_2) = \begin{cases} \{(q_1, \rho_1; \rho_2^{-1}, q_2, \infty)\} & |H| > 2r \\ \{(q_1, (\hat{\rho}_1; \hat{\rho}_2^{-1})^{\lhd(q_1,q_2)}, q_2, |H|) \mid \rho_i \subseteq \hat{\rho}_i \wedge \mathsf{rng}(\hat{\rho}_i) = H\} & |H| \leq 2r \end{cases}$$

The essence of the above representation is the abstracting away from the register assignments ρ_1, ρ_2 to a partial permutation $\sigma \in \mathcal{IS}_{2r}$. If the history is large, then σ is simply a matching between the common values of ρ_1 and ρ_2. If, on the other hand, H contains at most $2r$ elements then σ is obtained by extending each ρ_i to some $\hat{\rho}_i$ that stores the full history H, and these pairs $(\hat{\rho}_1, \hat{\rho}_2)$ are then represented by recording their indices containing matching values.

We proceed with defining symbolic bisimulations. The clauses (a)-(f) in the definition below cover all possible kinds of simulation scenarios. Partial bijections help to capture the conditions under which simulation is possible.

▶ **Definition 10.** Let $\mathcal{A} = \langle \Sigma, Q, q_0, \mu, \delta, F \rangle$ be an r-DFRA. A *symbolic simulation* on $\mathcal{A}$ is a relation $R \subseteq \mathcal{U}$, with elements $(q_1, \sigma, q_2, h) \in R$ written $q_1 \, R^h_\sigma \, q_2$, such that all $(q_1, \sigma, q_2, h) \in R$ satisfy the (FSyS) conditions in R. We say that a tuple (q_1, σ, q_2, h) satisfies the *fresh symbolic simulation conditions* (FSyS) *in* R if the following conditions hold, where (a-c) apply to $h \leq 2r$, and (d-e) to $h = \infty$:

(a) for all $q_1 \xrightarrow{t,i} q_1'$,
  1. if $\sigma(i) \in \mu(q_2)$ then there is some $q_2 \xrightarrow{t,\sigma(i)} q_2'$ with $q_1' \, R^h_{\sigma'} \, q_2'$ and $\sigma' = \sigma^{(q_1', q_2')\lhd}$,
  2. if $\sigma(i) = j' \in [1, 2r] \setminus \mu(q_2)$ then there is some $q_2 \xrightarrow{t,j^\bullet} q_2'$ with $q_1' \, R^h_{\sigma'} \, q_2'$ and $\sigma' = (\sigma; (j \, j'))^{(q_1', q_2')\lhd}$;

(b) for all $q_1 \xrightarrow{t,i^\bullet} q_1'$ and $i' \in \mathsf{dom}(\sigma) \setminus \mu(q_1)$,
  1. if $\sigma(i') \in \mu(q_2)$ then there is some $q_2 \xrightarrow{t,\sigma(i')} q_2'$ with $q_1' \, R^h_{\sigma'} \, q_2'$ and $\sigma' = ((i \, i'); \sigma)^{(q_1', q_2')\lhd}$,
  2. if $\sigma(i') = j' \in [1, 2r] \setminus \mu(q_2)$ then there is some $q_2 \xrightarrow{t,j^\bullet} q_2'$ with $q_1' \, R^h_{\sigma'} \, q_2'$ and $\sigma' = ((i \, i'); \sigma; (j \, j'))^{(q_1', q_2')\lhd}$;

(c) for all $q_1 \xrightarrow{t,\ell_i} q_1'$ with $\ell_i \in \{i^\bullet, i^\circledast\}$ there is some $q_2 \xrightarrow{t,\ell_j} q_2'$ with $\ell_j \in \{j^\bullet, j^\circledast\}$ and,
  1. if $h < 2r$ then $q_1' \, R^{h+1}_{\sigma'} \, q_2'$ with $\sigma' = ((i \, 2r); \sigma[2r \mapsto 2r]; (j \, 2r))^{(q_1', q_2')\lhd}$,
  2. if $h = 2r$ then $q_1' \, R^\infty_{\sigma'} \, q_2'$ with $\sigma' = \sigma[i \mapsto j] \restriction (q_1', q_2')$;

(d) for all $q_1 \xrightarrow{t,i} q_1'$,
  1. if $\sigma(i) \in \mu(q_2)$ then there is some $q_2 \xrightarrow{t,\sigma(i)} q_2'$ with $q_1' \, R^\infty_{\sigma'} \, q_2'$ and $\sigma' = \sigma \restriction (q_1', q_2')$,
  2. if $i \in \mu(q_1) \setminus \mathsf{dom}(\sigma)$ then there is some $q_2 \xrightarrow{t,j^\bullet} q_2'$ with $q_1' \, R^\infty_{\sigma'} \, q_2'$ and $\sigma' = \sigma[i \mapsto j] \restriction (q_1', q_2')$;

(e) for all $q_1 \xrightarrow{t,i^\bullet} q_1'$ and $j \in \mu(q_2) \setminus \mathsf{rng}(\sigma)$, there exists $q_2 \xrightarrow{t,j} q_2'$ with $q_1 \, R^\infty_{\sigma'} \, q_2'$ and $\sigma' = \sigma[i \mapsto j] \restriction (q_1', q_2')$;

(f) for all $q_1 \xrightarrow{t,\ell_i} q_1'$ with $\ell_i \in \{i^\bullet, i^\circledast\}$ there is some $q_2 \xrightarrow{t,\ell_j} q_2'$ with $\ell_j \in \{j^\bullet, j^\circledast\}$, $q_1' \, R^\infty_{\sigma'} \, q_2'$ and $\sigma' = \sigma[i \mapsto j] \restriction (q_1', q_2')$, and $\ell_i = i^\bullet \implies \ell_j = j^\bullet$.

Define now the inverse of R by $R^{-1} = \{\,(q_2, \sigma^{-1}, q_1, h) \mid (q_1, \sigma, q_2, h) \in R\,\}$ and call R a **symbolic bisimulation** if both R and R^{-1} are symbolic simulations. We let *s-bisimilarity*, denoted $\overset{\mathsf{s}}{\sim}$, be the union of all symbolic bisimulations.

In the rest of the paper, given $R \subseteq \mathcal{U}$ and $h \in [1, 2r] \cup \{\infty\}$, we shall write R^h for the projection of R on h: $R^h = \{(q, \sigma, q') \mid (q, \sigma, q', h) \in R\}$.

▶ Remark 11. To gain some further intuition about the definition above, let us consider the 2-DFRA configurations $\kappa_i = (q_i, \rho_i, H)$, $i = 1, 2$, where: $\mu(q_1) = \mu(q_2) = \{1, 2\}$, $\rho_1 = \{(1, a), (2, b)\}$, $\rho_2 = \{(1, a), (2, c)\}$ and $H = \{a, b, c\}$.
The pair (κ_1, κ_2) can be represented symbolically by $(q_1, \sigma, q_2, 3) \in \mathsf{symb}(\kappa_1, \kappa_2) \subseteq \mathcal{U}$, where $\sigma = \{(1, 1), (2, 3), (3, 2)\}$. This represents the fact that ρ_1, ρ_2 share the data value a in their first register and each have a private value in their second register.[2] The (FSYS) conditions express symbolically what it takes for κ_2 to simulate κ_1, i.e. what is needed for $(q_1, \sigma, q_2, 3)$ to belong to a (symbolic) simulation R. Let us look at two sample cases.

- Suppose $q_1 \xrightarrow{t,1} q_1'$. Then, $\kappa_1 \xrightarrow{(t,a)} \kappa_1'$ and, in order for κ_2 to match this, it must be the case that $q_2 \xrightarrow{t,1} q_2'$. This is imposed by Condition (a)1 of (FSYS).
- If $q_1 \xrightarrow{t,2} q_1'$ then $\kappa_1 \xrightarrow{(t,b)} \kappa_1'$. Then, κ_2 can only match a transition on b using a locally fresh transition (Condition (a)2), so we must have e.g. $q_2 \xrightarrow{t,1^\bullet} q_2'$, yielding some $\kappa_2 \xrightarrow{(t,b)} \kappa_2'$.

In each of the cases above, the (FSYS) conditions also stipulate that the resulting representation of (κ_1', κ_2') must also be in R. In the second case, assuming $\kappa_i' = (q_i', \rho_i', H)$ and $\mu(q_i') = \{1, 2\}$, we have that $\rho_1' = \{(1, a), (2, b)\}$ and $\rho_2' = \{(1, b), (2, c)\}$, and the pair (κ_1', κ_2') is represented by $(q_1', \sigma', q_2', 3)$ with $\sigma' = \{(1, 3), (2, 1), (3, 2)\}$. Because $\sigma' = \sigma; (3\ 1) = (\sigma; (3\ 1))^{(q_1', q_2')\triangleleft}$, the (FSYS) conditions require $(q_1', \sigma', q_2', 3) \in R$.

The importance of symbolic bisimulations lies in that they precisely represent actual bisimulations in a finite way. Below, we first show that the symbolic representations of pairs of configurations are well defined (the choice of extensions $\hat{\rho}_i$ for the case of $|H| \leq 2r$ does not matter for $\overset{\mathsf{s}}{\sim}$), and then prove the representation property.

▶ **Lemma 12.** *For any κ_1, κ_2 with $\kappa_i = (q_i, \rho_i, H)$ and $|H| \leq 2r$, either $\mathsf{symb}(\kappa_1, \kappa_2) \subseteq \overset{\mathsf{s}}{\sim}$ or $\mathsf{symb}(\kappa_1, \kappa_2) \cap \overset{\mathsf{s}}{\sim} = \emptyset$.*

▶ **Proposition 13.** For any κ_1, κ_2 with common history, $\kappa_1 \sim \kappa_2$ iff $\mathsf{symb}(\kappa_1, \kappa_2) \subseteq \overset{\mathsf{s}}{\sim}$.

Although finite, symbolic bisimulations are of exponential size in the worst case (with respect to the automaton size) because of including the partial bijections σ. Our equivalence-testing algorithm for r-DFRA will rely on representations of candidate symbolic bisimulations in a succinct way. In order to spell out in what sense these representations will capture subsets of $\mathcal{U}$ we need to introduce the following closure operations.

▶ **Definition 14.** Let $R \subseteq \mathcal{U}$. Then $Cl(R)$ is defined to be the smallest subset X of $\mathcal{U}$ such that $R \subseteq X$ and X is closed under the following rules.

$$\frac{S = \mu(q)^{\triangleleft h} \quad h \leq 2r}{(q, \mathsf{id}_S, q) \in X^h} \qquad \frac{}{(q, \mathsf{id}_{\mu(q)}, q) \in X^\infty} \qquad \frac{(q_1, \sigma, q_2) \in X^h}{(q_2, \sigma^{-1}, q_1) \in X^h}$$

$$\frac{(q_1, \sigma, q_2) \in X^\infty \quad \sigma \subseteq \sigma'}{(q_1, \sigma', q_2) \in X^\infty} \qquad \frac{(q_1, \sigma_1, q_2) \in X^h \quad (q_2, \sigma_2, q_3) \in X^h}{(q_1, \sigma_1; \sigma_2, q_3) \in X^h}$$

[2] E.g. the value b is in register 2 of ρ_1 but is not present in ρ_2. Seeing $\hat{\rho}_2$ as an expansion of ρ_2 to 3 registers (with register 3 containing forgotten values), we set $\hat{\rho}_2(3) = b$ and therefore $\sigma(2) = 3$.

The next lemma provides a handle on proving that closures $Cl(R)$ satisfy (FSyS) conditions.

▶ **Lemma 15.** *Let $R, P \subseteq \mathcal{U}$ with $R = R^{-1}$. If all $g \in R$ satisfy the* (FSyS) *conditions in P then all $g' \in Cl(R)$ satisfy the* (FSyS) *conditions in $Cl(P)$.*

▶ **Corollary 16.** $Cl(\overset{s}{\sim}) = \overset{s}{\sim}$.

Proof. It suffices to show the left-to-right inclusion. All elements in $\overset{s}{\sim}$ satisfy the (FSyS) conditions in $\overset{s}{\sim}$. Hence, by the previous lemma, all elements of $Cl(\overset{s}{\sim})$ satisfy the (FSyS) conditions in $Cl(\overset{s}{\sim})$. This implies that $Cl(\overset{s}{\sim})$ is a symbolic bisimulation. Thus, $Cl(\overset{s}{\sim}) \subseteq \overset{s}{\sim}$. ◀

▶ Remark 17. One may wonder to what extent our techniques apply to simulation rather than bisimulation. Although symbolic simulation can be related to simulation, our methods crucially exploit the fact that bisimilarity is symmetric. This is reflected in the top right rule of Definition 14, which introduces inverses, and enables us to develop a group-theoretic representation scheme in the next section.

4 Representation

Our algorithm for DFRA equivalence will rely on manipulating sets $\mathcal{H} \subseteq \mathcal{U}$ that, for positive instances, will ultimately converge to a symbolic bisimulation relation. We shall handle them through succinct representations based on group theory, whose shape is inspired by the structure of bisimulation relations [13]. The backbone of a generating system, to be defined next, is an equivalence relation $\diamond^h$ on states. As explained in Definition 19, the relation specifies which pairs of states may actually feature in tuples of the represented subset of $\mathcal{U}$.

▶ **Definition 18.** A *generating system* $\mathcal{R}$ consists of a set $\{\mathcal{R}^h \mid h \in [0, 2r] \cup \{\infty\}\}$, where each $\mathcal{R}^h = \langle \diamond^h, \{(q_C^h, X_C^h, G_C^h) \mid C \in Q/\diamond^h\}, \{\sigma_q^h \mid q \in Q\}\rangle$ satisfies the following constraints.

- $\diamond^h \subseteq Q \times Q$ is an equivalence relation.
- For any $\diamond^h$-equivalence class C:
  - q_C^h is a state from C (class representative);
  - $X_C^h = \mu(q_C^h)^{\triangleleft h}$ for $h \in [0, 2r]$ and $X_C^\infty \subseteq \mu(q_C^\infty)$;
  - $\emptyset \neq G_C^h \subseteq \mathcal{S}_{X_C^h}$.
- For any $q \in Q$, $C = [q]_{\diamond^h}$ and $h \in [0, 2r]$, we have $\sigma_q^h \in \mathcal{IS}_{2r}$ with $\mathsf{dom}(\sigma_q^h) = \mu(q_C^h)^{\triangleleft h}$ and $\mathsf{rng}(\sigma_q^h) = \mu(q)^{\triangleleft h}$. Moreover, $\sigma_q^\infty \in \mathcal{IS}_r$ and $\mathsf{dom}(\sigma_q^\infty) = X_C^\infty$. Finally, $\sigma_{q_C^h}^h = \mathsf{id}_{X_C^h}$.

Thus, at each level h, a generating system partitions the set of states into equivalence classes according to $\diamond^h$ and each class has a representative q_C^h, which is "connected" to each element of the class via σ_q^h. Each representative q_C^h is also equipped with a subset $X_C^h \subseteq [0, 2r]$ and a set G_C^h of permutations (generators) from $\mathcal{S}_{X_C^h}$.

▶ **Definition 19.** Let $\mathcal{R}$ be a generating system. The subset of $\mathcal{U}$ represented by $\mathcal{R}$, written $\mathsf{Gen}(\mathcal{R})$, is defined to be $Cl(\mathcal{H}_\mathcal{R})$, where $\mathcal{H}_\mathcal{R} = \bigcup_{h=0}^{2r} \mathcal{H}_\mathcal{R}^h \cup \mathcal{H}_\mathcal{R}^\infty$ and, for any $h \in [0, 2r] \cup \{\infty\}$, we take $\mathcal{H}_\mathcal{R}^h = \{\, (q_C^h, g_C^h, q_C^h, h) \mid C \in Q/\diamond^h,\ g_C^h \in G_C^h \,\} \cup \{\, (q_C^h, \sigma_q^h, q, h) \mid q \in Q, C = [q]_{\diamond^h} \,\}$.

▶ **Example 20.** The representation system $\mathcal{R}_{init}$ is defined by the following components.

- $\diamond^h = \{(q, q) \mid q \in Q\}$. Note that $[q]_{\diamond^h} = \{q\}$.
- For any equivalence class $C = \{q\}$ we have: $q_C^h = q$, $X_C^h = \mu(q)^{\triangleleft h}$ ($h \in [0, 2r]$), $X_C^\infty = \mu(q)$, $G_C^h = \{\mathsf{id}_{X_C^h}\}$.
- For any q, $\sigma_q^h = \mathsf{id}_{X_C^h}$.

Note that $\mathsf{Gen}(\mathcal{R}_{init}) = Cl(\emptyset)$.

Next we examine how generating systems can be employed in algorithms. We are particularly interested in membership testing and a special kind of updates.

4.1 Membership

The next lemma reduces testing for membership in $\mathsf{Gen}(\mathcal{R})$ to the classic problem of group membership testing [6]. Given $G \subseteq \mathcal{S}_X$, we let $\mathsf{Sub}(G)$ be the subgroup of $\mathcal{S}_X$ spanned by G.

▶ **Lemma 21.** *Let $\mathcal{R}$ be a generating system, $u = (q_1, \sigma, q_2, h) \in \mathcal{U}$ and $\overline{\sigma} = \sigma^h_{q_1}; \sigma; (\sigma^h_{q_2})^{-1}$. Then $u \in \mathsf{Gen}(\mathcal{R})$ if and only if $q_1 \diamond^h q_2$ and $\overline{\sigma} \in \mathsf{Sub}(G^h_C)$, where $C = [q_1]_{\diamond^h} = [q_2]_{\diamond^h}$.*

4.2 Update

Suppose $\mathsf{Gen}(\mathcal{R}) = Cl(\mathcal{H})$. We explain how, given $u = (q_1, \sigma, q_2, h) \in \mathcal{U}$, one can update $\mathcal{R}$ to $\mathcal{R}'$ so that $\mathsf{Gen}(\mathcal{R}') = Cl(\mathcal{H} \cup \{u\})$. Of course, if $u \in \mathsf{Gen}(\mathcal{R})$ then it suffices to take $\mathcal{R}' = \mathcal{R}$. Thus, let us assume $u \notin \mathsf{Gen}(\mathcal{R})$. By Lemma 21, this corresponds to the following cases, where $\overline{\sigma} = \sigma^h_{q_1}; \sigma; (\sigma^h_{q_2})^{-1}$.

1. $q_1 \diamond^h q_2$ and either (a) or (b) holds, where $C = [q_1]_{\diamond^h} = [q_2]_{\diamond^h}$:
   - **(a)** $\overline{\sigma} \in \mathcal{S}_{X^h_C} \setminus \mathsf{Sub}(G^h_C)$,
   - **(b)** $\overline{\sigma} \notin \mathcal{S}_{X^h_C}$, i.e. $\mathsf{dom}(\overline{\sigma}) \subsetneq X^h_C$.
2. $q_1 \diamond^h q_2$ does not hold.

Observe that 1.(b) will never arise for $h \neq \infty$ due to the definitions of $\mathcal{U}$ and $\mathcal{R}$. Note also that, for $h \neq \infty$, X^h_C is uniquely determined by q^h_C. However, this is not the case for X^∞_C.

Before we explain how to tackle each case, we introduce several technical lemmas that examine how partial permutations interact. They will inform the performance of updates based on modifying X^∞_C.

▶ **Lemma 22.** *Given $I \subseteq \mathcal{IS}_r$, let $\chi_I = \{\sigma \mid \sigma = \sigma_1^{\epsilon_1}; \cdots; \sigma_k^{\epsilon_k},\ k > 0,\ \sigma_i \in I,\ \epsilon_i \in \{1, -1\}\}$ and $\mathcal{D}_I = \{\mathsf{dom}(\sigma) \mid \sigma \in \chi_I\}$. Then χ_I is closed under composition and inversion, and $\mathcal{D}_I$ is closed under intersection.*

▶ **Lemma 23.** *Given $I \subseteq \mathcal{IS}_r$, let $B_I = \bigcap_{X \in \mathcal{D}_I} X$ be called the* base *of I. Then we have:*

1. *$B_I \in \mathcal{D}_I$ and $\mathsf{id}_{B_I} \in \chi_I$.*
2. *Given $\sigma \in \mathcal{IS}_r$ and $X \subseteq [1, r]$, let us write $\sigma \restriction X$ for $\mathsf{id}_X; \sigma$. Then, for any $\sigma \in I$, $\sigma \restriction B_I \in \chi_I$ and $\sigma \restriction B_I$ is a permutation of B_I.*

Next we show that, given I, the base B_I can be calculated via graph reachability.

▶ **Lemma 24.** *Let $I \subseteq \mathcal{IS}_r$. Consider the undirected graph $G_I = (V, E)$ with $V = [1, r]$, where $\{j_1, j_2\} \in E$ iff there exists $\sigma \in I$ such that $\sigma(j_1) = j_2$ or $\sigma(j_2) = j_1$. We shall call $v \in [1, r]$* endangered *if there exists $\sigma \in I$ such that $v \notin \mathsf{dom}(\sigma)$ or $v \notin \mathsf{rng}(\sigma)$. For any $i \in [1, r]$, $i \in B_I$ if and only if no endangered vertex is reachable from i in G_I.*

4.3 Update implementation

Finally, we are ready to return to the main issue of representation update. We discuss the three cases (1.(a), 1.(b) and 2.) in turn. Recall that $u = (q_1, \sigma, q_2, h) \in \mathcal{U}$ and $\overline{\sigma} = \sigma^h_{q_1}; \sigma; (\sigma^h_{q_2})^{-1}$.

1. **(a)** Here we have $\overline{\sigma} \in \mathcal{S}_{X^h_C} \setminus \mathsf{Sub}(G^h_C)$. To update the system in order to represent σ, it suffices to add $\overline{\sigma}$ to G^h_C without changing anything else.

1. **(b)** Here we have $\mathsf{dom}(\overline{\sigma}) \subsetneq X^h_C$ and $h = \infty$. In order to capture $\overline{\sigma}$, we replace X^∞_C with B_I, where $I = G^\infty_C \cup \{\overline{\sigma}\}$, and set $G^\infty_C = \{\sigma \restriction B_I \mid \sigma \in I\}$. Note that, by Lemma 23, all the elements are permutations, as required. Similarly to G^∞_C, we replace σ^∞_q with $\sigma^\infty_q \restriction B_I$ for each $q \in C$. Other elements of the system remain the same.

```
1  i=0; R_0 = R_init; Δ = {u_0}; Δ_0 = ∅;
2  while (Δ is not empty) do {
3      u = Δ.get();
4      if u ∉ Gen(R_i) {
5          if one-step test fails for u return NO;
6          Δ.add(succ-set(u));
7          Δ_{i+1} = Δ_i.add({u});
8          R_{i+1} = R_i updated with u;
9          i=i+1;
10     }
11 }
12 return YES
```

Figure 1 Bisimilarity checking algorithm.

2. This case is the hardest as we need to merge two different equivalence classes, namely, $C_1 = [q_1]_{\diamond^h}$ and $C_2 = [q_2]_{\diamond^h}$ into a single one $C = C_1 \cup C_2$ (formally, this is a change to $\diamond^h$). For the new class C, we take $q^h_C = q^h_{C_1}$.
   Next we discuss $X^h_{q_C}$. Given $\tau \in G^h_{q_{C_2}}$, let $\widehat{\tau} = \overline{\sigma}; \tau; (\overline{\sigma})^{-1}$ and consider $I = G^h_{q_{C_1}} \cup \{\widehat{\tau} \mid \tau \in G^h_{q_{C_2}}\}$. We shall set $X^h_{q_C}$ to B_I. Note that, if $h \neq \infty$, all elements of I will have the same domains, so in this case $X^h_{q_C}$ will not change. As before, we set $G^h_C = \{\sigma \restriction B_I \mid \sigma \in I\}$. We also modify σ^h_q, but only for $q \in C_1 \cup C_2$. If $q \in C_1$, we take $\sigma^h_q \restriction B_I$ instead of σ^h_q. For $q \in C_2$, we need to take the change of representative into account and take $(\overline{\sigma}; \sigma^h_q) \restriction B_I$ instead of σ^h_q.
   (For this to be a correct choice, we need to show that $\mathsf{dom}(\overline{\sigma}; \sigma^h_q) \supseteq B_I$. This is indeed so, because $\mathsf{dom}(\overline{\sigma}; \sigma^h_q) = \mathsf{dom}(\overline{\sigma}; \mathsf{id}_{X^h_{q_{C_2}}})$, by $\mathsf{dom}(\sigma^h_q) = X^h_{q_{C_2}}$, and $\mathsf{dom}(\overline{\sigma}; \mathsf{id}_{X^h_{q_{C_2}}}) = \mathsf{dom}(\overline{\sigma}; \tau) \supseteq \mathsf{dom}(\overline{\sigma}; \tau; \overline{\sigma}^{-1}) = \mathsf{dom}(\widehat{\tau}) \supseteq B_I$ for any $\tau \in G^h_{q_{C_2}}$.)

Recall that we work under the assumption that $\mathsf{Gen}(\mathcal{R}) = Cl(\mathcal{H})$ and let us write $\mathcal{R}'$ for the updated representation system. In each of the above cases, the modifications contribute to $\mathcal{H}_{\mathcal{R}'}$ only elements from $Cl(\mathcal{H} \cup \{u\})$. This is completely clear for 1.(a). For 1.(b) and 2., we need to appeal to Lemma 23 ($\sigma \restriction B_I \in \chi_I$) and the use of composition/inversion during construction. Consequently, $\mathsf{Gen}(\mathcal{R}') \subseteq Cl(\mathcal{H} \cup \{u\})$.

Conversely, $Cl(\mathcal{H} \cup \{u\}) \subseteq \mathsf{Gen}(\mathcal{R}')$, because all elements of $\mathcal{R}$ as well as u have been integrated into $\mathcal{R}'$, either directly or through composition and reductions to X^∞_C. Thanks to the defining rules for Cl (notably, closure under composition and inclusion), such changes preserve representability.

5 Algorithm

Finally, we present the algorithm for deciding whether two configurations $\kappa_i = (q_i, \rho_i, H)$ are bisimilar. Let $u_0 = (q_1, \sigma, q_2, h)$ be an arbitrary element of $\mathsf{symb}(\kappa_1, \kappa_2)$. By Lemma 12 and Proposition 13, bisimilarity of κ_1, κ_2 amounts to checking whether u_0 belongs to a symbolic bisimulation. Our algorithm will determine whether or not this is the case.

The algorithm is presented in Figure 1. It is similar in flavour to the classic Hopcroft-Karp algorithm for DFA [8], which maintains *sets of pairs of states*. In contrast, we work with *sets of elements from the set* $\mathcal{U}$, i.e. four-tuples (q_1, σ, q_2, h). As subsets of $\mathcal{U}$ may have exponential size, we do not store them explicitly. Instead we take advantage of the representation systems developed in the previous section.

Starting from u_0, the algorithm maintains generating systems $\mathcal{R}_i$, beginning with $\mathcal{R}_{init}$. We assume the availability of a data structure Δ for storing multisets of elements of $\mathcal{U}$ (e.g. a queue), equipped with emptiness testing, a *get* method that removes an occurrence of an element u from Δ and returns it as a result, and an *add* method that extends Δ with the elements listed as its argument .

▶ Remark 25. Each of the conditions for (FSYS) relies on finding a matching transition satisfying an extra constraint spelt out in terms of R^h. If (FSYS) fails for u or u^{-1} because no potential transition exists, we shall say that the *one-step* test fails for $u \in \mathcal{U}$. Note that we are not concerned whether the extra constraint is satisfied – we only check if a transition with the specified source and label exists.
Because we work with deterministic automata, the availability of a transition implies uniqueness. Consequently, if u passes the one-step test, the (FSYS) rules for u and u^{-1} deliver a unique set of conditions that need to be checked in order for (FSYS) to be satisfied (for u and u^{-1}). Formally, these conditions can be captured as a subset of $\mathcal{U}$ and we shall call them the *successor set* of u, written $\mathsf{succ\text{-}set}(u)$. In the code above the membership test ($u \notin \mathsf{Gen}(\mathcal{R}_i)$) is performed as specified in Section 4.1, while the extension of $\mathcal{R}_i$ with u follows Section 4.2.

The correctness arguments rely on the following invariants.

▶ **Lemma 26.** *The loop satisfies the following invariants.*

(a) *For any $i \geq 0$, $\mathsf{Gen}(\mathcal{R}_i) = Cl(\Delta_i)$ and, for all $v \in \Delta_i$, v, v^{-1} satisfy the* (FSYS) *conditions in $Cl(\Delta_i \cup \Delta)$.*

(b) *For any symbolic bisimulation relation R, if $u_0 \in R$ then $\Delta \subseteq R$.*

▶ **Theorem 27** (Partial Correctness)**.** *When the Algorithm returns YES, there exists a symbolic bisimulation containing u_0. When the Algorithm returns NO, no symbolic bisimulation can contain u_0.*

Proof. When the Algorithm returns YES, Δ is empty. Consequently, Lemma 26 (a) implies that each element of $\Delta_i \cup \Delta_i^{-1}$ satisfies the (FSYS) conditions in $Cl(\Delta_i)$, so $Cl(\Delta_i)$ is a symbolic bisimulation relation by Lemma 15.

- If $u_0 \notin \mathsf{Gen}(\mathcal{R}_{init})$ then $i > 0$ and $u_0 \in \Delta_0 \subseteq \Delta_i$. Thus, $u_0 \in Cl(\Delta_i)$.
- If $u_0 \in \mathsf{Gen}(\mathcal{R}_{init})$ then the Theorem is also true, because $\mathsf{Gen}(\mathcal{R}_{init})$ is a symbolic bisimulation.

Thus, in each case, there exists a symbolic bisimulation containing u_0. The NO case follows immediately from Lemma 26 (b). ◀

Next we argue why the algorithm terminates and its complexity is polynomial. To that end, it will be useful to introduce the following measure on representation systems.

▶ **Definition 28.** Given $\mathcal{R}$, let $m_{\mathcal{R}} : ([0, 2r] \cup \{\infty\}) \times Q \to \mathbb{N} \times \mathcal{P}(\mathcal{IS}_{2r})$ be defined as follows.

$$m_{\mathcal{R}}(h, q) = (|Q/\diamond^h| + |X_{[q]_{\diamond^h}}|, \mathsf{Sub}(G^h_{[q]_{\diamond^h}}))$$

Given $(n_1, H_1), (n_2, H_2) \in \mathbb{N} \times \mathcal{P}(\mathcal{IS}_{2r})$, let $(n_1, H_1) \leq (n_2, H_2)$ stand for $n_1 < n_2$ or ($n_1 = n_2$ and $H_1 \supseteq H_2$). For $\mathcal{R}_1, \mathcal{R}_2$, we then write $m_{\mathcal{R}_1} \leq m_{\mathcal{R}_2}$ iff for all (h, q), $m_{\mathcal{R}_1}(h, q) \leq m_{\mathcal{R}_2}(h, q)$.

▶ **Lemma 29.** *Given a representation system $\mathcal{R}$ and $u \in \mathcal{U}$, let $\mathcal{R}'$ be its extension by u constructed in Section 4.2. Then $m_{\mathcal{R}'} \lneq m_{\mathcal{R}}$.*

▶ **Theorem 30.** *The Algorithm terminates.*

Proof. We argue by contradiction. Observe that, if the Algorithm does not terminate, there can be no bound on the number of times that elements are added to the queue. This will generate an infinite sequence of generating systems $\mathcal{R}_0, \mathcal{R}_1, \cdots, \mathcal{R}_i, \mathcal{R}_{i+1}, \cdots$, where each $\mathcal{R}_{i+1}$ extends $\mathcal{R}_i$ according to Section 4.2. By Lemma 29, $m_{\mathcal{R}_0} \gneq m_{\mathcal{R}_1} \gneq \cdots \gneq m_{\mathcal{R}_i} \gneq \cdots$. Given that the first components (numbers) in $m_{\mathcal{R}i}(h, q)$ are bounded by $|Q| + 2r$, for this to happen, we would need to have an infinite chain of subgroups of $\mathcal{S}_X$ for some $X \subseteq [1, 2r]$. This contradicts the bound from [2]. ◀

Following a similar pattern of reasoning, we can establish a bound on the number of generating systems that can be produced by the Algorithm, which happens to correspond to the value of i. We have already observed that the integers in the first component of $m_{\mathcal{R}i}(h, q)$ are bounded by $|Q| + 2r$. Consequently, that particular component can decrease $|Q| + 2r$ times for $h \in [0, 2r]$ and $|Q|$ times for $h = \infty$ (the sets X^h_C are not modified in this case). As for the second component, the bound on the number of times it can change is $2r + O(1)$ [2]. Because the decreases may occur for any q, h, the overall bound on i is $\underbrace{|Q|(2r+1)(|Q|+2r)2r}_{h\in[0,2r]} + \underbrace{|Q||Q|2r}_{h=\infty} = O(|Q|^2r^2 + |Q|r^3) + O(|Q|^2r)$. Each increase of i is accompanied by the addition of one-step successors to the queue. There are $O(r)$ such successors and their generation can take $O(r)$ steps due to rearrangements on permutations. Consequently, the handling of each element of u may require $O(r^2)$ steps ($O(r)$ steps for $h = \infty$). This does not take group membership tests into account, for which there exist polynomial-time algorithms [6]. Thus, the complexity can be conservatively bounded by $O(|Q|^2r^5p(r))$ steps, where $p(r)$ refers to the complexity of membership testing for $\mathcal{S}_{2r}$ (which bounds those for $\mathcal{S}_X$, where $X \subseteq [1, 2r]$). Note that for $h = \infty$, the complexity is $O(|Q|^2r^2p(r))$. Knuth [10] reports on an algorithm for which $p(r) = O(r^5 + mr^2)$, where m is the number of membership queries, adding that it runs considerably faster in practice.

▶ **Theorem 31.** *The language equivalence problem for r-DFRA is in PTIME.*

A natural question for further study is whether the problem is PTIME-complete. It is certainly NL-hard, by reduction from DFA.

Implementation

An implementation of our algorithm is available from `http://github.com/stersay/deq`. Although we leave a full analysis of our empirical results to a future publication, it is worth mentioning that initial case studies indicate that the high-degree of r in the worst case is not a hindrance in practice. For example, in comparing two encodings of automata simulating finite stack machines (considered previously by [12]), bisimulations for automata with $r \leq 1500$ can be computed in less than one minute.

6 Inclusion

Equivalence can often be attacked by reduction to the associated inclusion problem. As we explain next, for DFRA this route would not yield a PTIME bound.

▶ **Theorem 32.** *The inclusion problem for r-DFRA is in PSPACE-complete.*

Proof. For membership in PSPACE, we first note that inclusion can be reduced to simulation. Now observe that if there is a winning strategy for Attacker over the infinite alphabet then there will be one if $2r + 1$ letters are used. This is because $2r + 1$ letters are sufficient to

simulate the effect of attacks that rely on global freshness: with $2r + 1$ letters available it is always possible to choose a letter that is not stored in either set of the r-registers and, thus, attacks based on global freshness can be simulated. Consequently, failures of inclusion can be detected by guessing the relevant word using $2r + 1$ letters on the understanding that for globally fresh transitions we need to choose a letter not occurring in any of the $2r$ registers. To this end, polynomial space is needed to keep track of the current content of both sets of registers.

We can show PSPACE-hardness already for DFRA without global freshness, which we refer to as DRA. Because DRA can be complemented easily, we actually show that the equivalent problem of DRA intersection emptiness is PSPACE-hard. This is done by reduction from non-emptiness of deterministic linear-bounded Turing machines. The main difficulty in the argument is to represent the tape through registers. This seems impossible at first given that a register assignment must contain different data values. We overcome this by constructing two $(n + 1)$-DRA $\mathcal{A}_1$, $\mathcal{A}_2$ such that whenever they synchronise on a data word, their register assignments ρ_1, ρ_2 represent the content of n tape cells as follows: 0 in the ith cell is represented by $\rho_1(i) = \rho_2(i)$, and 1 by $\rho_1(i) \notin \mathsf{rng}(\rho_2)$. The $(n + 1)$th register plays a technical role that helps us to maintain the representation. The position of the head and state of the machine are maintained in the state of the automata. ◀

On W[1]-Hardness as Evidence for Intractability

Ralph Christian Bottesch

Abstract

The central conjecture of parameterized complexity states that FPT $\neq$ W[1], and is generally regarded as the parameterized counterpart to P $\neq$ NP. We revisit the issue of the plausibility of FPT $\neq$ W[1], focusing on two aspects: the difficulty of proving the conjecture (assuming it holds), and how the relation between the two classes might differ from the one between P and NP.

Regarding the first aspect, we give new evidence that separating FPT from W[1] would be considerably harder than doing the same for P and NP. Our main result regarding the relation between FPT and W[1] states that the closure of W[1] under relativization with FPT-oracles is precisely the class W[P], implying that either FPT is not low for W[1], or the W-Hierarchy collapses. This theorem also has consequences for the A-Hierarchy (a parameterized version of the Polynomial Hierarchy), namely that unless W[P] is a subset of some level A[t], there are structural differences between the A-Hierarchy and the Polynomial Hierarchy. We also prove that under the unlikely assumption that W[P] collapses to W[1] in a specific way, the collapse of any two consecutive levels of the A-Hierarchy implies the collapse of the entire hierarchy to a finite level; this extends a result of Chen, Flum, and Grohe (2005).

Finally, we give weak (oracle-based) evidence that the inclusion W[t] $\subseteq$ A[t] is strict for $t > 1$, and that the W-Hierarchy is proper. The latter result answers a question of Downey and Fellows (1993).

1 Introduction

The central conjecture of parameterized complexity theory states that FPT $\neq$ W[1]. The complexity class FPT is a generalization of P, and it also contains this class in the sense that regardless of which parameter we associate with the instances of a problem in P, the resulting *parameterized problem* is in FPT. This inclusion is strict, as FPT also contains parameterized versions of problems that are provably not in P. The class W[1] can be regarded as a parameterized counterpart to NP. It can be defined in different ways, all

of them quite technical, but the most common definition is in terms of a parameterized version of a particular NP-complete problem (much like NP can be defined in terms of a Boolean circuit satisfiability problem). However, W[1] is not known or believed to contain *all* parameterized versions of problems in NP, and by defining complexity classes in terms of parameterizations of other NP-complete problems, one actually obtains a large set of seemingly distinct parameterized analogues of NP, some of which we list here:

$$\mathsf{A}[1] = \mathsf{W}[1] \subseteq \mathsf{W}[2] \subseteq \mathsf{W}[3] \subseteq \ldots \mathsf{W}[t] \ldots \subseteq \mathsf{W}[\mathsf{P}] \subseteq \mathsf{para\text{-}NP}.$$

Among these, the most interesting classes are W[1] (a.k.a. A[1]) and W[P], due to having many natural complete problems.

The basic intuition for why W[1] (and hence all classes in the above sequence) should differ from FPT is the same as for P ≠ NP, namely that we do not know of any way to efficiently simulate nondeterministic computations deterministically. This intuition is often used to justify considering the W[1]-hardness of a problem as evidence for its intractability. But because FPT is strictly larger than P, while W[1] does not appear to capture all of the complexity of NP, it seems that proving the central conjecture of parameterized complexity theory may be harder than separating P and NP. We investigate qualitative differences between the two conjectures, as well as the more general question of whether FPT occupies the same place within W[1] as P does within NP. We start by giving a brief summary of some relevant prior results.

That the central parameterized conjecture is at least as strong as its classical counterpart is easy to prove: If NP = P, then, as noted above, every parameterized version of every problem in NP(= P) must be in FPT, hence W[1] = FPT (and, in fact, para-NP = W[P] = ... = FPT). Thus we have that FPT ≠ W[1] ⇒ P ≠ NP. The converse of this implication is not known to hold, but Downey and Fellows [9] were the first to observe that a collapse of W[1] to FPT would at least imply the existence algorithms with sub-exponential running time for the NP-complete problem 3Sat. This would contradict the *Exponential Time Hypothesis (ETH)*, first introduced by Imagliazzo, Paturi, and Zane [13], which states that for some constant $c > 0$, 3Sat can not be solved in time $O^*(2^{cn})$ by deterministic Turing machines (TMs). This conjecture has enjoyed much popularity recently, because, assuming ETH, for many problems it is possible to prove a complexity lower bound that matches that of the best known algorithm up to lower-order factors (see [14] for a survey of such results). Nevertheless, one should keep in mind that ETH is a much stronger statement than P ≠ NP, since it rules out not only the existence of polynomial-time algorithms for 3Sat, but also of those that run in up to exponential-time (for some bases). Putting all of these facts together, we have:

$$\text{ETH} \Longrightarrow \mathsf{FPT} \neq \mathsf{W}[1] \Longrightarrow \ldots \Longrightarrow \mathsf{FPT} \neq \mathsf{W}[\mathsf{P}] \Longrightarrow \mathsf{FPT} \neq \mathsf{para\text{-}NP} \Longrightarrow \mathsf{P} \neq \mathsf{NP}.$$

The above sequence relates parameterized complexity conjectures to two classical ones, but it does not say which of them are closer in strength to ETH and which are closer to P ≠ NP. The only known fact here is that FPT ≠ para-NP ⇔ P ≠ NP (see [11, Corollary 2.13]), but there is strong evidence suggesting that all of the other parameterized conjectures listed above are considerably stronger than P ≠ NP (although possibly still weaker than ETH[1]). First, Downey and Fellows [8] construct an oracle relative to which P and NP differ while W[P]

[1] There is, in fact, a subclass of W[1], called M[1], of which it is known that FPT ≠ M[1] is equivalent to ETH (see [10]). The similarities between M[1] and W[1] can be seen as a further indication that the conjecture FPT ≠ W[1] is nearly as strong as ETH, but, evidently, both FPT ≠ M[1] and M[1] ≠ W[1] are wide open conjectures.

collapses to FPT, so we know that any proof of the implication $\mathsf{P} \neq \mathsf{NP} \Rightarrow \mathsf{FPT} \neq \mathsf{W[P]}$ can not be as simple as the proof of the converse implication sketched above. More importantly, $\mathsf{FPT} \neq \mathsf{W[P]}$ can be related much more precisely to other classical complexity conjectures.

How strong the assumption $\mathsf{FPT} \neq \mathsf{W[P]}$ is, can be elegantly expressed in terms of *limited nondeterminism*. If f is a poly-time-computable function, denote by $\mathsf{NP}[f(n)]$ the class of problems that can be solved by a nondeterministic TM in polynomial-time by using at most $O(f(n))$ bits of nondeterminism (n denotes the size of the input). Note that $\mathsf{NP}[\log n] = \mathsf{P}$, since a deterministic TM can cycle through all possible certificates of length $O(\log n)$ in polynomial-time. A remarkable theorem of Cai, Chen, Downey, and Fellows [6] states that $\mathsf{FPT} \neq \mathsf{W[P]}$ holds *if and only if* for *every* poly-time-computable non-decreasing unbounded function h, we have that $\mathsf{P} \neq \mathsf{NP}[h(n) \log n]$ (see [11, Theorem 3.29] for a proof of the theorem in this form). The class of functions referred to in this theorem contains functions with very slow growth, such as the iterated logarithm function, $\log^*$. In fact, there is no poly-time-computable non-decreasing unbounded function that has the slowest growth, because if some function h satisfies these conditions, then so does $\log^* h$. It is not even intuitively clear whether P is different from NP when the amount of allowed nondeterminism is arbitrarily close to trivial. At the very least, the fact that an infinite number of increasingly strong separations must hold in order for W[P] to not collapse to FPT, suggests that separating these two classes is much farther out of our reach than a separation of P and NP.

The evidence we have seen so far indicates that proving a separation of W[1] and FPT may be harder than proving $\mathsf{P} \neq \mathsf{NP}$. But assuming that both conjectures hold, it is meaningful to ask whether the internal structure of W[1] resembles that of NP, and there is indeed some positive evidence in this direction. For example, a parameterized version of Cook's Theorem connects Boolean circuit satisfiability to W[1]-completeness (see [9]), a parameterized version of Ladner's Theorem states that if $\mathsf{FPT} \neq \mathsf{W[1]}$, then there is an infinite hierarchy of problems with different complexities within W[1] (see [9]), and the machine-based characterizations of this class, due to Chen, Flum, and Grohe [7], establish that W[1] can indeed be defined in terms of nondeterministic computing machines. Nevertheless, there are also previously unexplored ways in which W[1] may not behave the same way as NP.

Our main goal in this work is to provide further evidence that the classes FPT and W[1] are close not only in the sense of being difficult to separate, but also in the sense that the relationship between the two differs from that of P and NP, in a way that indicates that FPT is larger within W[1] than P is within NP (assuming the latter pair does not collapse). These results contrast with those in [4], where we showed how certain theorems about FPT and the levels of the A-Hierarchy can be proved in the same way as for their classical counterparts.

1.1 Summary of our results

The difficulty of separating W[P] from FPT. Assuming that we could prove a separation of the form $\mathsf{P} \neq \mathsf{NP}[h(n) \log n]$ for a particular, slow-growing function h, how much progress would we have made towards proving the separation where $h(n)$ is replaced by $\log h(n)$? Intuitively, the difficulty of proving non-equality should increase when a function with a slower growth is chosen. On the other hand, if $\mathsf{FPT} \neq \mathsf{W[P]}$ holds, then all such classical separations hold as well (by the above-mentioned theorem of Cai *et al.* [6]), and therefore any one of them implies the others. It is not clear, however, whether a proof of $\mathsf{FPT} \neq \mathsf{W[P]}$ with $\mathsf{P} \neq \mathsf{NP}[h(n) \log n]$ as a hypothesis would be significantly simpler than a proof from scratch. We show that this is unlikely to be the case, by proving (Theorem 9) that for any poly-time-computable non-decreasing unbounded function h, there exists a computable oracle O_h such that:

$$\mathsf{P}^{O_h} \neq \mathsf{NP}[h(n) \log n]^{O_h}, \text{ but } \mathsf{W[P]}^{O_h} = \mathsf{FPT}^{O_h}.$$

Theorem 9 is an improvement over the above-mentioned oracle construction of Downey and Fellows [8][2]. It is weak as a barrier result, since the relativization barrier has been repeatedly overcome in the last three decades, but nevertheless the theorem succinctly expresses how much harder the conjecture $\mathsf{FPT} \neq \mathsf{W}[\mathsf{P}]$ is compared to classical questions regarding nondeterministic vs. deterministic computation: No matter how small the amount of nondeterminism that provably yields a class strictly containing P, we will always be a non-trivial proof step away from separating $\mathsf{W}[\mathsf{P}]$ (or $\mathsf{W}[1]$) from FPT.

The structure of W[1] and its relation to FPT. The class $\mathsf{A}[1](=\mathsf{W}[1])$[3] can be characterized in terms of random access machines that perform *tail-nondeterministic* computations [7]. Such computations consist of two phases: 1. a (deterministic) FPT-computation; 2. a short nondeterministic computation that can use any data computed in phase 1. Tail-nondeterministic machines that perform only the second phase of the computation (without a longer deterministic computation preceding it), can not solve every problem in FPT, but, paradoxically, they can solve many problems that are complete for $\mathsf{A}[1]$ (we give an example in Section 4). As we will see, this simple observation has important consequences for the structure of this class.

A first consequence is that giving an $\mathsf{A}[1]$-machine very restricted oracle access to even a tractable (FPT) problem, may increase its computational power, because then the use of nondeterminism can be combined with the ability to solve instances of an FPT-problem via the oracle. Thus, FPT-computations appear to constitute a non-trivial computational resource for $\mathsf{A}[1]$ (unlike P-computations for NP). Somewhat suprisingly, we can actually identify the complexity class resulting from endowing $\mathsf{A}[1]$ with FPT-oracles, if a suitable, highly restricted type of oracle access is used. We have (Theorem 12, Corollary 13) that:

$$\mathsf{A}[1]^{\mathsf{FPT}} = \mathsf{W}[\mathsf{P}] \quad \text{and} \quad \forall t \geq 1 : \mathsf{W}[t]^{\mathsf{FPT}} = \mathsf{W}[\mathsf{P}],$$

where we used the common notation $\mathcal{C}_1^{\mathcal{C}_2} := \bigcup_{Q \in \mathcal{C}_2} \mathcal{C}_1^Q$. This means that either $\mathsf{W}[\mathsf{P}] = \mathsf{W}[1]$, in which case $\mathsf{W}[\mathsf{P}]$ is smaller than generally believed, or FPT is larger within $\mathsf{W}[1]$ than P is within NP.

Putting the known and new facts together, Theorem 9 and the result of Cai *et. al.* [6] mentioned in the introduction indicate that $\mathsf{W}[\mathsf{P}]$ is likely to be closer to FPT than any class $\mathsf{NP}[h(n) \log n]$ is to P (see Figure 1). The case for this figure being accurate is further strengthened by Theorem 12 and Corollary 13, which exhibit another way in which at least two of the classes FPT, $\mathsf{W}[1]$, and $\mathsf{W}[\mathsf{P}]$ are close.

Theorem 12 and the observation preceding it also have consequences for the A-Hierarchy, which is a parameterized analogue of PH. Although they share some essential properties [7, 4], a corollary of Theorem 12 is that, unless some unlikely inclusions between complexity classes occur, the two hierarchies have structural differences that indicate that consecutive levels of the A-Hierarchy are closer to each other than the corresponding levels of PH (see

[2] Actually, Downey and Fellows [8] use a different computational model to define and relativize $\mathsf{W}[\mathsf{P}]$, so the two results, although in the same spirit, may not be directly comparable at a technical level.

[3] $\mathsf{W}[1]$ and $\mathsf{A}[1]$ coincide as complexity classes, but in [7], Chen, Flum, and Grohe give two machine-based characterizations, one which can be generalized to get the levels of the W-Hierarchy, and one which generalizes to the levels of the A-Hierarchy. The machine model for $\mathsf{A}[1]$ is easier to handle when working with oracles, so we typically use this model when relativizing this class, and write "$\mathsf{A}[1]$" to emphasize this fact. However, oracle $\mathsf{W}[1]$-machines can also be defined so that our theorems hold for this model as well (see Section 3).

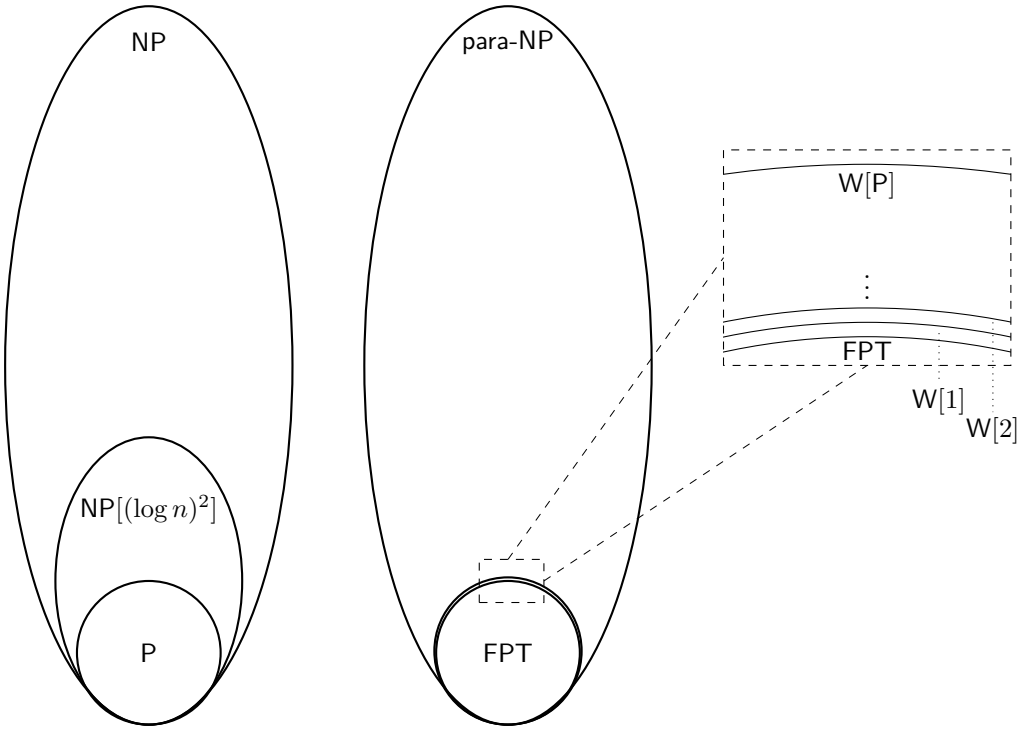

Figure 1 The mutual closeness of the parameterized complexity classes, compared to that of their classical analogues, as suggested by [6, 8], Theorems 9 and 12, and Corollary 13. Regardless of which class $\mathsf{NP}[h(n)\log n]$ we choose to represent between P and NP on the left side (whether it is $\mathsf{NP}[(\log n)^2]$ as in the picture, $\mathsf{NP}[\log^* n \log n]$, or something even smaller), it will be much larger compared to P than $\mathsf{W}[\mathsf{P}]$ is compared to FPT.

Section 4). Conversely, using a similar idea as in the proof of Theorem 12, we can show (Theorem 15) that if $\mathsf{W}[\mathsf{P}]$ were to collapse to $\mathsf{W}[1]$ in a specific way, we would get a *downward separation* theorem for the A-Hierarchy (i.e., that if two levels collapse, the entire hierarchy collapses to the smaller of the two). Proving such a theorem for the A-Hierarchy has been a long-standing open problem in parameterized complexity theory, and although our theorem falls short of this goal (since it requires an unlikely collapse to occur), it marks the first progress on this front in over a decade (since [7]).

Level-by-level relativized separations of the W- and the A-Hierarchy. We also give some evidence that certain collapses do not occur. The only relations that are known to hold between the classes $\mathsf{W}[t]$ and $\mathsf{A}[t]$ are that $\mathsf{W}[1] = \mathsf{A}[1]$ and that $\mathsf{W}[t] \subseteq \mathsf{A}[t]$ for $t \geq 2$. We show that in a relativized setting, the known inclusions can be made strict and some unexpected inclusions can be ruled out.

Separations of complexity classes relative to oracles count only as very weak evidence that the unrelativized versions of the classes are distinct, due to the fact that such oracles can in some cases be constructed even when two classes coincide (the most famous example being $\mathsf{IP} = \mathsf{PSPACE}$ [16] – see [12] for an oracle separating the two). Nevertheless, there are a few reasons why level-by-level relativized separations for the W- and the A-Hierarchy are interesting: First, since it is generally assumed that these hierarchies are proper and distinct, we should expect to have at least this weak form of evidence supporting the assumption.

Second, we have seen a number of results which suggest that the levels of these hierarchies are in various ways close to each other, so proving even relativized separations between them may be non-trivial. Finally, relativization in the parameterized setting is still mostly unexplored, and although the proofs of the following theorems rely on standard diagonalization arguments, the details of the machine models and how they are allowed to access oracles require special care in order to make the arguments work.

In Section 5 we show (Theorem 16, Corollary 17) that there exists a computable parameterized oracle O such that

$$\forall t \geq 2 : \mathsf{A}[t]^O \not\subset \mathsf{W}[t]^O.$$

Note that this is a *single* oracle relative to which all inclusions are simultaneously made strict. Also note that, although we use machine-based characterizations of classes $\mathsf{A}[t]$ and $\mathsf{W}[t]$ which result in distinct characterizations of the class $\mathsf{A}[1] = \mathsf{W}[1]$, fortunately, this oracle does not appear to separate $\mathsf{A}[1]$ from $\mathsf{W}[1]$. Such a separation would have suggested that the strict inclusions are mere artifacts of the machine models used.

Finally, we give evidence which suggests that the W-Hierarchy is not contained within any finite level of the A-Hierarchy (Theorem 18): For all $t \geq 1$, there exists a computable parameterized oracle O_t such that

$$\mathsf{W}[t+1]^{O_t} \not\subset \mathsf{A}[t]^{O_t}.$$

Since it holds that $\mathsf{W}[t]^{O_t} \subseteq \mathsf{A}[t]^{O_t}$, each oracle O_t separates two consecutive levels of the W-Hierarchy. This answers a question of Downey and Fellows [8], although we do not have a single oracle that simultaneously separates the entire hierarchy.

2 Preliminaries

We assume familiarity with standard facts and notations from both classical and parameterized complexity theory, and refer to [2] and to [11] for the necessary background in the respective branches. Since the characterizations of various parameterized complexity classes in terms of computing machines [7] are less well known, we give a brief overview of the main definitions.

Many parameterized complexity classes can only be naturally characterized in terms of *random access machines (RAMs)*, which can store entire integers in each of their registers, perform the operations addition, subtraction, and division by 2 on integers in unit time, and can access any part of their memory in constant time (see [15] or the introduction of [7]). The input of a RAM can be a sequence of non-negative integers, and we allow the instances of problems to be encoded in this way whenever we are working only with RAMs (as opposed to TMs). Since the size of a sequence of non-negative integers is calculated as the sum of the length of the binary representations of the individual numbers, RAMs have no significant computational advantage over TMs [15, Theorem 2.5]. However, this encoding does make a difference when considering oracle RAMs, because the query instances will also be encoded in this fashion.

We give two examples of definitions of complexity classes in terms of RAMs. It is not difficult to see that these are equivalent to the standard (TM-based) definitions (see [11]). Note that we use the Downey-Fellows definition of parameterized problems [9], where the parameter value, encoded in unary, is given together with the input.

▶ **Definition 1.** Let Q be a parameterized problem. We say that $Q \in \mathsf{FPT}$ if and only if there exists a RAM M, a computable function f, and a constant $c \geq 0$, such that for every input (x, k) with $x \in \mathbb{N}^*$ and $k \geq 0$, M runs in time $f(k)(|x| + k)^c$ and accepts if $(x, k) \in Q$, otherwise it rejects. The class $\mathsf{para\text{-}NP}$ is defined similarly, except with RAMs which can nondeterministically guess, in unit time, positive integers of size upper-bounded by the $f(k)(|x| + k)^c$ (the bound on the running time).

We also collect several useful definitions and notations in the following:

▶ **Definition 2.** Let $\mathcal{C}_1, \mathcal{C}_2$ be complexity classes, where $\mathcal{C}_1$ is defined in terms of computing machines that can be given access to an oracle, and let $P_0, P_1 \subseteq \{0,1\}^*$ be classical languages. We define: $\mathcal{C}_1^{\mathcal{C}_2} := \bigcup_{P \in \mathcal{C}_2} \mathcal{C}_1^P$ and $P_0 \oplus P_1 := \{0x \mid x \in P_0\} \cup \{1x \mid x \in P_1\}$. We say that P_0 is *low for* $\mathcal{C}_1$ if $\mathcal{C}_1^{P_0} = \mathcal{C}_1$, and we say that $\mathcal{C}_2$ is *low for* $\mathcal{C}_1$ if $\mathcal{C}_1^{\mathcal{C}_2} = \mathcal{C}_1$.

2.1 The A-Hierarchy and the W-Hierarchy

The following classes are defined in terms of *alternating random access machines (ARAMs)*, which are RAMs that can nondeterministically guess, in unit time, integers of size bounded by the running time of the machine on a given input, either in the existential or the universal mode (see [7]).

▶ **Definition 3** ([7])**.** For each $t \geq 1$, let $\mathsf{A}[t]$ be the class of parameterized problems that are solved by some ARAM A which, for some computable functions f and h, and a constant $c \geq 0$, satisfies the following conditions on every input (x, k):

1. A runs in time at most $f(k)(|x| + k)^c$;
2. throughout the computation, the values in A's registers do not exceed $f(k)(|x| + k)^c$;
3. all nondeterministic guesses are made during the last $h(k)$ steps of the computation;
4. the first nondeterministic guess is existential and the machine alternates at most $t - 1$ times between existential and universal guesses.

The class $\mathsf{co\text{-}A}[1]$ is defined in terms of ARAMs which satisfy conditions 1–3, but only make universal nondeterministic guesses (one can verify, just as in the classical setting, that a problem is in $\mathsf{co\text{-}A}[1]$ if and only if it is the complement of a problem in $\mathsf{A}[1]$). ARAMs satisfying conditions 1 and 2 are called *parameter-bounded* in [4], those satisfying conditions 3 and 4 are called, respectively, *tail-nondeterministic* and *t-alternating* [7].

The classes $\mathsf{W}[t]$ ($t \geq 1$) can be defined in terms of $\mathsf{A}[t]$-machines (parameter-bounded tail-nondeterministic t-alternating ARAMs) that are further restricted so that: 1. Every block of nondeterministic guess instructions of the same kind, except the first one, is made up of at most c' guess instructions, where c' is a constant that is independent of the input. 2. All nondeterministically guessed integers are placed in a special set of *guess registers*, which can not be read from directly, and can only be accessed via special instructions that use the guessed values as indices for accessing standard registers. We will not need further details regarding these machines, and therefore refer the reader to [7] or [5] for more complete definitions. We will, however, define oracle $\mathsf{W}[t]$-machines (Definition 10).

▶ **Definition 4** ([4])**.** An *oracle (A)RAM* is a machine with an additional set of registers called *oracle registers*, instructions that allow the machine to copy values from its standard registers to the oracle registers, as well as a QUERY instruction, the execution of which results in one of the values 1 or 0 being placed into the first standard register of the machine, depending on whether the instance encoded in the oracle registers at that time constitute a 'yes'- or a 'no'-instance of a problem for which the machine is said to have an oracle.

An oracle (A)RAM has *balanced oracle access* to a parameterized oracle, if there is a computable function g such that on every input (x, k), the machine queries the oracle only with instances whose parameter value is $\leq g(k)$ (in other words, the parameter values of the instances for which the oracle is called should be upper-bounded by some function of k, but may not depend on n, even though the machine may have time to construct such a query instance). An oracle (A)RAM has *tail-restricted oracle access*, if its access to the oracle is balanced and, furthermore, there is a computable function h such that the machine makes oracle queries only within the last $h(k)$ steps of the computation on input (x, k). Note that tail-restricted access is also balanced.

For a parameterized complexity class $\mathcal{C}$ that is defined in terms of (A)RAMs, we write $\mathcal{C}(O)$ if $\mathcal{C}$ has unrestricted access to the oracle O, $\mathcal{C}(O)_{bal}$ if it has balanced access, and $\mathcal{C}(O)_{tail}$ if it has tail-restricted access. If $\mathcal{C}$ is defined in terms of tail-nondeterministic ARAMs, we also write $\mathcal{C}^O$ instead of $\mathcal{C}(O)_{tail}$ (so $\mathsf{A}[1]^O$ means $\mathsf{A}[1]$ with tail-restricted access to O). Note that for $\mathcal{C}(O)$, the oracle can be either classical or parameterized, but for balanced or more restricted oracle access, it must be parameterized.

2.2 W[P] and the W[P]-Hierarchy

We define W[P] both in terms of TMs and in terms of RAMs, and use both definitions at different points in the paper.

▶ **Definition 5** ([7]). Let Q be a parameterized problem. We say that $Q \in \mathsf{W}[\mathsf{P}]$ if and only if there exists a nondeterministic TM M, computable functions f and h, and a constant $c \geq 0$, such that for any input (x, k) with $x \in \{0, 1, \#\}^*$ and $k \geq 0$, M runs in time $f(k)(|x| + k)^c$, uses at most $h(k)\lceil \log(|x| + k) \rceil$ nondeterministic bits, and accepts if and only if $(x, k) \in Q$.

The following problem is complete for W[P] under fpt-reductions.

p-WSatCircuit	
Input:	A Boolean circuit C with n input bits, $k \in \mathbb{N}$.
Parameter:	k
Problem:	Decide whether C has a satisfying assignment of weight k.

The class W[P] can also be defined in terms of RAMs [7]. One can also define a hierarchy that is similar to PH, except in terms of alternating nondeterminism that matches the nondeterminism of W[P].

▶ **Definition 6** ([4]). For each $t \geq 1$, let $\Sigma_t^{[P]}$ be the class of parameterized problems that are solved by some ARAM A which, for some computable functions f and h, and a constant $c \geq 0$, satisfies, on every input (x, k), conditions 1, 2, and 4 from Definition 3, as well as:

3'. *A* nondeterministically guesses at most $h(k)$ numbers throughout the computation.

We denote the class $\bigcup_{t=1}^{\infty} \Sigma_t^{[P]}$ by W[P]H, the W[P]-*Hierarchy*.

It is not difficult to see that $\mathsf{W}[\mathsf{P}] = \Sigma_1^{[P]}$. Note that we will use the term "W[P]-machine" to designate both the TMs from Definition 5 as well as the $\Sigma_1^{[P]}$-machines from Definition 6 (which are RAMs), but it should be clear from the context which type of machine is meant.

For each $t \geq 1$, the following generalizations of the problem p-WSatCircuit can easily be seen to be, respectively, complete problems for $\Sigma_t^{[P]}$.

p-AWSatCircuit$_t$	
Input:	A Boolean circuit C with n input bits, $k \in \mathbb{N}$, and a partition of the input variables of C into t sets $I_1, \ldots, I_t$.
Parameter:	k
Problem:	Decide whether there exists a set $J_1 \subseteq I_1$ of size k such that for all subsets $J_2 \subseteq I_2$ of size k there exists ... such that setting precisely the variables in $J_1 \cup \ldots \cup J_t$ to 'true' results in a satisfying assignment of C.

As in the case of the Polynomial Hierarchy, and unlike the case of the A-Hierarchy, it is known that the collapse of levels of the W[P]-Hierarchy would propagate upward:

▶ **Fact 7** (Corollary 17 of [4]). *If for any $t \geq 1$, $\Sigma_{t+1}^{[P]} = \Sigma_t^{[P]}$, then* $\mathsf{W[P]H} = \Sigma_t^{[P]}$.

▶ **Definition 8** ([4]). An oracle ARAM has *parameter-bounded oracle access* to a parameterized oracle, if its access to the oracle is balanced and, furthermore, there is a computable function g such that on every input (x, k), the machine makes at most $g(k)$ oracle queries.

If $\mathcal{C}$ is a class that is defined in terms of ARAMs, we write $\mathcal{C}(O)_{para}$ to denote that $\mathcal{C}$ has parameter-bounded access to the oracle O. If $\mathcal{C} = \Sigma_t^{[P]}$, for some $t \geq 1$, we may also write $\mathcal{C}^O$ to mean $\mathcal{C}(O)_{para}$ (so $\mathsf{W[P]}^O = \mathsf{W[P]}(O)_{para}$).

3 The difficulty of separating W[P] from FPT

In this section we show that there is likely no shortcut to proving $\mathsf{FPT} \neq \mathsf{W[P]}$ via any finite number of separations of the form $\mathsf{P} \neq \mathsf{NP}[h(n) \log n]$. Due to space restrictions, the proofs of the theorems in this section can be found in the full version of the paper.

To prove the theorem, we need to construct an oracle relative to which two conditions hold simultaneously: the collapse of one pair of complexity classes and the separation of another. One approach to achieving this is to construct the oracle in stages, and to work towards one goal in the odd-numbered stages and towards the other in the even-numbered ones, while ensuring that the two constructions do not interfere with each other (see [3, Theorem 5.1] for one example of an application of this technique). However, this approach does not always work, and in this case it fails because one pair of classes is parameterized (specifically, it is not possible to computably list all FPT- or W[P]-machines, but this appears to be necessary in this type of staged construction). To overcome this obstacle, we use an idea of Allender [1], who constructs an oracle with two parts: the first part is designed so as to ensure that one pair of classes collapses *regardless of what the second part of the oracle is*; the second part can then be freely used in a diagonalization argument to separate the remaining pair of classes.

▶ **Theorem 9.** *For every polynomial-time-computable non-decreasing unbounded function h, there exists a computable oracle B such that*

$$\mathsf{P}^B \neq \mathsf{NP}[h(n) \log n]^B, \quad \textit{but} \quad \mathsf{W[P]}(B) = \mathsf{FPT}(B).$$

For this result we have used unrestricted oracle access to relativize the parameterized complexity classes, rather than the parameter-bounded type that we argued is natural for W[P] [4]. This is because restricting the oracle access to being balanced (or more) makes it possible to collapse even para-NP to FPT, with the classical separation unchanged. Thus we would get an oracle relative to which NP and P differ while para-NP and FPT coincide, which is clearly an artifact of the restrictions placed on the oracle access, since we know that, unrelativized, a collapse of para-NP to FPT is equivalent to a collapse of NP to P (see [11]).

It seems reasonable to expect that if W[P] collapses to FPT relative to some oracle, then so should any class W[t]. But to show that this is indeed the case, we first need to define oracle W[t]-machines. Recall that a W[t]-machine is similar to an A[t]-machine, but the numbers it guesses nondeterministically are placed in a special set of *guess registers*, to which the machine has only limited access [7] (see also [5]). Naturally, an oracle W[t]-machine should then have three sets of registers: the standard registers, guess registers (which the machine can not read from directly), and oracle registers. For such machines, the usual way to read from or write to the oracle registers is very limiting, because the machines' nondeterminism would only weakly be able to influence the query instances. For example, nondeterministically guessed numbers could not be written to the oracle registers. The interaction between the nondeterminism of such machines and their ability to form query instances can be strengthened without allowing the W[t]-specific restrictions to be circumvented. We achieve this by making the oracle registers *write-only*, and adding instructions that allow the machine to copy values from the guess registers to the oracle registers and to use numbers from the guess registers to address oracle registers. In this way, the machine can still not read the guessed numbers directly or use them in arithmetic computations, but can nevertheless use them for oracle queries. In many cases, this allows oracle W[t]-machines to match A[t]-machines in the way the oracle is used.

▶ **Definition 10.** An *oracle* W[t]*-machine* is a W[t]-machine that, in addition to the standard registers $r_0, r_1, \ldots$, and guess registers $g_0, g_1, \ldots$ (to which the machine has only restricted access), also possesses a set of oracle registers $o_0, o_1, \ldots$. The contents of oracle registers are never read from and are only affected by the following new instructions:

SO_MOVE - copy the contents of standard register r_0 to oracle register o_{r_1};
GO_MOVE - copy the contents of guess register g_{r_0} to oracle register o_{r_1};
ADDR_GO_MOVE - copy the contents of register r_0 to $o_{g_{r_1}}$;
OO_MOVE - copy the contents of o_{r_0} to o_{r_1}.

Additionally, the machine has a QUERY instruction that places either the value 0 or 1 into r_0, depending on whether the contents of the oracle registers at the time when the instruction is executed represent a 'no'- or a 'yes'-instance of the problem to which the machine has oracle access.

Note that for such machines, it again makes sense to speak of unrestricted, balanced, parameter-bounded, or tail-restricted oracle access. With the above definition in mind, we can now prove Corollary 11, where oracle access is unrestricted.

▶ **Corollary 11.** *For any function h as in Theorem 9, and the corresponding oracle B, we have that* $\mathsf{FPT}(B) = \mathsf{W}[1](B) = \mathsf{A}[1](B) = \mathsf{W}[2](B) = \mathsf{A}[2](B) = \ldots = \mathsf{W}[\mathsf{P}](B)$.

4 The structure of W[1] and its relation to FPT

Under the assumption that $\mathsf{P} \neq \mathsf{NP}$, it is meaningful to ask whether the relation between the two classes is the same as the one between FPT and W[1]. So far, we have seen evidence that the two parameterized classes are closer to each other in the sense that proving a separation between them is more difficult than proving $\mathsf{P} \neq \mathsf{NP}$. In this section we look at other ways in which W[1] is closer to FPT than NP is to P.

In this section, the definitions of classes in terms of RAMs are used, instances of problems and oracles query instances are encoded as integer sequences, and oracles are parameterized.

Is FPT *low for* W[1]*?*

Given that FPT is the class of tractable problems in parameterized complexity, and that P-oracles add no computational power to NP (or to any class $\mathsf{NP}[h(n)\log n]$), one might expect FPT to also be low for W[1]. It turns out, however, that allowing tail-nondeterministic machines to make even tail-restricted queries to an FPT-oracle can increase their computational strength to that of W[P]. We prove this for A[1] first, since this machine model is more easily relativizable.

▶ **Theorem 12.** $\mathsf{A}[1]^{\mathsf{FPT}} = \mathsf{W}[\mathsf{P}]$. *Therefore,* FPT *is low for* A[1] *if and only if* $\mathsf{W}[\mathsf{P}] = \mathsf{A}[1]$ *and the* W*-Hierarchy collapses to its first level.*

Proof. We have that $\mathsf{A}[1]^{\mathsf{FPT}} \subseteq \mathsf{A}[1](\mathsf{FPT})_{bal} \subseteq \mathsf{W}[\mathsf{P}](\mathsf{FPT})_{bal} = \mathsf{W}[\mathsf{P}]$, with the final equality holding because a W[P]-machine can replace balanced oracle calls to FPT-problems by fpt-length computations.

To show that $\mathsf{W}[\mathsf{P}] \subseteq \mathsf{A}[1]^{\mathsf{FPT}}$, we define the following problem:

p-WSatCircuit-with-assignment	
Input:	A circuit C with n inputs, $k \in \mathbb{N}$, and vector $v \in \{0,1\}^n$ of weight k.
Parameter:	k.
Problem:	Decide whether v is a satisfying assignment for C.

Since the output of a circuit can be computed in time polynomial in its size, the above problem is obviously in FPT[4]. Any problem $Q \in \mathsf{W}[\mathsf{P}]$ can be solved by some A[1]-machine A with tail-restricted access to p-WSatCircuit-with-assignment as an oracle: First, A reduces in fpt-time the input instance (x,k) to an instance (y,k') of p-WSatCircuit, where k' depends computably only on k. Let m be the number of input bits of the circuit encoded in y. If $m < k'$, A rejects, otherwise it writes y, 0^m, and $1^{k'}$ to its oracle registers, thus forming a valid instance of p-WSatCircuit-with-assignment, except that the assignment vector has weight 0. Now A enters the nondeterministic phase of its computation by guessing k' pairwise distinct integers $i_1, \ldots, i_{k'} \in [m]$. It then modifies the assignment vector in the oracle registers by changing the zeroes at positions $i_1, \ldots, i_{k'}$ of the vector 0^m to 1, queries the oracle, and accepts if the answer is 'yes', otherwise it rejects.

It is easy to see that what this machine actually does is nondeterministically guess a satisfying assignment of the p-WSatCircuit-instance, if one exists, and delegate the verification to the oracle. The trick here is that the all-zero assignment vector must be written to the oracle registers deterministically, because during the nondeterministic phase at the end of the computation there may not be enough time to do so. Then the machine only needs to change the vector at k' positions to obtain an assignment with the right weight, which takes only $O(k')$ steps with random access memory. ◀

Note that the proof that a W[P]-machine can simulate A[1]-machines with FPT-oracles only works if the oracle access of the A[1]-machines is tail-restricted or at least parameter-restricted. On the other hand, the proof that $\mathsf{A}[1]^{\mathsf{FPT}} \supseteq \mathsf{W}[\mathsf{P}]$ only requires tail-restricted oracle access. We regard this as further evidence (in addition to the results from [4]) that tail-restricted oracle access is the natural type to consider for the class A[1].

[4] In fact, this problem is clearly in P, meaning that we can actually prove the stronger statement $\mathsf{W}[\mathsf{P}] \subseteq \mathsf{A}[1]^{\mathsf{P}}$. However, we choose FPT instead of P because the instance with which the oracle is queried will be fpt-sized, and because it is more natural to have A[1]-machines query a parameterized oracle, rather than a classical one.

Since $\mathsf{A}[1] \subseteq \mathsf{W}[t] \subseteq \mathsf{W}[\mathsf{P}]$ holds for all $t \geq 1$, and by Theorem 12 we have that $\mathsf{A}[1]^{\mathsf{FPT}} = \mathsf{W}[\mathsf{P}] = \mathsf{W}[\mathsf{P}](\mathsf{FPT})_{tail}$, it seems reasonable to expect that $\mathsf{W}[t]^{\mathsf{FPT}} = \mathsf{W}[\mathsf{P}]$ holds for all t as well. In order to prove that this is indeed the case, we need to use oracle $\mathsf{W}[t]$-machines (Definition 10), with tail-restricted access to the oracle. Then the proof is based on a combination of ideas from the proofs of Corollary 11 and Theorem 12.

▶ **Corollary 13.** *For every $t \geq 1$ it holds that $\mathsf{W}[t]^{\mathsf{FPT}} = \mathsf{W}[\mathsf{P}]$.*

In [4] we showed that for every $t \geq 1$ the class $\mathsf{A}[t+1]$ can be obtained as $\mathsf{A}[1]^{O_t}$, where O_t is a specific $\mathsf{A}[t]$-complete oracle, but we also observed that $\mathsf{A}[1]^{\mathsf{FPT}}$ does not appear to be a subset of $\mathsf{A}[t]$ for any t. Theorem 12 provides support for this intuition by identifying $\mathsf{A}[1]^{\mathsf{FPT}}$ as a class which is not known or believed to be a subset of any class $\mathsf{A}[t]$.

▶ **Corollary 14.** *For every $t \geq 1$ we have that if $\mathsf{A}[t+1] = \mathsf{A}[1]^{\mathsf{A}[t]}$, then $\mathsf{W}[\mathsf{P}] \subset \mathsf{A}[t+1]$. In particular, if $\mathsf{W}[\mathsf{P}] \not\subset \mathsf{A}[2]$, we have that $\mathsf{A}[1]^{\mathsf{A}[1]} \neq \mathsf{A}[2]$.*

Corollary 14 shows that the above-mentioned oracle characterization of the A-Hierarchy from [4] can probably not be improved significantly: Although it may be possible to obtain $\mathsf{A}[t+1]$ by providing $\mathsf{A}[1]$ with other $\mathsf{A}[t]$-complete oracles, it is unlikely that O_t can be replaced by the entire class $\mathsf{A}[t]$, for the somewhat counter-intuitive reason that $\mathsf{A}[t]$ contains all *tractable* problems. More importantly, Corollary 14 implies, assuming $\mathsf{W}[\mathsf{P}] \not\subset \mathsf{A}[t+1]$ and that PH is proper, that each class $\mathsf{A}[t+1]$ is closer to the class $\mathsf{A}[t]$ than Σ_{t+1}^P is to Σ_t^P, in the precise sense that $\mathsf{A}[t+1] \subsetneq \mathsf{A}[1]^{\mathsf{A}[t]}$, whereas $\Sigma_{t+1}^P = \mathsf{NP}^{\Sigma_t^P}$. The use of a highly restricted type of oracle access for the parameterized classes can only make this conclusion more legitimate.

A weak downward separation theorem for the A-Hierarchy.

It is a long-standing open problem whether the collapse of any class $\mathsf{A}[t+1]$ to $\mathsf{A}[t]$ would cause all higher levels of the A-Hierarchy to coincide with $\mathsf{A}[t]$ (or, equivalently, whether a separation of two classes $\mathsf{A}[t+1]$ and $\mathsf{A}[t]$ would imply that all levels below $\mathsf{A}[t]$ are distinct, whence the name "downward separation"). Given the similarities with PH, one might expect such a theorem to hold for the A-Hierarchy as well. Nevertheless, the proof of the downward separation theorem for the Polynomial Hierarchy does not appear to carry over directly to the parameterized setting. So far, the best result in this direction has been a theorem of Chen *et al.* [7], who showed that $\mathsf{W}[\mathsf{P}] = \mathsf{FPT}$ implies $\mathsf{FPT} = \mathsf{A}[1] = \mathsf{A}[2] = \ldots$. This result is already non-trivial, since $\mathsf{A}[t]$ is not known to be a subset of $\mathsf{W}[\mathsf{P}]$ for $t > 1$, and can be viewed as a parameterized version of $\mathsf{P} = \mathsf{NP} \Rightarrow \mathsf{PH} = \mathsf{P}$, except that the stronger collapse $\mathsf{W}[\mathsf{P}] = \mathsf{FPT}$ is required instead of $\mathsf{A}[1] = \mathsf{FPT}$ (in fact, the proof of the parameterized theorem in [7] is adapted from the proof of the corresponding classical theorem). Previously it was not known whether assuming a weaker collapse, for example $\mathsf{W}[\mathsf{P}] = \mathsf{A}[1]$, might also suffice to prove that $\forall t \geq 1 : \mathsf{A}[t] = \mathsf{A}[t+1] \Rightarrow \text{A-Hierarchy} = \mathsf{A}[t]$. In what follows we prove such a theorem.

Let $\mathsf{A}[1]_c$ be the class of parameterized problems Q such that there exists an $\mathsf{A}[1]$-machine that solves any instance (x, k) of Q in a number of steps depending only on k. This subclass of $\mathsf{A}[1]$ contains the problems that can be solved by $\mathsf{A}[1]$-machines *without* the need for a precomputation that runs in fpt-time. It is provably not closed under fpt-reductions, but contains many important $\mathsf{W}[1]$-complete problems, provided that the input is given in an appropriate format. For example, p-IndependentSet $\in \mathsf{A}[1]_c$, if the input graph is given in the form of an adjacency matrix, because then an $\mathsf{A}[1]$-machine can first guess k vertices (recall that a nondeterministic RAM can guess an integer between 1 and n in a single step; see Section 2.1) and use its random access memory to verify in $O(k^2)$ steps that none of the edges between two guessed vertices are in the graph. One can similarly show that p-ShortTMAcceptance and other $\mathsf{W}[1]$-complete problems are in $\mathsf{A}[1]_c$.

If W[P] were to collapse to A[1], then the W[P]-complete problem p-WSatCircuit would also be A[1]-complete, and therefore it would seem reasonable to expect that it is also in $\mathsf{A}[1]_c$, given an appropriate, efficiently computable encoding of the input. Thus, p-WSatCircuit $\in \mathsf{A}[1]_c$ seems only slightly less likely than $\mathsf{W}[\mathsf{P}] = \mathsf{A}[1]$ (although, strictly speaking, both p-WSatCircuit $\in \mathsf{A}[1]_c$ and p-WSatCircuit $\in \mathsf{FPT}$ (used by Chen *et al.* [7]) are strictly stronger assumptions than p-WSatCircuit $\in \mathsf{A}[1]$, and probably mutually incomparable). Under this assumption, we can prove the following:

▶ **Theorem 15.** *Assume that p-WSatCircuit $\in \mathsf{A}[1]_c$, meaning that there exists an* A[1]*-machine which solves any instance (x, k) of p-WSatCircuit in a number of steps depending computably on k alone. Then $\forall t \geq 1$ we have that $\mathsf{A}[t] = \mathsf{A}[t+1] \Rightarrow (\forall u \geq 1 : \mathsf{A}[t] = \mathsf{A}[t+u])$.*

Proof. We show that under the first assumption in the theorem statement, we have for every $t \geq 1$ that $\mathsf{A}[t+1] = \Sigma_{t+1}^{[P]}$. Since we already have a downward separation theorem for W[P]H (Fact 7), it follows that the desired conclusion holds for the A-Hierarchy.

First, we have for every $t \geq 1$ that $\Sigma_{t+1}^{[P]} \subseteq \mathsf{A}[t]^{p\text{-WSatCircuit}}$, by a similar proof as that of Theorem 12: To solve a problem $Q \in \Sigma_{t+1}^{[P]}$, an $\mathsf{A}[t]^{p\text{-WSatCircuit}}$-machine will first compute a reduction to the canonical $\Sigma_{t+1}^{[P]}$-complete problem p-AWSatCircuit$_{t+1}$, and, if t is odd, modify the resulting circuit so that its output is flipped. The machine then uses its t-alternating nondeterminism to guess the variables to set to 1 in the first t sets of the partition of the circuit's inputs, and hardwires this partial assignment into the circuit. The result is an instance of p-WSatCircuit, which can be solved with a single query to the oracle, and the oracle A[t]-machine now outputs the oracle's answer if t is odd, otherwise it outputs the opposite answer. It is easy to verify that this solves the problem Q.

Finally, we outline the proof that $\mathsf{A}[t]^{p\text{-WSatCircuit}} \subseteq \mathsf{A}[t+1]$, under the assumption that the algorithm for p-WSatCircuit mentioned in the theorem statement exists. This inclusion is proved in the same manner as $\mathsf{A}[1]^{p\text{-MC}(\Sigma_t[3])} \subseteq \mathsf{A}[t+1]$ [4, Theorem 13], which is itself a parameterized version of the proof of the well-known fact that $\mathsf{NP}^{\Sigma_t\mathrm{SAT}} \subseteq \Sigma_{t+1}^P$ (see [2, Section 5.5]). An $\mathsf{A}[t+1]$-machine can first perform the deterministic part of the oracle A[t]-machine's computation, and then use its $(t+1)$-alternating nondeterminism to guess the answers to the subsequent oracle queries of the simulated machine (existentially), all of its t-alternating nondeterministic guesses, as well as (suitably quantified) witnesses for the query instances. Oracle queries are then replaced by computations in which the guessed witnesses are used instead of nondeterministic guesses. The fact that evaluations of p-WSatCircuit-queries can be performed in this manner, is due to the assumption that this problem has a nondeterministic algorithm running in time dependent on k alone.

Since $\mathsf{A}[t+1] \subseteq \Sigma_{t+1}^{[P]}$ holds unconditionally, we conclude that the two classes are equal, which completes the proof. ◀

5 Level-by-level relativized separations of the W- and the A-Hierarchy

In this section we give oracle-based evidence that the main parameterized hierarchies do not collapse in unforeseen ways. We start by constructing a single oracle relative to which the inclusion of every W[t] in A[t] is strict, except for the first level. In fact, we accomplish this by proving the strongest possible relativized separation between co-nondeterminism and (existential) nondeterminism in the parameterized setting: the weakest co-nondeterministic class with tail-restricted oracle access, against the strongest nondeterministic class with unrestricted oracle access.

The proofs of the theorems in this section are based on standard diagonalization arguments that have been adapted to the parameterized setting, and can be found in the full version of the paper.

▶ **Theorem 16.** *There exists a computable oracle O such that* $\mathsf{co\text{-}A}[1]^O \not\subset \mathsf{para\text{-}NP}(O)$.

Since $\mathsf{co\text{-}A}[1]^O \subseteq \mathsf{A}[t]$ for all $t \geq 2$, and $\mathsf{W}[t]^O \subseteq \mathsf{para\text{-}NP}(O)$ for all $t \geq 1$, we immediately get the next corollary. Note, however, that the oracle constructed here does not appear to separate $\mathsf{A}[1]$ from $\mathsf{W}[1]$, since the separating problem in $\mathsf{co\text{-}A}[1]^O \setminus \mathsf{para\text{-}NP}(O)$ is not in $\mathsf{A}[1]^O$. Had a separation of two coinciding classes occured, this would have made the conclusion of Theorem 16 much less convincing.

▶ **Corollary 17.** *There exists a computable oracle O such that for every $t \geq 2$,* $\mathsf{W}[t]^O \subsetneq \mathsf{A}[t]^O$.

Finally, we show that the W-Hierarchy is not likely to be contained in any finite level of the A-Hierarchy.

▶ **Theorem 18.** *There exists for each $t \geq 1$ a computable oracle O_t such that* $\mathsf{W}[t+1]^{O_t} \not\subset \mathsf{A}[t]^{O_t}$*, where both machines have tail-restricted access to O_t, but the* $\mathsf{W}[t]$*-machine has the stronger type of oracle access mentioned in Section 3.*

As mentioned in the introduction, each oracle O_t also separates the classes $\mathsf{W}[t]$ and $\mathsf{W}[t+1]$ in the relativized setting, since $\mathsf{W}[t]^{O_t} \subseteq \mathsf{A}[t]^{O_t}$ but $\mathsf{W}[t+1]^{O_t} \not\subset \mathsf{A}[t]^{O_t}$.

6 Conclusions

Our results, together with the previously known theorems mentioned in the introduction, strongly indicate that if the central conjecture of parameterized complexity theory holds at all, proving it may be hard *even under the additional assumption of a separation between arbitrarily-weakly-nondeterministic polynomial-time and* P (and, in particular, that $\mathsf{P} \neq \mathsf{NP}$). Of course, the same also applies to the nowadays "standard" conjecture ETH. Additionally, we have seen that $\mathsf{W}[1]$ and FPT are in some ways unexpectedly close, unless much of what is generally assumed in parameterized complexity theory (such as the W-Hierarchy not collapsing) is false. All of this suggests that the hardness of a problem for up to $\mathsf{W}[\mathsf{P}]$ should not be treated as strong evidence of intractability, at least not with a similar level of confidence as when NP-hardness is considered evidence of computational intractability.

A Simple Augmentation Method for Matchings with Applications to Streaming Algorithms

christian.konrad@bristol.ac.uk

Abstract

Given a graph G, it is well known that any maximal matching M in G is at least half the size of a maximum matching M^*. In this paper, we show that if G is bipartite, then running the Greedy matching algorithm on a sampled subgraph of G produces enough additional edges that can be used to augment M such that the resulting matching is of size at least $(2-\sqrt{2})|M^*| \approx 0.5857|M^*|$ (ignoring lower order terms) with high probability.

The main applications of our method lie in the area of data streaming algorithms, where an algorithm performs few passes over the edges of an n-vertex graph while maintaining a memory of size $O(n \operatorname{polylog} n)$. Our method immediately yields a very simple two-pass algorithm for Maximum Bipartite Matching (MBM) with approximation factor 0.5857, which only runs the Greedy matching algorithm in each pass. This slightly improves on the much more involved 0.583-approximation algorithm of Esfandiari et al. [ICDMW 2016]. To obtain our main result, we combine our method with a residual sparsity property of the random order Greedy algorithm and give a one-pass random order streaming algorithm for MBM with approximation factor 0.5395. This substantially improves upon the one-pass random order 0.505-approximation algorithm of Konrad et al. [APPROX 2012].

1 Introduction

Computing Large Matchings. Given a bipartite graph $G = (A, B, E)$, a matching $M \subseteq E$ in G is a subset of non-adjacent edges. In this paper, we address the Maximum Bipartite Matching (MBM) problem, which consists of finding a matching of maximum size. Many classic algorithms for MBM, such as the Hopcroft-Karp algorithm [20] or Edmonds' algorithm [11], as well as many more recent algorithms, first compute an arbitrary matching and then iteratively improve it by finding augmenting paths until it is of maximum size. A good starting point is a *maximal matching*, i.e., a matching that cannot be enlarged by adding an edge outside the matching to it, which is known to be of size at least $1/2$ times the size of a *maximum matching*, i.e., one of maximum size. A maximal matching is for example produced by the Greedy matching algorithm, which processes the edges of a graph in arbitrary order and adds the current edge to an initially empty matching if the resulting set is still a matching. For an integer $k \geq 1$, a $(2k+1)$-*augmenting path* $P = e_1, e_2, e_3, \ldots, e_{2k+1}$ with respect to a matching M is a path of odd length that alternates between edges outside M and edges contained in M such that both e_1 and e_{2k+1} are incident to vertices that are not matched in M. Since P contains $k+1$ edges outside M and k edges of M, removing the matched edges

in P from M and inserting the unmatched edges in P into M thus increases the size of M by 1. It is known that a non-maximum matching always admits an augmenting path, and, thus, repeatedly finding one and augmenting eventually yields a maximum matching.

To decrease the number of improvement steps required, one common approach is to compute a large *set of disjoint augmenting paths* and augment along each of them simultaneously. This approach is particularly beneficial when designing algorithms in restricted computational models such as the data streaming model (see below) or various distributed computational models, since typically the number of passes (streaming) or rounds (distributed algorithms) grows linearly with the number of augmentation rounds.

Our Results. In this paper, we give a new method that allows us to find a large fraction of disjoint 3-augmenting paths such that, when augmenting along those paths, the resulting matching is of size at least $(2-\sqrt{2})|M^*| - o(|M^*|) \approx 0.5857|M^*| - o(|M^*|)$ with high probability, where M^* is a maximum matching (**Theorem 8**). The strength of our method lies both in its simplicity and effectiveness: It only requires running the Greedy matching algorithm on a random subgraph to produce the necessary edges. Despite its simplicity, it outperforms other more complicated methods and yields improvements over the state-of-the-art one- and two-pass data streaming algorithms for matchings (see below). Our method can also be applied repeatedly and for example yields a 3-pass streaming algorithm that also outperforms the currently best 3-pass streaming algorithm known.

Applications to Data Streaming Algorithms. While our method can be applied in essentially all computational models that allow an implementation of the Greedy matching algorithm, it has been designed with the *data streaming model* in mind. Given an n-vertex graph $G = (V, E)$, a p-pass, s-space data streaming algorithm processing G performs p passes over the edges E of G (the edges may arrive in arbitrary, potentially adversarial order) while maintaining a memory of size s. Since many graph problems require space $\Omega(n \log n)$ (observe that storing a large matching already requires this amount of space) [32], research has focussed on the *semi-streaming model* [16], where a graph streaming algorithm is allowed to use space $O(n \operatorname{polylog} n)$. Concerning the MBM problem, Feigenbaum et al. [16] observed that the Greedy matching algorithm constitutes a one-pass $\frac{1}{2}$-approximation semi-streaming algorithm for MBM. Interestingly, despite intense research efforts, no better one-pass streaming algorithms are known, even if space $O(n^{2-\delta})$ is granted, for any $\delta > 0$, while lower bounds only rule out the existence of semi-streaming algorithms with approximation ratio larger than $1 - 1/e \approx 0.6321$ [22, 18]. Konrad et al. [26] studied minimal extensions to the one-pass semi-streaming model that allow us to improve on Greedy. They showed that approximation ratios strictly larger than $\frac{1}{2}$ can be obtained if either the edges of the input graph arrive in uniform random order, or a second pass is granted. More specifically, they gave a symbolic improvement showing that a $(\frac{1}{2} + 0.005)$-approximation can be obtained if edges arrive in random order, and a $(\frac{1}{2} + 0.02)$-approximation can be achieved if two passes are allowed. Their two-pass result has since been improved by Kale and Tirodkar [21] to $\frac{1}{2} + \frac{1}{16} = \frac{1}{2} + 0.0625$ and independently by Esfandiari et al. to $\frac{1}{2} + 0.083$ [14].

Our method for finding augmenting paths immediately yields a two-pass semi-streaming algorithm with approximation factor 0.5857 (**Theorem 9**), thus slightly improving over the algorithm of Esfandiari et al. [14]. Our algorithm has constant update time (i.e., the running time between two read operations from the stream) and does not need a post-processing step, while the algorithm of Esfandiari et al. requires the computation of a maximum matching in the post-processing step. Our main result is a one-pass random order semi-streaming

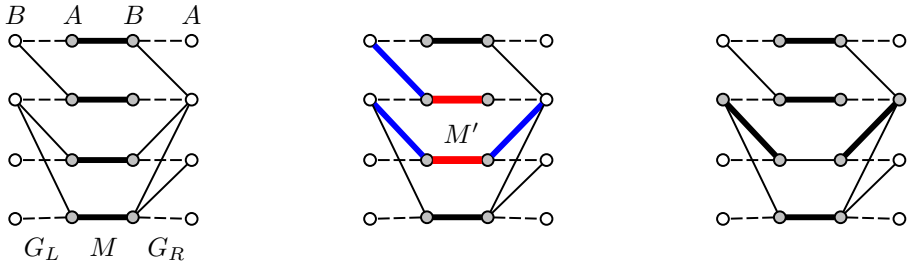

Figure 1 Left: Bipartite graph $G = (A, B, E)$ with maximal matching M. The dotted edges show a perfect matching in G. Matched vertices are grey, free vertices are white. Center: Subset $M' \subseteq M$ is highlighted in red. The blue edges are produced by the runs of Greedy on G'_L and G'_R. Observe that one 3-augmenting path is found. Right: M after the augmentation.

algorithm with approximation factor 0.5395 (**Theorem 16**), showing that more substantial improvements over $\frac{1}{2}$ than the symbolic improvement given by Konrad et al. [26] are possible in the random order scenario. This algorithm is obtained by combining our method for finding augmenting paths with a residual sparsity property of the random order Greedy matching algorithm (e.g. [25]) that has recently been exploited in various contexts [25, 1, 17].

Techniques. For illustration purposes, consider a bipartite graph $G = (A, B, E)$ that contains a *perfect matching* M^*, i.e., a matching that matches all vertices, and a maximal matching M with $|M| = \frac{1}{2}|M^*|$. It can be seen that $M \oplus M^* := (M \setminus M^*) \cup (M^* \setminus M)$ forms a set of $\frac{1}{2}|M^*|$ disjoint 3-augmenting paths. In other words, there exists a matching of size $\frac{1}{2}|M^*|$ in graph $G_L := G[A(M) \cup \overline{B(M)}]$, where $A(M)$ is the set of matched A-vertices, and $\overline{B(M)} := B \setminus B(M)$, and also one of size $\frac{1}{2}|M^*|$ in $G_R = G[\overline{A(M)} \cup B(M)]$, see Figure 1.

We now sample a random subset of edges $M' \subseteq M$ such that every edge $e \in M$ is included in M' with probability p. Using an argument by Konrad et al. [26], it follows that when running the Greedy matching algorithm on the subgraph $G'_L := G[A(M') \cup \overline{B(M)}] \subseteq G_L$, then in expectation a $\frac{1}{1+p}$ fraction of the vertices $A(M')$ is matched. Observe that if we chose $p = 1$, then half of the vertices get matched, which is what we expect from the Greedy matching algorithm. However, if we chose p substantially smaller than 1, then a large fraction of vertices of $A(M')$ is matched. We also apply this argument to subgraph $G'_R := G[B(M') \cup \overline{A(M)}] \subseteq G_R$, which thus allows us to find large matchings in both subgraphs G'_L and G'_R and in turn extract many 3-augmenting paths. Observe that this method directly yields a two-pass semi-streaming algorithm, by computing a maximal matching in the first pass, and augmenting it using the described method in the second pass.

The main shortcoming of this method is that the result by Konrad et al. [26] only holds in expectation, which would imply that our result also only holds in expectation. We therefore strengthen their result and prove that a similar version holds with high probability. Our proof models the execution of the algorithm with a Doob martingale and applies Azuma's inequality to obtain a concentration result. We then use our result and additional combinatorial arguments to bound the number of 3-augmenting paths found.

Our one-pass random order streaming algorithm combines our method for finding 3-augmenting paths with a *residual sparsity* property of the random order Greedy algorithm. We run Greedy on the first $\frac{1}{\log n}$ fraction of edges in the stream to produce a matching M. The residual sparsity property states that the residual graph $H = G[V \setminus V(M)]$ contains $O(n \operatorname{polylog} n)$ edges with high probability, which we then collect while processing the remaining edges in the stream. Our main argument is as follows: If $|M|$ is relatively small, then the residual graph H contains a sufficiently large matching. On the other hand, if $|M|$ is relatively large (close to a $\frac{1}{2}$-approximation), then we can use the remainder of the stream to find 3-augmenting paths using the method described above.

Comparison to Esfandiari et al. [14] and Kale and Tirodkar [21]. The two-pass streaming algorithms of Esfandiari et al. and Kale and Tirodkar proceed similarly in that they compute a maximal matching M in the first pass and then find additional edges in the second pass that are used to augment M. Their algorithms are in fact almost identical and only differ in the post-processing stage. With $G_L = G[A(M) \cup \overline{B(M)}]$ and $G_R = G[B(M) \cup \overline{A(M)}]$ being as above, they compute *incomplete semi-matchings* S_L in G_L and S_R in G_R, i.e., subsets of edges such that every vertex in $A(M)$ ($B(M)$) is matched at most once in S_L (resp. S_R) and every vertex $\overline{B(M)}$ (resp. $\overline{A(M)}$) is matched at most k times, for some integer k. Using a Greedy algorithm for computing S_L and S_R, it can be seen that a large fraction of vertices $A(M)$ (resp. $B(M)$) are matched in S_L (resp. S_R). This allows the extraction of multiple 3-augmenting paths. In Kale and Tirodkar, the extraction step is done greedily, which is efficient but leads to a worse approximation factor than in Esfandiari et al. Esfandiari et al. solve an optimization problem in a post-processing phase that allows the extraction of more 3-augmenting paths, which in turn leads to an improved approximation guarantee. Our method is much simpler in this regard, since our additional edges form matchings and it is thus straightforward to extract 3-augmenting paths.

Comparison to Konrad et al. [26]. The one-pass random order algorithm by Konrad et al. proceeds as follows: First, run Greedy on roughly the first third of the edges in the input stream and obtain a matching M. Konrad et al. prove that if Greedy on the entire input stream produces a matching that is close to a $\frac{1}{2}$-approximation, then the matching is built early on, i.e., $|M|$ is relatively large. They then use the remaining part of the stream for finding 3-augmenting paths. To this end, they compute a matching in G_L on roughly the next third of the edges, and then use the last third to compute a matching in G_R to complete the 3-augmenting paths. Their method only yields a marginal improvement over 1/2 and their result only holds in expectation.

Observe that we also argue that the matching M is large, which we achieve by exploiting the residual sparsity property of Greedy. While Konrad et al. have already processed a third of the edges at this stage, we have only processed a $\frac{1}{\log(n)}$ fraction, and there are thus more remaining edges to our disposal for finding 3-augmenting paths. Further, our method produces more 3-augmenting paths than the method proposed by Konrad et al.

Further Related Work. Matching problems are the most studied graph problems in the data streaming model. Besides the already mentioned works, algorithms have been designed for weighted matchings (e.g. [16, 29, 33, 9, 31]), multiple passes (e.g. [29, 12, 2]), insertion/deletion streams (e.g. [10, 6, 24, 7, 4, 30]), sparse graphs (e.g. [13, 8]), and other variants of the matching problem [27]. Regarding random order streams, Kapralov et al. [23] showed that the size of a maximum matching can be estimated within a poly-log factor using poly-log space, and a $(2/3 - \epsilon)$-approximation can be computed using $\tilde{O}(n^{3/2})$ space [3].

Outline. We proceed as follows. We first give notation and definitions in Section 2. We then present our method for finding a large set of disjoint 3-augmenting paths in Section 3. Implementation details when implementing our method in the adversarial order streaming model are then discussed in Section 4. In Section 5, we give our one-pass random order algorithm. Finally, we conclude in Section 6 with open problems.

2 Preliminaries

Notation. Let $G = (A, B, E)$ be a bipartite graph. We generally use n to denote the number of vertices, i.e., $n = |A| + |B|$, and $m = |E|$ to denote the number of edges. For a subset of vertices $U \subseteq A \cup B$ and a subset of edges $F \subseteq E$, we denote the vertex induced subgraph of G by vertices U by $G[U]$, and the edge induced subgraph of G by edges F by $G[F]$. Let M be a matching in G. We denote by $A(M)$ ($B(M)$) the vertices of A (resp. B) that are matched by M, and we write $V(M) = A(M) \cup B(M)$. Similarly, for an edge $e \in E$, we write $A(e)$ to denote its incident A-vertex, $B(e)$ to denote its B vertex, and $V(e) = \{A(e), B(e)\}$. The complement of a subset $A' \subseteq A$ ($B' \subseteq B$) is denoted by $\overline{A'} = A \setminus A'$ (resp. $\overline{B'} = B \setminus B'$).

The *matching number* of a graph G, i.e., the size of a maximum matching in G, is denoted $\mu(G)$. We write $opt(G)$ to denote an arbitrary but fixed maximum matching in G. For two sets X, Y, we write $X \oplus Y := (X \setminus Y) \cup (Y \setminus X)$ to denote their symmetric difference. For a graph G, $\Delta(G)$ denotes the maximum degree.

Concentration Bounds. In this paper, we will use two concentration bounds. The first one is Azuma's inequality for martingales (we refer the reader to [28] for the an introduction to martingales and Azuma's inequality), and the second is a Chernoff-type bound for weakly dependent random variables.

▶ **Theorem 1** (Azuma's Inequality ([5, 28])). *Suppose that $X_0, X_1, X_2, \ldots$ is a martingale and let $|X_i - X_{i-1}| \leq c_i$ for suitable constants c_i. Then:*

$$\mathbb{P}\left[|X_n - X_0| \geq t\right] \leq 2\exp\left(\frac{-t^2}{2\sum_{i=1}^{n} c_i^2}\right) .$$

▶ **Theorem 2** (Chernoff Bound for Weakly Dependent Variables, e.g. [15]). *Let $X_1, X_2, \ldots, X_n$ be 0/1 random variables for which there is a $p \in [0,1]$ such that for all $k \in [n]$ the inequality*

$$\mathbb{P}\left[X_k = 1 \,|\, X_1, X_2, \ldots, X_{k-1}\right] \leq p$$

holds (i.e., the probability of $X_k = 1$ conditioned on any possible outcome of $X_1, \ldots, X_{k-1}$ is at most p). Let further $\mu \geq p \cdot n$. Then, for every $\delta > 0$:

$$\mathbb{P}\left[\sum_{i=1}^{n} X_i \geq (1+\delta)\mu\right] \leq \left(\frac{e^{\delta}}{(1+\delta)^{1+\delta}}\right)^{\mu} .$$

We will say that an event occurs with *high probability in variable x*, if the the probability of the event occurring is at least $1 - x^{-C}$, for some $C \geq 1$. If we do not mention x explicitly, then the high probability statement is in n, the number of vertices of the input graph.

We say that an algorithm is a C-approximation algorithm for MBM if it computes a matching M of size at least $C \cdot \mu(G) - o(\mu(G))$.

3 Finding a Large Set of Disjoint 3-augmenting Paths

We now present an algorithm that, given a maximal matching M in a bipartite graph $G = (A, B, E)$, finds a set of disjoint 3-augmenting paths $\mathcal{P}$ by running the Greedy matching algorithm on a random subgraph of G. The set $\mathcal{P}$ is such that, when augmenting M along the paths $\mathcal{P}$, a matching of size at least $(2-\sqrt{2})\mu(G) - o(\mu(G)) \approx 0.5857\mu(G) - o(\mu(G))$ is obtained.

Algorithm 1 Finding a large set of 3-augmenting paths.

Input: Bipartite graph $G = (A, B, E)$, maximal matching M, parameter $0 < p < 1$

1. Sample each edge $e \in M$ with probability p; let M' be the resulting sample
2. $M_L \leftarrow \textsc{Greedy}(G[A(M') \cup \overline{B(M)}])$; $M_R \leftarrow \textsc{Greedy}(G[\overline{A(M)} \cup B(M')])$
3. $\mathcal{P} \leftarrow \{\text{paths } b'a, ab, ba' \mid b'a \in M_L, ab \in M, ba' \in M_R\}$
4. **return** $\mathcal{P}$

Our algorithm is illustrated in Algorithm 1. For the sake of a clear presentation, the algorithm employs two invocations of Greedy on two disjoint subgraphs. This is equivalent to invoking Greedy only once on their union. Our algorithm is parametrized by a sampling probability p. To obtain the claimed bound stated above, we will later optimize p.

To obtain a better understanding of our algorithm, we first discuss structural properties that help us locate 3-augmenting paths in G with respect to the matching M.

Let M^* be a maximum matching in G and let ϵ be such that $|M| = (\frac{1}{2} + \epsilon)|M^*|$. Observe first that $M \oplus M^*$ contains a collection of $(\frac{1}{2} - \epsilon)|M^*|$ disjoint augmenting paths. Further, observe that the endpoints of each augmenting path are a free vertex in A (i.e., a vertex in $\overline{A(M)}$) and a free vertex in B. Hence, the subgraphs $G_L := G[A(M) \cup \overline{B(M)}]$ and $G_R := G[\overline{A(M)} \cup B(M)]$ each contain a matching of size $(\frac{1}{2} - \epsilon)|M^*|$. We summarize this in Observation 3:

▶ **Observation 3.** *Let ϵ be such that $|M| = (\frac{1}{2} + \epsilon)\mu(G)$. Then:*

$$\min\{\mu(G_L), \mu(G_R)\} \geq (\frac{1}{2} - \epsilon)\mu(G) \ .$$

Suppose now that ϵ is small. Further, suppose that we could compute maximum matchings M_L^* in G_L and M_R^* in G_R. Then for almost every edge $e \in M$ there are edges $e_l \in M_L$ and $e_r \in M_R$ such that $e_l e e_r$ forms a 3-augmenting path. We will call e_l a left wing for edge e and e_r a right wing for edge e.

Our augmentation method should of course not be based on computing maximum matchings themselves. We therefore proceed differently. First, observe that if we computed maximal matchings, i.e., $\frac{1}{2}$-approximations, in G_L and G_R, then we may not find any 3-augmenting path at all, since it may happen that we find left wings for half of the edges of M, and right wings for the other half. Our strategy therefore is as follows: We first sample a subset of edges $M' \subseteq M$, where each edge of M is included in M' with probability p, and we attempt to augment only the edges in M' by computing Greedy matchings in the subgraphs $G'_L := G[A(M') \cup \overline{B(M)}]$ and $G'_R := G[\overline{A(M)} \cup B(M')]$. Konrad et al. [26] proved that, in expectation, the resulting matchings are essentially $\frac{1}{1+p} \geq \frac{1}{2}$-approximations, albeit for a slightly different notion of approximation, which is nevertheless suitable for our purposes:

▶ **Theorem 4** (Konrad et al. [26])**.** *Let $G = (U, V, E)$ be a bipartite graph, and let $U' \subseteq U$ be such that every vertex $u \in U$ is included in U' with probability p ($p \in [0, 1]$). Then, for any arbitrary but fixed order in which* Greedy *processes the edges, the following holds:*

$$\mathbb{E}_{U'}|\textsc{Greedy}(G[U' \cup V])| \geq \frac{p}{1+p}\mu(G) \ .$$

Hence, if ϵ is close to 0, and p is substantially smaller than 1, then it follows from the previous theorem that a large fraction of the vertices $A(M')$ will be matched by Greedy in G'_L, and a large fraction of the vertices of $B(M')$ will be matched by Greedy in G'_R. This

in turn implies that a substantial amount of edges of M' both have left and a right wings and are thus included in 3-augmenting paths.

Before we make this intuition formal, we point out one shortcoming of applying the previous theorem by Konrad et al. directly. They prove that the resulting matching is large only *in expectation*, which in turn would imply that our result only holds in expectation. We therefore first strengthen their result and prove that a similar version holds with high probability. To this end, we first prove a technical lemma that is employed in the proof of our strengthened theorem.

▶ **Lemma 5.** *Let $G = (U, V, E)$ be a bipartite graph and let $u \in U, v \in V$ be arbitrary vertices. Let $U' \subseteq U$ be such that every vertex $u \in U$ is included in U' with probability p. Then, for any arbitrary but fixed order in which* Greedy *processes the edges, the following holds:*

$$0 \leq \mathbb{E}_{U'}|\textsc{Greedy}(G[U' \cup V])| - \mathbb{E}_{U'}|\textsc{Greedy}(G[(U' \cup V) \setminus \{u, v\}])| \leq 2 \ .$$

Proof. First, observe that

$$\mathbb{E}_{U'}|\textsc{Greedy}(G[U' \cup V])| - \mathbb{E}_{U'}|\textsc{Greedy}(G[(U' \cup V) \setminus \{u, v\}])| = \mathbb{E}_{U'}\left(|\textsc{Greedy}(G[U' \cup V])| - |\textsc{Greedy}(G[(U' \cup V) \setminus \{u, v\}])|\right) \ .$$

We will prove next that $0 \leq \textsc{Greedy}(G[U' \cup V]) - \textsc{Greedy}(G[U' \cup V - \{u, v\}]) \leq 2$ holds for any $U' \subseteq U$, which then proves the lemma. We will in fact argue the stronger statement that for any graph $G = (V, E)$ and any vertex $v \in V$, the inequality $0 \leq \textsc{Greedy}(G) - \textsc{Greedy}(G \setminus \{v\}) \leq 1$ holds. The result then follows by applying this statement twice.

Consider thus an arbitrary graph $G = (V, E)$ and a vertex $v \in V$. First observe that if $\textsc{Greedy}(G)$ leaves v unmatched, then $\textsc{Greedy}(G) = \textsc{Greedy}(G \setminus \{v\})$. If $\textsc{Greedy}(G)$ matches v, then it is not hard to see that $\textsc{Greedy}(G) \oplus \textsc{Greedy}(G \setminus \{v\})$ consists of one alternating path whose one endpoint is v. This further implies that $\textsc{Greedy}(G \setminus \{v\}) \leq \textsc{Greedy}(G) \leq \textsc{Greedy}(G \setminus \{v\}) + 1$, which completes the proof. ◀

We now give our strengthened version of Theorem 4.

▶ **Theorem 6.** *Let $G = (U, V, E)$ be a bipartite graph, and let $U' \subseteq U$ be such that every vertex $u \in U$ is included in U' with probability p ($p \in [0, 1]$). Then, for any arbitrary but fixed order in which* Greedy *processes the edges, the following holds with probability at least $1 - (\mu(G))^{-12}$:*

$$|\textsc{Greedy}(G[U' \cup V])| \geq \frac{p}{1+p}\mu(G) - o(\mu(G)) \ .$$

Proof. Let $X := |\textsc{Greedy}(G[U' \cup V])|$. By Theorem 4 we have $\mathbb{E}X \geq \frac{p}{1+p}\mu(G)$.

For $1 \leq i \leq n$, let Z_i be the ith edge selected by Greedy, and let $Z_i = \perp$ if $i > X$. Let Y_i be the Doob martingale induced by the first i choices of the algorithm, i.e.,

$$Y_i := \mathbb{E}_{Z_{i+1}, Z_{i+2}, \ldots, Z_n}(X \mid Z_1, \ldots, Z_i) \ .$$

Observe that the expectation in the previous expression is in itself a random variable, since the expectation is only taken over $Z_{i+1}, \ldots, Z_n$, while $Z_1, \ldots, Z_i$ are random variables. It is not hard to check that the sequence $(Y_i)_i$ always forms a martingale, independently of the underlying sequence Z_i. Observe next that $Y_0 = \mathbb{E}X$ and $Y_n = X$. We thus need to show that $|Y_n - Y_0|$ is small with high probability. To this end, we will apply Azuma's inequality, which requires bounding the differences $|Y_{i+1} - Y_i|$, for every i, first.

First, observe that $|Y_{i+1} - Y_i| = 0$ for every $i \geq X$. Next, we claim that $|Y_{i+1} - Y_i| \leq 1$, for every $i < X$. Indeed, observe that Y_i is the expected size of the computed matching conditioned on the first i choices of the algorithm. We can thus rewrite Y_i as:

$$Y_i = i + \mathbb{E}_{U'}|\textsc{Greedy}(H_i)| \ ,$$

where $H_i := G[(U' \cup V) \setminus \cup_{j \leq i} V(Z_j)]$ is the residual graph obtained when removing the vertices incident to the first i selected edges. We thus obtain:

$$\begin{aligned} Y_{i+1} - Y_i &= 1 + \mathbb{E}_{U'}|\textsc{Greedy}(H_{i+1})| - \mathbb{E}_{U'}|\textsc{Greedy}(H_i)| \\ &= 1 + \mathbb{E}_{U'}|\textsc{Greedy}(H_i \setminus V(Z_{i+1}))| - \mathbb{E}_{U'}|\textsc{Greedy}(H_i)| \in \{-1, 0, 1\} \ , \end{aligned}$$

where we applied Lemma 5.

Next, since $X \leq \mu(G[U' \cup V]) \leq \mu(G)$, we have $|Y_{i+1} - Y_i| \leq 1$ for every $i \leq \mu(G)$, and $|Y_{i+1} - Y_i| = 0$ for every $i > \mu(G)$. Applying Azuma's Inequality (Theorem 1), we obtain:

$$\mathbb{P}\left[|Y_n - Y_0| \geq 5\sqrt{\mu(G)\ln(\mu(G))}\right] \leq \mu(G)^{-12} \ . \qquad \blacktriangleleft$$

Equipped with Theorem 6, we now show that our algorithm finds many disjoint 3-augmenting paths, provided that M is close to a $\frac{1}{2}$-approximation.

▶ **Lemma 7.** *Consider Algorithm 1 and suppose that $|M| = (\frac{1}{2} + \epsilon)\mu(G)$. Then, with probability at least $1 - \mu(G)^{-10}$,*

$$|\mathcal{P}| \geq \mu(G)p\left(\frac{1-2\epsilon}{1+p} - \frac{1}{2} - \epsilon\right) - o(\mu(G)) \ .$$

Proof. First, by an application of a Chernoff bound, we obtain $|M'| = p|M| \pm O(\sqrt{|M|\ln(|M|)})$, with probability at least $1 - |M|^{-C}$, for an arbitrarily large constant C. Next, by Theorem 6 and Observation 3, with probability at least $1 - 2(\mu(G))^{-12}$, we have $|M_L| \geq \frac{p}{1+p}(\frac{1}{2} - \epsilon)\mu(G) - o(\mu(G))$ and $|M_R| \geq \frac{p}{1+p}(\frac{1}{2} - \epsilon)\mu(G) - o(\mu(G))$. Observe that at most $|M'| - |M_L|$ edges of M' do not have a left wing, and at most $|M'| - |M_R|$ edges of M' do not have a right wing. Hence, at least $|M'| - (|M'| - |M_L|) - (|M'| - |M_R|) = |M_L| + |M_R| - |M'|$ edges have both left and right wings and therefore form 3 augmenting paths. We thus obtain:

$$\begin{aligned} |\mathcal{P}| &\geq |M_L| + |M_R| - |M'| \\ &\geq 2 \cdot \frac{p}{1+p}(\frac{1}{2} - \epsilon)\mu(G) - o(\mu(G)) - p|M| - O(\sqrt{|M|\ln(|M|)}) \\ &\geq 2 \cdot \frac{p}{1+p}(\frac{1}{2} - \epsilon)\mu(G) - p(\frac{1}{2} + \epsilon)\mu(G) - o(\mu(G)) \\ &= \mu(G)p\left(\frac{1-2\epsilon}{1+p} - \frac{1}{2} - \epsilon\right) - o(\mu(G)) \ . \end{aligned}$$

By the union bound, the error is bounded by $|M|^{-C} + 2(\mu(G))^{-12} \leq (\mu(G))^{-10}$. $\blacktriangleleft$

We are now ready to prove our main theorem:

▶ **Theorem 8.** *Let M be a maximal matching. Then, setting $p = \sqrt{2} - 1$ in Algorithm 1 guarantees that M augmented by $\mathcal{P}$ gives a matching of size at least $(2 - \sqrt{2})\mu(G) - o(\mu(G)) \approx (\frac{1}{2} + 0.0857)\mu(G) - o(\mu(G))$ with high probability in $\mu(G)$.*

Proof. Observe that the final matching is of size $|M| + |\mathcal{P}|$. Let ϵ be such that $|M| = (\frac{1}{2} + \epsilon)\mu(G)$. By Lemma 7, we have

$$|M| + |\mathcal{P}| \quad \geq \quad (\frac{1}{2} + \epsilon)\mu(G) + \mu(G)p\left(\frac{1-2\epsilon}{1+p} - \frac{1}{2} - \epsilon\right) - o(\mu(G)) \ . \tag{1}$$

It can be seen that for any value of p, the right side of Inequality 1 is minimized for $\epsilon = 0$. On the other hand, for any value of ϵ, the value $p(\epsilon) = \sqrt{\frac{1-2\epsilon}{\frac{1}{2}+\epsilon}} - 1$ maximizes Inequality 1. Using $\epsilon = 0$ and $p(0) = \sqrt{2} - 1$ in Inequality 1 gives $|M| + |\mathcal{P}| \geq (2 - \sqrt{2})\mu(G) - o(\mu(G))$. ◀

Multiple augmentation rounds with decreasing values of p allow further improvements. For example, a second round with $p = \sqrt{\frac{2-\sqrt{2}}{\sqrt{2}-1}} - 1 \approx 0.1892$ guarantees that the resulting matching is of size at least $0.6067\mu(G) - o(\mu(G))$. As we will discuss in the next section, this can give a 3-pass streaming algorithm for MBM with approximation factor 0.6067, which slightly improves the 3-pass 0.605-approximation algorithm by Esfandiari et al. [14].

4 Adversarial Order Streams

Our method for finding augmenting paths given in Section 3 can directly be implemented in the streaming model. In the first pass, we compute a maximal matching M. If the current edge is added to M, then with probability p we add the edge to M' as well. In the second pass, we run Greedy on the subgraphs G'_L and G'_R and as soon as a 3-augmenting path is completed, we augment M. This can be done with constant update times.

Since we would like our streaming algorithm to succeed with high probability in n, the number of vertices, we need to address the fact that our method as stated in Theorem 8 only succeeds with high probability in $\mu(G)$, the size of a maximum matching in G. If $\mu(G)$ is of size at least, say, $\Omega(n^{\frac{1}{4}})$, our method can also gives a high probability result with respect to n. To deal with the case $\mu(G) = o(n^{\frac{1}{4}})$ we run the 1-pass algorithm of Chitnis et al. [7] in parallel to our algorithm, which computes a subset of edges $E' \subseteq E$ of size $O(n^{\frac{1}{2}})$ that contains a maximum matching provided that $\mu(G) = O(n^{\frac{1}{4}})$. Observe that after the first pass, we know in which of the two cases we are. We then run the Hopcroft-Karp maximum matching algorithm [20] in time $O(\sqrt{n} \cdot \sqrt{n}) = O(n)$ on the set of collected edges. To obtain a streaming algorithm with constant update time, we amortize the previous computation during the processing of the second pass, which is possible under the natural assumption that $m = \Omega(n)$. This gives the following theorem:

▶ **Theorem 9.** *There is a two-pass streaming algorithm for* MBM *with approximation factor* $2 - \sqrt{2} \approx \frac{1}{2} + 0.0857$ *that succeeds with high probability (in* n*). Using one additional pass, a* 0.6067*-approximation algorithm can be obtained.*

5 1-pass Random Order Streaming Algorithm

In this section, we assume that $\mu(G) = \Omega(n^{\frac{1}{4}})$. To deal with the case $\mu(G) = o(n^{\frac{1}{4}})$ we run the algorithm of Chitnis et al. [7] as outlined in Section 4 in parallel and compute and output a maximum matching after processing the stream. We also assume that the input graph has at least $C_1 \cdot n \log^{C_2} n$ edges, for suitably large constants C_1, C_2. If this is not the case then we could simply store all edges within the semi-streaming space constraint and compute and output a maximum matching.

Algorithm 2 One-pass random order matching algorithm.

Input: Bipartite graph $G = (A, B, E)$ with m edges, parameter $0 < p < 1$

Let $\pi = \pi[1], \pi[2], \ldots \pi[m]$ be the edges of G in uniform random order

1. $M \leftarrow$ Greedy$(\pi[1, \frac{m}{\log n}])$
2. Let $M' \subseteq M$ be such that every edge of M is included in M' with probability p
3. **while** processing $\pi(\frac{m}{\log n}, m]$ **do in parallel:**
   a. Compute set E_M of edges $ab \in \pi(\frac{m}{\log n}, m]$ with $a, b \notin V(M)$; if $|E_M| \geq C \cdot n \log^2 n$, for some appropriate large constant C, then **abort**
   b. $M_L \leftarrow$ Greedy(G_L^r), where G_L^r is the subgraph of G induced by all edges $\pi(\frac{m}{\log n}, m]$ between $A(M')$ and $\overline{B(M)}$
   c. $M_R \leftarrow$ Greedy(G_R^r), where G_R^r is the subgraph of G induced by all edges $\pi(\frac{m}{\log n}, m]$ between $\overline{A(M)}$ and $B(M')$
4. $\mathcal{P} \leftarrow \{\text{paths } b'a, ab, ba' \mid b'a \in M_L, ab \in M, ba' \in M_R\}$
5. **if** $|\mathcal{P}| \geq \mu(G[E_M])$ **then return** M augmented by $\mathcal{P}$
   else return $M \cup opt(G[E_M])$

Our 1-pass random order streaming algorithm combines our method for finding augmenting paths with a *residual sparsity* property of the random order Greedy matching algorithm:

▶ **Theorem 10** (Residual Sparsity of Greedy)**.** *Suppose that* Greedy *processes the edges E of a graph $G = (V, E)$ with $m = |E|$ in uniform random order. Let M_i be the matching produced by* Greedy *after having processed the ith edge. Then:*

$$\Delta(G[V \setminus V(M_i)]) = O(\frac{m \log n}{i})$$

with probability $1 - n^{-12}$ (over the uniform random ordering of the edges).

This theorem is implied by a similar theorem concerning the random order Greedy algorithm for independent sets as given in [25]. Observe that the Greedy algorithm for matchings on a randomly ordered sequence of the edges of a graph G can be seen as the Greedy algorithm for independent sets on a randomly ordered sequence of the vertices of the line graph $L(G)$.

Our one-pass random order algorithm is parametrized by a probability p, and is illustrated in Algorithm 2. In this listing, we write $\pi = \pi[1], \pi[2], \ldots, \pi[m]$ to be a uniform random ordering of the edges E. For $a < b$ we also write $\pi[a, b]$ to denote edges $\pi[a], \pi[a+1], \ldots, \pi[b]$, and $\pi(a, b]$ to denote edges $\pi[a+1], \pi[a+2], \ldots, \pi[b]$.

We run Greedy on the first $\frac{m}{\log n}$ edges to compute a matching M. Theorem 10 implies that the maximum degree in the residual graph $H := G[V \setminus V(M)]$ is $O(\log^2 n)$. This allows us to collect the entire residual graph (i.e., set E_M) within the semi-streaming space bound, since it has $O(n \log^2 n)$ edges with high probability. We abort if $|E_M|$ becomes too large.

In the next stage, we proceed as in our two-pass algorithm: We sample a subset of edges $M' \subseteq M$ and we try to find 3-augmenting paths for M' by computing matchings M_L and M_R in the subgraphs G_L^r and G_R^r. Ideally we would like to search for left and right wings in the subgraphs $G_L := G[A(M) \cup \overline{B(M)}]$ and $G_R := G[\overline{A(M)} \cup B(M)]$. Since however the first $\frac{1}{\log n}$ fraction of edges in the stream has already been processed, we can only search for augmenting paths in G_L^r and G_R^r. Concentration bounds however allow us to prove that not many important edges have arrived among the first $\frac{1}{\log n}$ fraction of edges (Lemma 14).

Our analysis is build on the following important observation. Suppose first that the matching M is small, i.e., $|M| = \alpha|M^*|$, for a small value of α. Then we will argue in the next lemma that a maximum matching in the residual graph is large:

▶ **Lemma 11.** *Let α be such that $|M| = \alpha|M^*|$, and let $H := G[E_M]$ $(= G[V \setminus V(M)])$ be the residual graph. Then:*

$$\mu(H) \geq (1 - 2\alpha)|M^*| \ .$$

Proof. Let M^* be a maximum matching in G. Let $M_1^* \subseteq M^*$ be those edges of M^* that share at least one endpoint with an edge in M, and let $M_2^* = M^* \setminus M_1^*$. Then $|M_1^*| \leq 2|M|$, since each edge of M can only be incident to at most two edges of M^*. Observe further that $M_2^* \subseteq E_M$. Hence: $\mu(H) \geq |M_2^*| = |M^*| - |M_1^*| \geq |M^*| - 2|M| = (1 - 2\alpha)|M^*|$. ◀

By combining M with a maximum matching in H we obtain the following corollary:

▶ **Corollary 12.** *Algorithm 2 finds a matching of size at least $(1-\alpha)|M^*|$ with high probability.*

The previous corollary shows that either the matching $M \cup opt(H)$ is large (if α is small), or the matching M itself is already reasonably large (if α is large). This is an important property since we next attempt to augment M, which necessitates that M is already close to a $\frac{1}{2}$-approximation. For this to succeed, we need to show that $\mu(G_L^r)$ and $\mu(G_R^r)$ are large. To this end, let δ be such that $|M| + \mu(G[E_M]) = (\frac{1}{2} + \delta)\mu(G)$. We will first bound $\mu(G_L)$ and $\mu(G_R)$ and then prove a similar bound for $\mu(G_L^r)$ and $\mu(G_R^r)$.

▶ **Lemma 13.** *Suppose that $|M| + \mu(G[E_M]) = (\frac{1}{2} + \delta)\mu(G)$. Then:*

$$\min\{\mu(G_L), \mu(G_R)\} \geq (\frac{1}{2} - \delta)\mu(G) \ .$$

Proof. Let M^* be a maximum matching in G and let M_H^* be an arbitrary maximum matching in $H(= G[E_M])$. First, it is not hard to see that $M \cup M_H^*$ is a maximal matching. Next, consider the set of edges $M^* \oplus (M \cup M_H^*)$. Since $|M| + |M_H^*| = (\frac{1}{2} + \delta)\mu(G)$, the set $M^* \oplus (M \cup opt(H))$ contains $(\frac{1}{2} - \delta)\mu(G)$ augmenting paths.

Observe that none of these augmenting paths only contain edges of M^* and M_H^*, since this would imply that M_H^* is not maximum in H. Consider now one such augmenting path P and remove all edges of M_H^* from P. Then P contains at least one augmenting path that only contains edges from M and M^*. Applying this argument to all augmenting paths, this proves that there are matchings in G_L and G_R of sizes $(\frac{1}{2} - \delta)\mu(G)$. ◀

▶ **Lemma 14.** *Suppose that $|M| + \mu(G[E_M]) = (\frac{1}{2} + \delta)\mu(G)$. Then, with high probability,*

$$\min\{\mu(G_L^r), \mu(G_R^r)\} \geq (1 - \frac{4}{\log n}) \cdot (\frac{1}{2} - \delta)\mu(G) \ .$$

Proof. We only give the argument for G_L^r, the argument for G_R^r is identical. Let $M_L^* = opt(G_L)$. We will show that most edges of M_L^* are included in $\pi(\frac{m}{\log n}, m]$ with high probability.

By Lemma 13, we have $|M_L^*| \geq (\frac{1}{2} - \delta)\mu(G)$. Let e_i be the i-th edge of M_L^*, let t_i be its position in the stream, and let Y_i be the indicator variable of the event "$t_i \leq \frac{m}{\log n}$". Our aim is to bound the probabilities $\mathbb{P}[Y_i = 1 \,|\, Y_1, \ldots, Y_{i-1}]$ and then apply the Chernoff bound stated in Theorem 2.

In the following, all our arguments are conditioned on the event "$|E(G[V \setminus V(M)])| = O(n \log^2 n)$" (without explicitly mentioning it), which we denote by E_1. This implies that

the algorithm does not abort in Line 3a. By the residual sparsity property as stated in Theorem 10, E_1 occurs with probability at least $1 - n^{-12}$.

We will argue now that

$$\mathbb{P}\left[\pi[\frac{m}{\log n}+1] \cup M \text{ is not a matching} \wedge \pi[\frac{m}{\log n}+1] \notin M_L^* \,|\, Y_1, \ldots, Y_{i-1}\right] \geq 1 - \frac{1}{\log^5 n}. \tag{2}$$

Since E_1 happens, observe that the second part of the stream consists of $m(1-\frac{1}{\log n}) - O(n\log^2 n)$ edges that cannot be added to matching M, at most $n/2$ edges of M_L^* (depending on the outcome of variables $Y_1, \ldots, Y_{i-1}$), and at most $O(n\log^2 n)$ edges that could extend M. Further, the arrival order of the edges $\pi(\frac{m}{\log n}, m]$ in the second part of the stream is uniform random, since the computed matching M is not affected by their order. Hence,

$$\mathbb{P}\left[\pi[\frac{m}{\log n}+1] \cup M \text{ is not a matching } \wedge \pi[\frac{m}{\log n}+1] \notin M_L^* \,|\, Y_1, \ldots, Y_{i-1}\right] \geq \frac{m(1-\frac{1}{\log n}) - O(n\log^2 n)}{m(1-\frac{1}{\log n})} \geq 1 - \frac{1}{\log^5 n},$$

using the assumption that the graph has at least $C \cdot n\log^{10} n$ edges, for a large enough C.

The key part of our argument is as follows: Let Π be the set of permutations that fulfill the event in Inequality 2. Given Π, we generate a set of permutations Π' with $\Pi' \supseteq \Pi$, which thus implies that the respective event is more likely to happen than the event in Inequality 2. Let $\pi \in \Pi$ be any permutation. Consider edge e_i and let j_i be such that $\pi[j_i] \in M$ is the edge incident to e_i. Since $e_i \in M_L^*$, we know that $t_i > j_i$. Construct now new permutations such that e_i is removed from its position t_i and is inserted at every position $\{t_i+1, t_i+2, \ldots, m\}$ and add the resulting permutations to Π'. Observe that for any permutation π' created this way, the exact same matching M is computed, which uses the fact that $\pi[\frac{m}{\log n}+1]$ cannot be added to M, which is important if e_i is inserted at a position larger than $\frac{m}{\log n}+1$. Observe further that the conditionings Y_j stay the same, which uses the fact that $\pi[\frac{m}{\log n}+1] \notin M_L^*$. Observe that Π' and Π are not identical, since we do not necessarily have that $\pi'[\frac{m}{\log n}+1] \cup M$ is not a matching for $\pi' \in \Pi'$. By construction, at least a $(1-\frac{1}{\log n})$-fraction of the permutations in Π' imply $Y_i = 0$. We thus obtain:

$$\begin{aligned}
&\mathbb{P}\left[Y_i = 0 \,|\, Y_1, \ldots, Y_{i-1}\right] \geq \\
&(1-\frac{1}{\log n}) \cdot \mathbb{P}\left[\pi[\frac{m}{\log n}+1] \cup M \text{ is not a matching} \wedge \pi[\frac{m}{\log n}+1] \notin M_L^* \,|\, Y_1, \ldots, Y_{i-1}\right] \\
&\quad \geq (1-\frac{1}{\log n})(1-\frac{1}{\log^5 n}) \geq 1 - \frac{2}{\log n}\ .
\end{aligned}$$

We now use the Chernoff bound for dependent variables stated in Theorem 2. Using $k = (\frac{1}{2}-\delta)\mu(G)$, we obtain (using $\mu = 2k/\log n$, and $\delta = 1$ in Theorem 2):

$$\mathbb{P}\left[\sum_{i=1}^{k} Y_i \geq 2\frac{2k}{\log n}\right] \leq \left(\frac{e}{4}\right)^{\frac{2k}{\log n}} \leq n^{-10}\ ,$$

using the assumption $\mu(G) = \Omega(n^{\frac{1}{4}})$. The result follows. ◀

In the remaining analysis, with the help of the previous lemma we bound the number of augmenting paths found in Lemma 15. We then conclude with our main theorem, where we show that one of the two computed matchings returned by the algorithm is necessarily large.

▶ **Lemma 15.** *Let $p = \Omega(1)$, suppose that $|M| + \mu(H) = (\frac{1}{2} + \delta)\mu(G)$, and let $|M| = \alpha\mu(G)$. Then, with high probability,*

$$|\mathcal{P}| \geq p\mu(G)\left(\frac{1-2\delta}{1+p} - \alpha\right) - o(\mu(G)) \ .$$

Proof. We follow the structure of the proof of Lemma 7. By an application of a Chernoff bound, we obtain $|M'| = p|M| \pm O(\sqrt{|M|\ln(|M|)})$, with probability at least $1 - |M|^{-C}$, for an arbitrarily large constant C. Next, by Theorem 6 and Lemma 14, with high probability in $\mu(G)$ we have

$$\min\{|M_L|, |M_R|\} \geq \frac{p}{1+p}(\frac{1}{2} - \delta)\mu(G) - o(\mu(G)) \ .$$

Since we assumed that $\mu(G) = \Omega(n^{\frac{1}{4}})$, this event also holds with high probability in n. As argued in the proof of Lemma 7, the quantity $|M_L| + |M_R| - |M'|$ bounds the number of 3-augmenting paths found, which then completes the proof:

$$\begin{aligned} |\mathcal{P}| &\geq |M_L| + |M_R| - |M'| \geq \frac{2p}{1+p}(\frac{1}{2} - \delta)\mu(G) - p|M| - o(\mu(G)) \\ &= p\mu(G)\left(\frac{2}{1+p}(\frac{1}{2} - \delta) - \alpha\right) - o(\mu(G)) = p\mu(G)\left(\frac{1-2\delta}{1+p} - \alpha\right) - o(\mu(G)) \ . \end{aligned}$$ ◀

▶ **Theorem 16.** *Setting $p = \sqrt{2} - 1$ in Algorithm 2 gives a one-pass random order semi-streaming algorithm for* MBM *with approximation ratio $\frac{1}{2} + \frac{2\sqrt{2}-3}{4\sqrt{2}-10} \geq 0.5390$ that succeeds with high probability.*

Proof. Suppose that $|M| = \alpha\mu(G)$ and $|M| + \mu(H) = (\frac{1}{2} + \delta)\mu(G)$. By Lemma 11, we have $\mu(H) \geq (1 - 2\alpha)\mu(G)$. Hence, $(1 - \alpha)\mu(G) \leq (\frac{1}{2} + \delta)\mu(G)$, which in turn implies $\alpha \geq \frac{1}{2} - \delta$. Plugging this into the bound given in Lemma 15, we obtain (ignoring the $o(\mu(G))$ term):

$$\begin{aligned} |M| + |\mathcal{P}| &\geq \alpha\mu(G) + p\mu(G)\left(\frac{1-2\delta}{1+p} - \alpha\right) = \mu(G)\left(\alpha(1-p) + p\left(\frac{1-2\delta}{1+p}\right)\right) \\ &\geq \mu(G)\left((\frac{1}{2} - \delta)(1-p) + p\left(\frac{1-2\delta}{1+p}\right)\right) \ . \end{aligned}$$

The quantity $|M| + \max\{|\mathcal{P}|, \mu(H)\}$, i.e., the size of the resulting matching, is minimizes if $|\mathcal{P}| = \mu(H)$. Hence, setting the right side of the previous inequality equal to $(\frac{1}{2} + \delta)\mu(G)$, we obtain $\delta = \frac{p(p-1)}{2p^2-6p-4}$, which is maximized for $p = \sqrt{2} - 1$ (observe that this is the same value as in the proof of Theorem 8). In this case, we obtain $\delta = \frac{2\sqrt{2}-3}{4\sqrt{2}-10} \approx 0.03950$, which completes the proof. ◀

6 Conclusion

In this paper, we gave a new method for finding a set of disjoint 3-augmenting paths that allows the augmentation of a maximal matching such that the resulting matching is of size at least $\sqrt{2} - 2$ times the size of a maximum matching. Our method is simple and only requires running the Greedy matching algorithm on a random subgraph. We applied this method in the data streaming setting and improved over the state-of-the-art one-pass random order algorithm and the state-of-the-art two- and three-pass adversarial order algorithms.

How large a matching can we compute in a single pass in the random order setting? All relevant known lower bounds for matchings [18, 22, 19] are highly sensitive to the arrival order of the edges and do not translate to the random order setting. Can we compute a

2/3-approximation in a single pass in the random order semi-streaming setting? In the adversarial order setting, it is known how to obtain a $2/3 - \delta$ approximation in $O(\frac{1}{\delta})$ passes. How many passes are required to obtain a 2/3-approximation?

Abstract

Under the reconfiguration framework, we consider the various ways that a target graph H is a *minor* of a host graph G, where a subgraph of G can be transformed into H by means of *edge contraction* (replacement of both endpoints of an edge by a new vertex adjacent to any vertex adjacent to either endpoint). Equivalently, an *H-model* of G is a labeling of the vertices of G with the vertices of H, where the contraction of all edges between identically-labeled vertices results in a graph containing representations of all edges in H.

We explore the properties of G and H that result in a connected *reconfiguration graph*, in which nodes represent H-models and two nodes are adjacent if their corresponding H-models differ by the label of a single vertex of G. Various operations on G or H are shown to preserve connectivity. In addition, we demonstrate properties of graphs G that result in connectivity for the target graphs K_2, K_3, and K_4, including a full characterization of graphs G that result in connectivity for K_2-models, as well as the relationship between connectivity of G and other H-models.

1 Introduction

Graph minors have been studied extensively as a means for categorizing graphs and exploiting their properties. A graph H is a *minor* of a graph G if H can be formed from a subgraph of G by a series of edge contractions, where the *contraction* of the edge uv results in the replacement of both u and v by a new vertex w that is adjacent to any vertex that was adjacent to u or v (or both). Much of the research in the area has focused on classes of graphs that are closed under the taking of minors, and on exploiting properties of graphs known not to contain certain graphs as minors. For example, it is known that for every minor

closed class, that class is characterized by a finite set of forbidden minors [12]. Additionally, it has been shown that for any fixed graph H, every H-minor-free graph of treewidth w has an $\Omega(w) \times \Omega(w)$ grid as a minor [2].

In our work, we instead focus on the solution space of H-models of a graph G using the reconfiguration framework [6, 11, 14], where an H-model is a mapping that labels the vertices of G with the vertices of H. A *reconfiguration graph* for an instance of a problem consists of a node for each possible feasible solution and an edge between any two nodes representing solutions that are adjacent. The definition of adjacency may be presented as a *reconfiguration step* used to transform a solution into a neighbouring solution. Structural properties of the reconfiguration graph, including its diameter and whether it is connected, are of interest both in their own right and as keys to solving algorithmic problems, such as determining whether there is a path (or *reconfiguration sequence*) in the graph between two given vertices and, if so, finding the shortest such path.

The reconfiguration framework has been used to explore the relationships among solutions to instances of many graph problems, such as Independent Set, Shortest Path, and k-Colouring. Practical uses of such work include determining whether and how it is possible to make incremental changes to form one solution from another, ensuring that at each step along the way, the intermediate configuration is also a solution. The study of minor reconfiguration is a natural extension of work that determines conditions under which reconfiguration graphs are guaranteed to be connected, as well as recent work on mappings between graphs, in which each node in the reconfiguration graph represents a subgraph in a specified class [5, 10]. In addition, our results widen the scope of work in which configurations are represented as labelings, which previously had been limited to problems entailing moving labels from a source to a target configuration using the minimum number of exchanges of labels on adjacent vertices (detailed in a survey of reconfiguration [11]), and the use of labeled edges in the reconfiguring of triangulations [8].

In this paper, we consider how the connectivity of the reconfiguration graph depends on the choices of the host G and target H. We consider an instance of Minor Reconfiguration to consist of a *host graph* G and *target graph* H such that H is a minor of G. Each node in the reconfiguration graph consists of a labeling of the vertices of G with the vertices of H (or, more simply, integers in $\{1, \ldots, |V(H)|\}$) such that the contraction of each edge with identically-labeled endpoints results in a graph that, upon deletion of zero or more edges, yields H. We consider two H-models to be adjacent if they differ by a single label.

We begin by establishing properties of k-connected graphs and minors in Section 2, based on which we form a toolkit of techniques used in reconfiguration (Section 3). We consider various properties of G and H that determine whether or not the reconfiguration graph is connected. For a target graph H, we define host(H) to be the set of host graphs G such that the reconfiguration graph for G and H is connected (Definition 8). We then focus on characterizing host(K_2) (Section 4), host(K_3) (Section 5), and host(K_4) (Section 6). Finally, in Section 7, we summarize the results and present directions for future work.

2 Preliminaries

We define key terms used in the description of graphs; for common terms not defined in this paper, the reader is referred to a resource on graph theory [3]. We will frequently focus on subsets of the vertices; for a subgraph $V \subseteq V(G)$, the *induced subgraph* $G[V]$ is the subgraph with vertex set V and edge set $\{uv \in V(G) \mid u, v \in V\}$. As shorthand, for G a graph and S a set of vertices, we use $G \setminus S$ to denote $G[V(G) \setminus S]$. In order to avoid confusion with the vertices in graphs G and H, we refer to the *nodes* of a reconfiguration graph.

2.1 Properties of k-connected graphs

We focus on various ways of connecting vertices in the graph. A *cut set* S of G is a set of vertices such that $G \setminus S$ consists of at least two components; the member of a cut set of size one is also called a *cut vertex*. A *bridge* is an edge whose deletion disconnects the graph. A graph is k-connected if there is no cut set of size k. Equivalently, in a k-connected graph there exist k vertex-disjoint paths between any pair of vertices in the graph. At times we will focus on how highly connected a specific vertex might be. A *universal vertex* is adjacent to all other vertices in the graph. In a *complete graph* on j vertices, denoted K_j, all vertices are universal vertices.

To characterize the behaviour of various host and target graphs, we make use of characterizations of graphs in terms of a base graph class and a series of operations. *Adding an edge* consists of adding an edge between two vertices in $V(G)$. To *split* a vertex v is to first delete v from G, and then add two vertices v_1 and v_2 to G such that $v_1v_2 \in E(G)$, each neighbour of v in G is a neighbour of exactly one of v_1 or v_2, and $\deg(v_i) \geq 3$ for $i \in \{1, 2\}$.

We make use of Tutte's characterization of 3-connected graphs and Ding and Qin's characterization of a subset of the 4-connected graphs, given below. The base case for Tutte's characterization is a wheel, defined as follows.

▶ **Definition 1.** A *k-wheel* W_k is a graph on $k + 1$ vertices, the *rim vertices* $r_1, \ldots, r_k$ and the *hub vertex* h, where there is a cycle induced on the rim vertices and an edge between h and each rim vertex.

▶ **Theorem 2.** *[13] A graph is 3-connected if and only if it is obtained from a wheel by repeatedly adding edges and splitting vertices.*

To state Ding and Qin's result, we need a few additional definitions. The *line graph* $L(G)$ of a graph G has a vertex corresponding to each edge of G and two vertices are adjacent if their corresponding edges share an endpoint in G. A graph is *cubic* if each vertex has degree three. Furthermore, a cubic graph with at least six vertices is *internally 4-connected* if its line graph is 4-connected. One of the base classes for their characterization is a square of a cycle, as defined below.

▶ **Definition 3.** The *square of a cycle* C_k^2 is formed from the cycle C_k by adding an edge between any pair of vertices joined by a path of length two.

Finally, we say a sequence of 4-connected graphs $G_1, \ldots, G_n$ form a (G_1, G_n)*-chain* if for all $i \in \{1, \ldots, n-1\}$, there exists an edge e such that G_{i+1} is formed from G_i by removal of the edge e. Theorem 4 is a generalization of a well-known theorem of Martinov [9].

▶ **Theorem 4.** *[4] Let $\mathcal{C} = \{C_k^2 : k \geq 5\}$ and $\mathcal{L} = \{H : H$ is the line graph of an internally 4-connected cubic graph$\}$. Let G be a 4-connected graph not in $\mathcal{C} \cup \mathcal{L}$. Then if G is planar, there is a (G, C_6^2)-chain. Otherwise, there is a (G, K_5)-chain.*

2.2 Branch sets, H-models, host(H), and block trees

For the purposes of reconfiguration, we make use of an equivalent definition of a minor as a mapping of each vertex of host graph G to a vertex of target graph H. For convenience, we sometimes represent the vertices of H as integer labels.

▶ **Definition 5.** For graphs G and H and mapping $f : V(G) \to V(H)$, we refer to $f(v)$ as the *label* of v and define the *branch set* $G(f, i)$ to be the subgraph of G induced on the set of vertices with label i.

For ease, we will make use of $|G(f,i)|$ to denote $|V(G(f,i))|$. Given a mapping between $V(G)$ and $V(H)$, an edge of G is a *connecting edge* if its endpoints are members of two different branch sets, and we say that it *connects* those two branch sets. A mapping is equivalent to a minor when two additional properties hold, as indicated in Definition 6.

▶ **Definition 6.** For graphs G and H and mapping $f : V(G) \to V(H)$, we say that H is a *minor of* G and that f is an *H-model of G* if the following conditions hold:
1. for each $i \in V(H)$, each branch set $G(f,i)$ is nonempty and connected, and
2. for each edge $ij \in E(H)$, there exists an edge in $E(G)$ connecting $G(f,i)$ and $G(f,j)$.

▶ **Definition 7.** For any graphs G and H such that H is a minor of G, the *branch set reconfiguration graph* of G and H consists of a node for each H-model of G and, for each pair of H-models f and g, an edge between the nodes corresponding to f and g if and only if there exists a $v \in V(G)$ such that $f(v) \neq g(v)$ and for all $u \neq v$, $f(u) = g(u)$.

▶ **Definition 8.** For any graphs G and H such that H is a minor of G, $G \in \text{host}(H)$ if and only if the branch set reconfiguration graph of G and H is connected.

We will often find it convenient to view each branch set in terms of the tree structure of its 2-connected components. A *block* of a connected graph is either a maximal 2-connected subgraph or one of the endpoints of a bridge. The *block tree* of a connected graph consists of a node for each block B; there is an edge between the nodes corresponding to blocks B and B' if there exists a cut vertex v of G such that $V(B) \cap V(B') = \{v\}$. Given a graph G, an H-model f, and a label a, we use $T(G, f, a)$ to denote the block tree for $G(f,a)$. In addition, for a subgraph A of G, we use $T(G, f, a, A)$ to denote the subtree of $T(G, f, a)$ induced by the blocks containing vertices in $V(G(f,a)) \cap V(A)$. For convenience, we sometimes use "block of $G(f,a)$" to refer to a block of $T(G, f, a)$.

To make use of the tree structure, our algorithms typically process a block tree starting with blocks that are leaves of their block trees, or *leaf blocks*; a branch set that is 2-connected can be viewed as having a block tree consisting of a single leaf block. For ease of description, we will refer to the cut vertices of G that appear in multiple blocks as *joining vertices* and all other vertices as *interior vertices*.

2.3 Essential edges, crucial vertices, weak connections, and lynchpins

When considering how labelings can be reconfigured, we need to ensure that we retain the connecting edges as required in Definition 6. In doing so, we need to pay particular attention to vertices and edges whose relabeling will cause problems.

When there exists only a single edge that connects a pair of branch sets with labels a and b, $ab \in E(H)$, we call such an edge an *essential edge*, and denote it as $\text{ess}(a,b)$. If all the edges between branch sets with labels a and b have the same endpoint in a, we call that vertex an *essential vertex for b*; clearly every endpoint of an essential edge is an essential vertex, but not every essential vertex is the endpoint of an essential edge.

The presence of essential vertices will be important in determining when it is easy to relabel vertices. For any two labels, if the branch set with label a contains an essential vertex for b or if the branch set with label b contains an essential vertex for a, we will say that the branch sets with labels a and b are *weakly connected*, or form a *weak connection*.

Our results rely on the interplay between the presence of weak connections and the connectivity of a graph. For each weak connection, we identify a vertex as the *lynchpin* for the connection. When the branch sets with labels a and b are weakly connected by an essential edge, then either of the endpoints of the essential edge can be designated as the

lynchpin. Otherwise, the (single) essential vertex giving rise to the weak connection is the lynchpin for that connection. We will use lynchpins to form cut sets between non-lynchpins and other branch sets.

A vertex v with label a is a *crucial vertex* if it is an essential vertex for b and an essential vertex for c, for $b \neq c$, and a *non-crucial vertex* otherwise. If for some distinct labels a, b, and c, a vertex $v \in G(f, a)$ is essential for c and also has at least one neighbour in $G(f, b)$, then v is a *b-crucial vertex*. Clearly, a vertex in $G(f, a)$ that is essential for b and c is crucial, b-crucial, and c-crucial.

2.4 Properties of H-models of k-connected graphs

When G is k-connected, we are able to establish properties of connecting edges of branch sets, as shown in Lemma 9 and Lemma 10, as well as the structure of weak edges (Lemma 11). The results make use of the fact that in a k-connected graph there cannot be a cut set of size less than k separating any two vertices; cut sets are typically formed from the joining vertices of leaf blocks and lynchpins, and vertices separated by cut sets are typically non-lynchpins. Proofs of results marked with (*) have been omitted due to space limitations.

▶ **Lemma 9 (*).** *Given a k-connected graph G and an H-model f of G for some graph H, for any branch set $G(f, a)$, each leaf block has $k - 1$ interior vertices that are endpoints of connecting edges.*

▶ **Lemma 10.** *Given a k-connected graph G and an H-model f of G, where $|V(H)| = k$, suppose there exist branch sets $G(f, \ell)$ and $G(f, m)$ such that $\ell m \in E(H)$ and there are weak connections between $G(f, \ell)$ and each branch set other than $G(f, m)$ (where a weak connection between $G(f, \ell)$ and $G(f, m)$ is possible but not required). Then, the following hold:*

1. *Each leaf block in $G(f, \ell)$ must contain an interior vertex that is the endpoint of a connecting edge to $G(f, m)$.*
2. *If it is possible to designate lynchpins of the weak connections such that $G(f, \ell)$ contains a non-lynchpin, then each leaf block in $G(f, m)$ must contain an interior vertex that is the endpoint of a connecting edge to $G(f, \ell)$.*

Proof. To see why the first point holds, suppose instead that no such interior vertex existed in a leaf block of $G(f, \ell)$. Then, each path between an interior vertex u in the leaf block in $G(f, \ell)$ and any vertex v in $G(f, m)$ must pass through either the joining vertex of the leaf block or one of the lynchpins for the weak connections. However, u and v are thus separated by a cut set of size at most $k - 1$, contradicting the k-connectivity of G.

The argument for the second point is similar; we can show that the joining vertex of the leaf block in $G(f, m)$ and the lynchpins of the weak connections form a cut set of size at most $k - 1$ separating any interior vertex in the leaf block and the non-lynchpin in $G(f, \ell)$. ◀

▶ **Lemma 11 (*).** *Given a k-connected graph G and a K_k-model f of G such that there is a branch set B with weak connections to all other branch sets, it is not possible to designate lynchpins such that B contains at least one vertex x that is not a lynchpin for any of the weak connections, and at least one other branch set contains a vertex y that is not a lynchpin for any of the weak connections.*

3 Toolkit for reconfiguration of minors

In this section, we introduce techniques and properties that are exploited in the results found in the rest of the paper. In particular, we focus on the types of steps used in reconfiguration and the properties that need to be satisfied for each type of transformation. In Lemmas 12

and 13 we determine conditions under which a vertex can be relabeled in a single step. In the remainder of the section, we present results that can be used to handle more complex situations in which one or more of the conditions do not hold.

Lemma 12 delineates the conditions necessary for a vertex to be able to be relabeled from a to b in a single reconfiguration step: it cannot be the only vertex with label a, it cannot be a cut vertex in its branch set, it must be connected to a vertex with label b, and it is not incident with every edge between the branch sets for labels a and c, where $c \neq b$.

▶ **Lemma 12 (*).** *Given a graph G and an H-model f of G, a vertex v can be relabeled from a to b in a single reconfiguration step if and only if the following conditions hold:*

1. $|G(f, a)| > 1$;
2. *v is not a cut vertex in $G(f, a)$;*
3. *v has at least one neighbour in $G(f, b)$; and*
4. *v is not a b-crucial vertex.*

Because several of the conditions hold automatically for a universal vertex, the following lemma lists a smaller number of conditions:

▶ **Lemma 13 (*).** *Given a graph G and an H-model f of G, a vertex v can be relabeled from a to b in a single reconfiguration step if the following conditions hold:*

1. *$G(f, a)$ contains a universal vertex u such that $u \neq v$; and*
2. *v has at least one neighbour in $G(f, b)$.*

When neither Lemma 12 nor Lemma 13 applies, the relabeling of a vertex requires a series of reconfiguration steps. When the vertex to be relabeled is the only member of its branch set or a crucial vertex, we first need to fill its branch set with new vertices that can provide the necessary connecting edges to other branch sets. When the vertex to be relabeled is a cut vertex, we will need to siphon away vertices from its branch set so that it is no longer a cut vertex among the remaining vertices with its label.

When a branch set is a block tree, both filling and siphoning entail the relabeling of vertices in a branch set block by block, starting at the leaf blocks. If we are able to relabel all the interior vertices of a leaf block, we can simplify the block tree by removing the leaf block. We will show in Lemma 20 that such relabeling is possible as long as we can avoid certain bad situations involving *leaf-crucial models* and *leaf-ℓ-crucial models*, as outlined in Definitions 14, 15, and 16.

▶ **Definition 14.** Given a graph G and an H-model f of G, we say that a vertex v is a *leaf-crucial vertex* if v is a crucial vertex that is an interior vertex in a leaf block in its branch set. An H-model that contains a leaf-crucial vertex is a *leaf-crucial model*.

▶ **Definition 15.** Given a graph G and an H-model f of G, we say that a vertex v is a *leaf-ℓ-crucial vertex* if v is an ℓ-crucial vertex that is an interior vertex in a leaf block in its branch set. An H-model that contains a leaf-ℓ-crucial vertex is a *leaf-ℓ-crucial model*.

▶ **Definition 16.** Given a graph G, an H-model f of G, a label a, and a subgraph A of $G(f, a)$, we say that *f hits a leaf-crucial model on relabeling A* if any relabeling of f that changes only the vertices of A can be extended by relabeling only the vertices of A to reach a leaf-crucial model, and that *f hits a leaf-ℓ-crucial model on relabeling A* if any relabeling of f that changes only the vertices in A can be extended by relabeling only the vertices of A to reach a leaf-ℓ-crucial model.

▶ **Observation 17.** *Given a graph G, an H-model f of G, a label a, and a subgraph A of $G(f,a)$, if f does not hit a leaf-ℓ-crucial model on relabeling A, then for each model g reachable from f by relabeling only the vertices of A, no interior vertex in a leaf block of $T(G,g,a)$ is ℓ-crucial.*

In Lemma 18, we show that each time we relabel an interior vertex in a leaf block, if the leaf block still has interior vertices, one will be a neighbour of the relabeled vertex. We use the result in Lemma 19 to show that if we can avoid leaf-crucial models, then it is possible to relabel all the interior vertices in a leaf block (and hence remove it from the branch set). By repeatedly relabeling leaf blocks, an entire connected component can be siphoned away, as shown in Lemma 20.

▶ **Lemma 18.** *Given a graph G and an H-model f of G, suppose there exist labels a and b and a vertex v such that $|G(f,a)| \geq 2$, v is in a leaf block L of $T(G,f,a)$, and relabeling v to b (and no other vertices) results in another H-model g. Then v has a neighbour in $G(g,a)$, and if $|V(L) \setminus \{v\}| \geq 2$, then v has a neighbour u in $G(g,a)$ such that $u \in V(L)$ and u is an interior vertex in a leaf block of $T(G,g,a)$.*

Proof. We observe that since Lemma 12 holds for the relabeling of v from a to b, $|G(f,a)| \geq 2$, and since each branch set is connected, v must then have a neighbour in $G(g,a)$.

We now suppose that $|V(L) \setminus \{v\}| \geq 2$. At least one neighbour $u \in V(L)$ of v is in a leaf block L_g of $T(G,g,a)$, as v is not a cut vertex of $G(f,a)$ (by Lemma 12, condition 2) and L is a 2-connected leaf block of $T(G,f,a)$. If u is an interior vertex in $G(g,a)$, we are done. If instead u is a joining vertex and there exists no interior vertex in L_g that is a neighbour of v, then for each interior vertex $w \in V(L_g)$, u lies on every path from v to w in L, which contradicts the fact that L is 2-connected. Hence, v is adjacent to an interior vertex in $G(g,a)$. ◀

▶ **Lemma 19 (*).** *Given a graph G, an H-model f of G, a label a, and a leaf block L of $T(G,f,a)$, suppose that $|V(G(f,a)) \setminus V(L)| \geq 1$, L contains at least one interior vertex that is the endpoint of a connecting edge, and f does not hit a leaf-crucial model on relabeling L. Then we can reconfigure f to a model g such that $g(v) \neq f(v)$ for each $v \in V(L)$ that is an interior vertex of $G(f,a)$ and $g(u) = f(u)$ for all other vertices u.*

▶ **Lemma 20.** *Given a 2-connected graph G and an H-model f of G, suppose there exist $ab \in E(H)$, a cut vertex x of $G(f,a)$, and a connected component C of $G(f,a) \setminus \{x\}$ that contains at least one vertex with a neighbour in $G(f,b)$ such that f does not hit a leaf-crucial model or a leaf-b-crucial model on relabeling C. Then we can reconfigure f to a model g such that $g(v) \neq f(v)$ for each $v \in V(C)$, $g(u) = f(u)$ for all $u \notin V(C)$, and x has a neighbour in $G(g,b)$.*

Proof. We use B to denote the block of $T(G,f,a,C)$ containing x, and view $T(G,f,a,C)$ as rooted at B. We observe that any leaf block of $T(G,f,a,C)$ is also a leaf block of $T(G,f,a)$.

To reconfigure f to g, we work up the tree $T(G,f,a,C)$ from leaf blocks up to B, at each step relabeling all the vertices in the current block with labels different from a. Specifically, if a leaf block does not have an interior vertex with a neighbour labeled b, then in Case 1 below, we can relabel the vertices in the block; such a relabeling removes the block from the branch set for label a. If instead a leaf block does have an interior vertex with a neighbour labeled b, then in Case 2 below, we can relabel the block with b. Such a relabeling not only removes the block from the branch set for label a, but also ensures that the joining vertex of the block has a neighbour with label b. Repeated applications of the two cases suffice

to ensure that we eventually reach a point in the process at which B is a leaf block and contains an interior vertex with a neighbour labeled b; using Case 2, we can then satisfy the statement of the lemma by ensuring that every vertex in B except x receives label b.

Case 1: A leaf block L of $T(G, f, a, C)$ does not contain an interior vertex with a neighbour in $G(f, b)$.

Since G is 2-connected, by Lemma 9, L has at least one interior vertex that is an endpoint of a connecting edge. Because f does not hit a leaf-crucial model and $|V(G(f, a)) \setminus V(L)| \geq 1$, by Lemma 19, we can relabel the interior vertices of L.

Case 2: A leaf block L of $T(G, f, a, C)$ contains an interior vertex v with a neighbour in $G(f, b)$.

We first observe that we can relabel v to b: since f does not hit a leaf-b-crucial model on relabeling C, v is not b-crucial (Observation 17), and hence all the conditions of Lemma 12 hold. We can then repeat the same argument on the resulting model h, as follows. For L_h the leaf block of $T(G, h, a, C)$ such that $V(L_h) = V(L) \setminus \{v\}$, if one exists, by Lemma 18, L_h contains an interior vertex u that is a neighbour of v. We can then use the fact that f does not hit a leaf-b-crucial model on relabeling C to again apply Observation 17 to conclude that u is not b-crucial and that Lemma 12 is satisfied for the labeling of u to b. Further repetitions of the argument result in the relabeling of all interior vertices of L to b. ◀

4 Characterizing host(K_2)

Theorem 21 fully characterizes host(K_2); as a consequence, we can use membership in host(K_2) as an alternate definition of 2-connectivity. The reconfiguration of a 2-connected graph G is achieved by defining a canonical model (one in which one vertex has one label and all other vertices have the other label) and then showing it is possible both to reconfigure any K_2-model to a canonical model and to reconfigure between canonical models. In contrast, when G is not 2-connected, the presence of a cut vertex prevents reconfiguration, as no ordering of relabeling steps can prevent a branch set from being disconnected.

▶ **Theorem 21 (*).** *$G \in$ host(K_2) if and only if G is 2-connected.*

5 Characterizing host(K_3)

To show that every 3-connected graph is in host(K_3), we make use of Tutte's characterization in Theorem 2. In order to prove Theorem 22, it suffices to show that wheels are in host(K_3) (Corollary 24) and that connectivity is preserved under the splitting of vertices (Lemma 27) and adding of edges (Lemma 30).

▶ **Theorem 22 (*).** *Every 3-connected graph is in host(K_3).*

The result for wheels (Corollary 24) follows from a result on a generalization of wheels by allowing multiple hub vertices, each of which is a universal vertex, and replacing each rim vertex by a connected graph. To obtain a more general result, we use $W(G_1, G_2, \ldots, G_m, n, \ell, m)$ to denote a generalized wheel, for each G_i a connected graph on n vertices, $V(G_i) = \{v_{(i,1)} \ldots v_{(i,n)}\}$, and ℓ and m both positive integers. The graph $W(G_1, G_2, \ldots, G_m, n, \ell, m)$ consists of ℓ *hub vertices*, $V_H = \{h_1, \ldots, h_\ell\}$, and mn *subgraph vertices*, $V_S = \{s_{i,j} \mid 1 \leq i \leq m, 1 \leq j \leq n\}$, where $s_{i,j}$ corresponds to $v_{(i,j)}$. The edge set consists of the *hub edges*,

$E_H = \{h_i h_j \mid 1 \leq i \leq \ell, 1 \leq j \leq \ell, i \neq j\}$, the *subgraph edges*, $E_s = \{s_{i,j}s_{i,k} \mid v_{(i,j)}v_{(i,k)} \in E(G_i), 1 \leq i \leq m\}$, the *rim edges*, $E_R = \{s_{(i,j)}s_{(k,j)} \mid k \equiv i+1 \bmod m, 1 \leq j \leq n\}$, and the *connecting edges*, $E_C = \{h_k s_{(i,j)} \mid 1 \leq k \leq \ell, 1 \leq i \leq m, 1 \leq j \leq n\}$. Observe that $W(G_1, G_2, \ldots, G_m, n, l, m)$ has a K_{l+2}-minor when $m \geq 3$.

▶ **Lemma 23 (*).** *For any graphs G_i, $W(G_1, G_2, \ldots, G_m, n, \ell, m)$ is in host$(K_{\ell+2})$ for any $m \geq 3$.*

▶ **Corollary 24.** *W_n is in host(K_3).*

We consider the splitting of vertices in two steps. In Lemma 25, which applies more generally to K_k for any $k > 2$, we show that we can reconfigure between models in which the vertices resulting from the split have the same label. Then, in Lemma 27, which uses Lemma 26, we consider cases in which the vertices can have different labels.

▶ **Lemma 25.** *Let G be a 2-connected graph and G' be formed from G by splitting a vertex v into vertices x and y. For any $k > 2$, let f and g be K_k-models of G and f' and g' be K_k models of G' such that $f(v) = f'(x) = f'(y)$, $g(v) = g'(x) = g'(y)$ and for all $u \in V(G) \setminus \{v\}$, $f(u) = f'(u)$ and $g(u) = g'(u)$. If f and g are reconfigurable, then f' and g' are reconfigurable.*

Proof. Since f and g are reconfigurable, there is a reconfiguration sequence $\sigma = f = f_1, \ldots, f_\ell = g$ for some value of ℓ. Using σ, we wish to form a reconfiguration sequence σ' from f' to g' in the reconfiguration graph for G'. In forming the sequence, we observe that if there is a prefix τ of σ such that v is not relabeled in any of the steps, then we can form a prefix τ' of σ' by executing the same sequence of steps.

We now consider the first relabeling of v in σ, say from f_j to f_{j+1}; we wish to show that in σ', we can relabel both x and y in the same way. Without loss of generality, we assume that $f_j(v) = f'_j(x) = f'_j(y) = a$ and that $f_{j+1}(v) = b$.

We can use the fact that Lemma 12 holds for the labeling of v by b to establish useful properties of x and y. Because v is not in a branch set of size one (condition 1), x and y are not the only two vertices in $G'(f'_j, a)$. Since v is a not a cut vertex of its branch set (condition 2), x and y together cannot form a cut set. As v has a neighbour with label b (condition 3), either x or y (or both) must have a neighbour with label b under f'_j. Finally, because v is not a b-crucial vertex (condition 4), there must exist some vertex other than x or y in $G'(f'_j, a)$ that has a neighbour with label b.

Without loss of generality, we assume that x has a neighbour with label b, and consider two cases, depending on whether or not x is a joining vertex in the block tree of $G'(f'_j, a)$.

Case 1: x is a not a joining vertex of the block tree of $G'(f'_j, a)$

By our observations above, all conditions of Lemma 12 hold for the relabeling of x to b. As a consequence of the relabeling, y now has a neighbour with label b. Because v was not a cut vertex in $G(f_j, a)$, the removal of both x and y cannot disconnect $G'(f'_j, a)$, and hence condition 2 holds for y. As the remaining conditions of Lemma 12 were established in the argument above, we can now relabel y to b, as needed.

Case 2: x is a joining vertex in the block tree of $G'(f'_j, a)$

We first show that the component C of $G'(f'_j, a)$ containing y consists solely of the vertex y. If instead there existed another vertex in C, then the removal of both x and y would separate the vertex from the other components of $G'(f'_j, a) \setminus \{x\}$, and consequently v would be a cut vertex in $G(f_j, a)$, which contradicts Lemma 12 for the relabeling of v to b.

By the definition of the split operation, $\deg(y) \geq 3$; because x is y's only neighbour with label a, y must have at least one neighbour with label b or c, for some $c \notin \{a, b\}$. If y has a neighbour with label b, we can use Case 1 to complete the relabeling of y and then x. Otherwise, we will show that we can first relabel y to c, relabel x to b, and finally relabel y to b. In each case, we show that we can use Lemma 12.

To see that we can relabel y to c, it suffices to observe that y is not c-crucial, as x has a neighbour in b, and if y were essential for some $d \notin \{b, c\}$, then v would be essential for d in f_j, and hence b-crucial in f_j, which is a contradiction. Now, since x is now no longer a cut vertex, we can relabel x to b. Finally, since y now has a neighbour with label b (that is, x), we can relabel y with b, as needed. ◀

▶ **Lemma 26.** *Given a 3-connected graph G and a K_3-model f of G, suppose there exists a cut vertex x of $G(f, a)$ with a neighbour in $G(f, b)$ such that x is not essential for c. Then there exists a component D of $G(f, a) \setminus \{x\}$ such that we can reconfigure f to a model g in which $g(v) = f(v)$ for each $v \in V(D)$, $g(x) = b$, and $g(u) \neq f(u)$ for all other vertices of $G(f, a)$.*

Proof. We form model g by first siphoning all components of $G(f, a) \setminus \{x\}$ except D out of $G(f, a)$ and then by relabeling x to b.

Because x is not essential for c, there must exist at least one component of $G(f, a) \setminus \{x\}$ that contains a vertex with a neighbour in $G(f, c)$; we choose D to be one such component.

By Lemma 9, each other component C must have a neighbour in either $G(f, b)$ or $G(f, c)$. Since x has a neighbour in $G(f, b)$ and D has a neighbour in $G(f, c)$, f does not hit a leaf-crucial model, a leaf-b-crucial model, or a leaf-c-crucial model on relabeling C, and hence we can use Lemma 20 to relabel all vertices of C with either b or c.

After the vertices of every component except D have been relabeled, all the conditions for Lemma 12 now hold for the relabeling of x to b: the branch set for label a has at least one vertex other than x, x is no longer a cut vertex, x has a neighbour labeled b, and a vertex in D has a neighbour labeled c. ◀

▶ **Lemma 27.** *Suppose G is a 3-connected graph such that $G \in host(K_3)$ and G' is a graph formed from G by splitting a vertex v into vertices x and y. Then G' is in $host(K_3)$.*

Proof. We show that for any source and target K_3-models of G', we can find a reconfiguration sequence from the source to the target. We know from Lemma 25 that we can reconfigure between any two K_3-models in which x and y have the same labels. Here, we show that we can reconfigure any K_3-model to a K_3-model in which x and y have the same labels. This suffices to demonstrate the existence of a reconfiguration sequence between the source and target K_3-models, as we reconfigure from the source K_3-model to a K_3-model in which x and y have the same labels, then to another K_3-model in which x and y have the same labels, and finally to the target K_3-model.

Without loss of generality, we assume that the labels are a, b, and c, and that in the starting K_3-model, $f'(x) = a$ and $f'(y) = b$. If Lemma 12 holds for either relabeling x to b or relabeling y to a, then we can accomplish the reconfiguration in a single step. Similarly, the reconfiguration can be accomplished using Lemma 26 if either x or y is a cut vertex that is not essential for c.

Thus, it suffices to consider the cases in which either condition 1 or 4 of Lemma 12 must be violated for both relabeling x to b and relabeling y to a. In any case, both x and y will be essential for c. By Lemma 11, it is not possible for both x and y to be essential for c unless $|G'(f', a)| = |G'(f', b)| = 1$. Thus, it suffices to consider the case $|G'(f', a)| = |G'(f', b)| = 1$.

Due to the 3-connectivity of G, x and y will each have at least two neighbours in $G'(f', c)$. We will show that one of y's neighbours w can be relabeled b, after which y can be relabeled a.

If Lemma 12 does not apply for the relabeling of w to b, then because w is not b-crucial, the only possible condition of Lemma 12 that can be violated is condition 2. Suppose that every neighbour of y in $G'(f', c)$ is a cut vertex. Since by Lemma 9, each leaf block in $G'(f', c)$ has two interior vertices that are endpoints of connecting edges, each of these edges must connect to x. By 3-connectivity, there must be three vertex-disjoint paths to y from an interior vertex in a leaf block in $G(f', c)$. As only one can pass through x and only one can pass through the joining vertex of the leaf block, there can only be two paths at most, forming a contradiction. Because all conditions of Lemma 12 must hold, we can relabel w to b.

To see that we can now relabel y to a, we observe that since $G'(f', c)$ was connected, z has a neighbour with label c. This implies that y is not essential for c, as needed to satisfy all conditions of Lemma 12. ◀

Finally, in Lemma 30, we show that for G' the graph formed by adding an edge xy to a 3-connected graph $G \in \text{host}(K_3)$, G' is also in $\text{host}(K_3)$. We achieve the result by showing that we can handle situations in which xy plays a role not played by any other edge, either as an essential edge or as a bridge within a branch set. The proof relies on the following results:

▶ **Lemma 28 (*).** *Given a 2-connected graph G and a K_3-model f of G, any branch set containing at least two vertices has no crucial vertex.*

▶ **Lemma 29.** *Given a 3-connected graph G and a K_3-model f of G, suppose that $x \in G(f, a)$, $y \in G(f, b)$, and xy is an essential edge. Then we can reconfigure f to a K_3-model g such that $g(v) \neq f(v)$ for each $v \in G(f, c)$, $c \notin \{a, b\}$, $g(u) = f(u)$ for all other vertices u, and xy is not an essential edge in g.*

Proof. We consider two cases, depending on whether or not $G(f, c)$ is 2-connected.

Case 1: $G(f, c)$ is not 2-connected.

By Lemma 9, each leaf block L in $G(f, c)$ has at least two interior vertices that are endpoints of connecting edges. Due to 3-connectivity, we can further show that each leaf block in $G(f, c)$ has edges to both $G(f, a)$ and $G(f, b)$, as otherwise the joining vertex of the leaf block and either x or y would form a cut set of size two separating internal vertices of the leaf block at one of the branch sets.

The fact that all other leaf blocks connect to both $G(f, a)$ and $G(f, b)$ ensure that f does not hit a leaf-crucial model on relabeling L. We can then use Lemma 19 to relabel all interior vertices of L. Due to the connectivity of L and the fact that it contained neighbours in both $G(f, a)$ and $G(f, b)$, it follows that xy is not an essential edge in the resulting model g.

Case 2: $G(f, c)$ is 2-connected.

We first use 3-connectivity to show that $|G(f, c)| > 1$ and that $G(f, c)$ contains vertices u and v such that u has a neighbour in $G(f, a)$ and v has a neighbour in $G(f, b)$. If $|G(f, c)| = 1$, then the vertex in $G(f, c)$ and either x or y form a cut set of size two separating the branch sets $G(f, a)$ and $G(f, b)$. Similarly, if $G(f, c)$ contained only a single endpoint of a connecting edge, then the endpoint and either x or y would also form a cut set of size two.

We can choose u and v such that P is a (u, v)-path in $G(f, c)$ such that no vertex in P other than u or v has a neighbour in $G(f, a)$ or $G(f, b)$. We let $u = v_1, \ldots, v_t = v$ be the

vertices of P with edges v_iv_{i+1}, $i \in \{1, \ldots, t\}$. Since G is 3-connected and xy is an essential edge, $G(f, c)$ must contain vertices $w \notin \{u, v\}$ and $z \notin \{u, v\}$ such that w has an edge to $G(f, a)$ and z has an edge to $G(f, b)$.

We will attempt to relabel all of P to label a. As $G(f, c)$ is 2-connected, we can relabel v_1 to a. If the resulting branch set is 2-connected, then we attempt relabel v_2,v_3, $\ldots$, v_t in that order until we relabel the entire path. If this succeeds, then we are done. Otherwise, at some step relabeling along the path we obtain a K_3 model g such that $G(g, c)$ is not 2-connected. Now we apply Case 1 to g to complete the claim. ◀

▶ **Lemma 30.** *Suppose G is a 3-connected graph such that $G \in host(K_3)$ and G' is formed from G adding an edge xy. Then $G' \in host(K_3)$.*

Proof. We first observe that any K_3-model of G is also K_3-model of G'. Consequently, to show that we can reconfigure between any K_3-models of G', it suffices to show that we can reconfigure between any K_3-model of G' and a K_3-model of G, as the fact that $G \in \text{host}(K_3)$ ensures that we can reconfigure between any two K_3-models of G.

There are only two cases in which a K_3-model f of G' is not a K_3-model of G, namely cases in which the role xy plays in the K_3-model is not played by any other edge. In both cases we can assume that $G' \neq G$, and consequently that $|V(G')| > 3$.

Case 1: xy is the essential edge connecting $G'(f, f(x))$ and $G'(f, f(y))$

Without loss of generality, we assume $f(x) = a$ and $f(y) = b$. By Lemma 29, we can reconfigure f to a K_3-model f' by relabeling only vertices in $G(f, c)$ such that xy is not an essential edge in f', which means f' is also a K_3-model of G.

Case 2: $f(x) = f(y)$ and xy is a bridge in $G'(f, f(x))$

We show that we can reconfigure to a model in which x and y have different labels so that xy is a connecting edge. Depending on whether xy is then an essential edge, we have either completed the reconfiguration or we have reduced the situation to Case 1.

Without loss of generality, we assume that $f(x) = f(y) = a$, and observe that the removal of xy separates $G'(f, a)$ into two components C_1 (containing x) and C_2 (containing y), each of which contains at least one leaf block.

By Lemma 9, each of the leaf blocks has two vertices with neighbours in $G'(f, b)$ or $G'(f, c)$. We will show that we can reconfigure to a K_3-model in which either C_1 or C_2 has no vertex with label a, so that xy is no longer a bridge.

Case 2a: One component has edges to both $G'(f, b)$ and $G'(f, c)$.

Without loss of generality, let C_1 have connecting edges to both $G'(f, b)$ and $G'(f, c)$. Then f does not hit a leaf-b-crucial model or a leaf-c-crucial model on relabeling C_2 because there are necessary connecting edges from C_1. Also, f does not hit a leaf-crucial model on relabeling C_2 because there are at least two vertices labeled a in each model in the reconfiguration sequence, and so by Lemma 28, there never exists a crucial vertex labeled a. Now by Lemma 20, since x is a cut vertex of $G'(f, a)$, we can relabel all the vertices of C_2, which ensures xy is a connecting edge.

Case 2b: One component has two edges to $G'(f, b)$ and one component has two edges to $G'(f, c)$.

Without loss of generality, let C_1 have connecting edges to $G'(f, b)$ and C_2 have connecting edges to $G'(f, c)$. Then f does not hit a leaf-c-crucial model on relabeling C_2 because C_1 has edges to $G'(f, b)$. Also, it follows from Lemma 28 that f does not hit a leaf-crucial model on relabeling C_2 because there are at least two vertices labeled a in each model in the reconfiguration sequence. Hence, by Lemma 20, since x is a cut vertex of $G'(f, a)$, we can relabel all the vertices of C_2, which ensures xy is a connecting edge. ◀

6 Characterizing host(K_4)

In order to use Ding and Qin's characterization in Theorem 4, we show that $C_6^2 \in \text{host}(K_4)$ (Lemma 32) and $K_5 \in \text{host}(K_4)$ (a special case of Lemma 33) and present analogues of Lemmas 27 and 30 (Lemmas 37 and 38), showing that host(K_4) is closed under the splitting of vertices or adding of edges for 4-connected graphs. The four results are sufficient to prove the following theorem:

▶ **Theorem 31 (*).** *Every 4-connected graph is in host(K_4), provided it is not in $\mathcal{L}$, where $\mathcal{L} = \{H : H$ is the line graph of an internally 4-connected cubic graph$\}$.*

The results establishing the base cases of the characterization are relatively straightforward. Lemma 32 makes use of various properties of the structure of C_6^2, most notably the fact that for each vertex v, there is a unique vertex $s(v)$ such that there is no edge between v and $s(v)$. As an immediate consequence, any four vertices form a 4-cycle, which permits the use of Theorem 21 for reconfiguration of part of the graph. Lemma 33, a generalization of $K_5 \in \text{host}(K_4)$, follows easily from the high connectivity of cliques.

▶ **Lemma 32 (*).** *C_6^2 is in host(K_4).*

▶ **Lemma 33 (*).** *For any $m > \ell$, $K_m \in$ host(K_ℓ).*

As essential edges can result from either the splitting of vertices or the adding of edges, Lemma 36 plays a crucial role in the proofs of both Lemma 37 and Lemma 38. The proof of Lemma 36 makes extensive use of Lemmas 11, 34, and 35 in covering all possible cases of weak connections among branch sets, where branch sets of size one are handled separately.

▶ **Lemma 34 (*).** *Given a 4-connected graph G and a K_4-model f of G such that for labels a, b, c, d there exist weak connections between branch sets with labels a and b, b and c, c and d, and d and a, then it is not possible to designate lynchpins such that the branch set with label a contains at loeast one vertex x that is not a lynchpin and the branch set with label d contains at least one vertex y that is not a lynchpin.*

▶ **Lemma 35.** *Given a 3-connected graph G and an K_4-model f of G, suppose xy is an essential edge and there exists an essential edge e from $G(f, f(y))$ to $G(f, f(z))$, $z \neq x$, such that y is not the endpoint of e. Then it is possible to reconfigure f to a model g in which $g(x) = g(y) = f(x)$, and for all $a \neq f(y)$, for $v \in G(f, a)$, $g(v) = f(v)$.*

Proof. Without loss of generality, we let $f(x) = a$, $f(y) = b$, and $f(z) = c$, so that there is an essential edge ess(b, c). We consider two cases, depending on whether or not y is a cut vertex.

When y is not a cut vertex, we verify that all conditions of Lemma 12 hold for relabeling y to a: condition 1 follows as $G(f, b)$ contains at least y and an endpoint v of ess(b, c), condition 2 follows by assumption, condition 3 follows from the existence of xy, and condition 4 follows

from the observation that if y is an a-crucial vertex, then it must be essential for d, which implies $\{y, z\}$ is a 2-cut in G, contradicting the fact that G is 3-connected.

If instead y is a cut vertex, by removing y we can break $T(G, f, b)$ into components such that one of the components C contains the endpoint of $\text{ess}(b, c)$. By Lemma 9, each leaf block of C must contain at least two vertices with neighbours in other branch sets, and hence C must contain an edge with a neighbour in $G(f, d)$. As C has all necessary connecting edges, we can apply Lemma 20 to siphon away the vertices in every other component $C' \neq C$. Consequently, y will no longer be a cut vertex, we can then relabel y to a, as needed. ◀

▶ **Lemma 36 (*).** *Suppose G is a 4-connected graph such that $G \in host(K_4)$, $|V(G)| \geq 5$, and xy is an essential edge under the K_4-model f. Then it is possible to reconfigure G to a K_4-model in which x and y have the same label.*

Lemma 37 follows the structure of the proof of Lemma 27, relying on Lemma 25 for the reconfiguring between K_4-models in which x and y have the same label and on Lemma 36 for the case in which xy is an essential edge. The two possible cases for Lemma 38 are xy being an essential edge (handled by Lemma 36) and xy being a bridge in a branch set.

▶ **Lemma 37 (*).** *Suppose G is a 4-connected graph such that $G \in host(K_4)$ and G' is a 4-connected graph formed from G by splitting a vertex v into vertices x and y. Then G' is in $host(K_4)$.*

▶ **Lemma 38 (*).** *Suppose G is a 4-connected graph such that $G \in host(K_4)$ and G' is formed from G adding an edge xy. Then $G' \in host(K_4)$.*

7 Conclusions and open questions

We have developed a toolkit for the reconfiguration of minors, and specific results for H-models of small cliques H. Our results imply an alternate definition of 2-connectivity, whereby a graph is 2-connected if and only if it is in host(K_2). Furthermore, we have shown that every 3-connected graph is in host(K_3) and that every 4-connected graph is in host(K_4), provided that it is not in $\mathcal{L}$, where $\mathcal{L} = \{H : H$ is the line graph of an internally 4-connected cubic graph$\}$.

It remains to be shown whether similar results can be obtained for larger cliques, or for other graphs H. As our results rely on characterizations of k-connected graphs, further work is likely to depend on further progress on such results.

As there are alternate ways of defining adjacency relations, further work is needed to determine which definitions are equivalent and for those that are not, what results can be obtained. In our work, we can view each label as a token; based on this viewpoint, the adjacency relation we have considered can be viewed as *Token relabeling (TR)*, changing the label of one vertex in G. Two other possibilities worthy of consideration are *Token sliding (TS)*, swapping the labels of two adjacent vertices in G, and *Token jumping (TJ)*, swapping the labels of any two vertices in G. Both TS [6] and TJ [7] are well-studied for other types of reconfiguration problems, many of which have unlabeled or distinctly labeled tokens. The use of TS instead of TR is instrumental in handling degree-one vertices in G, which otherwise can rarely be relabeled.

Moreover, it is worth considering an alternate formulation in which solutions are considered to be adjacent if one can be formed from another by reassigning labels to vertices according to some permutation on the labels.

Future directions for research include considering other ways of assessing the reconfiguration graph, such as determining its diameter or, in cases in which the reconfiguration graph

is connected, to form algorithms that determine whether there is a path between an input pair of solutions. It remains open how to characterize isolated vertices in the reconfiguration graph, known as *frozen configurations* [1].

Throughout the paper, we required every vertex of G to be a member of a branch set in an H-model. If instead we considered a subgraph of G, a solution might entail the labeling of a subset of the vertices of G. We observe that when the number of labels is equal to the number of vertices in H, the problem is reduced subgraph isomorphism [5]. Alternative mappings can be considered as well, such as topological embedding of one graph in another.

Abstract

We prove a weighted Feferman-Vaught decomposition theorem for disjoint unions and products of finite structures. The classical Feferman-Vaught Theorem describes how the evaluation of a first order sentence in a generalized product of relational structures can be reduced to the evaluation of sentences in the contributing structures and the index structure. The logic we employ for our weighted extension is based on the weighted MSO logic introduced by Droste and Gastin to obtain a Büchi-type result for weighted automata. We show that for disjoint unions and products of structures, the evaluation of formulas from two respective fragments of the logic can be reduced to the evaluation of formulas in the contributing structures. We also prove that the respective restrictions are necessary. Surprisingly, for the case of disjoint unions, the fragment is the same as the one used in the Büchi-type result of weighted automata. In fact, even the formulas used to show that the respective restrictions are necessary are the same in both cases. However, here proving that they do not allow for a Feferman-Vaught-like decomposition is more complex and employs Ramsey's Theorem. We also show how translation schemes can be applied to go beyond disjoint unions and products.

1 Introduction

The Feferman-Vaught Theorem [6] is one of the fundamental theorems in model theory. The theorem describes how the computation of the truth value of a first order sentence in a generalized product of relational structures can be reduced to the computation of truth values of first order sentences in the contributing structures and the evaluation of a monadic second order sentence in the index structure. The theorem itself has a long-standing history. It builds upon work of Mostowski [17], and was later shown to hold true for monadic second order logic (MSO logic) as well [5, 8, 9, 12, 21]. For a survey and more background information, see [13].

In this paper, we show that under appropriate assumptions, the Feferman-Vaught Theorem also holds true for a weighted MSO logic with arbitrary commutative semirings as weight structure. The logic we employ is based on the weighted logic by Droste and Gastin [3]. In this logic, formulas can take values which convey a quantitative meaning. The logic's connectives and quantifiers hence also adopt quantitative roles. The disjunction becomes a sum, the conjunction a product. The existential quantifier, instead of only checking whether some element with a certain property exists, now takes the truth value of this property for every element in the universe and sums over these values. Under appropriate assumptions, the result of this summation can for instance be the exact number of elements that satisfy the given property. One example of a property which can be expressed using this logic is the number of cliques of a given size in an undirected graph. In [3], the authors prove a Büchi-like result for a specific fragment of the MSO logic, showing that for finite and infinite words, this fragment is expressively equivalent to semiring-weighted automata [20]. The study of a weighted Feferman-Vaught Theorem for disjoint unions, employing the same logic as we do, was initiated by Ravve et al. in [19], where the authors also point out several algorithmic uses and possible applications of a weighted Feferman-Vaught Theorem.

The classical Feferman-Vaught Theorem considers finite and infinite structures without any need for distinction between them. This results from the fact that, in the Boolean setting, infinite joins and meets are well-defined. In particular, existential and universal quantification, which are essentially joins and meets ranging over the whole universe of a structure, are well-defined for finite and infinite structures alike. However, for arbitrary semirings, infinite sums and products are usually not defined. For lack of space, here we consider only finite structures and finite disjoint unions and products of these structures. We note that an extension to infinite structures is possible by employing *bicomplete* semirings. Bicomplete semirings are equipped with infinite sum and product operations that naturally extend their respective finite operations. Our main results are the following.

- We provide a Feferman-Vaught Theorem for disjoint unions of structures with our weighted MSO logic, where the first order product quantifier is restricted to quantify only over formulas which do not contain any sum or product quantifier themselves. Surprisingly, this restriction and the resulting fragment are the same as the one working for the Büchi-like result of [3].
- We show that no similar theorem can hold for disjoint unions if the first order product quantifier is not restricted. The formulas we employ for this in fact also occurred in [3] and [4] as examples of weighted formulas whose semantics could not be described by weighted automata. While in these papers, it was elementary to show that the formulas given define weighted languages not recognizable by weighted automata, here proving that they do not allow for a Feferman-Vaught-like decomposition is more complex and employs a weak version of Ramsey's Theorem [18].
- We show that a Feferman-Vaught Theorem also holds for products of structures for the product-quantifier-free first order fragment of our logic.
- We show that no similar theorem can hold for products if we include the first order product quantifier.
- We show that our theorems are also true for more general disjoint unions and products defined by *translation schemes* [13, 22, 2].

With respect to our proofs, here we just note that in comparison to the universal quantifier of the Boolean setting, the product quantifier requires a separate and new consideration. While universal quantification can simply be expressed using negation and existential quantification, it is in general not possible to express multiplication by addition.

Translation schemes are a model theoretic tool to "translate" structures over one logical signature into structures over another signature in a well behaved fashion, namely in an MSO-defined fashion. They can be applied, for example, to translate between *texts* and *trees* [11], and between *nested words*, *alternating texts*, and *hedges* [16]. These particular translations were employed in [15, 14, 16] to prove that weighted automata over texts, hedges, and nested words are expressively equivalent to weighted logics over these structures. Translation schemes are a rather natural concept and therefore they have been frequently rediscovered and named differently [13, 22, 2]. Our notion of a translation scheme is mostly due to [13].

Related work. A concept related to weighted logics is that of many-valued logics. In both models the evaluation of a formula on a structure produces a quantitative piece of information. In many approaches to many-valued logics, values are taken in the interval $[0, 1]$, cf. [10, 7]. In contrast to this, weights in weighted logics are taken from a semiring and may occur as atomic formulas which enables the modeling of quantitative properties.

2 Preliminaries

Let $\mathbb{N} = \{1, 2, \ldots\}$ and $\mathbb{N}_0 = \mathbb{N} \cup \{0\}$. A *signature* σ is a pair $(\mathrm{Rel}_\sigma, \mathrm{ar}_\sigma)$ where Rel_σ is a set of relation symbols and $\mathrm{ar}_\sigma \colon \mathrm{Rel}_\sigma \to \mathbb{N}$ the arity function. A *σ-structure* $\mathfrak{A}$ is a pair $(\mathcal{U}_\mathfrak{A}, \mathcal{I}_\mathfrak{A})$ where $\mathcal{U}_\mathfrak{A}$ is a set, called the *universe of* $\mathfrak{A}$, and $\mathcal{I}_\mathfrak{A}$ is an *interpretation*, which maps every $R \in \mathrm{Rel}_\sigma$ to a set $R^\mathfrak{A} \subseteq \mathcal{U}_\mathfrak{A}^{\mathrm{ar}_\sigma(R)}$. A structure is called *finite* if its universe is a finite set. By $\mathrm{Str}(\sigma)$ we denote the class of all σ-structures.

For two σ-structures $\mathfrak{A} = (A, \mathcal{I}_\mathfrak{A})$ and $\mathfrak{B} = (B, \mathcal{I}_\mathfrak{B})$, we define the *product* $\mathfrak{A} \times \mathfrak{B} \in \mathrm{Str}(\sigma)$ *of* $\mathfrak{A}$ *and* $\mathfrak{B}$ and the *disjoint union* $\mathfrak{A} \sqcup \mathfrak{B} \in \mathrm{Str}(\sigma)$ *of* $\mathfrak{A}$ *and* $\mathfrak{B}$ as follows. For the product we let $\mathfrak{A} \times \mathfrak{B} = (A \times B, \mathcal{I}_{\mathfrak{A}\times\mathfrak{B}})$ with $R^{\mathfrak{A}\times\mathfrak{B}} = \{((a_1, b_1), \ldots, (a_k, b_k)) \mid (a_1, \ldots, a_k) \in R^\mathfrak{A} \text{ and } (b_1, \ldots, b_k) \in R^\mathfrak{B}\}$. For the disjoint union, let $A \sqcup B$ be the disjoint union (i.e., the set theoretic coproduct) of A and B with inclusions ι_A and ι_B. Then $\mathfrak{A} \sqcup \mathfrak{B} = (A \sqcup B, \mathcal{I}_{\mathfrak{A}\sqcup\mathfrak{B}})$ with $R^{\mathfrak{A}\sqcup\mathfrak{B}} = \{(\iota_A(a_1), \ldots, \iota_A(a_k)) \mid (a_1, \ldots, a_k) \in R^\mathfrak{A}\} \cup \{(\iota_B(b_1), \ldots, \iota_A(b_k)) \mid (b_1, \ldots, b_k) \in R^\mathfrak{B}\}$. Throughout the paper, we identify $a \in A$ with $\iota_A(a) \in A \sqcup B$ and $b \in B$ with $\iota_B(b) \in A \sqcup B$.

A *commutative semiring* is a tuple $(S, +, \cdot, \mathbb{0}, \mathbb{1})$, abbreviated by S, with operations sum $+$ and product $\cdot$ and constants $\mathbb{0}$ and $\mathbb{1}$ such that $(S, +, \mathbb{0})$ and $(S, \cdot, \mathbb{1})$ are commutative monoids, multiplication distributes over addition, and $s \cdot \mathbb{0} = \mathbb{0}$ for every $s \in S$.

The following definitions are due to [3] in the form of [1]. We provide a countable set $\mathcal{V}$ of first and second order variables, where lower case letters like x and y denote first order variables and capital letters like X and Y denote second order variables. We define monadic second order formulas β over σ and weighted monadic second order formulas φ over σ and S through

$$\beta ::= \mathtt{false} \mid R(x_1, \ldots, x_n) \mid x \in X \mid \neg\beta \mid \beta \vee \beta \mid \exists x.\beta \mid \exists X.\beta$$
$$\varphi ::= \beta \mid s \mid \varphi \oplus \varphi \mid \varphi \otimes \varphi \mid \bigoplus x.\varphi \mid \bigotimes x.\varphi \mid \bigoplus X.\varphi \mid \bigotimes X.\varphi,$$

with $R \in \mathrm{Rel}_\sigma$, $n = \mathrm{ar}_\sigma(R)$, $x, x_1, \ldots, x_n \in \mathcal{V}$ first order variables, $X \in \mathcal{V}$ a second order variable and $s \in S$. We also allow the usual abbreviations $\wedge$, $\forall$, $\to$, $\longleftrightarrow$ and $\mathtt{true}$. By $\mathrm{MSO}(\sigma)$ and $\mathrm{wMSO}(\sigma, S)$ we denote the sets of all monadic second order formulas over σ and all weighted monadic second order formulas over σ and S, respectively. The sets of first order formulas $\mathrm{FO}(\sigma)$ and weighted first order formulas $\mathrm{wFO}(\sigma, S)$ are defined as the sets of all formulas from $\mathrm{MSO}(\sigma)$ and $\mathrm{wMSO}(\sigma, S)$, respectively, which do not contain any subformulas of the form $x \in X$, $\exists X.\beta$, $\bigoplus X.\varphi$ and $\bigotimes X.\varphi$.

The notion of *free variables* is defined as usual, i.e., the operators $\exists, \forall, \bigoplus$ and $\bigotimes$ bind variables. We let $\mathrm{Free}(\varphi)$ be the set of all free variables of φ. A formula φ with $\mathrm{Free}(\varphi) = \emptyset$ is called a *sentence*. For a vector $\bar{\varphi} = (\varphi_1, \dots, \varphi_n) \in \mathrm{wMSO}(\sigma, S)^n$, we define the set of free variables of $\bar{\varphi}$ as $\mathrm{Free}(\bar{\varphi}) = \bigcup_{i=1}^{n} \mathrm{Free}(\varphi_i)$.

We now define the semantics of MSO and wMSO. Let σ be a signature, $\mathfrak{A} = (A, \mathcal{I}_{\mathfrak{A}})$ a σ-structure and $\mathcal{V}$ a set of first and second order variables. A $(\mathcal{V}, \mathfrak{A})$-assignment ρ is a partial function $\rho\colon \mathcal{V} \nrightarrow A \cup \mathcal{P}(A)$ such that, whenever $x \in \mathcal{V}$ is a first order variable and $\rho(x)$ is defined, we have $\rho(x) \in A$, and whenever $X \in \mathcal{V}$ is a second order variable and $\rho(X)$ is defined, we have $\rho(X) \subseteq A$. The reason we consider partial functions is that in our Feferman-Vaught theorems for the disjoint union of structures we want to be able to restrict the range of a variable assignment to a subset of the universe. For a first order variable, this restriction may cause the variable to become undefined. Let $\mathrm{dom}(\rho)$ be the domain of ρ. For a first order variable $x \in \mathcal{V}$ and an element $a \in A$, the *update* $\rho[x \to a]$ is defined through $\mathrm{dom}(\rho[x \to a]) = \mathrm{dom}(\rho) \cup \{x\}$, $\rho[x \to a](\mathcal{X}) = \rho(\mathcal{X})$ for all $\mathcal{X} \in \mathcal{V} \setminus \{x\}$ and $\rho[x \to a](x) = a$. For a second order variable $X \in \mathcal{V}$ and a set $I \subseteq A$, the update $\rho[X \to I]$ is defined in a similar fashion. By $\mathfrak{A}_{\mathcal{V}}$ we denote the set of all $(\mathcal{V}, \mathfrak{A})$-assignments.

For $\rho \in \mathfrak{A}_{\mathcal{V}}$ and a formula $\beta \in \mathrm{MSO}(\sigma)$ the relation "$(\mathfrak{A}, \rho)$ satisfies β", denoted by $(\mathfrak{A}, \rho) \models \beta$, is defined as usual, with the minor addition that $(\mathfrak{A}, \rho)$ can satisfy $x \in X$ and $R(x_1, \dots, x_n)$ only if all of the occurring variables are in $\mathrm{dom}(\rho)$. In the following, for all sums and products to be well-defined, we assume that A is finite. For a formula $\varphi \in \mathrm{wMSO}(\sigma, S)$ and a structure $\mathfrak{A} \in \mathrm{Str}(\sigma)$, the *(weighted) semantics* of φ is a mapping $[\![\varphi]\!](\mathfrak{A}, \cdot)\colon \mathfrak{A}_{\mathcal{V}} \to S$ inductively defined as

$$
\begin{aligned}
[\![\beta]\!](\mathfrak{A}, \rho) &= \begin{cases} \mathbb{1} & \text{if } (\mathfrak{A}, \rho) \models \beta \\ \mathbb{0} & \text{otherwise} \end{cases} \\
[\![s]\!](\mathfrak{A}, \rho) &= s \\
[\![\varphi_1 \oplus \varphi_2]\!](\mathfrak{A}, \rho) &= [\![\varphi_1]\!](\mathfrak{A}, \rho) + [\![\varphi_2]\!](\mathfrak{A}, \rho) \\
[\![\varphi_1 \otimes \varphi_2]\!](\mathfrak{A}, \rho) &= [\![\varphi_1]\!](\mathfrak{A}, \rho) \cdot [\![\varphi_2]\!](\mathfrak{A}, \rho)
\end{aligned}
\qquad
\begin{aligned}
[\![\textstyle\bigoplus x.\varphi]\!](\mathfrak{A}, \rho) &= \textstyle\sum_{a \in A} [\![\varphi]\!](\mathfrak{A}, \rho[x \to a]) \\
[\![\textstyle\bigotimes x.\varphi]\!](\mathfrak{A}, \rho) &= \textstyle\prod_{a \in A} [\![\varphi]\!](\mathfrak{A}, \rho[x \to a]) \\
[\![\textstyle\bigoplus X.\varphi]\!](\mathfrak{A}, \rho) &= \textstyle\sum_{I \subseteq A} [\![\varphi]\!](\mathfrak{A}, \rho[X \to I]) \\
[\![\textstyle\bigotimes X.\varphi]\!](\mathfrak{A}, \rho) &= \textstyle\prod_{I \subseteq A} [\![\varphi]\!](\mathfrak{A}, \rho[X \to I]).
\end{aligned}
$$

We will usually identify a pair $(\mathfrak{A}, \emptyset)$ with $\mathfrak{A}$. For a vector of formulas $\bar{\varphi} \in \mathrm{wMSO}(\sigma, S)^n$, we define $[\![\bar{\varphi}]\!](\mathfrak{A}, \rho) = ([\![\varphi_1]\!](\mathfrak{A}, \rho), \dots, [\![\varphi_n]\!](\mathfrak{A}, \rho)) \in S^n$.

We give some examples of how weighted formulas can be interpreted. For more examples, see also [19].

▶ **Example 1.** If $S = \mathbb{B}$ is the Boolean semiring, we obtain the classical Boolean logic.

▶ **Example 2.** Assume that $S = (\mathbb{Q}, +, \cdot, 0, 1)$ is the field of rational numbers and that σ is the signature of an (undirected) graph, i.e., $\mathrm{Rel}_\sigma = \{\mathrm{edge}\}$ with edge binary. Then for every fixed $n \in \mathbb{N}$, we can count the number of n-cliques of a graph with no loops $\mathfrak{G} \in \mathrm{Str}(\sigma)$ using the formula $\varphi = \frac{1}{n!} \otimes \bigoplus x_1 \dots \bigoplus x_n . \bigwedge_{i \neq j} (\mathrm{edge}(x_i, x_j) \vee \mathrm{edge}(x_j, x_i))$.

▶ **Example 3.** We consider the *minimum cut* of directed acyclic graphs. For this, we interpret these graphs as *flow networks* in the following way. Every vertex which does not have a predecessor is considered a *source*, every vertex without successors is considered a *drain*, and every edge is assumed to have a capacity of 1. Let $G = (V, E)$ be a directed acyclic graph where V is the set of vertices and $E \subseteq V \times V$ the set of edges. A cut (S, D) of G is a partition of V, i.e., $S \cup D = V$ and $S \cap D = \emptyset$, such that all sources of G are in S, and all drains of G are in D. The *minimum cut* of G is the smallest number $|E \cap (S \times D)|$ such that (S, D) is a cut of G.

We can express the minimum cut of directed acyclic graphs by a weighted formula as follows. We let σ be the signature from the previous example and this time interpret it as the signature of a directed graph. For our semiring, we choose the tropical semiring $\mathrm{Trop} = (\mathbb{R}_{\geq 0} \cup \{\infty\}, \min, +, \infty, 0)$. Then using the abbreviation

$$\mathrm{cut}(X,Y) = \forall x.\Big((x \in X \leftrightarrow \neg(x \in Y)) \wedge (\exists y.\mathrm{edge}(y,x) \vee x \in X) \wedge (\exists y.\mathrm{edge}(x,y) \vee x \in Y)\Big)$$

we can express the minimum cut of a directed acyclic graph $\mathfrak{G} \in \mathrm{Str}(\sigma)$ using the formula

$$\varphi = \bigoplus X.\bigoplus Y.\Big(\mathrm{cut}(X,Y) \otimes \bigotimes x.\bigotimes y.(1 \oplus \neg(x \in X \wedge y \in Y \wedge \mathrm{edge}(x,y)))\Big).$$

For $\varphi \in \mathrm{wMSO}(\sigma, S)$ and a first order variable x which does not appear in φ as a bound variable, we define φ^{-x} as the formula obtained from φ by replacing all atomic subformulas containing x, i.e., all subformulas of the form $x \in X$ and $R(\ldots, x, \ldots)$ for $R \in \mathrm{Rel}_\sigma$, by `false`. It is easy to show by induction that for all σ-structures $\mathfrak{A} = (A, \mathcal{I}_\mathfrak{A})$ and $(\mathcal{V}, \mathfrak{A})$-assignments ρ with $x \notin \mathrm{dom}(\rho)$ we have $[\![\varphi]\!](\mathfrak{A}, \rho) = [\![\varphi^{-x}]\!](\mathfrak{A}, \rho)$. As in the sequel we will deal with disjoint unions and products of structures, we need to define the restrictions of a variable assignment to the contributing structures of the disjoint union or product. Fix two structures $\mathfrak{A}, \mathfrak{B} \in \mathrm{Str}(\sigma)$ with universes A and B. For a $(\mathcal{V}, \mathfrak{A} \sqcup \mathfrak{B})$-assignment ρ, we define the restriction $\rho|_\mathfrak{A} \colon \mathcal{V} \rightharpoonup A$ as

$$\rho|_\mathfrak{A}(\mathcal{X}) = \begin{cases} \rho(\mathcal{X}) \cap A & \text{if } \mathcal{X} \text{ is a second order variable} \\ \rho(\mathcal{X}) & \text{if } \mathcal{X} \text{ is a first order variable and } \rho(\mathcal{X}) \in A \\ \text{undefined} & \text{if } \mathcal{X} \text{ is a first order variable and } \rho(\mathcal{X}) \notin A. \end{cases}$$

The restriction $\rho|_\mathfrak{B}$ is defined similarly.

For a $(\mathcal{V}, \mathfrak{A} \times \mathfrak{B})$-assignment ρ, we define the restrictions $\rho|_\mathfrak{A}$ and $\rho|_\mathfrak{B}$ by projection on the corresponding entries. That is, we let π_A be the projection on the first and π_B be the projection on the second entry of $A \times B$ and let $\rho|_\mathfrak{A} = \pi_A \circ \rho$ and $\rho|_\mathfrak{B} = \pi_B \circ \rho$.

The *union* of two assignments ρ and ς with $\mathrm{dom}(\rho) \cap \mathrm{dom}(\varsigma) = \emptyset$, denoted by $\rho \cup \varsigma$, is defined by $\mathrm{dom}(\rho \cup \varsigma) = \mathrm{dom}(\rho) \cup \mathrm{dom}(\varsigma)$, $(\rho \cup \varsigma)(\mathcal{X}) = \rho(\mathcal{X})$ for $\mathcal{X} \in \mathrm{dom}(\rho)$ and $(\rho \cup \varsigma)(\mathcal{X}) = \varsigma(\mathcal{X})$ for $\mathcal{X} \in \mathrm{dom}(\varsigma)$.

Fix two disjoint sets of variables $(x_i)_{i \in \mathbb{N}}$ and $(y_i)_{i \in \mathbb{N}}$. For $n \in \mathbb{N}$ we define the set of *expressions* $\mathrm{Exp}_n(S)$ over a semiring S by the grammar

$$E ::= x_i \mid y_i \mid E \oplus E \mid E \otimes E,$$

where $i \in \{1, \ldots, n\}$. The *(weighted) semantics* of an expression $E \in \mathrm{Exp}_n(S)$ is a mapping $\langle\!\langle E \rangle\!\rangle \colon S^n \times S^n \to S$ defined for $\bar{s}, \bar{t} \in S^n$ inductively by

$$\langle\!\langle x_i \rangle\!\rangle(\bar{s}, \bar{t}) = s_i \qquad \langle\!\langle E_1 \oplus E_2 \rangle\!\rangle(\bar{s}, \bar{t}) = \langle\!\langle E_1 \rangle\!\rangle(\bar{s}, \bar{t}) + \langle\!\langle E_2 \rangle\!\rangle(\bar{s}, \bar{t})$$
$$\langle\!\langle y_i \rangle\!\rangle(\bar{s}, \bar{t}) = t_i \qquad \langle\!\langle E_1 \otimes E_2 \rangle\!\rangle(\bar{s}, \bar{t}) = \langle\!\langle E_1 \rangle\!\rangle(\bar{s}, \bar{t}) \cdot \langle\!\langle E_2 \rangle\!\rangle(\bar{s}, \bar{t}).$$

For expressions over the Boolean semiring $\mathbb{B} = (\{\mathtt{false}, \mathtt{true}\}, \vee, \wedge, \mathtt{false}, \mathtt{true})$ we will usually write $\vee$ instead of $\oplus$ and $\wedge$ instead of $\otimes$.

▶ **Construction 4.** We call an expression $E \in \mathrm{Exp}_n(S)$ a *pure product* if

$$E = \mathrm{x}_1 \otimes \ldots \otimes \mathrm{x}_l \otimes \mathrm{y}_1 \otimes \ldots \otimes \mathrm{y}_m$$

with $\mathrm{x}_i \in \{x_1, \ldots, x_n\}$ for $i \in \{1, \ldots, l\}$ and $\mathrm{y}_j \in \{y_1, \ldots, y_n\}$ for $j \in \{1, \ldots, m\}$. We define a substitution procedure as follows. Let $\bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^{2} \in \mathrm{wMSO}(\sigma, S)^n$ be given. Let $i \in \{1, \ldots, l\}$ and assume $\mathrm{x}_i = x_k$ for some k, then we define $\xi_i = \varphi_k^{\mathbb{1}}$. Likewise, for $j \in \{1, \ldots, m\}$ and $\mathrm{y}_j = y_k$, we define $\theta_j = \varphi_k^{2}$. We let $\xi = \xi_1 \otimes \ldots \otimes \xi_l$ and $\theta = \theta_1 \otimes \ldots \otimes \theta_m$. Then for $\mathfrak{A}, \mathfrak{B} \in \mathrm{Str}(\sigma)$, every $(\mathcal{V}, \mathfrak{A})$-assignment ρ and every $(\mathcal{V}, \mathfrak{B})$-assignment ς we have

$$\langle\!\langle E \rangle\!\rangle([\![\bar{\varphi}^{\mathbb{1}}]\!](\mathfrak{A}, \rho), [\![\bar{\varphi}^{2}]\!](\mathfrak{B}, \varsigma)) = [\![\xi]\!](\mathfrak{A}, \rho) \cdot [\![\theta]\!](\mathfrak{B}, \varsigma).$$

We define $\mathrm{PRD}^{\mathbb{1}}(E, \bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^{2}) = \xi$ and $\mathrm{PRD}^{2}(E, \bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^{2}) = \theta$.

Pure products $B \in \mathrm{Exp}_n(\mathbb{B})$ are also called *pure conjunctions*. For a pure conjunction $B \in \mathrm{Exp}_n(\mathbb{B})$, formulas $\bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^{2} \in \mathrm{MSO}(\sigma)$ and ξ_i, θ_j as above, we define the $\mathrm{MSO}(\sigma)$-formulas $\mathrm{CON}^{\mathbb{1}}(B, \bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^{2}) = \xi = \xi_1 \wedge \ldots \wedge \xi_l$ and $\mathrm{CON}^{2}(B, \bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^{2}) = \theta = \theta_1 \wedge \ldots \wedge \theta_m$. We then have

$$\langle\!\langle B \rangle\!\rangle([\![\bar{\varphi}^{\mathbb{1}}]\!](\mathfrak{A}, \rho), [\![\bar{\varphi}^{2}]\!](\mathfrak{B}, \varsigma)) = \mathtt{true} \text{ iff } (\mathfrak{A}, \rho) \models \xi \text{ and } (\mathfrak{B}, \varsigma) \models \theta. \qquad \lozenge$$

We say that an expression $E \in \mathrm{Exp}_n(S)$ is in *normal form* if $E = E_1 \oplus \ldots \oplus E_m$ for some $m \geq 1$ and pure products E_i. By applying the laws of distributivity of the semiring S, every expression $E \in \mathrm{Exp}_n(S)$ can be transformed into normal form. More precisely, we have the following lemma.

▶ **Lemma 5.** *For every $E \in \mathrm{Exp}_n(S)$ there exists an expression $E' \in \mathrm{Exp}_n(S)$ in normal form with the same semantics as E.*

3 The classical Feferman-Vaught Theorem

For convenience, we recall the Feferman-Vaught Theorem for disjoint unions and products of two structures. Let σ be a signature.

▶ **Theorem 6** ([6])**.** *Let $\mathcal{V}$ be a set of first and second order variables and $\beta \in \mathrm{MSO}(\sigma)$ with variables from $\mathcal{V}$. Then there exist $n \geq 1$, vectors of formulas $\bar{\beta}^{\mathbb{1}}, \bar{\beta}^{2} \in \mathrm{MSO}(\sigma)^n$ and an expression $B_\beta \in \mathrm{Exp}_n(\mathbb{B})$ such that $\mathrm{Free}(\bar{\beta}^{\mathbb{1}}) \cup \mathrm{Free}(\bar{\beta}^{2}) \subseteq \mathrm{Free}(\beta)$ and for all structures $\mathfrak{A}, \mathfrak{B} \in \mathrm{Str}(\sigma)$ and all $(\mathcal{V}, \mathfrak{A} \sqcup \mathfrak{B})$-assignments ρ:*

$$(\mathfrak{A} \sqcup \mathfrak{B}, \rho) \models \beta \text{ iff } \langle\!\langle B_\beta \rangle\!\rangle([\![\bar{\beta}^{\mathbb{1}}]\!](\mathfrak{A}, \rho|_{\mathfrak{A}}), [\![\bar{\beta}^{2}]\!](\mathfrak{B}, \rho|_{\mathfrak{B}})) = \mathtt{true}.$$

▶ **Theorem 7** ([6])**.** *Let $\mathcal{V}$ be a set of first and second order variables and $\beta \in \mathrm{FO}(\sigma)$ with variables from $\mathcal{V}$. Then there exist $n \geq 1$, vectors of formulas $\bar{\beta}^{\mathbb{1}}, \bar{\beta}^{2} \in \mathrm{FO}(\sigma)^n$ and an expression $B_\beta \in \mathrm{Exp}_n(\mathbb{B})$ such that $\mathrm{Free}(\bar{\beta}^{\mathbb{1}}) \cup \mathrm{Free}(\bar{\beta}^{2}) \subseteq \mathrm{Free}(\beta)$ and for all structures $\mathfrak{A}, \mathfrak{B} \in \mathrm{Str}(\sigma)$ and all $(\mathcal{V}, \mathfrak{A} \times \mathfrak{B})$-assignments ρ:*

$$(\mathfrak{A} \times \mathfrak{B}, \rho) \models \beta \text{ iff } \langle\!\langle B_\beta \rangle\!\rangle([\![\bar{\beta}^{\mathbb{1}}]\!](\mathfrak{A}, \rho|_{\mathfrak{A}}), [\![\bar{\beta}^{2}]\!](\mathfrak{B}, \rho|_{\mathfrak{B}})) = \mathtt{true}.$$

4 Translation schemes

Theorems 6 and 7 consider disjoint unions and products only. So far, there is no interaction between the two constituting structures. *Translation schemes* allow us to create such interactions in an MSO-defined manner. More precisely, translation schemes "translate" structures over one signature into structures over another signature. Applying this to disjoint unions and products, we can extend Theorems 6 and 7 to more complex constructs. The usefulness of such extensions by translation schemes was discussed in [13], which we follow here.

Let σ and τ be two signatures, $\mathcal{Z} = \{z, z_1, z_2, \ldots\}$ be a set of distinguished first order variables and $\mathcal{W}$ be a set of first and second order variables with $\mathcal{W} \cap \mathcal{Z} = \emptyset$. A *$\sigma$-$\tau$-translation scheme Φ over $\mathcal{W}$ and $\mathcal{Z}$* is a pair $(\phi_\mathcal{U}, (\phi_T)_{T\in\mathrm{Rel}_\tau})$ where $\phi_\mathcal{U}, \phi_T \in \mathrm{MSO}(\sigma)$, $\phi_\mathcal{U}$ has variables from $\mathcal{W} \cup \{z\}$ and ϕ_T has variables from $\mathcal{W} \cup \{z_1, \ldots, z_{\mathrm{ar}_\tau(T)}\}$. The variables from $\mathcal{Z}$ may not be used for quantification, i.e., all variables from $\mathcal{Z}$ must be free. We set $\mathrm{Free}(\Phi) = \mathrm{Free}(\phi_\mathcal{U}) \cup \bigcup_{T\in\mathrm{Rel}_\tau} \mathrm{Free}(\phi_T)$. The formulas $\phi_\mathcal{U}$ and $(\phi_T)_{T\in\mathrm{Rel}_\tau}$ depend on $\mathcal{Z}$ in the following way. For a first order variable x not occurring in $\phi_\mathcal{U}$, the formula $\phi_\mathcal{U}(x)$ is obtained from $\phi_\mathcal{U}$ by replacing all occurrences of z by x. Similarly, for $T \in \mathrm{Rel}_\tau$ and first order variables $x_1, \ldots, x_{\mathrm{ar}_\tau(T)}$ not occurring in ϕ_T, the formula $\phi_T(x_1, \ldots, x_{\mathrm{ar}_\tau(T)})$ is obtained from ϕ_T by replacing all occurrences of z_i by x_i for $i \in \{1, \ldots, \mathrm{ar}_\tau(T)\}$.

For a σ-structure $\mathfrak{A} = (A, \mathcal{I}_\mathfrak{A})$ and a $(\mathcal{W}, \mathfrak{A})$-assignment ς, we define the *Φ-induced τ-structure of $\mathfrak{A}$ and ς*, denoted by $\Phi^\star(\mathfrak{A}, \varsigma)$, as a τ-structure with universe $\mathcal{U}_\mathfrak{C}$ and interpretation $\mathcal{I}_\mathfrak{C}$ as follows.

$$\mathcal{U}_\mathfrak{C} = \{a \in A \mid (\mathfrak{A}, \varsigma[z \to a]) \models \phi_\mathcal{U}\} \qquad \mathcal{I}_\mathfrak{C}(T) = \{\bar{c} \in \mathcal{U}_\mathfrak{C}^{\mathrm{ar}_\tau(T)} \mid (\mathfrak{A}, \varsigma[\bar{z} \to \bar{c}]) \models \phi_T\}$$

▶ **Example 8.** A translation scheme can be used to cut a subtree from a given tree at a specified node in the tree. For this let $\sigma = \tau = (\{\mathrm{edge}\}, \mathrm{edge} \mapsto 2)$ be the signature of a directed graph. For a σ-structure $\mathfrak{G} = (V, \mathrm{edge} \mapsto E)$ let E' be the transitive closure of the relation $E \subseteq V \times V$. We say that $\mathfrak{G}$ is a directed rooted tree with root $r \in V$ if (1) E' is irreflexive, (2) $(r, v) \in E'$ for all $v \in V \setminus \{r\}$ and (3) for all $v \in V \setminus \{r\}$ there is exactly one $v' \in V$ with $(v', v) \in E$. We define the following abbreviation which describes the reflexive transitive closure of E.

$$(x \leq y) = \forall X\, (x \in X \wedge (\forall z.(\exists z'.z' \in X \wedge \mathrm{edge}(z', z)) \to z \in X)) \to y \in X$$

We define a σ-σ-translation scheme $\Phi = (\phi_\mathcal{U}, \phi_\mathrm{edge})$ through $\phi_\mathcal{U} = (x \leq z)$ and $\phi_\mathrm{edge} = \mathrm{edge}(z_1, z_2)$. Then with $\mathfrak{G}$ as above and $v \in V$, the structure $\mathfrak{C} = \Phi^*(\mathfrak{G}, x \mapsto v)$ is the subtree of $\mathfrak{G}$ at the node v, i.e.,

$$\mathcal{U}_\mathfrak{C} = \{v\} \cup \{v' \in V \mid (v, v') \in E'\} \qquad \mathcal{I}_\mathfrak{C} = E \cap (\mathcal{U}_\mathfrak{C} \times \mathcal{U}_\mathfrak{C}).$$

We have the following fundamental property of translation schemes [13].

▶ **Lemma 9** ([13]). *Let $\Phi = (\phi_\mathcal{U}, (\phi_T)_{T\in\mathrm{Rel}_\tau})$ be a σ-τ-translation scheme over $\mathcal{W}$ and $\mathcal{Z}$, $\mathcal{V}$ be a set of first and second order variables such that $\mathcal{V}$, $\mathcal{W}$, and $\mathcal{Z}$ are pairwise disjoint, and $\beta \in \mathrm{MSO}(\tau)$ with variables from $\mathcal{V}$. Then there exists a formula $\alpha \in \mathrm{MSO}(\sigma)$ such that $\mathrm{Free}(\alpha) \subseteq \mathrm{Free}(\beta) \cup \mathrm{Free}(\Phi)$ and for all structures $\mathfrak{A} \in \mathrm{Str}(\sigma)$, all $(\mathcal{W}, \mathfrak{A})$-assignments ς and all $(\mathcal{V}, \Phi^\star(\mathfrak{A}, \varsigma))$-assignments ρ:*

$$(\Phi^\star(\mathfrak{A}, \varsigma), \rho) \models \beta \text{ iff } (\mathfrak{A}, \varsigma \cup \rho) \models \alpha.$$

Together with Theorems 6 and 7, this gives us the following Feferman-Vaught decomposition theorems for disjoint unions and products with translations schemes.

▶ **Theorem 10** ([13]). *Let $\Phi = (\phi_\mathcal{U}, (\phi_T)_{T\in\mathrm{Rel}_\tau})$ be a σ-τ-translation scheme over $\mathcal{W}$ and $\mathcal{Z}$, $\mathcal{V}$ be a set of first and second order variables such that $\mathcal{V}$, $\mathcal{W}$, and $\mathcal{Z}$ are pairwise disjoint, and $\beta \in \mathrm{MSO}(\tau)$ with variables from $\mathcal{V}$. Then there exist $n \geq 1$, vectors of formulas $\bar{\beta}^{\mathbb{1}}, \bar{\beta}^2 \in \mathrm{MSO}(\sigma)^n$ and an expression $B_\beta \in \mathrm{Exp}_n(\mathbb{B})$ such that $\mathrm{Free}(\bar{\beta}^{\mathbb{1}}) \cup \mathrm{Free}(\bar{\beta}^2) \subseteq \mathrm{Free}(\beta) \cup \mathrm{Free}(\Phi)$ and for all structures $\mathfrak{A}, \mathfrak{B} \in \mathrm{Str}(\sigma)$, all $(\mathcal{W}, \mathfrak{A} \sqcup \mathfrak{B})$-assignments ς and all $(\mathcal{V}, \Phi^\star(\mathfrak{A} \sqcup \mathfrak{B}, \varsigma))$-assignments ρ:*

$$(\Phi^\star(\mathfrak{A} \sqcup \mathfrak{B}, \varsigma), \rho) \models \beta \text{ iff } \langle\!\langle B_\beta \rangle\!\rangle([\![\bar{\beta}^{\mathbb{1}}]\!](\mathfrak{A}, (\varsigma \cup \rho)|_\mathfrak{A}), [\![\bar{\beta}^2]\!](\mathfrak{B}, (\varsigma \cup \rho)|_\mathfrak{B})) = \mathtt{true}.$$

▶ **Theorem 11** ([13]). *Let $\Phi = (\phi_{\mathcal{U}}, (\phi_T)_{T\in \mathrm{Rel}_\tau})$ be a σ-τ-translation scheme over $\mathcal{W}$ and $\mathcal{Z}$, $\mathcal{V}$ be a set of first and second order variables such that $\mathcal{V}$, $\mathcal{W}$, and $\mathcal{Z}$ are pairwise disjoint, and $\beta \in \mathrm{FO}(\tau)$ with variables from $\mathcal{V}$. Then there exist $n \geq 1$, vectors of formulas $\bar{\beta}^{\mathbb{1}}, \bar{\beta}^{2} \in \mathrm{FO}(\sigma)^n$ and an expression $B_\beta \in \mathrm{Exp}_n(\mathbb{B})$ such that $\mathrm{Free}(\bar{\beta}^{\mathbb{1}}) \cup \mathrm{Free}(\bar{\beta}^{2}) \subseteq \mathrm{Free}(\beta) \cup \mathrm{Free}(\Phi)$ and for all structures $\mathfrak{A}, \mathfrak{B} \in \mathrm{Str}(\sigma)$, all $(\mathcal{W}, \mathfrak{A} \sqcup \mathfrak{B})$-assignments ς and all $(\mathcal{V}, \Phi^\star(\mathfrak{A} \times \mathfrak{B}, \varsigma))$-assignments ρ:*

$$(\Phi^\star(\mathfrak{A} \times \mathfrak{B}, \varsigma), \rho) \models \beta \text{ iff } \langle\!\langle B_\beta \rangle\!\rangle([\![\bar{\beta}^{\mathbb{1}}]\!](\mathfrak{A}, (\varsigma \cup \rho)|_{\mathfrak{A}}), [\![\bar{\beta}^{2}]\!](\mathfrak{B}, (\varsigma \cup \rho)|_{\mathfrak{B}})) = \mathtt{true}.$$

We give a short example to illustrate Theorem 10.

▶ **Example 12.** We consider the signature σ of a labeled graph, i.e., $\mathrm{Rel}_\sigma = \{\mathrm{edge}, \mathrm{lab}_a, \mathrm{lab}_b\}$ where edge has arity 2 and $\mathrm{lab}_a, \mathrm{lab}_b$ both have arity 1. Given two directed rooted labeled trees $\mathfrak{G}_1, \mathfrak{G}_2$ in this signature (see Example 8), we can use a translation scheme to add edges between all leaves of $\mathfrak{G}_1$ and the root of $\mathfrak{G}_2$ in $\mathfrak{G}_1 \sqcup \mathfrak{G}_2$. For this scenario we have to distinguish between the vertices from the first and the second graph, so the use of an intermediate signature is necessary. We define the signature σ' to be σ extended by the relation symbols G_1 and G_2 of arity 1. Then for $i \in \{1, 2\}$ we define a σ-σ'-translation scheme $\Phi_i = (\phi_{\mathcal{U}}, \phi'_{\mathrm{edge}}, \phi_{\mathrm{lab}_a}, \phi_{\mathrm{lab}_b}, \phi^i_{G_1}, \phi^i_{G_2})$ by

$$\phi_{\mathcal{U}} = \mathtt{true} \qquad \phi_{\mathrm{lab}_a} = \mathrm{lab}_a(z_1) \qquad \phi^i_{G_j} = \begin{cases} \mathtt{true} & \text{if } i = j \\ \mathtt{false} & \text{otherwise.} \end{cases}$$
$$\phi'_{\mathrm{edge}} = \mathrm{edge}(z_1, z_2) \qquad \phi_{\mathrm{lab}_b} = \mathrm{lab}_b(z_1)$$

With the abbreviations $\mathrm{root}(x) = \neg\exists y.\mathrm{edge}(y, x)$ and $\mathrm{leaf}(x) = \neg\exists y.\mathrm{edge}(x, y)$ we then define the σ'-σ-translation scheme $\Phi = (\phi_{\mathcal{U}}, \phi_{\mathrm{edge}}, \phi_{\mathrm{lab}_a}, \phi_{\mathrm{lab}_b})$ through

$$\phi_{\mathrm{edge}} = \mathrm{edge}(z_1, z_2) \vee (G_1(z_1) \wedge G_2(z_2) \wedge \mathrm{leaf}(z_1) \wedge \mathrm{root}(z_2)).$$

Then $\mathfrak{G} = \Phi^*(\Phi_1^*(\mathfrak{G}_1) \sqcup \Phi_2^*(\mathfrak{G}_2))$ is exactly $\mathfrak{G}_1 \sqcup \mathfrak{G}_2$ with the leaves of $\mathfrak{G}_1$ connected to the root of $\mathfrak{G}_2$. We now consider the formula

$$\beta = \exists x.\exists y.(\mathrm{edge}(x, y) \wedge \mathrm{lab}_a(x) \wedge \mathrm{lab}_b(y))$$

which asks whether there is some edge between an a-labeled and a b-labeled vertex. We can apply Lemma 9 and Theorem 10 to obtain the following decomposition of β. Let

$$\bar{\beta}^{\mathbb{1}} = (\beta, \exists x.\mathrm{lab}_a(x) \wedge \mathrm{leaf}(x)) \qquad B_\beta = x_1 \vee y_1 \vee (x_2 \wedge y_2).$$
$$\bar{\beta}^{2} = (\beta, \exists y.\mathrm{lab}_b(y) \wedge \mathrm{root}(y))$$

Then we have $\mathfrak{G} \models \beta$ iff $\langle\!\langle B_\beta \rangle\!\rangle([\![\bar{\beta}^{\mathbb{1}}]\!](\mathfrak{G}_1), [\![\bar{\beta}^{2}]\!](\mathfrak{G}_2)) = \mathtt{true}$.

5 Weighted Feferman-Vaught Decomposition Theorems

Our goal is to prove weighted versions of Theorems 10 and 11. That is, we would like to replace FO by wFO and MSO by wMSO in those theorems. This, however, is not possible as we will see in Sections 5.2 and 5.3. For disjoint unions, we have to restrict the use of the first order product quantifier and entirely remove the second order product quantifier in wMSO. For products, it is not possible to include the first order product quantifier at all.

5.1 Formulation of the theorems

Let σ be a signature and S a commutative semiring. We define two fragments of our logic and formulate our weighted versions of Theorems 10 and 11 for these fragments.

▶ **Definition 13** (Product-free weighted first order logic)**.** We define the *product-free* first order fragment $\mathrm{wFO}^{\bigotimes\text{-free}}(\sigma, S)$ of our logic as the set of all formulas from $\mathrm{wFO}(\sigma, S)$ which do not contain any first order product quantifier. Using this fragment, we will formulate a weighted Feferman-Vaught decomposition theorem for products of structures.

▶ **Definition 14** (Product-restricted weighted monadic second order logic)**.** In order to define the *product-restricted* fragment of our weighted monadic second order logic, we first define the fragment of so-called *almost-Boolean* formulas through the grammar

$$\psi ::= \beta \mid s \mid \psi \oplus \psi \mid \psi \otimes \psi.$$

This fragment, which we denote by $\mathrm{wMSO}^{\text{a-bool}}(\sigma, S)$, already appeared in [3] in the form of *recognizable step functions*. To obtain the main theorem of [3], the product quantifier was restricted to quantify only over recognizable step functions. We employ the same restriction and define the product-restricted fragment of our logic through the grammar

$$\varphi ::= \beta \mid s \mid \varphi \oplus \varphi \mid \varphi \otimes \varphi \mid \bigoplus x.\varphi \mid \bigotimes x.\psi \mid \bigoplus X.\varphi,$$

where $\beta \in \mathrm{MSO}(\sigma)$ is a monadic second order formula, $s \in S$, x is a first order variable, X is a second order variable and $\psi \in \mathrm{wMSO}^{\text{a-bool}}(\sigma, S)$ is an almost-Boolean formula. By $\mathrm{wMSO}^{\bigotimes\text{-res}}(\sigma, S)$ we denote the set of all such formulas. The set $\mathrm{wMSO}^{\bigotimes\text{-res}}(\sigma, S)$ contains all formulas from $\mathrm{wMSO}(\sigma, S)$ which do not contain any second order quantifier and where for every subformula of the form $\bigotimes x.\psi$ we have that ψ is an almost-Boolean formula. Our weighted Feferman-Vaught decomposition theorem for disjoint unions of structures will be formulated for this fragment. In [3] it was shown that for finite and infinite words, this fragment is expressively equivalent to weighted finite automata.

We note that the restrictions we impose on the product quantifier are necessary as we will show in Sections 5.2 and 5.3. We formulate the weighted versions of Theorems 10 and 11 as follows.[1] Let τ, $\mathcal{W}$ and $\mathcal{Z}$ be as in Section 4.

▶ **Theorem 15.** *Let S be a commutative semiring. Let $\Phi = (\phi_{\mathcal{U}}, (\phi_T)_{T \in \mathrm{Rel}_\tau})$ be a σ-τ-translation scheme over $\mathcal{W}$ and $\mathcal{Z}$, $\mathcal{V}$ be a set of first and second order variables such that $\mathcal{V}$, $\mathcal{W}$, and $\mathcal{Z}$ are pairwise disjoint, and $\varphi \in \mathrm{wMSO}^{\bigotimes\text{-res}}(\tau, S)$ with variables from $\mathcal{V}$. Then there exist $n \geq 1$, vectors of formulas $\bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^2 \in \mathrm{wMSO}^{\bigotimes\text{-res}}(\sigma, S)^n$ with $\mathrm{Free}(\bar{\varphi}^{\mathbb{1}}) \cup \mathrm{Free}(\bar{\varphi}^2) \subseteq \mathrm{Free}(\varphi) \cup \mathrm{Free}(\Phi)$ and an expression $E_\varphi \in \mathrm{Exp}_n(S)$ such that the following holds. For all finite structures $\mathfrak{A}, \mathfrak{B} \in \mathrm{Str}(\sigma)$, all $(\mathcal{W}, \mathfrak{A} \sqcup \mathfrak{B})$-assignments ς and all $(\mathcal{V}, \Phi^\star(\mathfrak{A} \sqcup \mathfrak{B}, \varsigma))$-assignments ρ we have*

$$[\![\varphi]\!](\Phi^\star(\mathfrak{A} \sqcup \mathfrak{B}, \varsigma), \rho) = \langle\!\langle E_\varphi \rangle\!\rangle([\![\bar{\varphi}^{\mathbb{1}}]\!](\mathfrak{A}, (\varsigma \cup \rho)|_{\mathfrak{A}}), [\![\bar{\varphi}^2]\!](\mathfrak{B}, (\varsigma \cup \rho)|_{\mathfrak{B}})).$$

[1] In [19] a weighted version of Theorem 10 similar to ours is stated (without proof) to hold without any restriction on the first order product quantifier. However, in Subsection 5.2 we show that a restriction on the product quantifier is necessary.

▶ **Theorem 16.** *Let S be a commutative semiring. Let $\Phi = (\phi_{\mathcal{U}}, (\phi_T)_{T\in \mathrm{Rel}_\tau})$ be a σ-τ-translation scheme over $\mathcal{W}$ and $\mathcal{Z}$, $\mathcal{V}$ be a set of first and second order variables such that $\mathcal{V}$, $\mathcal{W}$, and $\mathcal{Z}$ are pairwise disjoint, and $\varphi \in \mathrm{wFO}^{\bigotimes\text{-free}}(\tau, S)$ with variables from $\mathcal{V}$. Then there exist $n \geq 1$, vectors of formulas $\bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^{2} \in \mathrm{wFO}^{\bigotimes\text{-free}}(\sigma, S)^n$ with $\mathrm{Free}(\bar{\varphi}^{\mathbb{1}}) \cup \mathrm{Free}(\bar{\varphi}^{2}) \subseteq \mathrm{Free}(\varphi) \cup \mathrm{Free}(\Phi)$ and an expression $E_\varphi \in \mathrm{Exp}_n(S)$ such that the following holds. For all finite structures $\mathfrak{A}, \mathfrak{B} \in \mathrm{Str}(\sigma)$, all $(\mathcal{W}, \mathfrak{A}\times\mathfrak{B})$-assignments ς and all $(\mathcal{V}, \Phi^\star(\mathfrak{A}\times\mathfrak{B}, \varsigma))$-assignments ρ we have*

$$[\![\varphi]\!](\Phi^\star(\mathfrak{A}\times\mathfrak{B}, \varsigma), \rho) = \langle\!\langle E_\varphi \rangle\!\rangle([\![\bar{\varphi}^{\mathbb{1}}]\!](\mathfrak{A}, (\varsigma \cup \rho)|_{\mathfrak{A}}), [\![\bar{\varphi}^{2}]\!](\mathfrak{B}, (\varsigma \cup \rho)|_{\mathfrak{B}})).$$

The proofs of both theorems are deferred to Section 5.4. For formulas without free variables and a trivial translation scheme, i.e., $\phi_{\mathcal{U}} = \mathtt{true}$ and $\phi_T = T(z_1, \ldots, z_{\mathrm{ar}_\tau(T)})$ for all $T \in \mathrm{Rel}_\tau$, the theorems reduce to the following, simplified versions.

▶ **Theorem 17.** *Let S be a commutative semiring and $\varphi \in \mathrm{wMSO}^{\bigotimes\text{-res}}(\sigma, S)$ be a sentence. Then there exist $n \geq 1$, vectors of sentences $\bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^{2} \in \mathrm{wMSO}^{\bigotimes\text{-res}}(\sigma, S)^n$ and an expression $E_\varphi \in \mathrm{Exp}_n(S)$ such that the following holds. For all finite structures $\mathfrak{A}, \mathfrak{B} \in \mathrm{Str}(\sigma)$ we have*

$$[\![\varphi]\!](\mathfrak{A} \sqcup \mathfrak{B}) = \langle\!\langle E_\varphi \rangle\!\rangle([\![\bar{\varphi}^{\mathbb{1}}]\!](\mathfrak{A}), [\![\bar{\varphi}^{2}]\!](\mathfrak{B})).$$

▶ **Theorem 18.** *Let S be a commutative semiring and $\varphi \in \mathrm{wFO}^{\bigotimes\text{-free}}(\sigma, S)$ be a sentence. Then there exist $n \geq 1$, vectors of sentences $\bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^{2} \in \mathrm{wFO}^{\bigotimes\text{-free}}(\sigma, S)^n$ and an expression $E_\varphi \in \mathrm{Exp}_n(S)$ such that the following holds. For all finite structures $\mathfrak{A}, \mathfrak{B} \in \mathrm{Str}(\sigma)$ we have*

$$[\![\varphi]\!](\mathfrak{A} \times \mathfrak{B}) = \langle\!\langle E_\varphi \rangle\!\rangle([\![\bar{\varphi}^{\mathbb{1}}]\!](\mathfrak{A}), [\![\bar{\varphi}^{2}]\!](\mathfrak{B})).$$

▶ **Example 19.** To illustrate Theorem 17 we consider the semiring of natural numbers $\mathbb{N}_0 = (\mathbb{N}_0, +, \cdot, 0, 1)$ and the signature σ of a labeled graph, i.e., $\mathrm{Rel}_\sigma = \{\mathrm{edge}, \mathrm{lab}_a, \mathrm{lab}_b\}$ with edge binary and $\mathrm{lab}_a, \mathrm{lab}_b$ both unary. Consider the following formula which multiplies the number of vertices labeled a with the number of edges between two vertices labeled b.

$$\Big(\underbrace{\textstyle\bigoplus x.\mathrm{lab}_a(x)}_{=\varphi_a}\Big) \otimes \Big(\underbrace{\textstyle\bigoplus x.\bigoplus y.\mathrm{edge}(x,y) \wedge \mathrm{lab}_b(x) \wedge \mathrm{lab}_b(y)}_{=\varphi_b}\Big)$$

The formula can be decomposed as follows. Let $\bar{\varphi}^{\mathbb{1}} = \bar{\varphi}^{2} = (\varphi_a, \varphi_b)$ and $E_\varphi = (x_1 \oplus y_1) \otimes (x_2 \oplus y_2)$. Then for all σ-structures $\mathfrak{G}_1, \mathfrak{G}_2$ we have $[\![\varphi]\!](\mathfrak{G}_1 \sqcup \mathfrak{G}_2) = \langle\!\langle E_\varphi \rangle\!\rangle([\![\bar{\varphi}^{\mathbb{1}}]\!](\mathfrak{G}_1), [\![\bar{\varphi}^{2}]\!](\mathfrak{G}_2))$.

▶ **Example 20.** In [19], it is discussed how translation schemes can be applied for Feferman-Vaught-like decompositions of weighted properties. Theorems 15 and 16 show that this is possible for all properties which can be expressed by formulas in our weighted logic fragments.

5.2 Necessity of restricting the logic for disjoint unions

In this section, we show that the restrictions we impose on the product quantifiers are indeed necessary. For disjoint unions, we will prove that already Theorem 17 does not hold over the tropical semiring $\mathrm{Trop} = (\mathbb{R}_{\geq 0} \cup \{\infty\}, \min, +, \infty, 0)$ and over the arctic semiring $\mathrm{Arct} = (\mathbb{R}_{\geq 0} \cup \{-\infty\}, \max, +, -\infty, 0)$ for the formulas $\bigotimes x. \bigotimes y.1$ and $\bigotimes X.1$. Here, $\mathbb{R}_{\geq 0}$ denotes the set of non-negative real numbers. To prove this, we employ Ramsey's Theorem. Then we show that for the formula $\bigotimes x. \bigoplus y.1$, Theorem 17 does not hold over the semiring $\mathbb{N}_0 = (\mathbb{N}_0, +, \cdot, 0, 1)$. We note that these types of formulas also occurred in [3] and [4] as examples of weighted formulas whose semantics could not be described by weighted automata.

We will employ the following version of Ramsey's Theorem. For a set X, we denote by $\binom{X}{2}$ the set of all subsets of X of size 2.

▶ **Theorem 21** ([18]). *Let* $f\colon \left[\frac{\mathbb{N}}{2}\right] \to \{1,\dots,k\}$ *be a function. Then there exists an infinite subset* $E \subseteq \mathbb{N}$ *such that* $f|_{\left[\frac{E}{2}\right]} \equiv i$ *for some* $i \in \{1,\dots,k\}$.

▶ **Theorem 22.** *Let* $S \in \{\mathrm{Trop}, \mathrm{Arct}\}$, $\sigma = (\emptyset,\emptyset)$ *be the empty signature and for* $l \in \mathbb{N}$ *consider the* σ*-structures* $\mathfrak{S}_l = (\{1,\dots,l\},\emptyset)$. *Then for* $\varphi = \bigotimes x.\bigotimes y.1$ *there do not exist* $n \in \mathbb{N}$, $\bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^2 \in (\mathrm{wMSO}(\sigma,S))^n$ *and* $E_\varphi \in \mathrm{Exp}_n(S)$ *such that for all* $l,m \in \mathbb{N}$ *we have*

$$[\![\varphi]\!](\mathfrak{S}_l \sqcup \mathfrak{S}_m) = \langle\!\langle E_\varphi \rangle\!\rangle([\![\bar{\varphi}^{\mathbb{1}}]\!](\mathfrak{S}_l), [\![\bar{\varphi}^2]\!](\mathfrak{S}_m)). \tag{5.1}$$

Proof (Sketch). First, consider $S = \mathrm{Trop}$. For contradiction, suppose that $n, \bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^2$ and E_φ as above satisfying (5.1) exist. We may assume that $E_\varphi = E_1 \oplus \ldots \oplus E_k$ is in normal form with all E_i pure products. For $l \geq 1$ and $i \in \{1,\dots,k\}$ we let $a_{li} = [\![\mathrm{PRD}^{\mathbb{1}}(E_i, \bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^2)]\!](\mathfrak{S}_l)$ and $b_{li} = [\![\mathrm{PRD}^2(E_i, \bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^2)]\!](\mathfrak{S}_l)$. Then by assumption we have

$$(l+m)^2 = [\![\varphi]\!](\mathfrak{S}_l \sqcup \mathfrak{S}_m) = \min_{i=1}^{k}(a_{li} + b_{mi}). \tag{5.2}$$

Given $l \geq 1$ and $m \geq 1$, for at least one index $j \in \{1,\dots,k\}$ we have $(l+m)^2 = a_{lj} + b_{mj}$. We define j_{lm} as the smallest such index. Then we define a function $f\colon \left[\frac{\mathbb{N}}{2}\right] \to \{1,\dots,k\}$ by $f(\{l,m\}) = j_{lm}$ for $l < m$. Now take $E \subseteq \mathbb{N}$ according to Ramsey's Theorem. As E is infinite, there are $l,\lambda,m,\mu \in E$ with $l < \lambda < m < \mu$. With $j = j_{lm}$, we thus have $(l+m)^2 = a_{lj} + b_{mj}$, $(\lambda+m)^2 = a_{\lambda j} + b_{mj}$, $(l+\mu)^2 = a_{lj} + b_{\mu j}$, and $(\lambda+\mu)^2 = a_{\lambda j} + b_{\mu j}$. Using the first three of these equalities, an elementary calculation shows that we have $a_{\lambda j} + b_{\mu j} < (\lambda+\mu)^2$. This is clearly a contradiction to the fourth equality. Therefore, $n, \bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^2$ and E_φ as chosen cannot exist. To prove the theorem for the arctic semiring, it suffices to replace min by max in equation (5.2). ◀

With similar methods, we can show the following.

▶ **Theorem 23.** *Let* $S \in \{\mathrm{Trop}, \mathrm{Arct}\}$, $\sigma = (\emptyset,\emptyset)$ *be the empty signature and for* $l \in \mathbb{N}$ *consider the* σ*-structures* $\mathfrak{S}_l = (\{1,\dots,l\},\emptyset)$. *Then for* $\varphi = \bigotimes X.1$ *there do not exist* $n \in \mathbb{N}$, $\bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^2 \in (\mathrm{wMSO}(\sigma,S))^n$ *and* $E_\varphi \in \mathrm{Exp}_n(S)$ *such that for all* $l,m \in \mathbb{N}$ *we have*

$$[\![\varphi]\!](\mathfrak{S}_l \sqcup \mathfrak{S}_m) = \langle\!\langle E_\varphi \rangle\!\rangle([\![\bar{\varphi}^{\mathbb{1}}]\!](\mathfrak{S}_l), [\![\bar{\varphi}^2]\!](\mathfrak{S}_m)).$$

The nesting of a first order sum quantifier into the first order product quantifier also leads to formulas which do not allow for a Feferman-Vaught-like decomposition as the following theorem shows.

▶ **Theorem 24.** *Let* $S = (\mathbb{N}_0, +, \cdot, 0, 1)$, $\sigma = (\emptyset,\emptyset)$ *be the empty signature and for* $l \in \mathbb{N}$ *consider the* σ*-structures* $\mathfrak{S}_l = (\{1,\dots,l\},\emptyset)$. *Then for* $\varphi = \bigotimes x.\bigoplus y.1$ *there do not exist* $n \in \mathbb{N}$, $\bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^2 \in (\mathrm{wMSO}(\sigma,\mathbb{N}_0))^n$ *and* $E_\varphi \in \mathrm{Exp}_n(\mathbb{N}_0)$ *such that for all* $l,m \in \mathbb{N}$ *we have*

$$[\![\varphi]\!](\mathfrak{S}_l \sqcup \mathfrak{S}_m) = \langle\!\langle E_\varphi \rangle\!\rangle([\![\bar{\varphi}^{\mathbb{1}}]\!](\mathfrak{S}_l), [\![\bar{\varphi}^2]\!](\mathfrak{S}_m)). \tag{5.3}$$

Proof (Sketch). We proceed by contradiction and assume $n, \bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^2$ and E_φ as above satisfying (5.3) exist. We may assume that $E_\varphi = E_1 \oplus \ldots \oplus E_k$ is in normal form with all E_i pure products. For $l \geq 1$ and $i \in \{1,\dots,k\}$ we let $a_{li} = [\![\mathrm{PRD}^{\mathbb{1}}(E_i, \bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^2)]\!](\mathfrak{S}_l)$ and $b_{li} = [\![\mathrm{PRD}^2(E_i, \bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^2)]\!](\mathfrak{S}_l)$. Then by assumption we have

$$(l+m)^{(l+m)} = [\![\varphi]\!](\mathfrak{S}_l \sqcup \mathfrak{S}_m) = \textstyle\sum_{i=1}^{k}(a_{li} \cdot b_{mi}). \tag{5.4}$$

For every $j \in \{1, \dots, k\}$ we choose $L_j \geq 1$ such that $a_{L_j j} \neq 0$, or let $L_j = 0$ if for all $l \geq 1$ we have $a_{lj} = 0$. Assume $m \geq 1$ and $j \in \{1, \dots, k\}$ with $L_j \neq 0$, then $a_{L_j j} \geq 1$, hence

$$(L_j + m)^{(L_j+m)} = \textstyle\sum_{i=1}^{k} (a_{L_j i} \cdot b_{mi}) \geq (a_{L_j j} \cdot b_{mj}) \geq b_{mj}.$$

In particular, with $L = \max\{L_i \mid i \in \{1, \dots, k\}\}$, we have that for every $j \in \{1, \dots, k\}$ either (i) $b_{mj} \leq (L + m)^{(L+m)}$ for all $m \geq 1$ or (ii) $a_{lj} = 0$ for all $l \geq 1$. Note that from equation (5.4) it follows that $L = 0$ is impossible. In the same fashion, we can find $M \geq 1$ such that for every $l \geq 1$ and every $j \in \{1, \dots, k\}$ either (i) $a_{lj} \leq (l + M)^{(l+M)}$ for all $l \geq 1$ or (ii) $b_{mj} = 0$ for all $m \geq 1$.

Now consider (5.4) for $l = m$. If $j \in \{1, \dots, k\}$ such that either $a_{lj} = 0$ for all $l \geq 1$ or $b_{mj} = 0$ for all $m \geq 1$, then clearly also $(a_{lj} \cdot b_{lj}) = 0$ for all l. If j is not like this, we have

$$(a_{lj} \cdot b_{lj}) \leq (l + M)^{(l+M)} \cdot (L + l)^{(L+l)} \leq (l + C)^{2(l+C)}$$

for $C = \max\{L, M\}$. It follows that $(2l)^{2l} \leq k(l + C)^{2(l+C)}$ for every $l \geq 1$. Elementary calculus can be used to show that this is not true. ◀

5.3 Necessity of restricting the logic for products

The proof of Theorem 22 can also be used to show that no Feferman-Vaught-like theorem holds for products if the first order product quantifier is included in the weighted logic. More precisely, already Theorem 18 does not hold over the tropical and arctic semirings for the formula $\varphi = \bigotimes x.1$ even if $\bar{\varphi}^{\mathbb{1}}$ and $\bar{\varphi}^{2}$ are allowed to be from $\mathrm{wMSO}(\sigma, S)$.

▶ **Theorem 25.** *Let $S \in \{\mathrm{Trop}, \mathrm{Arct}\}$, $\sigma = (\emptyset, \emptyset)$ be the empty signature and for $l \in \mathbb{N}$ consider the σ-structures $\mathfrak{S}_l = (\{1, \dots, l\}, \emptyset)$. Then for $\varphi = \bigotimes x.1$ there do not exist $n \in \mathbb{N}$, $\bar{\varphi}^{\mathbb{1}}, \bar{\varphi}^{2} \in (\mathrm{wMSO}(\sigma, S))^n$ and $E_\varphi \in \mathrm{Exp}_n(S)$ such that for all $l, m \in \mathbb{N}$ we have*

$$[\![\varphi]\!](\mathfrak{S}_l \times \mathfrak{S}_m) = \langle\!\langle E_\varphi \rangle\!\rangle([\![\bar{\varphi}^{\mathbb{1}}]\!](\mathfrak{S}_l), [\![\bar{\varphi}^{2}]\!](\mathfrak{S}_m)).$$

5.4 Proofs of Theorems 15 and 16

We now come to the proof of Theorems 15 and 16. By the following result, we can reduce the proofs to the case where the translation scheme is the identity.

▶ **Lemma 26.** *Let $\Phi = (\phi_{\mathcal{U}}, (\phi_T)_{T \in \mathrm{Rel}_\tau})$ be a σ-τ-translation scheme over $\mathcal{W}$ and $\mathcal{Z}$, $\mathcal{V}$ be a set of first and second order variables such that $\mathcal{V}$, $\mathcal{W}$, and $\mathcal{Z}$ are pairwise disjoint, and $\varphi \in \mathrm{wMSO}(\tau, S)$ with variables from $\mathcal{V}$. Then there exists a formula $\psi \in \mathrm{wMSO}(\sigma, S)$ with $\mathrm{Free}(\psi) \subseteq \mathrm{Free}(\varphi) \cup \mathrm{Free}(\Phi)$ such that the following holds. For all finite structures $\mathfrak{A} \in \mathrm{Str}(\sigma)$, all $(\mathcal{W}, \mathfrak{A})$-assignments ς and all $(\mathcal{V}, \Phi^\star(\mathfrak{A}, \varsigma))$-assignments ρ we have*

$$[\![\varphi]\!](\Phi^\star(\mathfrak{A}, \varsigma), \rho) = [\![\psi]\!](\mathfrak{A}, \varsigma \cup \rho).$$

If φ is from $\mathrm{wMSO}^{\bigotimes\text{-res}}(\tau, S)$ or $\mathrm{wFO}^{\bigotimes\text{-free}}(\tau, S)$, then ψ can also be chosen as a formula from $\mathrm{wMSO}^{\bigotimes\text{-res}}(\sigma, S)$ or $\mathrm{wFO}^{\bigotimes\text{-free}}(\sigma, S)$, respectively.

Lemma 26 can be proved by induction on the structure of formulas.

Proof of Theorem 15 (Sketch). We proceed by induction. By Lemma 26 it suffices to prove the case $\tau = \sigma$ and $\Phi^\star(\mathfrak{A} \sqcup \mathfrak{B}, \varsigma) = \mathfrak{A} \sqcup \mathfrak{B}$.

- Assume $\varphi = \beta$ for some $\beta \in \mathrm{MSO}(\sigma)$. We apply Theorem 6 to the formula β and obtain $l \geq 1$, vectors of formulas $\bar{\beta}^{\mathbb{1}}, \bar{\beta}^{2} \in \mathrm{MSO}(\sigma)^l$ and an expression $B_\beta \in \mathrm{Exp}_l(\mathbb{B})$ such that

  $$(\mathfrak{A} \sqcup \mathfrak{B}, \rho) \models \beta \text{ iff } \langle\!\langle B_\beta \rangle\!\rangle([\![\bar{\beta}^{\mathbb{1}}]\!](\mathfrak{A}, \rho|_{\mathfrak{A}}), [\![\bar{\beta}^{2}]\!](\mathfrak{B}, \rho|_{\mathfrak{B}})) = \mathtt{true}.$$

  We may assume that $B_\beta = B_1 \vee \ldots \vee B_m$ is in normal form with all B_i pure conjunctions. We let $\gamma_i = \mathrm{CON}^{\mathbb{1}}(B_i, \bar{\beta}^{\mathbb{1}}, \bar{\beta}^{2})$ and $\delta_i = \mathrm{CON}^{2}(B_i, \bar{\beta}^{\mathbb{1}}, \bar{\beta}^{2})$ for $i \in \{1, \ldots, m\}$ (see Construction 4). We set $n = 2m$ and define

  $$\bar{\varphi}^{\mathbb{1}} = (\gamma_1, \ldots, \gamma_m, \neg\gamma_1, \ldots, \neg\gamma_m) \qquad \bar{\varphi}^{2} = (\delta_1, \ldots, \delta_m, \neg\delta_1, \ldots, \neg\delta_m).$$

  Intuitively, we would now define the expression E_φ as $x_1 \otimes y_1 \oplus \ldots \oplus x_m \otimes y_m$, but this expression is not necessarily evaluated to $\mathbb{1}$ in S if $\gamma_i \wedge \delta_i$ is true for more than one index i. Instead, we define expressions $E_k \in \mathrm{Exp}_n(S)$ for $k \in \{1, \ldots, m\}$ inductively by $E_1 = x_1 \otimes y_1$ and

  $$E_k = (E_{k-1} \otimes ((x_{k+m} \otimes y_k) \oplus y_{k+m})) \oplus (x_k \otimes y_k)$$

  and set $E_\varphi = E_m$. In a sense, E_k is evaluated to $\mathbb{1}$ if $\gamma_k \wedge \delta_k$ is true, and otherwise, if either γ_k or δ_k does not hold, it is evaluated to E_{k-1}.
- Assume $\varphi = s$ for some $s \in S$. We let $n = 1$, $\varphi^{\mathbb{1}}_1 = \varphi^{2}_1 = s$ and $E_\varphi = x_1$.
- For $\varphi = \zeta \oplus \eta$, we assume the theorem is true for ζ with $\bar{\zeta}^{\mathbb{1}}, \bar{\zeta}^{2} \in \mathrm{wMSO}^{\bigotimes\text{-res}}(\sigma, S)^l$ and $E_\zeta \in \mathrm{Exp}_l(S)$, and for η with $\bar{\eta}^{\mathbb{1}}, \bar{\eta}^{2} \in \mathrm{wMSO}^{\bigotimes\text{-res}}(\sigma, S)^m$ and $E_\eta \in \mathrm{Exp}_m(S)$. We set $\bar{\varphi}^{\mathbb{1}} = (\zeta^{\mathbb{1}}_1, \ldots, \zeta^{\mathbb{1}}_l, \eta^{\mathbb{1}}_1, \ldots, \eta^{\mathbb{1}}_m)$, $\bar{\varphi}^{2} = (\zeta^{2}_1, \ldots, \zeta^{2}_l, \eta^{2}_1, \ldots, \eta^{2}_m)$ and $E_\varphi = E_\zeta \oplus E'_\eta$, where E'_η is obtained from E_η by replacing every variable x_i by x_{i+l} and every variable y_i by y_{i+l}.
- For $\varphi = \zeta \otimes \eta$, the proof is the same as for the previous case, only that here we define $E_\varphi = E_\zeta \otimes E'_\eta$.
- For $\varphi = \bigoplus x.\zeta$, we assume the theorem is true for ζ with $\bar{\zeta}^{\mathbb{1}}, \bar{\zeta}^{2} \in \mathrm{wMSO}^{\bigotimes\text{-res}}(\sigma, S)^l$ and $E_\zeta \in \mathrm{Exp}_l(S)$. We may assume that $E_\zeta = E_1 \oplus \ldots \oplus E_m$ is in normal form with all E_i pure products and that x does no occur as a bound variable in any of the $\zeta^{\mathbb{1}}_i$ or ζ^{2}_i. We let $\xi_i = \mathrm{PRD}^{\mathbb{1}}(E_i, \bar{\zeta}^{\mathbb{1}}, \bar{\zeta}^{2})$ and $\theta_i = \mathrm{PRD}^{2}(E_i, \bar{\zeta}^{\mathbb{1}}, \bar{\zeta}^{2})$. We set $n = 2m$ and define

  $$\begin{aligned} \varphi^{\mathbb{1}} &= (\textstyle\bigoplus x.\xi_1, \ldots, \bigoplus x.\xi_m, \xi_1^{-x}, \ldots, \xi_m^{-x}) \\ \varphi^{2} &= (\textstyle\bigoplus x.\theta_1, \ldots, \bigoplus x.\theta_m, \theta_1^{-x}, \ldots, \theta_m^{-x}) \end{aligned} \qquad E_\varphi = \textstyle\bigoplus_{i=1}^{m}((x_i \otimes y_{m+i}) \oplus (x_{m+i} \otimes y_i)).$$

- For $\varphi = \bigoplus X.\zeta$, we assume that the theorem is true for ζ with $\bar{\zeta}^{\mathbb{1}}, \bar{\zeta}^{2} \in \mathrm{wMSO}^{\bigotimes\text{-res}}(\sigma, S)^l$ and $E_\zeta \in \mathrm{Exp}_l(S) = E_\zeta = E_1 \oplus \ldots \oplus E_m$ in normal form with all E_i pure products. We let $\xi_i = \mathrm{PRD}^{\mathbb{1}}(E_i, \bar{\zeta}^{\mathbb{1}}, \bar{\zeta}^{2})$ and $\theta_i = \mathrm{PRD}^{2}(E_i, \bar{\zeta}^{\mathbb{1}}, \bar{\zeta}^{2})$. We set $n = m$ and define

  $$\begin{aligned} \varphi^{\mathbb{1}}_j &= (\textstyle\bigoplus X.\xi_1, \ldots, \bigoplus X.\xi_m) \\ \varphi^{2}_j &= (\textstyle\bigoplus X.\theta_1, \ldots, \bigoplus X.\theta_m) \end{aligned} \qquad E_\varphi = \textstyle\bigoplus_{i=1}^{m}(x_i \otimes y_i).$$

- Assume $\varphi = \bigotimes x.\zeta$ with $\zeta \in \mathrm{wMSO}^{\text{a-bool}}(\sigma, S)$ almost boolean. Using the laws of distributivity in S and the fact that for two boolean formulas $\alpha, \beta \in \mathrm{MSO}(\sigma)$ we have $[\![\alpha]\!] \cdot [\![\beta]\!] \equiv [\![\alpha \otimes \beta]\!]$, we may assume that $\zeta = (s_1 \otimes \beta_1) \oplus \ldots \oplus (s_l \otimes \beta_l)$ for some $l \geq 1$, $s_i \in S$ and $\beta_i \in \mathrm{MSO}(\sigma)$. Applying a simple construction, we may even assume that $\beta_1, \ldots, \beta_l$ form a partition, i.e., that for all $(\mathcal{V}, \mathfrak{A} \sqcup \mathfrak{B})$-assignments ρ' there is exactly one $i \in \{1, \ldots, l\}$ with $(\mathfrak{A} \sqcup \mathfrak{B}, \rho') \models \beta_i$. Let $X_1, \ldots, X_l \in \mathcal{V}$ be second order variables not occurring in ζ. We define the abbreviation

  $$(x \in X_i) \rhd s_i = ((x \in X_i) \otimes s_i) \oplus \neg(x \in X_i).$$

One can check elementarily that

$$[\![\varphi]\!] \equiv [\![\bigoplus X_1 \ldots \bigoplus X_l. \left(\bigwedge_{i=1}^{l} \forall x.(x \in X_i \leftrightarrow \beta_i)\right) \otimes \bigotimes_{i=1}^{l} \bigotimes x.((x \in X_i) \rhd s_i)]\!].$$

Therefore, it suffices to show this case for formulas of the form

$$\varphi = \bigotimes x.((x \in X) \rhd s).$$

For this, we let $n = 1$ and define $\varphi^{\mathbb{1}} = \varphi^{\mathbb{2}} = (\bigotimes x.((x \in X) \rhd s))$ and $E_\varphi = x_1 \otimes y_1$. ◀

Proof of Theorem 16 (Sketch). Again we proceed by induction and assume that $\tau = \sigma$ and $\Phi^\star(\mathfrak{A} \times \mathfrak{B}, \varsigma) = \mathfrak{A} \times \mathfrak{B}$. The proofs for the cases $\varphi = \beta$, $\varphi = s$, $\varphi = \zeta \oplus \eta$ and $\varphi = \zeta \otimes \eta$ are identical to the ones used in the proof of Theorem 15 for the corresponding cases. For the case $\varphi = \bigoplus x.\zeta$ we proceed as for the case $\varphi = \bigoplus X.\zeta$ in the proof of Theorem 15. ◀

6 Conclusion

We have derived a weighted version of the Feferman-Vaught Theorem for disjoint unions and products of finite structures. We just mention here three possible extensions that were left out due to lack of space. First, Theorems 15 and 16 also hold for infinite structures if the commutative semiring S is bicomplete, i.e., if it is equipped with infinite sum and product operations that naturally extend its finite sum and product operations. Second, in the particular case that the semiring S is a De Morgan algebra, both theorems hold without any need for restrictions on the product quantifiers; that is, Theorem 15 holds for the full weighted MSO logic, and Theorem 16 holds for the full weighted FO logic. Third, both theorems may be extended to employ transductions as defined by Courcelle [2] in place of the present translation schemes.

Abstract

Given a point set $S = \{s_1, \ldots, s_n\}$ in the unit square $U = [0,1]^2$, an *anchored square packing* is a set of n interior-disjoint empty squares in U such that s_i is a corner of the ith square. The *reach* $R(S)$ of S is the set of points that may be covered by such a packing, that is, the union of all empty squares anchored at points in S.

It is shown that $\text{area}(R(S)) \geq \frac{1}{2}$ for every finite set $S \subset U$, and this bound is the best possible. The region $R(S)$ can be computed in $O(n \log n)$ time. Finally, we prove that finding a maximum area anchored square packing is NP-complete. This is the first hardness proof for a geometric packing problem where the size of geometric objects in the packing is unrestricted.

1 Introduction

Let $S = \{s_1, \ldots, s_n\}$ be a set of n points in the unit square $U = [0,1]^2$. We say that a square q is *empty* if no point in S lies in the interior of q, and q is *anchored* at a point s if one of its four corners is s. An *anchored square packing for* S is a set $Q = \{q_1, \ldots, q_n\}$ of interior-disjoint axis-aligned empty squares that lie in U such that q_i is anchored at s_i for $i = 1, \ldots, n$. A *lower-left* anchored square packing is an anchored square packing in which s_i is the lower-left corner of q_i, for $i = 1, \ldots, n$ [2]. No polynomial-time algorithm is known for

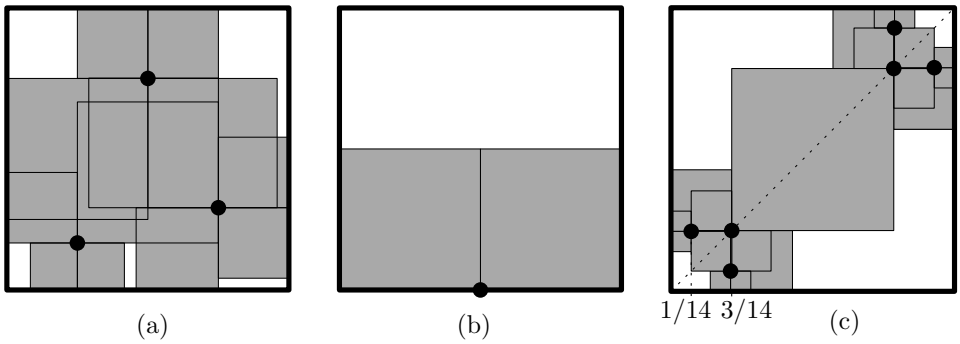

Figure 1 (a) The reach $R(S)$ for a set S of three points. (b) The area of $R(S)$ is $\frac{1}{2}$ for $S = \{(\frac{1}{2}, 0)\}$. (c) The reach $R(S)$ touches all four sides of U, and its area is $\frac{4}{7}$.

computing the maximum area of an anchored square packing for a given point set S; the problem admits a PTAS using a reduction to the maximum weight independent set problem (MWIS) [1]. The empty squares anchored at S do not always cover U entirely (Fig. 1(a)). For finding a maximum anchored square packing for S, it suffices to consider the subset of U that can be reached by anchored empty squares. Specifically, we define the *reach* of S, denoted $R(S)$, as the union of all axis-aligned empty squares contained in U and anchored at some point in S.

For computing the reach $R(S)$, we can take the union of all maximal empty squares anchored at the points in S, as follows. For $i = 1, \ldots, n$, let q_i^1 be the maximal axis-aligned empty square in U whose lower-left corner is s_i, and similarly define q_i^2, q_i^3, and q_i^4 where s_i is the upper-left, upper-right, and lower-right corner, respectively. We say that a point $s \in S$ *blocks* a square q_i^1 if s is incident to the top or right edge of q_i^1. Similarly, s blocks q_i^j if $j = 2$ (resp., 3, 4) and s is incident to the bottom or right edges of q_i^j (resp., bottom or left edges, or top or left edges of q_i^j). It is now clear that $R(S) = \bigcup_{i=1}^{n} \bigcup_{j=1}^{4} q_i^j$.

Summary of Results. We prove that for every finite set $S \subset U$, the area of $R(S)$ is at least $\frac{1}{2}$, and this bound is the best possible (Section 2). This settles in the affirmative a conjecture by Balas et al. [1]. We show how to compute $R(S)$ in $O(n \log n)$ time where $n = |S|$ (Section 3). We also show that finding the maximum area anchored square packing for a given point set S is NP-complete (Section 4). This is the first NP-hardness result for a geometric packing problem, where the size of the geometric objects in the packing is unrestricted. We conclude with related open problems (Section 5).

Motivation and Related Previous Work. Geometric packing and covering problems have a long and revered history, going back to Kepler's problem about the densest packing of congruent balls in Euclidean space. In a classical packing problem, we are given a container region C, and a set O of geometric objects, and we wish to find a maximum subset $O' \subseteq O$ such that congruent copies (or translates) of the objects in O' fit in C without overlap.

Anchored variants, where each geometric object needs to contain a given point (*anchor*) initially emerged in VLSI design, where the anchors represent the endpoints of wires. Allen Freedman [15] conjectured that for every finite set $S \subset [0, 1]^2$, which contains the origin (i.e., $\mathbf{0} \in S$), there is a lower-left anchored rectangle packing of area at least $\frac{1}{2}$. This lower bound would match an easy upper bound construction, where n points are equally distributed on the diagonal. The current best lower bound is 0.091 [6].

More recently, a broad family of anchored packing problems were proposed in the context of *map labelling*, where the anchors represent cities in a map, and axis-aligned rectangles represent labels [7, 8, 9, 10, 12, 13, 16]. Variants of the problem require the anchor to be at a corner, at a side, or anywhere in the rectangle, and the objective is to maximize the number of labels that can be packed in the map. Many of these problems are known to be NP-complete. However, in all previous reductions, the label boxes have a finite number of possible sizes [7, 12, 16] or bounded size [8].

In this paper, we consider the variant of Freedman's problem: We need to place an axis-aligned square at each anchor, and the sizes of the squares are not given in advance. Our objective is to maximize the total area of an anchored square packing. Balas et al. [1] showed that a greedy strategy finds an $\frac{5}{32}$-approximation, and a reduction to MWIS yields a PTAS that achieves an $(1-\varepsilon)$-approximation in time $n^{O(1/\varepsilon)}$. It is known that the number of maximum-area square anchored packings may be exponential in n [2].

2 The Minimum Area of the Reach

In this section, we prove $\text{area}(R(S)) \geq \frac{1}{2}$ for every set S of n points in $U = [0,1]^2$ (Theorem 12). Note that this bound is the best possible for all $n \in \mathbb{N}$. Indeed, if S is the one-element set $S = \{(\frac{1}{2}, 0)\}$, then $\text{area}(R(S)) = \frac{1}{2}$; see Fig. 1(b). By placing n points in an ε-neighborhood of $(\frac{1}{2}, 0)$ in U, we see that for every $\varepsilon > 0$ and every $n \in \mathbb{N}$, there exists a set S of n points in U such that $\text{area}(R(S)) < \frac{1}{2} + \varepsilon$. Note that in this construction all maximal anchored squares are disjoint from the top side of U. Under this constraint, the upper bound $\frac{1}{2}$ is always attained.

We call a point set S *trivial* if $R(S)$ is disjoint from one of the sides of U. The following lemma shows that $\text{area}(R(S)) \geq \frac{1}{2}$ for trivial instances.

▶ **Lemma 1.** *If $R(S)$ does not touch one of the sides of U, then* $\text{area}(R(S)) \geq \frac{1}{2}$.

Proof. Without loss of generality, $R(S)$ does not touch the top side of U. Let $s = (x, y)$ be a point in S with maximum y-coordinate. Consider the maximal empty squares whose lower-left and lower-right corners are at s. Since these squares do not touch the top side of U, and s has maximum y-coordinate, they touch the left and right side of U, respectively. Consequently, their combined area is $x^2 + (1-x)^2 \geq (\frac{1}{2})^2 + (\frac{1}{2})^2 = \frac{1}{2}$. Hence $\text{area}(R(S)) \geq \frac{1}{2}$, as claimed. ◀

▶ Remark. We do not know of any nontrivial point set S that attains the lower bound $\text{area}(R(S)) \geq \frac{1}{2}$. Our best lower bound construction for nontrivial instances yields $\frac{4}{7}$; see Fig. 1(c).

Outline. In the remainder of Section 2, we consider nontrivial instances $S \subset U$. A *gap* is a connected component of $U \setminus R(S)$, i.e., of the complement of the reach. Section 2.1 presents basic properties of $R(S)$ and its gaps, Section 2.2 classifies the possible gaps into five types, and Section 2.3 presents a charging scheme in which we define for every gap C a region $R_C \subset R(S)$ such that $\text{area}(C) \leq \text{area}(R_C)$, and the regions R_C are pairwise interior-disjoint. Summation over all gaps yields $\text{area}(U \setminus R(S)) \leq \sum_C \text{area}(R_C) \leq \text{area}(R(S))$, consequently $\text{area}(R(S)) \geq \frac{1}{2}\text{area}(U) = \frac{1}{2}$.

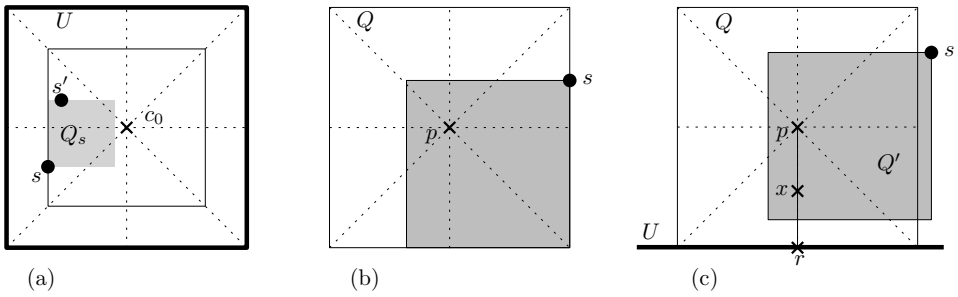

Figure 2 (a) A point $s \in S$ where the anchored square Q_s does not contain c_0. (b) If $s \in \partial Q$, $x(p) \leq x(s)$, and $y(p) \leq y(s)$, then the lower-left square anchored at s contains p. (c) ∂Q intersects the bottom side of U, and r lies below p.

2.1 Properties of the Reach and its Gaps

▶ **Lemma 2.** *For every finite set $S \subset U$, the reach $R(S)$ is connected.*

Proof. Let $S \subset U$ be a finite set, and let $c_0 = (\frac{1}{2}, \frac{1}{2})$ denote the center of U. We show that for each $s \in S$, there is an empty square Q_s anchored at s that contains c_0 **or** whose boundary contains an anchor $s' \in S$ such that $\|s' - c_0\|_\infty < \|s - c_0\|_\infty$ (i.e., s' is closer to c_0 in L_∞ norm than s). This implies that Q_s (hence $R(S)$) contains a line segment from s to c_0 or to s'. Consequently, $R(S)$ contains a polyline from every $s \in S$ to c_0. By the definition of $R(S)$, this further implies that $R(S)$ contains a polyline between any two points in $R(S)$.

It remains to prove the claim. Let $s \in S$. We may assume without loss of generality that $x(s) \leq y(s) \leq \frac{1}{2}$, hence $\|s - c_0\|_\infty = \frac{1}{2} - x(s)$. Let Q_s be the maximal empty square whose lower-left corner is s. Refer to Fig. 2(a). If $c_0 \in Q_s$, then our proof is complete. Otherwise, the side length of Q_s is $a_s < \frac{1}{2} - x(s)$, and there is a point s' in the right or the top side of Q_s. The anchor s' lies in the interior of the L_∞-ball of radius $\frac{1}{2} - x(s)$ centered at c_0, hence $\|s' - c_0\|_\infty < \|s - c_0\|_\infty$, as claimed. ◀

▶ **Lemma 3.** *For every point $p \in U \setminus R(S)$, there exists a point $r \in \partial U$ such that the line segment pr is horizontal or vertical; and $pr \subset U \setminus R(S)$.*

Proof. Let $p \in U \setminus R(S)$, and let Q be the maximal empty axis-aligned square centered at p. Refer to Fig. 2(b). The boundary of this square, ∂Q, intersects S or ∂U, otherwise Q would not be maximal.

First assume that ∂Q contains a point $s \in S$. Without loss of generality, we may assume that $x(p) \leq x(s)$ and $y(p) \leq y(s)$. Since Q is empty, the maximal anchored square with upper-right corner at s contains p, hence $p \in R(S)$, contradicting our assumption that $p \notin R(S)$.

We can now assume that ∂Q intersects ∂U. Without loss of generality, $\partial Q \cap \partial U$ lies in the bottom side of both Q and U. Let $r \in \partial Q \cap \partial U$ be a point vertically below p (see Fig. 2(c) for an example). Suppose that segment pr intersects $R(S)$. Then some point $x \in pr$ lies in a square Q' anchored at a point $s \in S$. Since Q is empty, the anchor s lies outside of Q, and so the side length of Q' is at least half of that of Q, i.e., the side length of Q' is at least $|pr|$. However, then $y(s) \geq |pr|$, and the square Q' contains the segment px, contradicting our assumption that $p \notin R(S)$. Therefore there is no such point $x \in pr$, and $pr \subset U \setminus R(S)$, as claimed. ◀

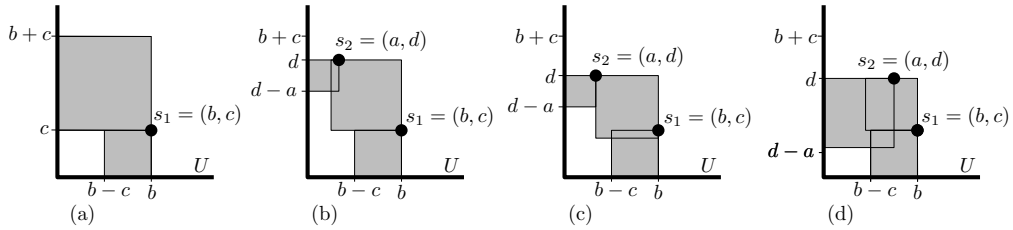

Figure 3 (a) A corner gap of type 1. (b–d) Corner gaps of type 2.

▶ **Corollary 4.** *The reach is simply connected.*

Proof. By Lemma 2, $R(S)$ is connected. Suppose that $R(S)$ is not simply connected. Then there is a gap $C \subset U \setminus R(S)$ such that $\partial C \subset R(S)$. Let $p \in \text{int}(C)$ be an arbitrary point in the interior of C. By Lemma 3, there is a point $r \in \partial U$ such that $pr \subset U \setminus R(S)$, which implies $r \in \partial C$, contradicting our assumption $\partial C \subset R(S)$. Therefore $R(S)$ is simply connected, as required. ◀

2.2 Classification of Gaps

In this section we classify the possible shapes of the gaps in $U \setminus R(S)$ for nontrivial instances. To simplify our analysis, we assume that $S \subset \text{int}(U)$ and no two points in S have the same x- or y-coordinates. This assumption is justified by the following lemma.

▶ **Lemma 5.** *If* $\text{area}(R(S)) \geq \frac{1}{2}$ *for every finite point set* $S \subset U$ *such that* $S \subset \text{int}(U)$ *and no two points in* S *have the same* x- *or* y*-coordinates, then* $\text{area}(R(S)) \geq \frac{1}{2}$ *for every finite point set* $S \subset U$*.*

Proof. Let $S \subset U$ be a finite point set that contains a point in ∂U or two points with the same x- or y-coordinate. Let ε_0 be minimum positive difference between x- and y-coordinates of points in S. For every $\varepsilon \in (0, \varepsilon_0/2)$, translate each point in S by a random vector of length at most ε into $\text{int}(U)$. The resulting point set S_ε lies in $\text{int}(U)$ and have distinct x- and y-coordinates with probability 1; the side length of each maximal anchored square may increase by at most 2ε, but could decrease substantially. Consequently, $\text{area}(R(S_\varepsilon)) \leq \text{area}(R(S)) + 4n\varepsilon$, hence $\lim_{\varepsilon \to 0} \text{area}(R(S_\varepsilon)) \leq \text{area}(R(S))$. ◀

We distinguish a *corner gap*, which is incident to a corner of U; and a *side gap*, which is adjacent to exactly one side of U. We show that every gap is bounded by ∂U and by squares anchored at up to three points in S. We define five types of gaps (two types of corner gaps and three types of side gaps). Each type is defined together with an empty rectangle $B \subset U$ and 1–3 anchors on the boundary of B. In each case, the gap is determined by the maximal empty squares that lie entirely in B and are anchored at points in $S \cap B$.

We describe each type modulo the symmetry group of U (i.e., the dyhedral group D_4). Specifically, we restrict ourselves to corner gaps incident to the lower-left corner of U, and side gaps adjacent to the bottom side of U. Reflection in the line $x = y$ (resp., $x = \frac{1}{2}$) maintains corner gaps incident to the origin (resp., side gaps along the bottom side of U); and we describe only one variant modulo reflection.

1. Let $0 < c < b < 1$. If $B = [0, b] \times [0, b + c]$ is empty and $s_1 = (b, c) \in S$, then the squares anchored at s_1 form a corner gap $[0, b - c] \times [0, c]$. See Fig. 3(a).

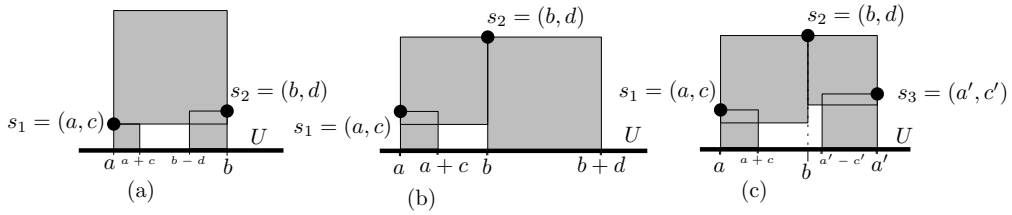

Figure 4 (a–c) Side gaps of type 3, 4, and 5, respectively.

2. Let $0 < a < b < 1$ and $0 < c < d < 1$ such that $c < b$ and $d < b + c$. If $B = [0, b] \times [0, d]$ is empty and $s_1 = (b, c), s_2 = (a, d) \in S$, then the squares anchored at s_1 and s_2 form a corner gap $[0, b - c] \times [0, \min(c, d - a, d - b + a)] \cup [0, \min(a, b - c, b - d + c)] \times [0, d - a]$. See Fig. 3(b–d).
3. Let $0 < a < b < 1$ and $0 < c, d < 1$ with $\max(c, d) < b - a$. If $B = [a, b] \times [0, \min(c, d) + (b - a)]$ is empty and $s_1 = (a, c), s_2 = (b, d) \in S$, then the squares anchored at s_1 and s_2 form a side gap $[a + c, b - d] \times [0, \min(c, d)]$. See Fig. 4(a).
4. Let $0 < a < b < 1$ and $0 < c < d < 1$ with $b - a < d$. If $B = [a, b + d] \times [0, d]$ is empty and $s_1 = (a, c), s_2 = (b, d) \in S$, then the squares anchored at s_1 and s_2 form a side gap $[a + c, b] \times [0, \min(c, d - b + a)]$. See Fig. 4(b).
5. Let $0 < a < b < a' < 1$ and $0 < c < c' < d < 1$ with $b - a < d$ and $a' - b < d$. If $B = [a, a'] \times [0, d]$ is empty and $s_1 = (a, c), s_2 = (b, d), s_3 = (a', c') \in S$, then the squares anchored at s_1, s_2, and s_3 form a side gap $[a + c, \min(b, a' - d + c')] \times [0, \min(c, d - b + a)] \cup [\min(b, a' - d + c'), a' - c'] \times [0, \min(c', d - a' - b)]$. See Fig. 4(c) for an example.

▶ **Lemma 6.** *Every gap C of type 1–5 is disjoint from all empty squares that are anchored at points in S and lie in the exterior of the defining box B of C. Consequently, C is bounded by ∂U and some empty squares anchored at points in $S \cap B$.*

Proof. In each of the five cases, $\partial B \cap \mathrm{int}(U)$ is covered by empty squares anchored at the points in S that define C. More precisely, each point in $\partial B \cap \mathrm{int}(U)$ lies in an empty square anchored at a point in $S \cap \partial B$ blocked by some point in $S \cap \partial B$ or $\partial U \cap \partial B$. For $s_i \in S$ lying in the exterior of B, let Q_i be a square anchored at s_i. If Q_i intersects B, then its interior intersects $\partial B \cap \mathrm{int}(U)$, hence it intersects a square Q_j anchored at some $s_j \in \partial B$ and blocked by some point $p_j \in S \cap \partial B$ or $\partial U \cap \partial B$. Since $\mathrm{int}(Q_i)$ contains neither s_j nor p_j, we have $Q_i \cap B \subset Q_j$, and so Q_i is disjoint from the gap C, as claimed. ◀

We prove the following classification result for the gaps in the full paper.

▶ **Lemma 7.** *Every gap of a nontrivial instance is of one of the five types defined above.*

It is now easy to check that the following properties hold for all five types of gaps.

▶ **Corollary 8.**

(i) *Each gap is either a rectangle incident to a side of U, or the union of two rectangles incident to the same side of U (which we call an* L-shaped *gap).*

(ii) *Every edge uv of a gap is contained in either ∂U or a maximal anchored rectangle. Consequently, the square built on the side uv outside of the gap lies either outside of U or in $R(S)$.*

We say that a point $p \in \partial U$ is a *lead* if it is a vertex of a maximal anchored square q_i^j, and ps_i is a diagonal of q_i^j. We observe that one or two vertices of a gap along ∂U is a lead.

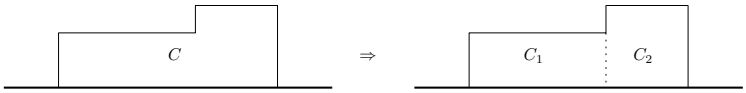

Figure 5 An L-shaped side gap C is subdivided into two rectangles $C_1, C_2 \in \mathcal{C}^*$.

▶ **Corollary 9.**

- *If C is a rectangular gap, then at least one endpoint of $C \cap \partial U$ is a lead,*
- *otherwise both endpoints of $C \cap \partial U$ are leads.*

2.3 Charging Scheme

For every gap C, we define a region $R_C \subset R(S)$; and then we show that $\text{area}(R_C) \geq \text{area}(C)$ and the regions R_C are pairwise interior-disjoint.

For ease of exposition, we subdivide every L-shaped side gap C into two rectangles $C = C_1 \cup C_2$, then define interior-disjoint regions R_{C_1} and R_{C_2}, and let $R_C := R_{C_1} \cup R_{C_2}$. Specifically, let $\mathcal{C}^*$ be a set of regions that contains: (1) all corner gaps, (2) all rectangular side gaps, and (3) for each L-shaped side gap C, the two interior-disjoint rectangles C_1 and C_2, such that $C = C_1 \cup C_2$ and both C_1 and C_2 have a common side with ∂U (see Fig. 5 for an example). By Corollary 9, at least one vertex of every rectangle in $\mathcal{C}^*$ is a lead, and two vertices of every L-shaped corner gap in $\mathcal{C}^*$ are leads.

We are now ready to define a region R_C for each region $C \in \mathcal{C}^*$.

- Let $C = (a, b, c, d)$ be a rectangle in $\mathcal{C}^*$. Assume w.l.o.g. that bc is contained in the bottom side of U, and c is a lead (a symmetric construction applies if bc is contained in another side of U or b is the only lead). Refer to Fig. 6(a). Let ℓ_1 and ℓ_2 be lines of slope 1 passing through a and c, respectively. Let p_1 be the intersection of ℓ_1 with the vertical line through cd, and let p_2 be the intersection of ℓ_2 with the horizontal line through da. Let z_1 (resp., z_2) be the intersection point of ℓ_2 (resp., ℓ_1) with the line of slope -1 passing through p_1 (resp., p_2). Then R_C is the smaller pentagon out of (a, d, c, z_1, p_1) and (a, d, c, p_2, z_2).
- Let $C = (a, b, c, d, e, f)$ be a L-shaped corner gap in $\mathcal{C}^*$. Assume w.l.o.g. that b is the lower-left corner of U. By Corollary 9, both a and c are leads. Refer to Fig. 6(b). Let ℓ_1 and ℓ_2 be lines of slope 1 passing through a and c, respectively. Let $p_1, p_2 \in S$ be the anchors on ℓ_1 and ℓ_2, respectively (which exist since both a and c are leads). Let z_1 (resp., z_2) be the intersection point of line ℓ_2 (resp., ℓ_1) with the line of slope -1 passing through p_1 (resp., p_2). Then R_C is the smaller heptagon out of $(a, f, e, d, c, z_1, p_1)$ and $(a, f, e, d, c, p_2, z_2)$.

▶ **Lemma 10.** *For every $C \in \mathcal{C}^*$, we have:*

(P1) $R_C \subseteq R(S)$,

(P2) $\text{int}(R_C)$ *does not contain any anchors, and*

(P3) $\text{area}(C) \leq \text{area}(R_C)$.

Proof. The region $C \in \mathcal{C}^*$ is either a gap or a rectangle within an L-shaped side gap; Fig. 6(b). Let C^* be the gap that contains C, and B the box defining the gap C^*. For all five types of gaps, $\text{int}(B)$ does not contain any anchor, and $B \setminus C^* \subset R(S)$. By Corollaries 8(ii) and 9, the points p_1 and p_2 lie in B. Consequently, $R_C \subset B$, hence $R_C \subset B \setminus C^*$. This confirms (P1) and (P2).

To prove (P3), we distinguish two cases. First assume that C is an $x \times y$ rectangle. Let T be an isosceles right triangle whose hypotenuse has length $x + y$. It is easy to check that $\text{area}(C) \leq \text{area}(T)$. Indeed, $\text{area}(T) = \left(\frac{1}{2}(x+y)\right)^2 = \frac{1}{2}\left(\frac{x^2}{2} + xy + \frac{y^2}{2}\right) \geq xy = \text{area}(C)$.

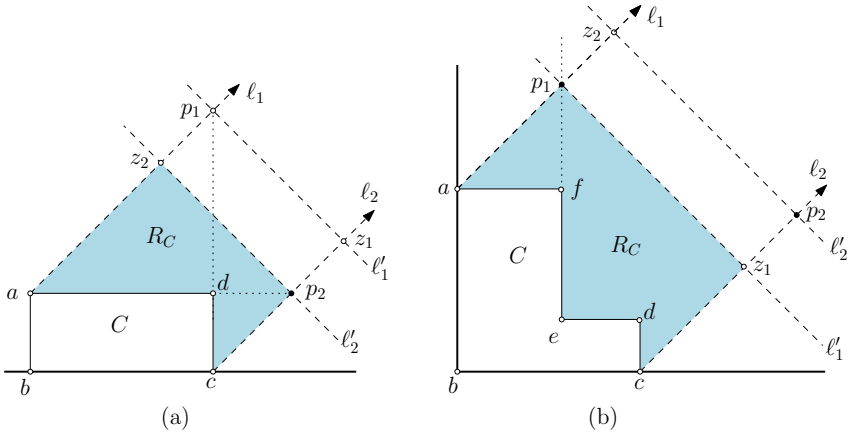

Figure 6 Region R_C. (a) $C \in \mathcal{C}^*$ is a rectangle. (b) $C \in \mathcal{C}^*$ is an L-shaped corner gap.

By definition, R_C contains a triangle congruent to T, consequently $\text{area}(C) \leq \text{area}(T) \leq \text{area}(R_C)$, as claimed.

Next assume that $C \in \mathcal{C}^*$ is an L-shaped corner gap; Fig. 6(b). Assume that C is formed by three interior-disjoint axis-aligned rectangles defined by diagonals ae, be, and ce. Let their dimensions respectively be $x \times y$, $x \times z$, and $w \times z$. Let T_1 and T_2 be isosceles right triangles whose hypotenuses are of length $x + y$ and $w + z$, respectively. Let T_3 and T_4 be isosceles right triangles whose legs are of length x and z, respectively. By definition, R_C contains interior-disjoint triangles congruent to T_1, T_2, T_3, and T_4: the hypotenuses of the respective triangles are in the same supporting lines as ef, ed, ap_1, and cp_2 respectively. Using the same argument as in the previous case, we can show that $\text{area}(T_1)$ and $\text{area}(T_2)$ are, respectively, greater or equal than the areas of the $x \times y$ and $w \times z$ rectangles. It remains to show that $\text{area}(T_3) + \text{area}(T_4)$ is greater or equal than the area of the $x \times z$ rectangle. By definition, we have $\text{area}(T_3) + \text{area}(T_4) = \left(\frac{x^2}{2} + \frac{z^2}{2}\right) \geq xz$ for all $x, z > 0$. ◀

We prove that the regions R_C, $C \in \mathcal{C}^*$, are pairwise interior-disjoint in the full paper.

▶ **Lemma 11.** *For every two regions $C, C' \in \mathcal{C}^*$, $C \neq C'$, we have $\text{int}(R_C) \cap \text{int}(R_{C'}) = \emptyset$.*

▶ **Theorem 12.** *For every finite set $S \subset U$, we have $\text{area}(R(S)) \geq \frac{1}{2}$, and this bound is the best possible.*

Proof. By Lemma 5, it suffices to prove the lower bound when $S \subset \text{int}(U)$ and no two points in S have the same x- or y-coordinate. For all gaps $C \subset U \setminus R(S))$, we have defined interior-disjoint regions $R_C \subset R(S)$ such that $\text{area}(C) \leq \text{area}(R_C)$. Consequently, $\sum_C \text{area}(C) \leq \sum_C \text{area}(R_C) \leq \text{area}(R(S))$, which immediately yields $\text{area}(R(S)) = 1 - \sum_C \text{area}(C) \geq 1 - \text{area}(R(S))$, and $\text{area}(R(S)) \geq 1/2$, as claimed. This bound is the best possible: the point set $S = \{(\frac{1}{2}, 0)\}$ attains $\text{area}(R(S)) = \frac{1}{2}$. ◀

3 Algorithm for Computing the Reach

In this section, we show how to compute efficiently the reach of a given point set.

▶ **Theorem 13.** *For a set $S \subset U$ of n points, $R(S)$ can be computed in $O(n \log n)$ time.*

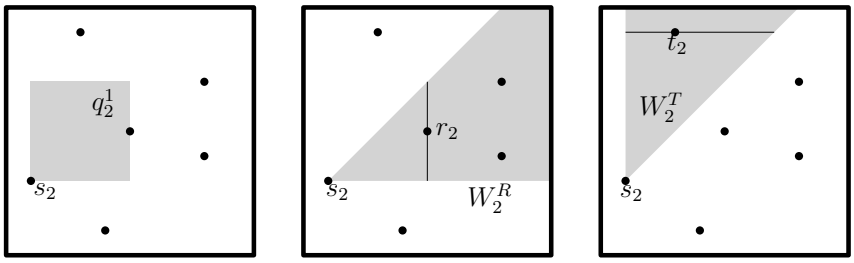

Figure 7 A set S of 6 anchors in $U = [0,1]^2$. (a) The maximal empty anchored square q_2^1; (b) wedge W_2^R; and (c) wedge W_2^T.

Recall that, for a set $S = \{s_1, \ldots, s_n\}$, the reach is defined as a union of $4n$ squares, $R(S) = \bigcup_{i=1}^{n} \bigcup_{j=1}^{4} q_i^j$, where q_i^1 is the maximal axis-aligned empty square in U whose lower-left corner is s_i, and q_i^2, q_i^3, and q_i^4 are defined similarly where s_i is the upper-left, upper-right, and lower-right corner, respectively. Since any two squares cross in at most two points, the $4n$ squares q_i^j ($i = 1, \ldots, n$ and $j = 1, \ldots, 4$) form a pseudo-circle arrangement. It is well known that the union of $O(n)$ pseudo-circles has $O(n)$ vertices [11]. The union of $4n$ axis-aligned *squares* can be computed by a sweep-line algorithm in $O(n \log n)$ time [3].

We note that Bentley's sweep-line algorithm can compute the *area* of the union of n axis-aligned *rectangles* in $O(n \log n)$ time (without computing the union itself, which may have $\Theta(n^2)$ complexity). Computing the volume of the union of axis-aligned hyper-rectangles in $\mathbb{R}^d$ is known as *Klee's measure problem*, and the current best algorithms [4] for $d \geq 3$ run in $O(n^{d/2})$ time in general, and in $O(n^{(d+1)/3} \operatorname{polylog}(n))$ time for hypercubes (see also [17]).

It remains to compute the $4n$ anchored maximal empty squares q_i^j. We focus on the n *lower-left* anchored squares q_i^1 ($i = 1, \ldots, n$), the other three types can be computed analogously. For every $i = 1, \ldots, n$, the lower-left corner of q_i^1 is s_i, and its left *or* top side contains another anchor or a point in ∂U; we say that this point is the *blocker* of q_i^1. For each i, we find a first point that may block the square q_i^1 on the left and on the top side, independently. The blocker of q_i^1 is the points closest to s_i in L_∞ norm. We continue with the details. We define two wedges with apex at the origin: Let $W^L = \{(x, y) \in \mathbb{R}^2 : 0 < y < x\}$ and $W^T = \{(x, y) \in \mathbb{R}^2 : 0 < x < y\}$; see Fig. 7(b–c). The Minkowski sums $W_i^L := s_i + W_L$ and $W_i^T := s_i + W^T$ are the translates of these wedges with apex at s_i. Let r_i be a point of minimum x-coordinate in $W_i^L \cap (S \cup \partial U)$; and let t_i be a point of minimum y-coordinate in $W_i^T \cap (S \cup \partial U)$. Then the blocker of q_i^1 is either r_i or t_i, whichever is closer to s_i in L_∞ norm.

For every $i = 1, \ldots, n$, we find points r_i and t_i, independently. Consider the points $r_i \in W_i^R$, for $i = 1, \ldots, n$ (the case of the points $t_i \in W_t^T$ is analogous). We use a data structure originally developed for computing Θ-graphs in the context of geometric spanners by Narasimhan and Smid [14, Section 4.1.2]. They developed the following dynamic data structure for n points in the plane:

▶ **Lemma 14** ([14], Lemma 4.1.9). *Let H be a nonvertical line through the origin. There is a data structure that maintains a set P of n points in the plane and supports the following queries: (i)* MinBelow(p)*: Given a query point $p \in P$, compute a point with the minimum x-coordinate among all points in P that are below $p + H$; (ii) insert a point into P; (iii) delete a point from P. The data structure has $O(n)$ space, $O(n \log n)$ preprocessing time, and $O(\log n)$ query time.*

▶ **Corollary 15.** *Given a point set $S = \{s_i : i = 1\ldots, n\} \subset U$, the points r_i and t_i $(i = 1, \ldots, n)$ can be computed in $O(n \log n)$ time. Consequently, the squares q_i^1 can also be computed in $O(n \log n)$ time.*

Proof. Assume that S is sorted in decreasing order by their y-coordinates. We use the data structure in Lemma 14 with the line $H : y = x$ as follows. Initially $P = \emptyset$. For $i = 1, \ldots, n$, we insert s_i into P. If MinBelow(s_i) returns a point in P, then let this be r_i, otherwise let r_i be the point in the right side of U that has the same y-coordinate as s_i. Since P contains all points in S whose y-coordinates are greater or equal to that of s_i, if wedge W_i^R contains any anchor, then MinBelow(s_i) returns one with the minimum x-coordinate. This shows that r_i is computed correctly for all $i = 1, \ldots, n$.

The points t_i $(i = 1, \ldots, n)$ can be computed analogously in $O(n \log n)$ time. In $O(1)$ additional time for each $i = 1, \ldots, n$, we can compare r_i and t_i, find the blocker of q_i^1, and determine the maximal anchored square q_i^1. ◀

Proof of Theorem 13. By a repeated application of Corollary 15, we can compute all $4n$ anchored squares q_i^j $(i = 1, \ldots, n;\ j = 1, \ldots, 4)$. As noted above, a sweep-line algorithm can compute the union $R(S) = \bigcup_{i=1}^{n} \bigcup_{j=1}^{4} q_i^j$ in $O(n \log n)$ time. This completes the proof. ◀

4 NP-Hardness of Maximum-Area Anchored Square Packings

We now prove that the maximum-area anchored square packing problem is NP-complete. We define the decision version of the problem as follows. Instead of the unit square $[0, 1]^2$, we use the square $U = [0, W]^2$, for some integer $W > 0$. For a finite set $S \subset [0, W]^2$ of anchors with integer coordinates, we ask whether there is an anchored square packing of area W^2.

We prove NP-hardness by a reduction from Planar-Monotone-3SAT (described below). For every instance of Planar-Monotone-3SAT, we construct an instance $S \subset [0, W]^2$. We say that an anchored empty square is *forced* if every packing of area W^2 contains it. An anchor in S is *forced* if it is the anchor of a forced square; otherwise it is *free*. A forced square A and its anchor $s \in S$ form a *forced pair* (A, s). We construct an instance in which most of the anchors are forced, and a small number of anchors encode the truth value of the variables in a 3SAT instance.

To prove that the two instances are equivalent, we shall argue that a set of squares and anchors are forced. In an intermediate step, we assume that $\mathcal{F} = \{(A_i, s_i) : i = 1\ldots, f\}$ is a set of forced square-anchor pairs, and we would like to show that another square-anchor pair (A, s) is also forced. Let $P = U \setminus \bigcup_{i=1}^{f} A_i$ be the complement of the forced squares in $\mathcal{F}$. By construction, P is an orthogonal polygon (possibly with holes). An anchor s is *undecided* if there is no forced pair (A, s) anchored at s in $\mathcal{F}$ (i.e., s is either free or its forced pair is not in $\mathcal{F}$).

We show (Lemma 16) that the following two properties each imply that the pair (A, s) is forced (given that all pairs in $\mathcal{F}$ are forced). We define both properties for the orientations shown in Fig. 8, but they generalize to all other orientations obtained through the symmetry group of U. Let $s \in S$, and let A be a maximal empty square anchored at s such that $\text{int}(A) \subset P$. Without loss of generality, assume that s is the upper-right corner of A.

1. The lower-left corner of A is a convex vertex of P and there is no undecided anchor in the closure of the bottom and left edges of A.

Figure 8 Identifying forced points. (a) Property 1. (b) Property 2.

2. The lower-left corner of A is a convex vertex of P, the side length of A is greater than 1, and the bottom edge of A is contained in ∂P. There is a unique undecided anchor $s' \in \partial A$ located one unit above the lower-left corner of A. There is no undecided anchor one unit to the right of s or to the right of the lower-right corner of A.

▶ **Lemma 16.** *Given a set of forced pairs $\mathcal{F} = \{(A_i, s_i) : i = 1 \ldots, f\}$, if a pair (A, s) has properties 1 or 2, then (A, s) is a forced pair.*

Proof. Suppose, to the contrary, that there is a anchored square packing Q of area W^2 that does not use the square A anchored at s. Let $B \subseteq A$ be the unit square incident to the lower-left corner of A. Since all anchors have integer coordinates, every empty square containing B is also contained in A. If a pair (A, s) has property 1, apart from A, no such empty square has a corner at an undecided anchor and, hence, B cannot be covered. If a pair (A, s) has property 2, B must be covered by a square anchored at its upper-left corner, which is undecided by hypothesis. Hence, $B \in Q$. Let B' be a unit square with integer coordinates to the right of B. Then the maximal empty square in $P \setminus B$ containing B' satisfies property 1, but that there is no point at its upper-right corner. In this case, B' is not covered. ◀

▶ **Theorem 17.** *It is NP-hard to compute the maximum area anchored square packing of a given set S of n anchors with integer coordinates in a square $U = [0, W]^2$.*

Proof. We reduce from Planar-Monotone-3SAT which is NP-complete [5]. An instance of such problem consists of a boolean formula Φ in 3CNF with n variables $\{x_1, \ldots, x_n\}$ and m clauses, and a planar rectilinear drawing of the a bipartite graph of Φ. The drawing given by an Planar-Monotone-3SAT instance represents variables and clauses by rectangles, and edges by vertical line segments. It has the additional property that the rectangles of variables (and only variables) intersect the line $y = 0$ and the rectangles of clauses lies in the upper (resp., lower) half-plane contain only positive (resp., negative) literals. A literal is called *negative* if it is the negation of a variable, and *positive* otherwise. We need to decide whether we can satisfy all m clauses, each of which is a disjunction of three literals.

For a given instance of Planar-Monotone-3SAT, we construct an instance $S \subset [0, W]^2$ of the maximal area anchored square packing problem, and then show that the two instances are equivalent. We first modify the rectilinear graph of the Planar-Monotone-3SAT instance in the following way. Replace each rectangle by a cycle along its boundary and denote by G the resulting geometric graph. Delete the left, right, and the top (resp., bottom) edges of the rectangles representing positive (resp., negative) clauses. Each clause is now represented by a horizontal segment (a path of length 2 in G). We designate the middle vertex of this path, which has degree 3, as a *clause vertex*. For each cycle in G that represents a variable, delete the right vertical edges, and designate the left vertical edge as a *variable edge*. All remaining edges in G called *wires* and all remaining vertices of degree 3 are called *split vertices*. We orient the wires such that they form directed paths from the variable edges to clause vertices. Assume that the feature size of the resulting rectilinear graph is 1 and the

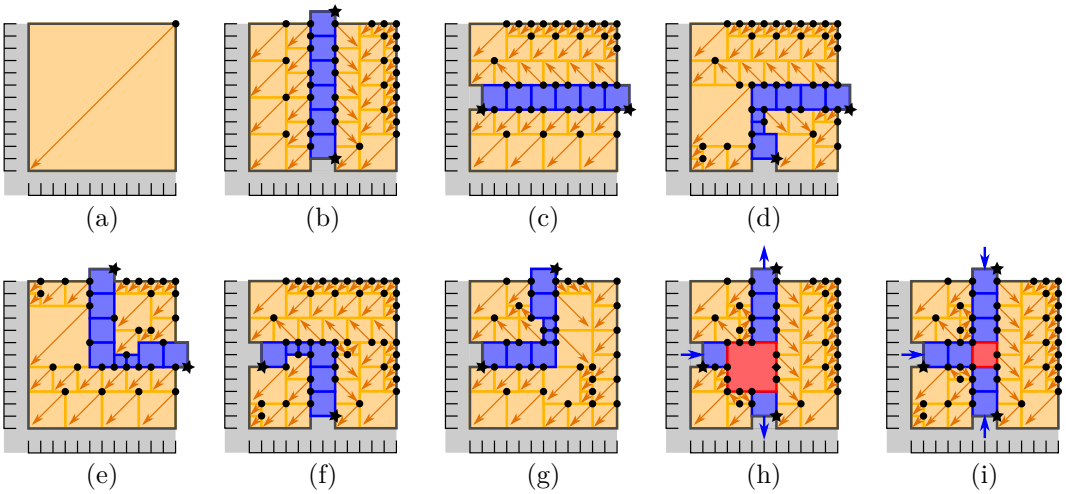

Figure 9 Gadgets. (a) is a *filler* gadget, (b–c) are *wire* gadgets, (d–g) are *turn* gadgets, (h) is a split gadget, and (i) is a *clause* gadget. The rhombus in (h) represents 2 anchors placed at the same position.

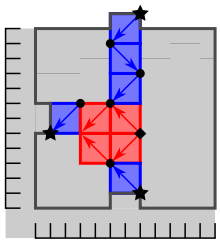

Figure 10 Square packing for the split gadget connected to negative wires.

side length of a minimum enclosing axis-aligned square is k. We set $W = 48k + 48$ and let $U = [0, W]^2$. Scale up the drawing by a factor of 48 and place it in U so that every vertex is at distance at least 24 from ∂U.

We tile U with orthogonal polygons. Every tile is congruent to one of the tiles shown in Fig. 9. We call these tiles *gadgets*: (a) is a *filler* gadget, (b–c) are *wire* gadgets, (d–g) are *turn* gadgets, (h) is a split gadget, and (i) is a *clause* gadget. The filer gadget is a 12×12 square, all other tiles are constructed from a 12×12 square by possibly adding or deleting 1×2 rectangular features in two or three side of the squares. In a tiling of $[0, W]^2$, each such feature matches a feature of an adjacent tile. Choose a tile for each variable that contains part of the variable edge and add the anchors shown in Fig. 9(b) (only the star contained in the 12×12 square is added). Do the same for split and clauses using the tiles shown in Fig. 9(h) and (i), respectively. Connect the gadgets as they are connected in the original drawing using wires and turns. The directions of the wires attached to split and clause gadgets are indicated by blue arrows in Fig. 9. For all remaining tiles, we use filler gadgets with one anchor. This completes the description of the instance $S \subset [0, W]^2$.

We now prove that a Planar-Monotone-3SAT instance admits a positive solution if and only if the corresponding point set $S \subset [0, W]^2$ admits an anchored square packing of area W^2.

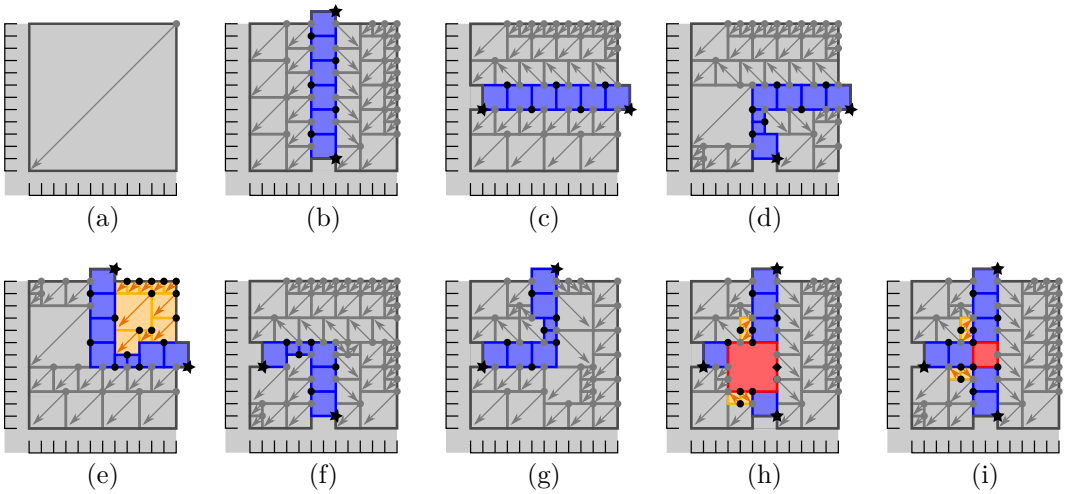

Figure 11 Forced squares and anchors.

Assume that the Planar-Monotone-3SAT instance admits a positive solution. We show that the corresponding instance $S \subset [0, W]^2$ admits an anchored square packing of area W^2. Choose every orange square in each gadget assigning its anchor as the origin of the arrow contained in it (as shown in Fig. 9). For each of the n wire gadgets placed on variable edges, if the corresponding variable is assigned `true` (resp., `false`) add all blue squares assigning its anchor as the only point on its bottom (resp., top) edge. Every connected component formed by blue squares represents a path of wires. We say that a wire is *positive* if it is in the upper half of U and its corresponding variable is assigned `true`, or if it is in the lower half of U and its corresponding variable is assigned `false`. A wire is *negative* otherwise. If a wire is positive (resp., negative), assign the corner that is behind (resp., ahead of) the blue square as its anchor, considering the direction of the wire. For split gadgets connected to positive wires assign the top-left corner of the red square as its anchor. For negative wires, the red square is reached by four equal squares as shown in Fig. 10. Since there exists at least one positive wire connected to a clause vertex, there will be at least one point in a corner of the red square in the clause gadget that has not yet been assigned a square. We complete the square packing by adding such a square with a corresponding anchor. Since the anchored squares cover all gadgets, the overall area of the square packing is W^2.

Assume that the anchored square packing instance $S \subset [0, W]^2$ admits a positive solution (of area W^2). Recall that $[0, W]^2$ is tiled with gadgets. Sort them in lexicographic order by the coordinates of their lower-left corners (i.e., the first gadget is incident to the origin). We use Lemma 16 to prove the following property for each gadget:

> **Property (i).** If the left and bottom boundaries are part of the perimeter of a forced polygon P and contain no free anchor relative to P except for the points shown by a star, then (i.a) every orange and blue square shown in Fig. 9 in the corresponding gadget is forced; and (i.b) if P' is the union of P and the orange and blue squares inside the gadget, then there is no free anchor relative to P' on the boundary of the gadget except for points shown by a star.

Initially, in every gadget, we can determine at least one pair of a forced square and a corresponding forced anchor using Lemma 16. Fig. 11 shows the result of recursively adding a forced square into the forced polygon, and applying Lemma 16 to another pair until there

are no more forced pairs in the gadget. We now show that all blue squares are forced. In each case, we can take the lower-left blue square and conclude that if the square packing covers it entirely, then it is covered by a square anchored at one of its corners. After we add this square to the forced polygon P, the same argument holds for every lower-left blue square not in P. Consequently, all blue squares are forced. The remaining orange squares are forced by recursively applying Lemma 16. Then, if property (i) is satisfied, every gadget satisfies (i.a) and (i.b). Property (i) is trivially satisfied for the lower-left gadget and inductively satisfied by assuming that all gadgets to the left and below satisfy (i.a) and (i.b).

We now show how to convert a square packing of area W^2 into a solution of the Planar-Monotone-3SAT instance. Wire gadgets have two points indicates by a star: one that is ahead and one behind using the direction of the wire (recall that the direction points from the variable edge to the clause). A wire gadget that does not use the star that is ahead in its direction as an anchor for one of the squares contained in it is called *positive*. A wire gadget is called *negative* otherwise. For all wire gadgets satisfying (i.a) and (i.b), if a star is not used as an anchor for a square in the gadget, then the other point marked by a star must be used as anchor in this gadget. This implies that, for a pair of adjacent wire gadgets, if the one ahead in the wire direction is positive, so is the other gadget. Now assume that one of the outputs of the split gadget satisfying (i.a) and (i.b) is connected to a positive gadget. A point in the middle of an edge of the red square in Fig. 11(h) must be used as an anchor of a blue square. Then, the only way to cover all the red area is to use a single square anchored at its upper-left corner. Therefore, the wire connected to the input of the split gadget must also be positive. Finally, assume that the red square in a clause gadget that satisfies (i.a) and (i.b) (see Fig. 11(i)) is covered. Then, it must be anchored at one of its corners. If it is anchored at the upper-left (resp., bottom-left, bottom-right) corner, then the star at the top (resp., left, bottom) of the gadget is used as an anchor of a blue square in this gadget. Therefore, it must be adjacent to a positive wire. Combining all arguments, we set a variable `true` if its first wire gadget (that was placed on the variable edge) is positive and `false` otherwise, and then this assignment will satisfy the boolean formula of the Planar-Monotone-3SAT instance. ◀

5 Open Problems

We have shown that at least half of the area of the unit square $U = [0, 1]^2$ can be reached by empty squares anchored at S for any finite set $S \subset U$, and this bound is the best possible. We have also given the first NP-hardness proof for a packing problem over geometric objects of arbitrary sizes. Our results raise several intriguing open problems. Does our result generalize to higher dimensions, that is, is there a lower bound for the maximal volume covered by empty hypercubes anchored at a finite set of points in $[0, 1]^d$ for $d > 2$? Axis-aligned squares are balls in L_∞-norm: Over all finite sets S of anchors in a unit-diameter ball U in L_p-norm, $p \geq 1$, what is the maximum area of a packing of L_p-balls that each contain an anchor? Is there a polynomial-time algorithm for computing the minimum area *lower-left anchored* square packing for a given set S of n points in the unit square $[0, 1]^2$? Is it NP-hard to compute the maximum area anchored *rectangle* packing of a given set $S \subset [0, 1]^2$? For the last two problems, simple greedy strategies achieve constant-factor approximations [6], and a QPTAS is available for rectangles and a PTAS for squares [1].

Abstract

We give a deterministic algorithm for counting the number of satisfying assignments of any $\mathrm{AC}^0[\oplus]$ circuit C of size s and depth d over n variables in time $2^{n-f(n,s,d)}$, where $f(n,s,d) = n/O(\log(s))^{d-1}$, whenever $s = 2^{o(n^{1/d})}$. As a consequence, we get that for each d, there is a language in E^{NP} that does not have $\mathrm{AC}^0[\oplus]$ circuits of size $2^{o(n^{1/(d+1)})}$. This is the first lower bound in E^{NP} against $\mathrm{AC}^0[\oplus]$ circuits that beats the lower bound of $2^{\Omega(n^{1/2(d-1)})}$ due to Razborov and Smolensky for large d. Both our algorithm and our lower bounds extend to $\mathrm{AC}^0[p]$ circuits for any prime p.

1 Introduction

In circuit complexity, we are interested in understanding the power and weaknesses of various circuit models. This understanding can take various forms for any given circuit class $\mathfrak{C}$. One indication of a deeper understanding is to be able to show *lower bounds* against $\mathfrak{C}$, i.e., prove that some "explicit" function cannot be computed by small circuits in $\mathfrak{C}$. Other indications come from efficient or at least non-trivial solutions for various *meta-algorithmic* tasks involving $\mathfrak{C}$, such as satisfiability algorithms for $\mathfrak{C}$, learning algorithms for $\mathfrak{C}$ or pseudo-random generators useful against $\mathfrak{C}$. There are some formal connections between lower bounds and efficient solvability of meta-algorithmic tasks for classes $\mathfrak{C}$ satisfying some natural closure properties, for example, an equivalence between pseudo-random generators against $\mathfrak{C}$ and average-case lower bounds in linear exponential time against $\mathfrak{C}$ [18], an implication from

[2] This work was supported by the European Research Council under the European Union's Seventh Framework Programme (FP7/2007-2014)/ERC Grant Agreement No. 615075.

non-trivial satisfiability algorithms for $\mathfrak{C}$ to lower bounds in non-deterministic exponential time against $\mathfrak{C}$ [26], and an implication from non-trivial learning algorithms for $\mathfrak{C}$ to lower bounds in probabilistic exponential time against $\mathfrak{C}$ [20].

For the class of Boolean circuits in general, our understanding is very limited in these terms. We have no super-linear lower bounds against general Boolean circuits for any explicit function, nor do we have non-trivial solutions for any of the meta-algorithmic tasks mentioned. The situation is far better for more restricted classes of circuits, especially circuits of *constant depth* where the gates have unbounded fan-in, both with respect to lower bounds and to meta-algorithmic questions.

In this paper, we focus on constant-depth circuits with AND, OR and PARITY gates (or more generally, AND, OR and MODp gates for some prime p). This is a class that has been intensively studied. Razborov [21] and Smolensky [23] showed super-polynomial size lower bounds against this class for very simple functions such as the MAJORITY function and the MODq function where q is a prime different from 2. As we discuss in Section 2, non-trivial randomized algorithms for deciding satisfiability of circuits from this class are implicit in [27, 16]. Recently, [5] gave quasi-polynomial time algorithms for learning $\mathrm{AC}^0[\oplus]$ circuits in the membership query model.

However, there are still several gaps in our understanding of these $\mathrm{AC}^0[\oplus]$ circuits. With regard to lower bounds, we still do not have *tight* lower bounds for functions like Majority or MODq. The Razborov-Smolensky approximation method yields size lower bounds of the form $2^{\Omega(n^{1/2(d-1)})}$ for Majority against $\mathrm{AC}^0[\oplus]$ circuits of depth d over n variables. The best known upper bound is $2^{\tilde{O}(n^{1/(d-1)})}$ using a standard divide-and-conquer strategy. Closing this quadratic gap in the exponent between upper and lower bounds has been a long-standing open question in the complexity theory of constant-depth circuits. Note that, in contrast, tight bounds are known up to constant factors in the exponent when only AND and OR gates are allowed - Parity is known to have complexity $2^{\Theta(n^{1/(d-1)})}$ in this simpler model [1, 9, 29, 11].

With regard to meta-algorithmic tasks, despite the learning breakthrough of [5] mentioned previously, the situation for pseudo-random generators (PRGs) and satisfiability algorithms is still unclear. While we have super-polynomial worst-case lower bounds against $\mathrm{AC}^0[\oplus]$ circuits, we do not have good average-case lower bounds, and as a consequence, do not have good PRGs. In the case of satisfiability algorithms, randomized algorithms improving non-trivially over brute force search are implicit in previous work, but good deterministic algorithms were unknown prior to this work.

Deterministic satisfiability algorithms are important for a couple of reasons. First, they indicate an improved structural understanding of the circuit class in question, often requiring new techniques to design. Second, they imply circuit lower bounds via the connection of Williams [26] - such an implication is not known from randomized algorithms.[3]

Note that even under standard derandomization assumptions, it is unclear how to get a non-trivial deterministic satisfiability algorithm from a non-trivial randomized satisfiability algorithm. The reason is that derandomization inherently incurs a quadratic slowdown. The deterministic simulation of a randomized algorithm running in time T will take time at least T^2 when a PRG is used to do the derandomization, as the range of the PRG will have size at least T. This quadratic slowdown is unaffordable in the parametric regime

[3] One-sided error randomized algorithms, and more generally, co-non-deterministic algorithms for satisfiability for the circuit class also imply lower bounds via the result of Williams [26]. However, it is easy to check that the previous randomized algorithms for $\mathrm{AC}^0[\oplus]$ were two-sided error algorithms.

under consideration here - we are interested in algorithms running in time $2^{n-g(n)}$, for some $g(n) = o(n)$. Hence the determinization procedure cannot be black-box, but must rather use refined structural information about the circuit class in question.

The main result of this paper is a deterministic algorithm for counting satisfying assignments to $\mathrm{AC}^0[\oplus]$ circuits that improves non-trivially over brute force search.

▶ **Theorem 1** (Main theorem). *The following holds for some absolute constant $\varepsilon_0 > 0$. There is a deterministic algorithm that given an $\mathrm{AC}^0[\oplus]$ circuit C over n variables such that C has depth at most d and size $s \leq 2^{(\varepsilon_0 n)^{1/d}}$, counts the number of satisfying assignments to C in time 2^{n-t} where $t = t(n, s, d) = n/O(\log s)^{d-1}$.*

▶ Remark. It is easy to generalize our results to work with $\mathrm{AC}^0[\mathrm{Mod}_p]$ circuits for any fixed prime p.

In terms of parameters, the savings over brute force search matches the savings in the randomized algorithm of [14] for AC^0 circuits when the circuit size is $n^{1+\Omega(1)}$. Thus any further improvement in savings in our result would give a corresponding improvement for AC^0 algorithms, and moreover via the connection of Williams [26] to circuit lower bounds, a strong improvement would give super-polynomial formula size lower bounds for non-deterministic exponential time.

A minor caveat is that we require the circuit size to be $2^{O(n^{1/d})}$ in Theorem 1, for technical reasons. One would expect that the analysis can be extended to circuit size up to $2^{n^{1/(d-1)}}$.

We use Theorem 1 to get better lower bounds against $\mathrm{AC}^0[\oplus]$ circuits than known before by using the connection of Williams [26]. In fact, we need a refinement of the connection due to [4]. Our lower bound holds for a language in E^{NP}. An intriguing open question is to use the more refined structural information about $\mathrm{AC}^0[\oplus]$ circuits exploited in the proof of Theorem 1 to prove a similar lower bound for more explicit problems or even for MAJORITY.

▶ **Theorem 2.** *For any positive integer d, there is a language in E^{NP} which does not have $\mathrm{AC}^0[\oplus]$ circuits of depth d and size $2^{o(n^{1/(d+1)})}$.*

2 Proof Outline for the Main Theorem

Our starting point is a *randomized* algorithm for the problem of checking satisfiability of an $\mathrm{AC}^0[\oplus]$ circuit C that runs in time 2^{n-m} where $m = n/O(\log s)^{d-1}$, and s, d represent the size, depth of C respectively (we also assume that s is suitably upper bounded, but we ignore it in this section). This algorithm is essentially due to Williams [27] and Lokshtanov, Paturi, Tamaki, Williams and Yu [16], though it does not appear explicitly in either of these papers.

The idea is to use a result of Razborov [21] that essentially says that small $\mathrm{AC}^0[\oplus]$ circuits C can be "approximated" by polynomials of small degree. More formally, there is a randomized algorithm that, when given a circuit C of size s over n variables, produces a (random) polynomial $\boldsymbol{P} \in \mathbb{F}_2[x_1, \ldots, x_n]$ of degree $O(\log s)^{d-1}$ that agrees with the value of a circuit C on any given input with good probability (say 0.9). Along with a fast polynomial evaluation algorithm [25], this immediately yields an *enumeration* algorithm for C (i.e. an algorithm to output the truth table of C) that runs in time $\mathrm{poly}(n)2^n + \mathrm{poly}(s)$, which beats (for large enough s) the trivial algorithm that simply evaluates C on each input and hence takes time $s \cdot 2^n$. Repeating the algorithm $\mathrm{poly}(n)$ times and taking the majority vote on each input, we get an enumeration algorithm that works with high probability.

To obtain a randomized satisfiability algorithm that runs in better-than-brute-force time, we use the above idea along with the "blowup-trick" [28, 6, 16]. For any $a \in \{0,1\}^m$, let C_a be the circuit obtained by setting the last m variables of C to a. Note that the satisfiability

of C can be computed by checking the satisfiability of $C' = \bigvee_{a\in\{0,1\}^m} C_a$, and C' is a circuit of larger size ($s \cdot 2^m$) but fewer variables ($n - m$). We now run the enumeration algorithm above on C' to check if it is satisfiable. Since the circuit is larger, the polynomial produced has larger degree: a careful analysis reveals the degree to be $m \cdot O(\log s)^{d-1}$. Setting $m = n/\Theta(\log s)^{d-1}$, we obtain a polynomial of degree $\ll n$, which can be computed in better-than-brute-force time. Running the enumeration algorithm as above gives the required satisfiability algorithm for C, which now runs in time $2^{n-n/\Theta(\log s)^{d-1}}$.

The above algorithm can further be modified to *count* satisfying assignments, by instead defining $C' = \sum_a C_a$ (a sum over $\mathbb{Z}$) instead of using an OR. Now, an additional idea is required since the polynomials $\boldsymbol{P}_a$ approximating each C_a are $\mathbb{F}_2$-polynomials whereas the sum is over the integers (in the satisfiability case above, the OR gate can further be approximated by a constant-degree polynomial using an idea of Razborov [21], but this idea is not available here). What comes to our rescue is an idea of Toda [24] and its subsequent quantitative refinement due to Beigel and Tarui [3] which tells us that we can simulate a sum (over $\mathbb{Z}$) of K many $\mathbb{F}_2$-polynomials of degree at most D as a polynomial (over $\mathbb{Z}$) of degree at most $D \log K$. Using this idea, we are able to obtain a polynomial of degree $m^2 \cdot O(\log s)^{d-1}$. Overall, this yields an algorithm with slightly worse running time $2^{n-\sqrt{n/\Theta(\log s)^{d-1}}}$.

A partial derandomization of these algorithms was obtained by Chan and Williams [6] in the case that the $\mathrm{AC}^0[\oplus]$ circuits are k-CNFs and generalized by Lokshtanov et al. [16] to the case of ANDs of degree-k polynomials.[4] Chan and Williams [6] observed that Razborov's random construction of polynomials could be suitably derandomized using *ε-biased spaces* [17]. Using this idea (and more work), it was shown that the number of satisfying assignments to a set of degree k-polynomials in n variables could be computed in time $2^{n-n/\Theta(k)}$, which meets the running time of the satisfiability algorithm mentioned above in this special case.

However, it is unclear how to extend the ideas to the setting of general $\mathrm{AC}^0[\oplus]$ circuits since these results used a very special property of the randomized polynomial construction for a single OR gate (and, dually, a single AND gate): namely, that there is a *constant-degree* polynomial whose bias perfectly predicts whether the input to an OR-gate is a 1 input or a 0 input.[5] Unfortunately, such a strong property is not known for general $\mathrm{AC}^0[\oplus]$ circuits: the best we can hope for is to construct a polynomial that with high probability, say $1-\varepsilon$, equals the output of the circuit on any given input, but then we have to pay for this precision in terms of the degree of the polynomial constructed. Further, it is not clear how to derandomize this general inductive construction.

We start by derandomizing the higher-depth random polynomial construction. Once again, ε-biased spaces play a crucial role, and we need to further use derandomized sampling using expanders for a near-optimal derandomization. Using this along with the idea of Beigel and Tarui [3] would yield a deterministic algorithm for counting satisfying assignments in time $2^{n-\sqrt{n/\Theta(\log s)^{d-1}}}$.

However, we further improve the running time to $2^{n-n/\Theta(\log s)^{d-1}}$, matching the running time of the randomized algorithm for checking satisfiability. The principal idea here is to observe (by looking inside the Razborov construction) that the polynomials $\boldsymbol{P}_a$ computed for approximating the individual circuits C_a mentioned above have a very special form: each $\boldsymbol{P}_a$

[4] Note that any k-clause is in particular a degree-k polynomial and hence the latter result generalizes the former.

[5] Briefly, the Razborov polynomial for the OR function on input bits $x_1, \ldots, x_s$ is as follows. Choose $a_1, \ldots, a_s \in \mathbb{F}_2$ independently and uniformly at random and compute $\boldsymbol{\ell}(x) = \sum_i a_i x_i$. Now, note that if $\mathrm{OR}(x_1, \ldots, x_s) = 1$, then $\ell(x)$ computes a uniformly random element of $\mathbb{F}_2$ and otherwise, $\ell(x) = 0$ with probability 1.

is a majority of $\ell = O(m)$ many polynomials $\boldsymbol{P}_{a,1}, \ldots, \boldsymbol{P}_{a,\ell}$ of degree $O(\log s)^{d-1}$ each. We use this and some basic Fourier analysis of Boolean functions to write $\boldsymbol{P}_a$ as a real-valued sum of polynomials of degree at most $O(\log s)^{d-1}$; this idea is inspired by a recent result of Chen and Papakonstantinou [7], who use it to give an improved depth-reduction result for constant-depth circuits with Mod_q gates for composite q. The advantage of doing this is that the degree blow-up in the randomized #SAT algorithm outline above is restricted to applying the idea of Beigel and Tarui, which means that the degree drops to $m \cdot O(\log s)^{d-1}$. Setting m suitably, we now obtain a deterministic algorithm running in time $2^{n-n/O(\log s)^{d-1}}$.

3 Preliminaries

We will consider polynomials over the fields $\mathbb{R}$ and $\mathbb{F}_2$. We identify $\mathbb{F}_2$ with $\{0,1\}$ in the natural way. We use $\binom{n}{\leq k}$ to denote $\sum_{i=0}^{k} \binom{n}{i}$. All algorithms will be implemented in the standard Turing machine with RAM model.

We recall that any function $f : \{0,1\}^n \to R$ for any commutative ring R has a unique representation as a multilinear polynomial. Given two such polynomials representing possibly different functions f_1 and f_2, we can compute the multilinear polynomial corresponding to their product by multiplying the polynomials f_1 and f_2 and "multilinearizing" by replacing each copy of x_i^2 by x_i. In particular, this idea yields the following easy algorithm.

▶ **Fact 3.** *Let R be either $\mathbb{F}_2$ or $\mathbb{Z}$. There is a deterministic algorithm which, when given as input multilinear polynomials $f_1, \ldots, f_t \in R[x_1, \ldots, x_n]$ (as a sum of monomials) of degree $d_1, \ldots, d_t$ such that $\sum_i d_i \leq D$, computes the multilinear polynomial corresponding to the product $f = f_1 \cdots f_t$. The algorithm runs in time $\mathrm{poly}(\binom{n}{\leq D})$ when $R = \mathbb{F}_2$ and time $\mathrm{poly}(\binom{n}{\leq D}, B)$ where B is the bit-complexity of the coefficients of $f_1, \ldots, f_t$ when $R = \mathbb{Z}$.*

3.1 Polynomials over $\mathbb{F}_2$ and Probabilistic polynomials

▶ **Definition 4** (Probabilistic Polynomials)**.** We recall [21, 23] that a *Probabilistic polynomial* from $\mathbb{F}_2[x_1, \ldots, x_n]$ is a random multilinear polynomial $\mathbf{P}$ (chosen according to some distribution) from $\mathbb{F}_2[x_1, \ldots, x_n]$. We say that $\mathbf{P}$ has degree at most D if the distribution of $\mathbf{P}$ is supported on polynomials of degree at most D (or equivalently $\Pr_{\mathbf{P}}[\deg(\mathbf{P}) \leq D] = 1$).

We say that $\mathbf{P}$ is an ε-error probabilistic polynomial for a function $f : \{0,1\}^n \to \{0,1\}$ if for each $a \in \{0,1\}^n$, we have $\Pr_{\mathbf{P}}[\mathbf{P}(a) \neq f(a)] \leq \varepsilon$.

3.2 Polynomials over $\mathbb{R}$ and Modulus-amplification

We recall the following basic facts about writing Boolean functions as multilinear polynomials over the the *reals*. See, e.g. O'Donnell [19] for proofs.

▶ **Fact 5.** *Let $f : \{0,1\}^\ell \to \{0,1\}$ be any Boolean function.*

1. *f can written as a unique* real-valued *linear combination*

$$f(x) = \sum_{S \subseteq [\ell]} \alpha_S \chi_S(x)$$

where $\chi_S(x) = \bigoplus_{i \in S} x_i$ (note that we interpret $\chi_S(x) \in \{0,1\}$ as a real number and the sum above is taken over $\mathbb{R}$).
2. *For each S, $\alpha_S \in [-1,1]$ and is moreover an integral multiple of $2^{-(\ell+1)}$.*
3. *There is a deterministic algorithm $\mathcal{C}$ which, given as input f (via its truth table), computes all the above α_S's in time $2^{O(\ell)}$.*

We also define the Fourier l_1 norm of f as $\|f\|_1 = \sum_S |\alpha_S|$.

The following is a useful *Modulus-amplification* lemma due to Beigel and Tarui [3]. This particular version is from the work of Chan and Williams [6].

▶ **Lemma 6** (Beigel-Tarui [3]). *For every positive integer t, the degree $2t-1$ polynomial $F_t(y) \in \mathbb{Z}[y]$ defined by*

$$F_t(y) = 1 - (1-y)^t \sum_{j=0}^{t-1} \binom{t+j-1}{j} y^j$$

has the property that for all $b \in \mathbb{Z}$,

- *if $b \equiv 0 \pmod 2$, then $F_t(b) \equiv 0 \pmod{2^t}$, and*
- *if $b \equiv 1 \pmod 2$, then $F_t(b) \equiv 1 \pmod{2^t}$.*

Many satisfiability algorithms for circuits are based on evaluating multivariate polynomials efficiently over grids. The following lemma can be found in, e.g., [25].

▶ **Lemma 7** (Fast Polynomial Evaluation). *There is a deterministic algorithm* FPE, *which given as input a multilinear polynomial $P \in \mathbb{Z}[x_1, \ldots, x_n]$ as a sum of monomials, computes the values $(P(a))_{a \in \{0,1\}^n}$ in time $\mathrm{poly}(n, B) \cdot 2^n$ where B is an upper bound on the bit complexity of the coefficients of P.*

3.3 Small-biased sets

We need the notion of *ε-biased sets* [17, 2], which are a standard tool in the derandomization literature.

▶ **Definition 8** (ε-biased sets [17]). For $\varepsilon \in \left(0, \frac{1}{2}\right)$, a set $S \subseteq \{0,1\}^n$ of n-dimensional vectors is ε-biased if for all non-zero $v \in \{0,1\}^n$,

$$\Pr_{w \in S}\{\langle v, w\rangle = 0 \pmod 2\} \in \left(\frac{1}{2} - \varepsilon, \frac{1}{2} + \varepsilon\right)$$

There are many explicit constructions for ε-biased sets. We use the following construction:

▶ **Theorem 9** ([2]). *There is a deterministic algorithm that, given as input n and $\varepsilon \in (0, 1/2)$, produces an ε-biased set $S \subseteq \{0,1\}^n$ of size $O(n^2/\varepsilon^2)$. The algorithm runs in time* $\mathrm{poly}(n/\varepsilon)$.

For any subspace W of $\{0,1\}^n$, define the indicator function $\mathbf{1}_W : \{0,1\}^n \to \{0,1\}$ as $\mathbf{1}_W(z) = 1$ if and only if the vector $z \in W$. From an Observation in O'Donnell's book [19], we see that

▶ **Observation 10** (Proposition 3.11 of [19]). *Let W be a subspace of $\{0,1\}^n$ and $W_\perp$ be its orthogonal complement such that $dim(W_\perp) = k$. Then, the constant term in the Fourier expansion of the indicator function $\mathbf{1}_W$ is $\frac{1}{2^k}$. Moreover, $\|\mathbf{1}_W\|_1 = 1$.*

Essentially, the proof for Observation 10 is based on the fact that a vector $z \in W$ if and only if the dot product of z with every basis vector of $W_\perp$ is 0.

De, Etesami, Trevisan and Tulsiani [8] observed that ε-biased spaces also fool functions with small Fourier l_1-norm.

▶ **Lemma 11** (Lemma 2.5 of [8]). *Let S be an ε-biased set. For every function $f : \{0,1\}^n \to \mathbb{R}$ we have,*

$$\left| \mathop{\boldsymbol{E}}_{y \in S}[f(y)] - \mathop{\boldsymbol{E}}_{x \sim U_n}[f(x)] \right| \leq \varepsilon \|f\|_1$$

where y is picked uniformly at random from S and U_n is the uniform distribution over $\{0,1\}^n$.

From Observation 10 and Lemma 11, we state the following useful corollary.

▶ **Corollary 12.** *Let W be a subspace of $\{0,1\}^n$, such that the co-dimension of W is k and let S be an ε-biased set. Then*

$$\Pr_{x \in S}\{x \in W\} \in \left(\frac{1}{2^k} - \varepsilon, \frac{1}{2^k} + \varepsilon\right)$$

where x is picked uniformly at random from S.

Intuitively speaking, Corollary 12 states that an ε-biased set also "fools" conjunctions of parities.

3.4 Expanders

Proofs of the following well-known facts may be found in the monograph of Hoory, Linial and Wigderson [13].

Given an undirected Δ-regular multigraph G, we denote by $A(G)$ its adjacency matrix and $\tilde{A}(G) = (1/\Delta)A(G)$ its *normalized* adjacency matrix. Then, we have the following.

- The all-1s vector $v \in \mathbb{R}^n$ is an eigenvector of $\tilde{A}(G)$ with eigenvalue 1.
- G is connected if and only if v is the only such eigenvector (up to scalar multiplication).

▶ **Definition 13** (Expanders [13])**.** An undirected multigraph G is an (N, Δ, λ) *expander* if it is a Δ-regular connected graph on N vertices (which we will identify with $[N]$), and all the eigenvalues (counted with multiplicity) of $\tilde{A}(G)$ other than 1 are bounded by λ in absolute value.

Let $(G_n)_{n\geq 1}$ be a sequence of expander graphs with G_n being an $(f(n), \Delta, \lambda)$-expander for some increasing function $f : \mathbb{N} \to \mathbb{N}$ and constants Δ and λ. We say that $(G_n)_{n\geq 1}$ is *explicit* if there is a deterministic algorithm that, when given as input n, produces the graph G_n in time $\mathrm{poly}(n, f(n))$.

We use Reingold, Vadhan and Wigderson's [22] explicit construction for an expander graph.

▶ **Theorem 14** ([22])**.** *For every fixed $\lambda > 0$ there exists a constant $\Delta > 0$ and an explicit sequence of expander graphs $(G_n)_{n\geq 1}$, where G_n is a $(2^n, \Delta, \lambda)$ expander graph, for some large enough constant Δ. Further, we can assume that Δ is a power of 2.*

We will need the following expander-based Chernoff bound due to Gillman [10]. The version below is due to Healy [12].

▶ **Theorem 15** ([10, 12])**.** *Let G be an (N, D, λ)-graph and let $S \subseteq [N]$ be a subset of the vertices of G such that $|S| = \beta N$. Consider the natural ℓ-step random walk on G defined by choosing a uniformly random vertex $u_1 \in [N]$ and repeatedly choosing random neighbours $\ell - 1$ times to obtain a (random) sequence $(u_1, \ldots, u_\ell)$ of vertices of G. Let X_S denote the number of $i \in [\ell]$ such that $u_i \in S$. For any fixed $\rho \in (0,1)$, we have*

$$\Pr_{u_1,\ldots,u_\ell}[|X_S - \beta\ell| \geq \rho\ell] \leq 2\exp\left(-\frac{1}{4}\rho^2(1-\lambda)\ell\right).$$

4 The #SAT algorithm

In this section we prove Theorem 1. We start with a deterministic algorithmic version of a lemma of Razborov [21] regarding approximating $\mathrm{AC}^0[\oplus]$ circuits by low-degree polynomials. Using this version, we then state formally the #SAT algorithm and analyze it.

4.1 Derandomized construction of probabilistic polynomials for $\mathbf{AC^0}[\oplus]$

The following lemma is an algorithmic version of a result of Razborov [21] (see also Kopparty-Srinivasan [15] for the dependence on ε). It can be viewed as a derandomization of a randomized algorithm due to Williams [27].

▶ **Lemma 16.** *For any $\varepsilon > 0$, an $\mathrm{AC}^0[\oplus]$ circuit C over n variables of depth d and size at most s has an ε-error probabilistic polynomial $\mathbf{P}$ from $\mathbb{F}_2[x_1, \ldots, x_n]$ of degree at most $D = (O(\log s)^{d-1} \cdot \log(1/\varepsilon))$. Moreover $\mathbf{P} = \mathrm{Maj}(\mathbf{P}_1, \ldots, \mathbf{P}_\ell)$, where $\mathbf{P}_1, \ldots, \mathbf{P}_\ell$ are probabilistic polynomials of degree $D_1 = O(\log s)^{d-1}$ and $\ell = O(\log(1/\varepsilon))$.*

Moreover, there is a deterministic procedure $\mathcal{S}$, which when given as input the circuit C, the parameter ε, and a uniformly random Boolean string $\boldsymbol{\sigma}$ of length $r = O(\log(s/\varepsilon))$, produces a random sample of the polynomials $\mathbf{P}_1, \ldots, \mathbf{P}_\ell$ as sums of monomials. The procedure $\mathcal{S}$ runs in time $\mathrm{poly}\left(\ell, s, \binom{n}{\leq D_1}\right)$.

Before we go into the proof of Lemma 16, we prove a weaker version that will be useful in the proof of Lemma 16. This result is a higher-depth analogue of a result of Chan and Williams [6] which itself may be viewed as a derandomization of the construction of Razborov [21] for depth-1 circuits.

▶ **Lemma 17.** *For every $\mathrm{AC}^0[\oplus]$ circuit C over n variables of depth d and size s, there exists a probabilistic polynomial $\mathbf{P}'$ with error at most $\frac{1}{4}$ with degree at most $D_1 = O(\log s)^{d-1}$. Further, there is a deterministic algorithm $\mathcal{S}_1$ that produces a random sample of $\mathbf{P}'$ as a sum of monomials given as input s, C and $O(\log s)$ random bits. The algorithm $\mathcal{S}_1$ runs in time* $\mathrm{poly}\left(s, \binom{n}{\leq D_1}\right)$.

Proof. Let C be the circuit input to the sampling algorithm. Let $m = s\log(40s), \varepsilon = 1/(20s)$ and $S \subseteq \{0,1\}^m$ be an ε-biased set of size $\mathrm{poly}(s)$ given by Theorem 9. Fix an input $a \in \{0,1\}^n$.

Fix some enumeration $g_1, \ldots, g_s$ of all the gates of C. Let $h \in \{g_1, \ldots, g_s\}$ be the output gate of C and let $C_1, \ldots, C_r$ ($r \leq s$) be the depth-$(d-1)$ sub-circuits of C feeding into h. First we construct a probabilistic polynomial of degree $O(\log s)$ for each gate $g \neq h$ in the circuit, following which we construct a constant degree probabilistic polynomial for the gate h. Composing these polynomials together gives the probabilistic polynomial for the circuit C of degree $O(\log s)^{d-1}$.

Fix any gate $g \neq h$ in C. If g is a NOT gate or a $\oplus$ gate, we can easily get a polynomial P_g of degree 1 which always agrees with the function computed by g and needs no random bits. Therefore, let g be an OR gate in C (a dual construction works for AND gates). Let $g_{i_1}, \ldots, g_{i_k}$ be the gates that are inputs to g and $v_g \in \{0,1\}^s$ such that $v_g[i] = 1$ iff $i \in \{i_1, \ldots, i_k\}$ and $g_i = 1$ (on the fixed input a). Observe that g outputs 1 iff v_g is not the zero vector.

Let $t = \log(40s)$. Construct the vectors $u_1, \ldots, u_t \in \{0,1\}^m$, such that for each u_p, $1 \leq p \leq t$, we divide u_p into t blocks, such that the p^{th} block contains v_g and all the other bits of u_p are set to 0. The dimension of the vector space $V \subseteq \mathbb{F}_2^m$ spanned by $\{u_1, \ldots, u_t\}$ is equal to t if v_g is a non-zero vector. Let $\boldsymbol{y} \in S$ be picked uniformly at random from S. We split $\boldsymbol{y}$ into t blocks $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_t$ of size s each. W.l.o.g. consider the vector u_1. The inner product $\langle u_1, \boldsymbol{y}\rangle$ which is exactly equal to the inner product $\langle v_g, \boldsymbol{y}_1\rangle$, can be calculated by hardwiring into a MOD_2 gate all the input gates of g for which the corresponding bit in $\boldsymbol{y}$ equals 1. In other words, the inner product $\langle u_1, \boldsymbol{y}\rangle$ is represented by the polynomial $q_1 = \sum_{j \in \{i_1, \ldots, i_k\}} g_j \cdot (\boldsymbol{y}_1)_j$ in the inputs $g_{i_1}, \ldots, g_{i_k}$. Repeating this construction for all t

vectors $u_1, \ldots, u_t$, we get polynomials $q_1^{\boldsymbol{y}}, \ldots, q_t^{\boldsymbol{y}}$. Finally, we compute the disjunction of these t terms using the polynomial $P_g^{\boldsymbol{y}} = 1 - \prod_{p=1}^{t}(1 - q_p^{\boldsymbol{y}})$, which is of degree $t = O(\log s)$ in the input variables of g.

We now analyze the behaviour of $P_g^{\boldsymbol{y}}$ on a fixed input to the gate g. If the gate g outputs 0, then for any $y \in S$, we get $\langle u_p, y\rangle = 0$ for every $1 \le p \le t$. In particular, $P_g^{\boldsymbol{y}}$ outputs 0 with probability 1. On the other hand, if g outputs 1, we see that $P_g^{\boldsymbol{y}}$ errs on this input iff for each $1 \le p \le t$, $q_p^{\boldsymbol{y}} = 0$. Let $V_\perp$ be the orthogonal complement to $V = \mathrm{span}(\{u_1, \ldots, u_t\})$. Note that the codimension of the vector space $V_\perp$ is t. We now use Corollary 12 to see that, if g outputs 1, a uniformly random element $\boldsymbol{y}$ from S belongs to $V_\perp$, or in other words, yields $\langle u_p, \boldsymbol{y}\rangle = 0$ for every $1 \le p \le t$, with probability at most $\frac{1}{2^t} + \varepsilon$. Thus, $P_g^{\boldsymbol{y}}$ disagrees with the output of g on *any fixed input* with probability at most $\frac{1}{2^t} + \varepsilon = \frac{1}{40s} + \frac{1}{20s} = \frac{3}{40s}$.

We pick a *single* $\boldsymbol{y}$ uniformly at random from S and then use it (for each OR and AND gate) to get the probabilistic polynomial $P_g^{\boldsymbol{y}}$ for each gate $g \neq h$ in C. For each $j \in [r]$, composing the polynomials representing the gates in C_j, we obtain a probabilistic polynomial $\mathbf{Q}_j$ of degree at most $O(\log s)^{d-1}$. Following this, we use the first $t_1 = 3$ blocks of $\boldsymbol{y}$ in a similar fashion to get a probabilistic polynomial $\mathbf{P}_h$ of degree $O(1)$ for the function computed by the output gate h with error at most $\frac{1}{2^{t_1}} + \varepsilon$. Now, for any input $a \in \{0,1\}^n$, $\mathbf{P}' = \mathbf{P}_h(\mathbf{Q}_1, \ldots, \mathbf{Q}_r)$ satisfies

$$\begin{aligned}
\Pr_{\mathbf{P}'}[C(a) \neq \mathbf{P}'(a)] &\le \Pr_{\mathbf{Q}_1,\ldots,\mathbf{Q}_r}[\exists j \in [r] : C_j(a) \neq \mathbf{Q}_j(a)] \\
&\quad + \Pr_{\mathbf{P_h}}[h(C_1(a), \ldots, C_r(a)) \neq \mathbf{P}_h(C_1(a), \ldots, C_r(a))] \\
&\le s \cdot \frac{3}{40s} + \frac{1}{2^{t_1}} + \varepsilon \\
&\le \frac{3}{40} + \frac{1}{8} + \frac{1}{20s} \le \frac{1}{4}
\end{aligned}$$

where the second inequality uses a union bound over the (at most s) gates g in C.

This gives us a probabilistic polynomial $\mathbf{P}'$ of degree $O(\log s)^{d-1}$ for the circuit C, with error at most $\frac{1}{4}$ and we need $O(\log |S|) = O(\log s)$ random bits to get this sample. This polynomial is multilinear and by expanding the monomials at each step we can ensure multilinearity of the intermediate polynomials. Using Fact 3 we see that the running time of the sampling algorithm is given by poly $\left(s, \binom{n}{\le D_1}\right)$. ◀

Proof of Lemma 16. Let $k = O(\log s)$ be the number of random bits needed by the algorithm $\mathcal{S}_1$ from Lemma 17. Consider an explicit $(2^k, \Delta, \lambda)$ expander graph G on $V = \{0,1\}^k$ given by Theorem 14, where Δ is a large enough constant given by the construction and $\lambda = \frac{1}{2}$. The graph G can be constructed in time poly$(2^k) =$ poly(s).

Let $\ell = 200 \log\left(\frac{2}{\varepsilon}\right)$. We define the algorithm $\mathcal{S}$ to be the following deterministic procedure which takes as input the circuit C, the parameter ε and a random string $\boldsymbol{\sigma}$ of length $r = k + (\ell - 1) \cdot \log \Delta$ and produces a random sample of the probabilistic polynomials $\mathbf{P}_1, \ldots, \mathbf{P}_\ell$, where each of the $\mathbf{P}_i$ is an instantation of the probabilistic polynomial constructed in Lemma 17.

1. Perform a length ℓ random walk in G using the bits of $\boldsymbol{\sigma}$ to obtain $\boldsymbol{u}_1, \ldots, \boldsymbol{u}_\ell \in V = \{0,1\}^k$. I.e. first choose $\boldsymbol{u}_1$ uniformly at random from V and for each $i \in \{2, \ldots, \ell\}$, let $\boldsymbol{u}_i$ be a random neighbour of $\boldsymbol{u}_{i-1}$ in the graph G.
2. For each $1 \le i \le \ell$, use $\boldsymbol{u}_i$ as the input string of random bits to algorithm $\mathcal{S}_1$ from Lemma 17 to obtain a random sample $\mathbf{P}_i$ of the 1/4-error probabilistic polynomial $\mathbf{P}'$ for C.

The number of random bits used by $\mathcal{S}$ to obtain a random sample of $\mathbf{P}_1, \ldots, \mathbf{P}_\ell$ is $r = O(k+\ell) = O(\log s + \log\left(\frac{1}{\varepsilon}\right)) = O\left(\log(s/\varepsilon)\right)$. At each step of the random walk we spend poly $\left(s, \binom{n}{\leq D_1}\right)$ time to get a sample and thus, the overall running time of $\mathcal{S}$ is poly $\left(\ell, s, \binom{n}{\leq D_1}\right)$.

Now, define the probabilistic polynomial $\mathbf{P} = \mathrm{Maj}(\mathbf{P}_1, \ldots, \mathbf{P}_\ell)$. Since, the majority of ℓ bits is a polynomial of degree at most ℓ, the degree of $\mathbf{P}$ is $O(\log s)^{d-1} \cdot \log(1/\varepsilon)$.

To show that $\mathbf{P}$ is a probabilistic polynomial with error ε for the circuit C, fix an input $a \in \{0,1\}^n$. For any $u \in V$, let P^u be the polynomial sampled by the algorithm $\mathcal{S}_1$ when given u as input. Let B be the set of vertices $u \in V$ such that $P^u(a) \neq C(a)$. Note that as $\mathcal{S}_1$ samples a $1/4$-error probabilistic polynomial for C, we must have $|B| \leq |V|/4$. Now, we have $\mathbf{P}(a) \neq C(a)$ iff a majority of the vertices on the random walk sampled by $\mathcal{S}$ belong to B. Using Theorem 15 we show that this event happens with a probability at most ε.

Let X_B be the random variable which denotes the number of $i \in [\ell]$ such that $i \in B$. Using Theorem 15 with the settings $\beta = \frac{|B|}{|V|} \leq \frac{1}{4}, \lambda = \frac{1}{2}, \rho = \frac{1}{4}$ and $\ell = 200\log(2/\varepsilon)$, we see that

$$\Pr_{u_1,\ldots,u_\ell}\left\{\left|X_B - \ell/4\right| > \ell/4\right\} \leq 2\exp\left(-\frac{1}{4}\rho^2(1-\lambda)\cdot 200\log\left(\frac{2}{\varepsilon}\right)\right) < 2\cdot 2^{-\log\left(\frac{2}{\varepsilon}\right)} < \varepsilon \quad \blacktriangleleft$$

4.2 The algorithm and its analysis

We begin by describing the #SAT algorithm $\mathcal{A}$.

Algorithm $\mathcal{A}$.

The algorithm $\mathcal{A}$ has the following desired input-output behaviour.

Input: An $\mathrm{AC}^0[\oplus]$ circuit C over n variables of size at most s and depth at most d. Recall that $s \leq 2^{(\varepsilon_0 n)^{1/d}}$ for some absolute constant $\varepsilon_0 > 0$ (to be chosen below). We assume $s \geq n$.

Desired Output: The number of satisfying assignments of C.

Notation. Let $m = \gamma n/(\log s)^{d-1}$ for a suitable absolute constant $\gamma > 0$ that will be fixed below. Let $\varepsilon = 1/2^{10m}$. For s and ε as defined above, choose $r = O(\log(s/\varepsilon))$ suitably so that the sampling algorithm $\mathcal{S}$ from Lemma 16 works as stated.

For each $\sigma \in \{0,1\}^r$, let $(P_1^\sigma, \ldots, P_\ell^\sigma)$ be the output of the algorithm $\mathcal{S}$ on string σ (note that the probabilistic polynomials $(\boldsymbol{P}_1, \ldots, \boldsymbol{P}_\ell)$ from Lemma 16 are exactly the polynomials $(P_1^{\boldsymbol{\sigma}}, \ldots, P_\ell^{\boldsymbol{\sigma}})$ for a uniformly random $\boldsymbol{\sigma}$ and hence $\boldsymbol{P} = \mathrm{Maj}(P_1^{\boldsymbol{\sigma}}, \ldots, P_\ell^{\boldsymbol{\sigma}})$).

For fixed $\sigma \in \{0,1\}^r$ and $c \in \{0,1\}^m$, let $P_i^{\sigma,c} \in \mathbb{F}_2[x_1, \ldots, x_{n-m}]$ be defined by $P_i^{\sigma,c} = P_i^\sigma(x_1, \ldots, x_{n-m}, c_1, \ldots, c_m)$ (i.e. the last m variables of P_i^σ are fixed to bits of c). Let $P^{\sigma,c} = \mathrm{Maj}(P_1^{\sigma,c}, \ldots, P_\ell^{\sigma,c})$.

For $S \subseteq [\ell]$, let $P_S^{\sigma,c} = \bigoplus_{i\in S} P_i^{\sigma,c}$. Let $Q_S^{\sigma,c}$ be the polynomial with integer coefficients obtained by treating the $\mathbb{F}_2$-coefficients of $P_S^{\sigma,c}$ as integers. Note that for each $b \in \{0,1\}^{n-m}$, $P_S^{\sigma,c}(b) \equiv Q_S^{\sigma,c}(b) \pmod 2$.

1. Using the algorithm $\mathcal{C}$ from Fact 5, compute[6] integers $k_S \in \{2^{-(\ell+1)}, \ldots, 2^{(\ell+1)}\}$ for each $S \subseteq [\ell]$ such that $\mathrm{Maj}(z_1, \ldots, z_\ell) = \frac{1}{2^{\ell+1}} \sum_{S\subseteq[\ell]} k_S \bigoplus_{i\in S} z_i$.

[6] There is actually an explicit description of the integers k_S (see, e.g., O'Donnell [19]) using which each k_S can each be computed in time poly(ℓ) as opposed to the $2^{O(\ell)}$ time taken by the algorithm $\mathcal{C}$. However, the algorithm we give here doesn't need this and works for any Boolean function in place of Maj.

2. For each $c \in \{0,1\}^m$, $\sigma \in \{0,1\}^r$ and $S \subseteq [\ell]$, construct (as a sum of monomials) the polynomial $Q_S^{\sigma,c}(x_1, \ldots, x_{n-m})$ using the algorithm $\mathcal{S}$ from Lemma 16.
3. Construct as a sum of monomials (Fact 3) the multilinear polynomial $R \in \mathbb{Z}[x_1, \ldots, x_{n-m}]$ defined by

$$R(x_1, \ldots, x_{n-m}) = \sum_{c \in \{0,1\}^m} \sum_{\sigma \in \{0,1\}^r} \sum_{S \subseteq [\ell]} k_S \cdot F_t(Q_S^{\sigma,c}(x_1, \ldots, x_{n-m}))$$

   where F_t is the modulus amplifying polynomial given by Lemma 6 and $t = A \log(s/\varepsilon)$ for a large absolute constant $A > 0$ chosen below.
4. Evaluate $R(b)$ for each $b \in \{0,1\}^{n-m}$ using the algorithm FPE from Lemma 7.
5. Let $R_t(b) = R(b) \pmod{2^t} \in \{0, \ldots, 2^t - 1\}$. Output $\sum_{b \in \{0,1\}^{n-m}} [R_t(b)/2^{\ell+1+r}]$ where $[x]$ denotes the integer closest to x (if x is a half-integer, $[x]$ is defined arbitrarily).

Theorem 1 follows directly from Lemmas 18 and 19 below.

▶ **Lemma 18** (Running time). *For any constant $A > 0$, there exist constants $\gamma > 0$ and $\varepsilon_0 > 0$ such that the algorithm $\mathcal{A}$, on an input circuit C of depth at most d and size at most $s \leq 2^{(\varepsilon_0 n)^{1/d}}$, has running time* $\mathrm{poly}(s) \cdot 2^{n/10} + \mathrm{poly}(n) \cdot 2^{n-m}$.

Proof. We analyse the running time of $\mathcal{A}$ by looking at the running times for each of its individual steps. From Fact 5, we see that Step 1 of the algorithm takes $2^{O(\ell)}$ running time. Since $\ell = O(\log(1/\varepsilon)) = O(m) = O(n/(\log s)^{d-1}) = o(n)$, this step takes at most $2^{o(n)} < 2^{n/10}$ time to run.

For Step 2, we see that the running time is $2^{\ell+m+r} \cdot \mathrm{poly}\left(\ell, s, \binom{n}{\leq D_1}\right)$, as we construct $2^{\ell+m+r}$ many polynomials using the algorithm $\mathcal{S}$, each of which takes $\mathrm{poly}(\ell, s, \binom{n}{\leq D_1})$ time to construct, as seen in Lemma 16. For the parameters we pick, we see that $2^{\ell+m+r} = 2^{o(n)}$ and $\binom{n}{\leq D_1} \leq n^{D_1} = n^{O(\log s)^{d-1}} = 2^{O(n^{(d-1)/d} \log n)}$. Thus, Step 2 takes at most $2^{n/10} \cdot \mathrm{poly}(n, s)$ time.

Step 3 takes time $2^{\ell+m+r} \cdot \mathrm{poly}\left(\ell, \binom{n}{\leq 2tD_1}\right)$, as the modulus amplifying polynomial F_t blows the degree of the polynomial up by a factor of $(2t-1)$ and the number of monomials in the multilinear expansion of the polynomial $R(x_1, \ldots, x_{n-m})$ is $\mathrm{poly}\left(\ell, \binom{n}{\leq 2tD_1}\right)$. To upper bound this running time, let $c' > 0$ be a constant such that the degree parameter D_1 from Lemma 16 is at most $c' \cdot (\log s)^{d-1}$. Then the degree of the polynomial R is at most

$$\begin{aligned} 2tD_1 &\leq 2t \cdot c'(\log s)^{d-1} \\ &= 2A \log(s/\varepsilon) \cdot c'(\log s)^{d-1} \\ &= 2Ac'(\log s)^d + 20Amc'(\log s)^{d-1} \\ &= 2Ac'(\log s)^d + 20A\gamma c' n \end{aligned}$$

where we have used $\log(1/\varepsilon) = 10m$ and $m = \gamma n/(\log s)^{d-1}$.

Fix the constants $\varepsilon_0 = \left(\frac{1}{400Ac'}\right)$ and $\gamma = \frac{1}{4000Ac'}$. This ensures that the $2tD_1 \leq 0.01n$. From this we see that, $\binom{n}{\leq 2tD_1}$ is at most $\left(\frac{ne}{2tD_1}\right)^{2tD_1} \leq \left(\frac{ne}{0.01n}\right)^{0.01n} < 2^{0.09n}$ and we see that step 3 takes at most $2^{n/10}$ time.

Note that each k_S computed in Step 1 is an $(\ell+1)$-bit integer and hence, the bit complexity of the coefficients of R is at most $O(\ell + m + r) \leq n$. From Lemma 7, we see that Step 4 takes $2^{n-m}\,\mathrm{poly}(n)$ time and Step 5 runs in the same time trivially. Thus, the algorithm $\mathcal{A}$ takes a total of $\mathrm{poly}(n, s) \cdot 2^{n/10} + \mathrm{poly}(n) \cdot (2^{n-m})$ to run. ◀

▶ **Lemma 19** (Correctness). *Assume that $A > 0$ is chosen large enough so that $t > m + r + \ell + 10$. Then the algorithm $\mathcal{A}$ above outputs the number of satisfying assignments of C.*

Proof. We need to show that the algorithm $\mathcal{A}$ computes correctly the number of satisfying assignments of C. To this end, define the function C' on $n-m$ input bits by

$$C'(x_1, \ldots, x_{n-m}) = \sum_{c \in \{0,1\}^m} C(x_1, \ldots, x_{n-m}, c_1, \ldots, c_m)$$

where the sum is over $\mathbb{Z}$. It suffices to show that, for every $b \in \{0,1\}^{n-m}$, $[R_t(b)/2^{\ell+1+r}]$ is a correct estimate of $C'(b)$ since this implies that the number of satisfying assignments of C, which is equal to $\sum_{b \in \{0,1\}^{n-m}} C'(b)$, is computed correctly.

From the definition of $R_t(b)$, we see that for any $b \in \{0,1\}^{n-m}$

$$\begin{aligned} R_t(b) &= R(b) \pmod{2^t} \\ &= \left(\sum_{c \in \{0,1\}^m} \sum_{\sigma \in \{0,1\}^r} \sum_{S \subseteq [\ell]} k_S \cdot F_t(Q_S^{\sigma,c}(b)) \right) \pmod{2^t} \\ &= \left(\sum_{c \in \{0,1\}^m} \sum_{\sigma \in \{0,1\}^r} \sum_{S \subseteq [\ell]} k_S \cdot \left(F_t(Q_S^{\sigma,c}(b)) \pmod{2^t} \right) \right) \pmod{2^t} \end{aligned}$$

For every $\sigma \in \{0,1\}^r, c \in \{0,1\}^m, S \subseteq [\ell]$ and $b \in \{0,1\}^{n-m}$, we use the property of the modulus amplifying polynomial F_t from Lemma 6, to observe that $F_t(Q_S^{\sigma,c}(b)) \pmod{2^t} = P_S^{\sigma,c}(b) = \oplus_{i \in S} P_i^{\sigma,c}(b)$. This observation, along with Step 1 of the algorithm $\mathcal{A}$ implies that the sum $\sum_{S \subseteq [\ell]} k_S \cdot (F_t(Q_S^{\sigma,c}(b)) \pmod{2^t})$ is the same as $2^{\ell+1}\mathrm{Maj}(P_1^{\sigma,c}(b), \ldots, P_\ell^{\sigma,c}(b)) = 2^{\ell+1} P^{\sigma,c}(b)$. In other words,

$$R_t(b) = \left(2^{\ell+1} \sum_{c \in \{0,1\}^m} \sum_{\sigma \in \{0,1\}^r} P^{\sigma,c}(b) \right) \pmod{2^t} = 2^{\ell+1} \sum_{c \in \{0,1\}^m} \sum_{\sigma \in \{0,1\}^r} P^{\sigma,c}(b)$$

where the last equality follows from the fact that $t > m + \ell + r + 10$.

Now, for every $b \in \{0,1\}^{n-m}$ and $c \in \{0,1\}^m$, we have

$$\sum_{\sigma \in \{0,1\}^r} P^{\sigma,c}(b) \begin{cases} \geq 2^r(1-\varepsilon) & \text{if } C(b,c) = 1 \\ \leq 2^r \varepsilon & \text{if } C(b,c) = 0 \end{cases}$$

where $\varepsilon = 2^{-10m}$. Since $C'(b) = \sum_{c \in \{0,1\}^m} C(b,c)$, we now have that for every $b \in \{0,1\}^{n-m}$,

$$\begin{aligned} R_t(b) &\geq 2^{\ell+1} \cdot 2^r(1-\varepsilon) C'(b), \text{ and} \\ R_t(b) &\leq 2^{\ell+1} \cdot (2^r(1-\varepsilon)C'(b) + \varepsilon(2^m - C'(b)) \cdot 2^r) \\ &\leq 2^{\ell+1} \cdot (2^r(1-\varepsilon)C'(b) + \varepsilon 2^m \cdot 2^r)\,. \end{aligned}$$

In particular, since $\varepsilon = 2^{-10m}$, for every $b \in \{0,1\}^{n-m}$, we see that the estimate returned by the algorithm, which is $[R_t(b)/2^{\ell+1+r}]$, is equal to $C'(b)$. ◀

4.3 A Consequence for Lower Bounds

Our #SAT algorithm can be used to obtain improved lower bounds against $\mathrm{AC}^0[\oplus]$ circuits (and more generally, against $\mathrm{AC}^0[p]$ circuits for prime p), using Williams' connection between algorithms and lower bounds. These lower bounds are, however, not very explicit - they hold for a language in E^{NP}.

We first remind the reader of the best explicit lower bounds that are known against $\mathrm{AC}^0[\oplus]$ circuits.

▶ **Theorem 20.** *[21, 23] For each positive integer d, there is a language computable in polynomial time that requires depth-d $\mathrm{AC}^0[\oplus]$ circuits of size $2^{\Omega(n^{1/2(d-1)})}$.*

In fact, there is a fixed explicit language in polynomial time, namely Majority, for which the lower bounds of Theorem 20 hold for all d.

In terms of parameters, the bound in Theorem 20 is weaker than the best known bound for AC^0 circuits as a function of d. Parity is known to require depth-d circuits of size $2^{\Omega(n^{1/(d-1)})}$. The exponent in the bound of Theorem 20 is quadratically smaller. It has been a longstanding open problem to improve the bound in Theorem 20 to match the known bounds for constant-depth circuits without prime modulus circuits. Using the algorithmic method of Williams and its refinements, we are able to use our #SAT algorithm to make progress on this problem.

The following lemma can be shown using the proof technique of Theorem 1.5 in [4].

▶ **Lemma 21.** *[26, 4] Let s be a size function and d a positive integer such that satisfiability can be solved deterministically in time $2^n/n^{\omega(1)}$ on $\mathrm{AC}^0[\oplus]$-circuits of size $O(s(n))$ and depth at most d on n variables. Then there is a language in E^{NP} which does not have $\mathrm{AC}^0[\oplus]$ circuits of depth $d-1$ and size $o(s(n))$.*

We now apply the lemma to get better lower bounds than Theorem 20 in terms of size against $\mathrm{AC}^0[\oplus]$ circuits when the depth is at least 3. A similar lower bound against $\mathrm{AC}^0[p]$ circuits can be shown for prime p using the analogue of Theorem 1 for $\mathrm{AC}^0[p]$ circuits. The following result is simply a re-statement of Theorem 2.

▶ **Theorem 22.** *For any positive integer d, there is a language in E^{NP} which does not have $\mathrm{AC}^0[\oplus]$ circuits of depth d and size $2^{o(n^{1/(d+1)})}$.*

Proof. Pick $\varepsilon < \varepsilon_0$, where ε_0 is the constant in Theorem 1. By Theorem 1, for any size $s \leq 2^{(\varepsilon n)^{1/(d+1)}}$, there is a deterministic algorithm solving satisfiability of $\mathrm{AC}^0[\oplus]$ circuits of size at most s and depth at most $d+1$ in time $2^n/n^{\omega(1)}$. Now using Lemma 21, we have that there is a language in E^{NP} which does not have $\mathrm{AC}^0[\oplus]$ circuits of depth d and size $o(s(n))$, which establishes our claim. ◀

donald.stull@inria.fr

Abstract

In this paper we investigate the (effective) dimension spectra of lines in the Euclidean plane. The dimension spectrum of a line $L_{a,b}$, $\mathrm{sp}(L)$, with slope a and intercept b is the set of all effective dimensions of the points $(x, ax + b)$ on L. It has been recently shown that, for every a and b with effective dimension less than 1, the dimension spectrum of $L_{a,b}$ contains an interval. Our first main theorem shows that this holds for every line. Moreover, when the effective dimension of a and b is at least 1, $\mathrm{sp}(L)$ contains a *unit* interval.

Our second main theorem gives lower bounds on the dimension spectra of lines. In particular, we show that for every $\alpha \in [0, 1]$, with the exception of a set of Hausdorff dimension at most α, the effective dimension of $(x, ax + b)$ is at least $\alpha + \frac{\dim(a,b)}{2}$. As a consequence of this theorem, using a recent characterization of Hausdorff dimension using effective dimension, we give a new proof of a result by Molter and Rela on the Hausdorff dimension of Furstenberg sets.

1 Introduction

This paper is concerned with the algorithmic dimension of points on a given line in the Euclidean plane. The most well-studied algorithmic dimensions for a point $x \in \mathbb{R}^n$ are the *effective Hausdorff dimension*, $\dim(x)$, and its dual, the *effective packing dimension*, $\mathrm{Dim}(x)$ [3, 1]. Given the pointwise nature of effective dimension, it is natural to consider the dimension spectrum, $\mathrm{sp}(A)$, of a set $A \subseteq \mathbb{R}^n$, which is defined to be the set of $\dim(x)$ for all $x \in A$.

In this paper, we study the behavior of $\mathrm{sp}(L_{a,b})$, where $L_{a,b}$ is the line with slope a and intercept b. Turetsky [13] gave the first result on the dimension spectra of lines, showing that, for every $n \geq 2$, the set of all points in $\mathbb{R}^n$ with effective Hausdorff 1 is connected, implying that $1 \in \mathrm{sp}(L_{a,b})$. It was then asked by J. Lutz, with the expectation of a negative answer, if there were lines in the plane whose dimension spectrum was the singleton $\{1\}$. N. Lutz and Stull [9] showed that this cannot happen by proving the following theorem.

▶ **Theorem 1** (N. Lutz and Stull [9]). *For all $a, b, x \in \mathbb{R}$,*

$$\dim(x, ax + b) \geq \dim^{a,b}(x) + \min\{\dim(a, b), \dim^{a,b}(x)\}.$$

Theorem 1 implies that, when $\dim(a, b) < 1$, the dimension spectrum of $L_{a,b}$ contains the interval $[2\dim(a, b), \dim(a, b) + 1]$. With this result, it is natural to conjecture that the dimension spectrum of every line $L_{a,b}$ contains an interval. Indeed, in a recent survey on effective dimension, N. Lutz [7] proposed the question of whether *every* line $L_{a,b}$ has a dimension spectrum containing a *unit* interval. Building upon the techniques of [9], N. Lutz and Stull [10] showed that this is the case for a restricted class of lines.

Table 1 Previously known results about the dimension spectra of lines.

$\forall a, b$	$1 \in \mathrm{sp}(L_{a,b})$ [13]
$\dim(a,b) = 2$	$\mathrm{sp}(L_{a,b}) = [1,2]$
$\dim(a,b) \geq 1$	$\mathrm{sp}(L_{a,b})$ infinite [10]
$\dim(a,b) = d < 1$	$[2d, 1+d] \subseteq \mathrm{sp}(L_{a,b})$ [9]
$\dim(a,b) = 0$	$\mathrm{sp}(L_{a,b}) = [0,1]$
$\dim(a,b) = \mathrm{Dim}(a,b) = d$	$[\min\{1,d\}, 1+\min\{1,d\}] \subseteq \mathrm{sp}(L_{a,b})$ [10]

▶ **Theorem 2** (N. Lutz and Stull [10]).
1. *If* $\dim(a,b) = \mathrm{Dim}(a,b)$*, then* $\mathrm{sp}(L_{a,b})$ *contains a unit interval.*
2. *If* $\dim(a,b) \geq 1$*, then* $\mathrm{sp}(L_{a,b})$ *is infinite.*

The second item, combined with Theorem 1, shows that for every line $L_{a,b}$, the dimension spectrum of $L_{a,b}$ is infinite. Table 1 gives a summary of these results.

The question of whether the dimension spectrum of every line contains an interval has remained open. Our first main theorem settles this question.

▶ **Theorem 3.** *Let* $(a,b) \in \mathbb{R}^2$ *such that* $\dim(a,b) \geq 1$*. Then, for every real number* $d \in [0,1]$*, there is a point* x *such that*

$$\dim(x, ax+b) = 1 + d.$$

Our second main theorem deals with providing lower bounds on the dimension spectrum of a given line in the plane. The previously discussed theorems have all focused on results proving that the spectrum of a given line contains certain values. However, very little is known about the lower bound of $\mathrm{sp}(L_{a,b})$ for arbitrary lines $L_{a,b}$. Our second main theorem gives a lower bound of the spectrum of arbitrary lines, disregarding a set of small Hausdorff dimension.

▶ **Theorem 4.** *For every* $a, b \in \mathbb{R}$ *and* $\alpha \in (0,1)$*, the set*

$$A = \{x \,|\, dim(x, ax+b) \leq \alpha + \frac{\dim(a,b)}{2}\}$$

has Hausdorff dimension at most α*.*

Apart from being intrinsically interesting, the study of the effective dimension of points on a line has strong connections to important problems in the field of Fractal Geometry. This connection is mediated by the following theorem relating the two notions of the effective dimension of points with the Hausdorff and packing dimension of sets.

▶ **Theorem 5** (Point-to-set principle [4]). *Let* $n \in \mathbb{N}$ *and* $E \subseteq \mathbb{R}^n$*. Then*

$$\dim_H(E) = \min_{A \subseteq \mathbb{N}} \sup_{x \in E} \dim^A(x), \text{ and}$$

$$\dim_P(E) = \min_{A \subseteq \mathbb{N}} \sup_{x \in E} \mathrm{Dim}^A(x).$$

Recent work has used effective dimension and the point-to-set principle to prove new results in Fractal Geometry [6, 8]. In particular, the point-to-set principle combined with Theorem 1 gives improved lower bounds on the Hausdorff dimension of a certain class of *Furstenberg sets* [9], an important open problem in Fractal Geometry (see Section 5 for definitions). As our final result, we show that our second main theorem, Theorem 4, gives a new proof of a result by Molter and Rela [12] on the dimension of Furstenberg sets.

2 Preliminaries

2.1 Kolmogorov Complexity in Discrete Domains

The *conditional Kolmogorov complexity* of $\sigma \in \{0,1\}^*$ given $\tau \in \{0,1\}^*$ is

$$K(\sigma|\tau) = \min_{\pi \in \{0,1\}^*} \{\ell(\pi) : U(\pi,\tau) = \sigma\} ,$$

where U is a fixed universal prefix-free Turing machine and $\ell(\pi)$ is the length of π. Any π that achieves this minimum is said to *testify* to the value $K(\sigma|\tau)$. The *Kolmogorov complexity* of σ is $K(\sigma) = K(\sigma|\lambda)$, where λ is the empty string. An important property, due to Levin, of Kolmogorov complexity is the *symmetry of information*:

$$K(\sigma|\tau, K(\tau)) + K(\tau) = K(\tau|\sigma, K(\sigma)) + K(\sigma) + O(1) .$$

Kolmogorov complexity extends naturally to other discrete domains (e.g., integers, rationals, etc.) via standard binary encodings.

We will also frequently use *relativized Kolmogorov complexity*. Letting U be a universal *oracle* machine, we may *relativize* the definition in this section to an arbitrary oracle set $A \subseteq \mathbb{N}$. The definitions of $K^A(\sigma|\tau)$ and $K^A(\sigma)$ are then identical to those above, except that U is given oracle access to A.

2.2 Kolmogorov Complexity in Euclidean Spaces

In this section we show how to lift the definition of Kolmogorogov complexity to Euclideans spaces by introducing precision parameters [5, 4]. Let $x \in \mathbb{R}^m$, and let $r, s \in \mathbb{N}$.[1]

The *Kolmogorov complexity of x at precision r* is

$$K_r(x) = \min \{K(p) \,:\, p \in B_{2^{-r}}(x) \cap \mathbb{Q}^m\} .$$

The *conditional Kolmogorov complexity of x at precision r given $q \in \mathbb{Q}^m$* is

$$\hat{K}_r(x|q) = \min \{K(p|q) \,:\, p \in B_{2^{-r}}(x) \cap \mathbb{Q}^m\} .$$

The *conditional Kolmogorov complexity of x at precision r given $y \in \mathbb{R}^n$ at precision s* is

$$K_{r,s}(x|y) = \max \left\{\hat{K}_r(x|q) \,:\, q \in B_{2^{-r}}(y) \cap \mathbb{Q}^n\right\} .$$

We abbreviate $K_{r,r}(x|y)$ by $K_r(x|y)$.

We will frequently use the following lemma, which shows that increasing an estimate of a point is at most linearly correlated with the number of extra bits.

▶ **Lemma 6** (Case and J. Lutz [2]). *There is a constant $c \in \mathbb{N}$ such that for all $n, r, s \in \mathbb{N}$ and $x \in \mathbb{R}^n$,*

$$K_r(x) \leq K_{r+s}(x) \leq K_r(x) + K(r) + ns + a_s + c ,$$

where $a_s = K(s) + 2\log(\lceil \frac{1}{2}\log n \rceil + s + 3) + (\lceil \frac{1}{2}\log n \rceil + 3)n + K(n) + 2\log n$.

In Euclidean spaces, we have a weaker version of symmetry of information.

[1] If we are given a nonintegral positive real as a precision parameter, we will always round up to the next integer. For example, $K_r(x)$ denotes $K_{\lceil r \rceil}(x)$ whenever $r \in (0, \infty)$.

▶ **Lemma 7** (J. Lutz and N. Lutz [4], N. Lutz and Stull [9]). *Let $x \in \mathbb{R}^m$ and $y \in \mathbb{R}^n$. For all $r, s \in \mathbb{N}$ with $r \geq s$,*

1. $K_r(x, y) = K_r(x|y) + K_r(y) + O(\log r)$.
2. $K_r(x) = K_{r,s}(x|x) + K_s(x) + O(\log r)$.

As in the case of Kolmogorov complexity in discrete domains, we can relativize the definitions of this section. We define $K_r^A(x)$ and $K_r^A(x|y)$ as before, except we replace the unrelativized complexity K with K^A.

2.3 Effective Dimensions

Although effective Hausdorff dimension was initially developed by J. Lutz using generalized martingales [3], it was later shown by Mayordomo [11] that it may be equivalently defined using the Kolmogorov complexity of Euclidean points of the previous section. We will be using this Kolmogorov characterization here as a definition.

The *effective Hausdorff dimension* and *effective packing dimension* of a point $x \in \mathbb{R}^n$ are

$$\dim(x) = \liminf_{r\to\infty} \frac{K_r(x)}{r} \quad \text{and} \quad \mathrm{Dim}(x) = \limsup_{r\to\infty} \frac{K_r(x)}{r}.$$

Intuitively, these dimensions measure the density of algorithmic information in the point x. Recently, J. Lutz and N. Lutz [4], developed the *lower* and *upper conditional dimension* of points $x \in \mathbb{R}^m$ given $y \in \mathbb{R}^n$, defined by

$$\dim(x|y) = \liminf_{r\to\infty} \frac{K_r(x|y)}{r} \quad \text{and} \quad \mathrm{Dim}(x|y) = \limsup_{r\to\infty} \frac{K_r(x|y)}{r}.$$

Again, we can relativize the definitions of this section. We define $\dim^A(x)$, $\mathrm{Dim}^A(x)$ $\dim^A(x|y)$, and $\mathrm{Dim}^A(x|y)$ as before, except we replace the unrelativized complexity K_r with K_r^A.

Of particular importance in this paper is the complexity of a point x *relative to another point* y, written $K_r^y(x)$. This is achieved by encoding the binary expansion of y into an oracle $A_y \subseteq \mathbb{N}$ in the standard fashion. We then write $K_r^y(x)$ for $K_r^{A_y}(x)$. J. Lutz and N. Lutz showed that $K_r^y(x) \leq K_{r,t}(x|y) + K(t) + O(1)$ [4].

3 Dimension Spectra of Lines of High Dimension

3.1 Approach and Previous Work

In this section we state the technical lemmas that underlie the proof of our first main theorem (Theorem 3). These lemmas were first stated and proved by N. Lutz and Stull [9, 10][2].

▶ **Lemma 8.** *Let $a, b, x \in \mathbb{R}$, $k \in \mathbb{N}$. Suppose that $r_1, \ldots, r_k \in \mathbb{N}$, $\delta \in \mathbb{R}_+$, and $\varepsilon, \eta_1, \ldots, \eta_k \in \mathbb{Q}_+$ satisfy the following conditions for every $1 \leq i \leq k$.*

1. $r_i \geq \log(2|a| + |x| + 6) + r_{i-1}$.
2. $K_{r_i}(a, b) \leq (\eta_i + \varepsilon)\, r_i$.
3. *For every $(u, v) \in \mathbb{R}^2$ such that $t = -\log \|(a, b) - (u, v)\| \in (r_{i-1}, r_i]$ and $ux + v = ax + b$, $K_{r_i}(u, v) \geq (\eta_i - \varepsilon)\, r_i + \delta \cdot (r_i - t)$.*

[2] Lemma 8 is stated here in a slightly stronger form than the version of [10]. The proof, however, is nearly identical. For completeness we give a proof in the Technical Appendix.

Then for every oracle set $A \subseteq \mathbb{N}$,

$$K^A_{r_k}(a,b,x \mid x, ax+b) \leq 2^k \left(K(\eta_1,\dots,\eta_k) + K(\varepsilon) + \frac{4\varepsilon}{\delta} r_k + O(\log r_k) \right) .$$

We will briefly describe the intuition behind Lemma 8. For $k = 1$, Lemma 8 roughly states that, if x and (a,b) satisfy the following properties, then we can compute an approximation of (a,b) given an approximation of $(x, ax+b)$.

1. $K_r(a,b)$ is small.
2. For every (u,v) such that $ux+v = ax+b$ either
   - $K_r(u,v)$ is large, or
   - (u,v) is close to (a,b)

This follows outputting a (u,v) of low complexity such that $ux+v = ax+b$. Under the above assumptions, any such pair must be close to (a,b), and so we can recover (a,b) with a small amount of extra information. Roughly, when $k > 1$, we do this procedure iteratively. That is, we begin by computing (a,b) to precision r_1 in the manner described above. Having done so, we do the same procedure, except that we restrict to finding a pair (u,v) *within* 2^{-r_1} of (a,b), and so on. This is useful when we can only guarantee that $K_r(u,v)$ is large when (u,v) is somewhat close to (a,b), which is the case in the proof of Theorem 3.

The next two lemmas will ensure that item (1) and (2) hold for a given pair (a,b).

▶ **Lemma 9** (N. Lutz and Stull [9]). *Let $a,b,x \in \mathbb{R}$. For all $(u,v) \in \mathbb{R}^2$ such that $ux+v = ax+b$ and $t = -\log \|(a,b)-(u,v)\| \in (0,r]$,*

$$K_r(u,v) \geq K_t(a,b) + K^{a,b}_{r-t}(x) - O(\log r) .$$

▶ **Lemma 10** (N. Lutz and Stull [10]). *Let $z \in \mathbb{R}^n$, $\eta \in \mathbb{Q} \cap [0, \dim(z)]$, and $k \in \mathbb{N}$. For all $r_1,\dots,r_k \in \mathbb{N}$, there is an oracle $D = D(r_1,\dots,r_k,z,\eta)$ such that*

1. *For every $t \leq r_1$, $K^D_t(z) = \min\{\eta r_1, K_t(z)\} + O(\log r_k)$*
2. *For every $1 \leq i \leq k$,*

$$K^D_{r_i}(z) = \eta r_1 + \sum_{j=2}^{i} \min\{\eta(r_j - r_{j-1}), K_{r_j, r_{j-1}}(z \mid z)\} + O(\log r_k) .$$

3. *For every $t \in \mathbb{N}$ and $x \in \mathbb{R}$, $K^{z,D}_t(x) = K^z_t(x) + O(\log r_k)$.*

3.2 First Main Theorem

In this section we prove our first main theorem, Theorem 3. To do so, we will break the proof into two cases. In the first we assume that, for arbitrarily long intervals, $K_r(a,b)$ is arbitrarily close to 1. In this case, it is "locally" as if $\dim(a,b) = \mathrm{Dim}(a,b)$, and we can use a similar proof to that of Theorem 2 in [10]. This case is formalized in the following lemma, whose proof if deferred to the appendix.

▶ **Lemma 11.** *Let $(a,b) \in \mathbb{R}^2$ such that $\dim(a,b) \geq 1$. Assume that, for every $\tau > 0$ and every $M \in \mathbb{N}$ there are infinitely many $R \in \mathbb{N}$ such that*

$$K_s(a,b) \leq (1+\tau)s,$$

for every natural number $s \in [R, MR]$. Then, for every real number $d \in (0,1]$, there is a point x such that $\dim(x, ax+b) = 1+d$.

Proof. Let $d \in (0,1]$. For every $n \in \mathbb{N}$, let $\tau_n = \frac{1}{n}$ and $M_n = \frac{2^n}{d}$. Let $R_1, R_2, \ldots$ be a sequence of natural numbers such that the following hold.

1. $2^{R_n} < R_{n+1}$.
2. For every n, R_n satisfies the hypothesis for the choices of τ_n and M_n.

We now define a real number x such that

$$\dim(x, ax+b) = 1 + d. \tag{1}$$

Let $y \in \mathbb{R}$ be a real number that is random relative to (a,b). That is, for every $r \in \mathbb{N}$,

$$K_r^{a,b}(y) \geq r - \log r.$$

For every $n \in \mathbb{N}$, define $h_n = \frac{(M_n - 1)R_n}{2}$. For every $r \in \mathbb{N}$, let

$$x[r] = \begin{cases} 0 & \text{if } \frac{r}{h_n} \in (d,1] \text{ for some } n \in \mathbb{N} \\ y[r] & \text{otherwise} \end{cases}$$

where $x[r]$ is the rth bit of x. Define $x \in \mathbb{R}$ to be the real number with this binary expansion.

We first claim that the dimension of $(x, ax+b)$ is at most $1+d$. For every $n \in \mathbb{N}$, by our construction of x and choice of y,

$$\begin{aligned} K_{h_n}(x) &= K_{dh_n}(x) + O(\log h_n) \\ &= K_{dh_n}(y) + O(\log h_n) \\ &\leq dh_n + O(\log h_n). \end{aligned}$$

Therefore, by the above bound and Lemma 7,

$$\begin{aligned} \dim(x, ax+b) &= \liminf_{r\to\infty} \frac{K_r(x, ax+b)}{r} \\ &= \liminf_{r\to\infty} \frac{K_r(x) + K_r(ax+b \,|\, x) + O(\log r)}{r} \\ &\leq \liminf_{r\to\infty} \frac{K_r(x) + r + O(\log r)}{r} \\ &\leq \liminf_{n\to\infty} \frac{K_{h_n}(x) + h_n + O(\log h_n)}{h_n} \\ &= d + 1. \end{aligned}$$

To complete the proof, it suffices to show that, for every $\eta \in \mathbb{Q} \cap (0,1)$ and $\varepsilon \in \mathbb{Q}_+$,

$$\dim(x, ax+b) \geq \eta + d - \varepsilon. \tag{2}$$

To that end, let $\eta \in \mathbb{Q} \cap (0,1)$ and $\varepsilon \in \mathbb{Q}_+$. To prove inequality (2), we will partition $\mathbb{N}$ into intervals, and focus on the complexity of $(x, ax+b)$ at each precision r in these intervals. For every $n \in \mathbb{N}$, let $I_n = (dh_n, dh_{n+1}]$.

Fix $n \in \mathbb{N}$, and let $m = \frac{1-d}{1-\eta}$. We will first consider $r \in (dh_n, mh_n]$. Let $k = \frac{r}{dh_n}$, and define $r_i = idh_n$ for every $1 \leq i \leq k$. It is important to note that k is bounded by a constant depending only on η and d. In particular, this implies that $o(r_k)$ is sublinear for all r_i. Let $D_r = D(r_1, \ldots, r_k, a, b, \eta)$ be the oracle defined in Lemma 10. We first note that, by our assumption of (a,b) on the interval $[R_n, MR_n]$ and Lemma 7,

$$\begin{aligned} K_{r_i, r_{i-1}}(a, b \,|\, a, b) &= K_{r_i}(a,b) - K_{r_{i-1}}(a,b) - O(\log r_i) \\ &\geq r_i - o(r_i) - (1 + \frac{1}{n}) r_{i-1} - O(\log r_i) \\ &= r_i - r_{i-1} - \frac{r_{i-1}}{n} - o(r_i), \end{aligned}$$

for all sufficiently large r. Since k is bounded by a constant, for all sufficiently large n, we have

$$K_{r_i,r_{i-1}}(a,b \,|\, a,b) > \eta(r_i - r_{i-1}) - o(r_i).$$

Hence, by Lemma 10,

$$|K^{D_r}_{r_i}(a,b) - \eta r_i| < o(r_k), \tag{3}$$

for all $1 \leq i \leq k$.

We now show that the conditions of Lemma 8 are satisfied relative to D_r. Item 1 of Lemma 8 holds for all sufficiently large r. For item 2, by the construction of D_r, for every $1 \leq i \leq k$,

$$\begin{aligned} K^{D_r}_{r_i}(a,b) &= \eta r_1 + \sum_{j=2}^{i} \min\{\eta(r_j - r_{j-1}), K_{r_j,r_{j-1}}(z \,|\, z)\} + O(\log r_k) \\ &\leq \eta r_1 + \sum_{j=2}^{i} \eta(r_j - r_{j-1} + O(\log r_k) \\ &\leq \eta r_i + O(\log r_k) \\ &\leq (\eta + \varepsilon) r_i, \end{aligned}$$

for all sufficiently large r.

Let $\delta = 1 - \eta$. To see that item 3 of Lemma 8 is satisfied for $i = 1$, let $(u,v) \in B_1(a,b)$ such that $ux + v = ax + b$ and $t = -\log \|(a,b) - (u,v)\| \leq r_1$. Then, by Lemmas 9 and 10, and our construction of x,

$$\begin{aligned} K^{D_r}_{r_1}(u,v) &\geq K^{D_r}_{t}(a,b) + K^{D_r}_{r_1-t,r_1}(x|a,b) - O(\log r_1) \\ &\geq \min\{\eta r_1, K_t(a,b)\} + K_{r_1-t}(x) - o(r_k) \\ &\geq \min\{\eta r_1, t - o(t)\} + (\eta + \delta)(r_1 - t) - o(r_k) \\ &\geq \min\{\eta r_1, \eta t - o(t)\} + (\eta + \delta)(r_1 - t) - o(r_k) \\ &\geq \eta t - o(t) + (\eta + \delta)(r_1 - t) - o(r_k)\,, \end{aligned}$$

We conclude that $K^{D_r}_{r_1}(u,v) \geq (\eta - \varepsilon) r_1 + \delta(r_1 - t)$, for all sufficiently large r. To see that that item 3 is satisfied for $1 < i \leq k$, let $(u,v) \in B_{2^{-r_{i-1}}}(a,b)$ such that $ux + v = ax + b$ and $t = -\log \|(a,b) - (u,v)\| \leq r_i$. Since $(u,v) \in B_{2^{-r_{i-1}}}(a,b)$,

$$r_i - t \leq r_i - r_{i-1} = idh_j - (i-1)dh_j \leq dh_j + 1 \leq r_1 + 1\,.$$

Therefore, by Lemma 9, inequality (3), and our construction of x,

$$\begin{aligned} K^{D_r}_{r_i}(u,v) &\geq K^{D_r}_{t}(a,b) + K^{D_r}_{r_i-t,r_i}(x|a,b) - O(\log r_i) \\ &\geq \min\{\eta r_i, K_t(a,b)\} + K_{r_i-t}(x) - o(r_i) \\ &\geq \min\{\eta r_i, t - o(t)\} + (\eta + \delta)(r_i - t) - o(r_i) \\ &\geq \min\{\eta r_i, \eta t - o(t)\} + (\eta + \delta)(r_i - t) - o(r_i) \\ &\geq \eta t - o(t) + (\eta + \delta)(r_i - t) - o(r_i)\,. \end{aligned}$$

We conclude that $K^{D_r}_{r_i}(u,v) \geq (\eta - \varepsilon) r_i + \delta(r_i - t)$, for all sufficiently large r. Hence the conditions of Lemma 8 are satisfied. Therefore, by applying Lemma 8 and appealing to

inequality (3),

$$\begin{aligned}
K_r(x, ax+b) \geq & K_r^{D_r}(x, ax+b) \\
\geq & K_r(a,b,x) - 2^k \left(K(\varepsilon) + K(\eta) + \frac{4\varepsilon}{1-\eta} r_k + O(\log r_k) \right) \\
= & K_r(a,b) + K_r(x \,|\, a,b) \\
& - 2^k \left(K(\varepsilon) + K(\eta) + \frac{4\varepsilon}{1-\eta} r_k + O(\log r_k) \right) \\
\geq & dr + \eta r - 2^k \left(K(\varepsilon) + K(\eta) + \frac{4\varepsilon}{1-\eta} r_k + O(\log r_k) \right).
\end{aligned}$$

To complete the proof, we give lower bounds of $K_r(x, ax+b)$ for every $r \in [mh_n, dh_{n+1})$. By Lemma 7 and our construction of x,

$$\begin{aligned}
K_r(x) &= K_{r,h_n}(x \,|\, x) + K_{h_n}(x) - o(r) \\
&= r - h_n + dh_n - o(r) \\
&\geq \eta r - o(r).
\end{aligned}$$

The proof of Theorem 1 gives

$$\begin{aligned}
K_r(x, ax+b) &\geq K_r(x) + \dim(x) r - o(r) \\
&\geq \eta r + dr - o(r) \\
&\geq r(d+\eta) - \varepsilon r.
\end{aligned}$$

Putting together the lower bounds of $K_r(x, ax+b)$ on the intervals (dh_n, mh_n) and $[mh_n, dh_{n+1}]$ shows that

$$\dim(x, ax+b) \geq 1 + d,$$

and the proof is complete. ◀

If (a,b) is not of the first case, then there is a bound $(1+\tau) > 1$ so that $K_r(a,b) \geq r(1+\tau)$ for some r in every sufficiently large interval. This implies that, for almost every precision r, the conditional complexity $K_{s,r}(a,b \,|\, a,b) > s - r$, for some s at most a constant multiple of r. This fact allows us to use the procedure outlined in Section 3.1 at precision s. We will now formalize this intuition.

▶ **Theorem 3.** *Let $(a,b) \in \mathbb{R}^2$ such that $\dim(a,b) \geq 1$. Then, for every real number $d \in [0,1]$, there is a point x such that*

$$\dim(x, ax+b) = 1 + d.$$

Proof. Let $(a,b) \in \mathbb{R}^2$ such that $\dim(a,b) \geq 1$. For $d = 1$, we may choose an $x \in \mathbb{R}$ that is random relative to (a,b). That is, there is some constant $c \in \mathbb{N}$ such that for all $r \in \mathbb{N}$, $K_r^{a,b}(x) \geq r - c$. By Theorem 1,

$$\begin{aligned}
\dim(x, ax+b) &\geq \dim^{a,b}(x) + \min\{\dim(a,b), 1\} \\
&= \liminf_{r\to\infty} \frac{K_r(x)}{r} + 1 \\
&= 2,
\end{aligned}$$

and the conclusion holds. For $d = 0$, the conclusion follows from Turetsky's theorem [13]. We therefore assume that $d \in (0, 1)$.

If (a, b) satisfy the conditions of Lemma 11, then the conclusion is immediate. So assume that the conditions of Lemma 11 do not hold. Let $\tau > 0$ and $M > 0$ be constants such that, for almost every $R \in \mathbb{N}$,

$$K_s(a, b) > (1 + \tau)s,$$

for some $s \in [R, MR]$.

Let $y \in \mathbb{R}$ be random relative to (a, b). Define the sequence of natural numbers $\{h_n\}_{n\in\mathbb{N}}$ inductively as follows. Define $h_0 = 1$. For every $n > 0$, let

$$h_n = \min\left\{h \geq 2^{h_{n-1}} : K_h(a, b) \geq \left(\operatorname{Dim}(a, b) - \frac{1}{n}\right) h\right\}.$$

Note that h_n always exists. For every $r \in \mathbb{N}$, let

$$x[r] = \begin{cases} 0 & \text{if } \frac{r}{h_n} \in (d, 1] \text{ for some } n \in \mathbb{N} \\ y[r] & \text{otherwise} \end{cases}$$

where $x[r]$ is the rth bit of x. Define $x \in \mathbb{R}$ to be the real number with this binary expansion. Then $K_{dh_n}(x) = dh_n + O(\log dh_n)$.

Claim 1: $\dim(x, ax + b) \leq 1 + d$.

Let $\eta \in \mathbb{Q} \cap (0, 1)$, $\varepsilon \in \mathbb{Q}$, $n \in \mathbb{N}$, and let $m = \frac{1-d}{1-\eta}$. We first give lower bounds of the complexity of $K_r(x, ax + b)$ on the interval (dh_n, mh_n). To begin, consider $r = h_n$. Let $k = \frac{r}{dh_n} = \frac{1}{d}$, and define $r_i = idh_n$ for every $1 \leq i \leq k$. As in the proof of Lemma 11, is important to note that k is bounded by a constant depending only on η and d.

Claim 2: $K_{h_n}(x, ax + b) \geq dh_n + \eta h_n - 2^k \left(K(\varepsilon) + kK(\eta) + \frac{4\varepsilon}{1-\eta} h_n + O(\log h_n)\right)$.

With this bound on the complexity of $(x, ax + b)$ at precision h_n, we will use a symmetry of information argument to give a lower bound on the complexity at precision $r \in (dh_n, h_n)$. We defer the proof of this claim to the appendix.

Claim 3: For all $r \in [dh_n, h_n)$,

$$K_r(x, ax + b) \geq r(d + \eta) - 2^k \left(K(\varepsilon) + K(\eta) + \frac{4\varepsilon}{1 - \eta} h_n + O(\log h_n)\right).$$

Note that this lower bound is useful for $r \in (dh_n, h_n)$, since h_n is a fixed constant multiple of r.

We now turn to proving lower bounds for the complexity of $(x, ax + b)$ on the interval (h_n, mh_n). To do so, we will make use of our assumption that the complexity of $K_s(a, b)$ is at least $(1 + \tau)s$. In particular, this assumption implies that there is a *fixed* constant c such that $K_{ch_n,h_n}(a, b \,|\, a, b) \geq \eta(ch_n - h_n)$. Moreover, this constant is independent of η and ε. To see this, let $s > h_n$ be a precision such that $K_s(a, b) \geq (1 + \tau)s$. By Lemma 7 and our assumption of a, b,

$$\begin{aligned} K_{s,h_n}(a, b \,|\, a, b) &\geq K_s(a, b) - K_{h_n}(a, b) - O(\log s) \\ &\geq (1 + \tau)s - \operatorname{Dim}(a, b)h_n - O(\log s) \\ &\geq (1 + \tau)s - 2h_n - O(\log s). \end{aligned}$$

Thus,

$$K_{s,h_n}(a, b \,|\, a, b) \geq \eta(s - h_n),$$

for any such $s > ch_n$, for some fixed constant c depending only on τ. With this fact we are able to show the following, whose proof is deferred to the appendix.

Claim 4: There is a precision $h_n < j \leq ch_n$ such that

$$K_j(x, ax+b) \geq j - (h_n - dh_n) + \eta j - 2^k \left(K(\varepsilon) + kK(\eta) + \frac{4\varepsilon}{1-\eta} j + O(\log j) \right).$$

With this bound, we will again prove lower bounds at precisions $r \in (h_n, j)$ using symmetry of information arguments. While this is similar in spirit to the proof of Claim 3, there is an important difference. At precisions greater than h_n, the complexity of x begins increasing again. In particular, the construction of x and Lemma 6 implies the following.

$$K_j(x, ax+b) \leq K_r(x, ax+b) + 2(j-r).$$

We are still, however, able to achieve the required lower bounds on the complexity of $(x, ax+b)$ for all $r \in (h_n, j)$. The proof of this claim is deferred to the appendix.

Claim 5: For every $r \in (h_n, j)$,

$$K_r(x, ax+b) \geq r(d+\eta) - cr(1-\eta) - 2^k \left(K(\varepsilon) + K(\eta) + \frac{4\varepsilon}{1-\eta} cr + O(\log cr) \right).$$

This lower bound is useful since $j \leq ch_n$, and c is a constant depending only on τ. In particular, this allows us to make $\frac{cr(1-\eta)}{r}$ arbitrarily small by having η go to 1.

To complete the proof for the interval (dh_n, mh_n), we will apply the same method as in Claims 4 and 5, except that we use j instead of h_n. Specifically, we choose the first $j_2 > j$ such that

$$K_{j_2,j}(a, b \,|\, a, b) \geq \eta(j_2 - j),$$

and note that $j_2 \leq cj$. We then apply the proof of Claim 4 to $K_{j_2}(x, ax+b)$, and the proof of Claim 5 to the interval (j, j_2). We then repeat this argument until we have given the appropriate lower bound for all $r \in (h_n, mh_n)$.

Finally, taking Claims 1, 2, 3, 4 and 5 together yields the following. For every $r \in (dh_n, m_n)$,

$$K_r(x, ax+b) \geq r(d+\eta) - cr(1-\eta) - 2^k \left(K(\varepsilon) + K(\eta) + \frac{4\varepsilon}{1-\eta} cr + O(\log cr) \right). \quad (4)$$

To complete the proof, we bound $K_r(x, ax+b)$ for every $r \in [mh_n, dh_{n+1})$. By Lemma 7 and our construction of x,

$$\begin{aligned} K_r(x) &= K_{r,h_n}(x \,|\, x) + K_{h_n}(x) + o(r) \\ &= r - h_n + nh_n + o(r) \\ &\geq \eta r + o(r). \end{aligned}$$

The proof of Theorem 1 gives $K_r(x, ax+b) \geq K_r(x) + \dim(x)r - o(r)$, and so $K_r(x, ax+b) \geq r(d+\eta) - \varepsilon r$. Combined with inequality (4), for every $r \in (dh_n, dh_{n+1})$,

$$\begin{aligned} \frac{K_r(x, ax+b)}{r} &\geq r(d+\eta) - cr(1-\eta) - 2^k \left(K(\varepsilon) + K(\eta) + \frac{4\varepsilon}{1-\eta} cr + O(\log cr) \right) \\ &= d + \eta - 2^k \left(\frac{K(\varepsilon)}{r} + \frac{K(\eta)}{r} + \frac{4\varepsilon}{1-\eta} c + \frac{O(\log cr)}{r} \right) \\ &\geq d + \eta - 2^{\frac{m}{d}} \left(\frac{K(\varepsilon)}{r} + \frac{K(\eta)}{r} + \frac{4\varepsilon}{1-\eta} c + \frac{O(\log cr)}{r} \right) \end{aligned}$$

for all sufficiently large n. Since η and ε were chosen arbitrarily and independently,

$$\dim(x, ax+b) \geq d+1,$$

and the proof is complete. ◀

4 Lower Bounding the Dimension Spectrum of a Line

In this section we give the first nontrivial lower bounds of the dimension spectrum of an arbitrary line. For intuition behind the proof, first note the following simple observation.

▶ **Observation 12.** *For every $x, y, a, b \in \mathbb{R}$,*

$$K_r(x, y, a, b) \leq K_r(x, ax+b) + K_r(y, ay+b) + 2t,$$

where $t = -\log \|x-y\|$.

Essentially, this is true since any two points identify a line, and this can be done in a computable way. The $2t$ extra information is due to the fact the precision which we can compute (a, b) to is linearly correlated to the distance between x and y. This immediately suggests an approach to give the lower bound

$$\dim(x) + \frac{\dim(a,b)}{2} \geq \dim(a,b).$$

While this observation is at the core of the proof of our second main theorem, it alone does not suffice. The principle issue is that the values of $K_r(x, ax+b)$, $K_r(y, ay+b)$ might be "out of phase"; that is, $K_r(x, ax+b)$ is small when $K_r(y, ay+b)$ is large, and vice versa. Our main theorem will show that the set of these points has low Hausdorff dimension.

Our first lemma builds upon Observation 12. In particular, it shows that, if $K_r(x, ax+b)$ is small, then every other y such that $K_r(y, ay+b)$ is small must satisfy certain properties.

▶ **Lemma 13.** *Let $\alpha \in (0,1)$, $x, a, b \in \mathbb{R}$, and $n, r \in \mathbb{N}$ such that $2r^{-\frac{1}{2}} < \frac{1}{n}$. Assume that $K_r(x, ax+b) < \alpha r + \frac{K_r(a,b)}{2} - \frac{r}{n}$, and $K_r^{a,b}(x) \geq \alpha r$. Then, for every $y \in \mathbb{R}$, if $K_r(y, ay+b) < \alpha r + \frac{K_r(a,b)}{2}$, at least one of the following holds.*

1. *$t := -\log \|x-y\| \leq r^{\frac{1}{2}}$.*
2. *$K_r(y \mid a, b, x) < \alpha r$.*

Proof. Assume the hypothesis, but assume that neither condition is satisfied for some y. Then,

$$\begin{aligned} K_r(a, b, x, y) &\leq K_r(x, ax+b) + K_r(y, ay+b) + 2t \\ &< 2\alpha r + K_r(a,b) - \frac{r}{n} + 2t. \end{aligned}$$

However, by our hypothesis and Lemma 7 we have

$$\begin{aligned} K_r(a, b, x, y) &\geq K_r(a,b) + K_r(x \mid a, b) + K_r(y \mid a, b, x) - \log r \\ &\geq K_r(a,b) + 2\alpha r - \log r. \end{aligned}$$

Since condition (1) was assumed to not hold, we see that

$$\frac{1}{n} < 2r^{-\frac{1}{2}},$$

a contradiction. ◀

For every $a, b \in \mathbb{R}$ and $\alpha \in (0,1)$, define the set

$$A(\alpha, a, b) = \{x \mid \dim(x, ax+b) < \alpha + \frac{\dim(a,b)}{2}\}.$$

▶ **Theorem 4.** *For every $a, b \in \mathbb{R}$ and $\alpha \in (0,1)$, $\dim_H(A(\alpha, a, b)) \leq \alpha$.*

Proof. Our goal is to show that $\dim_H(A(\alpha, a, b) \leq \alpha$. We will actually prove a stronger theorem. For every n, define

$$A_n(\alpha, a, b) = \{x \mid (\exists^\infty r)\, K_r(x, ax+b) < \alpha r + \frac{K_r(a,b)}{2} - \frac{r}{n}\}.$$

Note that to prove $\dim_H(A(\alpha, a, b) \leq \alpha$, it suffices to show that $\dim_H(A_n(\alpha, a, b)) \leq \alpha$ for every n. To see that $A(\alpha, a, b) \subseteq \cup_n A_n(\alpha, a, b)$, let $x \in A$. Then there is an $\epsilon > 0$ such that, for infinitely many r,

$$\begin{aligned} K_r(x, ax+b) &< \alpha r + \frac{\dim(a,b)}{2} r - \epsilon r \\ &< \alpha r + \frac{K_r(a,b) + g(r)}{2} - \epsilon r, \end{aligned}$$

where g is a sublinear function. Therefore, for sufficiently large n and r, $x \in A_n(\alpha, a, b)$. Since the Hausdorff dimension of a countable union of sets $\cup_n A_n$ is the supremum of $\dim_H(A_n)$, it suffices to show that, for every n, $\dim_H(A_n(\alpha, a, b)) \leq \alpha$.

Define the set

$$U = \{x \mid (\exists^\infty r)\, K_r^{a,b}(x) \leq \alpha r\}.$$

It is immediate that $\dim^{a,b}(x) \leq \alpha$, for all $x \in U$.

For every $r \in \mathbb{N}$, choose x_r such that

$$K_r^{a,b}(x) \geq \alpha r$$
$$K_r(x, ax+b) < \alpha r + \frac{K_r(a,b)}{2} - \frac{r}{n},$$

if such an x_r exists. To reduce the notational burden we will, without loss of generality, always assume that such an x_r does exist. We then define

$$V = \{y \mid (\exists^\infty r)\, y \in (x_r - 2^{-r^{\frac{1}{2}}}, x_r + 2^{-r^{\frac{1}{2}}})\}.$$

Define oracle $R \subseteq \mathbb{N}$ which encodes the sequence $x_1, x_2, \ldots$ in the standard manner. Let $y \in V$, and let $r \in \mathbb{N}$ such that $y \in (x_r - 2^{-r^{\frac{1}{2}}}, x_r + 2^{-r^{\frac{1}{2}}})$. Then,

$$\begin{aligned} K^R_{r^{\frac{1}{2}}}(y) &\leq O(\log r) \\ &= O(\log r^{\frac{1}{2}}). \end{aligned}$$

Thus

$$\dim^R(y) = 0.$$

Let $x_1, x_2, \ldots$ be the sequence chosen above. Define

$$W = \{y \mid (\exists^\infty r)\, K_r(y \mid a, b, x_r) < \alpha r\}.$$

Let $y \in W$, and let $r \in \mathbb{N}$ such that $K_r(y \mid a, b, x_r) < \alpha r$. Then we have

$$\begin{aligned} K_r^{R,a,b}(y) &\leq K_r(y \mid a, b, x_r) + O(\log r) \\ &< \alpha r + O(\log r). \end{aligned}$$

Thus

$$\dim^{R,a,b}(y) \leq \alpha.$$

We now show that $A_n(\alpha, a, b) \subseteq U \cup V \cup W$. Let $y \in A_n(\alpha, a, b)$, and assume that $y \notin U \cup V$. So then y has the following properties.

1. For infinitely many r, $K_r(y, ay + b) < \alpha r + \frac{K_r(a,b)}{2} - \frac{r}{n}$
2. For almost every r, $K_r^{a,b}(y) > \alpha r$.
3. For almost every r, $y \notin (x_r - 2^{-r\frac{1}{2}}, x_r + 2^{-r\frac{1}{2}})$.

Let $r \in \mathbb{N}$ be a sufficiently large integer such that item (1) holds. Then by Lemma 13, we must have that

$$K_r(y \mid a, b, x_r) < \alpha r.$$

Therefore, $y \in W$, and $A_n(\alpha, a, b) \subseteq U \cup V \cup W$. Hence $\dim^{R,a,b}(y) \leq \alpha$, and the proof is complete. ◀

5 Applications to Furstenberg Sets

In this section we will use the point-to-set principle, Theorem 5, in conjunction with the theorem of the previous section to give a new proof of a result by Molter and Rela on Furstenberg sets. Let $\alpha \in [0, 1]$. A *set of Furstenberg type* with parameter α is a set $E \subseteq \mathbb{R}^2$ such that, for every $e \in S^1$, there is a line ℓ_e in the direction e satisfying $\dim_H(E \cap \ell_e) \geq \alpha$. It is an important open problem in Fractal Geometry to find the minimum possible dimension of a set of Furstenberg type with paramater α.

Molter and Rela [12] have recently introduced a generalization of Furstenberg sets, by removing the restriction that *every* direction must intersect the set. A set $E \subseteq \mathbb{R}^2$ is in the class $F_{\alpha\beta}$ if there is some set $J \subseteq S^1$ such that

1. $\dim_H(J) \geq \beta$, and
2. for every $e \in J$, there is a line ℓ_e in the direction e satisfying $\dim_H(E \cap \ell_e) \geq \alpha$.

They proved the following lower bound on the dimension of such sets.

▶ **Theorem 14.** (Molter and Rela [12]) *For all $\alpha, \beta \in (0, 1]$ and every set $E \in F_{\alpha\beta}$,*

$$\dim_H(E) \geq \alpha + \frac{\beta}{2}.$$

We will now give a new proof of this theorem, using the theorems of the previous section.

Proof of Theorem 14. Let $\alpha, \beta \in (0, 1]$, $\epsilon > 0$, and $E \in F_{\alpha\beta}$. Let $A \subseteq \mathbb{N}$ be an oracle testifying to the Hausdorff dimension of E; i.e.,

$$\dim_H(E) = \sup_{z \in E} \dim^A(z).$$

Let $e \in S^1$ satisfy $\dim^A(e) > \beta - \epsilon$. Note that such a direction exists by the point-to-set principle. Let l_e be a line in direction e such that $\dim_H(l_e \cap E) \geq \alpha$. Let $a, b \in \mathbb{R}$ be the reals such that $L_{a,b} = l_e$. Note that $\dim^A(a, b) = \dim^A(e)$ because the mapping $e \mapsto a$ is

Table 2 Updated table of the dimension spectra of lines.

$\forall a, b$	$1 \in \text{sp}(L_{a,b})$	
$\dim(a,b) = 2$	$\text{sp}(L_{a,b}) = [1,2]$	
$\dim(a,b) \geq 1$	$[1,2] \subseteq \text{sp}(L_{a,b})$	$\text{sp}(L_{a,b}) \subseteq [1,2]$ Except for a set of dimension at most $\frac{1}{2}$
$\dim(a,b) = d < 1$	$[2d, 1+d] \subseteq \text{sp}(L_{a,b})$,	$\text{sp}(L_{a,b}) \subseteq [d, 1+d]$ Except a set of dimension at most $\frac{d}{2}$
$\dim(a,b) = 0$	$\text{sp}(L_{a,b}) = [0,1]$	
$\dim(a,b) = \text{Dim}(a,b)$	$[d, 1+d\}] \subseteq \text{sp}(L_{a,b})$, $d = \min\{1, \dim(a,b)\}$	

computable and bi-Lipschitz in a neighborhood of e. Let $S = \{x \mid (x, ax+b) \in E \cap l_e\}$. Note that this implies that $\dim_H(S) \geq \alpha$. We then have that

$$\dim_H(E) \geq \sup_{x \in S} \dim^A(x, ax+b).$$

Therefore, to complete the proof, it suffices to show that there exists a point $x \in S$ such that

$$\dim^A(x, ax+b) \geq \alpha + \frac{\beta}{2} - \epsilon. \tag{5}$$

By Theorem 4, relativized to A, the set of all x such that $\dim^A(x, ax+b) \leq \alpha + \frac{\beta}{2}$ has Hausdorff dimension at most $\alpha - \epsilon$. Since $\dim_H(S) \geq \alpha$, this implies that there is a point $x \in S$ which satisfies (5), and the proof is complete. ◀

6 Conclusion and Future Directions

In this paper, we have given two new results on the dimension spectra of lines in the plane, summarized in Table 2.

The first gives a partial answer to the question posed by Lutz, asking whether, for every line $L_{a,b}$, $\text{sp}(L_{a,b})$ contains a unit interval. We showed that if $\dim(a,b) \geq 1$, then this is true. Together with a previous result of N. Lutz and Stull, this implies the following.

▶ **Corollary 15.** *For every $a, b \in \mathbb{R}$, $\text{sp}(L_{a,b})$ contains an interval.*

However we still do not have complete answer to Lutz's question. This is an important open problem, and one that seems to require new techniques to solve.

We have also given the first nontrivial lower bound on the dimension spectrum of a given line. An important open problem is to improve the bounds given here. This would be not only an intrinsically interesting result, but would likely give improved bounds on Furstenberg sets. Another interesting direction for future research is to construct lines with "many" points of small dimension. In particular, for a given $\alpha > 0$, is there a line $L_{a,b}$ such that

$$\dim_H(A(\alpha, a, b)) = \alpha?$$

Abstract

We consider the classical broadcast problem in ad-hoc (that is, unknown topology) directed radio networks with no collision detection, under the additional assumption that at most h transmissions (shots) are available per node. We focus on adaptive deterministic protocols for small values of h. We provide asymptotically matching lower and upper bounds for the cases $h = 2$ and $h = 3$. While for $h = 2$ our bound is quadratic, similar to the bound obtained for oblivious protocols, for $h = 3$ we prove a sub-quadratic bound of $\Theta(n^2 \log\log n / \log n)$, where n is the number of nodes in the network. The latter is the first result showing an adaptive algorithm which is asymptotically faster than oblivious h-shot broadcast protocols, for which a tight quadratic bound is known for every constant h. Our upper bound for $h = 3$ is constructive, making use of constructions of graphs with large girth. We also show an improved upper bound of $O(n^{1+\alpha/\sqrt{h}})$ for $h \geq 4$, where α is an absolute constant independent of h. Our upper bound for $h \geq 4$ is non-constructive.

1 Introduction

1.1 Model of broadcast with limited transmissions per node

In this paper a *transmission network* is a directed graph $G = (V, E)$ with the set of nodes $V = \{0, 1, \ldots, n-1\}$, where node 0 is the *source node*, denoted also by s, and all other nodes are reachable from this node. Initially each node knows only its identifier and the size n of the network. The source node knows also the *message*, which is to be broadcast to all other nodes. Let $\mathcal{G} \equiv \mathcal{G}^{(n)}$ denote the family of all transmission networks of size n.

We consider the following model of *h-shot broadcast*. Nodes of the network transmit in globally synchronized steps (counted from 1), with each node transmitting in at most h steps. If a node v transmits in a given step, then each node w such that $(v, w) \in E$ receives the

[1] Research mainly conducted while this author was visiting the Department of Informatics, King's College London, on sabbatical leave from the National Technical University of Athens.
[2] Research supported by EPSRC grant EP/M005038/1.

transmitted message, unless a *collision* occurs at node w, that is, unless there is another edge (v', w), $v' \neq v$, with node v' transmitting in the same step. We assume that there is no collision detection: a node w cannot distinguish between no transmission from any of the neighbouring nodes and simultaneous transmissions by two or more neighbouring nodes. The only node transmitting in step 1 is the source node 0 and a node can transmit in the current step $t \geq 2$ only if it has already received the message in previous steps.

Most of the research on communication protocols for various models of radio networks has been concerned with minimizing the number of steps, without putting constraints on the number of transmissions by individual nodes or the total number of transmissions by all nodes. Limiting the maximum number of transmissions per node has received somewhat less attention, especially in the context of ad-hoc (that is, unknown) networks. This objective, however, may be important in practice, since it may mean limiting the maximum energy usage per node to keep all nodes alive for as long as possible.

An h-shot broadcast protocol can be viewed as a function $\Pi \equiv \Pi_n$ which for any node v, a time step $t \geq 1$, and the knowledge κ gathered by node v in steps $1, 2, \ldots, t-1$, tells node v whether it transmits in step t. The protocol has to ensure that, within all constraints of the model, for each transmission network $G \in \mathcal{G}$, all nodes eventually receive the message, that is, broadcast is always eventually completed. The design objective is to keep the worst-case completion time as small as possible.

An *oblivious h-shot protocol* is defined by a sequence of *transmission sets* $S_1 = \{0\}, S_2, S_3, \ldots$, which are subsets of the node set V. Once a node v receives the message in step t, it wakes up and transmits in the first h steps $\tau_i \geq t+1, 1 \leq i \leq h$, such that $v \in S_{\tau_i}$. The source node 0 is considered awake at time 0 and transmitting at step 1. (We remark that slightly different definitions of obliviousness may be used in other variants of radio network models.)

In a general *(adaptive) h-shot protocol*, nodes can take into account information which they have received in earlier steps when they decide whether to transmit in the current step. We do not put any limits on how much information can be transmitted in one step or stored in one node. In fact, for our lower bounds we assume that during a successful transmission from a node v to a node w, all knowledge accumulated so far by node v is transmitted to node w and is added to w's knowledge. We remark though that the (adaptive) protocols for our upper bounds include in the transmissions only the source message and the current count of step. They achieve a speed-up over oblivious protocols by using the current count of steps in a more subtle way.

1.2 Our results

We study adaptive deterministic protocols for h-shot broadcast (note that the term 'k-shot broadcasting' has been used in some literature for the same notion). We focus on small values of h and provide asymptotically matching lower and upper bounds on the (worst-case) number of steps for the cases $h = 2$ and $h = 3$, as well as improved upper bounds for larger values of h.

In particular, for $h = 2$ we provide a quadratic lower bound of $n^2/8 - O(n)$, showing that adaptive 2-shot broadcast protocols are not (asymptotically) faster than oblivious 2-shot protocols. On the other hand, for $h = 3$ we prove a sub-quadratic bound of $\Theta(n^2 \log\log n / \log n)$. To the best of our knowledge this is the first result showing an adaptive h-shot protocol which is asymptotically faster than oblivious h-shot protocols. For oblivious protocols a tight quadratic bound has been shown in [14] for every constant h. Our proof of existence of a $O(n^2 \log\log n / \log n)$-step 3-shot broadcast protocol is constructive, making use of constructions of graphs with large girth. The *girth of a graph* is the length of a shortest cycle.

Our improved upper bounds for $h \geq 4$ include a bound of $O(n^{1+\alpha/\sqrt{h}})$, where h is constant or grows (slowly) with n and α is an absolute constant independent of h. Our upper bounds for $h \geq 4$ are non-constructive and are based on hyper-graphs without small 2-covers. We give the precise definition of 2-covers in hyper-graphs in Section 4, noting here only that this notion can be viewed as a generalization of the notion of cycles in graphs.

1.3 Related previous work

Radio broadcasting with unlimited number of shots was first introduced by Chlamtac and Kutten [5] and has been extensively studied ever since. The first protocol, given by Bar-Yehuda, Goldreich and Itai [1], was randomized and worked in $O(D \log n + \log^2 n)$ expected time, where D is the diameter of the graph and n the number of nodes. Improved randomized protocols were later proposed in [10, 15] yielding a tight upper bound of $O(D \log(n/D) + \log^2 n)$ steps.

Deterministic radio broadcasting attracted much attention in the last two decades. Brusci and Del Pinto [4] proved a lower bound of $\Omega(D \log n)$ for undirected networks, which was subsequently improved for directed networks to $\Omega(n \log D)$ by Clementi et al. [9] and for undirected networks to $\Omega((n \log n)/\log(n/D))$ by Kowalski and Pelc [15]. The *round-robin* protocol, in which node i is the only node transmitting in steps $i + 1 + qn$, for each $q \geq 1$, gives a trivial $O(n^2)$ upper bound on deterministic broadcast. Chlebus et al. [6] presented the first sub-quadratic protocol of $O(n^{11/6})$ time complexity. The upper bound was then improved to $O(n^{5/3} \log^3 n)$ by De Marco and Pelc [17] and further by Chlebus et al. [7], who showed an $O(n^{3/2})$-time algorithm. Chrobak, Gąsieniec and Rytter [8] gave an $O(n \log^2 n)$ non-constructive protocol and De Marco [11] proved the best currently known upper bound of $O(n \log n \log \log n)$, again in a non-constructive manner.

Better upper bounds are known for undirected networks. Chlebus et al. [6] proposed a deterministic $O(n)$-time broadcasting algorithm, assuming *spontaneous wake-up* (that is, allowing the nodes to transmit before receiving the source message, learning that way the topology of the network). An optimal $O(n \log n)$-time broadcasting algorithm for undirected networks with non-spontaneous wake-up was given by Kowalski and Pelc [15].

Broadcasting with a limited number of shots ("h-shot broadcasting") in known-topology undirected networks was first studied by Gąsieniec et al. [12], who showed a lower bound of $D + \Omega((n - D)^{1/(2h)})$ and a randomized protocol which works in $D + O(hn^{1/(h-2)} \log^2 n)$ steps and has high probability of completing the broadcast. These lower and upper bounds were improved for the same setting (undirected known networks) by Kantor and Peleg [13] to $D + \Omega(h \cdot (n - D)^{1/2h})$ and $D + O(hn^{1/2h}) \log^{2+1/h} n)$, respectively. They also presented the first randomized h-shot broadcasting protocols for *unknown* undirected networks, which work in $O((D + \min\{Dh, \log n\})n^{1/(h-1)} \log n)$ steps for $h \geq 2$ and in $O(Dn^2 \log n)$ steps for $h = 1$. Still in the same setting, Berenbrink et al. [2] proposed, among other results, a randomized algorithm with optimal broadcasting time $O(D \log(n/D) + \log^2 n)$ that uses an expected number of $O(\log^2 n/\log(n/D)$ transmissions per node.

The first work to address deterministic h-shot broadcasting in directed *ad hoc* radio networks is due to Karmakar et al. [14], who proved a lower bound of $\Omega(n^2/h)$ for oblivious protocols and a matching upper bound of $O(n^2/h)$ for each $h \leq \sqrt{n}$, as well as an upper bound of $O(n^{3/2})$ for $h > \sqrt{n}$. They also presented a lower bound of $\Omega\left(n^{1+1/h}\right)$ for adaptive broadcasting protocols, leaving open the question whether there are upper bounds for adaptive h-shot broadcast which are better than the $O(n^2/h)$ bound achieved by oblivious protocols.

2 Lower bounds

2.1 Layered networks

We show lower bounds using the following *layered networks*. We assume $n \geq 4$, and in addition to the source node $s = 0$, we also distinguish the node $d = n - 1$ as the "target" of the broadcast. Node d will be the last node of a layered network to receive the message. We derive lower bounds on the number of steps needed by a broadcast protocol to deliver the message from node s to node d in the worst case.

Consider a partition $L_0, L_1, \ldots, L_k$ of the set of nodes V into $k \geq 2$ sets called *layers*, such that $L_0 = \{0\}$, $L_k = \{n-1\}$ and $L_i \neq \emptyset$ for $0 \leq i \leq k$. These layers define the following acyclic broadcast network $G \equiv G(L_0, L_1, \ldots L_k)$. For each $0 \leq i \leq k-1$, the consecutive layers L_i and L_{i+1} are fully connected, that is, there is a directed edge from each node of L_i to each node of L_{i+1}, and there are no any other edges.

For any pairwise disjoint non-empty subsets $L_0, L_1, \ldots, L_j$ of $V \setminus \{n-1\}$, where $j \geq 1$ and $L_0 = \{0\}$, we denote by $\mathcal{G}_j \equiv \mathcal{G}_j(L_0, L_1, \ldots L_j)$ the family of all layered networks $G(L_0, L_1, \ldots L_j, L_{j+1} \ldots L_k)$, where $k > j$, $L_k = \{n-1\}$ and $L_{j+1} \ldots L_{k-1}$ are non-empty sets partitioning $V \setminus \left(\{n-1\} \cup \bigcup_{i=0}^{j} L_i\right)$. In other words, $\mathcal{G}_j$ is the family of all layered networks which have the same fixed initial layers $L_0, L_1, \ldots, L_j$. In particular, $\mathcal{G}_0$ is the family of all layered networks.

We use layered networks in order to show that for any given protocol, there is an assignment of nodes to layers which makes the progress of broadcast slow because of relatively long delays at each layer.

2.2 Conditional transmission sets

Let Π be any h-shot broadcast protocol for n-node networks and let $T_{\max}$ denote the maximum broadcast time of Π over all n-node networks. We define below *conditional transmission sets* for families of layered graphs described above.

Let $i \geq 1$ and consider the family of networks $\mathcal{G}_{i-1}(L_0, L_1, \ldots, L_{i-1})$ for some arbitrary layer sets $L_0 = \{0\}, L_1, L_2, \ldots, L_{i-1}$, such that $|\bigcup_{j=0}^{i-1} L_j| \leq n-3$. This bound implies that the target node and at least two other nodes are still outside of the fixed layers. Protocol Π behaves in exactly the same way on any network $G \in \mathcal{G}_{i-1}(L_0, L_1, \ldots, L_{i-1})$ until (and including) the step T_{i-1} when the source message leaves layer $i-1$ for the first time. That is, T_{i-1} is the first step when a unique node in L_{i-1} transmits, sending the message simultaneously to all nodes in the next layer. Note that $T_0 = 1$ and step T_{i-1} is uniquely determined by the sets $L_0, L_1, \ldots, L_{i-1}$. We select the next layer L_i from the set

$$U_i = V \setminus \left(\{n-1\} \cup \bigcup_{j=0}^{i-1} L_j \right),$$

trying to maximize the *weighted delay* $(T_i - T_{i-1})/|L_i|$ at this layer.

For $t \geq 1$, the *conditional transmission set* $S_t \subseteq U_i$ contains a node $v \in U_i$, if and only if, node v transmits at step $T_{i-1} + t$, if v is included in the layer L_i. Set S_t is well defined since for each network $G \in \mathcal{G}_{i-1}(L_0, L_1, \ldots, L_{i-1})$ with $v \in L_i$, node v transmits in exactly the same steps, irrespectively of how the other nodes in $U_i \setminus \{v\}$ are distributed among the layers L_j, $j \geq i$. This follows from the fact that a node in one layer gets information, directly or indirectly, only from nodes in previous layers.

Since we consider h-shot protocols, each node $v \in U_i$ belongs to at most h conditional transmission sets S_t. We assume w.l.o.g. that v transmits in exactly h steps $T_{i-1}+t$, so it belongs to exactly h conditional transmission sets. (If v belongs to $k < h$ conditional sets, then add v to $h-k$ sets S_τ for $\tau = T_{\max} - T_{i-1} + 1, \ldots, T_{\max} - T_{i-1} + h - k$. This may create new transmission collisions, but only after step $T_{\max}$, that is, after the completion of broadcast.) For convenience, if it is clear from the context that we are discussing the selection of nodes for the layer L_i, then we will refer to the (global) transmission step $T_{i-1}+t$ as simply the transmission step t (the t-th step after step T_{i-1}). Also, "conditional transmission sets" will be abbreviated to "transmission sets".

At least one of the transmission sets S_t must be a singleton, or otherwise the message would never reach the target node in the network $G(L_0, L_1, \ldots, L_{i-1}, U_i, \{n-1\})$, that is, when layer i contains all remaining nodes (other than the target node $n-1$). Let $\tau_1 \geq 1$ be the smallest index of a singleton transmission set. Let $S_{\tau_1} = \{v_1\}$ and we also use $t_0(v_1)$ and $S_0(v_1)$ to denote τ_1 and S_{τ_1}, respectively.

Applying the same argument to sets $S'_t = S_t \setminus \{v_1\}$, we observe that there must be a singleton also among these sets. Indeed, if each non-empty set S'_t, $t \geq 1$, had size at least 2, then the message would never reach the target node in the network $G(L_0, L_1, \ldots, L_{i-1}, U_i \setminus \{v_1\}, \{v_1\}, \{n-1\})$. Let $S'_{\tau_2} = \{v_2\}$ be the first singleton among sets S'_t, and let $t_0(v_2)$ and $S_0(v_2)$ denote τ_2 and S_{τ_2}, respectively. We note that $S_0(v_2)$ is equal to either $\{v_2\}$ or $\{v_1, v_2\}$ and step $t_0(v_2)$ can be before or after step $t_0(v_1)$.

Continuing this way, we put all nodes of U_i in a sequence $v_1, v_2, \ldots, v_u$, where $u = |U_i| \geq 2$, and associate with them distinct transmission steps $t_0(v_j)$ and transmission sets $S(v_j)$ such that:

$$S_0(v_1) = \{v_1\} \text{ and } S_0(v_j) \setminus \{v_1, v_2, \ldots, v_{j-1}\} = \{v_j\}, \text{ for } 2 \leq j \leq u.$$

Note that for each $1 \leq j \leq u$, we have $\bigcup_{l=1}^{j} S_0(v_l) = \{v_1, v_2, \ldots, v_j\}$.

By construction, for any two distinct nodes v and w in U_i, the steps $t_0(v)$ and $t_0(w)$ are also distinct. Thus for at least $\lceil u/2 \rceil$ nodes in U_i, we have $t_0(v) > \lfloor u/2 \rfloor$. We denote the set of these nodes by U'_i, that is,

$$U'_i = \{v \in U_i : t(v) > \lfloor u/2 \rfloor\},$$

and let $u' = |U'_i| \geq \lceil u/2 \rceil$.

For each node $v \in U'_i$, we have designated one of the v's (conditional) transmission steps as the step $t_0(v) \geq |U_i|/2$ and we have denoted the corresponding transmission set by $S_0(v)$. We now further denote by $t_1(v) < t_2(v) < \cdots < t_{h-1}(v)$ and by $S_1(v), S_2(v), \ldots, S_{h-1}(v)$ the other $h-1$ steps when node v transmits (if in L_i) and the transmission sets at those steps. While for any two distinct nodes v' and v'' in U'_i, $t_0(v') \neq t_0(v'')$, we may have $t_q(v') = t_r(v'')$ for some $1 \leq q, r \leq h-1$.

The general idea for forcing a large weighted delay at layer i is to try to select for this layer a relatively small number of nodes $x_1, x_2, \ldots, x_k$ from U'_i which have transmission conflicts at all transmission steps $t_l(x_j)$, for $1 \leq j \leq k$ and $1 \leq l \leq h-1$. That is, for each $1 \leq j \leq k$ and $1 \leq l \leq h-1$, there is $1 \leq a \leq k$, $a \neq j$ such that $\{x_j, x_a\} \subseteq S_l(x_j)$. If we manage to select such a layer, then the progress of broadcast from this layer will have to rely on one of the steps $t_0(x_1), t_0(x_2), \ldots, t_0(x_k)$, so the weighted delay will be at least $\min\{t_0(x_1), t_0(x_2), \ldots, t_0(x_k)\}/k \geq |U_i|/(2k)$. This will be the basic case in our lower-bound analysis.

2.3 Lower bound for 2-shot broadcast

We consider now the case when each node has only two transmissions, with a node $v \in U'_i$ transmitting in steps $t_0(v)$ and $t_1(v)$. Recall that $u' = |U'_i| \geq \lceil u/2 \rceil$ and consider two cases: either there is a node $v \in U'_i$ with $t_1(v) \geq \lceil u/2 \rceil$ or, by the pigeonhole principle, there are two distinct nodes v and w in U'_i such that $t_1(v) = t_1(w) < \lceil u/2 \rceil$. We set $L_i = \{v\}$ in the former case, to get $T_i = T_{i-1} + \min\{t_0(v), t_1(v)\} \geq T_{i-1} + \lceil u/2 \rceil$, and $L_i = \{v, w\}$ in the latter case, to get $T_i = T_{i-1} + \min\{t_0(v), t_0(w)\} \geq T_{i-1} + \lceil u/2 \rceil$. Thus we can force the delay at layer i of at least $\lceil u/2 \rceil$ by putting one or two nodes into this layer, so we have the following lemma.

▶ **Lemma 1.** *For each 2-shot broadcast protocol Π for n-node networks and a family of networks $\mathcal{G}(L_0, L_1, \ldots, L_{i-1})$, where $|\bigcup_{j=0}^{i-1} L_j| \leq n-3$, there exists $L_i \subseteq U_i = V \setminus \left(\{n-1\} \cup \bigcup_{j=0}^{i-1} L_j\right)$ such that $1 \leq |L_i| \leq 2$ and for each network in $\mathcal{G}(L_0, L_1, \ldots, L_{i-1}, L_i)$, the message does not leave layer i (that is, is not delivered to the next layer $i+1$) before the step $T_{i-1} + \lceil |U_i|/2 \rceil$.*

Using this lemma iteratively, we prove the following lower bound on the worst-case time of 2-shot broadcast protocols.

▶ **Theorem 2.** *For each 2-shot broadcast protocol Π for n-node networks, there exists a network in $\mathcal{G}_0$ on which Π needs at least $n^2/8 - O(n)$ steps to complete broadcast.*

Proof. Starting from $L_0 = \{0\}$, we apply Lemma 1 iteratively for $i = 1, 2, \ldots$ to obtained a network $G(L_0 = \{0\}, L_1, L_2, \ldots, L_{k-1}, L_k = \{n-1\})$ such that $k \geq n/2$, $1 \leq |L_i| \leq 2$, for each $1 \leq i \leq k-1$, and $T_i \geq T_{i-1} + |U_i|/2$. We have $|U_1| = n-2$ and $|U_i| \geq |U_{i-1}| - 2 \geq n - 2i$, for $2 \leq i \leq k-1$, so the worst-case number of steps needed by protocol Π to complete the broadcast is at least

$$1 + \sum_{1 \leq i \leq k-1} |U_i|/2 \;\geq\; \sum_{1 \leq i \leq (n/2)-1} (n-2i)/2 \;=\; n^2/8 - O(n). \qquad \blacktriangleleft$$

2.4 Lower bound for 3-shot broadcast

We consider now a 3-shot broadcast protocol Π and, as before, the family of networks $\mathcal{G}_{i-1}(L_0, L_1, \ldots, L_{i-1})$ for some arbitrary layer sets $L_0 = \{0\}, L_1, L_2, \ldots, L_{i-1}$. The message leaves layer $i-1$ at time step T_{i-1} and we want to select nodes for the next layer i to force a relatively large weigthed delay $(T_i - T_{i-1})/|L_i|$. We refer to the notation of (conditional) transmission sets and the related terminology introduced in Sections 2.1 and 2.2. A node v in the set $U' = U'_i$ transmits in the step $t_0(v) \geq u/2$ and in steps $t_1(v) < t_2(v)$, where $u = n - 1 - \left|\bigcup_{j=0}^{i-1} L_j\right|$ and $|U'| \geq u/2$.

For an integer parameter $1 \leq p \leq u/2$, which will be set later, we put each node $v \in U'$ into one of the sets V_0, V_1 and V_2, depending on when the v's transmission steps $t_1(v)$ and $t_2(v)$ are in relation to step p:

$$\begin{aligned} V_0 &= \{v \in U' :\ p < t_1(v) < t_2(v)\}, \\ V_1 &= \{v \in U' :\ t_1(v) \leq p \text{ and } t_2(v) > p\}, \\ V_2 &= \{v \in U' :\ t_1(v) < t_2(v) \leq p\}. \end{aligned}$$

For the set V_2, we construct an undirected (multi-)graph H_2 with vertices $t_l(v)$, where $v \in V_2$ and $l = 1, 2$, and edges $\{t_1(v), t_2(v)\}$ for all $v \in V_2$. More precisely, the vertex set and the

edge (multi-)set of graph H_2 are

$$V(H_2) = \{t : t = t_l(v) \text{ for some } v \in V_2 \text{ and } 1 \le l \le 2\},$$
$$E(H_2) = \{\{t', t''\} : t' = t_1(v) \text{ and } t'' = t_2(v) \text{ for some } v \in V_2\}.$$

Thus graph H_2 has at most p vertices and exactly $|V_2| \le u'$ edges. There may be parallel edges in H_2 because there may be two nodes v', v'' in V_2 with $\{t_1(v'), t_2(v')\} = \{t_1(v''), t_2(v'')\}$. To avoid confusion, *nodes* are in the transmission *network*, while *vertices* are in the auxiliary *graph* H_2 (and in other similar auxiliary graphs constructed later). The vertices of graph H_2 correspond to (some) steps of the protocol and the edges of H_2 correspond to (some) nodes in the transmission network.

The underlying idea in our lower-bound argument is that if the number of edges in graph H_2 is relatively large in relation to p, that is, if H_2 is sufficiently dense, then it must contain a short cycle $\Gamma = (\tau_0, \tau_1, \ldots, \tau_{k-1}, \tau_k = \tau_0)$. Let $v_i \in V_2$ be the node in the transmission network which corresponds to the edge $\{\tau_i, \tau_{i+1}\}$ in this cycle, for $i = 0, 1, \ldots, k-1$. (Two parallel edges in H_2 would form a cycle of length $k = 2$.) If we set the next layer $L_i = \{v_0, v_1, \ldots, v_{k-1}\}$, then these nodes transmit in steps $\tau_0, \tau_1, \ldots, \tau_{k-1}$, but in each of these steps exactly two nodes in L_i transmit, resulting in a collision. This means that the progress of broadcast has to rely on one of the steps $t_0(v_0), t_0(v_1), \ldots, t_0(v_{k-1})$, but each of these steps is at least $u/2$, so the weighted delay at layer i is at least $u/(2k)$. Therefore we have the following lemma.

▶ **Lemma 3.** *If graph H_2 has a cycle Γ of length k, then taking for the layer L_i the set of transmission nodes which correspond to the edges of Γ gives the weighted delay at layer i at least $u/(2k)$.*

To proceed with our analysis, we need an upper bound on the *girth of a graph*, that is, on the length of a shortest cycle. The asymptotic bounds given below in Lemma 4 and in its corollary are widely known and sufficient for us, but we note that more precise bounds are available in the literature, for example, in [3].

▶ **Lemma 4.** *Every graph with p vertices and the minimum degree $d = d(p) \ge 3$ contains a cycle of length $O(\log p / \log d)$.*

Proof. Consider any graph H with p vertices and the minimum degree $d \ge 3$. Let v be any vertex in H, $k \ge 1$ and $H(v, k)$ the subgraph of G induced by the vertices within distance at most k from v. If H does not have a cycle of length $2k$ or less, then $H(v, k)$ is a tree and has more than $(d-1)^k$ vertices. This means that for $k = \lceil \log n / \log(d-1) \rceil$, $H(v, k)$ is not a tree and contains a cycle of length at most $2k = O(\log n / \log d)$. ◀

▶ **Corollary 5.** *Every graph of average degree d with p vertices contains a cycle of length $O(\log p / \log d)$.*

Proof. Any graph G of average degree d must contain a nonempty subgraph G' of minimum degree at least $d/2$. To see this, repeatedly remove from G all vertices of degree strictly less than $d/2$. Not all vertices can be removed in this process because otherwise G would contain fewer than $pd/2$ edges altogether, a contradiction. By applying Lemma 4 to G' the claim follows. ◀

▶ **Lemma 6.** *Let Π be any 3-shot broadcast protocol Π for n-node networks and consider any family of networks $\mathcal{G}(L_0, L_1, \ldots, L_{i-1})$, where $|\bigcup_{j=0}^{i-1} L_j| \le n/2$. There exists the next i-th layer $L_i \subseteq U_i = V \setminus \left(\bigcup_{j=0}^{i-1} L_j \cup \{n-1\}\right)$ such that for each network in $\mathcal{G}(L_0, L_1, \ldots, L_{i-1}, L_i)$, the weighted delay at layer i is $\Omega(n \log\log n / \log n)$.*

Proof. We set $p = n \log\log n / \log n$ and consider sets V_0, V_1 and V_2. If V_0 is not empty, then we take $L_i = \{v\}$ where v is an arbitrary node in V_0. All three steps $t_0(v), t_1(v)$ and $t_2(v)$ when node v transmits are at least p, so the weighted delay at layer i is at least p.

If $|V_1| > p$, then there must be two nodes v' and v'' in V_1 such that $t_1(v') = t_1(v'') \leq p$, but all other steps $t_0(v'), t_2(v'), t_0(v'')$ and $t_2(v'')$ when v' or v'' transmits are at least p. Taking $L_i = \{v', v''\}$ gives the weighted delay at layer i at least $p/2$.

If V_0 is empty and V_1 has fewer than p nodes, then V_2 has more than $u' - p$ nodes, so graph H_2 has $|V_2| > u' - p \geq |U_i|/2 - p \geq n/5$ edges but at most p vertices. This means that the average degree in H_2 is greater than $(2/5)n/p$, so, from Corollary 5, H_2 has a cycle Γ of length $O(\log p / \log(n/p)) = O(\log n / \log\log n)$. Thus Lemma 3 implies that taking for the layer L_i the set of transmission nodes which correspond to the edges of Γ gives the weighted delay at layer i at least $\Omega(n \log\log n / \log n)$. ◀

We are now ready to prove the lower bound for the 3-shot case.

▶ **Theorem 7.** *For each 3-shot broadcast protocol Π for n-node networks, there exists a network in $\mathcal{G}_0$ on which Π needs $\Omega(n^2 \log\log n / \log n)$ steps to complete broadcast.*

Proof. Starting from $L_0 = \{0\}$, we use Lemma 6 iteratively, obtaining layers $L_1, L_2, \ldots, L_m$ and stopping when $\bigcup_{0 \leq i \leq m} |L_i| > n/2$. From Lemma 6, there is a constant $c > 0$ such that for each layer $i = 1, 2, \ldots, m$, the weighted delay $(T_i - T_{i-1})/|L_i|$ is at least $cn \log\log n / \log n$. Therefore,

$$T_{\max} \geq T_m = 1 + \sum_{1 \leq i \leq m} (T_i - T_{i-1}) \geq \sum_{1 \leq i \leq m} (|L_i| cn \log\log n / \log n)$$
$$\geq (c/2) n^2 \log\log n / \log n.$$ ◀

3 Upper bounds for h-shot broadcast for $h \leq 3$

For the 2-shot case a trivial upper bound which matches asymptotically the $\Omega(n^2)$ lower bound of Section 2.3 is given by the oblivious Round Robin (which is actually a 1-shot broadcast protocol).

We provide in this section an upper bound of $O(n^2 \log\log n / \log n)$ for 3-shot broadcast, which matches our lower bound and shows that in contrast to the 2-shot case, the fastest adaptive 3-shot protocols are faster than the best oblivious protocols by a factor $\omega(1)$.[3] We base our approach on graph-theoretic results [16] showing that it is possible to construct relatively dense graphs of high girth. We use such graphs to specify appropriate transmission sets as detailed below.

To define the sequence of transmission sets in our protocol, we use a graph $H = H(n, p, g)$ with n edges, p vertices and girth g. Any graph $H(n, p, g)$ would do for the correctness of our protocol, but to achieve fast (worst case) broadcast, we need a graph with relatively small number of nodes p and high girth g. More precisely, to have asymptotically fastest broadcast, we need a graph $H(n, p, g)$ with $p = \Theta(n \log\log n / \log n)$ and $g = \Theta(\log n / \log\log n)$.

We identify the edge set $E(H)$ of graph H with the node set $V(G)$ of the transmission network G, and we number the vertices in H from 1 to p (in an arbitrary way). Let H_i denote the set of edges in H which are incident to vertex i. The sets $H_1, H_2, \ldots, H_p$ are (some of) the transmission sets of our protocol. Clearly, for any node v of G, v belongs to two

[3] Recall that the oblivious bound is $\Theta(n^2/k)$ for k-shot protocols and $k \leq \sqrt{n}$.

sets H_i and H_j, where $\{i,j\} \in E(H)$ is the edge identified with node v. Node v transmits in two steps with transmissions sets H_i and H_j, while the third transmission is within one Round-Robin sequence.

Formally, our protocol $\Pi(H)$ is defined by the repeated Round-Robin sequence $\langle R \rangle = (\{0\}, \{1\}, \ldots, \{n-1\})$ interleaved with the repeated sequence $\langle H \rangle = (H_1, H_2, \ldots, H_p)$. Let's say that we use the odd steps of the protocol for repeating the Round-Robin sequence and the even steps for repeating the sequence $\langle H \rangle$. If a node v receives the message in step t, then it transmits in its step of the first Round-Robin sequence which starts after step t, and in the steps H_i and H_j of the first copy of the sequence $\langle H \rangle$ which starts after step t, where $\{i,j\} \in E(H)$ is the edge identified with node v.

We now proceed with the analysis of protocol $\Pi(H)$. Consider any n-node transmission network G with source s and an arbitrary node $v \neq s$. Let $k \geq 1$ denote the distance from s to v. In order to upper-bound the time needed for the message to go from source node s to node v, we consider the partitioning $L_v(G)$ of the nodes within distance k to v into layers. These are breadth-first-search layers constructed from node v following the edges of G in reverse direction. For $0 \leq i \leq k$, the layer L_i is the set of all nodes in G with distance $k-i$ to v. Thus $L_k = \{v\}$, L_{k-1} is the set of all nodes with edges to v, and so on. The source node s belongs to layer L_0.

Note that for each $1 \leq i \leq k$, each node $u \in L_i$ and each edge (x,u), $x \in L_j$ for some $j \geq i-1$. Thus the message reaches layer L_i (any node in layer L_i) for the first time during a transmission by a node from layer L_{i-1}. We use T_i to denote the time step at which the message first reaches layer L_i. We have $T_1 = 1$ (layer L_1 must have at least one out-neighbour of the source) and the following lemma gives an upper bound on the delays at layers of relatively small cardinality.

▶ **Lemma 8.** *Consider an n-node transmission network G with source s, an arbitrary node v, the layers $L_0, L_1, \ldots, L_k$ corresponding to this node and the protocol $\Pi(H)$ defined by a graph $H = H(n,p,g)$. During the execution of this protocol, if $|L_i| < g$, then the time needed to transmit the message from L_i to L_{i+1}, that is, $T_{i+1} - T_i$, is at most $4p$.*

Proof. Let $L'_i \subseteq L_i$ be the set of nodes in L_i that have received the message by time $T_i + t$, where t is the smallest integer such that $(T_i + t) \bmod (2p) = 0$. Only nodes in L'_i will be transmitting at even steps between $T_i + t + 1$ and $T_i + t + 2p$.

Since $|L'_i| \leq |L_i| < g$, the edges corresponding to nodes of L'_i form an acyclic subgraph T of H, so for each vertex w_j in H with degree 1 in T (there must be at least two such vertices) the transmission set H_j contains exactly one node from L'_i. During each such step, the message is transmitted from layer L_i to layer L_{i+1}. Hence $T_{i+1} \leq T_i + t + 2j \leq T_i + 4p$. ◀

▶ **Theorem 9.** *Protocol $\Pi(H)$ defined by a graph $H = H(n,p,g)$ completes broadcast in an arbitrary n-node transmission network G within $O(n^2/g + np)$ steps.*

Proof. We take an arbitrary node $v \neq s$ and consider its layers $L_0, L_1, \ldots, L_k$. There can be at most n/g layers of size at least g. For each such layer L_i, when a message arrives at this layer, then it will reach the next layer L_{i+1} by the time the next full Round Robin is completed. That is, in this case $T_{i+1} \leq T_i + 4n$. Combining this with Lemma 8 gives the claimed bound on the number of steps, since the number of layers of size smaller than g is at most $n-1$. ◀

To minimize the upper bound $O(n^2/g + np) = O(n^2/\min\{g, d_{ave}\})$, where d_{ave} is the average degree in graph $H(n,p,g)$, we have to find a graph with n edges and $\min\{g, d_{ave}\}$ as large as possible. Corollary 5 implies that for all graphs, $\min\{g, d_{ave}\} = O(\min\{\log n / \log d_{ave},$

$d_{ave}\}) = O(\log n/\log\log n)$. It turns out that there are explicitly constructed graphs with n edges for which $\min\{g, d_{ave}\} = \Theta(\log n/\log\log n)$. We use the construction given in [16].

▶ **Theorem 10** ([16]). *For each positive odd integer $k \geq 3$ and a power of a prime q, there is an explicit construction of a q-regular bipartite graph $H(q,k)$ with $2q^k$ vertices and girth at least $k+5$.*

▶ **Corollary 11.** *There exists an explicit construction of a graph H with n edges, $p = \Theta(n\log\log n/\log n)$ vertices and girth $g = \Theta(\log n/\log\log n)$.*

Proof. For a given sufficiently large n, let $q \geq 4$ be the largest power of 2 not greater than $\log n/\log\log n$ and let $k = q-1 \geq 3$. Let $H(q,k)$ be the graph from Theorem 10. This graph has $2q^{q-1}$ vertices, $q^q \leq n$ edges and girth at least $q+4$.

Let H be a graph with exactly n edges obtained by taking copies of graph $H(q,k)$ as connected components. We remove (arbitrarily) some edges from the last copy of $H(q,k)$ so that the total number of edges is exactly n. We need $\lceil n/q^q \rceil$ copies of $H(q,k)$, so the number of vertices in graph H is at most $2q^{q-1}(n/q^q+1) \leq 4n/q \leq 8n\log\log n/\log n$. Graph H has the same girth as $H(q,k)$, so at least $q+4 \geq (1/2)\log n/\log\log n$. ◀

Using in protocol $\Pi(H)$ the graph H from Corollary 11, Theorem 9 gives us the following result.

▶ **Corollary 12.** *There exists a constructive 3-shot broadcast protocol which completes broadcast on any graph G with n nodes in time $O(n^2\log\log n/\log n)$.*

4 Upper bounds for h-shot broadcast for $h \geq 4$

It was shown in [14] that for any $h \geq 1$, an h-shot broadcast protocol requires $\Omega\left(n^{1+1/h}\right)$ steps. In previous sections, we improved this lower bound and provided matching upper bounds for the cases when h is equal to 2 and 3. In this section, we show upper bounds for $h \geq 4$. In particular, if h is a sufficiently large constant or is slowly growing with n, then we prove that there exist h-shot broadcast protocols with $O(n^{1+\alpha/\sqrt{h}})$ steps, where α is an absolute constant independent of h.

The general idea for h-shot broadcast protocols for $h \geq 4$ is similar to the idea of using a large girth graph to construct a 3-shot protocol. Now, however, we need to define $r = h-1 \geq 3$ transmission slots for each node (in addition to the transmissions defined by Round-Robin), so we use r-uniform hyper-graphs instead of graphs $H(n,p,g)$. Let $H_r = H_r(n,p,k)$ be an r-uniform hyper-graph (each edge is a set of r vertices) with n (hyper-)edges, p vertices, and no 2-cover of size k or smaller. A 2-*cover* of a hyper-graph is a non-empty subset $\mathcal{A}$ of edges such that each node which belongs to an edge in $\mathcal{A}$ belongs to at least two edges in $\mathcal{A}$. The notion of 2-covers in hyper-graphs generalizes the notion of cycles in graphs: minimal 2-covers in graphs are (simple) cycles.

Similarly as in the previous subsection, we identify the edge set $E(H_r)$ of the hyper-graph H_r with the node set $V(G)$ of the transmission network G. We number the vertices in H_r from 1 to p in an arbitrary order and denote by $H_r^{(i)}$ the set of edges in H_r which are incident to vertex i. If we use the sequence $\langle H_r\rangle = \langle H_r^{(1)}, H_r^{(2)}, \ldots, H_r^{(p)}\rangle$ as a sequence of transmission sets, then for each nonempty subset W of at most k nodes in G, one of these transmission sets has exactly one node from W – otherwise the set of edges in H_r corresponding to the nodes in W would form a 2-cover in H_r of size at most k.

The following simple counting argument shows how large k can be in an $H_r(n,p,k)$ hyper-graph.

▶ **Lemma 13.** *There is a constant C such that for each $n \geq 1$ and for each $p \geq r \geq 3$, there exists a hyper-graph $H_r = H_r(n, p, k)$ with $k = \lfloor p/(Crn^{2/r}) \rfloor$.*

Proof. We consider a random r-uniform hyper-graph $\mathcal{H}$ with p vertices and n edges (independently and uniformly selected from the family of sets of r vertices) and show that for k defined in the lemma (where constant C will come out from the calculations) and for a fixed $2 \leq q \leq k$, the probability that $\mathcal{H}$ has a 2-cover of size q is at most $1/2^q$. By summing up over all $2 \leq q \leq k$, we get the conclusion that there must exist a hyper-graph $H_r = H_r(n, p, k)$.

A 2-cover $\mathcal{A}$ of size q covers at most $qr/2$ vertices, or otherwise there would be a vertex belonging to exactly one edge in $\mathcal{A}$. Thus the probability that $\mathcal{H}$ has a 2-cover of size q is at most the probability that there exists in $\mathcal{H}$ a set $\mathcal{A}$ of q edges and a set X of $qr/2$ vertices such that each edge in $\mathcal{A}$ is a subset of X. Using the union bound over all possible $\mathcal{A}$ and X, the probability of the latter event is at most

$$\binom{n}{q}\binom{p}{qr/2}\frac{\binom{qr/2}{r}^q}{\binom{p}{r}^q} \leq \left(\frac{en}{q}\right)^q \left(\frac{2ep}{qr}\right)^{qr/2} \frac{(eqr/2)^{qr}/r^{qr}}{p^{qr}/r^{qr}} \leq \frac{1}{q^q}\left(\frac{Cqrn^{2/r}}{p}\right)^{qr/2} \leq \frac{1}{2^q},$$

where the second inequality holds for $C = (2e)^2$ and the last one holds for any $2 \leq q \leq p/(Crn^{2/r})$. For the first inequality, we use $\left(\frac{a}{b}\right)^b \leq \binom{a}{b} \leq \left(\frac{ea}{b}\right)^b$. ◀

For a hyper-graph $H_r = H_r(n, p, k)$, the protocol $\Pi(H_r)$ which interleaves repeated copies of $\langle H_r \rangle$ with copies of a Round-Robin sequence $\langle R \rangle$ is an h-shot broadcast protocol with $O(n^2/k + np)$ steps. This can be shown in an analogous way as in the proof of Theorem 9, by considering separately the layers with sizes at most k and the layers with sizes greater than k. If we consider hyper-graphs $H_r = H_r(n, p, k)$ with $k = \lfloor p/(Crn^{2/r}) \rfloor$, whose existence is guaranteed by Lemma 13, and take $p = r^{1/2}n^{1/2+1/r}$ to minimize $O(n^2/k + np)$, then we obtain an h-shot broadcast protocol with $O(h^{1/2}n^{3/2+1/(h-1)})$ steps. This gives, for example, upper bounds $O(n^{11/6})$ and $O(n^{7/4})$ for 4-shot and 5-shot broadcast, respectively, but no better bound than $O(n^{3/2})$ even if h grows to infinity.

To obtain upper bounds with the exponent at n decreasing to 1 for increasing values of h, we combine hyper-graphs $H_r(n, p, k)$ for a number of different values of k. More specifically, for $h = \rho^2/2+1$, where ρ is an even integer at least 4, let $H_{\rho,j} = H_\rho(n, C\rho n^{2j/\rho}, n^{2(j-1)/\rho})$, for $j = 1, 2, \ldots, J = \rho/2$, where C is the constant from Lemma 13. Our h-shot broadcast protocol Π_h is defined by the sequence of transmission sets obtained by interleaving $\rho + 1$ sequences $(\langle H_{\rho,1} \rangle, \langle H_{\rho,1} \rangle, \ldots)$, $(\langle H_{\rho,2} \rangle, \langle H_{\rho,2} \rangle, \ldots), \ldots, (\langle H_{\rho,J} \rangle, \langle H_{\rho,J} \rangle, \ldots)$, and $(\langle R \rangle, \langle R \rangle, \ldots)$, and by the following transmission schedule. For a node v in the transmission network G, if v receives the message for the first time in step t, then let $\overline{\langle H_{\rho,j} \rangle}$, for $j = 1, 2, \ldots, J$, and $\overline{\langle R \rangle}$ be, respectively, the first copies of $\langle H_{\rho,1} \rangle, \langle H_{\rho,2} \rangle, \ldots, \langle H_{\rho,J} \rangle$ and $\langle \mathcal{R} \rangle$ which start after step t. Node v transmits in the steps corresponding to the transmission sets in $\overline{\langle H_{\rho,1} \rangle}, \overline{\langle H_{\rho,2} \rangle}, \ldots, \overline{\langle H_{\rho,J} \rangle}$ and $\overline{\langle R \rangle}$ which include v. Thus v transmits in $\rho \cdot (\rho/2) + 1 = h$ steps.

▶ **Theorem 14.** *For $h = \rho^2/2+1$, where ρ is an even integer at least 4, the (non-constructive) protocol Π_h is an h-shot broadcast protocol with $O(hn^{1+\sqrt{8/(h-1)}})$ steps.*

Proof. By the definition of protocol Π, no node transmits more then h times. We show now the claimed bound on the number of steps.

Similarly to the analysis of the 3-shot protocol in Section 3, we consider an arbitrary node v and its in-neighbourhood layers $L_0, L_1, \ldots, L_k$, where $s \in L_0$ and $v \in L_k$. The delay

at layer L_i, that is, the number of steps between the time when the first node in L_i receives the message and the time when the first node in L_{i+1} receives the message (from one of the nodes in L_i), depends on the size of this layer. If $n^{2(j-2)/\rho} < |L_i| \leq n^{2(j-1)/\rho}$, for some $1 \leq j \leq J$, then the message is delivered from (one of the nodes of) layer L_i to (one of the nodes of) the next layer by the next copy of $\langle H_{\rho,j} \rangle$, so within $C\rho^2 n^{2j/\rho}$ steps. (Recall that the transmission sets of each $\langle H_{\rho,i} \rangle$ are scheduled every $\rho/2+1$ steps, hence the additional factor of ρ).

For a layer L_i such that $n^{2(J-1)/\rho} < |L_i|$, the message is delivered to the next layer by the next copy of Round-Robin, so within ρn steps. Thus the delay at each layer L_i is at most $C\rho^2 n^{4/\rho}|L_i|$ steps, so node v receives the message within $O(\rho^2 n^{1+4/\rho}) = O(hn^{1+\sqrt{8/(h-1)}})$ steps. ◀

We defined protocols Π_h only for values $h = \rho^2/2+1$, where ρ is an even integer at least 4. Since the h-shot broadcast protocol Π_h is also an h'-shot broadcast protocol for any $h' \geq h$, then Theorem 14 implies the following corollary.

▶ **Corollary 15.** *There is a constant α such that for any $1 \leq h = O(\log n)$, there exists an h-shot broadcast protocol with $O(\min\{n^2,\ n^{1+\alpha/\sqrt{h}}\})$ steps.*

Proof. It is enough to consider $h \geq 9$, since the case when $h < 9$ can be covered by taking sufficiently large α. For $h \geq 9$, take $\rho = \lfloor \sqrt{2(h-1)} \rfloor$, $\tilde{h} = \rho^2/2+1 \leq h$ and the protocol $\Pi_{\tilde{h}}$, which is an h-shot broadcast protocol. Theorem 14 implies that protocol $\Pi_{\tilde{h}}$ works in $O(\rho^2 n^{1+4/\rho})$ steps, which is $O(n^{1+5/\sqrt{h}})$ for $9 \leq h = O(\log n)$. ◀

For the cases $h = 2$ and $h = 3$, we have obtained asymptotically matching lower and upper bounds on the number of steps in h-shot broadcast protocols. For $h \geq 4$, however, we still have a gap between the lower bound of $\Omega\left(n^{1+1/h}\right)$ shown by Karmakar et al. [14] and our upper bounds.

Abstract

Let MAJ_n denote the Boolean majority function of n input variables. In this paper, we study the construction of depth two circuits computing MAJ_n where each gate in a circuit computes MAJ_m for $m < n$.

We first give an explicit construction of depth two $\mathsf{MAJ}_{\lfloor n/2 \rfloor + 2} \circ \mathsf{MAJ}_{\leq n-2}$ circuits computing MAJ_n for every $n \geq 7$ such that $n \equiv 3 \pmod 4$ where MAJ_m and $\mathsf{MAJ}_{\leq m}$ denote the majority gates that take m and at most m *distinct* inputs, respectively. A graph theoretic argument developed by Kulikov and Podolskii (STACS '17, Article No. 49) shows that there is no $\mathsf{MAJ}_{\leq n-2} \circ \mathsf{MAJ}_{n-2}$ circuit computing MAJ_n. Hence, our construction reveals that the use of a smaller fan-in gates at the bottom level is essential for the existence of such a circuit. Some computational results are also provided.

We then show that the construction of depth two $\mathsf{MAJ}_m \circ \mathsf{MAJ}_m$ circuits computing MAJ_n for $m < n$ can be translated into the construction of a newly introduced version of bipartite expander graphs which we call a *list expander*. Intuitively, a list expander is a c-leftregular bipartite graph such that for a given $d < c$, every d-leftregular subgraph of the original graph has a certain expansion property. We formalize this connection and verify that, with high probability, a random bipartite graph is a list expander of certain parameters. However, the parameters obtained are not sufficient to give us a $\mathsf{MAJ}_{n-c} \circ \mathsf{MAJ}_{n-c}$ circuit computing MAJ_n for a large constant c.

1 Introduction

Let MAJ_n denote the Boolean majority function of n variables, i.e.,

$$\mathsf{MAJ}_n(x_1, \ldots, x_n) \quad = \quad \mathbf{1}[\sum_{i=1}^{n} x_i \geq n/2],$$

here $\mathbf{1}[\cdot]$ denotes 1 if the condition in the bracket is satisfied, and 0 otherwise.

The problem of finding an efficient construction of circuits (or formulas) computing the majority function has attracted many researchers for a long time (e.g., [2, 10, 13]). The

[1] A part of this work was supported by JSPS Kakenhi 15K00006, 18K11152 and 18H04090.

famous AKS sorting network [1] can be viewed as an $O(\log n)$ depth circuit computing MAJ_n if we pick the middle bit of all the outputs. A probabilistic construction of $\sim 5.3 \log n$-depth Boolean formula by Valiant [13] is another beautiful result on this problem. Here we mention that both of these constructions are monotone, i.e., they do not use negation gates. For more backgrounds and results, see e.g., the introduction of [4] or [7].

Recently, Kulikov and Podolskii [7] initiated the study on the "down scale" version of this problem. Specifically, they studied the construction of a small depth circuit for MAJ_n consisting of gates computing MAJ_m such that $m < n$.

In this paper, we restrict our attention to the case of depth two. Namely, we consider the following type of problems: What is the minimum value of m such that MAJ_n can be computed by a depth two circuits consisting of $\mathsf{MAJ}_{\leq m}$ gates? How to compute MAJ_n by a depth two circuit consisting of $\mathsf{MAJ}_{\leq m}$ gates for $m < n$?

In spite of the simplicity of the problem statement, its solution might be highly non-trivial even for small values of n. For example, constructing a depth two circuit consisting of the 5-bit majority gates that computes the 7-bit majority function is already not trivial.

Formally, we consider depth two circuits of the form $M_2 \circ M_1$ for $M_1, M_2 \in \{\mathsf{MAJ}_m, \mathsf{MAJ}_{\leq m}\}$ where MAJ_m and $\mathsf{MAJ}_{\leq m}$ denote the majority gates that take m and at most m inputs, respectively. Here M_2 denotes the top gate and M_1 denotes the bottom gates. In addition, we impose the restriction that each MAJ_m (or $\mathsf{MAJ}_{\leq m}$) gate on the bottom level takes m (or at most m) *distinct* input variables. Note that this restriction affects the difficulties for computing MAJ_n. Kulikov and Podolskii [7, Lemma 11] showed that there is no $\mathsf{MAJ}_{n-2} \circ \mathsf{MAJ}_{n-2}$ circuit computing MAJ_n for every odd n under this restriction. On the other hand, the author of this paper and Yoshida [3] showed that such circuits do exist for every odd $n \geq 7$ if some of the bottom gates are allowed to read an input variable multiple times. For example, the following circuit (which was presented by Kulikov and Podolskii [7, Introduction]) computes MAJ_7.

$$\begin{aligned}&\mathsf{MAJ}_7(x_1, \ldots, x_7)\\ &\quad = \mathsf{MAJ}_5(\mathsf{MAJ}_5(x_1, x_2, x_3, x_4, x_5), \mathsf{MAJ}_5(x_1, x_2, x_5, x_6, x_7), \mathsf{MAJ}_5(x_1, x_3, x_4, x_6, x_6),\\ &\qquad \mathsf{MAJ}_5(x_2, x_3, x_3, x_5, x_6), \mathsf{MAJ}_5(x_2, x_4, x_5, x_7, x_7)).\end{aligned}$$

One of the most interesting problems in this line of research is to find the minimum value of m such that MAJ_n can be computed by a $\mathsf{MAJ}_{\leq m} \circ \mathsf{MAJ}_{\leq m}$ circuit. Kulikov and Podolskii [7] proved a lower bound of $m \geq n^{13/19+o(1)}$. This was then improved to $m = \Omega(n^{0.8})$ by Engels, Garg, Makino and Rao [4]. For the upper bound, the construction of such a circuit for $(n, m) = (7, 5), (9, 7)$ and $(11, 9)$ is provided by Kulikov and Podolskii [7]. This was then generalized to $(n, m) = (n, n-2)$ for all odd $n \geq 7$ by the author of this paper and Yoshida [3]. However, in all of these constructions some of the gates at the bottom level read an input variable multiple times. In our restricted setting, i.e., every bottom gate can read each variable only once, no non-trivial upper bounds were previously known.

Note that, throughout the paper, we only use the gates computing the *standard* majority, i.e., the majority gates with the threshold value $m/2$ where m denotes its fan-in. In [11], Posobin gave the construction of a depth two circuit for MAJ_n consisting of gates with fan-in $m = (2/3)n + 4$ where the threshold value of the bottom gates is not restricted to $m/2$.

Contributions

The contribution of this paper is twofolds. First, we present an explicit construction of $\mathsf{MAJ}_{\lfloor n/2 \rfloor + 2} \circ \mathsf{MAJ}_{\leq n-2}$ circuits computing MAJ_n for every $n \geq 7$ such that $n \equiv 3 \pmod 4$. The construction is quite simple, but as far as we know, this is the first non-trivial depth

two circuits for MAJ_n consisting of the standard majority gates of fan-in strictly less than n and without multiple weights. Since a graph theoretic argument developed by Kulikov and Podolskii [7] can show that there is no $\mathsf{MAJ}_{\leq n-2} \circ \mathsf{MAJ}_{n-2}$ circuit computing MAJ_n, our construction reveals that the use of a smaller fan-in is essential for the existence of such a circuit. Some computational results are also provided in the paper.

During this work, we *feel* that constructing such a circuit for (n, m) with $m \ll n$ or even $m = n - 4$ may be a hard problem. This motivates us to give an explanation or evidence on this hardness, which leads to the second contribution of this paper.

In the second part of the paper, we show that the construction of depth two $\mathsf{MAJ}_m \circ \mathsf{MAJ}_m$ circuits computing MAJ_n for $m < n$ can be translated into the construction of a newly introduced version of bipartite expander graphs which we call a *list expander*. Intuitively, a list expander is a c-leftregular bipartite graph such that for a given $d < c$, every d-leftregular subgraph of the original graph has a certain expansion property. We formalize this connection, and verify that, with high probability, a random bipartite graph is a list expander of certain parameters. However, the parameters obtained are not sufficient to give us a $\mathsf{MAJ}_{n-c} \circ \mathsf{MAJ}_{n-c}$ circuit computing MAJ_n for a large constant c.

Organization of the Paper

The organization of the paper is as follows. In Section 2, we give an explicit construction of $\mathsf{MAJ}_{\lfloor n/2 \rfloor + 2} \circ \mathsf{MAJ}_{\leq n-2}$ circuits computing MAJ_n for $n \equiv 3 \pmod 4$. The results of some computational experiments on the total fan-in of the bottom gates of a $\mathsf{MAJ}_{\leq n-1} \circ \mathsf{MAJ}_{\leq n-1}$ circuit are also provided. In Section 3, we discuss the connection between the construction of depth two $\mathsf{MAJ}_m \circ \mathsf{MAJ}_m$ circuits and the construction of a newly introduced notion of bipartite expander graphs, which we call a *list expander*. Then, in Section 4, we give an analysis on the expansion property of a random bipartite graph. We close the paper by giving the conclusions in Section 5.

2 Depth Two Majority Circuits for Majority

For an integer n, $[n]$ denotes the set $\{1, 2, \ldots, n\}$. For a set S, $|S|$ denotes the cardinality of S. For an n-bit string $\boldsymbol{x} \in \{0,1\}^n$, x_i denotes the i-th bit of $\boldsymbol{x}$ and $|\boldsymbol{x}|$ denotes the number of 1's in $\boldsymbol{x}$, i.e., $|\boldsymbol{x}| = |\{i \in [n] : x_i = 1\}|$.

In this section, we first give a simple construction of depth two majority circuits for MAJ_n.

▶ **Theorem 1.** *For every $n \geq 7$ such that $n \equiv 3 \pmod 4$, there is a $\mathsf{MAJ}_{\lfloor n/2 \rfloor + 2} \circ \mathsf{MAJ}_{\leq n-2}$ circuit computing MAJ_n.*

We should note that in Theorem 1 the use of gates with fan-in less than $n-2$ at the bottom level is necessary since Kulikov and Podolskii [7, Lemma 11] proved that, for every odd n, there is no depth two $\mathsf{MAJ}_{n-2} \circ \mathsf{MAJ}_{n-2}$ circuit computing MAJ_n, and a simple generalization of their proof can be extended to establish the non-existence of $\mathsf{MAJ}_{\leq n-2} \circ \mathsf{MAJ}_{n-2}$ circuits for MAJ_n.

Proof. The proof is by construction.

Let $n = 4k+3$ for some $k \geq 1$. We will construct a $\mathsf{MAJ}_{2k+3} \circ \mathsf{MAJ}_{\leq 4k+1}$ circuit computing MAJ_n. For $1 \leq i \leq 2k+1$, let $S_i := [n] \backslash \{2i-1, 2i\}$. Let $S_{2k+2} := \{1, 3, ..., 4k+1\}$ and $S_{2k+3} := \{2, 4, ..., 4k+2\}$. For $1 \leq i \leq 2k+3$, the i-th bottom gate g_i computes the majority

of all the x_j's such that $j \in S_i$. The top gate C computes the majority of all the g_i's, i.e., $C(\boldsymbol{x}) := \mathbf{1}[\sum_i g_i(\boldsymbol{x}) \geq k+2]$. For ease of understanding, we show below a 0/1-matrix representing our circuit (for $n = 11$). The (i, j)-th entry is 1 iff the gate g_i reads the variable x_j.

```
0 0 1 1 1 1 1 1 1 1 1
1 1 0 0 1 1 1 1 1 1 1
1 1 1 1 0 0 1 1 1 1 1
1 1 1 1 1 1 0 0 1 1 1
1 1 1 1 1 1 1 1 0 0 1
1 0 1 0 1 0 1 0 1 0 0
0 1 0 1 0 1 0 1 0 1 0
```

Below we verify that this circuit correctly computes MAJ_n. We first observe that it is sufficient to verify $C(\boldsymbol{x}) = 0$ only for every input $\boldsymbol{x}$ with $|\boldsymbol{x}| = 2k+1$. The correctness for $\boldsymbol{x}$ with $|\boldsymbol{x}| = n - (2k+1) = 2k+2$ will follow from the fact that every majority gate in our circuit has an odd number of inputs and hence computes a self-dual function. This implies that $C(x_1, \ldots, x_n) = 1 - C(\overline{x_1}, \ldots, \overline{x_n})$. Then, all other cases will follow from the monotonicity of our circuit.

It is convenient to consider a hypergraph G over the vertex set $V = \{1, 2, \ldots, n\}$ consisting of edges $E_1, \ldots, E_{2k+3}$ where $E_i = [n] \backslash S_i$ for $1 \leq i \leq 2k+3$. Note that G contains $2k+1$ edges of size two and two edges of size $2k+2$. We call the former small edges, and the latter large edges. For a set of vertices $S \subseteq V$ and an edge E, we say that S *covers* E if $|E \cap S| \geq |E|/2$.

For $\boldsymbol{x} \in \{0,1\}^n$, let $V_{\boldsymbol{x}} := \{i \in [n] \mid x_i = 1\}$. It is easy to observe that $g_i(\boldsymbol{x}) = 0$ iff $V_{\boldsymbol{x}}$ covers E_i for $|\boldsymbol{x}| = 2k+1$. Therefore, it is sufficient to verify that the number of edges that are covered by $V_{\boldsymbol{x}}$ is at least $\lceil \frac{2k+3}{2} \rceil = k+2$ for every $\boldsymbol{x} \in \{0,1\}^n$ with $|\boldsymbol{x}| = 2k+1$.

We divide the proof into two cases.

Case 1 $4k+3 \notin V_{\boldsymbol{x}}$.

Observe that $V_{\boldsymbol{x}}$ covers at least $k+1$ small edges. If $V_{\boldsymbol{x}}$ covers $k+2$ or more small edges, then we are done. Therefore, we can assume that $V_{\boldsymbol{x}}$ covers exactly $k+1$ small edges. However, in this case, $V_{\boldsymbol{x}}$ must cover one of two large edges, and hence $V_{\boldsymbol{x}}$ covers $k+2$ edges in total. This completes the proof.

Case 2 $4k+3 \in V_{\boldsymbol{x}}$.

We view that small edges form a bipartite matching between $2k+1$ left vertices (odd numbers up to $4k+1$) and $2k+1$ right vertices (even numbers up to $4k+2$). If $V_{\boldsymbol{x}}$ covers at least $k+1$ left vertices of small edges or at least $k+1$ right vertices of small edges, then at least $k+2$ edges are covered in total since $V_{\boldsymbol{x}}$ also covers one of two large edges. If $V_{\boldsymbol{x}}$ covers exactly k left vertices and k right vertices of small edges, then it also covers both large edges and hence $V_{\boldsymbol{x}}$ covers at least $k+2$ edges in total. This completes the proof. ◀

Remark that it is quite plausible that there are many other constructions of $\mathsf{MAJ}_{\leq n-2} \circ \mathsf{MAJ}_{\leq n-2}$ circuit for MAJ_n. For example, for every $n \geq 9$ with $n \equiv 3 \pmod 6$, it seems likely that the $\mathsf{MAJ}_{\frac{3}{2}n+1} \circ \mathsf{MAJ}_{\leq n-2}$ circuit given below also computes MAJ_n. Let $n = 3k$ and suppose that k is odd. For $i \in [k]$, $S_{2i-1} = [n] \backslash \{3i-2, 3i\}$ and $S_{2i} = [n] \backslash \{3i-1, 3i\}$. In

addition, we let $S_{2k+1} := \{3, 6, \ldots, 3k\}$. For $i \in [2k+1]$, the i-th bottom gate g_i is defined to be

$$g_i(\boldsymbol{x}) = \mathbf{1}\left[\sum_{i \in S_i} x_i \geq \frac{|S_i|}{2}\right],$$

and the top gate computes the majority of all the g_i's. We have computationally verified the correctness of this circuit up to $n = 27$, and it may be a good exercise to give a formal proof.

Sum of Bottom Fan-ins

Let $F(n)$ denote the smallest number of the total fan-ins of all the bottom gates of a depth two $\mathsf{MAJ}_{\leq n-1} \circ \mathsf{MAJ}_{\leq n-1}$ circuit that computes MAJ_n. It would be interesting to find the value of $F(n)$. The circuit constructed in the proof of Theorem 1 gives the upper bound of $F(n) \leq (n-2)\lfloor \frac{n}{2} \rfloor + \lfloor \frac{n}{2} \rfloor \cdot 2 = n\lfloor \frac{n}{2} \rfloor \sim n^2/2$.

We show below some computational results on $F(n)$ for small values of n. We obtain these results by using an IP solver [6]. More specifically, if we fix the fan-in of the top gate to m_2, then the optimal value of the following IP problem gives $F(n)$. Intuitively, for each $S \subseteq [n]$, G_S represents the number of wires connecting from the bottom gates $\mathbf{1}[\sum_{i \in S} x_i \geq \frac{|S|}{2}]$ to the top gate. The number of variables is $\sim 2^n$, and the number of constraints is $\sim 2\binom{n}{\lfloor n/2 \rfloor}$ as we only need to check for $\boldsymbol{x}$ with $|\boldsymbol{x}| \in \{\lceil n/2 \rceil, \lfloor n/2 \rfloor\}$ by monotonicity.

$$\begin{aligned}
\text{Minimize:} \quad & \sum_{\emptyset \neq S \subsetneq [n]} |S| G_S \\
\text{Subject to:} \quad & \sum_{\emptyset \neq S \subsetneq [n]} G_S = m_2, \\
& \sum_{S : |S \cap V_{\boldsymbol{x}}| \geq \frac{|S|}{2}} G_S \geq \frac{m_2}{2}, \quad (\forall \boldsymbol{x} \in \{0,1\}^n \text{ s.t. } \mathsf{MAJ}_n(\boldsymbol{x}) = 1), \\
& \sum_{S : |S \cap V_{\boldsymbol{x}}| \geq \frac{|S|}{2}} G_S < \frac{m_2}{2}, \quad (\forall \boldsymbol{x} \in \{0,1\}^n \text{ s.t. } \mathsf{MAJ}_n(\boldsymbol{x}) = 0). \\
& G_S \geq 0 : \text{ integer} \quad (\forall S).
\end{aligned}$$

Here $V_{\boldsymbol{x}}$ denotes $\{i \in [n] : x_i = 1\}$ as in the proof of Theorem 1.

Note that $F(n)$ is undefined for $n \leq 5$ since a simple exhaustive search shows that there is no $\mathsf{MAJ}_{\leq n-1} \circ \mathsf{MAJ}_{\leq n-1}$ circuit computing MAJ_n for $n \leq 5$. The result of our experiments is as follows.

- $F(6) = 18$.
- $F(7) = 21$. This is identical to the value given by the circuit in the proof of Theorem 1.
- $F(8) = 31$.
- $F(9) = 37$.
- $F(10) = 50$.
- $F(11) = 55$. This is identical to the value given by the circuit in the proof of Theorem 1.

We show an example of circuits that attain $F(n)$ for $n = 6, 8, 9$ and 10 in Table 1. Given these data, we conjecture that $F(n)$ is of the order of n^2.

▶ **Conjecture 2.** *$F(n) = \Theta(n^2)$. More ambitiously, $F(n) \sim \frac{n^2}{2}$.*

Table 1 The matrix representation of an example of a $\mathsf{MAJ}_{\leq n-1} \circ \mathsf{MAJ}_{\leq n-1}$ circuit for MAJ_n of a smallest total fan-ins for $n = 6, 8, 9$ and 10. Here the (i, j)-entry of each matrix represents whether the i-th bottom gate reads the variable x_j.

3 Connection between Circuits and List Expanders

For a $\mathsf{MAJ}_{m_2} \circ \mathsf{MAJ}_{m_1}$ circuit on n input variables, we naturally associate a bipartite graph over m_2 left vertices and n right vertices as follows.

▶ **Definition 3.** Let C be a $\mathsf{MAJ}_{m_2} \circ \mathsf{MAJ}_{m_1}$ circuit on n input variables where the bottom gates are labeled by $g_1, \ldots, g_{m_2}$. We define a bipartite graph $G_C = (L \cup R, E)$ *associated to* C as follows: Let $L = \{g_1, \ldots, g_{m_2}\}$ and $R = \{x_1, \ldots, x_n\}$, i.e., each left vertex is corresponding to a bottom gate and each right vertex is corresponding to an input variable. For $g_i \in L$ and $x_j \in R$, $(g_i, x_j) \in E$ iff the gate g_i *does not* read x_j as an input in C.

Let $G = (V, E)$ be a graph. For a vertex $v \in V$, $N_G(v)$ denotes the neighbors of v, and for a set of vertices $S \subseteq V$, $N_G(S)$ denotes the neighbors of S, i.e., $N_G(S) := \{u : \exists v \in S \text{ s.t. } (v, u) \in E\}$.

By Definition 3, a bipartite graph G_C associated to a $\mathsf{MAJ}_{m_2} \circ \mathsf{MAJ}_{n-\ell_1}$ circuit C is ℓ_1-*leftregular*, which means that every left vertex has exactly ℓ_1 neighbors, i.e., $|N_{G_C}(v)| = \ell_1$ for every $v \in L$.

The following is the main theorem in this section, which translates the construction of depth two circuits computing MAJ_n into the construction a bipartite graph with a certain expansion property.

▶ **Theorem 4.** *Suppose that n is an odd integer. For every even numbers $\ell_1, \ell_2 > 0$, the following are equivalent.*

- **(i)** *A depth two $\mathsf{MAJ}_{n-\ell_2} \circ \mathsf{MAJ}_{n-\ell_1}$ circuit C computes MAJ_n.*
- **(ii)** *Let $G_C = (L \cup R, E)$ be a ℓ_1-leftregular bipartite graph associated to C. Then, for every $(\ell_1/2 + 1)$-leftregular subgraph $G' \subseteq G_C$ over the same set of vertices of G_C,*

$$|N_{G'}(S)| \geq \left\lceil \frac{|R|}{2} \right\rceil + 1 \text{ for every } S \subseteq L \text{ with } |S| = \left\lceil \frac{|L|}{2} \right\rceil.$$

Proof. By using an argument similar to the one used in the proof of Theorem 1, we see that the statement (i) is equivalent to the statement that for every $\boldsymbol{x} \in \{0,1\}^n$ with $|\boldsymbol{x}| = \lceil n/2 \rceil$, $C(\boldsymbol{x}) = 1$, which we refer to as (i'). Here we use the assumption that n is odd as well as the fan-in of each gate is also odd.

(i') $\to$ (ii) Assume for contradiction that there exists an $(\ell_1/2 + 1)$-leftregular subgraph G' of G_C such that $|N_{G'}(S)| \leq \lceil |R|/2 \rceil$ for some $S \subseteq L$ with $|S| = \lceil |L|/2 \rceil$. Fix an arbitrary such S. Let $X_1 \subseteq R$ be an arbitrary superset of $N_{G'}(S)$ with $|X_1| = \lceil |R|/2 \rceil = \lceil n/2 \rceil$. Define

$\boldsymbol{x} = (x_1, \ldots, x_n) \in \{0,1\}^n$ so that $x_j = 1$ iff $x_j \in X_1$ for $j \in [n]$. For every $g_i \in S$, we have $g_i(\boldsymbol{x}) = 0$ and hence $C(\boldsymbol{x}) = 0$ since $|S| = \lceil |L|/2 \rceil$. This contradicts the statement (i'), completing the proof.

(ii) $\to$ (i') Assume for contradiction that there exists an input $\boldsymbol{x} = (x_1, \ldots, x_n) \in \{0,1\}^n$ such that $|\boldsymbol{x}| = \lceil n/2 \rceil$ and $C(\boldsymbol{x}) = 0$. Fix an arbitrary such $\boldsymbol{x}$. Define $X_1 \subseteq R$ as $X_1 := \{x_j : x_j = 1\}$, and for $1 \leq i \leq |L|$, let $V_i \subseteq R$ be the set of variables x_j such that g_i reads x_j. By the construction of the graph G_C, we have

$$\left| \left\{ g_i \in L : |V_i \cap X_1| \leq \left\lfloor \frac{n - \ell_1}{2} \right\rfloor \right\} \right| \geq \left\lceil \frac{|L|}{2} \right\rceil.$$

Since $|X_1| = \lceil n/2 \rceil$, this is equivalent to

$$\left| \left\{ g_i \in L : |\overline{V_i} \cap X_1| \geq \frac{\ell_1}{2} + 1 \right\} \right| \geq \left\lceil \frac{|L|}{2} \right\rceil,$$

where $\overline{V_i}$ denotes the set $R \backslash V_i$.

Let S be an arbitrary $\lceil |L|/2 \rceil$-element subset of $\left\{ g_i \in L : |\overline{V_i} \cap X_1| \geq \frac{\ell_1}{2} + 1 \right\}$. Then we can pick an $(\ell_1/2 + 1)$-leftregular subgraph G' of G_C such that $N_{G'}(g_i) \subseteq X_1$ for every $g_i \subseteq S$. For this graph G', $N_{G'}(S) \subseteq X_1$, and hence $|N_{G'}(S)| \leq |X_1| = \lceil n/2 \rceil$, contradicting the statement (ii). ◀

We see that the statement (ii) in Theorem 4 has a similar spirit to bipartite expander graphs. This leads us to the following definition.

▶ **Definition 5.** Let $d_1 \geq d_2 > 0$ be two integers. A d_1-leftregular bipartite graph $G = (L \cup R, E)$ with $|L| = m$ and $|R| = n$ is said to be an $((m,n),(d_1,d_2),K,A)$ *list expander* if for every d_2-leftregular subgraph G' of G over the same set of vertices of G, it holds that

$$|N_{G'}(S)| \geq A \text{ for every } S \subseteq L \text{ with } |S| = K.$$

When $d_1 = d_2$ we simply call it an expander. Formally, a d_1-leftregular bipartite graph $G = (L \cup R, E)$ with $|L| = m$ and $|R| = n$ is said to be an $((m,n),d_1,K,A)$ *expander* if

$$|N_G(S)| \geq A \text{ for every } S \subseteq L \text{ with } |S| = K.$$

Note that our definition of an expander is different from the usual definition in a sense that the expansion property is only required for the sets of size equal to K.

The existence of a $\mathsf{MAJ}_{n-4} \circ \mathsf{MAJ}_{n-4}$ circuit computing MAJ_n is equivalent to the existence of an $((n-4,n),(4,3),\lceil \frac{n-4}{2} \rceil, \lceil \frac{n}{2} \rceil + 1)$ list expander. Moreover, an explicit construction of such a circuit implies an explicit construction of such an expander, and vice versa. Currently, we do not know whether such an expander can be built from known constructions of expanders in the usual sense.

A similar argument to the proof of Theorem 4 can show that a list expander of the form "d_1 choose d_2" for $d_2 > d_1/2 + 1$ captures a promise version of the problem for constructing majority circuits. The proof of Theorem 6 is very similar to the proof of Theorem 4 and omitted in this version.

▶ **Theorem 6.** *Let n be an odd integer, and $c \geq 2$ be an even integer. Let C be a $\mathsf{MAJ}_{n-c} \circ \mathsf{MAJ}_{n-c}$ circuit over $\{x_1, \ldots, x_n\}$ and let G_C be a c-leftregular bipartite graph associated to C. Suppose that d is an integer such that $d \geq \frac{c}{2} + 1$. Then, the following are equivalent.*

(i) *$C(\boldsymbol{x}) = 1$ for every $|\boldsymbol{x}| = \lfloor \frac{n}{2} \rfloor - \frac{c}{2} + d$ and $C(\boldsymbol{x}) = 0$ for every $|\boldsymbol{x}| = \lceil \frac{n}{2} \rceil + \frac{c}{2} - d$.*

(ii) *G_C is an $((n-c,n),(c,d),\lceil \frac{n-c}{2} \rceil, \lfloor \frac{n}{2} \rfloor - \frac{c}{2} + d)$ list expander.*

Algorithm 1 Construct an witness for refuting an expansion property.

1: **procedure** CONVERT(G)
2: $\tilde{S} := S$ and $\tilde{T} := N_G(S)$
3: $d := d_1$
4: **while** $d > d_2$ **do**
5: $S' := \tilde{S}$ and $T' := \tilde{T}$
6: **repeat**
7: Let v^* be a vertex $v \in T'$ minimizing $|N_G(v) \cap S'|$. Ties are broken arbitrary.
8: Put $S_{v^*} := N_G(v^*) \cap S'$
9: Remove all edges connecting v^* and a vertex in S' from G
10: $\tilde{T} := \tilde{T} \backslash \{v^*\}$
11: $S' := S' \backslash S_{v^*}$
12: $T' := T' \backslash (N_G(S_{v^*}) \cap T')$
13: **until** $|\tilde{T}| < \left(1 + \frac{d-d_2}{5d_1^2}\right) A$
14: $d := d - 1$
15: **end while**
16: **end procedure**

3.1 List Expanders imply Expanders

In this subsection, we give a result roughly stating that a list expander implies an expander of a certain expansion factor, and observe that converse of it is not true.

▶ **Theorem 7.** *Let $d_1 > d_2 > 0$ be two integers. Suppose that a bipartite graph $G = (L \cup R, E)$ is an $((m,n),(d_1,d_2),K,A)$ list expander for $A \geq K$. Then, G is an $((m,n),d_1,K,(1+\epsilon)A)$ expander for $\epsilon = (d_1 - d_2)/(5d_1^2)$.*

Note that we did not optimize the constant ϵ in Theorem 7.

Proof. The proof is by contrapositive. Put $\epsilon = (d_1 - d_2)/(5d_1^2)$. Assume that a d_1-leftregular bipartite graph $G = (L \cup R, E)$ is not an $((m,n),d_1,K,(1+\epsilon)A)$ expander for $A \geq K$. This means that there exists a set of vertices $S \subseteq L$ with $|S| = K$ such that $|N_G(S)| < (1+\epsilon)A$. We will see that for this case, G is not an $((m,n),(d_1,d_2),K,A)$ list expander. In order to show this, it is sufficient to show that there exists a d_2-leftregular subgraph G' of G such that for some $\tilde{S} \subseteq L$ with $|\tilde{S}| = K$ and for some $\tilde{T} \subseteq R$ with $|\tilde{T}| < A$, $|N_{G'}(\tilde{S})| \subseteq \tilde{T}$ holds.

We set $\tilde{S} := S$. We will find a subgraph G' and a set $\tilde{T} \subseteq T$ by using Algorithm 1 shown above.

First we observe that whenever $|T'| \geq A$, there are at least $A/2$ v's in T' such that $|N_G(v) \cap \tilde{S}| \leq 2d_1$ since if otherwise, we have $\sum_{v \in T'} |N_G(v) \cap \tilde{S}| > Ad_1 \geq Kd_1$, which contradicts the assumption that G is d_1-leftregular. Suppose that a vertex v^* chosen in Line 7 satisfies $|S_{v^*}| \leq 2d_1$. We refer to this condition as (*). Then, in Line 12, $|T'|$ decreases at most $2d_1^2$. For every fixed d, the number of iterations of Lines 6 to 13 is at least $\frac{1}{5d_1^2}A$. Since $2d_1^2 \frac{1}{5d_1^2} A < \frac{1}{2}A$, the condition (*) is always satisfied.

A crucial observation is that after each execution of the **While** loop in the algorithm, G satisfies that $|N_G(v)| \geq d$ for every $v \in \tilde{S}$ and $N_G(\tilde{S}) \subseteq \tilde{T}$. Hence, after the execution of the entire algorithm, we have a graph G such that $|N_G(v)| \geq d_2$ for every $v \in \tilde{S}$ and $N_G(\tilde{S}) \subseteq \tilde{T}$ with $|\tilde{T}| < A$. Then, an arbitrary d_2-leftregular subgraph of G is not an expander for the parameter given in the statement of the theorem. ◀

We remark that an argument below suggests that the converse of Theorem 7 is not true. Let $G = (L \cup R, E)$ be a bipartite graph with $L = R = \mathbb{Z}_p$ and edge set $\{(x, x+1), (x, x-1), (x, x^{-1})\}_{x \in \mathbb{Z}_p}$ where all arithmetic is modulo p and define 0^{-1} to be 0. It was shown that this 3-leftregular bipartite graph has an expansion property with some constant expansion factor. (This was stated implicitly in [8]. See e.g., [12, Construction 4.26] for the statement in this form.) If we add the edges $\{(x, x)\}_{x \in \mathbb{Z}_p}$ to G (and make a slight rearrangement for $x = 0$ to avoid parallel edges $(0, 0)$), then it becomes a 4-leftregular expander. However, a 3-leftregular subgraph consisting of the edges $\{(x, x+1), (x, x), (x, x-1)\}_{x \in \mathbb{Z}_p}$ is not an expander anymore.

4 Probabilistic Constructions

In this section, we show a statement roughly saying that a random c-leftregular bipartite graph is a list expander of the form "c choose d" for $d \sim \frac{2}{3}c$ with a non-negligible probability. Note that this is not sufficient for obtaining a non-trivial depth two circuit computing the majority function, for which we need $d \sim \frac{1}{2}c$.

We first show a fact that will be used in our analysis.

▶ **Fact 8.** *Suppose that a, b, p are positive integers satisfying $a - p > b - p > 0$. Then,*

$$\frac{a^{a-p}}{b^{b-p}} \geq \frac{(a-p)^{a-p}}{(b-p)^{b-p}}.$$

Proof. The fact can be verified by the following series of inequalities.

$$\begin{aligned}
&a^{a-p}(b-p)^{b-p} - (a-p)^{a-p}b^{b-p} \\
&= (a-p+a)^{a-p}(b-p)^{b-p} - (a-p)^{a-p}(b-p+b)^{b-p} \\
&= \sum_{i=0}^{a-p} \binom{a-p}{i} (a-p)^{a-p-i} a^i (b-p)^{b-p} - \sum_{i=0}^{b-p} \binom{b-p}{i} (b-p)^{b-p-i} b^i (a-p)^{a-p} \\
&\geq \sum_{i=0}^{b-p} (a-p)^{a-p-i}(b-p)^{b-p-i} \left\{ \binom{a-p}{i}(b-p)^i - \binom{b-p}{i}(a-p)^i \right\} \qquad (1) \\
&\geq 0.
\end{aligned}$$

Here the last inequality follows from the fact that the value inside the bracket in Eq. (1) is non-negative for every fixed i. ◀

The following is the main theorem in this section.

▶ **Theorem 9.** *Let $\epsilon > 0$ be an arbitrary small positive constant. Suppose that c is a constant such that $\epsilon c \geq 3$, and let $m = n - c$. Then for every sufficiently large n, there is an $((m, n), (c, d), \lceil \frac{m}{2} \rceil, \lfloor \frac{n}{2} \rfloor - \frac{c}{2} + d)$ list expander, where $d = \lceil (\frac{2}{3} + \epsilon)c \rceil$.*

By Theorem 6 and Theorem 9, we can see that for every sufficiently large n, there exists a $\mathsf{MAJ}_{n-c} \circ \mathsf{MAJ}_{n-c}$ circuit C such that $C(\boldsymbol{x}) = \mathsf{MAJ}_n(\boldsymbol{x})$ for every $\boldsymbol{x} \in \{0,1\}^n$ such that $|\boldsymbol{x}| \lesssim \frac{n}{2} - \frac{c}{6}$ or $|\boldsymbol{x}| \gtrsim \frac{n}{2} + \frac{c}{6}$.

The rest of this section is devoted to prove Theorem 9. The proof relies on relatively basic but a bit lengthy calculations.

Proof. Consider a bipartite graph over the vertex set $L \cup R$ with $|L| = m (= n - c)$ and $|R| = n$. We view a c-leftregular bipartite graph as a union of c bipartite matchings. For $i \in [c]$, let M_i be a bipartite matching over $L \cup R$ in which the left vertices are saturated. A c-leftregular bipartite graph $G = (L \cup R, E)$ is specified by a sequence of c such matchings

$E = (M_1, \ldots, M_c)$, which we denoted by G_E. Let $\mathcal{E}$ denote the set of all possible E's and thus $|\mathcal{E}| = (\frac{n!}{c!})^c$. Notice that at this moment, a graph obtained in this way may have a multiedge. We will take into account this issue later.

Roughly speaking, a c-leftregular bipartite graph is a list expander if every d-leftregular subgraph of it is an expander. For $d \leq c$, a d-leftregular subgraph of G is specified by a sequence of m sets $D_i \subseteq [c]$ $(1 \leq i \leq m)$ of size d. Given a sequence of c matchings $E = (M_1, \ldots, M_c)$ and a sequence of m sets $\mathbf{D} = (D_1, \ldots, D_m)$, let $G_{E,\mathbf{D}}$ denote a d-leftregular bipartite graph such that for every $i \in [m]$, the set of edges connecting to the i-th left vertex consists of an edge in M_j for $j \in D_i$. Let $\mathcal{D}$ denote the set of all possible $\mathbf{D}$'s and thus $|\mathcal{D}| = \binom{c}{d}^m$.

We define $\mathcal{E}' \subseteq \mathcal{E}$ as the set of all E's in $\mathcal{E}$ such that G_E is a c-leftregular bipartite graph where G_E does not contain a multiedge. The following lemma says that the cardinality of $\mathcal{E}'$ is not too small compared to the cardinality of $\mathcal{E}$. Here e denotes the base of the natural logarithm. The proof of the lemma is postponed to the end of this section.

▶ **Lemma 10.** *For all sufficiently large n, the cardinality of $\mathcal{E}' \subseteq \mathcal{E}$ satisfies*

$$|\mathcal{E}'| \quad \geq \quad \frac{(n!)^c}{e^{\binom{c}{2}} n^{c^2}}.$$

Given a set $S \subseteq L$ and a set $T \subseteq R$ and a sequence $\mathbf{D} \in \mathcal{D}$, we count the number of $E \in \mathcal{E}$ such that $G_{E,\mathbf{D}}$ satisfies $N_{G_{E,\mathbf{D}}}(S) \subseteq T$, which we refer to as the property $P_{S,T}$.

For $j \in [c]$, let $a_j := |\{i \in S : j \notin D_i\}|$. Define an auxiliary function f as

$$f((m,n),(\ell,r),a) \quad = \quad \frac{r!(n-(\ell-a))!}{(r-(\ell-a))!(n-m)!}.$$

This represents the number of left saturated bipartite matchings in the $(m+n)$-vertex complete bipartite graph such that the neighbors of some specified $l-a$ left vertices are contained in some specified r right vertices. Then, the number of $E \in \mathcal{E}$ such that $G_{E,\mathbf{D}}$ satisfies $P_{S,T}$ is given by

$$\prod_{j \in [c]} f((m,n),(|S|,|T|),a_j). \tag{2}$$

We say that the a_j's are equally distributed if, for every $i, j \in [c]$, $|a_i - a_j| \leq 1$. The following lemma is useful for our calculation.

▶ **Lemma 11.** *Eq. (2) is maximized when the a_j's are equally distributed.*

Proof. Let $b_j = \ell - a_j$, i.e. b_j is the number of edges in M_j connecting to a vertex in S in the graph $G_{E,\mathbf{D}}$. Suppose that $a_i = a_j + \alpha$ for some $i, j \in [n]$ and for some $\alpha \geq 2$. In order to prove the lemma, it is sufficient to show that

$$g(a_i)g(a_j) \leq g(a_i - 1)g(a_j + 1),$$

where $g(a)$ stands for $f((m,n),(\ell,r),a)$. This is verified by the following.

$$\begin{aligned}
& g(a_i-1)g(a_j+1)-g(a_i)g(a_j) \\
&= \left(\frac{r!}{(n-m)!}\right)^2 \left(\frac{(n-(b_i+1))!}{(r-(b_i+1))!}\frac{(n-(b_i+\alpha-1))!}{(r-(b_i+\alpha-1))!} - \frac{(n-b_i)!}{(r-b_i)!}\frac{(n-(b_i+\alpha))!}{(r-(b_i+\alpha))!}\right) \\
&= \left(\frac{r!}{(n-m)!}\right)^2 \left(\frac{(n-(b_i+1))!}{(r-(b_i+1))!}\frac{(n-(b_i+\alpha))!}{(r-(b_i+\alpha))!}\right)\left(\frac{n-(b_i+\alpha-1)}{r-(b_i+\alpha-1)} - \frac{n-b_i}{r-b_i}\right) \\
&= \left(\frac{r!}{(n-m)!}\right)^2 \left(\frac{(n-(b_i+1))!}{(r-(b_i+1))!}\frac{(n-(b_i+\alpha))!}{(r-(b_i+\alpha))!}\right)\left(\frac{(n-r)(\alpha-1)}{(r-(b_i+\alpha-1))(r-b_i)}\right) \\
&\geq 0.
\end{aligned}$$

◀

We go back to the proof of Theorem 9.

Put $d=(\frac{2}{3}+\epsilon)c$, and put $|S|=\lceil\frac{n-c}{2}\rceil$ and $|T|=\lfloor\frac{n}{2}\rfloor-\frac{c}{2}+d$. Then, Eq. (2) is equal to

$$\prod_{i\in[c]}\frac{\left(\lfloor\frac{n}{2}\rfloor+\frac{c}{6}+c\epsilon\right)!\cdot\left(n-(\lceil\frac{n}{2}\rceil-\frac{c}{2}-a_j)\right)!}{\left(\lfloor\frac{n}{2}\rfloor+\frac{c}{6}+c\epsilon-(\lceil\frac{n}{2}\rceil-\frac{c}{2}-a_j)\right)!\cdot c!} = \prod_{i\in[c]}\frac{\left(\lfloor\frac{n}{2}\rfloor+\frac{c}{6}+c\epsilon\right)!\cdot\left(\lfloor\frac{n}{2}\rfloor+\frac{c}{2}+a_j\right)!}{\left(\frac{2}{3}c+c\epsilon-1+a_j\right)!\cdot c!}.$$

By Lemma 11, this is upper bounded by

$$\left(\frac{\left(\lfloor\frac{n}{2}\rfloor+\frac{c}{6}+c\epsilon\right)!\cdot\left(\lfloor\frac{n}{2}\rfloor+\frac{c}{2}+a\right)!}{\left(\frac{2}{3}c+c\epsilon-1+a\right)!\cdot c!}\right)^c,$$

where $a=(\frac{1}{3}-\epsilon)(\lceil\frac{n}{2}\rceil-\frac{c}{2})$. By substituting the RHS for a, the inside of the outer bracket of the above formula is upper bounded by

$$\frac{\left(\lceil\frac{n}{2}\rceil+\frac{c}{6}+c\epsilon\right)!\cdot\left(\frac{2}{3}n-\frac{\epsilon n}{2}+\frac{c}{3}+\frac{c\epsilon}{2}\right)!\cdot n^{C_0}}{\left(\frac{n}{6}-\frac{\epsilon n}{2}+\frac{c}{2}+\frac{3c\epsilon}{2}\right)!\cdot c!} \tag{3}$$

for some small positive constant C_0. Since c and ϵ are constants, there are large enough constants C_1 and C_2, Eq. (3) is upper bounded by

$$\begin{aligned}
\frac{\left(\frac{n}{2}\right)!\cdot\left(\frac{2}{3}n-\frac{\epsilon n}{2}\right)!\cdot n^{C_1}}{\left(\frac{n}{6}-\frac{\epsilon n}{2}\right)!} &\leq \frac{\left(\frac{n}{2}\right)^{\frac{n}{2}}\cdot\left(\frac{2}{3}n-\frac{\epsilon n}{2}\right)^{\left(\frac{2}{3}n-\frac{\epsilon n}{2}\right)}n^{C_2}}{\left(\frac{n}{6}-\frac{\epsilon n}{2}\right)^{\left(\frac{n}{6}-\frac{\epsilon n}{2}\right)}e^n} \\
&\leq \frac{\left(\frac{n}{2}\right)^{\frac{n}{2}}\cdot\left(\frac{2}{3}n\right)^{\left(\frac{2}{3}n-\frac{\epsilon n}{2}\right)}n^{C_2}}{\left(\frac{n}{6}\right)^{\left(\frac{n}{6}-\frac{\epsilon n}{2}\right)}e^n} \\
&= n^{C_2}\cdot\frac{n^n}{e^n}\cdot\left(\frac{2^{1/3}}{3^{1/2}}\right)^n\cdot\left(\frac{1}{2}\right)^{\epsilon n}. \qquad (4)
\end{aligned}$$

Here the first inequality is by the Stirling formula, and the second inequality is by Lemma 8.

The number of $E\in\mathcal{E}$ such that

$$^\exists S\subseteq L\ ^\exists T\subseteq R\ ^\exists\mathbf{D}\in\mathcal{D}\quad G_{E,\mathbf{D}}\text{ has the property }P_{S,T} \tag{5}$$

is at most

$$\frac{2^{n-c}\cdot 2^n\cdot(\text{Eq.}(4))^c\cdot|\mathcal{D}|}{\binom{c}{d}^{\lfloor\frac{m}{2}\rfloor}} = 2^{n-c}\cdot 2^n\cdot(\text{Eq.}(4))^c\cdot\binom{c}{d}^{\lceil\frac{m}{2}\rceil}. \tag{6}$$

By using the upper bound on the binomial coefficients (see e.g., [9, Lemma 9.2])

$$\binom{c}{\alpha c}\leq 2^{cH(\alpha)},$$

where $H(p) = -p\log_2(p) - (1-p)\log_2(1-p)$ is the binary entropy function, we have

$$\binom{c}{d}^{\lceil \frac{m}{2} \rceil} \leq 2^{H(\frac{1}{3}-\epsilon)\lceil \frac{m}{2} \rceil} < 2^{H(\frac{1}{3})\frac{n}{2}} = \left(\frac{3^{1/2}}{2^{1/3}}\right)^n.$$

Therefore, we have

$$\text{(Eq. (6))} \quad < \quad 2^{2n} n^{C_2 c} \cdot \frac{n^{cn}}{e^{cn}} \cdot \left(\frac{1}{2}\right)^{\epsilon cn}. \tag{7}$$

Recall that $\mathcal{E}' \subseteq \mathcal{E}$ is the set of all E's in $\mathcal{E}$ such that G_E is a c-leftregular bipartite graph where G_E does not contain a multiedge. The proof of Theorem 9 will be completed if we verify that Eq. (7) is smaller than the cardinality of $\mathcal{E}'$ since it implies the existence of a c-leftregular bipartite graph G_E not satisfying the condition Eq. (5), i.e., G_E is a list expander of the desired parameter.

By Lemma 10, we have

$$|\mathcal{E}'| \quad \geq \quad \frac{(n!)^c}{e^{\binom{c}{2}} n^{c^2}} \geq \frac{n^{cn}}{e^{cn}} \frac{1}{n^{C_3}},$$

for a sufficiently large constant C_3. We can see that when n goes to infinity the last term in the above is larger than Eq. (7) by recalling that $\epsilon c \geq 3$. ◀

Proof of Lemma 10. We use the result on counting the number of *Latin rectangles*. A $c \times n$ Latin rectangle is a $c \times n$ matrix L with symbols from $[n]$ such that each row and each column contains only distinct symbols. Let $L_{c,n}$ denote the number of $c \times n$ Latin rectangles. It was shown by Erdős and Kaplansky [5] that, for $c = O((\log^n)^{3/2-\epsilon})$,

$$L_{c,n} \sim \frac{(n!)^c}{e^{\binom{c}{2}}}.$$

It is easy to observe that a c-leftregular bipartite graph with $n-c$ left vertices and n right vertices can be naturally represented by a $c \times (n-c)$ matrix obtained from a $c \times n$ Latin rectangle by discarding the last c columns. Since we shall discard c^2 entries with symbols from $[n]$, the number of variations of such $c \times (n-c)$ matrices is at least $L_{c,n}/(n^{c^2})$, completing the proof of the lemma. ◀

5 Conclusions

In this paper, we introduce a new notion of expander graphs and give the translation result from the construction of depth two circuits computing the majority function. Currently, the existence of a $\mathsf{MAJ}_{n-c} \circ \mathsf{MAJ}_{n-c}$ circuit computing MAJ_n is open even for $c = 4$. We hope that our translation result leads us to a better understanding on this problem with the help of a rich theory on expander graphs. In addition, it would be interesting to find other applications of list expanders.

Abstract

Various key problems from theoretical computer science can be expressed as polynomial optimization problems over the boolean hypercube. One particularly successful way to prove complexity bounds for these types of problems are based on sums of squares (SOS) as nonnegativity certificates. In this article, we initiate optimization over the boolean hypercube via a recent, alternative certificate called sums of nonnegative circuit polynomials (SONC). We show that key results for SOS based certificates remain valid: First, there exists a SONC certificate of degree at most $n + d$ for polynomials which are nonnegative over the n-variate boolean hypercube with constraints of degree d. Second, if there exists a degree d SONC certificate for nonnegativity of a polynomial over the boolean hypercube, then there also exists a short degree d SONC certificate, that includes at most $n^{O(d)}$ nonnegative circuit polynomials. Finally, we show certain differences between SOS and SONC cones: we prove that, in contrast to SOS, the SONC cone is not closed under taking affine transformation of variables and that for SONC there does not exist an equivalent to Putinar's Positivestellensatz. We discuss these results both from algebraic and optimization perspective.

1 Introduction

An *optimization problem over a boolean hypercube* is an n-variate (constrained) polynomial optimization problem where the feasibility set is restricted to some vertices of an n-dimensional hypercube. This class of optimization problems belongs to the core of theoretical computer

[1] Swiss National Science Foundation project PZ00P2_174117 "Theory and Applications of Linear and Semidefinite Relaxations for Combinatorial Optimization Problems"
[2] DFG grant WO 2206/1-1

science. However, it is known that solving them is NP-hard in general, since one can easily cast, e.g., the Independent Set problem in this framework.

One of the most promising approaches in constructing theoretically efficient algorithms is the *sum of squares (SOS) hierarchy* [23, 45, 48, 55], also known as *Lasserre relaxation* [34]. The method is based on a Positivstellensatz result [50] saying that the polynomial f, which is nonnegative over the feasibility set, can be expressed as a sum of squares times the constraints defining the set. Bounding a maximum degree of a polynomial used in a representation of f provides a family of algorithms parametrized by an integer d. Finding a degree d SOS certificate for nonnegativity of f can be performed by solving a *semidefinite programming* (SDP) formulation of size $n^{O(d)}$. Finally, for every (feasible) n-variate hypercube optimization problem, with constraints of degree at most d, there exists a degree $2(n + \lceil d/2 \rceil)$ SOS certificate.

The SOS algorithm is a frontier method in algorithm design. It provides the best available algorithms used for a wide variety of optimization problems. The degree 2 SOS for the Independent Set problem implies the Lovász θ-function [40] and gives the Goemans-Williamson relaxation [20] for the Max Cut problem. The Goemans-Linial relaxation for the Sparsest Cut problem (analyzed in [2]) can be captured by the SOS of degree 6. Finally, the subexponential time algorithm for Unique Games [1] is implied by a SOS of sublinear degree [4, 24]. Moreover, it has been shown that SOS is equivalent in power to any SDP extended formulation of comparable size in approximating maximum constraint satisfaction problems (CSP) [39]. Recently SOS has been also applied to problems in dictionary learning [6, 54], tensor completion and decomposition [7, 26, 49], and robust estimation [28]. Other applications of the SOS method can be found in [4, 8, 12, 13, 16, 17, 24, 41, 42, 51], see also the surveys [14, 35, 37].

On the other hand it is known that the SOS algorithm admits certain weaknesses. For example, Grigoriev shows in [21] that a $\Omega(n)$ degree SOS certificate is needed to detect a simple integrality argument for the Knapsack problem, see also [22, 31, 36]. Other SOS degree lower bounds for Knapsack problems appeared in [11, 32]. Some lower bounds on the effectiveness of SOS has been shown for CSP problems [29, 56] and for planted clique problem [3, 43]. Finally degree $\Omega(\sqrt{n})$ SOS was proved to have problems scheduling unit size jobs on a single machine to minimize the number of late jobs [33]. The problem is solvable in polynomial time using the Moore-Hodgson algorithm. Finally, SOS has hard time proving global nonnegativity, as first proved by Hilbert [25]. Later an explicit example was given by Motzkin [44]. Moreover, as shown by Blekherman [9], there are significantly more nonnegative polynomials than SOS polynomials. The above arguments motivate the search of new nonnegativity certificates for solving optimization problems efficiently.

In this article, we initiate an analysis of hypercube optimization problems via *sums of nonnegative circuit polynomials (SONC)*. SONCs are a nonnegativity certificate introduced in [27], which are independent of sums of squares; see Definition 1 and Theorem 5 for further details. This means particularly that certain polynomials like the Motzkin polynomial, which have no SOS certificate for global nonnegativity, can be certified as nonnegative via SONCs. Moreover, SONCs generalize polynomials which are certified to be nonnegative via the arithmetic-geometric mean inequality [52]. Similarly as Lasserre relaxation for SOS, a Schmüdgen-like Positivstellensatz yields a converging hierarchy of lower bounds for polynomial optimization problems with compact constraint set; see [19, Theorem 4.8] and Theorem 6. These bounds can be computed via a convex optimization program called *relative entropy programming* [19, Theorem 5.3]. Our main question in this article is:

Can SONC certificates be an alternative for SOS methods for optimization problems over the hypercube?

We answer this question affirmatively in the sense that we prove SONC complexity bounds for boolean hypercube optimization analogous to the SOS bounds mentioned above. More specifically, we show:

1. For every polynomial which is nonnegative over an n-variate hypercube with constraints of degree at most d there exists a SONC certificate of nonnegativity of degree at most $n + d$; see Theorem 16 and Corollary 17.
2. If a polynomial f admits a degree d SONC certificate of nonnegativity over an n-variate hypercube, then the polynomial f admits also a *short* degree d SONC certificate that includes at most $n^{O(d)}$ nonnegative circuit polynomials; see Theorem 18.

Furthermore, we show some structural properties of SONCs:

1. We give a simple, constructive example showing that the SONC cone is not closed under multiplication. Subsequently we use this construction to show that the SONC cone is neither closed under taking affine transformations of variables, see Lemma 8 and Corollary 9 and the discussion afterwards.
2. We address an open problem raised in [19] asking whether the Schmüdgen-like Positivstellensatz for SONCs (Theorem 6) can be improved to an equivalent of Putinar's Positivstellensatz [50]. We answer this question negatively by showing an explicit hypercube optimization example, which provably does not admit a Putinar representation for SONCs; see Theorem 19 and the discussion afterwards.

Our article is organized as follows: In Section 2 we introduce the necessary background from theoretical computer sciences and about SONCs. In Section 3 we show that the SONC cone is closed neither under multiplication nor under affine transformations. In Section 4 we provide our two main results regarding the degree bounds for SONC certificates over the hypercube. In Section 5 we prove the non-existence of an equivalent of Putinar's Positivstellensatz for SONCs and discuss this result.

2 Preliminaries

In this section we collect basic notions and statements on sums of nonnegative circuit polynomials (SONC).

Throughout the paper, we use bold letters for vectors, e.g., $\mathbf{x} = (x_1, \dots, x_n) \in \mathbb{R}^n$. Let $\mathbb{N}^* = \mathbb{N} \setminus \{\mathbf{0}\}$ and $\mathbb{R}_{\geq 0}$ ($\mathbb{R}_{>0}$) be the set of nonnegative (positive) real numbers. Furthermore let $\mathbb{R}[\mathbf{x}] = \mathbb{R}[x_1, \dots, x_n]$ be the ring of real n-variate polynomials and the set of all n-variate polynomials of degree less than or equal to $2d$ is denoted by $\mathbb{R}[\mathbf{x}]_{n,2d}$. We denote by $[n]$ the set $\{1, \dots, n\}$ and the sum of binomial coefficients $\sum_{k=0}^{d} \binom{n}{k}$ is abbreviated by $\binom{n}{\leq d}$. Let $\mathbf{e_1}, \dots, \mathbf{e_n}$ denote the canonical basis vectors in $\mathbb{R}^n$.

2.1 Sums of Nonnegative Circuit Polynomials

Let $A \subset \mathbb{N}^n$ be a finite set. In what follows, we consider polynomials $f \in \mathbb{R}[\mathbf{x}]$ supported on A. Thus, f is of the form $f(\mathbf{x}) = \sum_{\boldsymbol{\alpha} \in A} f_{\boldsymbol{\alpha}} \mathbf{x}^{\boldsymbol{\alpha}}$ with $f_{\boldsymbol{\alpha}} \in \mathbb{R}$ and $\mathbf{x}^{\boldsymbol{\alpha}} = x_1^{\alpha_1} \cdots x_n^{\alpha_n}$. A lattice point is called *even* if it is in $(2\mathbb{N})^n$ and a term $f_{\boldsymbol{\alpha}} \mathbf{x}^{\boldsymbol{\alpha}}$ is called a *monomial square* if $f_{\boldsymbol{\alpha}} > 0$ and α even. We denote by $\mathrm{New}(f) = \mathrm{conv}\{\boldsymbol{\alpha} \in \mathbb{N}^n : f_{\boldsymbol{\alpha}} \neq 0\}$ the Newton polytope of f.

Initially, we introduce the foundation of SONC polynomials, namely *circuit polynomials*; see also [27]:

▶ **Definition 1.** A polynomial $f \in \mathbb{R}[\mathbf{x}]$ is called a *circuit polynomial* if it is of the form

$$f(\mathbf{x}) \;:=\; f_{\boldsymbol{\beta}}\mathbf{x}^{\boldsymbol{\beta}} + \sum_{j=0}^{r} f_{\boldsymbol{\alpha}(j)}\mathbf{x}^{\boldsymbol{\alpha}(j)}, \tag{2.1}$$

with $r \leq n$, exponents $\boldsymbol{\alpha}(j)$, $\boldsymbol{\beta} \in A$, and coefficients $f_{\boldsymbol{\alpha}(j)} \in \mathbb{R}_{>0}$, $f_{\boldsymbol{\beta}} \in \mathbb{R}$, such that the following conditions hold:

(C1) $\mathrm{New}(f)$ is a simplex with all even vertices $\boldsymbol{\alpha}(0), \boldsymbol{\alpha}(1), \ldots, \boldsymbol{\alpha}(r) \in \mathbb{Z}^n$.

(C2) The exponent $\boldsymbol{\beta}$ is in the strict interior of $\mathrm{New}(f)$. Hence, there exist unique *barycentric coordinates* λ_j relative to the vertices $\boldsymbol{\alpha}(j)$ with $j = 0, \ldots, r$ satisfying

$$\boldsymbol{\beta} \;=\; \sum_{j=0}^{r} \lambda_j \boldsymbol{\alpha}(j) \;\text{ with }\; \lambda_j \;>\; 0 \;\text{ and }\; \sum_{j=0}^{r} \lambda_j \;=\; 1.$$

We call the terms $f_{\boldsymbol{\alpha}(0)}\mathbf{x}^{\boldsymbol{\alpha}(0)}, \ldots, f_{\boldsymbol{\alpha}(r)}\mathbf{x}^{\boldsymbol{\alpha}(r)}$ the *outer terms* and $f_{\boldsymbol{\beta}}\mathbf{x}^{\boldsymbol{\beta}}$ the *inner term* of f.

For every circuit polynomial we define the corresponding *circuit number* as

$$\Theta_f \;:=\; \prod_{j=0}^{r} \left(\frac{f_{\boldsymbol{\alpha}(j)}}{\lambda_j}\right)^{\lambda_j}. \tag{2.2}$$

Note that the name of these polynomials is motivated by the fact that their support set forms a *circuit*, i.e. a minimal affine dependent set, see e.g. [47]. The first fundamental statement about circuit polynomials is that its nonnegativity is determined by its circuit number Θ_f and f_β entirely:

▶ **Theorem 2** ([27], Theorem 3.8)**.** *Let f be a circuit polynomial with inner term $f_{\boldsymbol{\beta}}\mathbf{x}^{\boldsymbol{\beta}}$ and let Θ_f be the corresponding circuit number, as defined in* (2.2)*. Then the following statements are equivalent:*

1. *f is nonnegative.*
2. *$|f_{\boldsymbol{\beta}}| \leq \Theta_f$ and $\boldsymbol{\beta} \notin (2\mathbb{N})^n$ or $f_{\boldsymbol{\beta}} \geq -\Theta_f$ and $\boldsymbol{\beta} \in (2\mathbb{N})^n$.*

We illustrate the previous definition and theorem by an example:

▶ **Example 3.** The *Motzkin polynomial* [44] is given by

$$M(x_1, x_2) \;:=\; x_1^4x_2^2 + x_1^2x_2^4 - 3x_1^2x_2^2 + 1.$$

It is a circuit polynomial since $\mathrm{New}(f) = \{(4,2), (2,4), (0,0)\}$, and $\boldsymbol{\beta} = (2,2)$ with $\lambda_0, \lambda_1, \lambda_2 = 1/3$. We have $|f_{\boldsymbol{\beta}}| = 3$ and compute $\Theta_f \;=\; \sqrt[3]{\left(\frac{1}{1/3}\right)^3} \;=\; 3$. Hence, we can conclude that $M(x_1, x_2)$ is nonnegative by Theorem 2.

▶ **Definition 4.** We define for every $n, d \in \mathbb{N}^*$ the set of *sums of nonnegative circuit polynomials* (SONC) in n variables of degree $2d$ as

$$C_{n,2d} \;:=\; \left\{ f \in \mathbb{R}[\mathbf{x}]_{n,2d} \;:\; f = \sum_{i=1}^{k} p_i,\; p_i \text{ is a nonnegative circuit polynomial},\; k \in \mathbb{N}^* \right\}$$

Note that the degree is attained at the outer terms and hence it is even.

We denote by SONC both the set of SONC polynomials and the property of a polynomial to be a sum of nonnegative circuit polynomials.

In what follows let $P_{n,2d}$ be the cone of nonnegative n-variate polynomials of degree at most $2d$ and $\Sigma_{n,2d}$ be the corresponding cone of sums of squares respectively. An important observation is, that SONC polynomials form a convex cone independent of the SOS cone:

▶ **Theorem 5** ([27], Proposition 7.2). *$C_{n,2d}$ is a convex cone satisfying:*

1. *$C_{n,2d} \subseteq P_{n,2d}$ for all $n, d \in \mathbb{N}^*$,*
2. *$C_{n,2d} \subseteq \Sigma_{n,2d}$ if and only if $(n, 2d) \in \{(1, 2d), (n, 2), (2, 4)\}$,*
3. *$\Sigma_{n,2d} \not\subseteq C_{n,2d}$ for all $(n, 2d)$ with $2d \geq 6$.*

For further details about the SONC cone see [18, 19, 27].

2.2 SONC certificates over a Constrained Set

In [19, Theorem 4.8], Iliman, the first, and the third author showed that for an arbitrary real polynomial which is strictly positive on a compact, basic closed semialgebraic set K there exists a SONC certificate of nonnegativity. Hereinafter we recall this result.

We assume that K is given by polynomial inequalities $g_i(\mathbf{x}) \geq 0$ for $i = 1, \ldots, s$ and is compact. For technical reason we add $2n$ redundant box constraints $l_j(\mathbf{x}) := N \pm x_j \geq 0$ for some sufficiently large $N \in \mathbb{N}$, which always exists due to our assumption of compactness of K; see [19] for further details. Hence, we have

$$K \;:=\; \{\mathbf{x} \in \mathbb{R}^n : g_i(\mathbf{x}) \geq 0 \text{ for } i \in [s] \text{ and } l_j(\mathbf{x}) \geq 0 \text{ for } j \in [2n]\}. \tag{2.3}$$

In what follows we consider polynomials $H^{(q)}(\mathbf{x})$ defined as products of at most $q \in \mathbb{N}^*$ of the polynomials g_i, l_j and 1, i.e.,

$$H^{(q)}(\mathbf{x}) \;:=\; \prod_{k=1}^{q} h_k(\mathbf{x}), \tag{2.4}$$

where $h_k \in \{1, g_1, \ldots, g_s, l_1, \ldots, l_{2n}\}$. Now we can state:

▶ **Theorem 6** ([19], Theorem 4.8). *Let $f, g_1, \ldots, g_s \in \mathbb{R}[\mathbf{x}]$ be real polynomials and K be a compact, basic closed semialgebraic set as in (2.3). If $f > 0$ on K then there exist $d, q \in \mathbb{N}^*$ such that we have an explicit representation of f of the form:*

$$f(\mathbf{x}) \;=\; \sum_{\text{finite}} s(\mathbf{x}) H^{(q)}(\mathbf{x}),$$

where the $s(\mathbf{x})$ are contained in $C_{n,2d}$ and every $H^{(q)}(\mathbf{x})$ is a product as in (2.4).

The central object of interest is the smallest value of d and q that allows f a decomposition as in Theorem 6. This motivates the following definition of a *degree d SONC certificate*.

▶ **Definition 7.** Let $f \in \mathbb{R}[\mathbf{x}]$ such that f is positive on the set K given in (2.3). Then f has a *degree d SONC certificate* if it admits for some $q \in \mathbb{N}^*$ the following decomposition:

$$f(\mathbf{x}) \;=\; \sum_{\text{finite}} s(\mathbf{x}) H^{(q)}(\mathbf{x}),$$

for $s(\mathbf{x})$ SONCs, the $H^{(q)}(\mathbf{x})$ products as in (2.4), and $\deg\left(\sum s(\mathbf{x}) H^{(q)}(\mathbf{x})\right) \;\leq\; d$.

For a given set $A \subseteq \mathbb{N}^n$, searching through the space of degree d certificates can be computed via a *relative entropy program (REP)* [19] of size $n^{O(d)}$. REPs are convex optimization programs which are slightly more general than geometric programs but still efficiently solvable with interior point methods; see e.g. [10, 46] for more details.

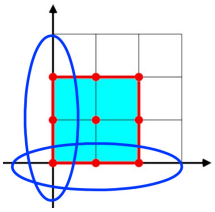

Figure 1 The Newton polytope and the support set of $r(x_1, x_k)$ with the supports of p_1 and p_2 in blue ovals.

3 Properties of the SONC cone

In this section we show that the SONC cone is neither closed under multiplication nor under affine transformations. First, we give a constructive proof for the fact that the SONC cone is not closed under multiplication, which is simpler than the initial proof of this fact in [19, Lemma 4.1]. Second, we use our construction to show that the SONC cone is not closed under affine transformation of variables.

▶ **Lemma 8.** *For every $d \geq 2$, $n \in \mathbb{N}^*$ the SONC cone $C_{n,d}$ is not closed under multiplication in the following sense: if $p_1, p_2 \in C_{n,d}$, then $p_1 \cdot p_2 \notin C_{n,2d}$ in general.*

Proof. For every $d = 2n$, $n \in \mathbb{N}^*$ we construct two SONC polynomials p_1, $p_2 \in C_{n,d}$ such that the product $p_1 p_2$ is an n variate, degree $2d$ polynomial that is not inside $C_{n,2d}$.

Let $n = 2$. We construct the following two polynomials $p_1,\ p_2 \in \mathbb{R}[x_1, x_2]$:

$$p_1(x_1, x_2) \ := \ (1 - x_1)^2, \qquad p_2(x_1, x_2) \ := \ (1 - x_2)^2.$$

First, observe that p_1, p_2 are nonnegative circuit polynomials, since, in both cases, $\lambda_1 = \lambda_2 = 1/2$, $f_{\boldsymbol{\alpha}(1)} = f_{\boldsymbol{\alpha}(2)} = 1$, and $f_{\boldsymbol{\beta}} = -2$, thus $2 = \Theta_f \geq |f_{\boldsymbol{\beta}}|$.

Now consider the polynomial $r(x_1, x_2) = ((1 - x_1)(1 - x_2))^2$. We show that this polynomial, even though it is nonnegative, is not a SONC polynomial. Note that $r(x_1, x_2) = 1 - 2x_1 - 2x_2 + 4x_1x_2 + x_1^2 + x_2^2 - 2x_1^2x_2 - 2x_1x_2^2 + x_1^2x_2^2$; the support of r is shown in Figure 1. Assume that $r \in C_{2,4}$, i.e., r has a SONC decomposition. This implies that the term $-2x_1$ has to be an inner term of some nonnegative circuit polynomial r_1 in this representation. Such a circuit polynomial necessarily has the terms 1 and x_1^2 as outer terms, that is, $r_1(x_1) = p_1(x_1, x_2) = 1 + x_1^2 - 2x_1$. Since $\Theta_{r_1} = 2$ the polynomial r_1 is indeed nonnegative and, in addition, we cannot choose a smaller constant term and preserve nonnegativity without simultaneously increasing the coefficient x_1^2. Next, also the term $-2x_2$ has to be an inner term of SONC r_2. Since this term again is on the boundary of New(r) the only option for such an r_2 is: $r_2(x_2) = p_2(x_1, x_2) = 1 + x_2^2 - 2x_2$. However, the term 1 has been already used in r_1, which leads to a contradiction, i.e., $r \notin C_{2,4}$. Since $C_{n,2d} \subseteq C_{n+1,2d}$, the general statement follows. ◀

Hereinafter we show another operation, which behaves differently for SONC than it does for SOS: Similarly as for multiplications, affine transformations also do not preserve the SONC structure. This observation is important for possible degree bounds on SONC certificates, when considering optimization problems over distinct descriptions of the hypercube.

▶ **Corollary 9.** *For every $d \geq 4$, $n \in \mathbb{N}^*$ the SONC cone $C_{n,d}$ is not closed under affine transformation of variables.*

Proof. Consider the polynomial $f(x_1, x_2) = x_1^2 x_2^2$. Clearly, the polynomial f is a nonnegative circuit polynomial since it is a monomial square, hence $u \in C_{n,d}$. Now consider the following affine transformation of the variables x_1 and x_2: $x_1 \to 1 - x_1$, $x_2 \to 1 - x_2$. After applying the transformation the polynomial f equals the polynomial $p_1 p_2$ from the proof of Lemma 8 and thus is not inside $C_{n,d}$. ◀

Corollary 9, from optimization perspective, implies that problem formulations obtained by applying affine transformations of variables can lead to problems of different tractability when using the SONC method. This means, on the one hand, that a choice of representation has to be done carefully, which makes the process of algorithm design more demanding. On the other hand, even a small change of representation might allow to find a SONC certificate or simplify an existing one. Note that whatever affine transformation of variables is applied to the Motzkin polynomial it *never* has a SOS certificate over reals, as the SOS cone is closed under affine transformations. The affine closure of the SONC cone, however, strictly contains the SONC cone and still yields a certificate of nonnegativity. In this sense, Corollary 9 motivates the following future research question:

Find an efficient algorithm to determine whether an affine transformation of a given polynomial f admits a SONC representation.

4 An Upper Bound on the Degree of SONC Certificates over the Hypercube

In this section we prove that every n-variate polynomial which is nonnegative over the boolean hypercube has a degree n SONC certificate. Moreover, if the hypercube is additionally constrained with some polynomials of degree at most d, then the nonnegative polynomial over such a set has degree $n + d$ SONC certificate. Motivated by the Corollary 9 and the discussion afterwards, we show this fact for *all* affine transformations of the 0/1 hypercube, that is for hypercubes $\{a_i, b_i\}^n$.

Formally, we consider the following setting: We investigate real multivariate polynomials in $\mathbb{R}[\mathbf{x}]$. For $j \in [n]$, and $a_j, b_j \in \mathbb{R}$, such that $a_j < b_j$ let

$$g_j(\mathbf{x}) \;:=\; (x_j - a_j)(x_j - b_j)$$

be a *quadratic polynomial with two distinct real roots*. Let $\mathcal{H} \subset \mathbb{R}^n$ denote the *n-dimensional hypercube* given by $\prod_{j=1}^n \{a_j, b_j\}$. Moreover, let

$$\mathcal{P} \;:=\; \{p_1, \ldots, p_m :\; p_i \in \mathbb{R}[\mathbf{x}],\; i \in [m]\}$$

be a set of polynomials, which we consider as constraints $p_i(\mathbf{x}) \geq 0$ with $\deg(p_i(\mathbf{x})) \leq d$ for all $i \in [n]$ as follows. We define

$$\mathcal{H}_{\mathcal{P}} \;:=\; \{\mathbf{x} \in \mathbb{R}^n :\; g_j(\mathbf{x}) = 0,\; j \in [n],\; p(\mathbf{x}) \geq 0,\; p \in \mathcal{P}\}$$

as the *n-dimensional hypercube $\mathcal{H}$ constrained by polynomial inequalities given by $\mathcal{P}$*. Throughout the paper we assume that $|\mathcal{P}| = \text{poly}(n)$, i.e. the size of the constraint set $\mathcal{P}$ is polynomial in n. This is usually the case, since otherwise the problem gets less tractable from the optimization point of view.

As a first step, we introduce a *Kronecker delta* function:

▶ **Definition 10.** For every $\mathbf{v} \in \mathcal{H}$ the function

$$\delta_{\mathbf{v}}(\mathbf{x}) \;:=\; \prod_{j \in [n]:\; v_j = a_j} \left(\frac{-x_j + b_j}{b_j - a_j}\right) \cdot \prod_{j \in [n]:\; v_j = b_j} \left(\frac{x_j - a_j}{b_j - a_j}\right) \tag{4.1}$$

is called the *Kronecker delta (function)* of the vector $\mathbf{v}$.

Next we justify the term "Kronecker delta", we show that for every $\mathbf{v} \in \mathcal{H}$ the function $\delta_{\mathbf{v}}(\mathbf{x})$ takes the value zero for all $\mathbf{x} \in \mathcal{H}$ except for $\mathbf{x} = \mathbf{v}$ where it takes the value one.

▶ **Lemma 11.** *For every $\mathbf{v} \in \mathcal{H}$ it holds that:*

$$\delta_{\mathbf{v}}(\mathbf{x}) \;=\; \begin{cases} 0, & \text{for every } \mathbf{x} \in \mathcal{H} \setminus \{\mathbf{v}\}, \\ 1, & \text{for } \mathbf{x} = \mathbf{v}. \end{cases}$$

Proof. On the one hand, if $\mathbf{x} \in \mathcal{H} \setminus \{\mathbf{v}\}$, then there exists an index k such that $\mathbf{x}_k \neq \mathbf{v}_k$. This implies that there exists at least one multiplicative factor in $\delta_{\mathbf{v}}$ which attains the value zero due to (4.1). On the other hand if $\mathbf{x} = \mathbf{v}$ then we have

$$\delta_{\mathbf{v}}(\mathbf{x}) \;=\; \prod_{j\in[n]:\ v_j=a_j} \left(\frac{-a_j+b_j}{b_j-a_j}\right) \prod_{j\in[n]:\ v_j=b_j} \left(\frac{b_j-a_j}{b_j-a_j}\right) \;=\; 1. \qquad \blacktriangleleft$$

The main result of this section is the following theorem.

▶ **Theorem 12.** *Let $f(\mathbf{x}) \in \mathbb{R}[\mathbf{x}]_{n,n}$. Then $f(\mathbf{x}) \geq 0$ for every $\mathbf{x} \in \mathcal{H}_{\mathcal{P}}$ if and only if f has the following representation:*

$$f(\mathbf{x}) \;=\; \sum_{\mathbf{v}\in\mathcal{H}_{\mathcal{P}}} c_{\mathbf{v}}\delta_{\mathbf{v}}(\mathbf{x}) + \sum_{\mathbf{v}\in\mathcal{H}\setminus\mathcal{H}_{\mathcal{P}}} c_{\mathbf{v}}\delta_{\mathbf{v}}(\mathbf{x})p_{\mathbf{v}}(\mathbf{x}) + \sum_{j=1}^{n} s_j(\mathbf{x})g_j(\mathbf{x}) + \sum_{j=1}^{n} s_{n+j}(\mathbf{x})(-g_j(\mathbf{x})), \quad (4.2)$$

where $s_1, \ldots, s_{2n} \in C_{n,n-2}$, $c_{\mathbf{v}} \in \mathbb{R}_{\geq 0}$ and $p_{\mathbf{v}} \in \mathcal{P}$.

Since we are interested in optimization on the boolean hypercube $\mathcal{H}$, we assume without loss of generality that the polynomial f considered in Theorem 12 has degree at most n. Otherwise, one can efficiently reduce the degree of f by applying iteratively the polynomial division with respect to polynomials g_j with $j \in [n]$. The remainder of the division process is a polynomial with degree at most n that agrees with f on all the vertices of $\mathcal{H}$.

We begin with proving the easy direction of the equivalence stated in Theorem 12.

▶ **Lemma 13.** *If f admits a decomposition* (4.2)*, then $f(\mathbf{x})$ is nonnegative for all $\mathbf{x} \in \mathcal{H}_{\mathcal{P}}$.*

Proof. The coefficients $c_{\mathbf{v}}$ are nonnegative, all $s_j(\mathbf{x})$ are SONC and hence nonnegative on $\mathbb{R}^n$. We have $\pm g_j(\mathbf{x}) \geq 0$ for all $\mathbf{x} \in \mathcal{H}$, and for all choices of $\mathbf{v} \in \mathcal{H}$ we have $p_{\mathbf{v}}(\mathbf{x}) \geq 0$ for all $\mathbf{x} \in \mathcal{H}_{\mathcal{P}}$, and $\delta_{\mathbf{v}}(\mathbf{x}) \in \{0, 1\}$ for all $\mathbf{x} \in \mathcal{H}$. Thus, the right hand side of (4.2) is a sum of positive terms for all $\mathbf{x} \in \mathcal{H}_{\mathcal{P}}$. ◀

We postpone the rest of the proof of Theorem 12 to the end of the section. Now, we state a result about the presentation of the Kronecker delta function $\delta_{\mathbf{v}}$. In what follows let K be the basic closed semialgebraic set defined by $g_1, \ldots, g_n$ and $l_1, \ldots, l_{2n}$ as in (2.3).

▶ **Lemma 14.** *For every $\mathbf{v} \in \mathcal{H}$ the Kronecker delta function can be written as*

$$\delta_{\mathbf{v}} \;=\; \sum_{j=1}^{2^n} s_j H_j^{(n)},$$

for $s_1, \ldots, s_{2^n} \in \mathbb{R}_{\geq 0}$ and every $H_j^{(n)}$ given as in (2.4) *with $q = n$.*

Proof. First note that the function $\delta_{\mathbf{v}}$ can be rewritten as

$$\delta_{\mathbf{v}}(\mathbf{x}) \;=\; \prod_{j=1}^{2n} \frac{1}{b_j-a_j} \prod_{j\in[n]:\ v_j=a_j} (-x_j+b_j) \prod_{j\in[n]:\ v_j=b_j} (x_j-a_j)\,,$$

where $\prod_{j=1}^{n} \frac{1}{b_j-a_j} \in \mathbb{R}_{\geq 0}$. Now, the proof follows just by noting that for every $j \in [n]$ both inequalities $-x_j + b_j \geq 0$ and $x_j - a_j \geq 0$ are in K. ◀

The following statement is well-known in similar variations; see e.g. [5, Lemma 2.2 and its proof]. For clarity, we provide an own proof in the appendix.

▶ **Proposition 15.** *Let $f \in \mathbb{R}[\mathbf{x}]_{n,2d}$ be a polynomial vanishing on $\mathcal{H}$. Then $f = \sum_{j=1}^{n} p_j g_j$ for some polynomials $p_j \in \mathbb{R}[\mathbf{x}]_{n,2d-2}$.*

Proof. Let $\mathcal{J} := \langle g_1, \dots, g_n \rangle$ be the ideal generated by the g_j's. Let $\mathcal{V}(\mathcal{J})$ denote the affine variety corresponding to $\mathcal{J}$, $\mathcal{I}(\mathcal{V}(\mathcal{J}))$ denote its radical ideal, and let $\mathcal{I}(\mathcal{H})$ denote the ideal of $\mathcal{H}$. It follows from $\prod_{j=1}^{n} g_j \in \mathcal{J}$ that $\mathcal{V}(\mathcal{J}) \subseteq \mathcal{H}$ and hence $\mathcal{I}(\mathcal{H}) \subseteq \mathcal{I}(\mathcal{V}(\mathcal{J})) = \mathcal{J}$. The last equality holds since $\mathcal{J}$ itself is a radical ideal. This results from Seidenberg's Lemma; see [30, Proposition 3.7.15] by means of the following observations. The affine variety $\mathcal{V}(\mathcal{J})$ consists exactly of the points defining $\mathcal{H}$, therefore we know that $\mathcal{J}$ is a zero-dimensional ideal. Furthermore, for every $j \in [n]$ the polynomials g_j satisfy $g_j \in \mathcal{J} \cap K[x_j]$ and $\gcd(g_j, g_j') = 1$. Thus, every $f \in \mathcal{I}(\mathcal{H})$ is of the form $f = \sum_{j=1}^{n} p_j g_j$.

Moreover $G := \{g_1, \dots, g_n\}$ is a Gröbner basis for $\mathcal{J}$ with respect to the graded lexicographic order $\prec_{\text{glex}}$. This follows from Buchberger's Criterion, which says that G is a Gröbner basis for $\mathcal{J}$ if and only if for all pairs $i \neq j$ the remainder on the division of the S-polynomials $S(g_i, g_j)$ by G with respect to $\prec_{\text{glex}}$ is zero. Consider an arbitrary pair g_i, g_j with $i > j$. Then the corresponding S-polynomial is given by

$$S(g_i, g_j) \;=\; (a_j + b_j)x_i^2 x_j - (a_i + b_i)x_i x_j^2 - a_j b_j x_i^2 + a_i b_i x_j^2 \,.$$

Applying polynomial division with respect to $\prec_{\text{glex}}$ yields the remainder 0 and hence G is a Gröbner basis for $\mathcal{J}$ with respect to $\prec_{\text{glex}}$. Therefore, we conclude that if $f \in \mathbb{R}[\mathbf{x}]_{n,2d}$, then $\deg(p_j) \leq 2d - 2$. ◀

For an introduction to Gröbner bases see for example [15].

▶ **Theorem 16.** *Let $d \in \mathbb{N}$ and $f \in \mathbb{R}[\mathbf{x}]_{n,2d+2}$ such that f vanishes on $\mathcal{H}$. Then there exist $s_1, \dots, s_{2n} \in C_{n,2d}$ such that $f = \sum_{j=1}^{n} s_j g_j + \sum_{j=1}^{n} s_{n+j}(-g_j)$.*

Proof. By Proposition 15 we know that $f = \sum_{j=1}^{n} p_j g_j$ for some polynomials p_j of degree $\leq 2d$. Hence, it is sufficient to show that every single term $p_j g_j$ is of the form $\sum_{j=1}^{n} s_j g_j - \sum_{j=1}^{n} s_{n+j} g_j$ for some $s_1, \dots, s_{2n} \in C_{n,2d}$. Let $p_j = \sum_{i=1}^{\ell} a_{ji} m_{ji}$ where every $a_{ji} \in \mathbb{R}$ and every m_{ji} is a single monomial. We show that $p_j g_j$ has the desired form by investigating an arbitrary individual term $a_{ji} m_{ji} g_j$.

Case 1: Assume the exponent of m_{ji} is contained in $(2\mathbb{N})^n$. If $a_{ji} m_{ji}$ is a monomial square, then $a_{ji} m_{ji}$ is a circuit polynomial. If $a_{ji} < 0$, then $-a_{ji} m_{ji}$ is a monomial square. In both cases we obtain a representation $s_{ji}(\pm g_{ji})$, where $s_{ji} \in C_{n,2d}$.

Case 2: Assume the the exponent $\boldsymbol{\beta}$ of m_{ji} contains odd numbers. Without loss of generality, assume that $\boldsymbol{\beta} = (\beta_1, \dots, \beta_k, \beta_{k+1}, \dots, \beta_n)$ such that the first k entries are odd and the remaining $n - k$ entries are even. We construct a SONC polynomial $s_{ji} = a_{\boldsymbol{\alpha}(1)} \mathbf{x}^{\boldsymbol{\alpha}(1)} + a_{\boldsymbol{\alpha}(2)} \mathbf{x}^{\boldsymbol{\alpha}(2)} + a_{ji} \mathbf{x}^{\boldsymbol{\beta}}$ such that

$$\boldsymbol{\alpha}(1) \;=\; \boldsymbol{\beta} + \sum_{j=1}^{\lceil k/2 \rceil} \mathbf{e}_j - \sum_{j=\lceil k/2 \rceil + 1}^{k} \mathbf{e}_j, \qquad \boldsymbol{\alpha}(2) \;=\; \boldsymbol{\beta} - \sum_{j=1}^{\lceil k/2 \rceil} \mathbf{e}_j + \sum_{j=\lceil k/2 \rceil + 1}^{k} \mathbf{e}_j, \tag{4.3}$$

$$|a_{ji}| \;\leq\; \sqrt{2 a_{\boldsymbol{\alpha}(1)} a_{\boldsymbol{\alpha}(2)}}. \tag{4.4}$$

By the construction (4.3) $\boldsymbol{\alpha}(1), \boldsymbol{\alpha}(2) \in (2\mathbb{N})^n$ and $\boldsymbol{\beta} = 1/2(\boldsymbol{\alpha}(1) + \boldsymbol{\alpha}(2))$. Thus, s_{ji} is a circuit polynomial and by (4.4) the coefficients $a_{\boldsymbol{\alpha}(1)}, a_{\boldsymbol{\alpha}(2)}$ are chosen large enough such that $|a_{ji}|$ is bound by the circuit number $\sqrt{2 a_{\boldsymbol{\alpha}(1)} a_{\boldsymbol{\alpha}(2)}}$ corresponding to s_{ji}. Thus, s_{ji} is nonnegative by [27, Theorem 1.1]. Thus, we obtain

$$a_{ji} m_{ji} g_j \;=\; s_{ji} g_j + (a_{\boldsymbol{\alpha}(1)} \mathbf{x}^{\boldsymbol{\alpha}(1)} + a_{\boldsymbol{\alpha}(2)} \mathbf{x}^{\boldsymbol{\alpha}(2)})(-g_j),$$

where s_{ji}, $a_{\boldsymbol{\alpha}(1)} \mathbf{x}^{\boldsymbol{\alpha}(1)}$, and $a_{\boldsymbol{\alpha}(2)} \mathbf{x}^{\boldsymbol{\alpha}(2)}$ are nonnegative circuit polynomials.

Degree: All involved nonnegative circuit polynomials are of degree at most $2d$. In Case 1 this follows by construction. In Case 2 we have for the circuit polynomial s_{ji} that $\deg(\boldsymbol{\alpha}(1)), \deg(\boldsymbol{\alpha}(2)) = \deg(\boldsymbol{\beta})$ if k is even, and $\deg(\boldsymbol{\alpha}(1)) = \deg(\boldsymbol{\beta}) + 1$, $\deg(\boldsymbol{\alpha}(2)) = \deg(\boldsymbol{\beta})$ if k is odd. Since $\boldsymbol{\beta}$ is an exponent of the polynomial f, we know that $\deg(\boldsymbol{\beta}) \leq 2d$. If k is odd, however, then

$$\deg(\boldsymbol{\beta}) \;=\; \sum_{j=1}^{k} \underbrace{\beta_j}_{\text{odd number}} + \sum_{j=k+1}^{n} \underbrace{\beta_j}_{\text{even number}} \;,$$

i.e., $\deg(\boldsymbol{\beta})$ is a sum of k many odd numbers, with k being odd, plus a sum of even numbers. Thus, $\deg(\boldsymbol{\beta})$ has to be an odd number and hence $\deg(\boldsymbol{\beta}) < 2d$. Therefore, all degrees of terms in s_{ji} are bounded by $2d$ and thus $s_{ji} \in C_{n,2d}$.

Conclusion: We have that

$$f \;=\; \sum_{j=1}^{n} p_j g_j \;=\; \sum_{j=1}^{n} \sum_{i=1}^{\ell_j} a_{ji} m_{ji} g_j \;=\; \sum_{j=1}^{n} \sum_{i=1}^{\ell_j} s_{ji} g_j.$$

By Cases 1 and 2 and the degree argument, we have $s_{ji} \in C_{n,2d}$ for every i, j and by defining $s_j = \sum_{i=1}^{\ell_j} s_{ji} \in C_{n,2d}$ we obtain the desired representation of f. ◀

4.1 Proof of Theorem 12

In this section we combine the results of this section and finish the proof of Theorem 12.

Due to Lemma 13, it remains to show that $f(\mathbf{x})$ admits a decomposition of the form (4.2) with $\mathcal{H}_\mathcal{P} = \mathcal{H}$ if $f(\mathbf{x}) \geq 0$ for every $\mathbf{x} \in \mathcal{H}$.

Hence, when restricted to the hypercube $\mathcal{H}$, the polynomial f can be represented as:

$$\begin{aligned} f(\mathbf{x}) &= f(\mathbf{x}) \sum_{\mathbf{v} \in \mathcal{H}_\mathcal{P}} \delta_\mathbf{v}(\mathbf{x}) + f(\mathbf{x}) \sum_{\mathbf{v} \in \mathcal{H} \setminus \mathcal{H}_\mathcal{P}} \delta_\mathbf{v}(\mathbf{x}) \qquad \text{for all } \mathbf{x} \in \mathcal{H} \\ &= \sum_{\mathbf{v} \in \mathcal{H}_\mathcal{P}} \delta_\mathbf{v}(\mathbf{x}) f(\mathbf{v}) + \sum_{\mathbf{v} \in \mathcal{H} \setminus \mathcal{H}_\mathcal{P}} \delta_\mathbf{v}(\mathbf{x}) f(\mathbf{v}) \qquad \text{for all } \mathbf{x} \in \mathcal{H}, \end{aligned}$$

where the last equality follows by Lemma 11 .

Note that there might exist a vector $\mathbf{v} \in \mathcal{H} \setminus \mathcal{H}_\mathcal{P}$ such that f attains a negative value at $\mathbf{v}$. If $f(\mathbf{v}) < 0$, then let $p_\mathbf{v} \in \mathcal{P}$ be one of the polynomials among the constraints satisfying $p_\mathbf{v}(\mathbf{v}) < 0$. Otherwise, let $p_\mathbf{v} = 1$. Since by Lemma 11 we have $\delta_\mathbf{v}(\mathbf{x}) p_\mathbf{v}(\mathbf{x}) = \delta_\mathbf{v}(\mathbf{x}) p_\mathbf{v}(\mathbf{v})$ for every $\mathbf{v}, \mathbf{x} \in \mathcal{H}$, we can now write:

$$f(\mathbf{x}) \;=\; \sum_{\mathbf{v} \in \mathcal{H}_\mathcal{P}} \delta_\mathbf{v}(\mathbf{x}) f(\mathbf{v}) + \sum_{\mathbf{v} \in \mathcal{H} \setminus \mathcal{H}_\mathcal{P}} \delta_\mathbf{v}(\mathbf{x}) p_\mathbf{v}(\mathbf{x}) \frac{f(\mathbf{v})}{p_\mathbf{v}(\mathbf{v})} \qquad \text{for all } \mathbf{x} \in \mathcal{H}.$$

Thus, the polynomial $f(\mathbf{x}) - \sum_{\mathbf{v} \in \mathcal{H}_\mathcal{P}} \delta_\mathbf{v}(\mathbf{x}) f(\mathbf{v}) - \sum_{\mathbf{v} \in \mathcal{H} \setminus \mathcal{H}_\mathcal{P}} \delta_\mathbf{v}(\mathbf{x}) p_\mathbf{v}(\mathbf{x}) \frac{f(\mathbf{v})}{p_\mathbf{v}(\mathbf{v})}$ has degree at most $n + d$ and vanishes on $\mathcal{H}$. By Theorem 16 we finally get

$$f(\mathbf{x}) \;=\; \sum_{j=1}^{n} s_j(\mathbf{x}) g_j(\mathbf{x}) + \sum_{j=1}^{n} s_{n+j}(\mathbf{x})(-g_j(\mathbf{x})) + \sum_{\mathbf{v} \in \mathcal{H}_\mathcal{P}} \delta_\mathbf{v}(\mathbf{x}) f(\mathbf{v}) + \sum_{\mathbf{v} \in \mathcal{H} \setminus \mathcal{H}_\mathcal{P}} \delta_\mathbf{v}(\mathbf{x}) p_\mathbf{v}(\mathbf{x}) \frac{f(\mathbf{v})}{p_\mathbf{v}(\mathbf{v})} \;,$$

for some $s_1, \ldots, s_{2n} \in C_{n,n-2}$ and $p_\mathbf{v} \in \mathcal{P}$. This finishes proof together with Lemma 14. ◀

▶ **Corollary 17.** *For every polynomial f, nonnegative over the boolean hypercube, constrained with polynomial inequalities of degree at most d, there exists a degree $n+d$ SONC certificate.*

Proof. The argument follows directly from Theorem 12 by noting that the right hand side of (4.2) is a SONC certificate of degree $n+d$ (see the Definition 7). ◀

4.2 Degree d SONC Certificates

In this section we show that if a polynomial f admits a degree d SONC certificate, then f also admits a short degree d certificate that involves at most $n^{O(d)}$ terms.

▶ **Theorem 18.** *Let f be an n-variate polynomial, nonnegative on the constrained hypercube $\mathcal{H}_\mathcal{P}$ with $|\mathcal{P}| = \text{poly}(n)$. Assume that there exists a degree d SONC certificate for f, then there exists a degree d SONC certificate for f involving at most $n^{O(d)}$ many nonnegative circuit polynomials.*

Proof. Since there exists a degree d SONC proof of the nonnegativity of f on $\mathcal{H}_\mathcal{P}$ we know that $f(\mathbf{x}) = \sum_j s_j H_j^{(q)}$, where the summation is finite, s_j's are SONCs, and $H_j^{(q)}$'s are product as defined in (2.4).

Step 1: We analyze the terms s_j. Since every s_j is a SONC, there exists a representation

$$s_j = \kappa_j \cdot \sum_{i=1}^{k_j} \mu_{ij} \cdot q_{ij}$$

such that $\kappa_j, \mu_{1j}, \ldots, \mu_{k_j j} \in \mathbb{R}_{>0}$, $\sum_{i=1}^{k_j} \mu_{ij} = 1$, and the q_{ij} are nonnegative circuit polynomials. Since s_j is of degree at most d, we know that $Q_j := \{q_{1j}, \ldots, q_{k_j j}\}$ is contained in $\mathbb{R}_{n,d}[\mathbf{x}]$, which is a real vector space of dimension $\binom{n+d}{d}$. Since s_j/κ_j is a convex combination of the q_{ij}, i.e. in the convex hull of Q_j, and $\dim(Q_j) \leq \binom{n+d}{d}$, applying Carathéodory's Theorem, see e.g. [57], yields that s_j/κ_j can be written as a convex combination of at most $\binom{n+d}{d}+1$ many of the q_{ij}.

Step 2: We analyze the terms $H_j^{(q)}$. By definition of the $\mathcal{H}_\mathcal{P}$ and the terms $H_j^{(q)}$ we have $H_j^{(q)} = g_{j_1} \cdots g_{j_s} \cdot l_{r_1} \cdots l_{r_t} \cdot p_{\ell_1} \cdot p_{\ell_v}$ with $j_1, \ldots, j_s \in [n]$, $r_1, \ldots, r_t \in [2n]$, and $\ell_1, \ldots, \ell_v \in [m]$. Since the maximal degree of $H_j^{(q)}$ is d, the number of different $H_j^{(q)}$'s is bounded from above by $\binom{n+2n+m}{d}$.

Conclusion: In summary, we obtain a representation:

$$f(\mathbf{x}) = \sum_{i=1}^{\binom{n+2n+m}{d}} H_j^{(q)} s_j = \sum_{i=1}^{\binom{n+2n+m}{d}} H_j^{(q)} \kappa_j \sum_{j=1}^{\binom{n+d}{d}+1} \mu_{ij} c_{ij}$$

Since we assume that m can bounded by $\text{poly}(n)$ the total number of summands is $\text{poly}(n)^{O(d)} = n^{O(d)}$, and we found a desired representation with at most $n^{O(d)}$ nonnegative circuit polynomials of degree at most d. ◀

The Theorem 18 states that when searching for a degree d SONC certificate it is enough to restrict to certificates containing at most $n^{O(d)}$ nonnegative circuit polynomials. Moreover, as proved in [19, Theorem 3.2] for a given set $A \subseteq \mathbb{N}^n$, searching through the space of degree d SONC certificates supported on a set A can be computed via a relative entropy program (REP) of size $n^{O(d)}$, see e.g. [19] for more information about REP. However, the above arguments do *not* necessarily imply that the search through the space of degree d SONC certificates can be performed in time $n^{O(d)}$. The difficulty is that one needs to restrict the

configuration space of n-variate degree d SONCs to a subset of order $n^{O(d)}$ to be able to *formulate* the corresponding REP in time $n^{O(d)}$. Since the current proof of Theorem 18 just guarantees the *existence* of a short SONC certificate, it is currently not clear, how to search for a short certificate efficiently. We leave this as an open problem.

5 There Exists No Equivalent to Putinar's Positivstellensatz for SONCs

In this section we address the open problem raised in [19] asking whether the Theorem 6 can be strengthened by requiring $q = 1$. Such a strengthening, for a positive polynomial over some basic closed semialgebraic set, would provide a SONC decomposition equivalent to Putinar's Positivstellensatz for SOS. The advantage of Putinar's Positivstellensatz over Schmüdgen's Positivstellensatz is that for every fixed degree d the cardinality of possible degree d certificates is smaller; for background see e.g., [38, 50] however, asymptotically still in both cases it is $n^{O(d)}$.

We answer this question in a negative way. More precisely, we provide a polynomial f which is strictly positive over the hypercube $\{\pm 1\}^n$ such that there does not exist a SONC decomposition of f for $q = 1$. Moreover, we prove it not only for the most natural choice of the box constraints that is $l_i = 1 \pm x_i$, but for a generic type of box constraints of the form $\ell_i = 1 + c_i \pm x_i$, for $c_i \in \mathbb{R}_{\geq 0}$. We close the section with a short discussion.

Let $\mathcal{H} = \{\pm 1\}^n$ and consider the following family of polynomials parametrized by a natural number a:

$$f_a(\mathbf{x}) \;:=\; (a-1)\prod_{i=1}^{n}\left(\frac{x_i+1}{2}\right)+1.$$

These functions take the value a for a vector $\mathbf{e} = \sum_{i=1}^{n} \mathbf{e}_i$ and the value 1 for every other $\mathbf{x} \in \mathcal{H} \setminus \{\mathbf{e}\}$. We define for every $d \in \mathbb{N}$

$$S_d \;:=\; \left\{ \sum_{\text{finite}} s \cdot h \;:\; s \in C_{n,2d},\; h \in \left\{1, \pm(x_i^2-1), 1+c_i \pm x_i \;:\; i \in [n], c_i \in \mathbb{R}_{\geq 0}\right\} \right\}$$

be the set of polynomials admitting a SONC decomposition over $\mathcal{H}$ given by Theorem 6 for $q = 1$. The main result of this section is the following theorem.

▶ **Theorem 19.** *For every $a > \frac{2^n-1}{2^{n-2}-1}$ we have $f_a \notin S_d$ for all $d \in \mathbb{N}$.*

Before we prove this theorem, we show the following structural results. Note that similar observations were already made for AGIforms by Reznick in [52] using a different notation.

▶ **Lemma 20.** *Every $s(\mathbf{x}) \in C_{n,2d}$ attains at most two different values on $\mathcal{H} = \{\pm 1\}^n$. Moreover, if $s(\mathbf{x})$ attains two different values, then each value is attained for exactly the half of the hypercube vertices.*

Proof. By Definition 1 every nonnegative circuit polynomial is of the form:

$$s(\mathbf{x}) \;=\; \sum_{j=0}^{r} f_{\boldsymbol{\alpha}(j)}\mathbf{x}^{\boldsymbol{\alpha}(j)} + f_{\boldsymbol{\beta}}\mathbf{x}^{\boldsymbol{\beta}}.$$

Note that for $j = 0, \ldots, r$, we have $\boldsymbol{\alpha}(j) \in (2\mathbb{N})^n$. Hence when evaluated over the hypercube $\mathbf{x} \in \mathcal{H} = \{\pm 1\}^n$, $s(\mathbf{x})$ can take only one of at most two different values $\sum_{j=0}^{r} f_{\boldsymbol{\alpha}(j)} \pm f_{\boldsymbol{\beta}}$.

If $s(\mathbf{x})$ attains two different values over $\mathcal{H}$, then there has to exist a non empty subset of variables that have an odd entry in $\boldsymbol{\beta}$. Let $I \subseteq [n]$ be this subset. Then $s(\mathbf{x}) = \sum_{j=0}^{r} f_{\boldsymbol{\alpha}(j)}(\mathbf{x}) - f_{\boldsymbol{\beta}}(\mathbf{x})$, for $\mathbf{x} \in \mathcal{H}$ if and only if $\mathbf{x}$ has an odd number of -1 entries in the set I. The number of such vectors is equal to

$$2^{n-|I|} \sum_{\substack{i=0,\\ i \text{ odd}}}^{|I|} 2^i \;=\; 2^{n-|I|}2^{|I|-1} \;=\; 2^{n-1}. \qquad \blacktriangleleft$$

▶ **Lemma 21.** *Every polynomial $s(\mathbf{x})\ell_i(\mathbf{x})$, with $s \in C_{n,2d}$ and $\ell_i = 1 + c_i \pm x_i$ being a box constraint, attains at most four different values on $\mathcal{H} = \{\pm 1\}^n$. Moreover, each value is attained for at least one forth of the hypercube vertices.*

Proof. By Lemma 20, $s(\mathbf{x})$ attains at most the two values $\left(\sum_{j=0}^{r} f_{\boldsymbol{\alpha}(j)} \pm f_{\boldsymbol{\beta}}\right)$ on $\mathcal{H}$. Similarly, $\ell_i(\mathbf{x})$ attains at most the two values $1 + c_i \pm x_i$ over $\mathcal{H}$. Thus, a polynomial $s(\mathbf{x})\ell_i(\mathbf{x})$ attains at most the four different values $\left(\sum_{j=0}^{r} f_{\boldsymbol{\alpha}(j)} \pm f_{\boldsymbol{\beta}}\right)(1 + c_i \pm x_i)$ on $\mathcal{H}$.

Let I be as in the proof of Lemma 20, i.e., the subset of variables that have an odd entry in $\boldsymbol{\beta}$. If $I = \emptyset$, then the first term $\sum_{j=0}^{r} f_{\boldsymbol{\alpha}(j)} + f_{\boldsymbol{\beta}}$ is constant over the hypercube $\mathcal{H}$, thus $s(\mathbf{x})\ell_i(\mathbf{x})$ takes two different values depending on the i-th entry of the vector. Each value is attained for exactly half of the vectors.

If $I \neq \emptyset$ and $i \notin I$ the claim holds since the value of the first term depends only on the entries in I and the value of the second term depends on the i-th entry. Hence, the polynomial $s(\mathbf{x})\ell_i(\mathbf{x})$ attains four values each on exactly one fourth of $\mathcal{H}$ vectors.

Finally, let $I \neq \emptyset$ and $i \in I$. Partition the hypercube vertices into two sets depending on the i-th entry. Each set has cardinality 2^{n-1}. Consider the set with $x_i = 1$. For the vectors in this set the second term takes a constant value $2 + c$. Over this set the polynomial s takes one of the values $\sum_{j=0}^{r} f_{\boldsymbol{\alpha}(j)}(\mathbf{x}) \pm f_{\boldsymbol{\beta}}(\mathbf{x})$, depending on whether $\mathbf{x}$ has an odd or even number of -1 entries in the set $I \setminus \{-1\}$. In both cases the number of such vectors is equal to

$$2^{n-|I|} \sum_{\substack{i=0,\\ i \text{ odd}}}^{|I|-1} 2^i \;=\; 2^{n-|I|}2^{|I|-2} = 2^{n-2}.$$

The analysis for the case $x_i = -1$ is analogous. $\blacktriangleleft$

Now we can provide the proof of Theorem 19.

Proof of Theorem 19. Assume $f_a \in S_d$ for some $a \in \mathbb{N}$ and $d \in \mathbb{N}$. We prove that a has to be smaller or equal than $\frac{2^n-1}{2^{n-2}-1}$. Since $f_a \in S_d$ we know that

$$f_a(\mathbf{x}) \;=\; s_0(\mathbf{x}) + \sum_{i=1}^{n} s_i(\mathbf{x})\ell_i(\mathbf{x}) + \sum_{j=1}^{n} \tilde{s}_j(\mathbf{x})(x_j^2 - 1) + \tilde{s}_{j+n}(\mathbf{x})(1 - x_j^2)$$

with $s_0, \ldots, s_n, \tilde{s}_1, \ldots, \tilde{s}_{2n} \in C_{n,2d}$. Since $\pm(x_j^2 - 1)$ for $j \in [n]$ vanishes over the hypercube $\mathcal{H}$, for some $s_0,\ s_i \in C_{n,2d}$ we can conclude

$$f_a(\mathbf{x}) \;=\; s_0(\mathbf{x}) + \sum_{i=1}^{n} s_i(\mathbf{x})\ell_i(\mathbf{x}) \qquad \text{for all } \mathbf{x} \in \mathcal{H} \tag{5.1}$$

Let $s_{0,k}$, and $s_{i,j}$ be some nonnegative circuit polynomials such that $s_0 = \sum_k s_{0,k}$, and $s_i = \sum_j s_{i,j}$. Thus, we get

$$\begin{aligned}\sum_{\mathbf{x}\in\mathcal{H}} \left(s_0(\mathbf{x}) + \sum_i s_i(\mathbf{x})\ell_i(\mathbf{x}) \right) &= \sum_k \sum_{\mathbf{x}\in\mathcal{H}} s_{0,k}(\mathbf{x}) + \sum_i \sum_j \sum_{\mathbf{x}\in\mathcal{H}} s_{i,j}(\mathbf{x})\ell_{i,j}(\mathbf{x}) \\ &\geq \sum_k 2^{n-1} s_{0,k}(\mathbf{e}) + \sum_i \sum_j 2^{n-2} s_{i,j}(\mathbf{e})\ell_{i,j}(\mathbf{e}) \\ &\geq 2^{n-2} \left(s_0(\mathbf{e}) + \sum_i s_i(\mathbf{e})\ell_i(\mathbf{e}) \right) = 2^{n-2} a,\end{aligned}$$

where the first inequality comes from Lemma 20 and 21 and the last equality from the fact that $f_a(\mathbf{e}) = a$. On the other hand, by the properties of f_a and the equality (5.1), we know that

$$\sum_{\mathbf{x}\in\mathcal{H}} \left(s_0(\mathbf{x}) + \sum_i s_i(\mathbf{x})\ell_i(\mathbf{x}) \right) = 2^n - 1 + a,$$

which makes the subsequent inequality a necessary requirement for $f_a \in S_d$:

$$a \leq \frac{2^n - 1}{2^{n-2} - 1}. \qquad \blacktriangleleft$$

Note that an easier example of polynomial nonnegative over the set $\mathcal{H}$ exists, that does not attain a SONC decomposition for $q = 1$. Consider a polynomial $\delta_{\mathbf{v}}(\mathbf{x})$ defined in Definition 10 for $x \in \mathbb{R}^n$, for $n \geq 3$. The analysis for this example is easier since the polynomial is zero on all vertices of $\mathcal{H}$ but one, thus by Lemma 21 it is impossible to fit a SONC certificate that matches those values. However, an important fact is that, by Theorem 6 a polynomial to admit a SONC certificate has to necessarily be strictly positive over the given set, which is not the case for $\delta_{\mathbf{v}}(\mathbf{x})$ and the set $\mathcal{H}$.

Speaking from a broader perspective, we interpret Theorem 19 as an indication that the real algebraic structures, which we use to handle sums of squares, do not apply in the same generality to SONCs. We find this not at all surprising from the point of view that in the 19th century Hilbert initially used SOS as a certificate for nonnegativity and many of the algebraic structures in question where developed afterwards with Hilbert's results in mind; see [53] for a historic overview. Our previous work shows that SONCs, in contrast, can, e.g., very well be analyzed with combinatorial methods. We thus see Theorem 19 as further evidence about the very different behavior of SONCs and SOS and as an encouragement to take methods beside the traditional real algebraic ones into account for the successful application of SONCs in the future.

Abstract

Given a graph with colors on its vertices, a path is called a rainbow vertex path if all its internal vertices have distinct colors. We say that the graph is rainbow vertex-connected if there is a rainbow vertex path between every pair of its vertices. We study the problem of deciding whether the vertices of a given graph can be colored with at most k colors so that the graph becomes rainbow vertex-connected. Although edge-colorings have been studied extensively under similar constraints, there are significantly fewer results on the vertex variant that we consider. In particular, its complexity on structured graph classes was explicitly posed as an open question.

We show that the problem remains NP-complete even on bipartite apex graphs and on split graphs. The former can be seen as a first step in the direction of studying the complexity of rainbow coloring on sparse graphs, an open problem which has attracted attention but limited progress. We also give hardness of approximation results for both bipartite and split graphs. To complement the negative results, we show that bipartite permutation graphs, interval graphs, and block graphs can be rainbow vertex-connected optimally in polynomial time.

1 Introduction

Graph coloring and graph connectivity are two of the most famous topics in graph algorithms. Many different types of colorings and connectivity measures have been considered throughout time. The concept of rainbow coloring brings these two extensively studied topics together, and it was first defined a decade ago by Chartrand et al. [8] using edge-colorings. Let G be a connected, edge-colored graph. A *rainbow path* in G is a path all of whose edges are colored

with distinct colors, and G is *rainbow-connected* if there is a rainbow path between every pair of its vertices. The resulting computational problem Rainbow Coloring (RC) takes as input a connected (uncolored) graph G and an integer k, and the task is to decide whether the edges of G can be colored with at most k colors so that G is rainbow-connected. This problem has various applications in telecommunications, data transfer, and encryption [25, 4, 11] and has been studied rather thoroughly from both graph-theoretic and complexity-theoretic viewpoints (see related work below and the surveys [19, 25]).

The intense interest in Rainbow Coloring led Krivelevich and Yuster [18] to define a natural variant on *vertex-colored* graphs. Here, a path in a vertex-colored graph H is a *rainbow vertex path* if all its *internal* vertices have distinct colors. We say that H is *rainbow vertex-connected* if there is a rainbow vertex path between every pair of its vertices. Similarly to the edge variant, Rainbow Vertex Coloring (RVC) is the decision problem in which we are given a connected (uncolored) graph H and an integer k, and the task is to decide whether the vertices of H can be colored with at most k colors such that H is rainbow vertex-connected. The *rainbow vertex connection number* of G, denoted by $\mathbf{rvc}(G)$, is the minimum k such that G has a rainbow vertex coloring with k colors. RVC is NP-complete for every $k \geq 2$ [10, 9], and remains NP-complete for $k = 3$ for bipartite graphs [23]. In addition, it is NP-hard to approximate $\mathbf{rvc}(G)$ within a factor of $2 - \varepsilon$ unless $\mathsf{P} \neq \mathsf{NP}$, for any $\varepsilon > 0$ [13]. It is also known that RVC is linear-time solvable on planar graphs for every fixed k [19]. Finally, assuming the Exponential Time Hypothesis, there is no algorithm for solving RVC in time $2^{o(n^{3/2})}$ for any $k \geq 2$ [19].

A stronger variant of rainbow vertex-colorings was introduced by Li et al. [24]. A vertex-colored graph H is *strongly rainbow vertex-connected* if between every pair of vertices of H, there is a *shortest* path that is also a rainbow vertex path. The Strong Rainbow Vertex Coloring (SRVC) problem takes as input a connected (uncolored) graph H and an integer k, and the task is to decide whether the vertices of H can be colored such that H is strongly rainbow vertex-connected. This definition is the vertex variant of the Strong Rainbow Coloring problem, which was also broadly studied (see related work below and the surveys [19, 25]). The *strong rainbow vertex connection number* of G, denoted by $\mathbf{srvc}(G)$, is the minimum k such that G has a strong rainbow vertex coloring with k colors. SRVC is NP-complete for every $k \geq 2$ [12] and linear-time solvable on planar graphs for every fixed k [19]. In addition, it is NP-hard to approximate $\mathbf{srvc}(G)$ within a factor of $n^{1/2-\varepsilon}$ unless $\mathsf{P} \neq \mathsf{NP}$, for any $\varepsilon > 0$ [13].

While RC has been widely studied in more than 300 published papers, we are unaware of any further complexity results on RVC and SRVC than those mentioned previously. In particular, the complexity of RVC and SRVC on structured graph classes is mostly open. This led Lauri [19, Open problem 6.6] to explicitly ask the following:

For what restricted graph classes do RVC *and* SRVC *remain NP-complete?*

Our Results. In this paper, we make significant progress towards addressing this open problem. In particular, we study bipartite graphs and chordal graphs, and some of their subclasses, and give hardness results and polynomial-time algorithms for RVC and SRVC. Our main result is a hardness result for bipartite apex graphs:

▶ **Theorem 1.** *Let G be a bipartite apex graph of diameter 4. It is* NP*-complete to decide both whether $\mathbf{rvc}(G) \leq 4$ and whether $\mathbf{srvc}(G) \leq 4$. Moreover, it is* NP*-hard to approximate $\mathbf{rvc}(G)$ and $\mathbf{srvc}(G)$ within a factor of $5/4 - \varepsilon$, for every $\varepsilon > 0$.*

This result is particularly interesting since no hardness result was known on a sparse graph class (like apex graphs) for any of the variants of rainbow coloring. Moreover, this result can be considered tight in conjunction with the known result that RVC and SRVC are linear-time solvable on planar graphs for every fixed number of colors k [19]. Finally, we observe (like Li et al. [23]) that $\mathbf{rvc}(G)$ and $\mathbf{srvc}(G)$ can be computed in linear time if G is a bipartite graph of diameter 3, providing further evidence that this result is tight.

For general bipartite graphs and for split graphs (a well-known subclass of chordal graphs), we exhibit stronger hardness results:

▶ **Theorem 2.** *Let G be a bipartite graph of diameter 4. It is* NP*-complete to decide both whether $\mathbf{rvc}(G) \leq k$ and whether $\mathbf{srvc}(G) \leq k$, for every $k \geq 3$. Moreover, it is* NP*-hard to approximate both $\mathbf{rvc}(G)$ and $\mathbf{srvc}(G)$ within a factor of $n^{1/3-\varepsilon}$, for every $\varepsilon > 0$.*

We remark that, previously, it was only known that deciding whether $\mathbf{rvc}(G) \leq 3$ for bipartite graphs G is NP-complete by the result of [23]. Our construction, however, is conceptually simpler, gives hardness for every $k \geq 3$, and is easily extended to the strong variant. Moreover, for RVC on general graphs, this result implies a considerable improvement over the previous result of Eiben et al. [13] which only excluded a polynomial-time approximation with a factor of less than 2 assuming $\mathsf{P} \neq \mathsf{NP}$.

▶ **Theorem 3.** *Let G be a split graph of diameter 3. It is* NP*-complete to decide both whether $\mathbf{rvc}(G) \leq k$ and whether $\mathbf{srvc}(G) \leq k$, for every $k \geq 2$. Moreover, it is* NP*-hard to approximate both $\mathbf{rvc}(G)$ and $\mathbf{srvc}(G)$ within a factor of $n^{1/3-\varepsilon}$, for every $\varepsilon > 0$.*

To the best of our knowledge, our results for split graphs give the first non-trivial graph class besides diameter-two graphs for which the complexity of the edge and the vertex variant differ (see e.g, [19, Table 4.2] but note that it contains a typo erroneously claiming that RVC can be solved in polynomial-time for split graphs). In particular, RC can be solved in polynomial time on split graphs when $k \geq 4$ [5, 7]. Moreover, we observe that $\mathbf{rvc}(G)$ and $\mathbf{srvc}(G)$ can be computed in linear time if G is a graph of diameter 2, providing evidence that this result is tight.

To contrast our hardness results, we show that both problems can be solved in polynomial time on several other subclasses of bipartite graphs and chordal graphs.

▶ **Theorem 4.** *If G is a bipartite permutation graph, a block graph, or a unit interval graph, then $\mathbf{rvc}(G)$ and $\mathbf{srvc}(G)$ can be computed in linear time. If G is an interval graph, then $\mathbf{rvc}(G)$ can be computed in linear time.*

Combined, these results paint a much clearer picture of the complexity landscape of RVC and SRVC than was possible previously.

Related Work. We briefly survey the known work for the edge variants of rainbow coloring; we refer to [19, 25] for more detailed surveys. RC is NP-complete for every $k \geq 2$ [4, 2, 22], even on chordal graphs [5]. On split graphs, RC is NP-complete when $k \in \{2, 3\}$, but solvable in polynomial time otherwise [5, 7]. It is also solvable in polynomial time on threshold graphs [5]. On bridgeless chordal graphs, there is a linear-time (3/2)-approximation algorithm for RC, however the problem cannot be approximated with a factor less than 5/4 on this graph class, unless $\mathsf{P} = \mathsf{NP}$ [6]. Some lower bounds on algorithms for solving RC are given by Kowalik et al. [17] and Agrawal [1] under the Exponential Time Hypothesis.

For the strong edge variant, an edge-colored graph is said to be *strongly rainbow-connected* if there is a rainbow shortest path between every pair of its vertices. The problem of deciding whether the edges of a given graph G can be colored in k colors to make G strongly rainbow-connected is referred to as SRC. For $k = 2$, it is not difficult to verify that RC is equivalent

to SRC. Not surprisingly, SRC is also NP-complete for $k \geq 2$ [2]. In contrast to RC, SRC remains hard on split graphs for every $k \geq 2$ [19, Theorem 4.1]. Moreover, on n-vertex split graphs, it is NP-hard to approximate SRC within a factor of $n^{1/2-\varepsilon}$ for any $\varepsilon > 0$, while RC admits an additive-1 approximation [5]. The former statement also holds for n-vertex bipartite graphs instead of split graphs [2]. For block graphs, computing SRC can be done in linear time [16], while RC on block graphs is conjectured to be hard (see [19, Conjecture 6.3] or [16]). In general, it appears that despite the interest, there are fewer complexity-theoretic results on SRC. In fact, the same is true when considering combinatorial results (see [25] for a broader discussion).

2 Preliminaries

In this paper, we work on undirected simple graphs. Such a graph is denoted by $G = (V, E)$, where V is the vertex set of G, and E is the edge set. We let n denote the number of vertices of G. For a vertex $x \in V$, $N(x)$ is the set of its *neighbors*, and $\deg(x) = |N(x)|$ is its *degree*. For a $S \subseteq V$, the subgraph of G induced by S is denoted by $G[S]$. A *cut vertex* of G is a vertex whose removal increases the number of connected components of G.

Given a path $P = x_1, x_2, \ldots, x_{p-1}, x_p$ in G, the vertices from x_2 to x_{p-1} are called the *internal vertices* of P. The *distance* between two vertices u and v in G, denoted by $\text{dist}(u, v)$, is the length of a shortest path between u and v. The *diameter* of G, denoted by $\text{diam}(G)$, is the maximum distance between any pair of vertices of G.

A *k-coloring of G* is a function $c : V \to \{1, 2, \ldots, k\}$. (From now on, we will denote a set of consecutive integers from 1 to k as $[k]$.) A *coloring* is simply a k-coloring for some $k \leq n$. A coloring c is *proper* if $c(u) \neq c(v)$ for every edge $uv \in E$. The *chromatic number* of G, denoted by $\chi(G)$, is the smallest k such that G has a proper k-coloring. A *d-distance coloring* of G is a coloring c of G such that $c(u) \neq c(v)$ whenever $\text{dist}(u, v) \leq d$. The minimum number of colors needed for a d-distance coloring of G is known as the *d-distance chromatic number* of G, and it is denoted by $\chi_d(G)$. Note that $\chi_d(G)$ is equivalent to $\chi(G^d)$, i.e., the chromatic number of the d^{th} power of G.

Since, in this paper, we will only be working on the vertex variant of the rainbow coloring and rainbow connectivity, we might sometimes omit the word "vertex" when there is no confusion. The parameter $\mathbf{srvc}(G)$ was defined by Li et al. [24], and they also verified that $\text{diam}(G) - 1 \leq \mathbf{rvc}(G) \leq \mathbf{srvc}(G) \leq n - 2$. The following upper bound was mentioned in [19] (see the same reference for further discussion and examples).

▶ **Proposition 5** ([19]). *Let G be a connected graph with $\text{diam}(G) = d \geq 3$. Then*

$$d - 1 \leq \mathbf{rvc}(G) \leq \mathbf{srvc}(G) \leq \chi_{d-2}(G).$$

Proof. There are at least two vertices in G connected by a shortest path of length d. Clearly, every coloring must use at least $d - 1$ colors to rainbow-connect this pair. On the other hand, between every pair of vertices u and v, there is a path of length at most d, meaning that it contains at most $d - 1$ internal vertices. As every $(d - 2)$-distance coloring colors these internal vertices distinctly, the statement follows. ◀

A *dominating set* of G is a set $D \subseteq V$ such that every vertex in $V \setminus D$ is adjacent to at least one vertex in D. If $G[D]$ is connected, then D is a *connected dominating set*. The minimum size of a connected dominating set in G, denoted by $\gamma_c(G)$, is known as the *connected domination number* of G. This parameter provides an upper bound on the rainbow

vertex connection number of a connected graph, since G becomes rainbow vertex-connected by simply coloring all vertices of the connected dominating set distinctly, and the remaining vertices with any of the already used colors. This observation can be derived from [18].

▶ **Proposition 6** ([18]). *If G is a connected graph, then* $\mathbf{rvc}(G) \leq \gamma_c(G)$.

2.1 Graph classes

As we will be studying the mentioned problems on some graph classes, let us give a brief definition of these classes here. More definitions and properties will be added as needed when we handle these graphs. A detailed background on these graph classes can be found, for example, in the book by Brandstädt, Le, and Spinrad [3].

A graph is an *apex graph* if it contains a vertex (called an *apex*) whose removal results in a planar graph. A graph is *chordal* if all of its induced simple cycles are of length 3. Some well-known subclasses of chordal graphs are interval graphs, split graphs, and block graphs. A graph is an *interval graph* if it is chordal and it contains no triple of non-adjacent vertices, such that there is a path between every two of them that does not contain a neighbor of the third. A graph is a *split graph* if its vertex set can be partitioned into an independent set and a clique. A graph is a *block graph* if every biconnected component (block) of G is a complete graph.

Let σ be a permutation of the integers between 1 and n. We can make a graph G_σ on vertex set $[n]$ in the following way. Vertices i and j are adjacent in G_σ if and only if they appear in σ in the opposite order of their natural order. A graph on n vertices is a *permutation graph* if it is isomorphic to G_σ for some permutation σ of the integers between 1 and n. A graph is a *bipartite permutation* graph if it is both a bipartite graph and a permutation graph.

2.2 Hypergraph coloring

For our hardness reductions we will use a well-known NP-complete problem called Hypergraph Coloring. A *hypergraph* $H = (N, \mathcal{E})$ with vertex set N and hyperedge set $\mathcal{E}$ is a generalization of a graph, in which edges can contain more than two vertices. Thus $\mathcal{E}$ consists of subsets of N of arbitrary size. The definition of a (vertex) coloring of a hypergraph is exactly that same as that of a graph. In a colored hypergraph, an edge is called *monochromatic* if all of its vertices received the same color. A *proper coloring* of a hypergraph generalizes a proper coloring of a graph in a natural way: we require that no hyperedge is monochromatic. To avoid trivial cases, we can assume from now on that every hyperedge contains at least two vertices. Thus a proper coloring must always use at least two colors.

The Hypergraph Coloring problem takes as input a hypergraph H and an integer k and asks whether there is a proper coloring of H with at most k colors. The problem is well-known to be NP-complete for every $k \geq 2$ [26]. The Graph Coloring problem takes as input an undirected graph G and asks to determine the smallest k such that G has a proper k-coloring. This problem is NP-hard to approximate within a factor of $n^{1-\varepsilon}$ for any $\varepsilon > 0$, where n is the number of vertices [30]. Finally, the Planar 3-Coloring problem takes as input a planar graph G and asks whether G has a proper 3-coloring. This problem is NP-complete [14].

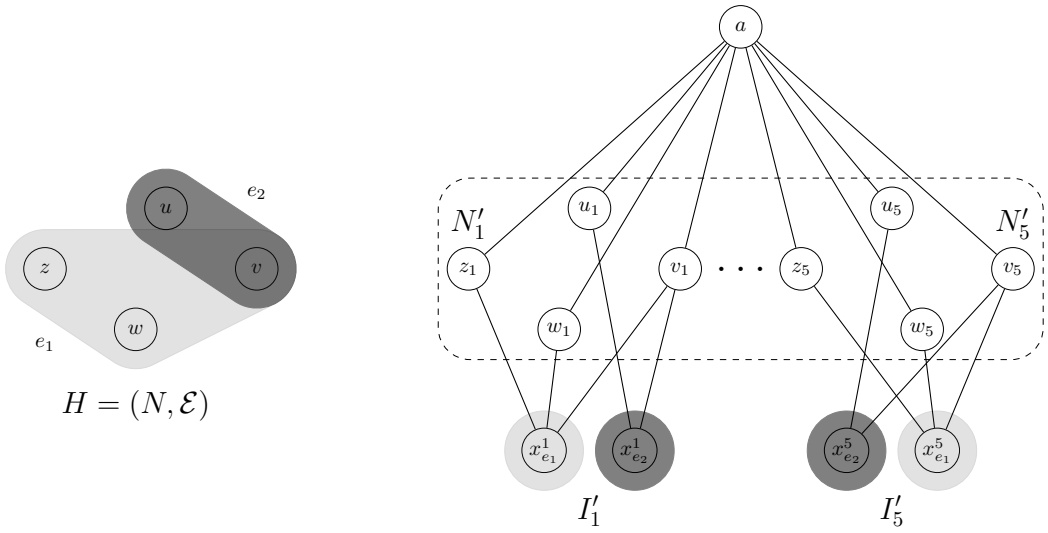

Figure 1 A hypergraph $H = (N, \mathcal{E})$ (left) transformed into a bipartite graph G (right) as described in the proof of Lemma 8. The dashed rectangle with rounded corners contains the sets in N'.

3 Bipartite graphs and their subclasses

In this section, we show that RVC and SRVC are hard on bipartite graphs for $k \geq 3$. We complement these results by showing that both problems can be solved in linear time on bipartite permutation graphs. We first observe that computing $\mathbf{rvc}(G)$ or $\mathbf{srvc}(G)$ is easy on bipartite graphs of diameter 3. The same observation was made by Li et al. [23].

▶ **Proposition 7** ([23]). *If G is a bipartite graph with $\mathrm{diam}(G) = 3$, then $\mathbf{rvc}(G) = \mathbf{srvc}(G) = 2$. Moreover, such a coloring can be found in linear time.*

Proof. The statement follows from Proposition 5 and the fact that every bipartite graph has a proper 2-coloring that can be found in linear time. ◀

It turns out that if $\mathrm{diam}(G) \geq 4$, then $\mathbf{rvc}(G)$ and $\mathbf{srvc}(G)$ of a bipartite graph G become much harder to compute, as claimed in Theorem 2. We prove the following general construction.

▶ **Lemma 8.** *Let H be a hypergraph on n vertices. Then in polynomial time we can construct a bipartite graph G of diameter 4 and with $O(n^3)$ vertices such that for any $k \in [n]$, H has a proper k-coloring if and only if G has a $(k+1)$-coloring under which G is (strongly) rainbow vertex-connected. Moreover, if H is a planar graph, then G is an apex graph.*

Proof. Let $H = (N, \mathcal{E})$ be an arbitrary hypergraph and let $n = |N|$. We construct a bipartite graph $G = (\{a\} \cup N' \cup I',\ E)$ where $N' = N'_1 \cup \cdots \cup N'_{n+1}$, $I' = I'_1 \cup \cdots \cup I'_{n+1}$, $N'_i := \{v_i \mid v \in N\}$, $I'_i := \{x^i_e \mid e \in \mathcal{E}\}$ and $E := \{av_i \mid v \in N, i \in [n+1]\} \cup \{v_i x^i_e \mid v \in N, e \in \mathcal{E}, i \in [n+1], v \in e\}$. Let $V = \{a\} \cup N' \cup I'$. A bipartition of G is given by $(\{a\} \cup I',\ N')$. Observe that $\mathrm{diam}(G) = 4$ and that G has $O(n^3)$ vertices. Moreover, if H is a planar graph, then G consists of vertex a plus $n+1$ copies of the graph obtained from H by subdividing each edge of H, and thus G is an apex graph. For an illustration of the construction, see Figure 1.

Consider any proper k-coloring $h : N \to [k]$ of H, i.e., no hyperedge of H is monochromatic under h. We construct a coloring $c : V \to [k+1]$ in the following way. First, for every $v \in N$, we give the vertices $v_1, v_2, \ldots, v_n$ of G the same color as v, i.e., $c(v_i) = h(v)$ for all $v \in N$ and $i \in [n+1]$. We give vertex a the color $k+1$, i.e., $c(a) = k+1$. The vertices in I all receive the same color, which is any arbitrary color in $[k+1]$. Now we prove that G is strongly rainbow vertex-connected under c by showing that there is a rainbow vertex shortest path between every pair of vertices. The only non-trivial case is when both vertices of the pair are in I. Consider two distinct vertices $x_e^i, x_f^j \in I$ (it is possible that $e = f$ or $i = j$ but not both). Since e and f are not monochromatic under h, we can pick two distinct vertices $u \in e$ and $v \in f$ such that $h(u) \neq h(v)$. It is clear that the path $x_e^i u a v x_f^j$ is a shortest path between x_e^i and x_f^j and that it is a rainbow vertex path. Hence, G is strongly rainbow vertex-connected under c.

Conversely, let c be a $(k+1)$-coloring of G under which G is (strongly) rainbow vertex-connected. For each $i \in [n+1]$, define h_i to be the vertex coloring of H such that $h_i(v) = c(v_i)$ for all $v \in N$. Let M_i be the set of vertices $v \in N$ such that $h_i(v) \neq c(a)$. Let $h_i'(v) = h_i(v)$ if $v \in M_i$ and $h_i'(v) = 1$ otherwise. We claim that there exists an $i \in [n+1]$ such that h_i' is a proper k-coloring of H. For the sake of contradiction, suppose that h_i' is not a proper k-coloring of H for every $i \in [n+1]$. For each $i \in [n+1]$, let $e_i \in \mathcal{E}$ be a monochromatic edge under h_i'. Suppose that, for some $i \in [n+1]$, all vertices in e_i are colored $c(a)$ under c. Then any path from $x_{e_i}^i$ to $x_{e_i}^j$ for some $j \neq i$ uses two vertices having color $c(a)$ under c. Hence, c would not be a rainbow vertex coloring, a contradiction. Therefore, for each $i \in [n+1]$, there is a vertex $v_i \in e_i$ for which $c(v_i) \neq c(a)$. Suppose now that for every $i \in [n+1]$, all vertices in e_i are colored either $c(v_i)$ or $c(a)$ under c. If $c(v_i) = c(v_j)$ for $i \neq j$, then any path from $x_{e_i}^i$ to $x_{e_j}^j$ uses either two vertices having color $c(a)$ or two vertices having color $c(v_i) = c(v_j)$ under c. This would contradict the assumption that G is rainbow vertex-connected under c. Hence, $c(v_i) \neq c(v_j)$ for all distinct $i, j \in [n+1]$. This implies that c uses at least $n+2$ colors, a contradiction to the assumptions that c is a $(k+1)$-coloring of G and that $k \in [n]$. Therefore, for some $i \in [n+1]$, there is a vertex $v_i' \in e_i$ for which $c(v_i') \neq c(a)$ and $c(v_i') \neq c(v_i)$. The latter implies that e_i is not monochromatic under h_i', a contradiction. The claim follows, and thus H has a proper k-coloring. ◀

Proof of Theorem 2. For membership in NP, a certificate that $\mathbf{rvc}(G) \leq k$ ($\mathbf{srvc}(G) \leq k$) consists of a k-coloring and a list of (shortest) paths, one for every pair of non-adjacent vertices, that are rainbow vertex connected. For NP-hardness, we observe that the transformation of Lemma 8 implies a straightforward reduction from Hypergraph Coloring. Since Hypergraph Coloring is NP-complete for each $k \geq 2$, this proves the first part of the theorem.

For the second part of the theorem, we consider an instance of Graph Coloring that consists of a graph on ℓ vertices and apply Lemma 8. Note that the total number of vertices in G is $n = O(\ell^3)$. From the hardness of approximation of Graph Coloring, we know that for all $\varepsilon > 0$, it is NP-hard to distinguish between the case when H is properly colorable with ℓ^ε colors and the case when H is not properly colorable with fewer than $\ell^{1-\varepsilon}$ colors [30]. By Lemma 8, this implies that it is NP-hard to distinguish between the case when G is (strong) rainbow vertex colorable with $\ell^\varepsilon + 1 \leq n^\varepsilon + 1$ colors and the case when G is not (strong) rainbow vertex colorable with fewer than $\ell^{1-\varepsilon} + 1 = \Omega(n^{1/3-\varepsilon})$ colors. The second statement of the theorem follows. ◀

We then proceed to give a proof of Theorem 1. This result can be considered as a first step to understand rainbow coloring on sparse graphs classes.

Proof of Theorem 1. The proof follows along the same lines as the proof of the first part of Theorem 2. Instead of Hypergraph Coloring, however, we reduce from Planar 3-Coloring, the problem of deciding whether a planar graph has a proper 3-coloring. This problem is NP-complete. The statement follows from Lemma 8, because the graph resulting from the construction is a bipartite apex graph of diameter 4.

For the hardness of approximation, we recall that any planar graph has a proper 4-coloring, and thus the graph G constructed in Lemma 8 has a 5-coloring under which G is rainbow vertex-connected. Hence, Lemma 8 combined with the NP-hardness of Planar 3-Coloring makes it NP-hard to decide whether G has a 5-coloring or a 4-coloring under which G is rainbow vertex-connected. ◀

We now complement the above hardness results with a positive result in the case when a bipartite graph is also a permutation graph, as claimed in Theorem 4. Bipartite permutation graphs have a desirable property, related to breadth-first search (BFS), that we will use heavily in our next result. Let us first define a chain graph. A bipartite graph is a *chain graph* if the vertices of the two independent sets A and B can be ordered as $\{a_1, a_2, \ldots, a_k\}$ and $\{b_1, b_2, \ldots, b_\ell\}$, such that $N(a_1) \subseteq N(a_2) \subseteq \cdots \subseteq N(A_k)$, equivalently, $N(b_\ell) \subseteq N(b_{\ell-1}) \subseteq \cdots \subseteq N(b_1)$.

In every bipartite permutation graph G it is possible to find a vertex v such that the levels $L_0, L_1, L_2, \ldots$ of the tree resulting from a BFS starting from v have the following properties. For all i, $L_0 = \{v\}$, L_i is an independent set and $G[L_i \cup L_{i+1}]$ is a chain graph. Moreover, for each level i, there exists a special vertex $a_i \in L_i$ such that $L_{i+1} \subset N(a_i)$. The vertex v can be picked as the first vertex of a *strong ordering*. It has been shown by Spinrad et al. [27] that a bipartite graph is a permutation graph if and only if it has a strong ordering, and such an ordering can be computed in linear time. The properties of the BFS tree above are well-known and easy to deduce from a strong ordering [29].

▶ **Theorem 9.** *If G is a bipartite permutation graph, then* $\mathbf{rvc}(G) = \mathbf{srvc}(G) = \mathrm{diam}(G) - 1$, *and the corresponding (strong) rainbow vertex coloring can be found in time that is linear in the size of G.*

Proof. Let $G = (V, E)$ be a bipartite permutation graph. Let v be a first vertex in a strong ordering for G. We start by doing a BFS on G with v as the root. Let k be the number of levels in the BFS tree in addition to level 0. Hence, L_i is the set of vertices in level i of the BFS tree, $0 \leq i \leq k$, with $L_0 = \{v\}$. Since $\mathrm{dist}(v, y) = k$ for every $y \in L_k$, we conclude that $\mathrm{diam}(G) \geq k$. Furthermore, if $\mathrm{dist}(x, y) > k - 1$ for some $x \in L_1$ and some $y \in L_k$, then we can conclude that $\mathrm{dist}(x, y) = k + 1$, where $x, v, a_1, a_2, \ldots, a_{k-1}, y$ is a shortest path between x and y. In this case, $\mathrm{diam}(G) = k + 1$. We distinguish between these two cases:

Case 1. $\mathrm{diam}(G) = k$.

We construct a strong rainbow vertex coloring $c : V \to [k - 1]$ for G in the following way. If $x \in L_i$, we define $c(x) = i$, for $1 \leq i \leq k - 1$. We define $c(v) = k - 1$, and we give arbitrary colors between 1 and $k - 1$ to the vertices of L_k. To see that G is indeed rainbow-connected under c, consider any pair $x, y \in V$. If $xy \in E$ or if they are in the same level of the BFS tree, there is nothing to prove, since $\mathrm{dist}(x, y) \leq 2$. Otherwise, we have exactly the following cases:

1. $x = v$ and $y \in L_j$: Then the path $v, a_1, \ldots, a_{j-1}, y$ is shortest and it is rainbow.
2. $x \in L_1$ and $y \in L_k$: In this case, $\mathrm{dist}(x, y) = k - 1$. Otherwise, since each L_i is an independent set, we would have $\mathrm{dist}(x, y) \geq k + 1$, which contradicts our assumption that

$\text{diam}(G) = k$. Since $\text{dist}(x, y) = k - 1$, every shortest path between x and y is rainbow, as every vertex of such a shortest path has to be in a distinct level of the BFS tree.

3. $x \in L_1$ and $y \in L_j$ with $2 \leq j \leq k - 1$: If $\text{dist}(x, y) = j - 1$, then again by the same argument used above, every shortest path between x and y is rainbow. If $\text{dist}(x, y) > j-1$, then $\text{dist}(x, y) = j + 1$, and the shortest path $x, v, a_1, \ldots, a_{j-1}, y$ has distinct colors on all its internal vertices. (Note that y might have the same color as v if $j = k - 1$, but this is fine since y is the end of the path.)
4. $x \in L_i$ and $y \in L_j$ with $2 \leq i < j \leq k$: If $\text{dist}(x, y) = j - i$, then every shortest path is rainbow. If $\text{dist}(x, y) > j - i$, then the path $x, a_{i-1}, a_i, \ldots, a_{j-1}, y$ is rainbow and has length $j - i + 1$, and it is therefore shortest.

Case 2. $\text{diam}(G) = k + 1$.

We construct a strong rainbow vertex coloring $c : V \to [k]$ for G in the following way. If $x \in L_i$, we define $c(x) = i$, for $1 \leq i \leq k - 1$. We define $c(v) = k$, and we give arbitrary colors between 1 and k to the vertices of L_k. To see that G is indeed rainbow-connected under c, consider any pair $x, y \in V$. Again, if $xy \in E$ or if they are in the same level of the BFS, there is nothing to prove, since $\text{dist}(x, y) \leq 2$. Otherwise, there is only one remaining case:

- $x \in L_i$ and $y \in L_j$, with $0 \leq i < j \leq k$: If $\text{dist}(x, y) = j - i$ then every shortest path between x and y is rainbow. Otherwise, the path $x, a_{i-1}, a_i, \ldots, a_{j-1}, y$ is rainbow and has length $j - i + 2$, therefore being shortest.

In both cases, c is a strong rainbow vertex coloring for G with $\text{diam}(G) - 1$ colors. By Proposition 5 we can conclude that $\mathbf{rvc}(G) = \mathbf{srvc}(G) = \text{diam}(G) - 1$. ◀

4 Chordal graphs and their subclasses

In this section, we investigate the complexity of RVC and SRVC on chordal graphs and some subclasses of chordal graphs. We start by proving that both problems are NP-complete when the input graph is a split graph, implying that they are also NP-complete on chordal graphs. On the positive side, we show that RVC is polynomial-time solvable on interval graphs, and both RVC and SRVC are polynomial-time solvable on block graphs and on unit interval graphs.

We start by observing that computing $\mathbf{rvc}(G)$ or $\mathbf{srvc}(G)$ is easy on graphs of diameter 2.

▶ **Proposition 10** ([18]). *If G is a graph with $\text{diam}(G) = 2$, then $\mathbf{rvc}(G) = \mathbf{srvc}(G) = 1$. Moreover, such a coloring can be found in linear time.*

Proof. Color each vertex of G with the same color. Since each shortest path between two vertices contains at most one internal vertex, G is strongly rainbow vertex-connected under this coloring. ◀

If G is a split graph of $\text{diam}(G) = 3$ (note that split graphs have diameter at most 3), then $\mathbf{rvc}(G)$ and $\mathbf{srvc}(G)$ become much harder to compute, as claimed in Theorem 3. We prove the following general construction, which closely mimics the construction of Lemma 8.

▶ **Lemma 11.** *Let H be a hypergraph on n vertices. Then in polynomial time we can construct a split graph G of diameter 3 and with $O(n^3)$ vertices such that for any $k \in [n]$, H has a proper k-coloring if and only if G has a k-coloring under which G is (strongly) rainbow vertex-connected.*

Proof. Let $H = (N, \mathcal{E})$ be an arbitrary hypergraph and let $n = |N|$. We construct a split graph $G = (N' \cup I',\ E)$ where $N' = N'_1 \cup \cdots \cup N'_{n+1}$, $I' = I'_1 \cup \cdots \cup I'_{n+1}$, $N'_i := \{v_i \mid v \in N\}$, $I'_i := \{x^i_e \mid e \in \mathcal{E}\}$ and $E := \{u_i v_j \mid u, v \in N,\ i, j \in [n+1]\} \cup \{v_i x^i_e \mid v \in N, e \in \mathcal{E}, i \in [n+1], v \in e\}$. Let $V = N' \cup I'$. The constructed graph G is a split graph since $G[I']$ is an independent set and $G[N']$ is a clique. Observe that $\mathrm{diam}(G) = 3$ and that G has $O(n^3)$ vertices. The construction is illustrated in Figure 1: note that since $G[N']$ is a clique, all possible edges now appear between the vertices inside the rectangle with rounded corners.

Consider any proper k-coloring $h : N \to [k]$ of H, i.e., no hyperedge of H is monochromatic under h. We construct a coloring $c : V \to [k]$ in the following way. First, for every $v \in N$, we give the vertices $v_1, v_2, \ldots, v_n$ of G the same color as v, i.e., $c(v_i) = h(v)$ for all $v \in N$ and $i \in [n+1]$. The vertices in I all receive the same color, which is any arbitrary color in $[k]$. Now, we prove that G is strongly rainbow vertex-connected under c by showing that there is a rainbow vertex shortest path between every pair of vertices. The only non-trivial case is when both vertices of the pair are in I. Consider two distinct vertices $x^i_e, x^j_f \in I$ (it is possible that $e = f$ or $i = j$ but not both). Since e and f are not monochromatic under h, we can pick two distinct vertices $u \in e$ and $v \in f$ such that $h(u) \neq h(v)$. It is clear that the path $x^i_e u v x^j_f$ is a shortest path between x^i_e and x^j_f and that it is rainbow vertex path.

Conversely, let c be a k-coloring of G under which G is (strongly) rainbow vertex-connected. For each $i \in [n+1]$, define h_i to be the vertex coloring of H such that $h_i(v) = c(v_i)$ for all $v \in N$. We claim that there exists an $i \in [n+1]$ such that h'_i is a proper k-coloring of H. For the sake of contradiction, suppose that h'_i is not a proper k-coloring of H for every $i \in [n+1]$. For each $i \in [n+1]$, let $e_i \in \mathcal{E}$ be a monochromatic edge under h'_i. Let v_i be an arbitrary vertex in e_i. Suppose now that for every $i \in [n+1]$, all vertices in e_i are colored $c(v_i)$ under c. If $c(v_i) = c(v_j)$ for $i \neq j$, then any path from $x^i_{e_i}$ to $x^j_{e_j}$ uses two vertices having color $c(v_i) = c(v_j)$ under c. This would contradict the assumption that G is rainbow vertex-connected under c. Hence, $c(v_i) \neq c(v_j)$ for all distinct $i, j \in [n+1]$. This implies that c uses at least $n+1$ colors, a contradiction to the assumptions that c is a k-coloring of G and $k \in [n]$. Therefore, for some $i \in [n+1]$, there is a vertex $v'_i \in e_i$ for which $c(v'_i) \neq c(a)$ and $c(v'_i) \neq c(v_i)$. The latter implies that e_i is not monochromatic under h'_i, a contradiction. The claim follows, and thus H has a proper H-coloring. ◀

Proof of Theorem 3. The proof follows in exactly the same way as Theorem 2, except that we apply Lemma 11 instead of Lemma 8. ◀

We now move on to the positive results. As a consequence of the following theorems, we complete the proof of Theorem 4.

▶ **Theorem 12.** *Let G be a block graph, and let ℓ be the number of cut vertices in G. Then $\mathbf{rvc}(G) = \mathbf{srvc}(G) = \ell$. The corresponding (strong) rainbow vertex coloring can be found in time that is linear in the size of G.*

Proof. Let $G = (V, E)$ be a block graph and $\{a_1, a_2, \ldots, a_\ell\}$ be the set of cut vertices of G. We construct a strong rainbow vertex coloring $c : V \to [\ell]$ for G by defining $c(a_i) = i$ for $i \in [\ell]$ and giving the other vertices arbitrary colors between 1 and ℓ. An important property of block graphs is that there is a unique shortest path between every pair of vertices. Moreover, each internal vertex of such a path is a cut vertex. Since all the cut vertices received distinct colors, these shortest paths are all rainbow. The proof follows by observing that $\mathbf{rvc}(G) \geq \mathbf{srvc}(G) \geq \ell$ as well. ◀

For our next result, we need to mention that every interval graph has a representation called an *interval model*. Let $\mathcal{I}$ be a set of n intervals of the real line. Then we can define a graph $G_{\mathcal{I}}$ with a vertex for each interval, such that two vertices are adjacent if and only if their corresponding intervals overlap. A graph G is an interval graph if and only if G is isomorphic to $G_{\mathcal{I}}$ for some set $\mathcal{I}$ of intervals. In this case $\mathcal{I}$ is called an interval model of G.

▶ **Theorem 13.** *If G is an interval graph, then* $\mathbf{rvc}(G) = \mathrm{diam}(G) - 1$*, and the corresponding rainbow vertex coloring can be found in time that is linear in the size of G.*

Proof. Let $G = (V, E)$ be an interval graph and $\mathcal{I}$ be an interval model for G. The interval corresponding to vertex v is denoted by I_v. For each interval $I \in \mathcal{I}$, we let $r(I)$ be its right endpoint and $\ell(I)$ its right endpoint. Let $I_u \in \mathcal{I}$ be such that $r(I_u) \leq r(I)$ for all $I \in \mathcal{I}$. Let $I_v \in \mathcal{I}$ be such that $\ell(I_v) \geq \ell(I)$ for all $I \in \mathcal{I}$. Let $P = u, x_1, x_2, \ldots, x_k, v$ be a shortest path between u and v in G. Observe that P is a connected dominating set. Furthermore, since P is a shortest path, $k \leq \mathrm{diam}(G) - 1$. By the way we defined u and v, we have that $N(u) \subseteq N(x_1)$ and $N(v) \subseteq N(x_k)$. This implies that the set $\{x_1, x_2, \ldots, x_k\}$ is also a connected dominating set. By Proposition 6, G has a rainbow vertex coloring $c : V \to [k]$ with $c(x_i) = i$, and we can give all the other vertices arbitrary colors. ◀

An interval graph is a *unit interval graph* if it has an interval model in which every interval has the same length (or no interval properly contains another interval). Unit interval graphs have the same BFS tree structure as that of bipartite permutation graphs, with the single difference that every level of the BFS tree is a clique instead of an independent set [15].

▶ **Theorem 14.** *If G is a unit interval graph, then* $\mathbf{rvc}(G) = \mathbf{srvc}(G) = \mathrm{diam}(G) - 1$*, and the corresponding (strong) rainbow vertex coloring can be found in time that is linear in the size of G.*

Proof. Let $G = (V, E)$ be a unit interval graph. Let v be the vertex corresponding to a first interval in an ordering of the intervals in the unit interval model of G by their right endpoints. Do a BFS on G with v as the root. Let L_i be the set of vertices in level i of the BFS tree, $0 \leq i \leq k$, with $L_0 = \{v\}$. Recall that, for $0 \leq i \leq k - 1$, there exists a special vertex $a_i \in L_i$ such that $L_{i+1} \subset N(a_i)$.

Consider a vertex $u \in L_k$. A shortest path between v and u has $k - 1$ internal vertices, which implies that $\mathrm{diam}(G) \geq k$. To construct a strong rainbow coloring $c : V \to [k - 1]$, we assign, for $1 \leq i \leq k - 1$, $c(x) = i$ if $x \in L_i$ and we give arbitrary colors to the vertices of L_k.

To see that G is strongly rainbow vertex-connected under c, consider $x, y \in V$. If both x and y are in the same level of the BFS tree, then they are adjacent. So let us consider the case when $x \in L_i$ and $y \in L_j$, with $1 \leq i < j \leq k$. If there is a shortest path between x and y each of whose vertices is in a distinct level of the BFS tree, then this path is rainbow. If this is not the case, we consider the path $x, a_i, a_{i+1}, \ldots, a_{j-1}, y$. In this case, this path is a shortest path between x and y, and its internal vertices have distinct colors, since only x and a_i belong to the same level of the BFS. This proves that c is indeed a strong rainbow coloring for G with $\mathrm{diam}(G) - 1$ colors. ◀

5 Concluding remarks and related problems

It should be mentioned that other variants of rainbow problems have been studied as well. When a coloring of the edges or the vertices of a graph is already given as input, we can ask whether the graph is rainbow-connected or rainbow vertex-connected. Both of these problems are known to be NP-complete even on highly restricted graphs, like interval graphs,

series-parallel graphs, and k-regular graphs for every $k \geq 3$ [21, 20, 28]. However, we stress that these problems are strictly different from RC and RVC. That is, complexity results on one problem are not transferable to the other.

Finally, we end our paper with the following open question.[1] A *diametral path* of a graph G is a shortest path whose length is equal to $\mathrm{diam}(G)$. A graph is a *diametral path* if every connected induced subgraph has a dominating diametral path.

▶ **Conjecture 15.** *Let G be a diametral path graph. Then* $\mathbf{rvc}(G) = \mathrm{diam}(G) - 1$.

Abstract

We investigate a decomposition technique for listing problems in graphs and set systems. It is based on the Cartesian product of some iterators, which list the solutions of simpler problems. Our ideas applies to several problems, and we illustrate one of them in depth, namely, listing all minimum spanning trees of a weighted graph G. Here iterators over the spanning trees for unweighted graphs can be obtained by a suitable modification of the listing algorithm by [Shioura et al., SICOMP 1997], and the decomposition of G is obtained by suitably partitioning its edges according to their weights. By combining these iterators in a Cartesian product scheme that employs Gray coding, we give the first algorithm which lists all minimum spanning trees of G in constant delay, where the delay is the time elapsed between any two consecutive outputs. Our solution requires polynomial preprocessing time and uses polynomial space.

1 Introduction

Listing problems in set systems have solutions corresponding to sets of elements from a ground set $\mathcal{U}$. Set systems formalize, among others, most subgraph listing problems as subgraphs are usually modeled as sets of vertices or edges (e.g. independent sets where $\mathcal{U}$ is the vertex set, or matchings where $\mathcal{U}$ is the edge set). A listing problem can be thus identified with the set $\mathcal{P} \subseteq 2^{\mathcal{U}}$ of its solutions to be listed, where typically each solution satisfies certain properties (e.g. maximality under inclusion).

In this paper we consider *decomposable* listing problems, where a problem $\mathcal{P}$ is decomposable if it can be modeled as the Cartesian product $\mathcal{P} = S_1 \times \cdots \times S_h$, with $S_1, \ldots, S_h \subseteq 2^{\mathcal{U}}$. We call this a *Cartesian decomposition*.

Many graph listing problems offer natural Cartesian decompositions. A trivial example is given by the (maximal or not) independent sets of a graph G, which can be decomposed using the connected components of G: indeed, any independent set of G corresponds to choosing an independent set from each of its connected components; hence letting S_i be all the independent sets in the i-th connected component in G, all those in G are obtained by combining them as $\mathcal{P} = S_1 \times \cdots \times S_h$, where $X \times Y$ returns all the unions of their vertex sets, $\{x \cup y : x \in X, y \in Y\}$. This same decomposition applies also to other types of subgraphs such as matchings and the edge sets.

This already can give improvements in the general case: even a simple reduction, such as reducing Steiner trees in a graph to combinations of Steiner trees in its biconnected components (see Section 4), already makes listing Steiner trees easier on graphs with small biconnected components. On the other hand, we will see in this paper that there are less trivial Cartesian decompositions, which allow us to reduce some problems to simpler ones, and design more efficient listing algorithms.

For a Cartesian decomposition $\mathcal{P} = S_1 \times \cdots \times S_h$, we observe that each set S_i is the output of some listing algorithm A_i, for $1 \leq i \leq h$. Thus S_i is not explicitly given, and may even have exponential size. As using polynomial space is one of the goals of this paper, among others, we consider A_i as a procedure that outputs all solutions of S_i in some order in polynomial space[1]. There are several definitions of efficiency for listing algorithms [15]: we consider the *delay*, that is, a worst-case measure representing the maximum time elapsed between any two consecutive outputs of A_i. If A_i has bounded delay (e.g. polynomial in the size of G for listing subgraphs of G), it is also called output-sensitive, as the total running time is proportional to the size $|S_i|$.

Given h listing algorithms $A_1, \ldots, A_h$, we model them as iterators over the sets $S_1, \ldots, S_h$, thus avoiding to store explicitly the latter ones. We thus consider the problem of listing implicitly the solutions of the Cartesian product $S_1 \times \cdots \times S_h$, which amounts to listing all the solutions of $\mathcal{P}$. This allow us to design the resulting listing algorithm that handle a complex counter with h digits with constant delay,[2] where the i-th digit goes through $|S_i|$ values and each configuration is a solution of $\mathcal{P}$. While intuitively a good representation, this is not the whole picture of the algorithmic challenge. For example, (re)setting digit i to "0" may be expensive, as we should pay for this solution the preprocessing cost of A_i; even if the latter is just $O(1)$ time, it does not guarantee a good delay as we may need to reset many counters at once, and this gives us a delay of $\Omega(h)$, and possibly worse; if opting for Gray codes, as we do, we should have some control on the order in which solutions of S_i are listed, which requires to modify A_i.

In this paper we propose a technique for iterating over the Cartesian product which allows us, under suitable conditions, to list the solutions of $\mathcal{P}$, with polynomial preprocessing cost and space usage, and with delay bounded by the worst case delay on any A_i. This exploits a form of Gray coding and common properties of state-of-the-art listing algorithms.

After describing how to list solutions using Cartesian decomposition in Section 2, we give some concrete examples of the wide class of problems which can be decomposed in Section 1.1 (or more in detail in Section 4), and study the case of minimum spanning trees

[1] Otherwise, if A_i takes exponential space, we can just use S_i directly, and our listing problem becomes of little interest.

[2] Constant amortized cost is easier to obtain, as shown in [10, Chapter 17].

(MSTs hereafter) in Section 3 to show how to iron all the details in a complete example. We will propose a decomposition which reduces the MSTs of a graph G to the Cartesian product among the spanning trees of a set of unweighted graphs $G_1, \ldots, G_h$. Furthermore, we will show that, by combining this decomposition with a modified version of the state of the art algorithm for listing spanning trees [29], we can obtain the first listing algorithm for MSTs with constant delay, using $O(mn)$ space.

1.1 Related Work

Solving complex problems by decomposing them into simpler problems is the main principle in algorithm design, and many techniques follow that principle: divide-and-conquer, dynamic programming, and so on. For enumeration and listing, some papers addressed this issue: backtracking algorithms [5, 27], and binary partition algorithms [4] in particular, can be seen as an implicit form of decomposition. Other forms of decompositions for listing include [24], which lists all arborescences in a digraph by modelling the solution space as a polynomial, and decomposing this into prime factors, [13] which deletes vertices and edges to generate formulas for counting subgraphs such as spanning trees and acyclic subgraphs, [25] which uses the treewidth decomposition for enumerating purposes, and [31] which shows how to decompose some problems into quasi-independent subproblems using clique separators.

In the case of fixed parameter algorithms, a form of decomposition has been explicited in the so-called *kernelization* which is a technique which preprocesses the input to get a smaller input, called *kernel*. The result of solving the problem on the kernel should either be the same as on the original input, or it should be easy to transform the output on the kernel to the desired output for the original problem [11]. As for listing algorithms for graphs, in many cases the instance of the problem can be partitioned in *several kernels*, so that the listing algorithm can be solved in each of them, and the result of the original problem can be obtained by the result of a Cartesian product among these set of solutions. Some examples are given next, and a more detailed discussion can be found in Section 4.

Application examples. Decomposition, for instance considering connected or biconnected components separately, applies to several listing problems including st-paths [4], unweighted spanning trees, Steiner trees, maximal independent sets [7], maximal induced matching [2], maximal k-degenerate subgraphs [8], minimal feedback vertex/arc sets [28], bipartite subgraphs [33], bounded girth subgraphs [9], dominating sets [19], and acyclic orientations [6] (see Section 4 for more details).[3] One of the goals of this paper is explicitly defining this Cartesian decomposition in a general way, so as to be used as a black box in future works.

MSTs, which we consider as case study for this technique, have a less trivial but powerful decomposition. Spanning trees (in short STs) and MSTs have a rich and long history which has been pointed out in several surveys [3, 26, 20, 14]. Due to this interest, several listing algorithms for STs and MSTs have been proposed over the years. One of the most popular listing algorithms for undirected unweighted graphs is the one by [16] which lists all the STs in optimal time, i.e. $O(\alpha+n+m)$ and space $O(nm)$, where α is the number of solutions. On the other hand, using reverse search, the algorithm in [22] has linear space with $O(m+n+\alpha n)$ time. The one in [29] is optimal time and has also linear memory. The algorithm in [30] lists all the STs in increasing order of weights with cost $O(\alpha m \log m + n^2)$ total time and $O(\alpha m)$ space.

[3] Moreover, it has been implicitly adopted in other graph enumeration papers, like [4].

Concerning more specifically weighted graphs, the algorithm in [23] works also for MSTs, as also one of the algorithms in [16] allows to list MSTs in a similar time bound, i.e. $O(\alpha n)$. Other algorithms have been proposed: the algorithm in [35] has cost per solution equal to $O(m \log n)$ and $O(m)$ space. A generalization of the Kruskal Algorithm for listing purposes has been done in [34]. The reduction in [12] allows us to reduce the enumeration of MSTs to STs in a different graph through edge sliding operations, which, using [16] as a subroutine, lists all MSTs in constant amortized time, but not constant delay. This reduction may be combined with the techniques proposed in this paper to obtain an alternative, equivalent, algorithm for listing MSTs with the same delay. To this end, our approach based on Cartesian decomposition is general and can be applied to a vast range of other graphs problems, as long as their set of solutions can be decomposed in some way.

1.2 Preliminaries

We consider an undirected, edge weighted, graph $G = (V(G), E(G))$. $N_G(v)$ represents the neighborhood of v in G. For simplicity, in the following we call $|V(G)| = n$ and $|E(G)| = m$. Whenever G is clear from the context, we may drop subscripts and use simplified notation like V, E, $N(v)$ instead of $V(G)$,$E(G)$, $N_G(v)$.

Let $W = \{w_1, \ldots, w_k\}$, with $w_1 < \cdots < w_k$, be the distinct edge weights of G, where $1 \leq k \leq m$. For a weight w_i, let $E_{<w_i}(G)$, $E_{w_i}(G)$, and $E_{>w_i}(G)$ be the sets of all edges in $E(G)$ which have weight respectively *smaller than* w_i, *equal to* w_i, and *larger than* w_i.

For a given edge $e = \{x, y\}$, we call *contracting* e in G the operation of deleting x and y from G, as well as all edges incident to them, and replacing them with a new node z such that $N(z) = N(x) \dot\cup N(y)$, observing that $N(z)$ can be a multiset (and thus we obtain a multigraph). We refer to the (multi)graph obtained by contracting e in G as G/e. We also implicitly maintain a correspondence between the new edges in G/e and those in G to make the operation reversible. Note that this is not a one-to-one correspondence as two edges $\{v, x\}$ and $\{v, y\}$ will correspond to the same edge $\{v, z\}$ in G/e. Instead, $G \setminus e$ represents the graph obtained by simply deleting e from G (but not its extremes). The operations G/X and $G \setminus X$ are similarly defined for a set of edges $X \subseteq E(G)$, where edges (or their corresponding ones) are respectively contracted or deleted one by one in any order.

Given a set of edges $E' \subseteq E(G)$, $V[E']$ is the set of nodes incident to at least one edge in E'. The subgraph of G *induced* by E' is the graph $G[E'] = (V[E'], E')$. A spanning tree of a connected graph G is a subgraph $T = G[E_T]$, for some E_T such that T is connected, acyclic, and contains all nodes of G, i.e., $V[E_T] = V(G)$. One can also define a spanning tree as a *maximal* set of edges E_T such that the corresponding subgraph $G[E_T]$ is acyclic. Yet another equivalent definition of spanning tree is a *minimal* set of of edges E_T which guarantees connectivity between all pairs of nodes, since any edge that partakes in a cycle may be deleted without affecting the connectivity of the graph [10]. We denote by $\mathcal{T}(G)$ the set of all spanning trees t_i of G.

When G is *not connected*, let $\mathcal{C}(G) = \{C_1, \ldots, C_j\}$ be the set of connected components of G; for simplicity, we define a spanning tree of the non connected graph G as the union of a spanning tree of each connected component. In this case, we can easily see how $\mathcal{T}(G)$ corresponds to the *Cartesian product* among the sets of trees of its connected components, i.e., $\mathcal{T}(C_1) \times \ldots \times \mathcal{T}(C_j)$.

2 Finding Solutions of the Cartesian Product via Gray Coding

In the previous section we have seen that the problem of listing patterns in several cases reduces to combining solutions from other listing subproblems in all the possible ways. This corresponds to our notion of decomposable problem and our goal here is to achieve efficient enumeration of the original problem knowing how to efficiently solve each of the subproblems, as summarized next.

Main Problem. Given h subproblems, whose solutions are sets $S_1, \ldots, S_h$, the solutions of our problem can be seen conceptually as tuples $\langle s_1, \ldots, s_h \rangle \in \mathcal{P} = S_1, \times \ldots \times S_h$. Now suppose that we have a listing algorithm which is able to iterate over the solutions of S_i for each i with polynomial setup time $O(P)$, delay time $O(D)$ and polynomial space, modeled as an iterator A_i which can yield the solutions of S_i one by one after an initial setup.[4] We say that the iterator A_i is *reversible* if there exists an iterator A_i^{-1} which scans the solutions of A_i in the opposite order with the same time and space costs. We will show that, having reversible iterators A_i, it is possible to build an iterator for $\mathcal{P}$, whose delay is the same of A_i.

▶ **Theorem 1.** *Given a reversible iterator A_i for each set of solutions S_i, $1 \leq i \leq h$, running with delay $O(D)$, setup time $O(P)$, and polynomial space, it is possible to list all the solutions in $\mathcal{P} = S_1, \times \cdots \times S_h$ with delay $O(D)$, setup $O(h \cdot P)$ and polynomial space.*

While the polynomial space of an iterator can increase by a factor h in the statement of Theorem 1, we observe that the delay does not depend on h nor includes the setup times. This is non-trivial as we could trivially start running the algorithm A_1 to get S_1, and each time a solution $s_j \in S_1$ is found, recursively start the iterator A_2 to scan all the solutions in S_2. This is not satisfactory as it requires, in the worst case, a delay which can be $O(h \cdot (P + D))$, so that for each solution $s_j \in S_i$ $(1 \leq i < h)$ we have to setup the iterator S_{i+1}. To meet the result in Theorem 1, we need to erase the setup cost from the delay, meaning that for each $s_j \in S_i$, the iterator for S_{i+1} is ready to use without calling a setup function, e.g. `init()` for A_{i+1}. On the other hand, we need to erase also the dependency from h. To overcome this we start from the well known *Gray coding* technique, in a generalized form given by Knuth, in "The Art of Computer Programming" Volume 4 Fascicle 2A [17]. This requires to design forward and backward iterators, i.e. meaning that for each iterator A_i that scans all the solutions of S_i (with $1 \leq i \leq h$) in a certain order we need to design a corresponding iterator, which we call A_i^{-1}, that scans the same solutions in the reversed order.

2.1 Setup costs

Given an iterator A_i, with $O(D)$ delay and a given setup cost of $O(P)$ time (corresponding to the cost of `init()`), the main objective of this section is showing that it is possible to scan the set of solutions S_i an arbitrary number of times, paying the setup cost $O(P)$ only once (the first time A_i is started), and without affecting the delay $O(D)$.

To this aim, first consider the trivial case in which the total execution time of A_i, after the setup is done, is equal or less than the setup cost $O(P)$. This implies that the output is bounded in size by $O(P)$. In this case, we can simply run A_i, and store the complete whole output: this takes $O(P)$ time and space, and clearly allows us to iterate on the solutions of A_i (i.e., the output) any number of times with an equal (or better) delay.[5]

[4] This can be realized for instance providing the well-known `init()` and `getNext()` methods of Java iterators, to respectively initialize and give the next solution for a given iterator.

[5] To recognize this case, we simply run A_i for $O(P)$ steps after the setup, without affecting its cost.

Otherwise, let M be the total amount of data generated by the setup of A_i. This can be anything, such as initialized data structures, pre-processed information on the input, buffered solutions, or other data. Once M is given, then A_i can start without further ado, so our goal is achieved by guaranteeing that an unaltered copy of M is ready at any time to start again.

To obtain this, we keep two copies of M, namely M_a and M_b. Initially these need $O(P)$ time to be computed, and clearly we can restore any of them at any time in $O(P)$ time by executing the setup again. Our strategy works as follows. The first time that A_i is executed it will use the data in M_a. After its execution, M_a may have been altered and may not be usable, but M_b is intact. For the second execution, we will run A_i using M_b, and restore M_a *while* running the algorithm: we perform alternatively one step of A_i and one step of restoring M_a. The next time A_i is run, it can use the data in M_a, and restore M_b while running in the same way. Hence, even executions of the iterator A_i use M_a and restore M_b, while odd ones use M_b while restoring M_a. Note that, since the execution of A_i takes $\Omega(P)$ time (we covered the other case above), M_a (or M_b) will have been fully restored before A_i terminates. As a result, we can start the iterator A_i any number of times, but the setup cost is only paid once in the beginning. Furthermore, this slows down A_i by just a factor of two, so the asymptotic complexity is unchanged.

2.2 Gray Coding via Forward and Backward Iterators

The idea of Gray coding is producing tuples one after the other such that any two consecutive tuples differ by just one entry, i.e. after the output of $\langle s_1, \ldots, s_{j-1}, s_j, s_{j+1} \ldots, s_h \rangle$ we output $\langle s_1, \ldots, s_{j-1}, s'_j, s_{j+1}, \ldots, s_h \rangle$ for some j. A result in [17] was given for explicit sets, but in the following we show how to generalize it for implicit sets, i.e. sets which are results of an iterator. Clearly, to do so, we take into account the delay between the output of s_j and s'_j in A_j, namely $O(D)$ in Theorem 1. The adaptation is not trivial as [17] assumes a certain ability of moving inside the objects in S_j, while a listing algorithm produces solutions in one fixed order.

Among the several variations of Gray coding, we consider *loopless reflected mixed-radix Gray generation* (Algorithm H in [17]), which we refer to as LRMG. This algorithm visits all the tuples changing only one coordinate ± 1 at each step. It maintains an array of focus pointers which says which iterator we have to call at each step, and an array of directions, which for each j (with $1 \leq j \leq h$) says whether we are iterating on S_j from the first solution to the last one or vice versa. Without loss of generality, we can assume $|S_i| > 1$ for each i, as if $|S_i| = 1$ then the only element in S_i is present in all solutions and needs to be output just once at the beginning.

The approach of LRMG can be generalized to deal with the tuples of $\mathcal{P} = S_1 \times \ldots \times S_h$, when the elements of each S_i are implicit, i.e. the result of an iterator. This generalization can be done if the following holds: for each i, on top of the iterator A_i that scans the solutions of S_i in a certain order π, with delay $O(D)$, we can obtain another iterator, called A_i^{-1}, that scans the same solutions in the *opposite* order of π, still with delay $O(D)$. The logic behind this is that the "direction" variable of each iterator is changed only at the end of each iteration, thus we only need to perform complete iteration on S_i in one order and its opposite.

An important remark is that whenever switching from using a certain A_i to the corresponding A_i^{-1}, we should not consider as output the first solution found by A_i^{-1}, since it is the same as the last one output by A_i. The same applies when switching from A_i^{-1} back to A_i. In both cases the delay and preprocessing cost remain the same.

If this is given, we can prove Theorem 1. Indeed, we can plug the suitable iterators A_i and A_i^{-1} into LRMG, and uses the setup cost factorization described in Section 2.1, obtaining an algorithm for iterating the solutions of $\mathcal{P}$ having as delay and setup time cost respectively the sum of the delay and setup time costs of A_i and A_i^{-1}, which asymptotically is the same.

Getting the backward iterator. We now show how to obtain A_i^{-1} given A_i, under suitable conditions which are met by most state-of-the-art listing algorithms. In particular, we assume A_i to be a recursive algorithm with a recursion tree in which each node outputs at most one solution, and generates children as nested recursive calls. Moreover, we assume to be able to generate children of a given recursive call in the opposite order as in A_i, which is generally true for binary partition [5, 4] or reverse search [1, 21] algorithms, where the i-th child call is not influenced by the computation of the subtrees of the previous $i-1$ children.

Let T be the tree induced by the recursive calls. Note that in reverse search algorithms each node in T outputs a solution, while in other backtracking algorithms output may be done in just some nodes, or some of the leaves of T. Consider the following two traversals of T, called FORWARD (resp. BACKWARD), starting from a node u, where d is the depth of the current recursion node in T.

1. If d is even (resp. odd) output u.
2. For each child i of u in increasing (resp. descending) order call FORWARD (u) (resp. BACKWARD (u)).
3. If d is odd (resp. even) output u.

The following observation clearly holds.

▶ **Observation 2.** *For any tree T, let π be the visiting order of the nodes of T obtained by* FORWARD. *Then* BACKWARD *scans the nodes of T in the opposite order with respect to π.*

The above traversal is similar to the so-called *alternative output* in [32], which is usually done to reduce the delay of listing algorithms, but we use this variation to get forward and backward iterators A_i and A_i^{-1} at the same time. In particular, we define A_i and A_i^{-1} as the iterators respectively induced by FORWARD and BACKWARD visit algorithms on T.

Applying Observation 2, we observe that in order to design A_i and A_i^{-1}, we only need a method to scan all the children in each internal node of T in one direction and in the opposite one with the same cost. As a result, both A_i have the same delay $O(D)$.

3 Case Study: Minimum Spanning Trees

In this section we describe how to use our technique to list all the MSTs of a graph, improving the state of the art to get constant delay for STs and applying the technique in Section 2 to get constant delay also for MSTs.

Overview. We will firstly reduce the problem of listing MSTs to the one of listing STs. To this aim, we order the weights of the graph as in the well-known Kruskal Algorithm, $w_1 < \cdots < w_k$, and we solve a STs listing problem for each different w_i, that is finding all the STs in a series of h graphs $C_1, \ldots, C_h$ (with $h \geq k$). For the latter task, on each C_i we run our improvement of the algorithm by [29], which achieves $O(1)$ delay to list STs and is presented in Section 3.2.1. We then need to compose the solutions, so that each combination of solutions for $C_1, \ldots, C_h$ corresponds to a different MSTs. As we have delay $O(1)$ on each C_i (with setup time $O(m^2)$ and space $O(mn)$), our main goal is to preserve these bounds when combining the solutions of $C_1, \ldots, C_h$. Indeed, the usual algorithm would setup an

iterator for C_1, and for each solution of C_1 would setup the iterator for the solutions of C_2 and so on. In this way, the delay can be up to $O(hm^2)$. Our goal is to reduce this delay to $O(1)$, which is the delay of a single iterator, maintaining polynomial space.

We hence apply the techniques in Section 2, adapting listing algorithms to use the Gray coding strategy, basically showing how to build backward iterators from forward iterators, how to factorize setup time costs and use and rebuild auxiliary data structures without afflicting the time complexity.

This problem is related to the more general problem of listing all the tuples of a Cartesian product which is usually solved using Gray coding. However, as in the scenario presented in Section 2, in our case the elements of the tuples are not explicitly given but they are generated through iterators which give solutions in a linear way (it is not possible to jump from one solution to an arbitrary one) and require setup time costs. In this section, we adapt our general solution to deal with the specific case of MSTs. In particular:

- we show how to reduce the problem of listing MSTs to the listing the solutions of a Cartesian product among h sets of solutions, each one corresponding to a set of STs in a graph.
- we show how to list STs with constant delay, as the state of the art algorithm [29] for STs runs in constant amortized time per solution but *linear* delay.
- we show how to use output queue technique to get rid of setup times and pay them just once at the beginning.
- we design *ad hoc* forward and backward iterators for STs, both with constant delay, which help us to successfully applying Gray coding to MSTs, so that the difference between two consecutive listed solutions is constant and can be computed in constant time.

3.1 From Minimum Spanning Trees to Spanning Trees

A well known way to compute a minimum spanning tree is using the greedy algorithm by Kruskal [18], which consists of the following steps:

1. Scan the edges of G according to an increasing weight order.
2. Add an edge to the solution T if it does not create a cycle in T, and discard it otherwise.
3. When all edges have been considered, T is a minimum spanning tree of G.

It is immediately evident how if all edges have different weights they will always be scanned in the same order, thus the algorithm will return the same result. However, if several edges have the same weight, the algorithm may scan them in different orders and produce different trees. Actually, it turns out that *any* minimum spanning tree of G may be found by Kruskal's algorithm, if that the adequate order of the edges is provided. More formally

▶ **Lemma 3.** *Let T be any* MST *of G, and $e_1, \ldots, e_m$ an ordering of $E(G)$ in increasing weight, such that any edge $e_i \in T$ appears in the order* before *any edge not in T which has the* same *weight as e_i. Running Kruskal's algorithm according to this order yields exactly T.*

By shifting our point of view, we can rephrase the algorithm in a more convenient way for our goal, considering the weights $w_1 < \cdots < w_k$ of G. The algorithm is essentially saying that we should greedily add as many edges of E_{w_1} as possible, without creating a cycle, before considering those of E_{w_2}. In other words, we are selecting a *maximal acyclic subgraph* of the graph $G[E_{w_1}]$, that is, a spanning tree T of $G[E_{w_1}]$. Once such a tree (or combination of trees, if $G[E_{w_1}]$ is not connected) has been found, all edges joining two vertices in the same connected component of T may be discarded, as they will create a cycle and not improve

the connectivity. Furthermore, adding to T any edge from a node x to any node in some connected component C of T is equivalent in terms of connectivity.

This means that we can *contract* each C into a single node to obtain a new graph G', and continue to execute Kruskal's algorithm, i.e., considering edges in E_{w_2}, without affecting the outcome. Greedily adding edges of E_{w_2} to T without creating cycles corresponds to selecting a maximal acyclic subgraph (i.e., spanning tree) of $G'[E_{w_2}]$. Again, once the edges of this spanning tree are selected and added to T, we can contract the connected components and connect as many nodes as possible using the edges of E_{w_3}.

A crucial point is that any spanning tree of $G[E_{w_1}]$ will contain exactly the same connected components as any other, corresponding to the connected components of $G[E_{w_1}]$. In other words, $G'[E_{w_2}]$ is always the same, regardless of which spanning tree of $G[E_{w_1}]$ was previously selected. This means that we can abstract the analysis of each weight w_i from all others: indeed, when considering w_i, we can consider as a single node all the nodes connected by edges of weights smaller than w_i, and we must create as many new connections as possible using edges of E_{w_i} without creating cycles. This corresponds to selecting a spanning tree in the graph obtained by contracting all edges of weight smaller than w_i, i.e., $E_{<w_i}$, and then deleting all those of weight greater than w_i; we call this graph G_i, whose formal definition is $G_i = (G/E_{<w_i}) \setminus E_{>w_i}$. We can thus give a recursive definition to the set of all minimum spanning trees of G, i.e. MSTs(G), as:

$$\text{MSTs}(G) = \prod_{w_i \in W} (\mathcal{T}(G_i)) \tag{1}$$

Where we recall that $\mathcal{T}(G_i)$ is the set of all spanning trees of G_i, $\prod$ corresponds to the Cartesian product between the given sets and, if G_i is not connected, we defined its spanning trees as combinations of a spanning tree of each connected components, as follows:

$$\mathcal{T}(G_i) = \prod_{C_j \in \mathcal{C}(G_i)} \mathcal{T}(C_j). \tag{2}$$

From what we said above, as all (and only) the minimum spanning trees of G are obtained by combining a minimum spanning tree of each G_i, for all $1 \leq i \leq k$, we get the following.

▶ **Lemma 4.** *Equation 1 gives all (and only) the minimum spanning trees of G.*

Furthermore, note that all edges in a single G_i have the same weight, so all spanning trees have the same weight as well, and listing minimum spanning trees correspond to just listing all spanning trees. As finding solutions for each G_i is relatively quick, modifying the constant amortized time provided by [29] in constant delay, combining these solutions maintaining the constant delay the same space bound is not trivial. In the following section, we will see that this corresponds to a more general problem, which is finding tuples of a Cartesian product among k sets, with time per solution independent from k and neglecting setup costs, where the elements of these sets are given implicitly, as result of an iterator.

3.2 MWST Gray Coding

In Section 3.1 we showed that we can solve the MST enumeration problem by listing (non weighted) STs in a series of multigraphs. In particular, we have seen that the problem of listing MSTs can be reduced to that of listing STs in several graphs and combining them in all the possible ways. Indeed, each MST in G corresponds to a tuple $\langle t_1, \ldots, t_k \rangle \in \mathcal{T}(G[w_1]) \times \ldots \times \mathcal{T}(G[w_k])$, where $k = |W|$ and $t_i \in \mathcal{T}(G_i)$ is one of the possible combination

of STs of the connected components of G_i according to Equation 2. Let $C_1, \ldots, C_h$ be a sequence containing the connected components of $G[w_1]$, followed by the ones of $G[w_2]$, and so on until those of $G[w_k]$. By combining Equations 1 and 2, we get that a MST is a tuple $\langle s_1, \ldots, s_h \rangle$ where s_i is any spanning tree of C_i, i.e. $s_i \in \mathcal{T}(C_i)$, for $1 \leq i \leq h$. Our goal is to list all the elements in $\mathcal{T}(C_1) \times \ldots \times \mathcal{T}(C_h)$ in an efficient way, given that we know how to list all the solutions in $\mathcal{T}(C_i)$ for each i. In this section, we show how to adapt the state of the art algorithm for listing STs to run in constant delay, and how to combine this resulting algorithm with the techniques in Section 2 to obtain a constant delay algorithm for listing MSTs.

3.2.1 Enumerating Spanning Trees in Constant Time Delay

In the following, we show how to improve the state of the art algorithm for listing STs to get constant delay per solution, proving the following result.

▶ **Lemma 5.** *There exists an algorithm* ST-CDEL *that lists spanning trees with constant delay, $O(m^2 n)$ preprocessing time, and $O(mn)$ space.*

The state of the art algorithm by Shoioura et al. [29], denoted as ST-CAT in the following, lists STs in constant amortized time per solution (CAT) in multigraphs,[6] but its delay is not constant. We will explain in the following how to modify ST-CAT properly to prove Lemma 5.

As each spanning tree has size $O(n)$, it is clearly impossible to output each solution entirely, so ST-CAT outputs just the first solution, and then the *differences* between one solution and the previous one. Combining all these differences, starting from the first solution output by the algorithm until the last differences output, will yield the "current solution" that the algorithm is considering.[7] In particular, using the notation in [29], this is done in the form of *output("$-e_k$, $+g$, tree,")*, meaning that the edge e_k must be deleted and edge g must be added with respect to the previously output solution, and *"tree"* means that a new solution has been reached, i.e., performing all the addition/deletion instructions output so far yields a new solution. However, ST-CAT has two features which cause its delay to be more than constant, namely *output size* and *update costs*. Both of these can be overcome by with proper use of deamortization techniques. We address them separately in the following.

Output size. Each time a recursive call is closed by ST-CAT, the changes done to the output are restored. Namely, each recursive call of the algorithm prints a first *output("$-e_k$, $+g$, tree,")*, then generates some children recursive calls, then prints a second *output("$-g$, $+e_k$,")* to undo these changes. When backtracking, several recursive calls may be terminated at once: in the worst case, up to the depth of the recursion tree, which is $O(n)$ for ST-CAT.

This causes the cumulative changes to be up to $\Omega(n)$, before the next output is performed by printing a "tree" token. Even if the computation time in reaching this output could be ignored, printing this number of changes clearly cannot be done in constant time.

An important property of this structure is that combining the output streams of all algorithms A_i will yield an output stream which iterates over the solutions of G: indeed, a solution of the main problem is a combination of solutions of the subproblems, and each output

[6] For reference, its pseudo code can be found in [29] at page 690.

[7] Reconstructing and outputting the whole solution from the stream would take more than constant time, but since all solutions have size $\Theta(n)$, a constant-delay algorithm for the problem would be impossible with this requirement.

of each A_i changes the solution of exactly one subproblem, we have that the combination of sub-solutions (i.e., the solution of G) will be a new one.

Furthermore, *every* recursive node X of A_i first alters the current solution with the *first* output, and then undoes these changes with the *second* output. Since the same is valid for children nodes of X, it follows that the "current solution" which can be read on the output stream *just before* the second output is equal to the one which can be read *just after* the first one.

In other words, we can chose to make the node X output a solution at the *end* of its execution (i.e., after its children nodes have terminated), rather than at the beginning, by simply printing the "tree" token at the beginning of the *second* output instruction instead of the end of the first. More formally, recursive calls which are tweaked to output the solution at the end will perform the first output call in the form *output("$-e_k$, $+g$,")*, and the second one in the form *output("tree, $-g$, $+e_k$,")*, instead of how described above.

With this property, we can apply the *alternative output* technique from [32]: for each recursive node X in the recursion tree T, we output its solution at the *beginning* of X if its depth is even, and at the *end* if it is odd.

This means that each output is performed after just a constant number of recursive calls has been either generated or closed by the algorithm. Since the changes performed by a single call are constant in size, it follows that the difference between one solution and the previously output one is always of constant size.

Finally, note that the differences between one solution and the next one are the same in the reversed order, thus this applies to the reversed iterator A^{-1} as well, which can be obtained as described in Section 2.2.

Update costs. Each recursive node of ST-CAT has to update some data structure. While the update cost is cleverly amortized to be just $O(1)$ per node, one update can be $O(m)$ in the worst case. We solve this issue using the technique from [32], called *output queue*. The general idea is to accumulate the output in memory, so that it is suitably delayed in a way that the time between the output of two "tree" tokens is constant.

Given the recursion tree T of ST-CAT, let T^* be an upper bound on the cumulative cost of nodes in a root-to-leaf path of T. As reported in [29], the depth of T is $O(n)$ and the maximum cost of a single recursive call is $O(m)$. Thus $T^* = O(mn)$. Furthermore, let $\bar{T}$ be the maximum, among all subtrees T' of T, of the total cost of T' divided by the number of nodes of T' corresponding to a solution. It can be seen that the amortization scheme in [29] that allows ST-CAT to have constant amortized time can be equivalently applied to any subtree, as it only considers the descendants of a recursive node. Thus we have that this ratio is constant for any subtree, and that $\bar{T} = O(1)$.

The output queue Q technique requires us to fill a queue containing $2 \cdot T^*/\bar{T} + 1 = O(mn)$ solutions, i.e. all the output required before printing $O(mn)$ "tree" tokens. By Theorem 2 in [32], the time required to initially fill the queue is bounded by $O(T^* + \bar{T}) = O(mn)$. As for the space, the first solution is output completely, but for all the others we just output the difference with respect to the previous solution, which as constant size, thus the size of the queue is always bounded by $O(mn)$.

As soon as the queue is full, dequeue the top solution (i.e. the set of changes before a "tree" token appear in the queue) and output it. Repeat this step every $O(\bar{T}) = O(1)$ time while the algorithm is executed. Finally, during the execution of the algorithm, each time an output is required, the request is enqueued in Q instead of being output. The output queue guarantees that Q is never empty until the end of the execution, and thus that the algorithm will have in this case $O(1)$ delay after the preprocessing time.

By combining what said so far in this section, we obtain an iterator A, which after a one time preprocessing cost of $O(mn)$, can iterate over all the spanning trees of a given graph with n vertices and m edges, not just once but any number of times without paying for the preprocessing cost again. Due to the memory requirements of the output queue, the space is $O(mn)$.

3.2.2 Forward and Backward Iterators for Spanning Trees

Given the iterator A, we need to show that is possible to obtain the backward iterator A^{-1}, which is the iterator processing the solutions in opposite order with respect to A, still ensuring constant delay. This follows by combining the techniques used above and in Section 2.2. Indeed, consider the design of A for spanning trees given above: if we do not consider the use of the *output queue* technique, this is a recursive algorithm which performs alternative-output and outputs at most one solution per recursion node. Indeed, we can invert the order in which the solutions are output precisely as described in Section 2.2, obtaining an A^{-1} algorithm. Furthermore, it's easy to see that the algorithm so obtained still maintains the same T^* and $\bar{T}$, as well as the same recursive structure, thus we can apply the output queue technique for A^{-1} as well, obtaining the following lemma.

▶ **Lemma 6.** *There exist forward and backward iterators for listing spanning trees with constant delay, $O(mn)$ preprocessing time, and $O(mn)$ space.*

3.2.3 Constant delay algorithm for MSTs

Finally, we present how to use the techniques presented in Sections 3.1, 2 and 3.2 to get a constant delay algorithm for the MSTs listing problem.

Preprocessing. Computing each G_i can clearly be done in $O(m)$ time by performing a BFS to identify the components connected by edges of $E_{<w_i}$, and then adding those of E_{w_i}. Note that, as every edge appears in at most one G_i, the total space for storing these graphs is $O(m)$ and the total computation time is $O(m^2)$.

Furthermore, as a spanning tree has $n-1$ edges, and all minimum spanning trees have the same number of edges of a given weight, there are at most $n-1$ distinct edge weights which can appear in any MST, thus at most n graphs G_i will be non-empty.

For each of these graphs, we must run the preprocessing phase of the ST-CDEL algorithm shown in Section 3.2.1, which takes $O(mn)$ time and uses $O(mn)$ space. Note that this is done twice for each G_i, as we need to start both the forward iterator A_i for the STs of G_i and the corresponding backward iterator A_i^{-1}. The preprocessing phase will thus take $O(m^2 + \sum_{i=1,\dots,h} |V(G_i)| \cdot |E(G_i)|)$ time. The space required to keep track of all the information is $O(\sum_{i=1,\dots,h} |V(G_i)| \cdot |E(G_i)|)$. While these are both trivially bounded by $O(mn^2)$, we can refine this bound: indeed, any edge of G appears in at most one G_i, we have $\sum_{i=1,\dots,h} |E(G_i)| = O(|E(G)|) = O(m)$, and while this is not true for the vertices, we have $|V(G_i)| \leq |V(G)| = n$, meaning that $\sum_{i=1,\dots,h} |V(G_i)| \cdot |E(G_i)| = n \cdot \sum_{i=1,\dots,h} |E(G_i)| = O(mn)$. We thus have that the preprocessing time is $O(m^2 + mn) = O(m^2)$ and the space usage is $O(mn)$.

Algorithm. Once all A_i and A_i^{-1} algorithms are ready, we can use them as iterators on their respective space of solutions, and run the Gray coding algorithm described in Section 2. The Gray coding algorithm alternatively uses A_i and A_i^{-1} depending on the direction set,

which for each i says whether we are iterating from the first solution to the last one or vice versa. The resulting algorithm has constant delay, as we have seen that both when we are using A_i or A_i^{-1} we get a new output with constant delay. Indeed, recall that both A_i and A_i^{-1} dequeue from their corresponding output queue until a "tree" token is found, and the number of dequeues is $O(1)$.

An important remark for A_i, the differences with respect to the previous ST output by A_i turns out to be differences with respect to the previous MSTs of G.

Indeed each output of A_i consists in a difference which turns one ST t'_i of G_i into the next one t''_i (which differ for a constant number of changes). The corresponding solutions for MSTs are tuples $\langle t_1, \ldots, t'_i, \ldots, t_h \rangle$ and $\langle t_1, \ldots, t''_i, \ldots t_h \rangle$ which still differ for a constant number of changes, as t_j corresponds to the same spanning tree for each G_j with $j \neq i$. Similarly, the same applies in the case of A_i^{-1}.

Finally, note that whenever switching from using A_i to A_i^{-1}, we must not output the first solution found by A_i^{-1}, as it corresponds to the last one output by A_i; the same applies when switching from A_i^{-1} to A_i. Clearly, this does not affect the complexity of the algorithm.

As a result, we have proved the following.

▶ **Theorem 7.** *There exists an algorithm which lists all the* MSTs *of a weighted graph with constant delay, $O(m^2)$ preprocessing time, and $O(mn)$ space.*

4 Applications

In this section, we consider several listing problems on graphs which turn out to be suitable for Cartesian decomposition. Some of them can be decomposed by looking at the biconnected components $B_1, \ldots B_h$ of the input graph. Applying Theorem 1, assuming to use forward and backward iterators for each B_i, we get that the delay of iterating over all the solutions of the graph is the maximum delay among the iterators for generating $S_1, \ldots, S_h$, where S_i is the set of solutions associated to B_i.

- ***st*-Paths.** Listing all the st-paths given two nodes s and t in a graph can be done looking at the bead string of biconnected components $B_1, \ldots, B_h$ for some h, with $s \in B_1$ and $t \in B_h$. In particular, let $b_1, \ldots, b_{h-1}$ be the corresponding sequence of articulation points, i.e. b_i is the articulation point between B_i and B_{i+1} $(1 \leq i < h)$. Then all the st-paths are all the tuples in $S_1 \times \ldots \times S_h$ where S_1 is the set of sb_1-paths, S_i is the set of $b_{i-1}b_i$-paths (with $2 \leq i \leq h-1$), S_h is the set of $b_{h-1}t$-paths.
- **Unweighted Spanning Trees.** Given a connected graph G and its biconnected components $B_1, \ldots, B_h$, it is easy to show that all the STs of G correspond to all the tuples in $S_1 \times \ldots \times S_h$, where S_i is the set of STs of B_i.
- **Steiner Trees.** Given a connected graph, all the Steiner trees with set of terminals W can be obtained looking at the biconnected components of G. For each B_i, S_i corresponds to the set of Steiner trees of the graph induced by B_i, fixing as set of terminals the nodes in $W \cap B_i$ and the articulation points x of G such that $x \in B_i$ and x can reach in G some node in W without passing through nodes in B_i.

Other problems on graphs turn out to be decomposable looking at the connected components. Given a graph G, let $Z_1, \ldots, Z_h$ be its connected components. Then the following patterns in G correspond to all the tuples in $S_1 \times \ldots \times S_h$, where S_i is the set of the same kind of patterns just for the graph Z_i. For instance, the following patterns, whose formal definition is given in the corresponding reference, belong to this category.

Maximal Independent Sets (see [7])
Maximal Induced Matching (see [2])
Maximal k-Degenerate Subgraph (see [8])
Minimal Feedback Vertex/Arc Sets (see [28])
Bipartite Subgraphs (see [33])
Bounded Girth Subgraphs (see [9])
Dominating Sets (see [19])
Acyclic Orientations (see [6])

Once again, designing forward and backward iterators as discussed in the previous section for the above problems, and running each of them for each Z_i, we get that the delay of the iterator over the solutions of G has delay equal to the maximum among the delays of the iterators over the solutions of $Z_1, \ldots, Z_h$.

Some other problems are decomposable in a more complex way which clearly is linked to their nature. This is the case of minimum spanning trees, which is object of the case study in Section 3.

5 Conclusions

In this paper we have studied a natural decomposition technique which consists in reducing an enumeration problem to the Cartesian product of the result of several easier sub-problems. We proposed an efficient way to implement this decomposition using a form of Gray coding and forward/backward iterators on the solutions of the sub-problems. In some cases, the sub-problems correspond to smaller instances of the input problem, while in others the problem itself may be a simpler one (e.g., for Minimum Weight Spanning Trees the sub-problem is listing spanning trees of an unweighted graph). We showed an in-depth analysis for the listing of Minimum Weight Spanning Trees, reducing with this technique the known bounds from Constant Amortized Time to Constant Delay. We also gave examples of several other problem which can benefit from this decomposition.
